grow. Moreover, the bounds on $N(k, r)$ given in Theorem 15 can probably be improved by a deeper analysis of the function $N(k, r)$.

Concerning the avoidability of anti-powers, we proved that there exist words avoiding 4 anti-powers and that there exist recurrent words avoiding 6-anti-powers. A natural problem is therefore that of determining what is the least k such that there exists a recurrent word avoiding k-anti-powers.

Another possible direction of investigation is related to the possible lengths of anti-powers appearing in a word. For an aperiodic uniformly recurrent word x, define $ap(x, k) = \min(AP(x, k))$, i.e., the minimum length m for which the prefix of x of length km is a k-anti-power. The first values of this function for the Thue-Morse word are displayed in Table 1 (where the value of $ap(x, k)$ is the ratio between the length of the k-anti-power prefix and the order k). We wonder whether it is possible to link the behavior of the function $ap(x, k)$ to the combinatorics of the word x, at least for special classes of words. For example, the values reported in Table 1 suggest that for the Thue-Morse word the function $ap(x, k)$ grows linearly in k.

Acknowledgements. We thank the anonymous referees for their careful reading of the paper and Filippo Mignosi for useful discussions.

Abstract

Transductions are binary relations of finite words. For rational transductions, i.e., transductions defined by finite transducers, the inclusion, equivalence and sequential uniformisation problems are known to be undecidable. In this paper, we investigate stronger variants of inclusion, equivalence and sequential uniformisation, based on a general notion of transducer resynchronisation, and show their decidability. We also investigate the classes of finite-valued rational transductions and deterministic rational transductions, which are known to have a decidable equivalence problem. We show that sequential uniformisation is also decidable for them.

1 Introduction

Transductions generalise finite word languages to binary relations of finite words. The notion of rationality for languages, and its correspondence with finite automata, has been extended to transductions and finite automata over pairs of words, called *finite transducers* [2]. In this paper, we study decision problems for finite transducers and prove new decidability results.

Finite transducers. (Finite) transducers are nondeterministic finite automata whose transitions are labelled by pairs of words. The (rational) transduction $\mathcal{R}_T$ defined by a transducer T consists of all the pairs of words (u, v) obtained by concatenating the pairs occurring on transitions of its successful computations. In this paper, we follow a dynamic vision of transducers, as a machine that processes input words u and produces output words v. Therefore, we may speak of the domain of a transduction, as the language of input words that admit at least one output word.

Equivalence problem. Unlike finite automata, finite transducers have undecidable inclusion and equivalence problems [17, 14], even when restricted to unary alphabets [19]. The largest known classes with decidable equivalence problem are those of finite-valued transducers and

deterministic transducers. A transducer is finite-valued if it produces at most k outputs per input, for a bound k that only depends on the transducer. It is decidable whether a transducer is k-valued for a given k [18], and whether there exists k such that it is k-valued [33]. Any finite-valued transducer is known to be (effectively) equivalent to a finite union of unambiguous transducers [32], and thus to a finitely ambiguous transducer. Equivalence of k-ambiguous transducers was shown to be decidable in [18], and equivalence of k-valued transducers was first shown to be decidable in [20, 32]. Other algorithms with better complexities appeared later, and the best known algorithm runs in exponential time, for a fixed k [8].

A transducer is deterministic if the transitions are deterministic in the classical sense, and furthermore each state processes either only input symbols or only output symbols. The class of deterministic rational transductions is also referred to as DRat, and it strictly extends the class of synchronous rational transductions (also called automatic relations), see e.g. [7] for an overview of these sub-classes of rational transductions. As opposed to the class of finite-valued transducers, it is undecidable whether a transduction is equivalent to a deterministic transduction [14]. However, the equivalence problem for DRat is known to be decidable [3], even in polynomial time [15]. This makes this class an interesting candidate for further investigations of decision problems.

Uniformisation problem. Two classes of interest are the rational and sequential functions, which are respectively defined by 1-valued transducers and sequential transducers. The latter read input words in a deterministic manner, and therefore produce a unique output word for each input. There are rational functions that are not sequential, but it is decidable in PTime whether a transducer defines a sequential function [34]. Since rational transductions do not define, in general, functions, an interesting question is whether a unique output word can be picked for each input word of a rational transduction R, in a regular way, thus defining a function $f \subseteq R$ with the same domain as R. Such a function f is called a *uniformiser* of R. It is known that any rational transduction admits a rational uniformiser [23, 10] and, in the case of DRat, even a *lexicographic* uniformiser that picks the smallest output words according to a lexicographic order, making the uniformiser only depend on the transduction [21, 27]. In this paper, we are interested in sequential uniformisers. Even rational functions do not admit sequential uniformisers in general, and therefore this gives rise to a decision problem: Given a finite transducer, does it admit a sequential uniformiser? It is worth noting that even if any rational transduction R can be uniformised by a rational uniformiser U, the sequential uniformisability of R does not imply, in general, that *any* of the uniformisers U is equivalent to a sequential transducer. As a matter of fact, it is known that the sequential uniformisation problem is undecidable for rational transductions [6].

The sequential uniformisation problem echoes a similar problem introduced by Church, the *synthesis problem*, which currently receives a lot of attention from the computer-aided verification community in the context of open reactive systems (see [24, 13, 4] for some work on this subject from the last decade). This problem asks whether given a logical specification of a system, there exists an implementation that satisfies it. In this context, reactive systems are non-terminating systems that react to some unpredictable environment stimuli in a *synchronised* fashion: for each environment input, they produce an output in a deterministic manner, such that the specification is met in the limit. Their executions are modelled by infinite words over a product alphabet, and the interaction with the environment makes game theory a powerful tool in this context. A seminal result due to Büchi and Landweber shows that the synthesis problem is decidable for MSO specifications [22] (see [31] for a modern presentation and an overview).

Restricted to finite words, the sequential uniformisation problem extends Church's problem to more general (asynchronous) classes of specifications and implementations, where the transduction R is the specification and the sequential uniformiser f the implementation.

Resynchronisers. One of the main difficulty of transducers is that two equivalent transducers may produce their outputs very differently: One transducer may go fast and be ahead of the other. By tagging symbols with two colours (for input and output), transductions can be seen as languages, called *synchronisation languages*. It is known by Nivat's theorem that rational transductions are synchronised by regular languages [26], and any transducer defines a regular synchronisation language. Other correspondences between classes of synchronisation languages and classes of rational transductions have been established in [11]. However in general, there is an infinite number of synchronisation languages for a single transduction, making problems such as equivalence and sequential uniformisation undecidable. To overcome this difficulty, Bojanczyk has introduced *transductions with origin information*, which amounts to adding the synchronisation information into the semantics of transducers, via an origin function mapping output positions to their originating input positions [5]. The main result of [5] is a machine-independent characterisation of transductions (with origin information) defined by two-way transducers. With respect to the equivalence problem, considering the origin information makes the problem easy: two transducers define the same transduction with same origin mappings if they have the same synchronisation language. In this paper, we generalise this idea and propose decision problems modulo resynchronisation. A *resynchroniser* $\mathbb{S}$ is a transduction, mapping a synchronisation language to another one. Then, we consider related equivalence and sequential uniformiser problems: for instance, given two transducers, are their synchronisation languages equal modulo $\mathbb{S}$? For the identity resynchroniser, it is the same as origin-equivalence.

Contributions. As a first contribution, we show that inclusion, equivalence and sequential uniformisation are decidable modulo *rational* resynchronisers. For equivalence, it easily reduces to an automata equivalence problem. For sequential uniformisation, it boils down to solving a two-player safety game. We then consider a particular class of resynchronisers, the *k-delay resynchronisers*, that can apply a fixed delay k to a synchronisation language, where the delay is a measure of how ahead an output word is from another one [1]. The k-delay resynchroniser is rational for each k, which implies the decidability of the corresponding decision problem. Interestingly, we show that for the class of real-time transducers (reading at least one input symbol in each transition), k-delay resynchronisers encompass all the power of rational synchronisers with respect to the decision problems we consider.

Our second main contribution is to show that equivalence and sequential uniformisation modulo k-delay resynchronisers are complete for finite-valued transducers. Given two finite-valued transducers, if they are equivalent, then some k can be computed such that they are k-delay equivalent. This yields another, delay-based, proof of the decidability of finite-valued transducer equivalence. We show a similar result for sequential uniformisation, by a pumping argument based on an analysis of the idempotent elements in the transition monoid of finitely-ambiguous transducers. This implies the following new result:

▶ **Theorem 16.** *The sequential uniformisation problem for finite-valued transducers is decidable.*

Finally, we consider deterministic rational transductions, i.e. transductions defined by deterministic transducers. A deterministic transducer is a deterministic automaton whose

states are partitioned into input and output states. They process pairs of words (u, v) as follows: two reading heads placed on u and v respectively process sequentially symbols from u and v. Whenever the current state is an input state, a symbol from u is read and the (input) head moves one step forward, and symmetrically on v when the current state is an output state. The equivalence problem for deterministic transducers is decidable [3], unlike the inclusion problem [14]. Our third main contribution is a decidability proof for the sequential uniformisation problem for deterministic rational transductions, extending a corresponding result for automatic relations from [6].

▶ **Theorem 18.** *The sequential uniformisation problem for deterministic transducers is decidable.*

Structure of the paper. In Section 2, we introduce automata, transducers and decision problems for them. In Section 3, we define the notion of resynchronisers for transductions and study their associated decision problems. We also introduce the particular class of bounded delay resynchronisers. In Section 4, we study the class of finite-valued rational transductions and prove decidability of their sequential uniformisation. Finally in Section 5, we prove decidability of sequential uniformisation for deterministic rational transductions.

2 Automata and Transducers

Let $\mathbb{N}$ denote the set of non-negative integers $\{0, 1, \dots\}$, and for every $n \in \mathbb{N}$, let $[n]$ denote the set $\{1, \dots, n\}$. Given a finite set A, let $|A|$ denote its cardinality.

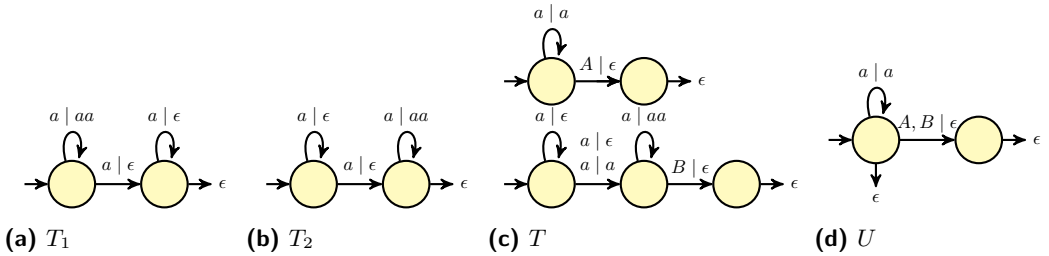
Languages and Transductions of Words. An alphabet Σ is a finite set of symbols. The elements of the free monoid Σ^* are called *words* over Σ. The length of a word w is the number of its symbols. It is written $|w|$. The empty word (of length 0) is denoted by ϵ, and $\Sigma^+ = \Sigma^* \setminus \{\epsilon\}$. The set Σ^* can be partially ordered by the word prefix relation $\preceq$.

We denote by Σ^{-1} the set of symbols σ^{-1} for all $\sigma \in \Sigma$. Any word $u \in (\Sigma \cup \Sigma^{-1})^*$ can be reduced into a unique irreducible word $\overline{u}$ by the equations $\sigma\sigma^{-1} = \sigma^{-1}\sigma = \epsilon$ for all $\sigma \in \Sigma$. Let G_Σ be the set of irreducible words over $\Sigma \cup \Sigma^{-1}$. The set G_Σ equipped with concatenation $u.v = \overline{uv}$ is a group, called the free group over Σ. We denote by u^{-1} the inverse of u. E.g. $(a^{-1}bc)^{-1} = c^{-1}b^{-1}a$. For $u \in G_\Sigma$, we denote by $|u|$ its number of symbols. E.g., $|a^{-1}b^{-1}| = 2$, $|a^{-1}bc^{-1}| = 3$.

A *language* L over Σ is a subset of Σ^*. A *transduction* R over Σ is a subset of $\Sigma^* \times \Sigma^*$. The *domain* of R is the set $\mathrm{dom}(R) = \{u \mid \exists v \in \Sigma^* \cdot (u, v) \in R\}$. For a word $u \in \Sigma^*$, we denote by $R(u)$ the set $\{v \mid (u, v) \in R\}$, and extend this notation to languages L by $R(L) = \bigcup_{u \in L} R(u)$. When R is a function, we simply write $R(u) = v$ instead of $R(u) = \{v\}$. Finally, we denote by id_{Σ^*} the identity relation on Σ^*.

Automata. A (finite state) *automaton* over an alphabet Σ is a tuple $A = (Q, I, F, \Delta)$, where Q is the finite set of states, $I \subseteq Q$ is the set of initial states, $F \subseteq Q$ is the set of final states, and $\Delta \subseteq Q \times \Sigma^* \times Q$ is the finite transition relation. Given a transition $(q, w, q') \in \Delta$, q is called its source, q' its target, and w its label. An automaton is called *deterministic* if each of its transition is labelled by a single letter, and it admits no pair of transitions that have same source, same label, and different targets.

A *run* of A on a word $u \in \Sigma^*$ from state q to state p is either a single state $q \in Q$ if $u = \epsilon$ and $q = p$, or a word $r = (q_1, u_1, p_1)(q_2, u_2, p_2) \dots (q_n, u_n, p_n) \in \Delta^+$ if $u \in \Sigma^+$, where $u = u_1 \dots u_n$, $q_1 = q$ and $p_n = p$, and for all $i \in \{1, \dots, n-1\}$, $p_i = q_{i+1}$. We write $q_1 \xrightarrow{u}_A p_n$



(a) T_1 **(b)** T_2 **(c)** T **(d)** U

Figure 1 Transducers such that $T_1 \equiv T_2$ and T is seq-uniformisable by U.

(or simply $q_1 \xrightarrow{u} p_n$) if such a run exists. A run r from a state q to a state p is *accepting* if q is initial and p is final. The *language* recognised by A, written $\mathcal{L}_A$, is the set of words $w \in \Sigma^*$ such that there exists an accepting run of A on w. If B is an automaton, we write $A \subseteq B$ (resp. $A \equiv B$) whenever $\mathcal{L}_A \subseteq \mathcal{L}_B$ (resp. $\mathcal{L}_A = \mathcal{L}_B$).

Transducers. A (finite state) *transducer* over an alphabet Σ is a tuple $T = (Q, I, F, \Delta, f)$, where Q is the finite set of states, $I \subseteq Q$ the set of initial states, $F \subseteq Q$ the set of final states, $\Delta \subseteq Q \times \Sigma^* \times \Sigma^* \times Q$ the transition relation, and $f : F \to \Sigma^*$ the final output function[1]

As for automata, a *run* of a transducer is either a single state or a sequence of transitions. The *input* (resp. *output*) of a run $r = (q_1, u_1, v_1, p_1) \dots (q_n, u_n, v_n, p_n) \in \Delta^*$ is $\text{in}(r) = u_1 \dots u_n$ (resp. $\text{out}(r) = v_1 \dots v_n$). If r is reduced to a single state, its input and output are both ϵ. We say that r is a run of T on $u_1 \dots u_n$. We write $q \xrightarrow{u|v} p$ to mean that there exists a run on input $u \in \Sigma^*$ whose output is $v \in \Sigma^*$. In particular, $q \xrightarrow{\epsilon|\epsilon} q$ for all $q \in Q$. The notion of accepting run of automata carries over to transducers. The *transduction* recognised by T, written $\mathcal{R}_T$ is the set of pairs $(u, vf(p)) \in \Sigma^* \times \Sigma^*$ such that there exists an accepting run of T on u from a state q to a state p whose output is v. We define $\text{dom}(T)$ as $\text{dom}(\mathcal{R}_T)$. The class of *rational transductions* is the class of relations definable by finite state transducers.

The *input automaton* of T is the automaton $A = (Q, I, F, \Delta')$ over the alphabet Σ, where $\Delta' = \{(q, u, q') | (q, u, v, q') \in \Delta\}$. A transducer is called *real time* if each of its transition is labelled by a pair (a, v), where $a \in \Sigma$ and $v \in \Sigma^*$. A transducer is called *sequential* if its input automaton is deterministic[2]. Sequential transducers define *sequential transductions*. A transducer is *trim* if all its accessible states are co-accessible, i.e. for all $q \in Q$, $q_0 \in I$, $u, v \in \Sigma^*$, if $q_0 \xrightarrow{u|v} q$, then there exist $u', v' \in \Sigma^*$ and $q_f \in F$ such that $q \xrightarrow{u'|v'} q_f$.

Decision Problems for Transducers. Let T_1, T_2 be two transducers over an alphabet Σ. We write $T_1 \subseteq T_2$ whenever $\mathcal{R}_{T_1} \subseteq \mathcal{R}_{T_2}$. The *inclusion problem* asks, given T_1, T_2, whether $T_1 \subseteq T_2$. Similarly, we define the equivalence problem by asking whether $\mathcal{R}_{T_1} = \mathcal{R}_{T_2}$, denoted $T_1 \equiv T_2$. Let T be a transducer over an alphabet Σ. A uniformiser of T is a transducer U such that $U \subseteq T$ and $\text{dom}(U) = \text{dom}(T)$. We sometimes write seq-uniformiser for sequential uniformiser. The *sequential uniformisation problem* (seq-uniformisation problem) asks, given a transducer T over Σ, whether T admits a seq-uniformiser.

[1] Allowing final output functions does not increase the expressiveness of the general model, but is required to define the notion of sequentiality

[2] The term subsequential was originally used in the literature. We follow the terminology of [25].

▶ **Example 1.** The transducers T_1 and T_2 of Fig. 1 both define the transduction $\{(a^n, a^{2i}) \mid n \geq 1, 0 \leq i \leq n-1\}$, thus are equivalent. The transducer T is over the alphabet $\{a, A, B\}$ and defines the transduction $\{(a^nA, a^n) \mid n \geq 0\} \cup \{(a^nB, a^i) \mid n \geq 1,\ 0 \leq i \leq 2n-1\}$. It is uniformisable by the sequential transducer U with $\mathcal{R}_U = \{(a^n\alpha, a^n) \mid n \geq 0, \alpha \in \{A, B\}\}$.

▶ **Theorem 2** ([17, 6]). *The inclusion, equivalence and sequential uniformisation problems for rational transductions are undecidable.*

3 Decision Problems Modulo Resynchronisers

A pair $(u, v) \in \Sigma^* \times \Sigma^*$ can be represented by a coloured word over $\Sigma \times \{\mathtt{i}, \mathtt{o}\}$, where the colours indicate whether a symbol in Σ is an input or an output symbol. Such a coloured word is called a synchronisation of (u, v). More generally, any language over the alphabet $\Sigma \times \{\mathtt{i}, \mathtt{o}\}$ represents a transduction $R \subseteq \Sigma^* \times \Sigma^*$, and is called a synchronisation language for R. This way of representing transductions is analysed in [11]. What we call a resynchroniser below, is a transduction of synchronisations, that is, over words in $(\Sigma \times \{\mathtt{i}, \mathtt{o}\})^*$, that preserves the represented pairs. In this section, we study stronger notion of inclusion, equivalence and sequential uniformisation, parametrised by such a resynchroniser. We show their decidability for rational resynchronisers and introduce the class of bounded delay resynchronisers, and show that it has appealing properties.

Synchronisations and resynchronisers. Given an alphabet Σ, we let $\Sigma_{\mathtt{io}} = \Sigma \times \{\mathtt{i}, \mathtt{o}\}$, $\Sigma_{\mathtt{i}} = \Sigma \times \{\mathtt{i}\}$ and $\Sigma_{\mathtt{o}} = \Sigma \times \{\mathtt{o}\}$. For $c \in \{\mathtt{i}, \mathtt{o}\}$, we write σ^c instead of (σ, c). The colouring c can be seen as a morphism $.^c : \Sigma^* \to \Sigma_c^*$ and we write u^c its application on a word $u \in \Sigma^*$. Conversely, for $c \in \{\mathtt{i}, \mathtt{o}\}$, we define two morphisms $\pi_c : \Sigma_{\mathtt{io}}^* \to \Sigma$ that extract the input and output words, by $\pi_c(\sigma^c) = \sigma$ and $\pi_c(\sigma^d) = \epsilon$, for all $\sigma \in \Sigma$, and $d \neq c$. Two words $u, v \in (\Sigma_{\mathtt{io}})^*$ are said to be *equivalent*, denoted by $u \sim_{\mathtt{io}} v$, if $\pi_c(u) = \pi_c(v)$ for all $c \in \{\mathtt{i}, \mathtt{o}\}$. For example, $a^{\mathtt{i}}b^{\mathtt{i}}a^{\mathtt{o}}$ and $a^{\mathtt{i}}a^{\mathtt{o}}b^{\mathtt{i}}$ are equivalent, and both are synchronisations of (ab, a). Any language $L \subseteq \Sigma_{\mathtt{io}}^*$ defines a transduction over Σ defined by $\mathcal{R}_L = \{(\pi_{\mathtt{i}}(w), \pi_{\mathtt{o}}(w)) \in \Sigma^* \times \Sigma^* \mid w \in L\}$, and L is called a *synchronisation* of a transduction $R \subseteq \Sigma^* \times \Sigma^*$ if $\mathcal{R}_L = R$. We also say that L synchronises R. Note that two different languages may synchronise the same transduction.

Mapping a synchronisation to another one is done through the notion of resynchroniser. A *resynchroniser* is a transduction $\mathbb{S} \subseteq \Sigma_{\mathtt{io}}^* \times \Sigma_{\mathtt{io}}^*$, such that (i) $\mathrm{id}_{\Sigma_{\mathtt{io}}^*} \subseteq \mathbb{S}$ and (ii) for all $(w, w') \in \mathbb{S}$, it holds $w \sim_{\mathtt{io}} w'$. For instance, the identity relation $\mathrm{id}_{(\Sigma_{\mathtt{io}})^*}$ is a resynchroniser that we shall denote by $\mathbb{I}$, as well as the relation $\mathbb{U}_{\Sigma_{\mathtt{io}}} = \{(w, w') \in \Sigma_{\mathtt{io}}^* \times \Sigma_{\mathtt{io}}^* \mid w \sim_{\mathtt{io}} w'\}$, called the *universal resynchroniser* over $\Sigma_{\mathtt{io}}$. We write $\mathbb{U}$ instead of $\mathbb{U}_{\Sigma_{\mathtt{io}}}$ when it is clear from the context. Note that for any resynchroniser $\mathbb{S}$, we have $\mathrm{id}_{\Sigma_{\mathtt{io}}^*} \subseteq \mathbb{S} \subseteq \mathbb{U}$. The properties (i) and (ii) of resynchronisers are chosen such that they preserve the represented transductions, as stated in the proposition below.

▶ **Proposition 3.** *For all $L \subseteq \Sigma_{\mathtt{io}}^*$ and all resynchronisers $\mathbb{S} \subseteq \Sigma_{\mathtt{io}}^* \times \Sigma_{\mathtt{io}}^*$, $\mathcal{R}_L = \mathcal{R}_{\mathbb{S}(L)}$.*

Classes of synchronisation languages and their correspondence with the classes of rational relations they synchronise have been studied in [11]. We can formulate in this framework a result known as Nivat's theorem [26] as follows.

▶ **Theorem 4.** *[26] A transduction R is rational iff it is synchronised by a regular language.*

A regular language synchronising a rational transduction can be obtained as follows. Any transducer $T = (Q, I, F, \Delta, f)$ naturally defines a regular synchronisation for $\mathcal{R}_T$ by its

underlying automaton, which is the automaton obtained by concatenating the pairs of input and output words on the transitions and marking them with the respective symbol from $\{\mathtt{i}, \mathtt{o}\}$. Formally, it is the automaton $A = (Q \cup \{q_\dashv\}, I, \{q_\dashv\}, \Delta')$ over $\Sigma_{\mathtt{io}}$, where $\Delta' = \{(q, v^{\mathtt{i}}w^{\mathtt{o}}, q') | (q, v, w, q') \in \Delta\} \cup \{(q, f(q)^{\mathtt{o}}, q_\dashv) | q \in F\}$. The *language recognised by* T is the language recognised by its underlying automaton, denoted by $\mathcal{L}_T$, i.e. $\mathcal{L}_T = \mathcal{L}_A$. Obviously, $\mathcal{L}_T$ is a synchronisation for the relation $\mathcal{R}_T$ (proving one direction of Thm 4).

Decision problems for transducers modulo resynchronisers. Let Σ be an alphabet, $\mathbb{S}$ be a resynchroniser over $(\Sigma_{\mathtt{io}})^*$, and T_1, T_2 be two transducers over Σ. We say that T_1 is *included in* T_2 *modulo* $\mathbb{S}$ (or $\mathbb{S}$-*included*), denoted by $T_1 \subseteq_{\mathbb{S}} T_2$, if $\mathcal{L}_{T_1} \subseteq \mathbb{S}(\mathcal{L}_{T_2})$. We say that T_1 is *equivalent to* T_2 *modulo* $\mathbb{S}$ (or $\mathbb{S}$-*equivalent*), denoted by $T_1 \equiv_{\mathbb{S}} T_2$, if $T_1 \subseteq_{\mathbb{S}} T_2$ and $T_2 \subseteq_{\mathbb{S}} T_1$. For a fixed synchroniser $\mathbb{S}$, the $\mathbb{S}$-*inclusion (resp.* $\mathbb{S}$-*equivalence) problem* asks, given two transducers T_1, T_2 over Σ, whether $T_1 \subseteq_{\mathbb{S}} T_2$ (resp. $T_1 \equiv_{\mathbb{S}} T_2$). We say that T_1 is *sequentially* $\mathbb{S}$-*uniformisable* if it admits a sequential uniformiser U such that $U \subseteq_{\mathbb{S}} T_1$, and in that case U is called a sequential $\mathbb{S}$-uniformiser of T_1 (seq-$\mathbb{S}$-uniformiser for short). The *sequential* $\mathbb{S}$-*uniformisation problem* asks whether a given transducer is seq-$\mathbb{S}$-uniformisable.

It should be clear from the definition that $\mathbb{I}$-inclusion implies $\mathbb{S}$-inclusion for any resynchroniser $\mathbb{S}$, which in turn implies $\mathbb{U}$-inclusion. As a matter of fact, it is easy to see that $\mathbb{U}$-inclusion is equivalent to classical inclusion. The same remarks can be made for equivalence and sequential uniformisation, and as a consequence of Theorem 2, we get:

▶ **Theorem 5.** *The* $\mathbb{U}$*-inclusion,* $\mathbb{U}$*-equivalence, sequential* $\mathbb{U}$*-uniformisation problems for rational transductions are undecidable.*

Decision problems for transducers modulo rational resynchronisers. The $\mathbb{U}$-decision problems are undecidable, this raises the question whether there is an interesting class of resynchronisers for which we can recover decidability. It turns out that $\mathbb{U}$ is not rational. In contrast, we show that, as long as $\mathbb{S}$ is rational, the $\mathbb{S}$-decision problems are reducible to the $\mathbb{I}$-decision problems, which in turn can be solved by reduction to decidable problems of automata and two-player games.

▶ **Proposition 6.** *The* $\mathbb{I}$*-inclusion and* $\mathbb{I}$*-equivalence problems are* PSpace-complete*. The sequential* $\mathbb{I}$*-uniformisation problem is* ExpTime-complete*.*

Proof. First, note that $T_1 \subseteq_{\mathbb{I}} T_2$ iff $\mathcal{L}_{T_1} \subseteq \mathcal{L}_{T_2}$ iff $A_1 \subseteq A_2$, where A_1, A_2 are the underlying automata of T_1, T_2 respectively. Automata inclusion and equivalence problems are PSpace-complete, and they easily reduce (by putting ϵ outputs) to $\mathbb{I}$-inclusion and $\mathbb{I}$-equivalence.

To get ExpTime membership of seq-$\mathbb{I}$-uniformisation, for a transducer T, we construct a two-player safety game $G_T = (V = V_{\mathsf{In}} \uplus V_{\mathsf{Out}}, v_0, E)$ between an adversary (Player In) who picks input symbols and controls positions in V_{In}, and a protagonist (Player Out) who picks sequences of output symbols and controls positions in V_{Out}. Wlog we assume that T has no final output function, by adding an endmarker $\dashv$ to words of its domain. Let $A = (Q, q_0, F, \delta)$ be a complete DFA equivalent to the the underlying automaton of T (whose size is at most exponential in the size of T). Player positions have three components: a residual language[3] of $\mathrm{dom}(T)$ controlling the possible continuations of the input word chosen so far by Player In, a state of A and a round $r \in \{\mathsf{In}, \mathsf{Out}\}$. Let $\mathcal{D} = \{u^{-1}\mathrm{dom}(T) \mid u \in \Sigma^*\}$ be the set of residuals of $\mathrm{dom}(T)$ (represented by the states of the minimal DFA for $\mathrm{dom}(T)$, computed in

[3] A residual of a language L over some alphabet Σ is a language $u^{-1}L = \{v \mid uv \in L\}$ for $u \in \Sigma^*$.

exponential time in the size of T). Then, $V_{\mathsf{In}} = \mathcal{D} \times Q \times \{\mathsf{In}\}$ and $V_{\mathsf{Out}} = \mathcal{D} \times Q \times \{\mathsf{Out}\}$. The initial position is $v_0 = (\mathrm{dom}(T), q_0, \mathsf{In})$ and the edge relation E as follows: from a position (D, q, In), there are outgoing edges to all states $(\sigma^{-1}D, \delta(q, \sigma^{\mathtt{i}}), \mathsf{Out})$ for all $\sigma \in \Sigma$. From a position (D, q, Out), Player Out can pick any state $q' \in Q$ such that there exists a sequence $v \in \Sigma_{\mathtt{o}}^*$ such that $q \xrightarrow{v}_A q'$, and in that case an outgoing edge to (D, q', In) is added to E. The *unsafe positions* for Player Out are all positions (D, q, In) such that $\epsilon \in D$ and $q \notin F$: at such positions, Player In could choose to terminate the sequence of input symbols (while staying in $\mathrm{dom}(T)$ since $\epsilon \in D$) and the sequence of output symbols chosen by Player Out, mixed with the input symbols chosen by Player In, does not belong to $L(A)$ (since $q \notin F$).

It can be shown that Player Out has a strategy to avoid the unsafe positions in G_T iff there exists a seq-$\mathbb{I}$-uniformiser of T. We briefly explain how to extract a uniformiser from a memoryless winning strategy. A memoryless winning strategy of Player Out can be represented by a function $\lambda : V_{\mathsf{Out}} \to V_{\mathsf{In}}$. The uniformiser U_λ has V_{In} as state set. Let v be a state of U_λ where $v = (D, q, \mathsf{In}) \in V_{\mathsf{In}}$ and $\sigma \in \Sigma$. Let $v' = (\sigma^{-1}D, \delta(q, \sigma^{\mathtt{i}}), \mathsf{Out})$ and $v'' = \lambda(v')$. By definition of G_T, $v'' = (\sigma^{-1}D, q', \mathsf{In})$ such that $\delta(q, \sigma^{\mathtt{i}}) \xrightarrow{w}_A q'$ for some word $w \in \Sigma^*$. We then add the transition (v, σ, w, v'') to U_λ. The word w can be uniquely chosen by taking the minimal word for some lexicographic order, making U_λ sequential. Accepting states are states $v = (D, q, \mathsf{In})$ with $\epsilon \in D$, thus ensuring $\mathrm{dom}(U_\lambda) = \mathrm{dom}(T)$. Since λ is winning, we then necessarily have $q \in F$, ensuring that the sequence of input and output symbols read and produced by U_λ belongs to $\mathcal{L}_A$, making U_λ an $\mathbb{I}$-uniformiser.

Since safety games can be solved in polynomial time and G_T has exponential size, we get the result. The results on safety games that we use here can be found, e.g., in [16].

For the ExpTime lower bound, we note that in our formalism we can model the synchronous uniformisation (or synthesis) problem, as considered in [28] for infinite words, by taking synchronisations that strictly alternate between input and output. It seems to be common knowledge in the synthesis community that the synchronous uniformisation problem is ExpTime-complete if the relation is given by a nondeterministic automaton. However, we were not able to find a reference for this result. We thus give a reduction from the acceptance problem for alternating Pspace Turing machines in a long version. ◀

For all transducers T and resynchronisers $\mathbb{S}$, $\mathbb{S}(\mathcal{L}_T)$ is a regular synchronisation language and by Nivat's theorem (Theorem 4), there exists a transducer $T^{\mathbb{S}}$ such that $\mathcal{L}_{T^{\mathbb{S}}} = \mathbb{S}(\mathcal{L}_T)$. It implies that the seq-$\mathbb{S}$-uniformisation of T reduces to the seq-$\mathbb{I}$-uniformisation of $T^{\mathbb{S}}$. Similar arguments apply for inclusion and equivalence and from Proposition 6 we obtain:

▶ **Theorem 7.** *Let $\mathbb{S}$ be a rational resynchroniser, given as a transducer. The $\mathbb{S}$-inclusion and $\mathbb{S}$-equivalence problems are* PSpace-complete. *The sequential $\mathbb{S}$-uniformisation problem is* ExpTime-complete.

Bounded delay resynchronisers. The notion of *delay* between outputs of transducers is a powerful way of comparing transducers, which has been used, for instance, to characterise sequential functions [2]. Intuitively, the delay between two runs on the same input is a parameter that measures how a run is ahead of the other, and the lag is the maximal delay over prefixes of the two runs. We adapt the notion of delay and lag to coloured words and define delay resynchronisers as resynchronisers that apply a fixed delay to words in $\Sigma_{\mathtt{io}}^*$ (our notion of lag is not related to the one from [11]). Our results show that delay resynchronisers form a fundamental class of resynchronisers.

The *delay* between two words u and v over an alphabet Σ is the element from the free group G_Σ defined by $\mathrm{delay}(u, v) = u^{-1}v$. E.g., $\mathrm{delay}(ab, acd) = b^{-1}cd$. Note that $\mathrm{delay}(u, v) \in \Sigma^*$ iff

$u \preceq v$, and $\text{delay}(u,v) \in (\Sigma^{-1})^*$ iff $v \preceq u$. The *lag mapping* $\text{lag} : (\Sigma_{\mathtt{i}\mathtt{o}})^* \times (\Sigma_{\mathtt{i}\mathtt{o}})^* \to \mathbb{N} \cup \{+\infty\}$ gives the maximal length of the delay between the output part of two words in $(\Sigma_{\mathtt{i}\mathtt{o}})^*$ that have the same input. It is the metric defined by $\text{lag}(u,v) = +\infty$ if $\pi_{\mathtt{i}}(u) \neq \pi_{\mathtt{i}}(v)$. If $\pi_{\mathtt{i}}(u) = \pi_{\mathtt{i}}(v)$, then u and v can be decomposed into $u = u_0 a_1 u_1 \dots u_{n-1} a_n u_n$ and $v = v_0 a_1 v_1 \dots a_{n-1} b_n v_n$, such that $a_1, \dots, a_n \in \Sigma_{\mathtt{i}}$, $u_0, v_0, \dots, u_n, v_n \in (\Sigma_{\mathtt{o}})^*$. Then $\text{lag}(u,v) = \max_{0 \leq i \leq n} |\text{delay}(u_0 \dots u_i, v_0 \dots v_i)|$. As an example, for $n \geq 1$, take $u_n = a^{\mathtt{i}} a^{\mathtt{o}} (a^{\mathtt{i}})^n$ and $v_n = (a^{\mathtt{i}})^n a^{\mathtt{i}} a^{\mathtt{o}}$. Then for all $n \geq 1$, $\text{lag}(u_n, v_n)$=1. Note that the occurrence of $a^{\mathtt{o}}$ in u_n is arbitrary far from that of $a^{\mathtt{o}}$ in v_n.

We now define the k-delay resynchroniser $\mathbb{D}_k$. Intuitively, it can shift output symbols of a word u to the left or to the right, as long as the lag between u and the new word obtained this way is bounded by k. Formally, the *k-delay resynchroniser* is defined by $\mathbb{D}_k = \{(u,v) \in (\Sigma_{\mathtt{i}\mathtt{o}})^2 \mid u \sim_{\mathtt{i}\mathtt{o}} v \wedge \text{lag}(u,v) \leq k\}$. We define the *$k$-inclusion*, *$k$-equivalence* and sequential *k-uniformisation* problems as the corresponding $\mathbb{D}_k$-decision problems, and write $\subseteq_k$ and $\equiv_k$ instead of $\subseteq_{\mathbb{D}_k}$ and $\equiv_{\mathbb{D}_k}$ respectively. We also say that a transduction is *seq-k-uniformisable* if it is seq-$\mathbb{D}_k$-uniformisable. An important property of $\mathbb{D}_k$ is:

▶ **Proposition 8.** *For all $k \geq 0$, $\mathbb{D}_k$ is rational.*

As a direct consequence of the latter proposition and Theorem 7, the k-delay decision problems are all decidable. We can be more precise:

▶ **Theorem 9.** *For all $k \geq 0$, the k-inclusion, k-equivalence and sequential k-uniformisation problems are decidable and* ExpSpace-hard *if k is part of the input. If k is fixed, then the k-inclusion and k-equivalence problems are* PSpace-complete*, and the sequential k-uniformisation problem is* ExpTime-complete*.*

Even if inclusion is undecidable while k-inclusion is decidable, it could be the case that inclusion reduces to k-inclusion, for some k that cannot be computed. We show that that it is not the case, by using the transducers of Fig. 1.

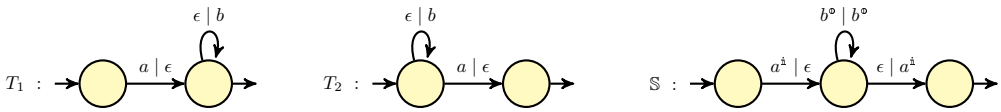
▶ **Proposition 10.** *There exist transducers T_1, T_2, T such that $T_1 \equiv T_2$, $T_1 \subseteq T_2$ and T is seq-uniformisable, but for all $k \geq 0$, $T_1 \not\equiv_k T_2$, $T_1 \not\subseteq_k T_2$, and T is not seq-k-uniformisable.*

Proof. Consider T_1, T_2 of Fig.1 and pairs of the form $(a^{n+1}, a^{2n}) \in \mathcal{R}_{T_1} = \mathcal{R}_{T_2}$. They both accept these pairs but T_2 will be arbitrarily late compared to T_1. Consider now the transducer T and its sequential uniformiser U. On inputs $a^n B$, U will be arbitrarily ahead of T, and one can show that is the case for *any* seq-uniformiser of T. ◀

Finally, we show that for real-time transductions, k-delay resynchronisers subsume any rational resynchroniser $\mathbb{S}$, in the sense that $\mathbb{S}$-inclusion implies k-inclusion, for some k that depends on $\mathbb{S}$. Similar results hold for equivalence and sequential uniformisation. The idea is that a rational synchroniser cannot advance or delay the production of outputs arbitrarily far away with a finite set of states.

▶ **Theorem 11.** *Let $\mathbb{S}$ be a rational synchroniser (given by a transducer). Let T_1, T_2, T be real-time transducers. There exists a computable integer $k \in \mathbb{N}$ such that:* (i) *if $T_1 \subseteq_{\mathbb{S}} T_2$, then $T_1 \subseteq_k T_2$,* (ii) *if $T_1 \equiv_{\mathbb{S}} T_2$, then $T_1 \equiv_k T_2$, and* (iii) *if T is seq-$\mathbb{S}$-uniformisable, then T is seq-k-uniformisable.*

One cannot drop the real-time assumption in the latter theorem. Indeed consider the following transducers $T_1, T_2, \mathbb{S}$, for which $T_1 \equiv_{\mathbb{S}} T_2$ but T_1, T_2 are not k-equivalent for any k:



4 Finite-valued transducers

Let $m \in \mathbb{N}$. We remind the reader that a transducer T is called *m-valued* if each input has at most m outputs, i.e. for all $w \in \mathrm{dom}(T)$, $|\mathcal{R}_T(w)| \leq m$. It is finite-valued if it is m-valued for some m. Finite-valuedness is decidable [33]. We prove that for the class of finite-valued transducers, k-inclusion and sequential k-uniformisation are complete. This yields, for finite-valued transducers, an alternative proof of the decidability of the inclusion problem, and a new result: The decidability of sequential uniformisation.

Let m be a natural number. An automaton A (resp. transducer T) is called *m-ambiguous* if it is real-time[4], and for any word $w \in \mathcal{L}_A$ (resp. $w \in \mathrm{dom}(T)$), there exist at most m accepting runs of A (resp. T) on w. An automaton (transducer) is called *finitely ambiguous* if there exists $m \in \mathbb{N}$ such that it is m-ambiguous, and *unambiguous* if it is 1-ambiguous. Our proofs uses the following known decomposition initially due to Weber:

▶ **Theorem 12.** *[32, 30] Any finite-valued transducer T is (effectively) equivalent to a union of unambiguous transducers.*

We first prove that, for the class of finitely ambiguous transducers, inclusion and equivalence reduces to k-inclusion and k-equivalence for some computable k. We state this result for inclusion, which immediately implies it for equivalence. The proof is based on similar pumping techniques than Lemma 2 in [9].

▶ **Theorem 13.** *Let T_1 and T_2 be two real-time transducers such that T_2 is m-ambiguous. Then there exists a computable integer k such that $T_1 \subseteq T_2 \implies T_1 \subseteq_k T_2$. Moreover, k can be chosen to be exponential in the size of T_2 and linear in the size of T_1.*

Since k-inclusion is decidable by Theorem 7, Theorem 13 implies that the inclusion and equivalence problems are decidable for finitely ambiguous transducers. From the decomposition of Theorem 12, we obtain an alternative proof of the decidability of equivalence of finite-valued transducers, which was proved in [20, 32].

▶ **Corollary 14** ([20, 32] Alternative proof)**.** *The inclusion and equivalence problems for finite-valued transducers are decidable.*

We now prove the two corresponding results for the sequential uniformisation problem.

▶ **Theorem 15.** *Let T be a real-time trim transducer given as a finite union of unambiguous transducers. Then there exists a computable integer N_T such that if T is sequentially uniformisable, then it is sequentially N_T-uniformisable.*

Sketch of proof. If T is seq-uniformisable, then there exists a sequential uniformiser U of T such that $\mathrm{dom}(U) = \mathrm{dom}(T)$ and $U \subseteq T$. The latter inclusion implies, by Theorem 13, that there exists an integer k such that $U \subseteq_k T$, and so U is a seq-k-uniformiser of T. However, k depends on the number of states of the hypothetical uniformiser U. We show how to construct, by simulating the behaviour of U, another seq-N_T-uniformiser U', where N_T only depends on T and can be computed.

More precisely, we define a function $\rho : \Sigma^* \to \Sigma^*$ and define U' such that on any input w, it simulates U on input $\rho(w)$. The function ρ iterates some well-chosen subwords of w to blow up the delay between the outputs of the runs of T on $\rho(w)$. On input $\rho(w)$, any

[4] For simplicity reasons, we put real-timeness in the definition, but it is known to be wlog.

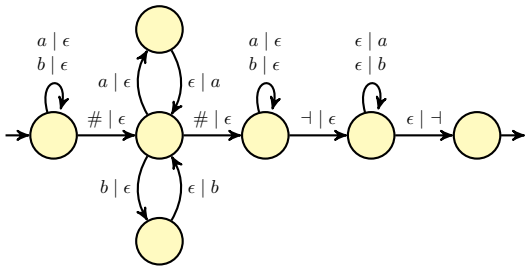


Figure 2 A deterministic transducer with endmarker for $\mathcal{R}_1$ from Ex. 17.

seq-k-uniformiser of T, and U in particular, is forced to make choices between possible outputs of T on $\rho(w)$, in order to decrease the delay. The main idea is that if, by making some good choice of output, U is able to react to a threat of exceeding delay k on $\rho(w)$, then by doing the same choice on w, U' can also react to a threat of exceeding delay N_T.

We identify several key properties that ρ must satisfy, in order to be able to construct U'. For instance, we require that $\rho(w)$ is a prefix of $\rho(wa)$ for all $w \in \Sigma^*$, $a \in \Sigma$, but also some property relating the delays between U and T on input w and on input $\rho(w)$.

The challenging part of the proof is to prove the existence of N_T and ρ. It is based on a study of the structural properties of the transition monoid of finitely ambiguous transducers (a monoid that captures the state behaviour of automata and transducers), and the effect of its elements on the delays. In particular, subwords of w that are iterated to define $\rho(w)$ correspond to idempotent elements in the transition monoid of T, and the bound N_T is obtained by an application of Ramsey's theorem. ◀

Since by Theorem 7 every finite-valued transducer is effectively equivalent to a finitely ambiguous transducer, the sequential uniformisation problem for finite-valued transducers reduces to sequential N-uniformisation, for computable integers N. Hence by Theorem 7 and the fact that any transducer can be trimmed in polynomial time, we get decidability of sequential uniformisation of finite-valued transducers, one of the main results of this paper.

▶ **Theorem 16.** *The sequential uniformisation problem for finite-valued transducers is decidable.*

5 Deterministic Rational Transductions

In this section we consider another subclass of rational transductions, namely the deterministic rational transductions, denoted by DRat. This class is defined in terms of specific deterministic transducers and some problems that are undecidable for general rational transductions are decidable in the case of DRat. For example, the equivalence problem is decidable [3] (while inclusion is easily seen to be undecidable [14]), and whether a given relation in DRat is recognisable [7] is also decidable. We obtain here another decidability result, namely that the sequential uniformisation problem is decidable for deterministic transducers.

For the definition of deterministic rational transducers, we work with endmarkers (this is the common way of doing it, see also [29]). The determinism includes the standard definition of unique successor states for each symbol and additionally a deterministic choice between input and output. This is enforced by a partition of the state space into states processing input symbols and states processing output symbols.

▶ **Example 17.** The transduction $\mathcal{R}_1 = \{(u\#v\#w, vx) \mid u, v, w, x \in \{a, b\}^*\}$ is in DRat since it is recognised by the deterministic transducer depicted in Fig. 2 over the alphabet $\{a, b, \#\}$ with endmarker $\dashv$. Note that for each state the outgoing transitions either all have ϵ as output component, or all have ϵ as input component. In the formal definition, this is captured by partitioning the states into input and output states.

Let Σ be an alphabet and $\dashv$ a fresh symbol used as endmarker. We let $\Sigma_\dashv := \Sigma \cup \{\dashv\}$. A deterministic transducer over the alphabet Σ with endmarker $\dashv$ is of the form $T = (Q^{\mathtt{i}}, Q^{\mathtt{o}}, F, q_0, \delta)$ with a set $Q^{\mathtt{i}}$ of input states, a set $Q^{\mathtt{o}}$ of output states (we write Q for the union of these two sets), a unique initial state q_0, a transition function $\delta : Q \times \Sigma_\dashv \to Q$, and a set $F \subseteq Q$ of accepting states. In the presence of endmarkers, the final output function is not required anymore.

For defining the semantics of such a deterministic transducer, one can transform it into a standard transducer. However, this transformation needs to take care of the endmarker only being allowed at the end of the word, which is not enforced in the definition of deterministic transducers. To avoid this, we rather define the semantics by extending the transition function to pairs of words (input and output word). For $(u, v) \in \Sigma_\dashv^* \times \Sigma_\dashv^*$ and $q \in Q$, we define $\delta^* : Q \times \Sigma_\dashv^* \times \Sigma_\dashv^* \to Q \times \Sigma_\dashv^* \times \Sigma_\dashv^*$ inductively as follows:

- If $q \in Q^{\mathtt{i}}$, then $\delta^*(q, \epsilon, v) = (q, \epsilon, v)$ and $\delta^*(q, au, v) = \delta^*(\delta(q, a), u, v)$.
- If $q \in Q^{\mathtt{o}}$, then $\delta^*(q, u, \epsilon) = (q, u, \epsilon)$ and $\delta^*(q, u, av) = \delta^*(\delta(q, a), u, v)$.

So δ^* applies δ to the next input letter from states in $Q^{\mathtt{i}}$ and to the next output letter from states in $Q^{\mathtt{o}}$ as long as possible. The transduction $\mathcal{R}_T$ defined by T is

$$\mathcal{R}_T = \{(u, v) \in \Sigma^* \times \Sigma^* \mid \delta^*(q_0, u \dashv, v \dashv) = (q, \epsilon, \epsilon) \text{ with } q \in F\}.$$

Recall from Section 4 that k-delay inclusion and equivalence are complete for finite-valued transducers, as stated in Theorem 13. We note that this is not the case for DRat.

▶ Remark. There are deterministic transducers T_1 and T_2 such that $T_1 \equiv T_2$ but there is no k such that $T_1 \equiv_k T_2$.

Proof. Consider the complete relation $\Sigma^* \times \Sigma^*$, and let T_1 be the deterministic transducer that first reads all input symbols (up to the endmarker $\dashv$), and then reads all output symbols. Let T_2 be the deterministic transducer that first reads all output symbols and then the input symbols. Obviously, $\mathcal{R}_{T_1} = \mathcal{R}_{T_2} = \Sigma^* \times \Sigma^*$. However, the lag for the two runs of T_1, T_2 on a pair (u, v) is $|v|$ and thus not bounded. ◀

Our main result for DRat is the following, which extends the corresponding result for automatic relations from [6].

▶ **Theorem 18.** *The sequential uniformisation problem for deterministic transducers is decidable.*

The proof uses the game-theoretic approach, building a game between players Input and Output. A winning strategy for player Output then corresponds to a sequential uniformiser. The moves of the game simulate the deterministic transducer T on the pairs of input and output word played by the two players in order to check whether the output indeed matches the input. However, Output might need to delay the moves to gain some lookahead on the input for making the next decisions. The main challenge in the proof is to find a way to keep the lookahead information bounded without losing too much information. It is not sufficient to simply store words of bounded length as lookahead. The information in the lookahead

rather provides information on the behaviour that the lookahead word induces in T. Player Output can delete parts of this information to reduce the size of the lookahead.

The sequential uniformiser that is constructed from the game in the decidability proof can be shown to have bounded delay. So we obtain the following result, showing that sequential k-uniformisation is complete for deterministic transducers.

▶ **Theorem 19.** *Any sequentially uniformisable deterministic transducer is sequentially k-uniformisable for some $k \in \mathbb{N}$ that can be computed from the given transducer.*

6 Conclusion

We have introduced the notion of resynchronisers, which are transformations for synchronisations of transductions. The decision problems of inclusion, equivalence, and sequential uniformisation, which are undecidable for general rational transductions, become decidable modulo rational resynchronisers. Furthermore, we have shown that it is sufficient to consider k-delay resynchronisers in the context of these decision problems. We have analysed two subclasses of transducers, finite-valued transducers and deterministic transducers. For both classes, sequential uniformisation is decidable, and the existence of a sequential uniformiser implies the existence of a sequential k-uniformiser. Additionally, for finite-valued transducers k-inclusion is shown to be complete. One interesting open question is the problem of deciding for a transducer whether it admits a sequential k-uniformiser for some k.

Abstract

In this paper, we exhibit a one-to-one correspondence between ω-regular languages and a subclass of regular cost functions over finite words, called ω-regular like cost functions. This bridge between the two models allows one to readily import classical results such as the last appearance record or the McNaughton-Safra constructions to the realm of regular cost functions. In combination with game theoretic techniques, this also yields a simple description of an optimal procedure of history-determinisation for cost automata, a central result in the theory of regular cost functions.

1 Introduction

The theory of regular cost functions [4] aims at offering a uniform framework dealing with boundedness questions in automata theory. It provides a toolbox of concepts and results for solving questions involving resource constraints, such as the star height problem over finite words [10, 12] and finite trees [7], the finite power property [14], the boundedness of fixpoints for monadic second-order logic [2] or over guarded logic [1], or for attacking the Mostowski index problem [7]. The strength of regular cost functions is that it is a quantitative setting where many of the crucial results of regular languages generalise, including the cornerstone effective equivalence between logic, automata, algebra and expressions.

For regular languages, determinising plays a central role, as for instance for complementing automata over infinite trees, or for solving games. The situation is different for cost functions, even over finite words: it is impossible to determinise cost automata, deterministic cost automata being strictly less expressive. The notion of history-deterministic automata overcomes this shortcoming. These are non-deterministic cost automata that have the semantical property that an oracle resolves the non-determinism in an optimal way. The non-determinisability issue is resolved by establishing that cost automata can be effectively transformed into history-deterministic ones [4]. This is crucially used for instance when

developing the theory of regular cost functions over finite trees [7]. However, the proof of this result is so far very complicated. The original version [4] was going through algebra (stabilisation monoids), incurring a double exponential blowup. An optimal version inspired by the construction of Safra is known [5], but its description and correctness proof are extremely complicated.

One aim of the present work is to give a simple description and correctness proof of the construction from [5] which, given a cost-automaton as input, produces an equivalent history-deterministic automaton. The key advantage of the novel presentation in this work is that it uses the determinisation of ω-regular languages as a *black box*. In particular, it does not depend at all on the details of the (relatively complicated) Safra construction. This also makes both the construction and the proof much simpler. Further, it is optimal, meaning that it yields an automaton of exponential size, matching known lower bound for the case of ω-regular languages [8].

In order to obtain this completely new presentation, we describe a one-to-one correspondence between the theory of ω-regular languages and a subclass of regular cost functions, called the ω-regular like cost functions. This correspondence allows us to readily import from ω-regular languages constructions such as the last appearance record or determinisation results to regular cost functions. In other words, ω-regular like cost functions are determinisable.

In a second step, combining game theoretic techniques with an idea of Bojańczyk [3], we obtain a simple, direct and optimal construction of history-deterministic cost automata.

Structure of the document

We define the class of ω-regular like cost functions in Section 3, and study its properties. We give in Section 4 the history-determinisation procedure, relying on the results about ω-regular like cost functions combined with game theoretic techniques.

2 Definitions

Let $\mathtt{A}$ and $\mathtt{B}$ be *alphabets*. An *initial automaton structure* is denoted $\mathcal{A} = (Q, \mathtt{A}, \mathtt{B}, I, \Delta)$, where $\mathtt{A}$ is the *input alphabet*, $\mathtt{B}$ is the *output alphabet*, Q is a finite *set of states*, $I \subseteq Q$ is the set of *initial states* and $\Delta \subseteq Q \times \mathtt{A} \times \mathtt{B} \times Q$ is the *transition relation*. An element $(p, a, b, q) \in \Delta$ is called a *transition*. An *automaton structure* $\mathcal{A} = (Q, \mathtt{A}, \mathtt{B}, I, \Delta, F)$ is an initial automaton structure enriched with a set $F \subseteq Q$ of accepting states.

A *run* (which can be finite or infinite) is a sequence of transitions of the form

$$(p_0, a_1, b_1, p_1)(p_1, a_2, b_2, p_2) \cdots$$

such that p_0 is initial. We denote by $\rho|_A$ its projection to the alphabet $\mathtt{A}$, and by $\rho|_B$ its projection to the alphabet $\mathtt{B}$. For w a finite or infinite word over $\mathtt{A}$, we say that a run ρ is a run of w if $\rho|_A = w$ and a prefix run of w if $\rho|_A$ is a prefix of w. When dealing with an automaton structure, we further require that a run of a finite word ends in an accepting state.

ω-automata

An *ω-automaton* is denoted $\mathcal{A} = (Q, \mathtt{A}, \mathtt{B}, I, \Delta, W)$, where $(Q, \mathtt{A}, \mathtt{B}, I, \Delta)$ is an initial automaton structure, and $W \subseteq \mathtt{B}^\omega$ is called the *accepting condition*. The ω-language recognised by the ω-automaton is the set

$$\{w \in \mathtt{A}^\omega \mid \text{there exists a run } \rho \text{ over } w \text{ such that } \rho|_B \in W\}.$$

We define some of the classical ω-accepting conditions.

$$\begin{aligned}
\texttt{Büchi} &= \{w \in \{0,1\}^\omega \mid w \text{ contains infinitely many } 0's\} \\
\texttt{coBüchi} &= \{w \in \{1,2\}^\omega \mid w \text{ contains finitely many } 1's\} \\
\texttt{Rabin}_1 &= \left\{ w \in \{I,R,\epsilon\}^\omega \;\middle|\; \begin{array}{l} w \text{ contains infinitely many } I's \\ \text{and finitely many } R's \end{array} \right\} \\
\texttt{Rabin}_k &= \left\{ w \in \left(\{I,R,\epsilon\}^k\right)^\omega \;\middle|\; \begin{array}{l} \text{for some } \ell \in \{1,\dots,k\}, \\ w \text{ contains infinitely many } I'_\ell s \\ \text{and finitely many } R'_\ell s \end{array} \right\} \\
\texttt{Parity}_k &= \left\{ w \in \{1,\dots,k\}^\omega \;\middle|\; \begin{array}{l} \text{the smallest colour appearing} \\ \text{infinitely often in } w \text{ is even} \end{array} \right\}
\end{aligned}$$

A *Rabin automaton* is an ω-automaton with a Rabin condition, and similarly for the other conditions. It is known that Büchi, parity and Rabin automata recognise the same ω-languages, that are called the *ω-regular languages*.

Regular cost functions

We consider functions from $\mathtt{A}^*$ to $\mathbb{N} \cup \{\infty\}$. Let f be such a function, and $X \subseteq \mathtt{A}^*$, we say that $f|_X$ is bounded if there exists $n \in \mathbb{N}$ such that $f(u) \leq n$ for all $u \in X$.

Let f, g be two such functions, then g *dominates* f, denoted $f \preccurlyeq g$, if for all $X \subseteq \mathtt{A}^*$, if $g|_X$ is bounded then $f|_X$ is bounded. We say that f and g are equivalent, denoted $f \approx g$, if $f \preccurlyeq g$ and $g \preccurlyeq f$. The following lemma is central, see [6] for more considerations on this equivalence relation.

▶ **Lemma 1.** *$f \preccurlyeq g$ if, and only if, $f \leq \alpha \circ g$ for some function $\alpha : \mathbb{N} \to \mathbb{N}$ such that $\lim \alpha = \infty$, extended with $\alpha(\infty) = \infty$.*

A *cost function* is an equivalence class for the relation $\approx$.

Many equivalent formalisms can be used in order to define regular cost functions; this paper studies automata.

▶ **Definition 2.** A *min-cost-automaton* is denoted $\mathcal{A} = (Q, \mathtt{A}, \mathtt{B}, I, \Delta, F, f)$, given by an automaton structure $(Q, \mathtt{A}, \mathtt{B}, I, \Delta, F)$ together with an *accepting map* $f : \mathtt{B}^* \to \mathbb{N} \cup \{\infty\}$. It recognises the cost function induced by the map

$$\begin{aligned}
[\![\mathcal{A}]\!]_{\min} : \mathtt{A}^* &\to \mathbb{N} \cup \{\infty\} \\
w &\mapsto \inf \{f(\rho|_B) \mid \rho \text{ run over } w\} \ .
\end{aligned}$$

A *max-cost-automaton* is defined similarly, recognising the cost function induced by the map

$$\begin{aligned}
[\![\mathcal{A}]\!]_{\max} : \mathtt{A}^* &\to \mathbb{N} \cup \{\infty\} \\
w &\mapsto \sup \{f(\rho|_B) \mid \rho \text{ run over } w\} \ .
\end{aligned}$$

We define some of the classical accepting maps for regular cost functions.

We first define the $\texttt{cost}_\mathtt{B}$ map for one counter. The value of the counter is initialised by 0. The letter `i` is an increment, it adds 1 to the value of the counter, the letter `r` is a

reset, it resets the value of the counter to 0, and the letter ϵ does nothing. Formally, the $\mathtt{cost}_{\mathtt{B}}$ map for one counter is defined by

$$\begin{aligned}\mathtt{cost}_{\mathtt{B}} : \{\mathtt{i},\mathtt{r},\epsilon\}^* &\to \mathbb{N}\cup\{\infty\}\\ w &\mapsto \max\{n\in\mathbb{N} \mid w\in\{\mathtt{i},\mathtt{r},\epsilon\}^*\,(\epsilon^*\mathtt{i})^n\,\{\mathtt{i},\mathtt{r},\epsilon\}^*\}\,.\end{aligned}$$

The restrictions over $\{\epsilon,\mathtt{i}\}^*$ and over $\{\mathtt{r},\mathtt{i}\}^*$ are called distance and desert, respectively denoted $\mathtt{dist}_{\mathtt{B}}$ and $\mathtt{desert}_{\mathtt{B}}$.

The $\mathtt{cost}_{\mathtt{B}}$ map for k counters is defined similarly as for one counter, over the alphabet $\{\epsilon,\mathtt{i},\mathtt{r}\}^k$, by taking the maximum over all counters.

The $\mathtt{cost}_{\mathtt{hB}}$ map for k hierarchical counters is the restriction of $\mathtt{cost}_{\mathtt{B}}$ over the alphabet $\{I_1,R_1,\ldots,I_k,R_k\}$, where I_ℓ increments the ℓ^{th} counter and resets all counters of smaller index, and R_ℓ resets all counters of index smaller than or equal to ℓ.

A *B-automaton* is a *min-cost-automaton* equipped with a $\mathtt{cost}_{\mathtt{B}}$ map. Similarly, a *hB-automaton* is equipped with a $\mathtt{cost}_{\mathtt{hB}}$ map. The class of cost functions recognised by B-automata (or equivalently, hB-automata) is called regular cost functions.

We will make use of the following special case of max-cost-automata.

▶ **Definition 3.** A *prefix-max-cost-automaton* is denoted $\mathcal{A}=(Q,\mathtt{A},\mathtt{B},I,\Delta,f)$, given by an initial automaton structure $(Q,\mathtt{A},\mathtt{B},I,\Delta)$ together with an *accepting map* $f:\mathtt{B}^*\to\mathbb{N}\cup\{\infty\}$. It recognises the cost function induced by the map

$$\begin{aligned}[\![\mathcal{A}]\!]_{\text{pmax}} : \mathtt{A}^* &\to \mathbb{N}\cup\{\infty\}\\ w &\mapsto \sup\{f(\rho|_B) \mid \rho \text{ prefix run over } w\}\ .\end{aligned}$$

3 Omega Regular like Cost Functions

In this section we introduce the subclass of regular cost functions called ω-regular like cost functions, that we show are in one-to-one correspondence with ω-regular languages.

In Subsection 3.1 we define an operator defining the class and fleshing out the correspondence. We then explain how to construct ω-regular like cost functions with different models: in Subsection 3.2 using automata, and in Subsection 3.3 using algebra.

This strong correspondence allows us to transfer results from ω-regular languages to ω-regular like cost functions; in Subsection 3.4 we show how to transfer the latest appearence record and the Safra constructions.

Finally, we show the interplay between ω-regular like cost functions and games in Subsection 3.5.

3.1 Bijection with Omega-Regular Languages

The following is the main definition of this paper.

▶ **Definition 4.** Given a language L over infinite words, $L^{\mathtt{ol}}$ is defined by

$$\begin{aligned}L^{\mathtt{ol}} : \mathtt{A}^* &\to \mathbb{N}\cup\{\infty\}\\ w &\mapsto \sup\{n \mid w = uv_1\cdots v_nu',\ v_1,\ldots,v_n\neq\varepsilon,\ u\cdot\{v_1,\ldots,v_n\}^\omega\subseteq L\}\,.\end{aligned}$$

A cost function is *ω-regular like* if it contains a map $L^{\mathtt{ol}}$ for some ω-regular language L.

Note that we will mostly be interested in using the definition of $\cdot^{\mathtt{ol}}$ with ω-regular languages.

▶ **Example 5.**

- $\texttt{Büchi}^{\texttt{ol}} = \texttt{dist}_{\texttt{B}}$: it is the function counting the number of 1's, *i.e.* the distance map where 1 is ϵ and 0 is $\texttt{i}$.
- $\texttt{coBüchi}^{\texttt{ol}} = \texttt{desert}_{\texttt{B}}$: it is the function counting the size of the largest block of 2's, *i.e.* the desert map where 1 is $\texttt{r}$ and 2 is $\texttt{i}$.
- $\texttt{Rabin}_1{}^{\texttt{ol}} = \texttt{cost}_{\texttt{B}}$: it is the function counting the number of I's in a block containing no R's, *i.e.* the $\texttt{cost}_{\texttt{B}}$ map for one counter where I is $\texttt{i}$ and R is $\texttt{r}$.
- $\texttt{Rabin}_k{}^{\texttt{ol}} \approx \texttt{cost}_{\texttt{B}}$: it is the $\texttt{cost}_{\texttt{B}}$ map for k counters where I_ℓ is increment for the ℓ^{th} counter and R_ℓ is reset for the ℓ^{th} counter. Note that here the functions are not equal, one can see that $\texttt{cost}_{\texttt{B}} \leq \texttt{Rabin}_k{}^{\texttt{ol}} \leq k \cdot \texttt{cost}_{\texttt{B}}$.
- $\texttt{Parity}_{2k}{}^{\texttt{ol}} \approx \texttt{cost}_{\texttt{hB}}$: it is the $\texttt{cost}_{\texttt{hB}}$ map for k counters, where I_ℓ is the colour $2(k-\ell)$ and R_ℓ is $2(k-\ell)-1$.

The following lemma is central, it shows the interplay between the above definition and ultimately periodic words.

▶ **Lemma 6.** *Let L be a language over infinite words, and u, v two finite words with v non-empty. The following statements are equivalent:*

1. $uv^\omega \in L$,
2. $(L^{\texttt{ol}}(uv^n))_{n\in\mathbb{N}}$ *tends to infinity.*

Note that this lemma does not make any assumption on the regularity of L; in the rest of the paper, we shall always look at $L^{\texttt{ol}}$ for L an ω-regular language.

Proof. One direction is clear: if $uv^\omega \in L$, then $(L^{\texttt{ol}}(uv^n))_{n\in\mathbb{N}}$ tends to infinity.

We prove the converse implication. Assume that $(L^{\texttt{ol}}(uv^n))_{n\in\mathbb{N}}$ tends to infinity, and let n be larger than $|uv|$. There exists k such that uv^k can be factorised $u'v_1\cdots v_n u''$ such that $u' \cdot \{v_1, \ldots, v_n\}^\omega \subseteq L$.

Consider the lengths $|u'v_1\cdots v_\ell|$ for $\ell \in \{|u|, \ldots, n\}$: two of them have the same value modulo $|v|$, denote the corresponding words $u'v_1\cdots v_i$ and $u'v_1\cdots v_j$, with $i < j$. Note that since $\ell \geq |u|$ and $v_1, \ldots, v_\ell$ are not empty, the word u is a strict prefix of $u'v_1\cdots v_i$. It follows that we have $u'v_1\cdots v_i = uv^p x$ for some p and $v = xy$, and $v_{i+1}\cdots v_j = yv^q x$ for some q.

Consider the infinite word

$$u'v_1\cdots v_i(v_{i+1}\cdots v_j)^\omega = uv^p x(yv^q x)^\omega \ ,$$

by assumption it belongs to L. Thanks to the equality $s(ts)^\omega = (st)^\omega$, the word above is equal to $uv^p(xyv^q)^\omega = uv^p(v^{q+1})^\omega = uv^\omega$. Thus, $uv^\omega \in L$. ◀

▶ **Theorem 7.** *The map $\cdot^{\texttt{ol}}$ is a bijection between ω-regular languages and ω-regular like cost functions.*

In particular, two ω-regular like cost functions $L^{\texttt{ol}}, L'^{\texttt{ol}}$ are equal if, and only if, $L = L'$.

Proof. The map is surjective by definition of ω-regular like cost functions.

We show that it is injective: consider L, L' two ω-regular languages such that $L^{\texttt{ol}} \approx L'^{\texttt{ol}}$. It follows from Lemma 6 that L and L' coincide on ultimately periodic words; being ω-regular, this implies that they are equal. ◀

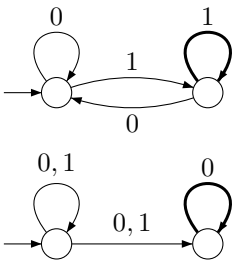

Figure 1 The Büchi automaton for Example 9.

3.2 Automata Constructions

The following theorem shows how to construct automata recognising ω-regular like cost functions. The construction is very simple, as it amounts to consider an ω-automaton and to see it as a prefix-max-cost-automaton, without any further changes. The correctness proof however is bit more involved.

▶ **Theorem 8.** *Let W be an ω-regular condition.*

Consider a W-automaton $\mathcal{A}$, and denote by L the language it recognises. The prefix-max-cost-automaton induced by $\mathcal{A}$ with the map $W^{\mathtt{ol}}$ recognises the cost function $L^{\mathtt{ol}}$.

Before proving this theorem, we give an example.

▶ **Example 9.** Consider the Büchi automaton represented in Figure 1. The alphabet is $\mathtt{A} = \{0, 1\}$, the Büchi transitions are represented by a boldface loop. The top part checks whether the word contains infinitely many 1's, and the bottom part checks whether the word contains finitely many 1's. It follows that this automaton recognises all ω-words, *i.e.* $L = \mathtt{A}^\omega$, so

$$\begin{aligned} L^{\mathtt{ol}} : \mathtt{A}^* &\to \mathbb{N} \cup \{\infty\} \\ w &\mapsto \text{length of } w \end{aligned}$$

The induced prefix-max-cost-automaton recognises the following cost function:

$$\begin{aligned} [\![\mathcal{A}]\!]_{\text{pmax}} : \mathtt{A}^* &\to \mathbb{N} \cup \{\infty\} \\ w &\mapsto \max\{\text{number of } 1's \text{ in } w, \text{size of the largest block of } 0's \text{ in } w\} . \end{aligned}$$

These two functions are indeed equivalent: $[\![\mathcal{A}]\!]_{\text{pmax}} \leq L^{\mathtt{ol}} \leq [\![\mathcal{A}]\!]^2_{\text{pmax}}$.

In the proof of Theorem 8, we will make use of Simon's theorem [13]. We state here the corollary that we use. Recall that a semigroup is a set equipped with an associative binary product, and that an idempotent in a semigroup is an element e such that $e \cdot e = e$.

For every morphism $\varphi : \mathtt{A}^+ \to M$ where M is a finite semigroup, there exists a function $\alpha : \mathbb{N} \to \mathbb{N}$ such that $\lim \alpha = \infty$ and for all words w of length n, there exists a factorisation $w = uv_1 \cdots v_{\alpha(n)}u'$ where the words $v_1, \ldots, v_{\alpha(n)}$ are non-empty and such that

$$\varphi(v_1) = \varphi(v_2) = \cdots = \varphi(v_{\alpha(n)})$$

is an idempotent.

Proof. For the sake of simplicity, we will assume that $\mathcal{A}$ is a parity automaton, *i.e.* W is the parity language. The proof generalises to the case of an ω-regular language W by considering a deterministic parity automaton recognising W.

We denote $\mathcal{A}^{\mathtt{ol}}$ the prefix-max-cost-automaton induced by $\mathcal{A}$ with the accepting map $\mathtt{Parity}^{\mathtt{ol}}$. By definition:

- $[\![\mathcal{A}^{\mathtt{ol}}]\!]_{\mathrm{pmax}}(w)$ is defined by

$$\sup\left\{\mathtt{Parity}^{\mathtt{ol}}(\rho|_B) \mid \rho \text{ prefix run over } w\right\}.$$

- $L^{\mathtt{ol}}(w)$ is defined by

$$\sup\left\{n \mid w = uv_1\cdots v_nu',\ v_1,\dots,v_n \neq \varepsilon,\ u\cdot\{v_1,\dots,v_n\}^\omega \subseteq L\right\}.$$

We will apply Simon's theorem twice, once for each direction. To this end, we construct a morphism $\varphi : \mathtt{A} \to M$, where M is the transition semigroup of $\mathcal{A}$. A transition profile is a tuple (p,c,q) where p and q are states and c is a colour. The product of transition profiles is (partially) defined by

$$(p,c,q)\cdot(r,c',s) = \begin{cases} (p,\min(c,c'),s) \text{ if } q=r \\ \text{undefined otherwise.}\end{cases}$$

An element of M is a set of transition profiles. The product is inherited by the product for transition profiles. The morphism φ associates to a letter a the set of transitions over the letter a in the automaton $\mathcal{A}$.

Assume $[\![\mathcal{A}^{\mathtt{ol}}]\!]_{\mathrm{pmax}}(w) \geq n$: there exists a prefix run ρ over w such that $\mathtt{Parity}^{\mathtt{ol}}(\rho|_B) \geq n$. It follows that ρ factorises $\rho\rho_1\cdots\rho_n\rho'$, where in each ρ_i the smallest colour appearing is even. We apply Simon's theorem to the word $\rho_1\cdots\rho_n$, seen as a word of length n, *i.e.* where we interpret each ρ_i as a single letter. Denote $m=\alpha(n)$. There exists a factorisation which we denote $\widetilde{\tau}\widetilde{\tau_1}\cdots\widetilde{\tau_m}\widetilde{\tau'}$ such that $\varphi(\widetilde{\tau_1}) = \cdots = \varphi(\widetilde{\tau_m})$ is idempotent, denoted S. This implies the existence of (q,c,q) in S, where c is even. Denote $w = uv_1\cdots v_mu'$ the factorisation of w it induces. Observe that $u\cdot\{v_1,\dots,v_m\}^\omega \subseteq L$, as for each such word one can construct a ultimately periodic run ρ in $\mathcal{A}$ whose smallest colour appearing infinitely often is c, hence such that $\rho|_B \in \mathtt{Parity}$. So $W^{\mathtt{ol}}(\rho) \geq \alpha(n)$.

It follows that $[\![\mathcal{A}^{\mathtt{ol}}]\!]_{\mathrm{pmax}} \preccurlyeq L^{\mathtt{ol}}$.

Conversely, assume $L^{\mathtt{ol}}(w) \geq n$: there exists a factorisation of w in $uv_1\cdots v_nu'$ as in the definition of $L^{\mathtt{ol}}(w)$. We apply Simon's theorem to the word $v_1\cdots v_n$, seen as a word of length n, *i.e.* where we interpret each v_i as a single letter. Denote $m=\alpha(n)$. There exists a factorisation which we denote $\widetilde{u}\widetilde{v_1}\cdots\widetilde{v_m}\widetilde{u'}$ such that $\varphi(\widetilde{v_1}) = \cdots = \varphi(\widetilde{v_m})$ is idempotent, denoted S. Note that each $\widetilde{v_\ell}$ and $\widetilde{u}$ is an infix $v_i\cdots v_j$; denote $\widetilde{w}$ the infix corresponding to $\widetilde{v_1}\cdots\widetilde{v_m}$. The element $\varphi(\widetilde{w})$ is idempotent equal to S. Since $u\cdot\{v_1,\dots,v_n\}^\omega \subseteq L$, in particular $u\widetilde{u}\cdot\widetilde{w}^\omega \in L$. Because $\mathcal{A}$ recognises L, there exists an accepting run of $u\widetilde{u}\cdot\widetilde{w}^\omega$. Now, $\varphi(\widetilde{w})$ being idempotent, this implies that there exist:

- a transition profile in $\varphi(u\cdot\widetilde{u})$ of the form $(p,\_,q)$ where p is initial, and
- a transition profile in $\varphi(\widetilde{w})$ of the form (q,c,q) where c is even.

Recall that each $\varphi(\widetilde{v_\ell})$ is equal to $S=\varphi(\widetilde{w})$, so it contains (q,c,q). Thus, we obtain a run $\rho = \rho_{u\widetilde{u}}\rho_{\widetilde{v_1}}\cdots\rho_{\widetilde{v_m}}$ over $u\widetilde{u}\widetilde{v_1}\cdots\widetilde{v_m}$ such that $\rho_{u\widetilde{u}}\left\{\rho_{\widetilde{v_1}},\dots,\rho_{\widetilde{v_m}}\right\}^\omega \subseteq W$. This implies that $[\![\mathcal{A}^{\mathtt{ol}}]\!]_{\mathrm{pmax}}(w) \geq \alpha(n)$.

It follows that $L^{\mathtt{ol}} \preccurlyeq [\![\mathcal{A}^{\mathtt{ol}}]\!]_{\mathrm{pmax}}$.

We conclude that $L^{\mathtt{ol}}$ and $[\![\mathcal{A}^{\mathtt{ol}}]\!]_{\mathrm{pmax}}$ are equivalent. ◀

Recall that if W is the Büchi language, then $W^{\circ 1}$ is the distance map. Similarly, the Rabin condition induces the $\mathtt{cost}_{\mathtt{B}}$ map and the parity condition the $\mathtt{cost}_{\mathtt{hB}}$ map.

In particular, Theorem 8 implies that if L is recognised by a Büchi automaton (resp. Rabin automaton, parity automaton), then $L^{\circ 1}$ is recognised by a prefix-max-cost-automaton with the distance map (resp. $\mathtt{cost}_{\mathtt{B}}$ map, $\mathtt{cost}_{\mathtt{hB}}$ map).

3.3 Syntactical Constructions

The above subsection shows how to construct ω-regular like cost functions using automata.

3.4 Transferring Results

We show in this subsection how to use the above correspondence to transfer two automata theoretic constructions.

The first construction is the latest appearance record construction, which allows to transform a Rabin condition into a parity condition, as stated in the following theorem.

▶ **Theorem 10.** *For every k, there exists a deterministic parity automaton with $k!$ states and k colours recognising the language $\mathtt{Rabin}_k$.*

This yields the following corollary.

▶ **Corollary 11.** *For every k, there exists a hierarchical B-automaton (hB-automaton) with $k!$ states and k counters recognising the cost function $\mathtt{cost}_{\mathtt{B}}$.*

Consequently, for every regular cost function, one can effectively construct an hB-automaton recognising it.

The first part is obtained by applying Theorem 8 to the automaton constructed by Theorem 10. For the second part, it amounts to compose the B-automaton with the automaton constructed by the first item to obtain an hB-automaton.

The second construction is the determinisation of Büchi automata.

▶ **Corollary 12.** *For every ω-regular like cost function, one can effectively construct a deterministic B-automaton recognising it.*

Proof. Consider an ω-regular language L given by a non-deterministic Büchi automaton, inducing the ω-regular like cost function $L^{\circ 1}$.

The McNaughton-Safra construction yields an equivalent deterministic Rabin automaton, denoted $\mathcal{A}$. Thanks to Theorem 8, this implies a prefix-max-cost-automaton equipped with the $\mathtt{Rabin}^{\circ 1}$ condition recognising $L^{\circ 1}$. Since $\mathcal{A}$ is deterministic and $\mathtt{Rabin}^{\circ 1}$ is the $\mathtt{cost}_{\mathtt{B}}$ map, $\mathcal{A}$ is in fact a deterministic B-automaton recognising $L^{\circ 1}$. ◀

3.5 Games with Omega-Regular like Cost Functions

In this subsection, we show how to solve games with ω-regular like cost functions.

We refer to [9] for materials about games; here we only give the basic definitions.

A *game* is denoted $G = (V, \mathtt{A}, V_E, V_A, E)$, where V is a set of vertices, $\mathtt{A}$ is the output alphabet, V_E is the set of vertices controlled by the first player Eve, V_A is the set of vertices controlled by the opponent Adam with $V = V_E \uplus V_A$ and $E \subseteq V \times \mathtt{A} \times V$ is the set of edges. A game is said finite if V is finite.

A token is initially placed on a given initial vertex v_0, and the player who controls this vertex pushes the token along an edge, reaching a new vertex; the player who controls this

new vertex takes over, and this interaction goes on forever, describing an infinite path called a play. A *winning condition* is a language $L \subseteq \mathtt{A}^\omega$: a play is won by Eve if its projection on $\mathtt{A}$ belongs to L. A *strategy* for Eve is a map $\sigma : E^* V_E \to E$. A *memory structure* is denoted $\mathcal{M} = (M, m_0, \mu)$, where M is the (finite) set of memory states, $m_0 \in M$ is the initial memory state and $\mu : M \times E \to M$ is the (deterministic) update function. A *finite-memory strategy* is given by a memory structure $\mathcal{M}$ and a next-move function $\sigma : M \times V_E \to E$.

▶ **Theorem 13.** *Consider a finite game G and L an ω-regular language. The following are equivalent:*

1. *There exists n, there exists a strategy for Eve, such that for all plays, the value for $L^{\mathtt{o1}}$ is less than n,*
2. *Eve wins for the winning condition $L^{\mathtt{C}}$.*

Proof. Since L is ω-regular, it is recognised by a deterministic Rabin automaton. By considering the product of the game with this automaton, we can assume without loss of generality that $L = \mathtt{Rabin}$, so $L^{\mathtt{o1}} = \mathtt{cost}_{\mathtt{B}}$.

The top to bottom direction is clear: indeed, for a play π, if $\mathtt{cost}_{\mathtt{B}}(\pi) \leq n$, then $\pi \in \mathtt{Rabin}^{\mathtt{C}}$.

To prove the converse implication, we rely on the fact that since $L^{\mathtt{C}}$ is an ω-regular condition, Eve has a finite-memory winning strategy. By considering the product of the game with the memory structure, we observe that in each cycle, for each counter, either it is not incremented or it is both incremented and reset. It follows that this strategy ensures that the values for $\mathtt{cost}_{\mathtt{B}}$ is bounded over all plays by twice the size of the graph times the size of the memory. ◀

We can strengthen this theorem:

▶ **Theorem 14.** *Consider a finite game G and L, L' two ω-regular languages. The following are equivalent:*

1. *For all n, there exists n', there exists a strategy for Eve, such that for all plays:*

   if the value for $L^{\mathtt{o1}}$ is less than n then the value for $L'^{\mathtt{o1}}$ is less than n',

2. *Eve wins for the condition $L \cup L'^{\mathtt{C}}$.*

Proof. Since L and L' are ω-regular, they are each recognised by a deterministic Rabin automaton. By considering the product of the game with the two automata, we can assume without loss of generality that the alphabet is $\{\epsilon, \mathtt{i}, \mathtt{r}\}^k \times \{\epsilon, \mathtt{i}, \mathtt{r}\}^{k'}$ with $L = \mathtt{Rabin}^1$ and $L' = \mathtt{Rabin}^2$. Thus $L^{\mathtt{o1}} = \mathtt{cost}^1_{\mathtt{B}}$ and $L'^{\mathtt{o1}} = \mathtt{cost}^2_{\mathtt{B}}$.

Assume that Eve wins for the condition $L \cup L'^{\mathtt{C}}$: since it is ω-regular, Eve has a finite-memory winning strategy. By considering the product of the game with the memory structure, we observe that for each cycle,

if for each counter in $\{\epsilon, \mathtt{i}, \mathtt{r}\}^k$, it is either reset or not incremented,
then for each counter in $\{\epsilon, \mathtt{i}, \mathtt{r}\}^{k'}$, it is either reset or not incremented.

Let n be twice the size of the graph times the size of the memory. It follows that this strategy ensures that for all plays, if the value for $\mathtt{cost}^1_{\mathtt{B}}$ is less than n then the value for $\mathtt{cost}^2_{\mathtt{B}}$ is less than n.

To prove the converse, we proceed by contrapositive. Assume that Eve does not win for the condition $L \cup L'^{\mathtt{C}}$, since the game is determined this implies that Adam wins, and again because the winning condition is ω-regular Adam has a finite-memory winning strategy. The same reasoning as before concludes that each cycle satisfies the negation of the above

property, which implies for the same value of n that this strategy ensures the following: for all n', there exists a play such that the value for $\mathtt{cost}^1_{\mathtt{B}}$ is less than n and the value for $\mathtt{cost}^2_{\mathtt{B}}$ is greater than n'. ◀

4 History-Determinisation of Cost Automata

In this section we give a simple and direct procedure for history-determinisation of B-automata: given a B-automaton, construct an equivalent history-deterministic B-automaton. Note that for the sake of simplicity we consider here hierarchical B-automata. Our contruction relies on the properties we obtained for ω-regular like cost functions in the above section together with game theoretic techniques inspired by Bojańczyk [3].

An automaton is *history-deterministic* if it is non-deterministic but its non-determinism can be resolved by a function considering only the input read so far. This notion has been introduced for studying ω-automata in [11]. We specialise it here to the case of cost functions, involving a relaxation on the values allowing for a good interplay with the definition of equivalence for cost functions.

A B-automaton $\mathcal{B}$ is *history-deterministic* if there exists a function $\alpha : \mathbb{N} \to \mathbb{N}$ such that $\lim \alpha = \infty$ and for every n, there exists a strategy $\sigma : \mathtt{A}^* \to \Delta$ such that for all words w, we have

$$[\![\mathcal{B}]\!]_{\min}(w) \leq n \implies [\![\mathcal{B}_\sigma]\!]_{\min}(w) \leq \alpha(n).$$

The automaton $\mathcal{B}_\sigma$ is infinite but deterministic, as for each situation the strategy σ chooses the transition to follow.

▶ **Theorem 15.** *For every hB-automaton, one can effectively construct an equivalent history-deterministic hB-automaton.*

Let $\mathcal{A} = (Q, \mathtt{A}, \{I_1, R_1, \ldots, I_k, R_k\}, I, \Delta, F, \mathtt{cost}_{\mathtt{hB}})$ be a hB-automaton. We first sketch the construction, which involves two automata:

- a deterministic hB-automaton $\mathcal{C}$ recognising an ω-regular like cost function denoted $L^{\circ\mathtt{l}}$,
- a history-deterministic min-cost-automaton $\mathcal{B}$ equipped with the map $L^{\circ\mathtt{l}}$.

Recall that for a word w, the value of $[\![\mathcal{A}]\!]_{\min}(w)$ is the minimum value for the $\mathtt{cost}_{\mathtt{hB}}$ map over all runs of w.

The automaton $\mathcal{B}$ simulates $\mathcal{A}$ and is in charge of guessing an optimal run, *i.e.* having minimal value for the $\mathtt{cost}_{\mathtt{hB}}$ map. However, we want $\mathcal{B}$ to be history-deterministic; to achieve this, $\mathcal{B}$ will do something easier than guessing *one* run, it will guess for each transition whether it belongs to *some* optimal run. In other words, $\mathcal{B}$ guesses a run tree (see Figure 2 for the representation of a run tree). As we shall see, thanks to the positionality of hB-games, $\mathcal{B}$ can guess a set of near optimal runs in a history-deterministic fashion. In effect, $\mathcal{B}$ inputs a word and outputs a run tree.

The automaton $\mathcal{C}$ recognises the cost function which given a run tree computes the maximum value for the $\mathtt{cost}_{\mathtt{hB}}$ map over all paths in the run tree. The crucial point is that this cost function is ω-regular like, so one can effectively construct a deterministic hB-automaton recognising it.

The composition of the automata $\mathcal{B}$ and $\mathcal{C}$ yields a history-deterministic hB-automaton equivalent to $\mathcal{A}$. The correctness of this construction relies on the following two properties:

- $[\![\mathcal{A}]\!]_{\min}$ and $[\![\mathcal{B}]\!]_{\min}$ are equivalent,
- $\mathcal{B}$ is history-deterministic.

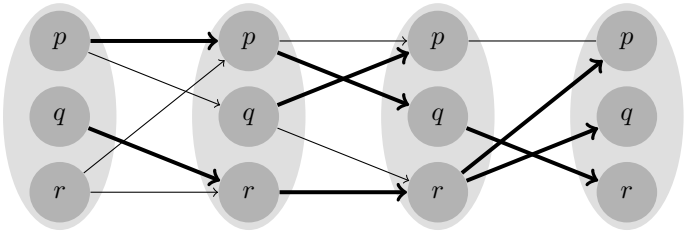

Figure 2 A run tree. Each state has at most one ingoing transition.

We proceed with the formal construction.

We define the alphabet $\mathtt{B}$, which is the output alphabet of $\mathcal{B}$ and the input alphabet of $\mathcal{C}$. A transition profile is a triple (p, act, q) where p and q are states and act is an action on the k counters, *i.e.* $act \in \{I_1, R_1, \dots, I_k, R_k\}$. An element of $\mathtt{B}$ is a set of transition profiles T such that for every state q, there exists *at most* one p such that $(p, act, q) \in T$ for some act. Equivalently, it is a partial function $T : Q \to \{I_1, R_1, \dots, I_k, R_k\} \times Q$; this backward point of view will be useful in proving that $\mathcal{B}$ is history-deterministic. A word over this alphabet is called a run tree; see Figure 2 for the representation of a run tree.

Construction of $\mathcal{C}$. The automaton $\mathcal{C}$ recognises an ω-regular like cost function; to construct it we define a parity automaton and turn it into a prefix-max-cost automaton relying on Theorem 8. Denote

$$L = \left\{ t \in \mathtt{B}^\omega \;\middle|\; \begin{array}{c} \text{there exists an infinite path in } t \text{ such that,} \\ \text{the minimal action performed infinitely often} \\ \text{for the ordering } I_1 < R_1 < \cdots < I_k < R_k \\ \text{is } R_\ell \text{ for some } \ell \end{array} \right\}.$$

The language L is recognised by a non-deterministic parity automaton of linear size which guesses the witnessing path. Formally, the parity automaton is

$$(Q, \mathtt{B}, \{I_1, R_1, \dots, I_k, R_k\}, I, \Delta_{\mathcal{C}}, \mathtt{Parity})$$

The transition relation is $\Delta_{\mathcal{C}} = \{(p, T, act, q) \mid (p, act, q) \in T\}$. The parity condition is obtained by seeing R_ℓ as the colour 2ℓ and I_ℓ as the colour $2\ell - 1$.

Theorem 8 implies that

$$L^{\mathtt{ol}} \approx \left\{ \begin{array}{lcl} \mathtt{B}^* & \to & \mathbb{N} \cup \{\infty\} \\ t & \mapsto & \max \{\mathtt{cost}_{\mathtt{hB}}(\pi) \mid \pi \text{ prefix path in } t\} \end{array} \right.$$

Following Corollary 12, we can effectively construct a deterministic hB-automaton $\mathcal{C}$ recognising $L^{\mathtt{ol}}$.

Construction of $\mathcal{B}$. The automaton $\mathcal{B}$ is a min-cost-automaton equipped with the map $L^{\mathtt{ol}}$, in charge of guessing a run tree and deterministically checking whether it contains a run.

Formally, $\mathcal{B} = (\mathcal{P}(Q), \mathtt{A}, \mathtt{B}, \mathcal{P}(I), \Delta_{\mathcal{B}}, F_{\mathcal{B}}, L^{\mathtt{ol}})$. The transition relation $\Delta_{\mathcal{B}}$ is defined by

$$\{(S, a, T, S') \mid S' \text{ is the set of states reached from } S \text{ using the transitions in } T\}.$$

The set of final states $F_{\mathcal{B}}$ is $\{S \subseteq Q \mid S \cap F \neq \emptyset\}$.

▶ **Lemma 16.** *$[\![\mathcal{A}]\!]_{\min}$ and $[\![\mathcal{B}]\!]_{\min}$ are equivalent.*

Proof. By definition

- $[\![\mathcal{A}]\!]_{\min}(w)$ is the minimum value for the $\mathtt{cost}_{\mathtt{hB}}$ map over all runs of w.
- $[\![\mathcal{B}]\!]_{\min}(w)$ is the minimum value for the $L^{\mathtt{o1}}$ map over all runs of w. By construction of $\mathcal{B}$, the runs of w are the run trees of w that contain a run of w over $\mathcal{A}$.

Thanks to the equivalence above about $L^{\mathtt{o1}}$, this implies that

$$[\![\mathcal{B}]\!]_{\min} \approx \left\{ \begin{array}{lcl} \mathtt{A}^* & \to & \mathbb{N} \cup \{\infty\} \\ w & \mapsto & \min \left\{ \mathtt{cost}_{\mathtt{hB}}(t) \;\middle|\; \begin{array}{c} t \text{ run tree of } w \text{ which} \\ \text{contains a run of } w \text{ over } \mathcal{A} \end{array} \right\}, \end{array} \right.$$

where $\mathtt{cost}_{\mathtt{hB}}(t) = \max\{\mathtt{cost}_{\mathtt{hB}}(\pi) \mid \pi \text{ prefix path in } t\}$.

Let $[\![\mathcal{A}]\!]_{\min}(w) \leq n$: there exists a run ρ of w such that $\mathtt{cost}_{\mathtt{hB}}(\rho) \leq n$. Consider the run tree t consisting of exactly ρ, it satisfies $\mathtt{cost}_{\mathtt{hB}}(t) \leq n$. It follows that $[\![\mathcal{B}]\!]_{\min} \preccurlyeq [\![\mathcal{A}]\!]_{\min}$.

Conversely, let $[\![\mathcal{B}]\!]_{\min}(w) \leq n$: there exists a run tree t of w such that $\mathtt{cost}_{\mathtt{hB}}(t) \leq n$. Because it is a run of $\mathcal{B}$, there exists a run ρ in t, and $\mathtt{cost}_{\mathtt{hB}}(t) \leq n$ implies that $\mathtt{cost}_{\mathtt{hB}}(\rho) \leq n$. It follows that $[\![\mathcal{A}]\!]_{\min} \preccurlyeq [\![\mathcal{B}]\!]_{\min}$.

We conclude that $[\![\mathcal{A}]\!]_{\min}$ and $[\![\mathcal{B}]\!]_{\min}$ are equivalent. ◀

▶ **Lemma 17.** *$\mathcal{B}$ is history-deterministic.*

This relies on the following positionality result, which is proved in [7]. It is also in essence in the proof of Bojańczyk [3].

▶ **Theorem 18** ([7])**.** *Eve has positional uniform strategies in hB-games.*

We now prove Lemma 17.

Proof. To prove that $\mathcal{B}$ is history-deterministic, we show that there exists a function $\alpha : \mathbb{N} \to \mathbb{N}$ such that $\lim \alpha = \infty$ and for every n, there exists a strategy $\sigma : \mathtt{A}^* \to \Delta_{\mathcal{B}}$ such that for all words w, if $[\![\mathcal{B}]\!]_{\min}(w) \leq n$ then $[\![\mathcal{B}_\sigma]\!]_{\min}(w) \leq \alpha(n)$.

Observe that $\sigma : \mathtt{A}^* \to \Delta_{\mathcal{B}}$ can equivalently defined as a partial function $\sigma : Q \times \mathtt{A}^* \to \{I_1, R_1, \ldots, I_k, R_k\} \times Q$; what $\mathcal{B}$ guesses is for each state q, at most one transition leading to q.

We define an hB-game. The set of vertices is $Q \times \mathtt{A}^*$. The edges are

$$\{((wa, q), act, (w, p)) \mid (p, a, act, q) \in \Delta\}.$$

By definition, for all words w such that $[\![\mathcal{B}]\!]_{\min}(w) \leq n$, there exists $q \in F$ such that Eve has a strategy ensuring $\mathtt{cost}_{\mathtt{hB}}(n) \cap \mathtt{Safe}(\varepsilon, Q \setminus I)$. It follows from Theorem 18 that there exists a uniform positional strategy, *i.e.* $\sigma : Q \times \mathtt{A}^* \to \Delta$. By definition, for this strategy we have $[\![\mathcal{B}_\sigma]\!]_{\min}(w) \leq n$. It follows that $\mathcal{B}$ is history-deterministic. ◀

Composing the two automata yields a history-deterministic automaton equivalent to $\mathcal{A}$. Denote n the number of states of $\mathcal{A}$, the constructed automaton has $2^n \times \mathtt{Safra}(n)$ states, where $\mathtt{Safra}(n)$ is the number of states obtained by applying the Safra determinisation on an ω-automaton with n states. Since $\mathtt{Safra}(n) = 2^{O(n \log(n))}$, the constructed automaton also has $2^{O(n \log(n))}$ states.

Abstract

We give NSPACE($n \log n$) algorithms solving the following decision problems. Satisfiability: Is the given equation over a free partially commutative monoid with involution (resp. a free partially commutative group) solvable? Finiteness: Are there only finitely many solutions of such an equation? PSPACE algorithms with worse complexities for the first problem are known, but so far, a PSPACE algorithm for the second problem was out of reach. Our results are much stronger: Given such an equation, its solutions form an EDT0L language effectively representable in NSPACE($n \log n$). In particular, we give an effective description of the set of all solutions for equations with constraints in free partially commutative monoids and groups.

1 Introduction

Free partially commutative monoids (a.k.a. *trace monoids*) and groups (a.k.a. *RAAGs*: *right-angled Artin groups*) are well-studied objects, both in computer science (latest since [18]) and in mathematics (with increasing impact since [24]). For years, decidability of the *satisfiability problem* (i.e., the problem whether a given equation is solvable) over these structures was open. A positive solution for trace monoids was obtained by Matiyasevich [17] and for RAAGs by Diekert and Muscholl [8]. The known techniques did not cope with the *finiteness problem* (i.e., the problem whether a given equation has only finitely many solutions). Decidability of finiteness for trace monoids was wide open, whereas for RAAGs a sophisticated generalization of Razborov-Makanin diagrams and geometric methods, available for groups, yielded decidability [3], but without any complexity estimation.

We give a simple and effective description of the set of all solutions for equations with constraints in free partially commutative monoids and groups; the correctness proof is mathematically challenging. Once the correctness is established, the simplicity is also reflected in a surprisingly low complexity. We give an NSPACE($n \log n$) upper bound for both

satisfiability and finiteness—each problem for trace monoids as well as for RAAGs. Even for satisfiability this complexity improves the previously known upper bounds. On the other hand these problems are NP-hard. It remains open whether $\mathsf{NSPACE}(n \log n)$ is optimal.

To obtain these results we apply a recent *recompression technique* [12], which was used as a simple method to solve word equations. It uses simple compression operations: compress ab into a letter c; and modify the equation so that such operations are sound. An algebraic setting of the current paper enables a shift of perspective: the inverse operation, replacing c by ab, is an endomorphism. Thus, the set of all solutions of an equation (solvable or not) can be represented as a graph, whose nodes are labeled with equations and edges by endomorphisms of free monoids. This graph can also be seen as a nondeterministic finite automaton (NFA) that accepts a rational set of endomorphisms over a free monoid. (Recall that a subset in a monoid M is *rational* if it is accepted by some NFA whose transitions have labels from M.) It is known that applying a rational set of endomorphisms to a letter yields an EDT0L language [1], and our construction guarantees that the obtained EDT0L language describes exactly the set of all solution of the given equation. Moreover, as usual in automata theory, the structure of the NFA reflects whether the solution set is finite. Last not least, our method is conceptually simpler than all previously known approaches to solving equations over free partially commutative structures.

Studying word equations is part of combinatorics on words for more than half a century [2]. From the very beginning, motivation came partly from group theory: the goal was to understand and parametrize solutions for equations in free groups. For example, Lyndon and Schützenberger needed sophisticated combinatorial arguments to give a parametrized solution to the equation $a^m = b^n c^p$ in a free group [14]. On the other hand, it is known that a parametric description of the solution set is not always possible [10]. The satisfiability of word equations in free monoids and free groups became a main open problem due to its connection with Hilbert's tenth problem. The problem was solved affirmative by Makanin in his seminal papers [15, 16]. His algorithms became famous also due to the difficulty of the termination proof and the extremely high complexity. A breakthrough to lower the complexity was initiated by Plandowski and Rytter [21], who were the first to apply compression techniques on word equations. Compression was also essential in showing that the satisfiability of word equations is in PSPACE [19]. This approach was further developed [12] using the "recompression technique", which simplified all existing proofs for solving word equations; in particular, it provided an effective description of all solutions; a similar representation was given earlier by Plandowski [20]. In free groups, an algorithmic description of all solutions was known much earlier due to Razborov [22]. His description became known as a *Makanin-Razborov diagram*, a major tool in the positive solution of Tarski's conjectures about the elementary theory in free groups [13, 23]. None of these results provided a structural result on the set of all solutions; interest in such results was explicitly expressed [11] by asking whether it is an "indexed language". Apparently, this question was posed without too much hope that a positive answer is within reach. However, the answer was positive for quadratic equations [9] (which is a severe restriction); the general case was established in [4]. Actually, a stronger result holds: the set of all solutions for equations in free monoids (as well as in free groups) is an EDT0L language, which is a proper subclass of indexed languages. The closest results on word equations with partial commutation are in [8], but techniques used there do not apply here as they boil down to a purely combinatorial construction of a normal form and ignore the algebraic structure as well as the set of all solutions.

2 Main result

Given a finite *alphabet* Γ, the *free monoid* Γ^* is the set of all finite words over Γ with concatenation. The empty word is denoted by 1. The length of a word w is denoted by $|w|$; by $|w|_a$ we count how often the letter a appears in w. A *resource function* $\rho : \Gamma \to 2^{\mathfrak{R}}$ maps elements of Γ to subsets of a finite *set of resources* $\mathfrak{R}$. We assume that $\mathfrak{R}$ is of constant size. The pair (Γ, ρ) is called a *resource alphabet*. If $\rho(a) = S$, then a is called an *S-constant*; a nonempty sequence of S-constants is an *S-run*.

A *resource monoid* $M(\Gamma, \rho)$ is the quotient of all finite words Γ^* by a partial commutation: $M(\Gamma, \rho) = \Gamma^* / \{ab = ba \mid \rho(a) \cap \rho(b) = \emptyset\}$, i.e., letters $a \neq b$ commute if and only if they do not share a resource. Resource monoids can equivalently be seen as *free partially commutative monoids* or *trace monoids*. We choose the resource-based approach as it best suits our purposes. Elements of a resource monoid are called *traces*. The natural projection π maps elements of the free monoid Γ^* to traces in $M(\Gamma, \rho)$; this is not a bijection and we view $w \in \Gamma^*$ as a word representation of the trace $\pi(w)$. In a monoid, an element v is a *factor* of w if $w = pvq$ for some p, q. We assume that the monoid $M(\Gamma, \rho)$ is equipped with an *involution*, that is, a bijection $x \mapsto \overline{x}$ on $M(\Gamma, \rho)$ such that $\overline{\overline{x}} = x$, $\overline{xy} = \overline{y}\,\overline{x}$ for all $x, y \in M(\Gamma, \rho)$. To make the definition well defined, we require that $\rho(x) = \rho(\overline{x})$ for $x \in \Gamma$. In the following, a *trace monoid* means a *resource monoid with involution*. A *morphism* $\varphi : M \to M'$ between monoids with involution is a homomorphism additionally respecting the involution. If Δ is a subset of M, then we often denote the restriction of φ to Δ by φ. If $\varphi(d) = d$ for all $d \in \Delta$, then φ is a *Δ-morphism*.

If there is no letter $a \in \Gamma$ with $a = \overline{a}$, then, by adding defining relations $a\overline{a} = 1$ for all $a \in \Gamma$, we obtain the *free partially commutative group* $G(\Gamma, \rho)$. Free partially commutative groups are also known as *right-angled Artin groups* or *RAAGs* for short. As a set, we can identify a RAAG $G(\Gamma, \rho)$ with the subset traces of the trace monoid $M(\Gamma, \rho)$ without factors $a\overline{a}$. Such traces are called *reduced*. We take inversion on groups as involution; the canonical projection of the monoid $M(\Gamma, \rho)$ onto the group $G(\Gamma, \rho)$ respects the involution.

Let (Γ, ρ) be a resource alphabet. An *equation* is a pair of words (U, V) over an alphabet $\Gamma = A \cup \mathcal{X}$ has a partition into *constants* A and *variables* $\mathcal{X}$, both sets are closed under involution. A *constraint* is a morphism $\mu : M(\Gamma, \rho) \to N$, where N is a finite monoid with involution. For our purposes, it is enough to consider constraints such that the elements of N can be represented by $\mathcal{O}(\log |\Gamma|)$ bits, and that all necessary computations in N (multiplication, involution, etc.) can be performed in space $\mathcal{O}(\log |\Gamma|)$ and the specification of these operations requires $\mathcal{O}(|\Gamma| \log |\Gamma|)$ space. If (U, V) is an equation over (Γ, ρ), then we define the input size of an equation with constraints as $n = |UV| + |\Gamma|$.

We write (U, V, μ) for an equation (U, V) with constraints μ. A *solution* of (U, V, μ) over $M(A, \rho)$ is an A-morphism $\sigma : M(A \cup \mathcal{X}, \rho) \to M(A, \rho)$ such that $\sigma(U) = \sigma(V)$ and $\mu\sigma(X) = \mu(X)$ for all $X \in \mathcal{X}$. If the equation is over $G(A, \rho)$, then instead of $\sigma(U) = \sigma(V)$ we require $\pi\sigma(U) = \pi\sigma(V)$ for the canonical projection $\pi : M(A, \rho) \to G(A, \rho)$. We also say that σ *solves* (U, V, μ) in $M(A, \rho)$ (resp. in $G(A, \rho)$). For equations over $G(A, \rho)$ we only allow solutions where the trace $\sigma(X)$ is reduced for all $X \in \mathcal{X}$. The main result of this paper is that the set of all solutions of a trace equation (resp. an equation in a RAAG) with rational constraints is an effectively computable EDT0L language, and the underlying automaton reflects whether there are infinitely many solutions.

▶ **Theorem 1.**

[Monoid version] *There is an* NSPACE$(n \log n)$ *algorithm for the following task. The input is a resource alphabet* $(A \cup \mathcal{X}, \rho)$ *with involution and a trace equation* (U, V, μ) *with constraints*

μ in constants A and variables $\mathcal{X} = \{X_1, \ldots, X_k\}$. The algorithm computes an alphabet $C \supseteq A$ of size $\mathcal{O}(n)$, constants $c_1, \ldots, c_k \in C$, and an NFA $\mathcal{A}$ accepting a rational set $\mathcal{R}$ of A-endomorphisms on C^* such that: $h(C^*) \subseteq A^*$ for all $h \in \mathcal{R}$ and under the canonical projection $\pi : A^* \to M(A, \rho)$ we have

$$\{(\pi h(c_1), \ldots, \pi h(c_k)) \mid h \in \mathcal{R}\} = \{(\sigma(X_1), \ldots, \sigma(X_k)) \mid \sigma \text{ solves } (U, V, \mu) \text{ in } M(A, \rho)\}.$$

Thus, the set of all solutions is an effectively computable EDT0L language. Furthermore, (U, V, μ) has a solution if and only if $\mathcal{A}$ accepts a nonempty set; (U, V, μ) has infinitely many solutions if and only if $\mathcal{A}$ has a directed cycle. These conditions can be tested in $\mathsf{NSPACE}(n \log n)$.

[Group version] *The same, but solutions σ satisfy $\sigma(U) = \sigma(V)$ in the RAAG $G(A, \rho)$ and for a variable X the solution $\sigma(X)$ is restricted to be a reduced trace.*

Theorem 1 generalizes to systems of equations. Another generalization are finitely generated *graph products* with involution over free monoids, free groups, and finite groups. See [7] for a definition and the known results concerning solvability of equations in graph products. This generalization is rather technical but does not reveal new ideas; it is done elsewhere.

3 Basic concepts

Equations in RAAGs can be reduced to equations in resource monoids [8], such an approach is standard since its introduction for free groups [5], which are reduced to free monoids. In essence, the reduction simulates the inverse operation by involution and it enforces that the solution in the monoids is in the reduced form by (additional) constraints. We employ a similar approach; thus, our presentation focuses on the equations over resource monoids.

Using a standard technique one can ensure that there are no self-involuting constants in the initial equation [8]. This step is not needed for RAAGs as $a = \overline{a} = a^{-1}$ implies $a^2 = 1$ in groups, but RAAGs are torsion-free. For technical reasons we introduce a new special symbol $\#$, which serves as a marker and becomes the only self-involuting constant; set $\rho(\#) = \mathfrak{R}$ and $\emptyset \neq \rho(a) \subsetneq \mathfrak{R}$ for all other constants. We let

$$W_{\text{init}} = \#X_1 \# \cdots X_k \# U \# V \# \overline{U} \# \overline{V} \# \overline{X_k} \# \cdots \overline{X_1} \#.$$

During the process, the $\#$'s will not be touched, so we keep control over the prefix corresponding to $\#X_1\# \cdots \#X_k\#$ which encodes the tuples $(\sigma(X_1), \ldots, \sigma(X_k))$. Moreover, we have $\sigma(U) = \sigma(V)$ if and only if $\sigma(W) = \sigma(\overline{W})$. Thus, we can treat a single trace as an equation. Solutions become A-morphisms σ satisfying $\sigma(W) = \sigma(\overline{W})$.

The equations that we consider are over a more general structure than a trace monoid. To simplify the notion, we denote the equation and a monoid over which it is by a tuple $(W, B, \mathcal{X}, \rho, \theta, \mu)$, where $W \in (B \cup \mathcal{X})^*$ is the "equation" with constants B and variables $\mathcal{X}$, the mapping $\rho : B \cup \mathcal{X} \to 2^{\mathfrak{R}}$ is the resource function, and $\mu : M(B \cup \mathcal{X}, \rho) \to N$ represents the constraints (given by the mapping $\mu : B \cup \mathcal{X} \to N$). Since $2^{\mathfrak{R}}$ is a commutative monoid, we shall view ρ as a morphism from $M(B \cup \mathcal{X}, \rho)$ to $2^{\mathfrak{R}}$, too. The symbol θ refers to a "type" which adds partial commutation. A type is given by a list of certain pairs $(x, y) \in (B \cup \mathcal{X})^+ \times B^+$; and each such pair yields a defining equation $xy = yx$. For example, we typically have $(X, y) \in \theta$ when considering a solution σ with $\sigma(X) \in y^+$. Then $\rho(X) = \rho(y)$, but we wish to use the fact that $\sigma(X)y = y\sigma(X)$. This is the purpose of a

type. We only use types in the subprocedures of block and quasi-block compression, see Section 4.3.1. Such a monoid is denoted as $M(B \cup \mathcal{X}, \rho, \theta, \mu)$. In most cases, θ is empty. Then we use $(W, B, \mathcal{X}, \rho, \mu)$ as an abbreviation of $(W, B, \mathcal{X}, \rho, \emptyset, \mu)$ and $M(B \cup \mathcal{X}, \rho, \theta, \mu)$ as an abbreviation of $M(B \cup \mathcal{X}, \rho, \mu)$.

A *B-solution* of $(W, B, \mathcal{X}, \rho, \mu)$ is a B-morphism $\sigma : M(B \cup \mathcal{X}, \rho, \mu) \to M(B, \rho, \mu)$ such that $\sigma(W) = \sigma(\overline{W})$ (i.e., it solves the equation) and $\mu(\sigma(X)) = \mu(X)$ (i.e., it satisfies the constraints).

During the algorithm we "increase the resources" of constants. It is useful to assume that for every constant $a \in A$ and every set of resources S with $\rho(a) \subsetneq S$ the alphabet A has a corresponding constant with set of resources S. We denote such a constant by (a, S), the involution on it is defined by $\overline{(a, S)} = (\overline{a}, S)$. We naturally identify a with $(a, \rho(a))$. We assume that the initial alphabet A is closed under taking such constants, i.e., if $a \in A$ and $\rho(a) \subseteq S$, then $(a, S) \in A$.

In some cases, when we "increase the resources", we prefer to use a fresh constant of appropriate resources: For a constant a with $\rho(a) \subsetneq S$, by $[a, S]$ we denote a "fresh" S-constant outside A such that $\rho([a, S]) = S$, $\mu([a, S]) = \mu(a)$ and $\overline{[a, S]} = [\overline{a}, S]$; replacing a with $[a, S]$ is called *lifting*.

During the algorithm we perform various operations on variables and constants. As a rule, whenever we perform such an operation, we perform a symmetric action on the involuted constants/variables. That is, whenever we replace X by aX, we replace $\overline{X}$ by $\overline{X}\,\overline{a}$; and when we replace ab by c, then we also replace $\overline{b}\,\overline{a}$ by $\overline{c}$. This simplifies the description, as actions performed on "the right side" of X are actions performed on "the left side" of $\overline{X}$.

Whenever we perform operations on variables/constants, we want the constraints and resources to remain unaffected (except for lifting, in which case we explicitly change the set of resources); if we replace a trace W by a trace W', then (if not explicitly stated otherwise) we ensure that $\rho(W) = \rho(W')$ and $\mu(W) = \mu(W')$. For instance, when replacing X by aX', we set $\mu(X')$ so that $\mu(aX') = \mu(X)$. The same applies to ρ. Similarly, when replacing ab by c, we set $\rho(c) = \rho(ab)$ and $\mu(c) = \mu(ab)$. In particular, we do not mention in the description of the procedures that we perform such operations.

A trace $a_1 a_2 \cdots a_n$ has many word representations and we would like to formalize a notion that some constants occur before others (in all word representations). To this end consider a set of positions $\{1, 2, \ldots, n\}$ and the smallest partial order $\preceq$ such that $i \preceq j$ if both $i \leq j$ and $\rho(a_i) \cap \rho(a_j) \neq \emptyset$. A *Hasse diagram* $H(W)$ of a trace $W = a_1 a_2 \cdots a_n$ is a graph with a set of nodes $\{1, 2, \ldots, n\}$, labeled with $a_1, a_2, \ldots, a_n$. It contains (directed) edges between immediate successors, i.e., (i, j) is an edge if $i \prec j$ and $i \preceq k \preceq j$ implies $k \in \{i, j\}$. By a standard result in trace theory [18], we have $W = W'$ in $M(\Gamma, \rho)$ if and only if $H(W)$ and $H(W')$ are isomorphic as abstract node-labeled directed graphs. When considering traces we usually work with their Hasse diagrams. If this causes no confusion, we identify $W = a_1 \cdots a_n$ with $H(W)$ and refer to labels $a_1, a_2, \ldots$ rather than to node names.

A constant $a \in A$ is *minimal* in a trace W if it is minimal in its Hasse diagram, which means that $W = aY$ for some trace Y. We denote the set of minimal elements of W by $\min(W)$. Maximal elements are left-right dual; they are denoted by $\max(W)$.

An arc $a \to b$ is an *S-arc* if $S \in \{\rho(a), \rho(b)\}$; it is *balanced* if $\rho(a) = \rho(b)$, *unbalanced* otherwise.

4 NFA recognising the set of all solutions

In this section we define the NFA $\mathcal{A}$ that recognises the set of all solutions of a trace equation, treated as a set of endomorphisms $\mathrm{End}(C^*)$ over an alphabet $C \supseteq A$.

4.1 The automaton

We first fix an alphabet of constants $C \supseteq A$ of size κn, where κ is a suitable constant (which depends on the number of resources $|\mathfrak{R}|$, viewed as $\mathcal{O}(1)$) and a set of variables Ω with $|\Omega| \leq |C|$. Henceforth, we assume $A \subseteq B \subseteq C$ and $\mathcal{X} \subseteq \Omega$.

The states of the automaton $\mathcal{A}$ are equations of the form $(W, B, \mathcal{X}, \rho, \theta, \mu)$. Each state $V = (W, B, \mathcal{X}, \rho, \theta, \mu)$ has a *weight* $\|V\|$ which is a 5-tuple of natural numbers:

$$\|V\| = (|W|, \omega, \omega', |\theta|, |B|) \in \mathbb{N}^5$$

with $\omega = \sum_{a \in B} (|\mathfrak{R}| - |\rho(a)|) \cdot |W|_a$ and $\omega' = |W| - |\{a \in B \mid |W|_a \geq 1\}|$. We order tuples in $\mathbb{N}^5$ lexicographically. The NFA contains only states V whose *max-norm* $\|V\|_\infty = \max\{|W|, \omega, \omega', |\theta|, |B|\} \in \mathbb{N}$ is at most $\kappa' n$ for a suitable constant κ'.

The initial state is $(W_{\mathrm{init}}, A_{\mathrm{init}}, \mathcal{X}_{\mathrm{init}}, \rho_{\mathrm{init}}, \mu_{\mathrm{init}})$, it corresponds to the input equation. A state $(W, B, \emptyset, \rho, \mu)$ without variables is final if $W = \overline{W}$ has the prefix $\#c_1\# \cdots \#c_k\#$, where $c_1, \ldots, c_k$ are the distinguished constants. We require that the initial state has no incoming and the final states no outgoing transitions.

The transitions, say between $V = (W, B, \mathcal{X}, \rho, \theta, \mu)$ and $V' = (W', B', \mathcal{X}', \rho', \theta', \mu')$, are labeled by A-morphisms and they either affect the variables (*substitution transitions*), or the monoid (*compression transitions*). The former is formalized using a B-morphism $\tau : M(B \cup \mathcal{X}, \rho, \theta, \mu) \to M(B' \cup \mathcal{X}', \rho', \theta', \mu')$. In this case we put several requirements on the equations: the new equation should be obtained by substitution $\tau(X)$ for each X, there are no new constants, resources and constraints of X and $\tau(X)$ should be the same; this is formalized as

$$W' = \tau(W), \quad B' = B, \quad \rho = \rho'\tau, \quad \mu = \mu'\tau. \tag{1}$$

Moreover, $\tau(X)$ is either the empty word (it removes X from W) or $\tau(X) \in \mathcal{X}^* B^+ \mathcal{X}^*$ (at least one constant pops up in the substituted variable). Note that the requirement $W' = \tau(W)$ implicitly upper-bounds the *size* $\|\tau\|$, defined as $\sum_{a \in B \cup \mathcal{X}} |\tau(a)|$, to be linear.

Furthermore, as $B' = B$ we have a natural identity morphism from $M(B', \rho', \theta', \mu')$ to $M(B, \rho, \theta, \mu)$, call it the *associated morphism* and denote it by ε. This morphism labels the transition, its direction is opposite of the transition and τ; we denote the transitions from V to V' with a corresponding morphism h by $V \xrightarrow{h} V'$.

A compression transition leaves the variables invariant and so it is defined by an $(A \cup \mathcal{X})$-morphism $h : M(B' \cup \mathcal{X}, \theta', \rho') \to M(B \cup \mathcal{X}, \theta, \rho)$, note that it could be that $\theta \neq \theta'$ which corresponds to a type introduction or removal; this is the associated morphism in this case. A morphism h defined by, say $h(c) = ab$, represents a compression of a factor ab into a single letter c. For its properties, W is obtained by decompression of new constants, and the resources and constraints are preserved:

$$W = h(W'), \quad \rho' = \rho h, \quad \mu' = \mu h. \tag{2}$$

As in the case of substitutions, the assumption that $W = h(W')$ implicitly upper-bounds $\|h\|$ to linear values.

The transition in the NFA is in the direction of the compression which is opposite to direction of the morphism h. Note that $W = h(W')$ implies $\|V'\| < \|V\|$. For technical reasons we do not allow compression transitions which introduce self-involuting letters (such as $c \mapsto a\overline{a}$); we never compress the marker symbol #. Moreover, following the last compression transition to final states, the restriction $\|V'\| < \|V'\|$ is not applied.

So far the defined NFA can have many useless states, so as a last step we *trim* the automaton, i.e., we remove all vertices not appearing on some accepting path.

The algorithmic part is finished: $\mathcal{A}$ can be constructed using standard arguments in $\mathsf{NSPACE}(n \log n)$.

By the usual definition, the recognized language $\mathcal{R}$ consists of all A-morphisms $h_1 \cdots h_k$, where $h_1, \ldots, h_k$ are consecutive labels on an accepting path. We claim that the set of all solutions is exactly $\{(\pi h(c_1), \ldots, \pi h(c_k)) \mid h \in \mathcal{R}\}$ where $\pi : A^* \to M(A, \rho)$ is the natural projection.

The correctness proof boils down to show that we can calculate the exact constants κ, κ' (depending on $\mathfrak{R}$ but not on n) and to prove soundness and completeness, i.e., that $h \in \mathcal{R}$ yields a solution and that every solution can be obtained in this way. Out of those, soundness is relatively easy to show, see Section 4.2, the completeness argument spans over Sections 4.3–4.4. Those arguments also show the other claims on the automaton (conditions for emptiness and acyclicity).

4.2 Soundness

As the final states have only one solution (identity), using an induction on the following Lemma, any accepting path labeled with $h_1, \ldots, h_k$ yields a solution $\pi h_1 \cdots h_k$, which shows soundness.

▶ **Lemma 2.** *Given two states $V = (W, B, \mathcal{X}, \rho, \theta, \mu)$ and $V' = (W', B', \mathcal{X}', \rho', \theta', \mu')$, if $V \xrightarrow{h} V'$ and V' has a B'-solution σ' then V has a B-solution $\sigma = h\sigma'$.*

The proof follows by a mechanical application of (1) or (2).

4.3 On-the-fly construction of the NFA

While we described the NFA recognizing all solutions, we did not discuss how to find the appropriate constants κ, κ' nor how to show completeness. For this it is easier to first describe the construction as an "on-the-fly" algorithm, that is, given an equation $(W, B, \mathcal{X}, \rho, \theta, \mu)$ (= current state V of the NFA) and its B-solution σ we will transform it into a different equation $(W', B', \mathcal{X}', \rho', \theta', \mu')$ (= next state V' of the NFA) and a corresponding B'-solution σ', where $V \xrightarrow{h} V'$ and $\sigma = h\sigma'$. Thus we moved from one state of the NFA to the other, without the knowledge of the full NFA. Note that the solutions are not given explicitly, but they are "used" in the nondeterministic choices of the algorithm.

For a fixed set of resources S traces consisting only of S-constants and variables behave as words and we apply to them the known recompression approach: we iteratively apply compression operations to S-runs (so we replace S-runs by new single S-constants). Those operations are applied on constants in the equation, but conceptually we apply them to a solution of the trace equation. To make this approach sound, we also modify the variables, by popping S-constants from them. We apply these operations until each S-run (in the solution) is reduced to a single S-constant; when the compressions and popping operations are applied in appropriate order, the size of the trace equation remains linear.

Compression of S-runs alone is not enough, as there are constants of different resources in the solution of the trace equation. To remedy this, we gradually linearize the solution. This is done by increasing the set of resources of particular constants: when we compressed each S-run to a single constant, we lift all S-constants, so that all S-constants and S-variables are eliminated from the equation. To make the whole approach work, we define an order $\leq$ on sets of resources: it is any linear order that extends the partial ordering by the size, i.e., $|S| \leq |T|$ implies $S \leq T$. A set of resources S is called *minimal* (for a solution σ), if it is minimal according to $\leq$ in the set $\{T \mid \text{there is a } T\text{-constant in } \sigma(W)\}$. We process the sets of resources according to $\leq$, each time treating a minimal sets of resources.

4.3.1 Fixed resources

We define the actions of the algorithm eliminating the S-constants for a fixed minimal set of resources S. To thi end, we need some notions of "easy" and "difficult" factors of $\sigma(W)$.

▶ **Definition 3.** Let $(W, B, \mathcal{X}, \rho, \mu)$ be a state and σ its B-solution. A factor v of $\sigma(W)$ is *visible* if for some occurrence at least one of its positions is obtained form a position labeled by a constant in W; a factor is *invisible* if it is not visible. A trace v is *crossing* if for some occurrence of v in $\sigma(W)$ some but not all positions belong to the substitution of a variable X by $\sigma(X)$; and this occurrence is *visibly crossing*. A trace is *noncrossing* if it is not crossing.

The factors that we typically consider are *pairs*, i.e., ab where $a \neq b \neq \overline{a}$, *$a$-blocks*, i.e., a maximal factor of the form a^ℓ (this occurrence of a^ℓ if not part of a factor $a^{\ell+1}$), and *a-quasi-blocks*, i.e., $(a\overline{a})^\ell$ that is not part of a factor $(a\overline{a})^{\ell+1}$. In the latter case, $a\overline{a}$ is called a *quasi-letter*. The intuitive meaning of a quasi-letter is that we cannot compress $a\overline{a}$ into a single constant as it is would be self-involuting, hence we treat those two letters as if they were a single constant.

Given a subalphabet $S_\pm$, we consider an *involuting partition* (S_+, S_-) that satisfies the conditions $\overline{S_+} = S_-$, $S_+ \cap S_- = \emptyset$ and $S_+ \cup S_- = S_\pm$. Such a partition is *crossing* if at least one pair $ab \in S_+S_-$ is; it has crossing quasi-blocks if there is $a \in S_+$ that has crossing quasi-blocks. Lastly, $S_\pm$ has crossing blocks if there is $a \in S_\pm$ that has crossing blocks.

Pair compression is implemented essentially in the same way as in the case of word equations. Given a pair ab with $a \neq b \neq \overline{a}$ we want to replace each factor ab in $\sigma(W)$ with a fresh constant c. This is easy, when ab is noncrossing: it is enough to perform this operation on W and each $\sigma(X)$, the latter is done implicitly and we obtain a different solution σ' in this way. We also set ρ and μ for c appropriately: $\rho(c) = \rho(ab)$ and $\mu(c) = \mu(ab)$. Performing several such compressions is possible for $ab \in S_+S_-$, where (S_+, S_-) is a noncrossing involuting partition, as for each constant in $\sigma(W)$ we can uniquely determine to which replaced pair it belongs (if any). We do not compress pairs $a\overline{a}$, though, as this would create a self-involuting letter.

We need to ensure that indeed (S_+, S_-) is noncrossing. A pair $ab \in S_+S_-$ is crossing if aX is a factor of W and $b \in \min(\sigma(X))$. The other option is that Xb is a factor and $a \in \max(\sigma(X))$; it is taken care by considering $\overline{b}\,\overline{X}$ and the pair $\overline{b}\overline{a}$. Then we replace X with bX. After doing this, for all variables, the partition (S_+, S_-) is noncrossing and so we can compress pairs in this partition.

Pair compression cannot be applied to aa, as it makes the compression of longer blocks ambiguous. However, when a has no crossing block, (in several steps) we replace each a-block a^λ by c_λ. Similarly as in the case of pair compression, we can compress blocks of several letters in parallel, as blocks of different letters do not overlap.

Again, to apply this subprocedure we need to ensure that each $a \in S_\pm$ has no crossing blocks. Given a visibly crossing block a^ℓ, popping one node may be not enough as this block may still be crossing. Thus for each variable X we pop its whole a-prefix whenever $a \in \min(X) \cap S$, where a^ℓ is the a-prefix of a trace V when ℓ is maximal with $V = a^\ell V'$.

We do not apply the pair compression to $a\overline{a}$ as this introduces self-involuting letters. Instead, we perform a variant of block compression on them: the quasi-block compression. We replace each a-quasi-block $(a\overline{a})^\lambda$ with $c_\lambda \overline{c_\lambda}$; note that we treat a and $\overline{a}$ asymmetrically. We again perform this operation in parallel (in several steps), for all $a \in S_+$, where (S_+, S_-) is an involuting partition.

For uncrossing of quasi-blocks we act the same as for uncrossing of blocks, but we pop the whole $(a\overline{a})$-prefix when $a \in S_+$; the $a\overline{a}$ prefix of V is the longest factor $V' \in \overline{a}(a\overline{a})^* \cup (a\overline{a})^*$ such that $V = V'V''$.

Using those operations we can process a minimal set of resources S: We iterate the following operations as long as something changes in the equation. For each variable we guess whether it has a minimal S-letter and if so we pop this letter. Then we compute the set $S_\pm$ of visible S-constants. We uncross blocks from $S_\pm$ and then compress blocks of $S_\pm$. We then arbitrarily partition $S_\pm$ into an involuting partition (S_+, S_-). Then we uncross quasi-blocks for S_+ and then compress quasi-blocks from S_+. We again partition $S_\pm$ into an involuting partition (S_+, S_-); the partition is chosen so that there are many occurrences of pairs in S_+S_- in the equation, see the appendix. Finally, we uncross (S_+, S_-) for pair compression and perform the pair compression for (S_+, S_-).

Using similar arguments as in the case of word equations, one can show that the procedure $\mathsf{FixedResources}(S)$ for a fixed set of resources uses linear space. Concerning the S-runs after $\mathsf{FixedResources}(S)$, ideally all S-runs are of length 1 and are either visible or invisible. This is not entirely true, as $a\overline{a}$ cannot be compressed, but those are the longest visible S-runs that can prevail.

▶ **Lemma 4.** *Let S be minimal. The length of the equation during* $\mathsf{FixedResources}(S)$ *is linear. After* $\mathsf{FixedResources}(S)$ *there are no crossing S-runs, no S-variables. Furthermore, visible S-runs have length at most* 2.

4.3.2 Lifting arcs

Compression of S-runs alone is not enough, as there are runs for different sets of resources. To remedy this we linearize the trace, for technical reasons it is easier to lift whole Hasse arcs rather than individual nodes.

To lift a Hasse arc $e = (a \to b)$ we want to relabel its ends by $[a, \rho(a) \cup \rho(b)]$ and $[b, \rho(a) \cup \rho(b)]$, i.e., by fresh $(\rho(a) \cup \rho(b))$-constants. For correctness reasons we need to also lift the edges that "correspond" to e; moreover, as in the case of compression, lifting may be difficult when an arc connects constants in the equation with constants in the substitution for a variable. Those notions are formalized below.

▶ **Definition 5.** Let $(W, B, \mathcal{X}, \rho, \mu)$ be a state and σ its B-solution. A Hasse-arc $a \to b$ in $\sigma(W)$ is *visible* (*invisible*, *visibly crossing*) if the corresponding factor ab in $\sigma(W)$ has this property. Let $\sim$ be the smallest equivalence relation which satisfies the following conditions:

- If $e = (a \to b)$ in $\sigma(W)$ and $f = (\overline{b} \to \overline{a})$ is the corresponding arc in $\sigma(\overline{W})$, then $e \sim f$.
- If e is invisible and inside some $\sigma(X)$ where $X \in \mathcal{X}$ and f is a corresponding arc in some different $\sigma(X)$, then $e \sim f$.

We say that e is *crossing* if there is exists a visibly crossing f with $f \sim e$; e is *free* otherwise.

Note that for arcs the notion of crossing/free is finer than for traces: since it is possible that $e \not\sim e'$ while both are of the form $(a \to b)$, in particular e could be free and e' crossing.

When $e = (a \to b)$ is a free unbalanced arc, the promised linearization of traces is done through *lifting*: let $S = \rho(a) \cup \rho(b)$, then for $f \sim e$ we change the label on each of its ends from $c \in \{a, b, \overline{a}, \overline{b}\}$ to $[c, S]$. Note that this balances f. To make this operation well defined, we partially linearizes a trace: each position that was before (after) any of relabeled a, b is now before (after) both of $[a, S], [b, S]$ (the same is done for arc $\overline{b} \to \overline{a}$).

We can lift free arcs "for free", but some S-arcs may be crossing. Freeing them is similar to uncrossing factors, but we need to take into the account that $\rho(a) \neq \rho(b)$. Thus ab could be a crossing arc in aX and b is not a minimal element of $\sigma(X)$, so it cannot be popped. Freeing is done in two stages: first we deal with the case when b is an S-letter. Then for $\sigma(X) = PbQ$, such that $S \neq \rho(P) \subsetneq \rho(X)$ we pop the whole P, which is done by introducing a fresh variable, i.e., we substitute $X \mapsto X'bX$. The new solution is $\sigma'(X') = P$ and $\sigma'(X) = Q$. Then we deal with the case when a is an S-letter (and b not). Thus for $\sigma(X) = PbQ$, where $\rho(a) \cap \rho(P) = \emptyset$, we substitute $X \mapsto X'bX$. The new solution is $\sigma'(X') = P$ and $\sigma'(X) = Q$. Those operations are called splitting of variables. Observe that the first splitting can be done for any set of S-constants and all variables in parallel, while the second can be performed in parallel for all variables and any set of constants that is a subset of $\{b \mid \rho(b) \cap S \neq \emptyset\}$.

We want to lift all unbalanced S arcs, but this is not possible for *all* such arcs in parallel due to involution: for an S-letter a and a trace bac we have to choose which arc, $b \to a$ or $a \to c$, we lift. But it can be done in stages: let (S_+, S_-) and (T_+, T_-) be involuting partitions of all S-constants and all constants having a common resource with S, i.e., $\{a \mid \rho(a) \cap S \neq \emptyset\}$. Then we process all S arcs in four groups S_+T_+, S_-T_+, S_+T_- and S_-T_-; processing of each one is similar, we describe processing of one — S_+T_+. We first split the variables for S_+ and then for T_+, as described above. Then each arc $(a \to b)$ with $ab \in S_+T_+$ is free, thus we lift those arcs. We continue with groups S_-T_+, S_+T_- and S_-T_-. Note that the processing may introduce new crossing arcs, but it can be shown that they are always in next groups. Afterwards, there are no S arcs.

Let $\mathsf{Remove}(S)$ be the above procedure for lifting the S-letters. It is easy to show that after $\mathsf{Remove}(S)$ all S-constants and S-variables are eliminated.

▶ **Lemma 6.** *After* $\mathsf{Remove}(S)$ *there are neither* S*-constants nor* S*-variables in* $\sigma(X)$*.*

4.3.3 The algorithm

TrEqSat considers possible sets of resources S in order $\leq$ on them. For a fixed S it first runs $\mathsf{FixedResources}(S)$ and then $\mathsf{Remove}(S)$.

4.4 Analysis

We begin with estimating the space usage. Firstly we upper-bound the number of introduced variables: they are introduced only during splitting of variables, which happens $\mathcal{O}(1)$ times per resource set, and each variable introduces $\mathcal{O}(1)$ variables, which have less resources; this yields that the number of occurrences of variables is linear in the size of the input equation.

We then estimate the length of the equation, which is also linear in the size of the input equation: Here the estimations are similar as in the case of word equations. For a fixed resource set S we claim that the number of S-constants in the equation stays linear and that processing S introduces in total $\mathcal{O}(1)$ constants per variable. Together with the estimation on the number of variables this yields a bound on the size of the equation.

This guarantees that our algorithm does not exceed a space limit, but may loop forever. Thus we want to show that solutions in consecutive steps get "smaller". Unfortunately, the length of $\sigma(W)$ is not good enough for our purposes, but we can define the weight of the solutions (for an equation) and indeed show that our subprocedures decrease it. This guarantees termination.

We then move to the correctness of the algorithm, i.e., we show how the algorithm transforms the solutions between different equations obtained on the way. In a first step we equip each solution with a function that tells us, what solution of the *input* equation it represents. Then we show that if subprocedure transforms one equation into the other, then the morphism associated with this transition transforms the solution of the latter equation to a solution of the former, so that they they represent the same solution of the input equation.

4.4.1 Space usage

The below estimations of space usage do not depend on the nondeterministic choices, they apply to *all* executions of the algorithm.

Comparing to the algorithms in the free monoid case, the main difference is that our algorithm introduces new variables to the equation. This is potentially a problem, as the whole recompression is based on the assumption that the number of constants is not altered. However, we can still bound the number of introduced variables.

▶ **Lemma 7.** *During* TrEqSat *there are $\mathcal{O}(n)$ occurrences of variables in the trace equation.*

Fix a variable X for which initially $T = \rho(X)$. Observe that $\rho(X)$ cannot increase, though it can decrease: resources increase by lifting arcs and we only lift free arcs, thus, each resource of the new constant was present on one of the ends of the arc. On the other hand, popping constants as well as splitting may decrease the resources of a variable.

We say that X *directly created* an occurrence of X' when X' was created in Split when it considered X; X created X' when there is a sequence $X = X_1, X_2, \ldots, X_k = X'$ such that X_i directly created X_{i+1}. Consider a variable X, it can be split at most eight times during lifting of crossing arcs when we consider $T' \subseteq \mathfrak{R}$. This gives all variables that are directly created by X. Note, that each of the directly generated variable has less resources than X: when we replace X with $X'bX$, then we require that $\rho(X') \subsetneq \rho(X'bX)$.

Let $f(k)$ be the maximal number of occurrences of variables that can be created by a variable with at most k resources. Using the above analysis we can write a recursive formula for f; as the number of resources is a constant, this yields the bound.

We show that during TrEqSat the length of the trace equation is linear in the size of the variables, this is similar as in the case of word equations and in fact the proof proceeds using similar steps. First, we focus on FixedResources and its processing of a fixed set of resources S. In each application of the while loop we introduce $\mathcal{O}(1)$ S-constants per variable (in case of block and quasi-block compression we may introduce long blocks but they are replaced with $\mathcal{O}(1)$ constants afterwards). On the other hand, using standard expected value argument we can show that compression of a randomly chosen partition results in removal of a constant fraction of S-constants from the equation.

Comparing the number of constants in the equation before and after processing S, it increases only by the S-factors that were popped from variables. There are $\mathcal{O}(1)$ such factors for a variable and each is of length at most 2. Thus for a fixed set of resources the size of the equation increases by $\mathcal{O}(n)$. Summing over possible sets of resources (which is of constant size) yields the claim.

▶ **Lemma 8.** *During* TrEqSat *the length of the trace equation is $\mathcal{O}(n)$.*

4.4.2 Weight of solutions

To guarantee the termination, we show that all subprocedures decrease the (appropriately defined) weight of a solution. This weight is in fact defined with respect to the original solution: The B-solution σ corresponds to some solution of the input equation, as letters of B correspond to some traces in the original equation. To keep track of those traces we use an A-morphism $\alpha : M(B, \rho, \theta, \mu) \to M(A, \rho_0, \mu_0)$; the idea is that $c \in B$ represents a trace $\alpha(c)$ in $M(A, \rho_0, \mu_0)$. Conceptually, $\alpha(\sigma(W))$ is the corresponding solution of the input equation. We call a pair (σ, α) a *solution* at $(W, B, \mathcal{X}, \rho, \mu)$, where σ is a B-solution. Note that this morphism is a tool of analysis and proof, it is neither computed nor stored anywhere by the algorithm.

Using the morphism we define the *weight* of a solution (α, σ) as $\|\alpha, \sigma\| = \sum_{X \in \mathcal{X}} |\alpha\sigma(X)|$. All subprocedures performed by our algorithm do not increase the weight. In order to ensure that they all decrease some "weight", we take into the account also the weight of the equations and define a weight of a solution (α, σ) at a state V as $(\|\alpha, \sigma\|, \|V\|)$ which is evaluated in lexicographic order. All subprocedures decrease such defined weight. Thus, the path in NFA for a fixed solution is finite and terminates in a final state.

4.4.3 Internal operations

So far all the described operations were performed on the equation and had some influence also on the solutions. However, there are also operations that are needed for the proof but are performed either on the monoid or on the solutions alone, hence they do not affect the equation at all. For this reason we call them *internal*. In essence, we apply them to the equation whenever this is possible.

A constant $a \in B \setminus A$ is *useless* if it does not occur in $\sigma(W)$; it is *useful* otherwise; useless constants are invisible. A variable is *useless* if it does not occur in W. We remove from the monoid all useless constants and variables.

Due to compression we can be left with invisible but useful constants, i.e., such that they occur in $\sigma(W)$ but not in W.

We cannot remove such constants from B, as we deal with all solutions. However, we can replace them with corresponding traces over $M(A, \rho_0, \mu_0)$. The idea is that we replaced $\alpha(c)$ with c too eagerly. We revert this compression. We do not revert the linearization of the trace, though. Thus we lift each letter in $\alpha(c)$ so that it has the same resources as c: we replace every invisible letter c with $(a_1, \rho(c))(a_2, \rho(c)) \cdots (a_\ell, \rho(c))$, where $\alpha(c) = a_1 a_2 \cdots a_\ell$, i.e., with a chain of letters corresponding to the trace compressed into c but lifted into current resources of c. Note that we use letters from $A \subseteq B$, so the procedure is not applicable to letters that it just introduced.

4.4.4 Completeness

The last step to show completeness is an observation that each given subprocedure corresponds to a composition of finitely many substitution and compression transitions: indeed, this is done by mechanical verification.

The completeness, formulated below, easily follows: given an equation with a solution (α, σ) we apply the subprocedures that lead to a final state. By observation above each subprocedure corresponds to a short path in the NFA. The guarantee on the size of the states follows from Lemma 8. Finally, we cannot iterate forever, as each subprocedure decreases the weight of the solution at a state.

▶ **Lemma 9.** *There is constant $\kappa'' \geq 1$ (depending on $\mathfrak{R}$ but independent of n) such that for all states V, if $\|V\| \leq \kappa'' \cdot n$ and V has a solution (α, σ), then there exists a path to final state labeled with $h_1, h_2, \ldots, h_k$ such that*

$$\sigma = h_1 h_2 \cdots h_k.$$

Abstract

Semi-linear sets, which are rational subsets of the monoid $(\mathbb{Z}^d, +)$, have numerous applications in theoretical computer science. Although semi-linear sets are usually given implicitly, by formulas in Presburger arithmetic or by other means, the effect of Boolean operations on semi-linear sets in terms of the size of description has primarily been studied for explicit representations. In this paper, we develop a framework suitable for implicitly presented semi-linear sets, in which the size of a semi-linear set is characterized by its norm – the maximal magnitude of a generator.

We put together a toolbox of operations and decompositions for semi-linear sets which gives bounds in terms of the norm (as opposed to just the bit-size of the description), a unified presentation, and simplified proofs. This toolbox, in particular, provides exponentially better bounds for the complement and set-theoretic difference. We also obtain bounds on unambiguous decompositions and, as an application of the toolbox, settle the complexity of the equivalence problem for exponent-sensitive commutative grammars.

1 Introduction

Semi-linear sets [20] are a generalisation of ultimately periodic sets of natural numbers to any dimension d. By a classic result due to Ginsburg and Spanier [6], they coincide with the sets of integers[1] definable in Presburger arithmetic (the first-order theory of the integers with addition and order), and hence enjoy closure under all Boolean operations. Their nice properties make them a versatile tool in many application domains such as formal language theory, automata theory, and database theory.

More formally, semi-linear sets are finitely represented finite and infinite subsets of $\mathbb{Z}^d$. For $d \geq 1$, a *semi-linear set* M in dimension d is a finite union of *linear sets*. The latter are presented as a base vector $\boldsymbol{b} \in \mathbb{Z}^d$ and a finite set of period vectors $P = \{\boldsymbol{p}_1, \ldots, \boldsymbol{p}_n\} \subseteq \mathbb{Z}^d$ and have the form

$$L(\boldsymbol{b}, P) := \boldsymbol{b} + \{\lambda_1 \cdot \boldsymbol{p}_1 + \cdots + \lambda_n \cdot \boldsymbol{p}_n : \lambda_1, \ldots, \lambda_n \in \mathbb{N}\}. \tag{1}$$

1 In the literature, semi-linear sets are often defined as subsets of $\mathbb{N}^d$ instead of $\mathbb{Z}^d$ as in this paper. All of our results do, however, carry over if one wishes to restrict semi-linear sets to $\mathbb{N}^d$.

Such representations are, in fact, only rarely encountered in applications, because in many contexts semi-linear sets are defined implicitly. A semi-linear set can, for instance, be succinctly encoded by a formula in Presburger arithmetic; or a set can be just *proved* to be semi-linear with an estimation of its *norm*, $\|M\|$. The norm is the absolute value of the largest number occurring in the smallest description of M as a union of sets of the form (1). Examples of implicitly presented semi-linear sets include languages of various types of commutative grammars [10, 18] and reachability sets of reversal-bounded counter automata [13, 9].

The effect of Boolean operations is, however, not easy to track in terms of the size of vectors $\boldsymbol{b}$ and $\boldsymbol{p}_i$ if semi-linear sets are only presented implicitly. As an example, consider the set of non-negative integer solutions to a system of linear inequalities $\mathfrak{S}\colon A \cdot \boldsymbol{x} \leq \boldsymbol{c}$, which is a semi-linear set $S \subseteq \mathbb{N}^d$ encoded by $\mathfrak{S}$ with exponential succinctness. Huynh [12, 11] shows that for a given semi-linear set M, in general, whenever the complement $\overline{M} := \mathbb{N}^d \setminus M$ of M (with respect to $\mathbb{N}^d$; the same holds for $\mathbb{Z}^d$) is non-empty, then there is some $\boldsymbol{u} \in \overline{M}$ whose entries are bounded by an exponential in the explicit representation of M – which amounts to doubly exponential in the size of description of $\mathfrak{S}$. This upper bound is far from optimal: by Farkas' lemma, $\overline{M}$ contains an element $\boldsymbol{u}$ whose magnitude $\|\boldsymbol{u}\|$ is at most singly-exponential in the size of description of $\mathfrak{S}$.

Somewhat surprisingly, to the best of the authors' knowledge, there has been no unified framework for deriving bounds of this kind for implicitly presented semi-linear sets. Even if we take an explicitly given linear set as in (1) and describe it by an existential formula $\Psi(\boldsymbol{x})$ in Presburger arithmetic, the representation of the complement with a universally quantified formula $\neg\Psi(\boldsymbol{x})$ provides poor estimates on the magnitude of small elements: although upper bounds can be derived from an analysis of quantifier-elimination procedures, these bounds are only doubly exponential (see, e.g., [25]) and hence far from being optimal.

Our contribution

In this paper, we develop a framework suitable for implicitly presented semi-linear sets (explicitly presented sets are, of course, included as the simplest special case). In this framework the size of a semi-linear set $M \subseteq \mathbb{Z}^d$ is characterised by its norm, $\|M\|$, rather than the full bit-size of the description of M. We prove novel upper bounds in which, as a rule of thumb, the norm of the result of an operation is upper-bounded by $\|M\|^E$ where the exponent E behaves in a "controlled" way (say, $E = \mathsf{poly}(d)$), thus *taming* the effect of Boolean operations and decompositions. In more detail, our contributions are as follows:

- We put together a "toolbox" of operations and decompositions for semi-linear sets, with *tame* bounds, unified presentation, and simplified proofs. This toolbox includes improved bounds on the norm of the complement and, as a corollary, improved bounds on the norm of the set-theoretic difference. These bounds can give an exponential advantage over previously known techniques that upper-bound the bit-size of the result by n^E where n is the bit-size of the description of M – because n can be exponential in $\|M\|$.
- We derive from our toolbox an alternative proof of the Π_2^{P} upper bound for deciding semi-linear set inclusion, shown originally by Huynh [12, 11]. As a further application, we settle the complexity of the equivalence problem for exponent-sensitive commutative grammars, which have recently been introduced by Mayr and Weihmann [18].
- We give a new proof of and provide an explicit upper bound on unambiguous decomposition of semi-linear sets. It was first asked by Ginsburg [5] whether any semi-linear set is equivalent to a semi-linear set in which every element is generated in a unique way by exactly one linear set. This question was independently positively answered by Eilenberg

and Schützenberger [3] and by Ito [14]. However, to the best of our knowledge, no bounds on this decomposition have been established so far.

We now give a brief guide to the developed techniques and to the remainder of the paper. Our starting point is the fact that the set of non-negative solutions of a system of inequalities $\mathfrak{S}$ can be obtained as $L(B,P) := \bigcup_{\boldsymbol{b}\in B} L(\boldsymbol{b},P)$ for some finite sets $B, P \subseteq \mathbb{N}^d$. We call semi-linear sets of the form $L(B,P)$ *hybrid linear sets* and use them, instead of linear sets, as basic building blocks for general semi-linear sets. A hybrid linear set preserves more structural information about the "infinitary behaviour" of the linear sets it contains; it is, in fact, a discrete analogue of the Minkowski–Weyl representation of a convex polyhedron as the sum of a polytope and a convex cone.

Since the effect of operations on linear sets is primarily dominated by the magnitude and number of period vectors, reasoning in terms of hybrid linear sets lets us treat a potentially exponential number of linear sets in a uniform way. This, in turn, enables us, for instance, to obtain bounds on the representation of the intersection of two hybrid linear sets of the form $L(B,P)$ where, as one would indeed expect, the magnitude of the generators of the result does not depend on the cardinality of B (Subsection 2.3).

Our further path to the results on the complement and set-theoretic difference of semi-linear sets (Section 4) goes through another development, a *proper disjoint decomposition theorem*. It splits a hybrid linear set into a union $\bigcup_{i\in I} L(B_i,P_i)$ where each P_i is *proper* (i.e., consists of linearly independent vectors) and the *convex hulls* of $L(B_i,P_i)$ are disjoint (Section 3). For this result, we use the concept of a generalised simplex in order to construct triangulations of infinite polyhedra in $\mathbb{Q}^d$, and use the technique of half-open decompositions to ensure the disjointness of the aforementioned convex hulls.

Decomposing $\mathbb{Q}^d$ into convex polyhedra is by no means a new technique in the study of semi-linear sets. In particular, such decompositions were used by Huynh [12, 11] and recently by Kopczyński [15] in the context of semi-linear set inclusion. However, our decomposition theorem is different from theirs and gives stronger corollaries, in that we obtain a full semi-linear representation of the complement and, through intersection, of the set-theoretic difference. While the window theorem of Kopczyński in [15] gives an upper bound on the magnitude of the smallest vector in the set difference, our results upper-bound the magnitude of the largest generator.

2 Preliminaries

2.1 Basic definitions

Let $\mathbb{Z}$, $\mathbb{N}$, $\mathbb{Q}$, and $\mathbb{Q}_{\geq 0}$ denote the set of integers, non-negative integers, rationals, and non-negative rationals, respectively. For $x \in \mathbb{Q}$, $\lfloor x \rfloor$ is the largest integer that does not exceed x. For subsets of numbers or vectors A and B, we use the Minkowski sum notation: $A + B := \{a + b : a \in A, b \in B\}$. In this and other contexts, we often omit the curly braces when referring to singletons. For sets of vectors $P = \{\boldsymbol{p}_1, \ldots, \boldsymbol{p}_n\}, Q \subseteq \mathbb{Z}^m$, we may assume some fixed ordering on their elements, e.g., a lexicographic ordering, and thus sometimes treat P as a matrix whose column vectors are $\boldsymbol{p}_1, \ldots, \boldsymbol{p}_n$. This leads to the notation $P \cdot \boldsymbol{\lambda}$ and $P \cdot Q$, for products of P with a vector $\boldsymbol{\lambda}$ and a matrix Q, respectively.

Linear, hybrid linear, and semi-linear sets

Suppose a natural $d \geq 1$ is fixed; we will call this d the *dimension*. A set $L \subseteq \mathbb{Z}^d$ is called *linear* if it is of the form

$$L = L(\boldsymbol{b}, P) := \{\boldsymbol{b} + \lambda_1 \boldsymbol{p}_1 + \cdots + \lambda_k \boldsymbol{p}_k : \lambda_1, \ldots, \lambda_k \in \mathbb{N}, \boldsymbol{p}_1, \ldots, \boldsymbol{p}_k \in P\} \tag{2}$$

where $\boldsymbol{b} \in \mathbb{Z}^d$ and $P \subseteq \mathbb{Z}^d$ is a finite set. We call the vector $\boldsymbol{b}$ the *base vector* and vectors $\boldsymbol{p} \in P$ the *period vectors* (or simply *base* and *periods*) of L. A set $S \subseteq \mathbb{Z}^d$ is called *semi-linear* if it is a finite union of linear sets. Semi-linear sets can be represented as

$$S = \bigcup_{i \in I} L(B_i, P_i) \quad \text{where} \tag{3}$$

$$L(B_i, P_i) := \bigcup_{\boldsymbol{b}_i \in B_i} L(\boldsymbol{b}_i, P_i) \tag{4}$$

and $L(\boldsymbol{b}_i, P_i)$ is as in (2); we call sets $L(B_i, P_i)$ in (4) *hybrid linear sets*. Every linear set is also a hybrid linear set, and every hybrid linear set is semi-linear, but the converse statements are not true in general.

A hybrid linear set $L(B_i, P_i)$ is *proper* if the vectors P_i are linearly independent. Moreover, a hybrid linear set $L(B_i, P_i)$, $\#P_i = r$, is called *unambiguous* if for every $\boldsymbol{x} \in L(B_i, P_i)$ there exist a unique $\boldsymbol{b} \in B_i$ and a unique $\boldsymbol{\lambda} \in \mathbb{N}^r$ such that $\boldsymbol{x} = \boldsymbol{b} + P_i \cdot \boldsymbol{\lambda}$. A representation $\bigcup_{i \in I} L(B_i, P_i)$ is an *unambiguous decomposition* if each hybrid linear set $L(B_i, P_i)$ is unambiguous and the union is disjoint.

From the computational perspective, it is standard to represent semi-linear sets of the form (3) by listing all vectors in the sets B_i, P_i for all $i \in I$; components of the vectors are written in binary. We use the following notation to refer to various size measures for this representation. For any set A, the number of elements of A is $\#A$. For any $\boldsymbol{v} = (v_1, \ldots, v_d) \in \mathbb{Z}^d$, $\|v\| := \max_{1 \le i \le d} |v_i|$; similarly, for any $A \subseteq \mathbb{Z}^d$ we denote $\|A\| := \max_{\boldsymbol{v} \in A} \|\boldsymbol{v}\|$; observe that $\#A \le (2\|A\| + 1)^d$. Finally, for the representation (3) of a semi-linear set S we write $\|S\| := \max(\max_{i \in I} \|B_i\|, \max_{i \in I} \|P_i\|, 2)$, $\#_{\mathsf{b}} S := \max_{i \in I} \#B_i$, and $\#_{\mathsf{p}} S := \max_{i \in I} \#P_i$.

Convex polyhedra

We now introduce some terminology and notation from convex geometry (see, e.g., [22, 4, 19, 23]). For a system of vectors $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k \in \mathbb{Q}^d$, a linear combination $\lambda_1 \boldsymbol{v}_1 + \ldots + \lambda_k \boldsymbol{v}_k$ with $\lambda_1, \ldots, \lambda_k \in \mathbb{Q}$ is called: *non-negative*, or *conical*, if all $\lambda_i \ge 0$; *affine* if $\sum_{i=1}^k \lambda_i = 1$; and *convex* if it is non-negative and affine. For a possibly infinite set of vectors $A \subseteq \mathbb{Q}^d$, by $\operatorname{cone} A$, $\operatorname{aff} A$, and $\operatorname{conv} A$ we denote the *(rational) cone generated by* A, the *affine hull of* A, and the *convex hull of* A, respectively: they are the sets of all non-negative, affine, and convex combinations of finite subsets of A, respectively. We use the convention that $\boldsymbol{0} \in \operatorname{cone} A$ for any A; in particular, $\operatorname{cone} \emptyset = \{\boldsymbol{0}\}$. However, $\operatorname{conv} \emptyset = \emptyset$. Sets of the form $\boldsymbol{b} + \operatorname{cone} A$, for $\boldsymbol{b} \in \mathbb{Q}^d$, are *shifted cones*; we often refer to them simply as cones.

For any non-empty set $X \subseteq \mathbb{Q}^d$ its affine hull satisfies $\operatorname{aff} X = X_0 + \boldsymbol{v}$ for some vector $\boldsymbol{v} \in \mathbb{Q}^d$ and a uniquely determined linear subspace of $\mathbb{Q}^d$ denoted X_0. The *dimension* of X, written as $\dim X$, is the dimension of the subspace X_0.

A *(rational) convex polyhedron* in $\mathbb{Q}^d$ is a set of the form $\{\boldsymbol{x} \in \mathbb{Q}^d : A \cdot \boldsymbol{x} \le \boldsymbol{c}\}$ where $A \in \mathbb{Z}^{m \times d}$, $\boldsymbol{c} \in \mathbb{Z}^m$ for some m, and $\le$ is interpreted compontent-wise. A *face* of a convex polyhedron $W \subseteq \mathbb{Q}^d$ is a set of points where some linear function $\eta \colon \mathbb{Q}^d \to \mathbb{Q}$ achieves its maximum η^* over W; if η is non-constant, the hyperplane $h = \{\boldsymbol{x} \in \mathbb{Q}^d : \eta(\boldsymbol{x}) = \eta^*\}$ is a *supporting hyperplane* of W. A face of a convex polyhedron is always a convex polyhedron itself. Faces of dimension 0, 1, and $\dim W - 1$ are *vertices*, *edges*, and *facets* respectively. All faces of W form a partial order with respect to set inclusion, the largest element being the set W itself (it is always a face).

For a hybrid linear set $L(B, P)$, we denote $K(B, P) := \operatorname{conv} L(B, P) = \operatorname{conv} B + \operatorname{cone} P$. Note that if B is a singleton, i.e., if $L(B, P)$ is a linear set, then $K(B, P)$ is a rational cone; in general, though, $K(B, P)$ is a convex polyhedron.

Given a set S, we call its representation (3) a *proper disjoint decomposition* if each hybrid linear set $L(B_i, P_i)$ is proper and $K(B_i, P_i) \cap K(B_j, P_j) = \emptyset$ for $i \neq j$.

2.2 Auxiliary tools: Systems of linear inequalities

Let $A \in \mathbb{Z}^{m \times n}$ be an integer $m \times n$ matrix and $\boldsymbol{c} \in \mathbb{Z}^m$. We call $\mathfrak{S}\colon A \cdot \boldsymbol{x} \leq \boldsymbol{c}$ a *system of linear inequalities* and $\mathfrak{T}\colon A \cdot \boldsymbol{x} = \boldsymbol{c}$ a *system of linear equations*. By $[\![\mathfrak{S}]\!], [\![\mathfrak{T}]\!] \subseteq \mathbb{Z}^n$ we denote the *solution set* of $\mathfrak{S}$ and $\mathfrak{T}$, i.e, the set of all $\boldsymbol{v} \in \mathbb{Z}^n$ such that $A \cdot \boldsymbol{v} \leq \boldsymbol{c}$ and $A \cdot \boldsymbol{v} = \boldsymbol{c}$, respectively. We use $[\![\mathfrak{T}]\!]_{\geq 0}$ as a shorthand for $[\![\mathfrak{T}]\!] \cap \mathbb{N}^n$, and write $(\!|\mathfrak{S}|\!)$ for the set of rational solutions from $\mathbb{Q}^n$ of $\mathfrak{S}$. Moreover, we define $\|\mathfrak{S}\|, \|\mathfrak{T}\| := \max\{\|A\|, \|\boldsymbol{c}\|\}$.

The following two propositions connect two representations of polyhedra in $\mathbb{Q}^d$.

▶ **Proposition 1** ([23]). *Let $\mathfrak{S}\colon A \cdot \boldsymbol{x} \leq \boldsymbol{c}$ be a convex polyhedron in $\mathbb{Q}^d$. Then there are $B \subseteq \mathbb{Q}^d$ and $P \subseteq \mathbb{Z}^d$ such that $(\!|\mathfrak{S}|\!) = \operatorname{conv} B + \operatorname{cone} P$, $\|P\| \leq 2^{O(d \log d)} \cdot \|\mathfrak{S}\|^d$, and all numerators and denominators in B are bounded by $2^{O(d \log d)} \cdot \|\mathfrak{S}\|^d$.*

Proof. By the Minkowski–Weyl theorem, there exist $C, Q \subseteq \mathbb{Q}^d$ such that $(\!|\mathfrak{S}|\!) = \operatorname{conv} C + \operatorname{cone} Q$. In fact, it is possible (cf. [23, Theorem 10.2]) to find C and Q in which all vectors have numerators and denominators of all entries bounded by $d! \cdot \|\mathfrak{S}\|^d$: they can essentially be chosen as solutions to linear systems defined by square submatrices of the matrix $\left[\begin{array}{c|c} A & \boldsymbol{c} \end{array}\right]$. ◀

▶ **Proposition 2** ([23]). *Let $M = L(\boldsymbol{b}, P) \subseteq \mathbb{Z}^d$ be a proper linear set with $r = \#P$. Then there exists a system of linear inequalities $\mathfrak{S}\colon A \cdot \boldsymbol{x} \leq \boldsymbol{c}$ such that*

- *A is a $(2d - r) \times d$ matrix that does not depend on $\boldsymbol{b}$;*
- *$\|A\| \leq 2^{O(r \log r)} \cdot \max(\|P\|, 1)^r$; $\|\boldsymbol{c}\| \leq d \cdot \|A\| \cdot \|\boldsymbol{b}\|$; and*
- *$\operatorname{conv} L(\boldsymbol{b}, P) = (\!|\mathfrak{S}|\!)$.*

Proof (sketch). Since M is proper, $\operatorname{conv} L(\boldsymbol{b}, P)$ has exactly r facets; r inequalities in $\mathfrak{S}$ define them, with another $2(d - r)$ for $\operatorname{aff} M$. It can be shown (cf. [23, Theorem 10.2]) that there exists an appropriate A such that $(\!|A \cdot \boldsymbol{x} \leq \boldsymbol{0}|\!) = \operatorname{conv} L(\boldsymbol{0}, P)$; and then $\boldsymbol{c} = A \cdot \boldsymbol{b}$. ◀

We will also need a result of von zur Gathen and Sieveking on the sets of all integer solutions of systems of linear inequalities [24].

▶ **Proposition 3.** *Let $\mathfrak{S}\colon A \cdot \boldsymbol{x} \leq \boldsymbol{c}$ be a system of inequalities such that $A \in \mathbb{Z}^{m \times n}$. Then $[\![\mathfrak{S}]\!] = \bigcup_{i \in I} L(B_i, P_i)$ such that*

- *$K(B_i, P_i) \cap K(B_j, P_j) = \emptyset$ for all $i \neq j$,*
- *$\max_{i \in I} \|B_i\|, \max_{i \in I} \|P_i\| \leq 2^{O(n \log n)} \cdot \|A\|^{n-1} \cdot \|\mathfrak{S}\|$, and*
- *$\#I \leq 2^n$.*

Next, we additionally recall a result on the sets of integer solutions of linear equalities that follows from results of Pottier [21].

▶ **Proposition 4.** *Let $\mathfrak{S}_0\colon A \cdot \boldsymbol{x} = \boldsymbol{0}$ and $\mathfrak{S}\colon A \cdot \boldsymbol{x} = \boldsymbol{c}$ be systems of linear Diophantine equations, where $A \in \mathbb{Z}^{m \times n}$. Then $[\![\mathfrak{S}_0]\!]_{\geq 0} = L(\boldsymbol{0}, P)$ and $[\![\mathfrak{S}]\!]_{\geq 0} = L(B, P)$ such that*

- *$\|B\| \leq ((n+1) \cdot \|A\| + \|\boldsymbol{c}\| + 1)^m$, $\|P\| \leq (n \cdot \|A\| + 1)^m$.*

Finally, we will need a discrete version of Carathéodory's theorem:

▶ **Proposition 5.** *Let $M = L(C, Q) \subseteq \mathbb{Z}^d$ be a hybrid linear set. Then $M = \bigcup_{i \in I} L(B_i, P_i)$ such that*

- *$\max_{i \in I} \|B_i\| \leq \|C\| + (\#Q \cdot \|Q\|)^{O(d)}$,*

- $\max_{i\in I} \#P_i \leq d$, $P_i \subseteq Q$ *and each* P_i *is linearly independent, and*
- $\#I \leq (\#Q)^d$.

The statement of Proposition 5 can essentially be shown by a combination of Lemmas 2.7 and 2.8 in [10], which, however, do not establish any concrete bounds. In our proof, we use the result on the intersection of hybrid linear sets from the following subsection 2.3.

2.3 Intersection of semi-linear sets

▶ **Theorem 6.** *Let* M *and* N *be semi-linear sets with representations* $M = \bigcup_{j\in J} L(C_j, Q_j)$, $N = \bigcup_{k\in K} L(D_k, R_k)$. *Then the set* $L := M \cap N$ *is a semi-linear set with representation* $L = \bigcup_{i\in I} L(B_i, P_i)$ *such that* $I = J \times K$,

- $\max_{i\in I} \|B_i\|, \max_{i\in I} \|P_i\| \leq ((\#_{\mathsf{p}} M + \#_{\mathsf{p}} N) \cdot \max(\|M\|, \|N\|))^{O(d)}$, *and*
- $\#I \leq \#J \cdot \#K$.

Moreover, if $Q_j \subseteq R_k$ *and* $i = (j, k)$ *then* $P_i = Q_j$.

Proof (sketch). We have $M \cap N = \bigcup_{j\in J} L(C_j, Q_j) \cap \bigcup_{k\in K} L(D_k, R_k) = \bigcup_{j\in J, k\in K} L(C_j, Q_j) \cap L(D_k, R_k)$. Hence it suffices to show that every $L(C_j, Q_j) \cap L(D_k, R_k)$ is some $L(B_{j,k}, P_{j,k})$ with the desired properties. To this end, one can obtain the set of elements in the intersection as the set of solutions to a suitable system of linear equations and then apply the bounds from Proposition 4. Finally, the fact that if $Q_j \subseteq R_k$ then $P_i = Q_j$ follows from Theorem 5.6.1 in [5, p. 180]. ◀

3 Hybrid linear sets

In the sequel, we develop a close connection between hybrid linear sets and convex polyhedra viewed as generalized convex hulls. Convex polyhedra in $\mathbb{Q}^d$ are sets of the form $\operatorname{conv} C + \operatorname{cone} Q$ for $C, Q \subseteq \mathbb{Q}^d$; they can be viewed as a convex hulls of a set of points C and *directions* Q. Suppose $C = \{\boldsymbol{b}_1, \ldots, \boldsymbol{b}_r\}$ and $Q = \{\boldsymbol{p}_1, \ldots, \boldsymbol{p}_m\}$. The connection builds upon on the similarity of the following sets:

$$\operatorname{conv} C + \operatorname{cone} Q = \left\{ \sum_{i=1}^{r} \lambda_i \boldsymbol{b}_i + \sum_{j=1}^{m} \mu_j \boldsymbol{p}_j : \lambda_i \in \mathbb{Q}_{\geq 0},\ \sum_{i=1}^{r} \lambda_i = 1,\ \mu_j \in \mathbb{Q}_{\geq 0} \right\} \text{ and}$$

$$L(C, Q) = \left\{ \sum_{i=1}^{r} \lambda_i \boldsymbol{b}_i + \sum_{j=1}^{m} \mu_j \boldsymbol{p}_j : \lambda_i \in \mathbb{N},\ \sum_{i=1}^{r} \lambda_i = 1,\ \mu_j \in \mathbb{N} \right\}.$$

As mentioned above, $\operatorname{conv} L(C, Q) = K(C, Q) = \operatorname{conv} C + \operatorname{cone} Q$.

3.1 Proper disjoint decompositions (PDD)

Recall that $S = \bigcup_{i\in I} L(B_i, P_i)$ is a proper disjoint decomposition if vectors in each P_i are linearly independent and the convex hulls $K(B_i, P_i) = \operatorname{conv} L(B_i, P_i)$ are pairwise disjoint.

▶ **Theorem 7** (PDD for hybrid linear sets)**.** *Every hybrid linear set* $M = L(C, Q)$ *has a proper disjoint decomposition* $\bigcup_{i\in I} L(B_i, P_i)$ *where each* P_i *is a subset of* Q *and the following inequalities hold:*

- $\|B_i\| \leq (\#Q + \|C\| + \|Q\| + d)^{O(d)} \leq \|M\|^{O(d^2)}$ *and*

- $\#I \leq (\#Q)^{d+1}$.

The idea of the proof of Theorem 7 is to rely on the connection between hybrid linear sets and convex polyhedra. We will use the observation that each set of the form $\operatorname{conv} C + \operatorname{cone} Q$ has a triangulation. While this term usually refers to the basic construction that splits a convex polygon in a plane into a number of non-overlapping triangles, we will use a construction that extends this concept in two ways: first, instead of $\mathbb{Q}^2$ the sets are in $\mathbb{Q}^d$, so triangles become simplices; second, the sets can be infinite, i.e., with $Q \neq \emptyset$.

The strategy of the proof of Theorem 7 is depicted in the following diagram:

$$\begin{array}{ccc} L(C,Q) & \xrightarrow{3} & \Pi, \text{ a proper disjoint decomposition of } L(C,Q) \\ \big\downarrow 1 & & \big\uparrow 3 \\ K(C,Q) & \xrightarrow{2} & \mathcal{T}, \text{ a triangulation of } K(C,Q) \end{array}$$

Step 1 is taking the convex hull, step 2 is triangulation in $\mathbb{Q}^d$, and step 3 constructs a proper disjoint decomposition given the original set $L(C,Q)$ and the triangulation of $K(C,Q)$.

A *generalized δ-dimensional simplex* T is a set of the form $T = \operatorname{conv} V + \operatorname{cone} D \subseteq \mathbb{Q}^d$ where $\#V + \#D = \delta + 1$, $V \neq \emptyset$, and the dimension of the affine hull of T is exactly δ (cf. [22, pp. 153f]). Elements of V are ordinary vertices of T, and elements of D are vertices at infinity and can be understood as directions. (The set D is, in fact, the set of *extreme directions* of the set T; see [22, p. 162].) Faces of generalized simplices $\operatorname{conv} V + \operatorname{cone} D$ are also generalized simplices and have the form $\operatorname{conv} V' + \operatorname{cone} D'$ where $V' \subseteq V$ and $D' \subseteq D$.

A *triangulation* of a set $W \subseteq \mathbb{Q}^d$ is a collection $\mathcal{T}$ of generalized simplices that satisfies the following properties:

1. $\bigcup_{F \in \mathcal{T}} F = W$.
2. For every $F \in \mathcal{T}$ and every face F' of F, it holds that $F' \in \mathcal{T}$.
3. The intersection of any two $F_1, F_2 \in \mathcal{T}$ is either empty or is a face of both F_1 and F_2.
4. All (generalized) simplices in the set of maxima of $\mathcal{T}$, denoted $\operatorname{Max} \mathcal{T} := \{F' \in \mathcal{T} : \nexists F \in \mathcal{T}.\ F' \text{ is a face of } F \text{ and } F \neq F'\}$, have the same dimension δ, denoted $\dim \mathcal{T}$.

In other words, a triangulation of W is a pure polyhedral complex (see, e.g., [4, Chapter 6]) that consists of generalized simplices and covers exactly W.

To simplify notation, we write $\mathcal{T} = (T_1, \ldots, T_m)$ whenever $\operatorname{Max} \mathcal{T} = \{T_1, \ldots, T_m\}$; of course, the set $\{T_1, \ldots, T_m\}$ is a subset of the set $\mathcal{T}$. It is straightforward that $W = T_1 \cup \ldots \cup T_m$ if $\mathcal{T} = (T_1, \ldots, T_m)$ is a triangulation of W. Conversely, if $T_1, \ldots, T_m$ are (generalized) simplices of equal dimension such that the collection $\mathcal{T}$ of all their faces satisfies Condition 3 in the definition of triangulation, then this collection $\mathcal{T}$ is a triangulation of $T_1 \cup \ldots \cup T_m$. Lemma 8 triangulates possibly unbounded convex polyhedra (for non-empty Q, it treats its elements as vertices at infinity) without introducing new vertices or directions.

▶ **Lemma 8.** *Every polyhedron of the form $W = \operatorname{conv} C + \operatorname{cone} Q \subseteq \mathbb{Q}^d$ has a triangulation $\mathcal{T} = (T_1, \ldots, T_m)$ where $m \leq (\#C + \#Q)^{d+1}$ and $T_i = \operatorname{conv} C_i + \operatorname{cone} Q_i$ with $C_i \subseteq C$ and $Q_i \subseteq Q$ for all i.*

Note that adjacent simplices T_i and T_j in a triangulation can share points in common lower-dimensional faces. However, for our purposes they should be made disjoint. Suppose U is a polyhedron of the form $X = \{\boldsymbol{x} \in \mathbb{Q}^d : \boldsymbol{a}_i \cdot \boldsymbol{x} \leq c_i, 1 \leq i \leq m\}$ where $\boldsymbol{a}_i \in \mathbb{Z}^d$ and $c_i \in \mathbb{Z}$ for all i. For any $A \subseteq \{1, \ldots, m\}$, we call the set

$$X_A = \{\boldsymbol{x} \in \mathbb{Q}^d : \boldsymbol{a}_i \cdot \boldsymbol{x} < c_i, i \in A, \text{ and } \boldsymbol{a}_i \cdot \boldsymbol{x} \leq c_i, i \in \{1, \ldots, m\} \setminus A\}$$

a *half-opening* of U obtained by cutting off the hyperplanes $\boldsymbol{a}_i \cdot \boldsymbol{x} = c_i$, $i \in A$.

▶ **Lemma 9.** *Let W be a δ-dimensional polyhedron in $\mathbb{Q}^d$. For each triangulation $\mathcal{T} = (T_1, \ldots, T_m)$ of W there exists a collection of sets $\mathcal{T}^0 = (T_1^0, \ldots, T_m^0) \subseteq \mathbb{Q}^d$ that satisfies the following conditions:*
1. *$T_1^0 \cup \ldots \cup T_m^0 = W$.*
2. *For every i, T_i^0 is a half-opening of T_i.*
3. *T_i and T_j are disjoint for $i \neq j$.*

Lemma 9 is the *half-open decomposition*, originally from [1] and [16]. Our formulation is a direct corollary of Theorem 3 in the latter paper; see also [8, Section 3.2].

▶ **Lemma 10.** *Suppose $T = \operatorname{conv} V + \operatorname{cone} D$ is a generalized δ-dimensional simplex in $\mathbb{Q}^d$ where $V, D \subseteq \mathbb{Z}^d$ and $\#V + \#D = \delta + 1$. Then for any half-opening T^0 of T it holds that $T^0 \cap \mathbb{Z}^d = L(E, D)$ where $\|E\| \leq \|V\| + (d+1) \cdot \|D\|$.*

Lemma 10 makes it possible to use half-open decomposition in the proof of Theorem 7.

Proof of Theorem 7 (sketch). Take a triangulation of $W = K(C, Q) = \operatorname{conv} C + \operatorname{cone} Q$, which exists by Lemma 8, and apply Lemma 9 to this triangulation. The result is a collection $\mathcal{T}^0 = (T_1^0, \ldots, T_m^0)$ where each T_i^0 is a half-opening of some generalized simplex $\operatorname{conv} C_i + \operatorname{cone} Q_i$ such that $C_i \subseteq C$ and $Q_i \subseteq Q$. By Lemma 10, $T_i^0 \cap \mathbb{Z}^d = L(D_i, Q_i)$. We now apply Theorem 6: since $Q_i \subseteq Q$, we have $L(D_i, Q_i) \cap L(C, Q) = L(B_i, P_i)$ where $P_i = Q_i$. Vectors in each set $P_i = Q_i$ are, in fact, linearly independent, because $\operatorname{conv} C_i + \operatorname{cone} Q_i$ is a generalized simplex. Moreover, $K(B_i, P_i) \subseteq \operatorname{conv} L(D_i, Q_i) \subseteq T_i^0$ for each i; since the sets $T_1^0, \ldots, T_m^0$ are pairwise disjoint, so are the sets $K(B_i, P_i)$. Finally,

$$\begin{aligned}\bigcup_{i=1}^{m} L(B_i, P_i) &= \bigcup_{i=1}^{m} T_i^0 \cap \mathbb{Z}^d \cap L(C, Q) = L(C, Q) \cap \bigcup_{i=1}^{m} T_i^0 \\ &= L(C, Q) \cap W = L(C, Q) \cap \operatorname{conv} L(C, Q) = L(C, Q).\end{aligned}$$ ◀

3.2 Unambiguous decompositions (UD)

The main results of this subsection are the following theorems:

▶ **Theorem 11** (UD for proper hybrid linear sets)**.** *Every proper hybrid linear set $M = L(C, Q)$ has an unambiguous decomposition $\bigcup_{i \in I} L(B_i, P_i)$ where each P_i is a subset of Q and the following conditions are satisfied:*
- *$\|B_i\| \leq \|C\|$ and*
- *$\#I \leq (2 \cdot \#C)^{\#Q}$.*

▶ **Theorem 12** (UD for hybrid linear sets)**.** *Every hybrid linear set $M = L(C, Q)$ has an unambiguous decomposition $\bigcup_{i \in I} L(B_i, P_i)$ where each P_i is a subset of Q and the following inequalities hold:*
- *$\|B_i\| \leq (\#Q + \|C\| + \|Q\| + d)^{O(d)} \leq \|M\|^{O(d^2)}$ and*
- *$\#I \leq ((\|C\| + \|Q\| + d)^{O(d)} + \#C)^d \cdot (d + \#Q)^{O(d^2)} \leq \|M\|^{O(d^3)}$.*

We now show how to prove Theorem 11. The idea is to reduce the disambiguation of a proper hybrid linear set to disambiguation of an ideal in a finitely generated commutative monoid, captured by the following lemma. Here and below, by $\boldsymbol{e}_1, \ldots, \boldsymbol{e}_r$ we denote coordinate vectors in $\mathbb{N}^r$.

▶ **Lemma 13.** *Every set of the form $U = L(F, \{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_r\}) = F + \mathbb{N}^r$ with a finite $F \subseteq \mathbb{N}^r$ has a representation $U = \bigcup_{k \in K} L(G_k, E_k)$ such that the following conditions are satisfied:*

- *each set* $L(G_k, E_k)$ *is unambiguous,*
- *the polyhedra* $\operatorname{conv} L(G_k, E_k)$ *and* $\operatorname{conv} L(G_{k'}, E_{k'})$ *are disjoint for* $k \neq k'$*,*
- $\|G_k\| \leq \|F\|$*,*
- $E_k \subseteq \{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_r\}$*, and*
- $\#K \leq (\#F + 1)^r$*.*

Proof (sketch). The condition that a vector $\boldsymbol{x}$ belongs to $F + \mathbb{N}^r$ can be specified by a logical formula Φ over predicates of the form $x_j \geq c$. These predicates break up $\mathbb{N}^r$ into at most $(\#F + 1)^r$ disjoint regions, and each region is described by a unambiguous hybrid linear set in a straightforward way. ◀

Proof of Theorem 11 (sketch). Take $M = L(C, Q) \subseteq \mathbb{Z}^d$ where $Q = \{\boldsymbol{q}_1, \ldots, \boldsymbol{q}_r\} \subseteq \mathbb{Z}^d$ and vectors in Q are linearly independent, $r \leq d$. Consider the *point lattice* $\mathcal{L} = Q \cdot \mathbb{Z}^r = \{Q \cdot \boldsymbol{\lambda} : \boldsymbol{\lambda} \in \mathbb{Z}^r\}$; see, e.g., [17, Chapter 2]. Vectors $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{Z}^r$ are *congruent* modulo $\mathcal{L}$, written $\boldsymbol{x} \equiv \boldsymbol{y} \pmod{\mathcal{L}}$, if and only if $\boldsymbol{x} - \boldsymbol{y} \in \mathcal{L}$. This congruence splits the set C into a disjoint union $C = C_1 \cup \ldots \cup C_s$ where $\boldsymbol{x} \in C_i$ and $\boldsymbol{y} \in C_j$ are congruent if and only if $i = j$. It is easy to see that $M = \bigcup_{1 \leq j \leq s} L(C_j, Q)$ is a disjoint union, and disambiguating each $L(C_j, Q)$ separately will disambiguate M.

Suppose $C_1 = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_m\} \subseteq \boldsymbol{x}_1 + \mathcal{L}$. Since the vectors in $Q = \{\boldsymbol{q}_1, \ldots, \boldsymbol{q}_r\}$ are linearly independent, each vector from the set $\boldsymbol{x}_1 + \mathcal{L}$ has a unique expansion of the form $\boldsymbol{x}_1 + \sum_{j=1}^r a_j \boldsymbol{q}_j$. Consider the mapping $\psi\colon \boldsymbol{x}_1 + \mathcal{L} \to \mathbb{Z}^r$ taking each vector $\boldsymbol{x}_1 + \sum_{j=1}^r a_j \boldsymbol{q}_j$ to the vector $(a_1, \ldots, a_r) \in \mathbb{Z}^r$. For each j, let a_j^0 be the smallest of the numbers $\psi(\boldsymbol{x}_t)[j]$ over $1 \leq t \leq m$; here $[j]$ refers to the jth component of an r-dimensional vector. Denote $\boldsymbol{a}^0 = (a_1^0, \ldots, a_r^0)$ and let $\psi'\colon \boldsymbol{x}_1 + \mathcal{L} \to \mathbb{Z}^r$ be given by $\psi'(\boldsymbol{x}) = \psi(\boldsymbol{x}) - \boldsymbol{a}^0$. Observe that the mapping ψ' is injective and maps C_1 to some finite set $F \subseteq \mathbb{N}^r$; in fact, $\psi'(L(C_1, Q_1)) = F + \mathbb{N}^r$. After this, it remains to apply Lemma 13. ◀

4 Semi-linear sets

In this section, we derive our main results on the complement, set-theoretic difference, and decompositions of semi-linear sets. We will rely on Theorems 7 and 11 from Section 3.

4.1 Geometric ingredients: Splitting into atomic polyhedra

Consider a semi-linear set given by $M = \bigcup_{j \in J} L(C_j, Q_j)$. Take the proper disjoint decomposition of each $L(C_j, Q_j)$ according to Theorem 7; this decomposes M as

$$M = \bigcup_{j \in J} \bigcup_{t \in T_j} L(C_{jt}, Q_{jt}) \tag{5}$$

where hybrid linear sets $L(C_{jt}, Q_{jt})$ are proper, $Q_{jt} \subseteq Q_j$, and, moreover, for any fixed j the polyhedra $K(C_{jt}, Q_{jt})$ are pairwise disjoint.

Denote by $\mathcal{H}$ the collection of principal supporting hyperplanes for shifted cones $K(\boldsymbol{b}, Q_{jt})$, $\boldsymbol{b} \in C_{jt}$, $t \in T_j$, and $j \in J$: for each cone, take its d principal supporting hyperplanes, i.e., the hyperplanes obtained in Proposition 2, each of the form $h\colon \boldsymbol{a} \cdot \boldsymbol{x} = c$ (with fixed $\boldsymbol{a} \in \mathbb{Z}^d$ and $c \in \mathbb{Z}$), and put them into $\mathcal{H}$. Note that each hyperplane h' is associated with half-spaces $h^-\colon \boldsymbol{a} \cdot \boldsymbol{x} \leq c$ and $h^+\colon \boldsymbol{a} \cdot \boldsymbol{x} \geq c+1$; moreover, we can pick the signs so that $K(\boldsymbol{b}, Q_{jt}) \subseteq (\!|h^-|\!)$. An *atomic polyhedron* with respect to $\mathcal{H}$ is a non-empty set of the form

$$A(H) = \bigcap_{h \in H} (\!|h^-|\!) \cap \bigcap_{h \in \mathcal{H} \setminus H} (\!|h^+|\!),$$

where $H \subseteq \mathcal{H}$. Clearly, $\mathbb{Z}^d \subseteq \bigcup_{H \subseteq \mathcal{H}} A(H)$, and $A(H) \cap A(H') = \emptyset$ whenever $H \neq H'$.

▶ **Lemma 14.** *For every $L(\boldsymbol{b}, Q_{jt})$ with $\boldsymbol{b} \in C_{jt}$ and every $A = A(H)$, either $A \subseteq \operatorname{conv} L(\boldsymbol{b}, Q_{jt})$ or $A \cap \operatorname{conv} L(\boldsymbol{b}, Q_{jt}) = \emptyset$.*

Take a hybrid linear set $L(C_{jt}, Q_{jt})$ and let $\boldsymbol{b} \in C_{jt}$. We say that the linear set $L(\boldsymbol{b}, Q_{jt})$ *shares* an atomic polyhedron A iff $A \subseteq \operatorname{conv} L(\boldsymbol{b}, Q_{jt})$; otherwise we say that it *avoids* A.

▶ **Lemma 15.** *Every atomic polyhedron $A(H)$ is the set of rational solutions to a system of at most $O(d \cdot \sum_{j\in J}(\#Q_j)^{d+1})$ linear inequalities with entries bounded by $\|M\|^{O(d^2)}$.*

▶ **Lemma 16.** *The number of atomic polyhedra is at most $\left(d \cdot \sum_{j\in J} \#C_j \cdot (\#Q_j)^{d+1}\right)^{d+1}$.*

Consider an atomic polyhedron A; we will assume in the remainder of this subsection that A is shared by at least one linear set of the form $L(\boldsymbol{b}, Q_{jt})$. Even though the total number of linear sets of this form that share A can be large, the following property holds.

▶ **Lemma 17.** *If linear sets $L(\boldsymbol{b}, Q_{jt})$ and $L(\boldsymbol{b}', Q_{jt'})$ share A, then $t = t'$. In particular, the number of pairs (j, t) such that some linear set $L(\boldsymbol{b}, Q_{jt})$ shares A does not exceed $\#J$.*

▶ **Lemma 18.** *For every A there exist finite sets $E \subseteq \mathbb{Q}^d$ and $G \subseteq \mathbb{Z}^d$ that satisfy the following conditions:*

1. *$A = \operatorname{conv} E + \operatorname{cone} G$.*
2. *For every linear set $L(\boldsymbol{b}, Q_{jt})$ that shares A, the set G is a subset of $L(\boldsymbol{0}, Q_{jt})$.*
3. *Numerators and denominators of all entries in all $\boldsymbol{e} \in E$ are bounded by $\|M\|^{O(d^3)}$.*
4. *$\|G\| \leq \|M\|^{\#J \cdot O(d^4)}$.*
5. *$\#G \leq \|M\|^{O(d^4)}$.*

The proof of Lemma 18 first applies Proposition 1 to the representation of A from Lemma 15. The upper bound on $\|G\|$ then relies on the fact that, for every $j \in J$, our decomposition (5) ensures disjointness of $K(C_{jt}, Q_{jt})$ among $t \in T_j$; the proof uses this property via Lemma 17.

4.2 Decompositions, complement, and difference

We first state the results on decompositions of semi-linear sets and on the semi-linear representation of the complement.

▶ **Theorem 19** (PDD for semi-linear sets)**.** *Every semi-linear set $M = \bigcup_{j\in J} L(C_j, Q_j)$ has a proper disjoint decomposition $\bigcup_{i\in I} L(B_i, P_i)$ where*

- *$\|B_i\| \leq \|M\|^{\#J \cdot O(d^6)}$,*
- *$\|P_i\| \leq \|M\|^{\#J \cdot O(d^4)}$, and*
- *$\#I \leq \|M\|^{O(d^5)}$.*

▶ **Corollary 20** (UD for semi-linear sets)**.** *Every semi-linear set $M = \bigcup_{j\in J} L(C_j, Q_j)$ has an unambiguous decomposition $\bigcup_{i\in I} L(B_i, P_i)$ where*

- *$\|B_i\| \leq \|M\|^{\#J \cdot O(d^6)}$ and*
- *$\|P_i\| \leq \|M\|^{\#J \cdot O(d^4)}$.*

▶ **Theorem 21** (complement of semi-linear sets)**.** *The complement of every semi-linear set $M = \bigcup_{j\in J} L(C_j, Q_j)$ has a representation of the form $\bigcup_{i\in I} L(B_i, P_i)$ where*

- *$\|B_i\| \leq \|M\|^{\#J \cdot O(d^4)}$ and*
- *$\|P_i\| \leq \|M\|^{\#J \cdot O(d^4)}$.*

We will state the results on set difference at the end of this subsection, and now we focus our attention on Theorems 19 and 21. Corollary 20 follows from Theorems 19 and 11.

Recall that in Subsection 4.1 we decomposed the space into disjoint atomic polyhedra A. Each $A = \operatorname{conv} E + \operatorname{cone} G$ by Lemma 18, with $E \subseteq \mathbb{Q}^d$ and $G \subseteq \mathbb{Z}^d$. By Carathéodory's theorem, for every vector $\boldsymbol{x} \in A$ there are $\nu_{\boldsymbol{e}} \in \mathbb{N}$, $\boldsymbol{e} \in E$, and $\mu_{\boldsymbol{g}} \in \mathbb{N}$, $\boldsymbol{g} \in G$, such that $\boldsymbol{x}$ has an expansion of the form

$$\boldsymbol{x} = \sum_{\boldsymbol{e} \in E} \nu_{\boldsymbol{e}} \cdot \boldsymbol{e} + \sum_{\boldsymbol{g} \in G'} \mu_{\boldsymbol{g}} \cdot \boldsymbol{g} = \tau(\boldsymbol{x}) + \pi(\boldsymbol{x}), \tag{6}$$

where $\tau(\boldsymbol{x}) = \sum_{\boldsymbol{e} \in E} \nu_{\boldsymbol{e}} \cdot \boldsymbol{e} + \sum_{\boldsymbol{g} \in G'} (\mu_{\boldsymbol{g}} - \lfloor \mu_{\boldsymbol{g}} \rfloor) \cdot \boldsymbol{g}$ denotes the *truncation* of $\boldsymbol{x}$, $\pi(\boldsymbol{x}) = \sum_{\boldsymbol{g} \in G'} \lfloor \mu_{\boldsymbol{g}} \rfloor \cdot \boldsymbol{g}$ denotes the *periodic part* of $\boldsymbol{x}$, and $G' \subseteq G$ is some subset of linearly independent vectors in G. We will consider sets $X = A \cap \mathbb{Z}^d \setminus M$ and $Y = A \cap \mathbb{Z}^d \cap M = A \cap M$.

It is not difficult to show that $\|\tau(X)\|$ and $\|\tau(Y)\|$ are bounded from above by $\|M\|^{\#J \cdot \mathsf{poly}(d)}$; these estimations are relevant, as we prove that the equalities $X = L(\tau(X), G)$ and $Y = L(\tau(Y), G)$ hold. While the latter equality requires no sophisticated arguments, a proof of the former turns out to be somewhat delicate. As an auxiliary statement, we show that $\tau(X) \subseteq X$; with this fact at hand, the proof of the inclusion $L(\tau(X), G) \subseteq X$ goes as follows. Suppose, for the sake of contradiction, that there exists a vector $\boldsymbol{z} \in L(\tau(X), G) \cap M$, say with $\boldsymbol{z} \in L(\boldsymbol{b}, Q_{jt})$ such that $L(\boldsymbol{b}, Q_{jt})$ shares A. This implies the existence of another vector $\boldsymbol{x} \in X$ with $\tau(\boldsymbol{x}) \in \boldsymbol{b} + Q_{jt} \cdot \mathbb{Z}^\delta$ where δ is the cardinality of Q_{jt}. At the same time, this $\tau(\boldsymbol{x})$ also belongs to X and thus to A and to the cone $K(\boldsymbol{b}, Q_{jt}) = \boldsymbol{b} + Q_{jt} \cdot \mathbb{Q}^\delta_{\geq 0}$. Since the vectors in Q_{jt} are linearly independent (recall that sets Q_{jt} come from a *proper* disjoint decomposition of $L(C_j, Q_j)$), it follows that $\tau(\boldsymbol{x}) \in \boldsymbol{b} + Q_{jt} \cdot \mathbb{N}^\delta = L(\boldsymbol{b}, Q_{jt})$, which contradicts the fact that $\tau(X) \subseteq X$, because X excludes M.

As seen from this sketch, our ability to construct the hybrid linear representation of X (which corresponds to the complement of M) relies on the fact that our decomposition of M in (5) uses linear sets with linearly independent periods only.

Proofs of Theorems 19 and 21 (sketch). Use equalities

$$M = \bigcup_{H \subseteq \mathcal{H}} A(H) \cap M \qquad \text{and} \qquad \mathbb{Z}^d \setminus M = \bigcup_{H \subseteq \mathcal{H}} A(H) \cap \mathbb{Z}^d \setminus M$$

where it suffices to consider only (non-empty) atomic polyhedra $A = A(H)$. Whenever all linear sets $L(\boldsymbol{b}, Q_{jt})$, $\boldsymbol{b} \in C_{jt}$ (see (5)) avoid a polyhedron A, we have $Y = A \cap M = \emptyset$ and $X = A \cap \mathbb{Z}^d \setminus M = A \cap \mathbb{Z}^d$. Here the case of Y is trivial, and the case of X sends us to Proposition 3. Otherwise, if at least one linear set shares A, we use the representations $X = L(\tau(X), G)$ and $Y = L(\tau(Y), G)$ as discussed above. For the purposes of proper disjoint decomposition (Theorem 19), we need to invoke Theorem 7 on $L(\tau(Y), G)$. Upper bounds on $\|B_i\|$, $\|P_i\|$, and $\#I$ follow from Lemmas 18 and 16 and from Theorem 7. ◀

▶ **Corollary 22** (difference of semi-linear sets). *The set-theoretic difference $M \setminus N$ of semi-linear sets $M = \bigcup_{j \in J} L(C_j, Q_j)$ and $N = \bigcup_{k \in K} L(D_k, R_k)$ has a representation of the form $L = \bigcup_{i \in I} L(B_i, P_i)$, where*

- $\max_{i \in I} \|B_i\|, \max_{i \in I} \|P_i\| \leq \left(\#_{\mathsf{p}} M + \|M\| + \|N\|^{\#K \cdot d^5}\right)^{O(d)}$.

The following result combines Corollary 22 with Proposition 5.

▶ **Corollary 23** (small vector in set difference). *Let M, N be semi-linear sets such that $\|M\|, \|N\| \leq m$ and $M \setminus N \neq \emptyset$. Then there is $\boldsymbol{v} \in M \setminus N$ such that $\|\boldsymbol{v}\| \leq 2^{m^{O(d^2)}}$.*

5 An application: Exponent-sensitive commutative grammars

In this section, we show that our bounds on the difference of semi-linear sets yield a novel and tight upper bound for the equivalence problem for a class of commutative grammars.

Let $\Sigma = \{a_1, \ldots, a_m\}$ be a finite alphabet. The free commutative monoid generated by Σ is denoted by $\Sigma^\odot$, and we treat elements of $\Sigma^\odot$ as vectors in $\mathbb{N}^d$ where $d = |\Sigma|$. By $\Sigma^\oplus := \Sigma^\odot \setminus \{\mathbf{0}\}$ we denote the free commutative semi-group generated by Σ. An *exponent-sensitive commutative grammar* (ESCG) is a tuple $G = (N, \Sigma, S, \Pi)$, where N is a finite set of non-terminal symbols; Σ is a finite alphabet, the set of terminal symbols such that $N \cap \Sigma = \emptyset$; $S \in N$ is the axiom; and $\Pi \subseteq (\bigcup_{U \in N} \{U\}^\oplus) \times (N \cup \Sigma)^\odot$ is a finite set of productions.

ESCG are essentially equivalent to a generalisation of communication-free Petri nets in which incoming arcs may have multiplicity greater than one [18]. The size $|G|$ of G is the number of symbols required write it down; in particular we assume that commutative words from $\Sigma^\odot$ are encoded in *binary*. Subsequently, we write $V \to W$ whenever $(V, W) \in \Pi$. Let $D, E \in (N \cup \Sigma)^\odot$, we say D directly generates E, written $D \Rightarrow_G E$, iff there are $F \in (N \cup \Sigma)^\odot$ and $\pi \in \Pi$ such that $\pi = V \to W$, $D = V + F$ and $E = F + W$. We write $U \Rightarrow_G^* W$ for the reflexive transitive closure of $\Rightarrow_G$ and say that U generates W in this case. If G is clear from the context, we omit the subscript G. The language $\mathcal{L}(G)$ generated by G is defined as

$$\mathcal{L}(G) := \{W \in \Sigma^\odot : S \Rightarrow^* W\}.$$

Given ESCG G, H and $w \in \Sigma^\odot$, the word problem is to decide whether $w \in \mathcal{L}(G)$, and equivalence is to decide whether $\mathcal{L}(G) = \mathcal{L}(H)$. The word problem is PSPACE-complete; the equivalence problem was shown PSPACE-hard and decidable in 2-EXPSPACE by Mayr and Weihmann [18]. The latter result has recently been improved to coNEXP-hardness and membership in co-2NEXP in [7]. An application of Corollary 23 enables us to settle the complexity of the equivalence problem for ESCG.

▶ **Theorem 24.** *Equivalence for ESCG is* coNEXP*-complete.*

Proof (sketch). Let G, H be ESCG such that $\mathcal{L}(G) \neq \mathcal{L}(H)$, and with no loss of generality assume that there is some $w \in \mathcal{L}(G) \setminus \mathcal{L}(H)$. It is shown in [18] that $M = \mathcal{L}(G)$ and $N = \mathcal{L}(H)$ are semi-linear with $\|M\|, \|N\| \leq 2^{p(|G|+|H|)}$ for some fixed polynomial p. Consequently, by Corollary 23 we may assume that $\|w\| \leq 2^{2^{q(|G|+|H|)}}$ for some fixed polynomial q, and hence the representation size n of w is upper-bounded by $2^{q(|G|+|H|)}$. Thus, for the coNEXP upper bound it only remains to show that $w \in \mathcal{L}(G)$ and $w \notin \mathcal{L}(H)$ can be checked in time polynomial in the n. This is not completely obvious since the word problem for ESCG is PSPACE-complete. In the full version of this paper, we show how this obstacle can be avoided, bringing in a strategy that was used by Huynh [10] in order to show a coNEXP upper bound for the equivalence problem for context-free commutative grammars. ◀

Characterizing Classes of Regular Languages Using Prefix Codes of Bounded Synchronization Delay

Volker Diekert[1] and Tobias Walter*†[2]

Abstract

In this paper we continue a classical work of Schützenberger on codes with bounded synchronization delay. He was interested in characterizing those regular languages where the groups in the syntactic monoid belong to a variety **H**. He allowed operations on the language side which are union, intersection, concatenation and modified Kleene-star involving a mapping of a prefix code of bounded synchronization delay to a group $G \in \mathbf{H}$, but no complementation. In our notation this leads to the language classes $\mathrm{SD}_G(A^\infty)$ and $\mathrm{SD}_{\mathbf{H}}(A^\infty)$. Our main result shows that $\mathrm{SD}_{\mathbf{H}}(A^\infty)$ always corresponds to the languages having syntactic monoids where all subgroups are in **H**. Schützenberger showed this for a variety **H** if **H** contains Abelian groups, only. Our method shows the general result for all **H** directly on finite and infinite words. Furthermore, we introduce the notion of *local Rees extensions* which refers to a simple type of classical Rees extensions. We give a decomposition of a monoid in terms of its groups and local Rees extensions. This gives a somewhat similar, but simpler decomposition than in Rhodes' synthesis theorem. Moreover, we need a singly exponential number of operations, only. Finally, our decomposition yields an answer to a question in a recent paper of Almeida and Klíma about varieties that are closed under Rees extensions.

1998 ACM Subject Classification F.4.3 Formal Languages

In memoriam: Marcel-Paul Schützenberger (1920–1996)

1 Introduction

A fundamental result of Schützenberger characterizes the class of star-free languages SF as exactly those languages which are group-free, that is, aperiodic [15]. One usually abbreviates this result by $\mathrm{SF} = \mathbf{AP}$. Schützenberger also found another, but less prominent characterization of SF: the star-free languages are exactly the class of languages which can be defined inductively by finite languages and closure under finite union, concatenation, and the Kleene-star restricted to prefix codes of bounded synchronization delay [17]. This result

is abbreviated by $\mathbf{AP} = \mathrm{SD}$. It is actually stronger than the famous $\mathrm{SF} = \mathbf{AP}$ because $\mathrm{SD} \subseteq \mathrm{SF} \subseteq \mathbf{AP}$ is relatively easy, see [11, Chapter VIII], so $\mathrm{SF} = \mathbf{AP}$ follows from $\mathbf{AP} \subseteq \mathrm{SD}$. The extension $\mathrm{SF} = \mathbf{AP}$ to infinite words is due to Perrin [10]. The result $\mathbf{AP} = \mathrm{SD}$ for infinite words was obtained much later in [5]. It became possible thanks to a "local divisor approach", which also is a main tool in this paper.

Schützenberger did not stop by showing $\mathbf{AP} = \mathrm{SD}$. In retrospective he started a program: in [16] he was able to prove an analogue of $\mathbf{AP} = \mathrm{SD}$ for languages where syntactic monoids have Abelian subgroups, only. In our notation $\mathbf{AP} = \mathrm{SD}$ means $\overline{\mathbf{1}}(A^\infty) = \mathrm{SD}_{\mathbf{1}}(A^\infty)$; and the main result in [16] is "essentially" equivalent to $\overline{\mathbf{Ab}}(A^*) = \mathrm{SD}_{\mathbf{Ab}}(A^*)$. (We write "essentially" because using the structure theory of Abelian groups, a sharper version than $\overline{\mathbf{Ab}}(A^*) = \mathrm{SD}_{\mathbf{Ab}}(A^*)$ is possible.) The proofs [16] use deep results in semigroup theory; and no such result beyond Abelian groups was known so far. Our result generalizes $\overline{\mathbf{Ab}}(A^\infty) = \mathrm{SD}_{\mathbf{Ab}}(A^\infty)$ to every variety $\mathbf{H}$ of finite groups: we show $\overline{\mathbf{H}}(A^\infty) = \mathrm{SD}_{\mathbf{H}}(A^\infty)$. We were able to prove it with much less technical machinery compared to [16]. For example, no knowledge in Krohn-Rhodes theory is required.

Actually, our result is a generalization of $\overline{\mathbf{Ab}}(A^*) = \mathrm{SD}_{\mathbf{Ab}}(A^*)$ [16] and also of $\mathbf{AP}(A^\infty) = \mathrm{SD}(A^\infty)$ [5]. More precisely, we give a characterization of languages which are recognized by monoids where all subgroups belong to $\mathbf{H}$. The characterization uses an inductive scheme starting with all finite subsets of finite words, allows concatenation, finite union, no (!) complementation, but a restricted use of a group-controlled star (resp. group-controlled ω-power). Let us explain the *group-controlled star* in our context. Instead of putting the star above a single language, consider first a disjoint union $K = \bigcup \{K_g \mid g \in G\}$ where G is a finite group and each K_g is regular in A^*. The "group-controlled star", more precisely the "G-controlled star", associates with such a disjoint union the following language:

$$\{u_{g_1} \cdots u_{g_k} \in K^* \mid u_{g_i} \in K_{g_i} \wedge g_1 \cdots g_k = 1 \in G\}\,.$$

Clearly, we obtain a regular language, but without any restriction, allowing such a "group star" yields all regular languages, even in the case of the trivial group. So, the construction is of no interest without a simultaneous restriction. The restriction considered in [16] yields an inductive scheme to define a class $\mathcal{C}$. The restriction says that such a group-controlled star is allowed only over a disjoint union $K = \bigcup \{K_g \mid g \in G\}$ where each K_g already belongs to $\mathcal{C}$ and where K is, in addition, a prefix code of bounded synchronization delay. The initials in "synchronization delay" led to the notation SD; and an indexed version SD_G (resp. $\mathrm{SD}_{\mathbf{H}}$) refers to *synchronization delay* over G (resp. over a finite group in $\mathbf{H}$). Since we also deal with infinite words we apply the same restriction to ω-powers.

Our results give also a new characterization for various other classes. For example, by a result of Straubing, Thérien and Thomas [20], the class of languages, having syntactic monoids where all subgroups are solvable, coincides with $(\mathrm{FO} + \mathrm{MOD})[<]$. Here, $(\mathrm{FO} + \mathrm{MOD})[<]$ means the class of languages defined by the logic $(\mathrm{FO} + \mathrm{MOD})[<]$. Thus, we are able to give a new language characterization: $(\mathrm{FO} + \mathrm{MOD})[<](A^\infty) = \mathrm{SD}_{\mathbf{Sol}}(A^\infty)$.

Moreover, as a sort of byproduct of $\overline{\mathbf{H}} = \mathrm{SD}_{\mathbf{H}}$, we obtain a simple and purely algebraic characterization of the monoids in $\overline{\mathbf{H}}$. Every monoid in $\overline{\mathbf{H}}$ can be decomposed in at most exponentially many iterated Rees extensions of groups in $\mathbf{H}$. The iteration uses only a very restricted version of Rees extensions: *local Rees extensions*. This means we obtain every finite monoid which is not a group as a divisor of a Rees extension between two proper divisors of M, one of them a proper submonoid, the other one a "local divisor".

Our decomposition result is similar to the synthesis theory of Rhodes and Allen [13]. Moreover, it yields a singly exponential bound on the number of operations whereas no such

bound was known by [13]. Finally, using this decomposition, we answer a recent question of Almeida and Klíma [1] concerning varieties which are closed under Rees extensions.

2 Preliminaries

Throughout, A denotes a finite alphabet and A^* is the free monoid over A. It consists of all finite words. The empty word is denoted by 1 as the neutral elements in other monoids or groups. The set of non-empty finite words is A^+; it is the free semigroup over A. By A^ω we denote the set of all infinite words with letters in A. For a set $K \subseteq A^*$, we let $K^\omega = \{u_1u_2\cdots \mid u_i \in K, u_i \text{ non-empty}, i \in \mathbb{N}\} \subseteq A^\omega$. In particular, $K^\omega = (K \setminus \{1\})^\omega$. Since our results concern finite and infinite words, it is convenient to treat finite and infinite words simultaneously. We define $A^\infty = A^* \cup A^\omega$ to be the set of finite or infinite words. Accordingly, a *language* L is a subset of A^∞. We say that L is *regular*, if first, $L \cap A^*$ is regular and second, $L \cap A^\omega$ is ω-regular in the standard meaning of formal language theory. In order to study regular languages algebraically, one considers finite monoids. A *divisor* of a monoid M is a monoid N which is a homomorphic image of a subsemigroup of M. In this case we write $N \preceq M$. A subsemigroup S of M is in our setting a divisor if and only if S is a monoid (but not necessarily a submonoid of M). A *variety* of finite monoids – hence, in Birkhoff's setting: a *pseudovariety* – is a class of finite monoids $\mathbf{V}$ which is closed under finite direct products and under division:

- If I is a finite index set and $M_i \in \mathbf{V}$ for each $i \in I$, then $\prod_{i\in I} M_i \in \mathbf{V}$. In particular, the trivial group $\{1\}$ belongs to $\mathbf{V}$.
- If $M \in \mathbf{V}$ and $N \preceq M$, then $N \in \mathbf{V}$.

Classical formal language theory states "regular" is the same as "recognizable". This means: $L \subseteq A^*$ is regular if and only if its syntactic monoid is finite; $L \subseteq A^\omega$ is regular if and only if its syntactic monoid in the sense of Arnold [2] is finite and, in addition, L is saturated by the syntactic congruence, see eg. [11, 21]. Here we use a notion of recognizability which applies to languages $L \subseteq A^\infty$. Let $\varphi : A^* \to M$ be a homomorphism to a finite monoid M. First, we define a relation $\sim_\varphi$ as follows. If $u \in A^*$ is a finite word, then we write $u \sim_\varphi v$ if v is finite and $\varphi(u) = \varphi(v)$. If $u \in A^\omega$ is an infinite word, then we write $u \sim_\varphi v$ if v is infinite and if there are factorizations $u = u_1u_2\cdots$ and $v = v_1v_2\cdots$ into finite nonempty words such that $\varphi(u_i) = \varphi(v_i)$ for all $i \geq 1$. It is easy to see that $\sim_\varphi$ is not transitive on infinite words, in general. Therefore, we consider its transitive closure $\approx_\varphi$. If $u, v \in A^*$, then we have

$$u \sim_\varphi v \iff u \approx_\varphi v \iff \varphi(u) = \varphi(v).$$

If $\alpha, \beta \in A^\omega$, then we have $\alpha \approx_\varphi \beta$ if and only if there is sequence of infinite words $\alpha_0, \ldots \alpha_k$ such that

$$\alpha = \alpha_0 \sim_\varphi \cdots \sim_\varphi \alpha_k = \beta.$$

We say that $L \subseteq A^\infty$ is *recognizable* by M if there exists a homomorphism $\varphi : A^* \to M$ such that $u \in L$ and $u \sim_\varphi v$ implies $v \in L$. We also say that M or φ recognizes L in this case. The connection to the classical notation is as follows. A regular language $L \subseteq A^\infty$ is recognizable (in our sense) by φ if and only if the syntactic monoids of $L \cap A^*$ and $L \cap A^\omega$ are divisors of M. Another equivalent definition can be given in terms of Wilke algebras [22].

Every variety $\mathbf{V}$ defines a family of regular languages $\mathbf{V}(A^\infty)$ as follows: we let $L \in \mathbf{V}(A^\infty)$ if there exists a monoid $M \in \mathbf{V}$ which recognizes L. Further, we define $\mathbf{V}(A^*) = \{L \subseteq A^* \mid L \in \mathbf{V}(A^\infty)\}$ and $\mathbf{V}(A^\omega) = \{L \subseteq A^\omega \mid L \in \mathbf{V}(A^\infty)\}$. A variety of finite groups is

a variety of finite monoids which contains only groups. Throughout $\mathbf{H}$ denotes a variety of finite groups. Special cases are the varieties

- $\mathbf{1}$: the trivial group $\{1\}$, only.
- $\mathbf{Ab}$: all finite Abelian groups.
- $\mathbf{Sol}$: all finite solvable groups.
- $\mathbf{Sol}_q$: all finite solvable groups where the order is divisible by some power of q.
- $\mathbf{G}$: all finite groups.

According to standard notation $\overline{\mathbf{H}}$ denotes the variety of finite monoids where all subgroups belong to $\mathbf{H}$. It is not completely obvious, but a classical fact [9], that $\overline{\mathbf{H}}$ is indeed a variety. In fact, it is the maximal variety $\mathbf{V}$ such that $\mathbf{V} \cap \mathbf{G} = \mathbf{H}$.

Clearly, $\overline{\mathbf{G}}$ is the class of all finite monoids. The most prominent subclass is $\overline{\mathbf{1}}$: it is the variety of aperiodic monoids $\mathbf{AP}$. The class $\mathbf{AP}(A^\infty) = \overline{\mathbf{1}}(A^\infty)$ admits various other characterizations as subsets of A^∞. For example, it is the class of star-free languages $\mathrm{SF}(A^\infty)$, it is the class of first-order definable languages, and it is the class of definable languages in linear temporal logic over finite or infinite words: $\mathrm{LTL}(A^\infty)$.

Local divisors. Let M be a finite monoid and $c \in M$. Consider the set $cM \cap Mc$ with a new multiplication $\circ$ which is defined as follows:

$$mc \circ cn = mcn.$$

A straightforward calculation shows that $cM \cap Mc$ becomes a monoid with this operation where the neutral element of M_c is c. Thus, the structure $M_c = (cM \cap Mc, \circ, c)$ defines a monoid. We say that M_c is the *local divisor* of M at c. If c is a unit, then M_c is isomorphic to M. If $c = c^2$, then M_c is the standard "local monoid" at the idempotent c.

The important fact is that M_c is always a divisor of M and that $|M_c| < |M|$ as soon as c is not a unit of M. Indeed, the mapping $\lambda_c : \{x \in M \mid cx \in Mc\} \to M_c$ given by $\lambda_c(x) = cx$ is a surjective homomorphism. Moreover, if c is not a unit, then $1 \notin cM \cap Mc$, hence $|M_c| < |M|$. Thus, if M belongs to some variety $\mathbf{V}$, then M_c belongs to the same variety. If M is not a group, then we find some nonunit $c \in M$ and the local divisor M_c is smaller than M. This makes the construction useful for induction. For a survey on the local divisor technique we refer to [6].

Rees extensions. Let N, L be monoids and $\rho : N \to L$ be any mapping. The *Rees extension* $\mathrm{Rees}(\mathrm{N}, \mathrm{L}, \rho)$ is a classical construction for monoids [12, 14], frequently described in terms of matrices. Here, we use an equivalent definition as in [7]. As a set we define

$$\mathrm{Rees}(\mathrm{N}, \mathrm{L}, \rho) = N \cup (N \times L \times N)\,.$$

The multiplication $\cdot$ on $\mathrm{Rees}(\mathrm{N}, \mathrm{L}, \rho)$ is given by

$$\begin{aligned}
n \cdot n' &= nn' && \text{for } n, n' \in N,\\
n \cdot (n_1, m, n_2) \cdot n' &= (nn_1, m, n_2 n') && \text{for } n, n', n_1, n_2 \in N, m \in L,\\
(n_1, m, n_2) \cdot (n_1', m', n_2') &= (n_1, m\rho(n_2 n_1')m', n_2') && \text{for } n_1, n_1', n_2, n_2' \in N, m, m' \in L.
\end{aligned}$$

The neutral element of $\mathrm{Rees}(\mathrm{N}, \mathrm{L}, \rho)$ is $1 \in N$ and $N \subseteq \mathrm{Rees}(\mathrm{N}, \mathrm{L}, \rho)$ is an embedding of monoids. In general, L is not a divisor of $\mathrm{Rees}(\mathrm{N}, \mathrm{L}, \rho)$. The following property holds.

▶ **Lemma 1.** *Let $N \preceq N'$ and $L \preceq L'$. Given $\rho : N \to L$, there exists a mapping $\rho' : N' \to L'$ such that* $\mathrm{Rees}(\mathrm{N}, \mathrm{L}, \rho)$ *is a divisor of* $\mathrm{Rees}(\mathrm{N}', \mathrm{L}', \rho')$.

Proof. First, assume that N (resp. L) is submonoid in N' (resp. L'). Let $\rho' : N' \to L'$ be any function such that $\rho'|_N = \rho$. The mapping $\pi : \mathrm{Rees(N, L, \rho)} \to \mathrm{Rees(N', L', \rho')}$ given by $\pi(n) = n$ and $\pi(n_1, \ell, n_2) = (n_1, \ell, n_2)$ is an injective homomorphism.

Second, let $\varphi : N' \to N$ and $\psi : L' \to L$ be surjective homomorphisms. Let $\rho' : N' \to L'$ be a function such that $\rho'(n) \in \psi^{-1}(\rho(\varphi(n)))$. Let $\pi : \mathrm{Rees(N', L', \rho')} \to \mathrm{Rees(N, L, \rho)}$ be the mapping defined by $\pi(n) = \varphi(n)$ and $\pi(n_1, \ell, n_2) = (\varphi(n_1), \psi(\ell), \varphi(n_2))$. It is clear that π is surjective. It is a homomorphism since

$$\pi((n_1, \ell, n_2) \cdot (n_1', \ell', n_2')) = \pi(n_1, \ell\rho'(n_2 n_1')\ell', n_2') = (\varphi(n_1), \psi(\ell) \underbrace{\psi(\rho'(n_2 n_1'))}_{=\rho(\varphi(n_2 n_1'))} \psi(\ell'), \varphi(n_2'))$$

$$= (\varphi(n_1), \psi(\ell), \varphi(n_2)) \cdot (\varphi(n_1'), \psi(\ell'), \varphi(n_2')) = \pi(n_1, \ell, n_2) \cdot \pi(n_1', \ell', n_2'). \qquad \blacktriangleleft$$

We are mainly interested in the case where N and L are proper divisors of a given finite monoid M. This leads to the notion of local Rees monoids. More precisely, let M be a finite monoid, N be a proper submonoid of M and M_c be a local divisor of M at c where c is not a unit. The *local Rees extension* $\mathrm{LocRees(N, M_c)}$ is defined as the Rees extension $\mathrm{Rees(N, M_c, \rho_c)}$ where ρ_c denotes the mapping $\rho_c : N \to M_c; x \mapsto cxc$.

For a variety $\mathbf{V}$ we define $\mathrm{Rees}(\mathbf{V})$ to be the least variety which contains $\mathbf{V}$ and is closed under taking Rees extensions and $\mathrm{LocRees}(\mathbf{V})$ to be the least variety which contains $\mathbf{V}$ and is closed under local Rees extensions.

2.1 Schützenberger's SD classes

Schützenberger gave a language theoretical characterization of the class of star-free languages $\mathrm{SF}(A^*)$ avoiding complementation, but allowing the star-operation to prefix codes of bounded synchronization delay [17].

A language $K \subseteq A^+$ is called *prefix code* if it is *prefix-free*. That is: $u, uv \in K$ implies $u = uv$. A prefix-free language K is a code since every word $u \in K^*$ admits a unique factorization $u = u_1 \cdots u_k$ with $k \geq 0$ and $u_i \in K$. Note that the empty set $\emptyset$ is considered to be a prefix code. More generally, if $L \subseteq A^+$ is any subset, then $K = L \setminus LA^+$ is a prefix code. A prefix code K has *bounded synchronization delay* if for some $d \in \mathbb{N}$ and for all $u, v, w \in A^*$ we have: if $uvw \in K^*$ and $v \in K^d$, then $uv \in K^*$. Note that the condition implies that for all $uvw \in K^*$ with $v \in K^d$, we have $w \in K^*$, too. If d is given explicitly, K is said to have synchronization delay d. Every subset $B \subseteq A$ (including the empty set) yields a prefix code with synchronization delay 0. If we have $c \in A \setminus B$, then B^*c is a prefix code with synchronization delay 1. If K is any prefix code with (or without) bounded synchronization delay, then K^m is a prefix code for all $m \in \mathbb{N}$, but for $m \geq 2$ it is never of bounded synchronization delay.

Consider a disjoint union $K = \bigcup \{K_g \mid g \in G\}$ of a prefix code K with bounded synchronization delay where G is a finite group and each K_g is regular in A^*. The *G-controlled star* associates with such a disjoint union the following language:

$$\{u_{g_1} \cdots u_{g_k} \in K^* \mid u_{g_i} \in K_{g_i} \wedge g_1 \cdots g_k = 1 \in G\}.$$

Another view of the G-controlled star of K is the following: Let $\gamma_K : K \to G$ be a mapping such that $K_g = \gamma_K^{-1}(g)$ and let $\gamma : K^* \to G$ denote the canonical extension of γ_K to a homomorphism from the free submonoid $K^* \subseteq A^*$ to G, then the G-controlled star of K is exactly the set $\gamma^{-1}(1)$. The generalization to infinite words $\gamma^{-1}(1)^\omega$ is called the G-controlled ω-power. Let $\mathcal{C}$ be a class of languages. We say that $\mathcal{C}$ is closed under G-controlled star (ω-power) if K is a prefix code with bounded synchronization delay, $K_g \in \mathcal{C}$ for all $g \in G$,

then the G-controlled star $\gamma^{-1}(1)$ (ω-power $\gamma^{-1}(1)^\omega$) is in $\mathcal{C}$. For a variety of groups $\mathbf{H}$ we say that $\mathcal{C}$ is closed under $\mathbf{H}$-controlled star (ω-power) if $\mathcal{C}$ is closed under G-controlled star (ω-power) for every group $G \in \mathbf{H}$. By $\mathrm{SD}_G(A^\infty)$ we denote the smallest class of regular languages such that $\emptyset \in \mathrm{SD}_G(A^\infty)$, $\{a\} \in \mathrm{SD}_G(A^\infty)$ for all letters $a \in A$, $\mathrm{SD}_G(A^\infty)$ is closed under finite union and concatenation, i.e., $L, K \in \mathrm{SD}_G(A^\infty)$ implies $L \cup K$ and $(L \cap A^*) \cdot K$ are both in $\mathrm{SD}_G(A^\infty)$, and $\mathrm{SD}_G(A^\infty)$ is closed under G-controlled star and G-controlled ω-power. We also define

$$\mathrm{SD}_G(A^*) = \{L \subseteq A^* \mid L \in \mathrm{SD}_G(A^\infty)\} \quad \text{and} \quad \mathrm{SD}_G(A^\omega) = \{L \subseteq A^\omega \mid L \in \mathrm{SD}_G(A^\infty)\}.$$

Note that for every homomorphism $\gamma : A^* \to G$ we have $\gamma^{-1}(1) \in \mathrm{SD}_G(A^*)$ and $\gamma^{-1}(1)^\omega \in \mathrm{SD}_G(A^\omega)$. This follows because first, A is a prefix code of bounded synchronization delay and second, all finite subsets of A are in $\mathrm{SD}_G(A^*)$.

Unlike the case of star-free sets, the definition of $\mathrm{SD}_G(A^\infty)$ does not use any complementation. By induction: for $L \subseteq A^\infty$ we have $L \in \mathrm{SD}_G(A^\infty)$ if and only if we can write $L = L_1 \cup L_2$ with $L_1 \in \mathrm{SD}_G(A^*)$ and $L_2 \in \mathrm{SD}_G(A^\omega)$. In the special case where $G = \{1\}$ is the trivial group, we also simply write SD instead of $\mathrm{SD}_{\{1\}}$. In this case closure under $\{1\}$-controlled stars (ω-powers) can be rephrased in simpler terms as follows: If $K \in \mathrm{SD}(A^*)$ is a prefix code of bounded synchronization delay, then $K^* \in \mathrm{SD}(A^*)$ and $K^\omega \in \mathrm{SD}(A^\omega)$.

In [16] Schützenberger showed (using a different notation) $\mathrm{SD}_{\mathbf{H}}(A^*) \subseteq \overline{\mathbf{H}}(A^*)$, but the converse only for $\mathbf{H} \subseteq \mathbf{Ab}$, see Proposition 6 for the first inclusion. Our aim is to show $\overline{\mathbf{H}}(A^\infty) \subseteq \mathrm{SD}_{\mathbf{H}}(A^\infty)$ for all $\mathbf{H}$, cf. Theorem 4. We begin with a technical lemma.

▶ **Lemma 2.** *Let $K \subseteq A^+$ be a prefix code of bounded synchronization delay and let $\gamma : K^* \to G$ be a homomorphism such that $\gamma^{-1}(g) \cap K \in \mathrm{SD}_G(A^*)$ for all $g \in G$, then we have $\gamma^{-1}(g) \in \mathrm{SD}_G(A^*)$ for all $g \in G$.*

Proof. For a word $w = u_1 \cdots u_k \in K^*$ we define $P(w) = \{\gamma(u_1 \cdots u_i) \mid 1 \le i \le k\} \subseteq G$ to be the set of prefixes of w in G. By an induction on $|P(w)|$ we construct languages $L(w) \in \mathrm{SD}_G(A^*)$ such that $w \in L(w) \subseteq \gamma^{-1}(\gamma(w))$ and the number $|\{L(w) \mid w \in K^*\}|$ of such languages is finite. The base case $|P(w)| = 0$ implies $g = 1$. We may choose $L(w) = \gamma^{-1}(1)$ and we are done, since $\gamma^{-1}(1) \in \mathrm{SD}_G(A^*)$ by definition. Hence, we may assume $|P(w)| \ge 1$. Let $g_1 = \gamma(u_1)$ and choose i maximal such that $g_1 = \gamma(u_1 \cdots u_i)$. Then we have $u_1 \cdots u_i \in (K \cap \gamma^{-1}(g_1)) \cdot \gamma^{-1}(1)$. Note that $P(w') = g_1^{-1} \cdot \{\gamma(u_1 \cdots u_j) \mid i < j \le k\}$ for $w' = u_{i+1} \cdots u_k$. By choice of i we have $g_1 \notin \{\gamma(u_1 \cdots u_j) \mid i < j \le k\}$ and therefore $|P(w')| = |\{\gamma(u_1 \cdots u_j) \mid i < j \le k\}| < |P(w)|$. By induction there exists $L(w')$ and we let $L(w) = (K \cap \gamma^{-1}(g_1)) \cdot \gamma^{-1}(1) \cdot L(w')$. The number of $|\{L(w) \mid w \in K^*\}|$ is therefore bounded by $\sum_{i=0}^{|G|} |G|^i$ which is less than $|G|^{|G|+1}$. The result follows because we can write $\gamma^{-1}(g) = \bigcup \{L(w) \mid w \in \gamma^{-1}(g)\}$ and this is a finite union. ◀

Clearly, we have for all G: if $K \in \mathrm{SD}_G(A^*)$ is a prefix code of bounded synchronization delay, then K^* and K^ω are both in $\mathrm{SD}_G(A^\infty)$. As a special case, using the prefix code $K = \emptyset$, it holds $K^* = \{1\} \in \mathrm{SD}_G(A^\infty)$. More generally, every finite language is in $\mathrm{SD}_G(A^\infty)$. Note also that for $G' \preceq G$ we have $\mathrm{SD}_{G'}(A^\infty) \subseteq \mathrm{SD}_G(A^\infty)$. In particular, $\bigcup \{\mathrm{SD}_{G_i}(A^\infty) \mid i \in I\} \subseteq \mathrm{SD}_{\prod_{i \in I} G_i}(A^\infty)$ for every finite index set I. This inclusion holds for every divisor of G as observed by the next lemma which can be proved by induction.

▶ **Lemma 3.** $\mathrm{SD}_H(A^\infty) \subseteq \mathrm{SD}_G(A^\infty)$ *holds for $H \preceq G$.*

We will formulate our some of results on the language classes $\mathrm{SD}_G(A^\infty)$ to obtain finer results. However, our main result concerns the language class

$$\mathrm{SD}_{\mathbf{H}}(A^\infty) = \bigcup \{\mathrm{SD}_G(A^\infty) \mid G \in \mathbf{H}\}.$$

▶ **Theorem 4.** *Let* $\mathbf{H}$ *be a variety of finite groups. Then* $\overline{\mathbf{H}}(A^\infty)$ *is the smallest class of languages* $\mathcal{C}$ *closed under finite union, concatenation,* $\mathbf{H}$*-controlled star and* $\mathbf{H}$*-controlled* ω*-power such that* $\mathcal{C}$ *contains all finite languages over* A^**. In other words, it holds* $\overline{\mathbf{H}}(A^\infty) = \mathrm{SD}_{\mathbf{H}}(A^\infty)$*.*

▶ **Corollary 5.** $\mathrm{SD}_{\mathbf{H}}(A^\infty)$ *is closed under complementation and intersection for every variety* $\mathbf{H}$ *of finite groups.*

An algebraic characterization of $\overline{\mathbf{H}}$ in terms of Rees extensions will be given in Theorem 15. The proof of Theorem 4 covers the next two sections.

3 Closure properties of $\mathrm{SD}_{\mathbf{H}}$

In this section we prove $\mathrm{SD}_{\mathbf{H}}(A^\infty) \subseteq \overline{\mathbf{H}}(A^\infty)$. Therefore one has to study the closure properties under the operations given in the definition of $\mathrm{SD}_{\mathbf{H}}(A^\infty)$, that is, one has to show that those operations do not introduce new groups.

The next proposition shows that the $\mathbf{H}$-controlled star does not introduce new groups.

▶ **Proposition 6** ([16])**.** *Let* $K = \bigcup\{K_g \mid g \in G\} \subseteq A^+$ *be a prefix code of bounded synchronization delay where each* K_g *is regular. Then all subgroups in the syntactic monoid of the* G*-controlled star are divisors either of* G *or of the direct product* $\prod_{g\in G} \mathrm{Synt}(K_g)$*.*

We will prove the same for $\gamma^{-1}(1)^\omega$, relying on Proposition 6 as a blackbox. The concept used for transfering the properties to infinite words are Birget-Rhodes expansions [3, 4]. The Birget-Rhodes expansion of a monoid M is the monoid $\mathrm{Exp(M)} = \{(X, m) \mid 1, m \in X \subseteq M\}$. The multiplication on Exp(M) is given as a semi-direct product: $(X, m)\cdot(Y, n) = (X \cup m\cdot Y, m\cdot n)$. Note that M is isomorphic to the submonoid $\{(M, m) \mid m \in M\}$ of Exp(M), that is, M is a divisor of Exp(M). Moreover, the following lemma shows that the Birget-Rhodes expansion has the same groups as M.

▶ **Lemma 7.** *Every subgroup of* Exp(M) *is isomorphic to some group in* M*.*

Proof. Let $G \subseteq \mathrm{Exp(M)}$ be a group contained in Exp(M) and let $(X, e) \in G$ be the unit in G. For every element $(Y, m) \in G$ we have $(X, e)(Y, m) = (X \cup eY, em) = (Y, m)$ and hence, $X \subseteq Y$. Furthermore, $(Y, m)^{|G|} = (Y \cup \cdots, m^{|G|}) = (X, e)$ and we conclude $X = Y$. Thus, $(X, m) \mapsto m$ is an injective embedding of G into M. ◀

The idea behind the Birget-Rhodes expansion is that it stores the seen prefixes in a set.

▶ **Lemma 8.** *Let* $\varphi : A^* \to M$ *be a homomorphism and* $\psi : A^* \to \mathrm{Exp(M)}$ *be the homomorphism given by* $\psi(a) = (\{1, \varphi(a)\}, \varphi(a))$*. Let* $u \in A^*$ *and* $\psi(u) = (X, \varphi(u))$*. For every* $m \in X$ *there exists a prefix* v *of* u *such that* $\varphi(v) = m$*.*

Proof. We will prove this inductively. The statement is true if u is the empty word. Thus, consider $u = va$ for some letter $a \in A$. Let $\psi(v) = (Y, \varphi(v))$, then

$$\psi(u) = \psi(v) \cdot (\{1, \varphi(a)\}, \varphi(a)) = (Y \cup \{\varphi(v), \varphi(v)\varphi(a)\}, \varphi(u)).$$

Inductively, we obtain prefixes of v, and therefore also prefixes of u, for all elements of Y. The only (potentially) new element in X is $\varphi(u)$. This proves the claim. ◀

A special kind of ω-regular languages are *arrow languages*. Let $L \subseteq A^*$ be a language. We define $\overrightarrow{L} = \{\alpha \in A^\omega \mid \text{infinitely many prefixes of } \alpha \text{ are in } L\}$ to be the arrow language

of L. The set of arrow languages is exactly the set of deterministic languages [21]. The Birget-Rhodes expansion can be used to obtain a recognizing monoid for $\overrightarrow{L}$, given a monoid for L. For a related result see [10].

▶ **Proposition 9.** *Let $L \subseteq A^*$ be some regular language and $\varphi : A^* \to M$ be a homomorphism which recognizes L, then $\overrightarrow{L}$ is recognized by* Exp(M).

Proof. Let $\psi : A^* \to \mathrm{Exp(M)}$ be the homomorphism given by $\psi(a) = (\{1, \varphi(a)\}, \varphi(a))$. Let $\alpha \in \overrightarrow{L}$ and $\alpha \sim_\psi \beta$. We show that $\beta \in \overrightarrow{L}$. Let $\alpha = u_1 u_2 \cdots$ and $\beta = v_1 v_2 \cdots$ be factorizations such that $\psi(u_i) = \psi(v_i)$. Since $\alpha \in \overrightarrow{L}$, we may assume that for every i there exists a decomposition $u_i = u_i' u_i''$ such that $u_1 \cdots u_{i-1} u_i' \in L$. By $\psi(u_i) = \psi(v_i)$ and Lemma 8, there exists a decomposition $v_i = v_i' v_i''$ such that $\varphi(u_i') = \varphi(v_i')$. Thus, $u_1 \cdots u_{i-1} u_i' \sim_\varphi v_1 \cdots v_{i-1} v_i'$ and therefore $v_1 \cdots v_{i-1} v_i' \in L$. This implies $\beta \in \overrightarrow{L}$. ◀

▶ **Proposition 10.** *If $L \in \mathrm{SD}_G(A^\infty)$, then all subgroups in* Synt(L) *are a divisor of a direct product of copies of G.*

Proof. We will prove this inductively on the definition of $\mathrm{SD}_G(A^\infty)$. The cases $\emptyset \in \mathrm{SD}_G(A^\infty)$ and $\{a\} \in \mathrm{SD}_G(A^\infty)$ for all letters $a \in A$ are straightforward, as they are recognized by aperiodic monoids. Let L, K be languages, such that their syntactic monoids contain only groups which are divisors of a direct product of G. The language $L \cup K$ is recognized by the direct product of their syntactic monoids which implies the statement. $(L \cap A^*) \cdot K$ is recognized by the Schützenberger product of their syntactic homomorphisms [10] and [8, Proposition 11.7.10]. The Schützenberger product does not introduce new groups [15].

Let $K \subseteq A^+$ be a prefix code of bounded synchronization delay and $\gamma : K^* \to G$ be a homomorphism of the free monoid K^* to the group G such that for all $g \in G$ every subgroup of Synt$(K \cap \gamma^{-1}(g))$ is a divisor of a direct product of copies of G. Proposition 6 implies that every subgroup of Synt$(\gamma^{-1}(1))$ is a divisor of a direct product of copies of G. Note that $\gamma^{-1}(1)^\omega = \overrightarrow{\gamma^{-1}(1)}$ and therefore Proposition 9 and Lemma 7 imply that every subgroup of Synt$(\gamma^{-1}(1)^\omega)$ is a divisor of a direct product of copies of G. ◀

4 The inclusion $\overline{\mathbf{H}}(A^\infty) \subseteq \mathrm{SD}_{\mathbf{H}}(A^\infty)$

We prove that if every subgroup of M is a divisor of G, then every language recognized by M is contained in $\mathrm{SD}_G(A^\infty)$. This result is again finer than just the inequality $\overline{\mathbf{H}}(A^\infty) \subseteq \mathrm{SD}_{\mathbf{H}}(A^\infty)$. The proof works by induction on $|M|$ and on the alphabet and decomposes every $\approx_\varphi$-class into several sets in $\mathrm{SD}_G(A^\infty)$. As a byproduct we obtain a normal form for the languages in $\mathrm{SD}_G(A^\infty)$.

▶ **Proposition 11.** *Let $L \subseteq A^\infty$ be recognized by $\varphi : A^* \to M$ and let G be a group such that every subgroup of M is a divisor of G, then $L \in \mathrm{SD}_G(A^\infty)$. Moreover, L can be written as finite union*

$$L = L_0 \cup \bigcup_{i=1}^{m} L_i \cdot \gamma_i^{-1}(1)^\omega$$

for $L_i \in \mathrm{SD}_G(A^*)$ and $\gamma_i : K_i^* \to G$ for prefix codes $K_i \in \mathrm{SD}_G(A^*)$ of bounded synchronization delay with $\gamma_i^{-1}(g) \cap K_i \in \mathrm{SD}_G(A^*)$ for all $g \in G$. All products in the expressions of L_i are unambiguous.

Proof. Let $[\![w]\!]_\varphi = \{v \in A^\infty \mid w \approx_\varphi v\}$ be the equivalence class of w. Since L is recognized by φ, it holds $L = \cup_{w\in L} [\![w]\!]_\varphi$. Our goal is to construct languages $L(w) \in \mathrm{SD}_G(A^\infty)$ such that

- $w \in L(w) \subseteq [\![w]\!]_\varphi$.
- the number of such languages is finite.
- every word in $L(w)$ starts with the same letter.

In particular, we want to saturate $[\![w]\!]_\varphi$ by sets in $\mathrm{SD}_G(A^\infty)$. The construction of the set $L(w)$ is by induction on $(|M|, |A|)$ with lexicographic order.

If $w = 1$, then we set $L(w) = \{1\}$. This concludes the induction base $|A| = 0$. Let us consider the case that $\varphi(A^*)$ is a group, that is, a divisor of G. Let $K = A$. The set K is a prefix code of synchronization delay 0 and we may choose the homomorphism $\gamma = \varphi$. Note that every subset of A is in $\mathrm{SD}_G(A^*)$. In particular, $K_g = K \cap \gamma^{-1}(g) \in \mathrm{SD}_G(A^*)$ for all $g \in \varphi(A^*)$. This shows $\gamma^{-1}(g) = \varphi^{-1}(g) \in \mathrm{SD}_G(A^*)$ for all $g \in \varphi(A^*)$ by Lemma 2 and Lemma 3. In order to satisfy the third condition let $w = av \in aA^*$ for some $a \in A$ and set $L(w) = a\varphi^{-1}(\varphi(v))$. It is clear that $w \in L(w) \subseteq [\![w]\!]_\varphi$ and $L(w) \in \mathrm{SD}_G(A^*)$ by the above. If $w \in aA^\omega$, then we obtain $w \in a\varphi^{-1}(g)\varphi^{-1}(1)^\omega$ for some $g \in \varphi(A^*)$ by the pigeonhole principle. Thus, we may set $L(w) = a\varphi^{-1}(g)\varphi^{-1}(1)^\omega$. Note that by the definition of $\sim_\varphi$, the inclusion $L(w) \subseteq [\![w]\!]_\varphi$ holds. In particular, these cases include the induction base $|M| = 1$.

In the following we assume that $\varphi(A^*)$ is not a group and therefore there exists a letter $c \in A$ such that $\varphi(c)$ is not a unit. Fix this letter $c \in A$ and set $B = A \setminus \{c\}$. If $w \in B^\infty$, the set $L(w)$ exists by induction. Let $w = uv$ with $u \in B^*$ and $v \in cA^\infty$. By induction we obtain $L(u) \in \mathrm{SD}_G(B^\infty) \subseteq \mathrm{SD}_G(A^\infty)$ and it remains to show $L(v) \in \mathrm{SD}_G(A^\infty)$. Note that the product $L(w) = L(u) \cdot L(v)$ is unambiguous. From now on we may assume $w \in cA^\infty$. Let us first consider the case $w = uv$ with $u \in c(B^*c)^*$ and $v \in B^\infty$, i.e., there are only finitely many occurrences of the letter c in w. By induction, there exists $L(v) \in \mathrm{SD}_G(B^\infty) \subseteq \mathrm{SD}_G(A^\infty)$ and by setting $L(w) = L(u) \cdot L(v)$ it remains to construct $L(u)$.

Consider the alphabet $T = \varphi(B^*) = \{\varphi(u) \mid u \in B^*\}$. Let M_c be the local divisor of M at $\varphi(c)$. Since M_c is a divisor of M, every subgroup of M_c is a divisor of G. Consider the homomorphism $\psi : T^* \to M_c$ given by $\psi(\varphi(u)) = \varphi(cuc)$ and the substitution $\sigma : (B^*c)^\infty \to T^\infty$ with $\sigma(u_1cu_2c\ldots) = \varphi(u_1)\varphi(u_2)\cdots$. Note that

$$\begin{aligned}\psi(\sigma(u_1cu_2c\ldots u_nc)) &= \psi(\varphi(u_1)\varphi(u_2)\cdots\varphi(u_n)) = \varphi(cu_1c)\circ\varphi(cu_2c)\circ\cdots\circ\varphi(cu_nc)\\ &= \varphi(cu_1cu_2c\ldots cu_nc)\end{aligned}$$

and thus $\varphi^{-1}(m) \cap c(B^*c)^* = c\sigma^{-1}(\psi^{-1}(m))$. Since $|M_c| < |M|$, we can apply induction on the monoid size and there exists a language $L(\sigma(u')) \in \mathrm{SD}_G(T^\infty)$ for all $u' \in (B^*c)^*$. We set $L(u) = c\sigma^{-1}(L(\sigma(u')))$ for $u = cu'$. In order to complete the case of finitely many c's, it suffices to show the following claim:

▶ **Claim.** *It is $\sigma^{-1}(K) \in \mathrm{SD}_G(A^\infty)$ for all $K \in \mathrm{SD}_G(T^\infty)$.*

Proof of the Claim: We prove the claim inductively on the definition of SD_G. For $K = \emptyset$, we obtain $\sigma^{-1}(K) = \emptyset \in \mathrm{SD}_G(A^\infty)$. Furthermore,

$$\sigma^{-1}(t) = \bigcup_{v\in B^*, t=\varphi(v)} L(v)c \in \mathrm{SD}_G(A^\infty).$$

Let $L, K \in \mathrm{SD}_G(T^\infty)$. A basic result from set theory yields $\sigma^{-1}(L \cup K) = \sigma^{-1}(L) \cup \sigma^{-1}(K)$. Let $\sigma(v) = w_1w_2$ for some $v \in (B^*c)^*$. Since B^*c is a prefix code, there exists a unique factorization $v = v_1v_2$ with $v_1, v_2 \in (B^*c)^*$ such that $\sigma(v_1) = w_1$ and $\sigma(v_2) = w_2$.

Thus, we conclude $\sigma^{-1}(K \cdot L) = \sigma^{-1}(K) \cdot \sigma^{-1}(L)$. Let now $K \in \mathrm{SD}_G(T^\infty)$ be a prefix code of synchronization delay d. We first show that $\sigma^{-1}(K)$ is a prefix code of bounded synchronization delay. Let $u, uv \in \sigma^{-1}(K)$, then $\sigma(u), \sigma(uv) = \sigma(u)\sigma(v) \in K$ and therefore $\sigma(v) = 1$. This implies $v = 1$ and $\sigma^{-1}(K)$ is a prefix code. We prove that $\sigma^{-1}(K)$ has synchronization delay $d + 1$. The incrementation of the synchronization delay by one comes from the fact that B^*c is not a suffix code, and thus we need another word in B^*c to pose as a left marker. Consider $uvw \in \sigma^{-1}(K)^*$ with $v \in \sigma^{-1}(K)^{d+1}$ and factorize $v = v_1cv_2$ with $v_2 \in \sigma^{-1}(K)^d = \sigma^{-1}(K^d)$. Then $\sigma(uvw) = \sigma(uv_1c)\sigma(v_2)\sigma(w)$, and by $\sigma(v_2) \in K^d$ this implies $\sigma(uv) = \sigma(uv_1c)\sigma(v_2) \in K^*$. Thus, $uv \in \sigma^{-1}(K)^*$. Let $\gamma : K^* \to G$ be some homomorphism and $K_g = K \cap \gamma^{-1}(g) \in \mathrm{SD}_G(T^\infty)$ for all $g \in G$. Inductively, $\sigma^{-1}(K_g) \in \mathrm{SD}_G(A^\infty)$ and $\sigma^{-1}(K) = \bigcup \sigma^{-1}(K_g)$. Let $\gamma' : \sigma^{-1}(K)^* \to G$ be induced by $\gamma'(u) = \gamma(\sigma(u))$. By definition of $\mathrm{SD}_G(A^\infty)$ we obtain $\gamma'^{-1}(1) \in \mathrm{SD}_G(A^\infty)$. However, $u_1 \cdots u_n \in \sigma^{-1}(\gamma^{-1}(1))$ if and only if $\gamma(\sigma(u_1 \cdots u_n)) = 1$. Furthermore, note that $\gamma(\sigma(u_1 \cdots u_n)) = \gamma(\sigma(u_1)) \cdots \gamma(\sigma(u_n)) = \gamma'(u_1) \cdots \gamma'(u_n) = \gamma'(u_1 \cdots u_n)$. Thus, we obtain $\sigma^{-1}(\gamma^{-1}(1)) = \gamma'^{-1}(1) \in \mathrm{SD}_G(A^\infty)$ and $\sigma^{-1}(\gamma^{-1}(1)^\omega) = \gamma'^{-1}(1)^\omega \in \mathrm{SD}_G(A^\infty)$. This concludes the proof of the claim. ◀

At this point we showed the proposition for languages $L \subseteq A^*$.

The last case of the proof is that w contains infinitely many c's, that is, $w = cv$ with $v \in (B^*c)^\omega$. By induction, we know that $\sigma(v) \in L_T \cdot \gamma_T^{-1}(1)^\omega \subseteq [\![\sigma(v)]\!]_\psi$ for some $L_T \in \mathrm{SD}_G(T^*)$ and $\gamma_T : K_T^* \to G$ for some prefix code $K_T \in \mathrm{SD}_G(T^*)$ of bounded synchronization delay with $\gamma_T^{-1}(g) \cap K_T \in \mathrm{SD}_G(T^*)$. By the calculation above, there exists a $\gamma : K^* \to G$ with the usual properties such that $\gamma^{-1}(1) = \sigma^{-1}(\gamma_T^{-1}(1))$. Let $L = \sigma^{-1}(L_T)$ and set $L(w) = cL\gamma^{-1}(1)^\omega$. It remains to show that $cL\gamma^{-1}(1)^\omega \subseteq [\![w]\!]_\varphi$. Let $cu \in cL\gamma^{-1}(1)^\omega$, then $\sigma(u) \in [\![\sigma(v)]\!]_\psi$, that is $\sigma(u) \approx_\psi \sigma(v)$. Since $\approx_\psi$ is the transitive closure of $\sim_\psi$, we show that $\sigma(u) \sim_\psi \sigma(v)$ implies $cu \approx_\varphi cv$ for all $u, v \in (B^*c)^\omega$ which concludes the proof. Now, let $\sigma(u) = \sigma(u_1c)\sigma(u_2c)\cdots$ and $\sigma(v) = \sigma(v_1c)\sigma(v_2c)\cdots$ such that $\psi(\sigma(u_ic)) = \psi(\sigma(v_ic))$. As observed above, this implies $\varphi(cu_ic) = \varphi(cv_ic)$. Thus,

$$\begin{aligned} cu &= (cu_1c)u_2(cu_3c)u_4(c\cdots \sim_\varphi (cv_1c)u_2(cv_3c)u_4(c\cdots \\ &= cv_1(cu_2c)v_3(cu_4c)\cdots \sim_\varphi cv_1(cv_2c)v_3(cv_4c)\cdots \\ &= cv. \end{aligned}$$

This implies the existence of finitely many sets $L(w) \in \mathrm{SD}_G(A^\infty)$ with $w \in L(w) \subseteq [\![w]\!]_\varphi$ in the case of infinitely many c's. ◀

5 Rees extension monoids

We need the fact that every group contained in $\mathrm{Rees}(\mathrm{N}, \mathrm{M}, \rho)$ is contained in N or in M.

▶ **Lemma 12** ([1]). *Let G be a subgroup of $\mathrm{Rees}(\mathrm{N}, \mathrm{M}, \rho)$, then there exists an embedding of G into N or into M.*

Thus, Lemma 12 implies $\mathrm{LocRees}(\mathbf{H}) \subseteq \mathrm{Rees}(\mathbf{H}) \subseteq \mathrm{Rees}(\overline{\mathbf{H}}) \subseteq \overline{\mathbf{H}}$ for any group variety $\mathbf{H}$. We want to prove equality, that is, every monoid which contains only groups in $\mathbf{H}$ is a divisor of an iterated Rees extension of groups in $\mathbf{H}$. However, we are able to prove a stronger statement using only local Rees extensions.

▶ **Lemma 13.** *Let M be a monoid, N be a submonoid of M and $c \in M$. If N and c generate M, then M is a homomorphic image of the local Rees extension $\mathrm{LocRees}(\mathrm{N}, \mathrm{M_c})$.*

Proof. Let $\varphi : \mathrm{LocRees}(\mathrm{N}, \mathrm{M_c}) \to M$ be the mapping given by $\varphi(n) = n$ for $n \in N$ and $\varphi(u, x, v) = uxv$ for $(u, x, v) \in N \times M_c \times N$. Since

$$\begin{aligned}\varphi((u,x,v)(s,y,t)) &= \varphi(u, x \circ cvsc \circ y, t) = \varphi(u, xvsy, t)\\ &= (uxv)(syt) = \varphi(u,x,v)\varphi(s,y,t),\end{aligned}$$

φ is a homomorphism. Obviously, $M = N \cup NM_cN$ and thus φ is surjective. ◀

A *Rees decomposition* of a monoid M is a sequence of monoids $M_1, \ldots, M_k = M$ such that for each $1 \le j \le k$ we have for M_j one of the following:

- M_j is a group which is a divisor of M.
- M_j is a divisor of a local Rees extension of a submonoid M_i of M_j and a local divisor M_ℓ of M_j with $i, \ell < j$.

▶ **Proposition 14.** *A finite monoid M has a Rees decomposition of length at most $2^{|M|} - 1$.*

Proof. We prove the statement with induction on $|M|$. If M is a group, we set $M_1 = M$. This includes the base case $|M| = 1$. If M is not a group, we may choose a minimal generating set of M. Let c be a nonunit of this generating set, then there exists a proper submonoid N of M such that N and c generate M. Since c is not a unit, the local divisor M_c is smaller than M, that is, $|M_c| < |M|$. By induction, there exist Rees decompositions $M'_1, \ldots, M'_{k'} = N$ and $M''_1, \ldots, M''_{k''} = M_c$ with $k', k'' \le 2^{|M|-1} - 1$. Note that every group, which is a divisor of N or M_c also is a divisor of M. Furthermore, M is a divisor of the local Rees extension of $M_{k'} = N$ and $M_{k'+k''} = M_c$ by Lemma 13. Therefore, choosing

- $M_i = M'_i$ for $1 \le i \le k'$
- $M_{i+k'} = M''_i$ for $1 \le i \le k''$
- $M_{k'+k''+1} = M$

leads to such a sequence for M. Since $k' + k'' + 1 \le 2 \cdot (2^{|M|-1} - 1) + 1 = 2^{|M|} - 1$, the bound on k holds. ◀

The inclusion $\overline{\mathbf{H}} \subseteq \mathrm{LocRees}(\mathbf{H})$ is immediate from Proposition 14. This yields

▶ **Theorem 15.** *Let $\mathbf{H}$ be a variety of finite groups. Then $\overline{\mathbf{H}} = \mathrm{LocRees}(\mathbf{H}) = \mathrm{Rees}(\mathbf{H})$.*

In particular, every monoid in $\overline{\mathbf{H}}$ is a divisor of an iterated Rees extension of groups in $\mathbf{H}$ by Lemma 1. We can draw the decomposition as a tree based on the decomposition of M in submonoids and local divisors. We do not describe this formally but content ourselves to give an example.

▶ **Example 16.** Let M be the monoid generated by $\{a, b, \delta, \sigma\}$ with the relations $a^2 = b^2 = ab = ba = 0$, $a\delta = a$, $\delta\sigma = \sigma\delta^2$, $\delta^3 = 1$, $\sigma^2 = 1$ and $d\delta = \delta d$, $d\sigma = \sigma d$ with $d \in \{a, b\}$. The subgroup generated by δ and σ is the symmetric group $\mathfrak{S}_3$; it is solvable but not abelian. The monoid M is syntactic for the language L which is a union of L_a and L_b. The language L_a is the set of all words uav with $uv \in \{\delta, \sigma\}^*$ and the sign of the permutation uv evaluates to -1. The language L_b is the set of all words ubv with $uv \in \{\delta, \sigma\}^*$ and uv evaluates in $\mathfrak{S}_3$ to δ. The decomposition in local Rees extensions from Proposition 14 is depicted in Figure 1. Here $M[a, \sigma, \delta]$ denotes the submonoid generated by $\{a, \sigma, \delta\}$. In particular, this yields

$$M \preceq \mathrm{Rees}(\mathrm{Rees}(\mathfrak{S}_3, \mathrm{Rees}(\mathbb{Z}/2\mathbb{Z}, \{1\}, \rho_1), \rho_2), \mathrm{Rees}(\mathfrak{S}_3, \{1\}, \rho_3), \rho_4)$$

for some $\rho_1, \rho_2, \rho_3, \rho_4$ by Lemma 1.

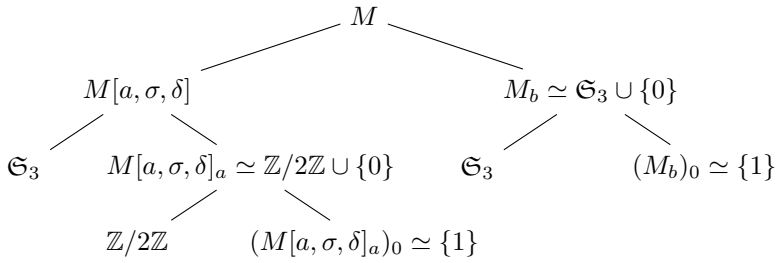

Figure 1 Decomposition tree of the monoid in Example 16.

6 Applications

An application of Proposition 14 is the solution to an open problem of Almeida and Klíma. Let $\mathbf{U}$ and $\mathbf{V}$ be varieties. Let $\mathrm{Rees}(\mathbf{U},\mathbf{V})$ be the variety generated by $\mathrm{Rees}(\mathrm{N},\mathrm{M},\rho)$ for $N \in \mathbf{U}$ and $M \in \mathbf{V}$. Note that in general $\mathrm{Rees}(\mathbf{V}) \neq \mathrm{Rees}(\mathbf{V},\mathbf{V})$. However $\mathrm{Rees}(\mathbf{V})$ can be defined as the limit of this operation. Let $\mathbf{V}_i = \mathrm{Rees}(\mathbf{V}_{i-1},\mathbf{V}_{i-1})$ and $\mathbf{V}_0 = \mathbf{V}$, then

$$\mathrm{Rees}(\mathbf{V}) = \bigcup_{i\in\mathbb{N}} \mathbf{V}_i.$$

The variety $\mathrm{Rees}(\mathbf{U},\mathbf{V})$ has recently been introduced by Almeida and Klíma under the name of *bullet operation* [1]. They defined a variety $\mathbf{V}$ to be *bullet idempotent* if $\mathbf{V} = \mathrm{Rees}(\mathbf{V},\mathbf{V})$ and they asked whether there are varieties apart from $\overline{\mathbf{H}}$ which are bullet idempotent. Using our decomposition above, we prove that the answer to this question is "No".

▶ **Theorem 17.** *Let $\mathbf{V}$ be a bullet idempotent variety and let $\mathbf{H} = \mathbf{V} \cap \mathbf{G}$, then $\mathbf{V} = \overline{\mathbf{H}}$.*

Proof. Since $\overline{\mathbf{H}}$ is the maximal variety with $\overline{\mathbf{H}} \cap \mathbf{G} = \mathbf{H}$, we have $\mathbf{V} \subseteq \overline{\mathbf{H}}$. Let $M \in \overline{\mathbf{H}}$. Inductively, we may assume that every proper divisor of M is in $\mathbf{V}$. If M is a group, then $M \in \mathbf{H}$ and thus $M \in \mathbf{V}$. Thus, there exists an nonunit element $c \in M$ and a proper submonoid N of M such that N and c generate M. By Lemma 13, M is a divisor of $\mathrm{LocRees}(\mathrm{N},\mathrm{M_c})$, and since $N, M_c \in \mathbf{V}$ and $\mathbf{V} = \mathrm{Rees}(\mathbf{V},\mathbf{V})$ we obtain $M \in \mathbf{V}$. ◀

Let $(\mathrm{FO}+\mathrm{MOD}_q)[<]$ be the fragment of first-order sentences which only use first-order quantifiers, modular quantifiers of modulus q and the predicate $<$. Then the following theorem holds.

▶ **Corollary 18.** $(\mathrm{FO}+\mathrm{MOD}_q)[<](A^\infty) = \mathrm{SD}_{\mathbf{Sol}_q}(A^\infty)$

Proof. By [20], see also [19] for a complete treatise, $(\mathrm{FO}+\mathrm{MOD}_q)[<]$ describes the family of all regular languages such that every group in the syntactic monoid is a solvable group of cardinality dividing a power of q, that is the languages in $\mathbf{Sol}_q$. Theorem 4 then implies the stated equality. ◀

The same language class has been described by Straubing with another operation, counting how many prefixes are in a given language, which resembles more closely the counting modulo q [18].

7 Summary

Our main theorem Theorem 4 states $\overline{\mathbf{H}}(A^\infty) = \mathrm{SD}_{\mathbf{H}}(A^\infty)$. An overview over the contributions for $\overline{\mathbf{H}}$ is given in Table 1.

Table 1 Overview of existing and new language characterizations of $\overline{\mathbf{H}}$.

	$\overline{\mathbf{1}}$	$\overline{\mathbf{Ab}}$	$\overline{\mathbf{Sol}}$	$\overline{\mathbf{Sol}_q}$	$\overline{\mathbf{H}}$
finite words	[17]	[16]	[18],**new**	[18],**new**	**new, unless $\mathbf{H} \subseteq \mathbf{Ab}$**
ω-words	[5]	**new**	**new**	**new**	**new, unless $\mathbf{H} = \mathbf{1}$**

As a byproduct we were able to give a simple decomposition of the monoids in $\overline{\mathbf{H}}$ as local Rees extensions and groups in $\mathbf{H}$, using only exponentially many operations.

An Optimal Dual Fault Tolerant Reachability Oracle*†

Keerti Choudhary

Department of Computer Science and Engineering, IIT Kanpur, Kanpur, India
keerti@cse.iitk.ac.in

Abstract

Let $G = (V, E)$ be an n-vertices m-edges directed graph. Let $s \in V$ be any designated source vertex. We address the problem of reporting the reachability information from s under two vertex failures. We show that it is possible to compute in polynomial time an $O(n)$ size data structure that for any query vertex v, and any pair of failed vertices f_1, f_2, answers in $O(1)$ time whether or not there exists a path from s to v in $G \setminus \{f_1, f_2\}$.

For the simpler case of single vertex failure such a data structure can be obtained using the dominator-tree from the celebrated work of Lengauer and Tarjan [TOPLAS 1979, Vol. 1]. However, no efficient data structure was known in the past for handling more than one failures. We, in addition, also present a labeling scheme with $O(\log^3 n)$-bit size labels such that for any $f_1, f_2, v \in V$, it is possible to determine in poly-logarithmic time if v is reachable from s in $G \setminus \{f_1, f_2\}$ using only the labels of f_1, f_2 and v.

Our data structure can also be seen as an efficient mechanism for verifying double-dominators. For any given $x, y, v \in V$ we can determine in $O(1)$ time if the pair (x, y) is a double-dominator of v. Earlier the best known method for this problem was using dominator chain from which verification of double-dominators of only a single vertex was possible.

1 Introduction

Networks in most real life applications are prone to failures. These failures, though unpredictable, are transient due to some simultaneous repair process that is undertaken in the application. This motivates the research on designing fault tolerant structures for various graph problems. In the past few years, a lot of work has been done in designing fault tolerant structures for various fundamental graph problems, see [7, 9, 14].

We address the problem of building a compact data structure for answering reachability queries from a designated source on vertex failures. The only previous known result for this problem was for single failure. The single fault tolerant reachability is closely related to the notion of *dominators* as follows. Given a directed graph G and a source vertex s, we say that a vertex x dominates a vertex v if every path from s to v contains x. Lengauer and Tarjan [12] introduced a data structure called *dominator tree* which is a tree rooted at s such that for any v in G, the set of ancestors of v in the tree is precisely the set of dominators of v. Thus, for any two vertices x and v in G, v becomes unreachable from s on failure of x if and

only if x is ancestor of v in the dominator tree. A lot of work has been done on computing dominators in optimal and near-optimal time, see [3, 10, 11, 12].

In this work, we focus on building efficient data structures for answering reachability queries upon two vertex failures. One simple solution to this problem is an $O(n)$ space and $O(n)$ query time data structure using the work of Baswana et. al [1] on fault tolerant reachability subgraphs (FTRS). They show that for every $k \geqslant 1$, we can compute in polynomial time a subgraph H of G with at most $2^k n$ edges that preserves the reachability information from s even after k edge/vertex failures. Such a subgraph is referred as a k-FTRS for G. Thus in this case a 2-FTRS serves as our data structure for answering reachability queries. To answer a reachability query after two vertex failures, we can run any standard graph traversal algorithm (BFS/DFS) from s in the 2-FTRS avoiding the failed vertices.

Another extreme solution to this problem is an $O(n^2)$ space data structure with $O(1)$ query time. This is possible by building n dominator trees, one for each graph $G \setminus \{y\}$, where $y \in V$. Now on failure of vertices x, y, a vertex v will be reachable from s if and only if x is not ancestor of v in the dominator tree of $G \setminus \{y\}$. To the best of our knowledge, these are the only known solutions for the dual failure case.

This brings us to the following central question of our work - Is it possible to achieve the best of the above two results? In other words, can we have an oracle of $O(n)$ space that still answers reachability queries in $O(1)$ time? We give an affirmative answer to this question. We also present a labeling scheme for this problem. Our results are summarized as follows:

Oracle: There exists a data structure of $O(n)$ size that given any two failing vertices f_1, f_2 and a query vertex v, takes $O(1)$ time to determine if v is reachable from s in $G \setminus \{f_1, f_2\}$.

Labeling Scheme: There exists a compact labeling scheme for answering reachability queries under two failures. Each vertex stores a label of $O(\log^3 n)$ bits such that for any two failing vertices f_1, f_2 and any destination vertex v, it is possible to determine whether v is reachable from s in $G \setminus \{f_1, f_2\}$ by processing the labels associated with f_1, f_2 and v only.

Our result also implies a data structure for the closely related problem of double dominator verification. A pair of vertices (x, y) is said to be *double-dominator* of a vertex v if each path from s to v contains either x or y, but none of x and y are dominators of v. Using our data structure together with the dominator-tree of Lengauer and Tarjan [12], one can obtain an $O(n)$ space data structure that for any given triplet $x, y, v \in V$ verifies in $O(1)$ time if (x, y) is double-dominator of v. The best previously known result for this could verify double-dominators only for a fixed s, v pair in $O(1)$ time using an $O(n)$ space data structure called dominator chain [16].

1.1 Related work

Demetrescu et al. [7] showed that any oracle for reporting distances from a single source, rather than just the reachability information upon vertex failures in a directed weighted graph must require $\Omega(m)$ space. Nonetheless, for the problem of reporting distances between an arbitrary pair of vertices, they give a construction of $O(n^2 \log n)$ size data structure that for any $u, v, x \in V$ reports the length of the shortest path from u to v avoiding x in constant time. Duan and Pettie [9] extended this result to dual failures by designing a data structure of $O(n^2 \log^3 n)$ space which could answer distance queries after any two vertex failures in an $O(\log n)$ time.

Parter and Peleg [14] addressed the problem of computing a sparse subgraph that preserves the distances from source s on failure of a single vertex. In particular, they show that for any given unweighted graph G we can compute a subgraph H with $O(n^{3/2})$ edges such that

for any two vertices v, x, the distance of v from s in the graph $H \setminus \{x\}$ is the same as that in $G \setminus \{x\}$. They also show that this bound is tight. Parter [13] extended this result to dual failure in undirected graphs by showing an upper bound of $O(n^{5/3})$, and also showed that this bound is tight. Baswana and Khanna [2] showed that for the undirected and single failure case if one is willing to settle for an approximation then there is a subgraph with $O(n \log n)$ edges that preserves the distances up to a multiplicative error of 3. Parter and Peleg [15] improved this result and obtained a subgraph with at most $3n$ edges.

Another closely related problem is the replacement paths problem. In this problem we are given a source s and a target t and for each edge e on the shortest path from s to t the algorithm computes the shortest path from s to t avoiding e. Many variants of this problem were studied along the years. For a recent overview see [17] and references therein.

The questions of finding graph spanners, approximate distance oracles and compact routing schemes that are resilient to f vertex or edge failures in undirected graphs were studied in [8, 5, 4].

1.2 Our Techniques

Consider a reachability tree T rooted at source s. Let v be any vertex in T, and P be the path from s to v in T. Let us first consider the simple case when only a single vertex, say x, fails in G. If x lies on P and v is still reachable from s, then we can find an alternate path consisting of - a prefix of P, followed by a "detour", say D, avoiding P (and x), followed by a suffix of P. This simple decomposition can be used to easily handle reachability queries for one vertex failure. However, in the case of the dual failure, non trivialities arise when the second failing vertex lies on detour D. A natural direction to proceed from here is to define secondary detours which are disjoint from both P as well as D, but handling secondary detours is quite complicated.

So we take an alternative approach in which instead of initially starting with a single tree we begin with two independent trees - T_1 and T_2, defined by Georgiadis and Tarjan [11]. They satisfy the condition that for any v, the path from s to v in two trees intersect only at the dominators of v. This allows us to reduce the problem to the case when exactly one failure is an ancestor of v in T_1, and the other failure is ancestor of v in T_2. Now let P_1, P_2 be the paths from s to v in T_1, T_2, and let f_1, f_2 be the failed vertices lying respectively on P_1, P_2. Then, the structure of an alternate path to v gets simplified as follows: It consists of a prefix of either P_1 or P_2 up to a vertex a (lying respectively before f_1 or f_2) followed by a detour which is disjoint from P_1, P_2 (and f_1, f_2), and followed again by a suffix of P_1 or P_2. Note that the starting and terminating vertices of detour need not lie on the same tree-path.

So, we get a very clean and simple representation of detours. The main challenge lies in how to efficiently search for an appropriate detour avoiding f_1, f_2. The problems arising and how they are tackled is discussed in detail in Section 4.

1.3 Organization of the paper

We describe notations and terminologies in Section 2. In Section 3, we briefly sketch the solution for the single failure case using detours. The overview of the paper is presented in Section 4. In Section 5, we present the reachability oracle for a simpler class of graphs that are 2-vertex strongly connected. In Section 6, we present the oracle for general graphs. The construction of the labeling scheme can be found in the full version of the paper.

2 Preliminaries

Given a directed graph $G = (V, E)$ on $n = |V|$ vertices and $m = |E|$ edges, and a source vertex $s \in V$, the following notations will be used throughout the paper.

- f_1, f_2: A given pair of failed vertices.
- $par_T(x)$: The parent of vertex x in tree T.
- $depth_T(x)$: The depth of vertex x in tree T.
- $\textsc{Path}_T(x, y)$: The path from vertex x to vertex y in tree T.
- $\textsc{Path}_T(\bar{x}, y)$: $\textsc{Path}_T(x, y) \setminus \{x\}$
- $\textsc{Path}_T(x, \bar{y})$: $\textsc{Path}_T(x, y) \setminus \{y\}$
- $\textsc{Path}_T(\bar{x}, \bar{y})$: $\textsc{Path}_T(x, y) \setminus \{x, y\}$
- $idom(x)$: The immediate dominator of vertex x. (See Definition 1).
- T_1, T_2: A pair of independent trees for G rooted at s. (See Definition 2).
- $P[x, y]$: The subpath of path P lying between vertices x, y, assuming x precedes y on P.
- $P::Q$: The path formed by concatenating paths P and Q in G. Here it is assumed that the last vertex of P is the same as the first vertex of Q.

We now define immediate dominators and independent spanning trees which are crucial to our fault tolerant reachability oracle.

▶ **Definition 1** ([12]). A vertex w is said to be the *immediate dominator* of v if (i) w is a dominator of v, and (ii) every dominator of v (other than v itself) is also a dominator of w.

▶ **Definition 2** (Georgiadis and Tarjan [11]). Given a directed graph G and a designated source s, a pair of trees T_1, T_2 rooted at s are said to be *independent spanning trees* if for each $v \neq s$ the paths from s to v in T_1 and T_2 intersect only at the dominators of v. (It was shown by Georgiadis and Tarjan [11] that such a pair of trees can be computed in an $O(m)$ time).

Below we state a few basic properties of dominators in a directed graph.

▶ **Property 1.** *Let T be a reachability tree rooted at s, and y_0, y_1 be vertices such that $y_0 = idom(y_1)$. Then for any $z \in \textsc{Path}_T(\bar{y}_0, y_1)$, $idom(z)$ belongs to $\textsc{Path}_T(y_0, y_1)$.*

▶ **Property 2.** *Let T be a reachability tree rooted at s, and y_1, y_2 be vertices such that y_1 is ancestor of y_2, and $idom(y_1) = idom(y_2)$. Then for any $z \in \textsc{Path}_T(y_1, y_2)$ either y_1 is a dominator of z or $idom(z) = idom(y_1)$.*

For efficient implementation of our oracle, we use the following optimal result by Demaine et. al [6] for answering the range minima queries on tree paths.

▶ **Theorem 3** (Demaine et al. [6]). *A tree T on n vertices and edge weights in the range $[0, n^3]$ can be preprocessed in $O(n \log n)$ time to build a data structure of $O(n)$ size so that given any $u, v \in T$, the edge of smallest weight on the tree path from u to v can be reported in $O(1)$ time.*

The following corollary is immediate from Theorem 3.

▶ **Corollary 4.** *Given a tree, say T, on n vertices, with each vertex assigned an integral weight in range $[0, n^3]$, we can obtain in polynomial time an $O(n)$ size data structure that for any two vertices x, y, outputs in $O(1)$ time the vertex with minimum weight on $\textsc{Path}_T(\bar{x}, y)$.*

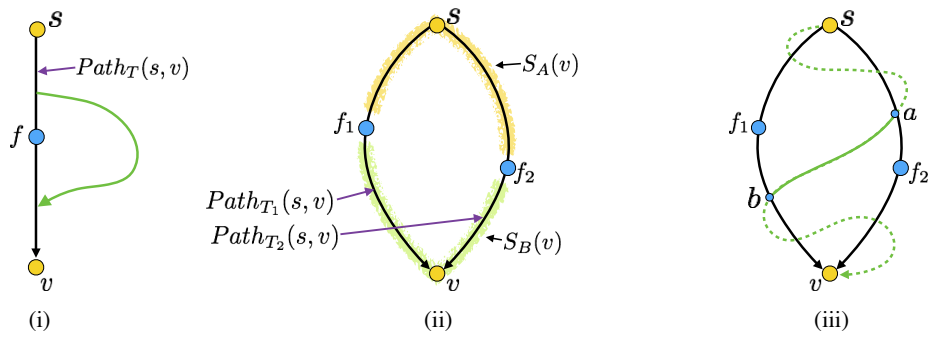

Figure 1 (i) Representation of a path bypassing f in the single vertex failure case; (ii) Representation of sets $S_A(v)$ and $S_B(v)$ when condition $\mathcal{C}$ is satisfied for vertex v; (ii) A path from $a \in S_A(v)$ to $b \in S_B(v)$ when v is reachable from s in $G \setminus \{f_1, f_2\}$.

3 Review of reachability oracle for single failure

In order to understand the dual fault tolerant reachability oracle we first briefly discuss the case of single failure. We here describe an alternative reachability oracle using detours instead of dominator tree. Let T be any reachability tree of G rooted at s, and f, v be respectively the failed and the query vertex. Also assume f is an ancestor of v in T. Notice that if v is reachable from s in $G \setminus \{f\}$, then there must exist a path starting from $\textsc{Path}_T(s, \bar{f})$ and terminating at $\textsc{Path}_T(\bar{f}, v)$ which, except for its endpoints, does not pass through any ancestor of v in T. (See Figure 1(i)). So for each $w \in V$, we can define a detour $D(w)$ to be a path starting from the highest possible ancestor of w in T and terminating at w such that none of the internal vertices of the path pass through an ancestor of w. Now on failure of f it suffices to search whether there exists a vertex lying in $\textsc{Path}_T(\bar{f}, v)$ whose detour starts from an ancestor of f. This can be achieved by assigning to each vertex w a weight equal to the depth of the first vertex on $D(w)$. By doing this the problem of reachability under one vertex failure reduces to the problem of solving range minima on weighted trees, for which already an optimal solution exists. (See Corollary 4).

4 Overview

Let us consider the failure of a pair of vertices f_1, f_2 in G, and let v be the query vertex. Note that if any of the tree paths - $\textsc{Path}_{T_1}(s, v)$ or $\textsc{Path}_{T_2}(s, v)$ is intact, then v will be reachable from s. Also, if both $\textsc{Path}_{T_1}(s, v)$ or $\textsc{Path}_{T_2}(s, v)$ contains a common failed vertex, say f_1, then v will not be reachable from s. This is because then f_1 would be a dominator of v. Thus the non-trivial case is when $\textsc{Path}_{T_1}(s, v)$ contains only f_1 and $\textsc{Path}_{T_2}(s, v)$ contains only f_2, or the vice-versa. So whenever a query vertex v is given to us, we may assume that the following condition is satisfied.

$$\mathcal{C}: f_1 \text{ lies on } \textsc{Path}_{T_1}(s, v) \setminus \textsc{Path}_{T_2}(s, v), \text{ and } f_2 \text{ lies on } \textsc{Path}_{T_2}(s, v) \setminus \textsc{Path}_{T_1}(s, v).$$

Now consider the sets $S_A(v)$ and $S_B(v)$ as defined below. (For a better understanding of these sets see Figure 1(ii)).

- $S_A(v)$: Set of vertices lying either above f_1 on $\textsc{Path}_{T_1}(s, v)$ or above f_2 on $\textsc{Path}_{T_2}(s, v)$.
- $S_B(v)$: Set of vertices lying either below f_1 on $\textsc{Path}_{T_1}(s, v)$ or below f_2 on $\textsc{Path}_{T_2}(s, v)$.

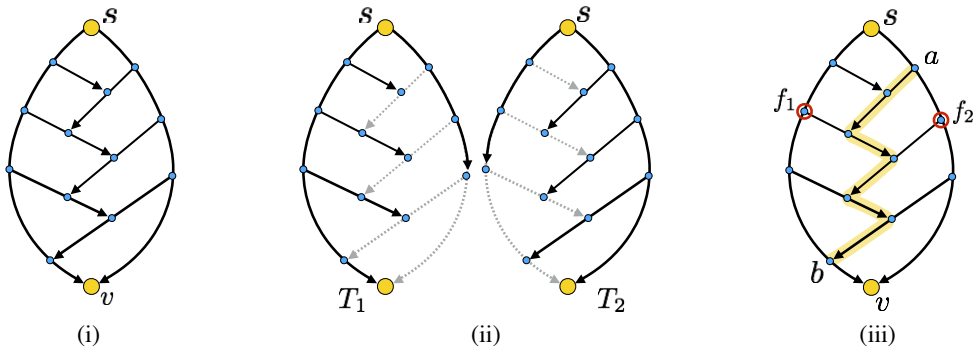

Figure 2 (i) A graph G with in-degree of each vertex bounded by two; (ii) A pair of independent spanning trees T_1 and T_2 for G; (iii) A path P from $a \in S_A(v)$ to $b \in S_B(v)$ in $G \setminus \{f_1, f_2\}$.

It turns out that if v is reachable from s in $G \setminus \{f_1, f_2\}$, then there must exists a path from set $S_A(v)$ to $S_B(v)$ avoiding the vertices of both $\text{PATH}_{T_1}(s, v)$ and $\text{PATH}_{T_2}(s, v)$. This fact is formally stated in the following lemma (refer to the full version of the paper for its proof).

▶ **Lemma 5.** *Given a pair of failed vertices f_1, f_2, a vertex v is reachable from s if and only if G contains a path P satisfying the following conditions. (See Figure 1(iii)).*
C1. *The first and last vertices of P lies respectively in sets $S_A(v)$ and $S_B(v)$.*
C2. *None of the internal vertices of P lies on $\text{PATH}_{T_1}(s, v)$ or $\text{PATH}_{T_2}(s, v)$.*

For simplicity we refer to a path satisfying the conditions *C1* and *C2* stated in the above lemma as an $S_{A,B}(v)$ path. In order to efficiently compute such a path we define a pair of detours $D^1(w)$ and $D^2(w)$ for each vertex $w \in V$ as follows.

- $\text{D}^i(w)$: a path starting from the highest possible ancestor of w in T_i and terminating at w such that none of the internal vertices of the path are ancestor of w in T_1 or T_2.

Note that the detours $D^1(w)$ and $D^2(w)$ can be seen as a simple generalization of the detour $D(w)$ which was defined for the single failure case in Section 3. However, we show that this simple generalization is not sufficient to answer the reachability queries in dual failure. To understand this subtle point consider an $S_{A,B}(v)$ path with a, b as its endpoints. If the endpoint b is equal to v, then P could be simply either $D^1(v)$ or $D^2(v)$. The problem arises when $b \neq v$. This is because if b is an ancestor of v in T_1, then P might contain vertices from $\text{PATH}_{T_2}(s, b)$. (Recall that the internal vertices of P are disjoint from $\text{PATH}_{T_2}(s, v)$, but not necessarily disjoint from $\text{PATH}_{T_2}(s, b)$). So in this case P can neither be $D^1(b)$ nor be $D^2(b)$. For a more clear insight into this consider the graph and its two independent spanning trees in Figure 2. Since in-degree of each vertex in the graph is at most two, $\text{D}^i(w)$ for each $w \in V$ is simply the incoming edge from $par_i(w)$ to w. Thus the path P connecting $S_A(v)$ to $S_B(v)$ is a concatenation of as many detours as there are number of edges in P. Determining whether a concatenation of all these single-edge detours can give us an $S_{A,B}(v)$ path is difficult to achieve in $O(1)$ time.

This shows that a simple generalization of detours from a single tree to two trees is not sufficient. To tackle the problem we extend the notion of detours to 'Parent Detours' and 'Ancestor Detours'. These detours unlike the normal detour terminates at an appropriate ancestor of w in T_1 or T_2. We formally define the parent-detours and ancestor-detours in the following sections, and show how they can be used to solve the problem of dual fault tolerant reachability.

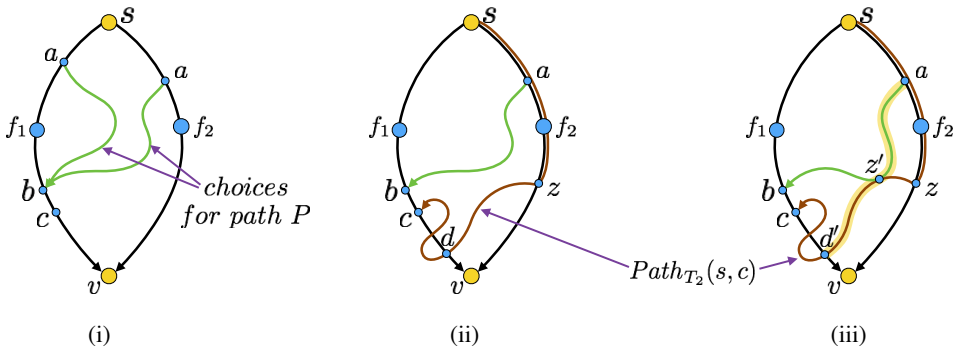

Figure 3 (i) Possibilities for path P when $b \in \text{PATH}_{T_1}(\bar{f_1}, \bar{v})$; (ii) Representation of $\text{PATH}_{T_2}(s, c)$ and $z = LCA(c, v)$ in T_2; (iii) Violation of assumption 2 if $P \cap \text{PATH}_{T_2}(z, c)$ is non-empty.

5 Reachability oracle for 2-vertex strongly connected graphs

In this section we describe an $O(n)$ space and $O(1)$ time reachability oracle for 2-vertex strongly connected graphs. By 2-vertex strongly connectedness we have that on removal of any vertex f ($f \neq s$), all the vertices in $G \setminus \{f\}$ are still reachable from s. Thus each vertex is dominated only by source s and by itself. This implies that for any vertex w, $\text{PATH}_{T_1}(s, w)$ and $\text{PATH}_{T_2}(s, w)$ intersects only at the endpoints s, w.

Consider a query vertex v which is reachable from s in $G \setminus \{f_1, f_2\}$. Let us assume that condition $\mathcal{C}$ is satisfied for v. Let P be any $S_{A,B}(v)$ path, and a, b be respectively the first and last vertices on P. Without loss of generality we can assume that b lies on $\text{PATH}_{T_1}(s, v)$. See Figure 3(i). We make the following additional assumptions.

1. None of the $S_{A,B}(v)$ paths terminates at v (i.e. b cannot be v).
2. b is the lowest vertex on $\text{PATH}_{T_1}(s, v)$ at which an $S_{A,B}(v)$ path terminates.

▶ Remark. The assumption 1 is justified since if $b = v$, then v will be reachable from s using the detours $D^1(v)$ or $D^2(v)$.

We now state a lemma which provides the motivation for defining the parent detours.

▶ **Lemma 6.** *Let a, b, P be as described above, and c be the child of b on $\text{PATH}_{T_1}(s, v)$. Then,*

(i) *Vertex f_2 is an ancestor of c in T_2.*

(ii) *None of the internal vertices of P lie on $\text{PATH}_{T_1}(s, c)$ or $\text{PATH}_{T_2}(s, c)$.*

Proof. Let z denote the LCA of vertices c and v in tree T_2. (See Figure 3(ii)). Consider the path $Q = \text{PATH}_{T_2}(z, c)$. It is easy to see that none of the internal vertices of Q lies on $\text{PATH}_{T_2}(s, v)$. Also, the internal vertices of Q appearing on $\text{PATH}_{T_1}(s, v)$ must lie below c on $\text{PATH}_{T_1}(s, v)$. This is because, by definition of independent spanning trees, $\text{PATH}_{T_1}(s, c)$ and Q can intersect only at the vertices s and c.

We now prove claim 1. Let d be the first point of intersection of Q with $\text{PATH}_{T_1}(c, v)$. (See Figure 3(ii)). Then the internal vertices of $Q[z, d]$ are disjoint from both $\text{PATH}_{T_1}(s, v)$ and $\text{PATH}_{T_2}(s, v)$. Now if z is an ancestor of f_2 in T_2, then $Q[z, d]$ forms an $S_{A,B}(v)$ path, terminating at descendant of b in T_1, thereby violating assumption 2. Hence f_2 must be either same as z or an ancestor of z. This shows that f_2 is an ancestor of c in T_2.

In order to prove claim 2, we first show that P is disjoint from Q. Let us suppose on the contrary, that there exists a vertex, say z', belonging to $P \cap Q$. Also let d' be the first vertex of $Q[z', c]$ lying on $\text{PATH}_{T_1}(c, v)$. (See Figure 3(iii)). Then $P[a, z']::Q[z', d']$ forms an

$S_{A,B}(v)$ path terminating at a descendant of b in T_1. This again violates assumption 2. Thus $P \cap Q = \emptyset$. Now since the internal vertices of P are disjoint from $\textsc{Path}_{T_1}(s,v), \textsc{Path}_{T_2}(s,v)$, they must be disjoint from $\textsc{Path}_{T_1}(s,c)$ and $\textsc{Path}_{T_2}(s,z)::Q = \textsc{Path}_{T_2}(s,c)$, as well. ◀

The above lemma implies that f_1 is an ancestor of c in T_1, and f_2 is an ancestor of c in T_2. Thus $S_A(v) = S_A(c)$. Hence we have the following corollary.

▶ **Corollary 7.** *P is an $S_{A,B}(c)$ path terminating at $par_{T_1}(c)$.*

In order to capture the above fact we define parent-detours for each $w \in V$ which instead of terminating at w terminates at either $par_{T_1}(w)$ or $par_{T_2}(w)$.

- $\text{PD}^i_j(w)$: a path starting from the highest possible ancestor of w in T_i and terminating at $par_{T_j}(w)$ s.t. none of the internal vertices of the path lie on $\textsc{Path}_{T_1}(s,w)$ or $\textsc{Path}_{T_2}(s,w)$.

By above definition of parent-detour it follows that P can be replaced by either $\text{PD}^1_1(c)$ or $\text{PD}^2_1(c)$ depending upon whether it starts from an ancestor of c in T_1 or T_2. Now let x_1 denote the child of f_1 in T_1 lying on $\textsc{Path}_{T_1}(s,v)$, and x_2 denote the child of f_2 in T_2 lying on $\textsc{Path}_{T_2}(s,v)$. Then the parent-detours of vertices x_1, x_2 may not be of any help, since they would terminate at f_1 and f_2. However, the parent-detours of vertices in $S_B(v) \setminus \{x_1, x_2\}$ will suffice to determine whether v is reachable from s or not.

Notice that in above discussion, we observed that P is an $S_{A,B}(c)$ path terminating at $b = par_{T_1}(c)$. This shows that for vertices lying on $\textsc{Path}_{T_1}(\bar{x}_1, v)$, we only need to worry about parent-detours terminating at $par_{T_1}(\cdot)$, i.e. $\text{PD}^1_1(\cdot)$ and $\text{PD}^2_1(\cdot)$. Whereas, for vertices on $\textsc{Path}_{T_2}(\bar{x}_2, v)$, we need to worry about parent-detours terminating at $par_{T_2}(\cdot)$, i.e. $\text{PD}^1_2(\cdot)$ and $\text{PD}^2_2(\cdot)$. We thus have the following lemma.

▶ **Lemma 8.** *Let x_1 and x_2 be as defined above. A vertex v is reachable from s in $G \setminus \{f_1, f_2\}$ if and only if at least one of the following vertices lie in $S_A(v)$.*

(i) *The first vertex of $\text{D}^1(v)$ or $\text{D}^2(v)$.*
(ii) *The first vertex of either $\text{PD}^1_1(w)$ or $\text{PD}^2_1(w)$ for some $w \in \textsc{Path}_{T_1}(\bar{x}_1, v)$.*
(iii) *The first vertex of either $\text{PD}^1_2(w)$ or $\text{PD}^2_2(w)$ for some $w \in \textsc{Path}_{T_2}(\bar{x}_2, v)$.*

5.1 Implementation of the oracle

We first introduce the following notations for detours and parent detours.

- $\beta^i(v)$: $depth_{T_i}$(first vertex on $\text{D}^i(v)$).
- $\gamma^i_j(v)$: $depth_{T_i}$(first vertex on $\text{PD}^i_j(v)$).

Now let f_1, f_2 be a given pair of failed vertices and v be a given query vertex. Our first step is to check if condition $\mathcal{C}$ is satisfied. Recall that this requires only verifying the ancestor-descendant relationship in trees T_1 and T_2. One simple method to achieve this for any given tree T is to perform the pre-order and the post-order traversal of T, and store the vertices in the order they are visited. Now x will be ancestor of y in T if and only if x appears before y in the pre-order traversal, and after y in the post-order traversal.

Algorithm 1 presents the pseudo-code for answering reachability query for a vertex v assuming condition $\mathcal{C}$ is satisfied. This can be explained in words as follows. For $i = 1, 2$, we first check if $D^i(v)$ starts from an ancestor of f_i in T_i or not. This is done by comparing the value of $\beta^i(v)$ with the depth of f_i in T_i. Next we compute the vertices x_1, x_2. Finally for $i, j \in \{1, 2\}$, we compute a vertex $w \in \textsc{Path}_{T_j}(\bar{x}_j, v)$ for which $\gamma^i_j(\cdot)$ is minimum. If $\gamma^i_j(w)$ is less than the depth of f_i in T_i, then it implies that $\text{PD}^i_j(w)$ starts from an ancestor of f_i in T_i, so we return True. If we reach to the end of code, that means we have not been able to find any path for v, so we return False.

Algorithm 1: Oracle for reachability to v in 2-vertex strongly connected graphs.

1 **if** $\beta^1(v) < depth_{T_1}(f_1)$ *or* $\beta^2(v) < depth_{T_2}(f_2)$ **then** Return True;
2 ;
3 $x_1 \leftarrow$ the vertex with minimum depth on $\text{PATH}_{T_1}(\bar{f}_1, v)$;
4 $x_2 \leftarrow$ the vertex with minimum depth on $\text{PATH}_{T_2}(\bar{f}_2, v)$;
5 **foreach** $i, j \in \{1, 2\}$ **do**
6 $\quad w \leftarrow$ a vertex on $\text{PATH}_{T_j}(\bar{x}_j, v)$ for which $\gamma^i_j(\cdot)$ is minimum;
7 $\quad$ **if** $\gamma^i_j(w) < depth_{T_i}(f_i)$ **then** Return True;
8 $\quad$;
9 **end**
10 Return False;

The above oracle can be easily implemented in $O(1)$ time, by having a total of six weight functions – one each for storing the depth of a vertex in trees T_1, T_2, and the other four for storing the values $\gamma^i_j(\cdot)$, for $i, j \in \{1, 2\}$. By doing this the vertices x_1, x_2 can be computed in constant time since they are respectively the vertices with minimum depth on the paths $\text{PATH}_{T_1}(\bar{f}_1, v)$ and $\text{PATH}_{T_1}(\bar{f}_1, v)$. Also Step 4 can be carried out in an $O(1)$ time. We can thus state the following theorem.

▶ **Theorem 9.** *A 2-vertex strongly connected graph on n vertices can be preprocessed in polynomial time for a given source vertex s to build a data structure of $O(n)$ size such that for any query vertex v, and pair of failures f_1, f_2, it takes $O(1)$ time to determine if there exists any path from s to v in $G \setminus \{f_1, f_2\}$.*

6 Reachability oracle for general graphs

In this section we explain the reachability oracle for general graphs. Consider a query vertex u in G. Let $u_0, u_1, ..., u_k$ be the dominators of u with $u_0 = s$ and $u_k = u$. Thus $\text{PATH}_{T_1}(s, u)$ and $\text{PATH}_{T_2}(s, u)$ intersect only at u_i's. (See Figure 4(i)). As in Section 5, we assume that condition $\mathcal{C}$ holds for u, so none of the u_i's can be equal to f_1 or f_2. Now let $i, j \in [1, k]$ be such that $f_1 \in \text{PATH}_{T_1}(\bar{u}_{i-1}, \bar{u}_i)$ and $f_2 \in \text{PATH}_{T_2}(\bar{u}_{j-1}, \bar{u}_j)$. It is easy to see that if $i \neq j$, then u is reachable from s by the path $\text{PATH}_{T_1}(s, u_{i-1})::\text{PATH}_{T_2}(u_{i-1}, u_i)::\text{PATH}_{T_1}(u_i, u)$. (See Figure 4(ii)). Thus we consider the case when $i = j$ [1]. For simplicity, we use symbols, v and $idom(v)$ to respectively denote the vertices u_i and u_{i-1}. Notice that in order to check reachability of u from s, it suffices to check if v is reachable from s in $G \setminus \{f_1, f_2\}$.

We now divide our analysis into various different cases as follows:

Case 1. *There exists an $S_{A,B}(v)$ path terminating at vertex v.*
In this case v will be reachable from s using either of the detours $D^1(v)$ or $D^2(v)$.

Case 2. *There exists a vertex $w \in S_B(v)$ for which $idom(w) \in S_A(v) \setminus \{idom(v)\}$.*
In this case also we can show that v is reachable from s by the following argument. Without loss of generality let us assume that w is an ancestor of v in T_1. Since $idom(w)$ is an

[1] One can verify in $O(1)$ time whether $u_{i-1} = u_{j-1}$ (i.e. if $i = j$) since vertex $u_{i-1} = LCA(f_1, v)$ and vertex $u_{j-1} = LCA(f_2, v)$ in the dominator tree of G.

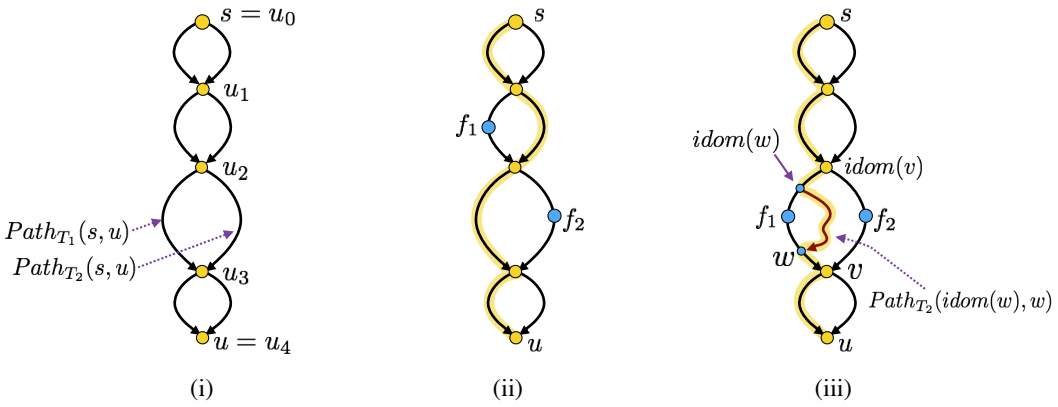

Figure 4 (i) Representation of dominators of u; (ii) A path from s to u (highlighted in yellow) when f_1 lies on $\textsc{Path}_{T_1}(\bar{u}_1, \bar{u}_2)$ and f_2 lies on $\textsc{Path}_{T_2}(\bar{u}_2, \bar{u}_3)$; (iii) A path from s to u (highlighted in yellow) when there exists a vertex $w \in S_B(v)$ for which $idom(w)$ lies in the set $S_A(v) \setminus \{idom(v)\}$.

ancestor of w in T_1, it must lie on $\textsc{Path}_{T_1}(\overline{idom(v)}, \bar{f}_1)$. (See Figure 4(iii)). Consider the path $Q = \textsc{Path}_{T_2}(idom(w), w)$. Note that f_2 cannot lie on Q. This is because otherwise $\textsc{Path}_{T_1}(idom(v), w)$ and $\textsc{Path}_{T_2}(idom(v), f_2)::Q[f_2, w]$ will form two vertex disjoint paths from $idom(v)$ to w, which would violate the fact that $idom(w) \neq idom(v)$. Also f_1 cannot lie on Q, as Q is disjoint from $\textsc{Path}_{T_1}(\overline{idom(w)}, \bar{w})$. Thus v is reachable from s by the path $\textsc{Path}_{T_1}(s, idom(w))::Q::\textsc{Path}_{T_1}(w, v)$.

Case 3. *None of the $S_{A,B}(v)$ path terminates at v, and there does not exist a vertex in $S_B(v)$ whose immediate dominator lies in $S_A(v) \setminus \{idom(v)\}$.*
This is the most non-trivial case of dual fault tolerant reachability oracle. We now provide analysis for this case.

Let us suppose v is reachable from s in $G \setminus \{f_1, f_2\}$. Then without loss of generality we can assume that there exists an $S_{A,B}(v)$ path (say P) terminating at an ancestor of v in T_1. In case there are multiple $S_{A,B}(v)$ paths, then we take P to be that path which terminates at lowest vertex on $\textsc{Path}_{T_1}(\bar{f}_1, \bar{v})$. Let a, b be respectively the first and last vertices on P. By Property 1, we know that $idom(b)$ cannot be an ancestor of $idom(v)$ in T_1. Therefore, $idom(b)$ must be equal to $idom(v)$. This is because $idom(b)$ cannot lie in $S_A(v) \setminus \{idom(v)\}$, and if $idom(b)$ lies in $S_B(v)$ then $P \cap S_B(v)$ will contain both b and $idom(b)$, which would violate the definition of an $S_{A,B}(v)$ path.

Now consider the vertex c which is child of b on $\textsc{Path}_{T_1}(s, v)$. It turns out that in a general graph the parent-detours of c may not be of any help. This is because the analysis for 2-vertex strongly connected graphs crucially exploited the fact that $idom(b) = idom(c) = s$. But in general graphs, if $idom(b)$ is not equal to $idom(c)$, then it can be shown that Lemma 6 no longer holds. To be more precise, we can show that the internal vertices of P might not be disjoint from $\textsc{Path}_{T_2}(s, c)$.

However, the problem can be resolved if we take c to be the first descendant of b on $\textsc{Path}_{T_1}(s, v)$ whose immediate dominator is the same as that of b. This motivates us to define the notion of pseudo-child (and pseudo-parent) as follows.

▶ **Definition 10.** Given a reachability tree T rooted at s, a vertex x is said to be pseudo-parent of y in T (and y is said to be pseudo-child of x) if x is the nearest ancestor of y in T whose immediate dominator is the same as that of y.

Note that in a 2-vertex strongly connected graph, the definition of pseudo-parent and pseudo-child degenerates to normal notion of parent and child. This is because, immediate dominator of all the vertices (other than s) in such graph is equal to s.

We now state a lemma which is an analogue of Lemma 6 for general graphs.

▶ **Lemma 11.** *Let a, b, P be as described above, and c be the pseudo-child of b on $\text{PATH}_{T_1}(s, v)$. Then,*

(i) *Vertex f_2 is an ancestor of c in T_2.*

(ii) *None of the internal vertices of P lie on $\text{PATH}_{T_1}(s, c)$ or $\text{PATH}_{T_2}(s, c)$.*

As a corollary of the above lemma we get that P is an $S_{A,B}(c)$ path terminating at pseudo-parent of c in T_1. We thus define ancestor-detours which are a generalization of parent-detours as follows.

- $\text{AD}^i_j(w)$: a path starting from the highest possible ancestor of w in T_i and terminating at pseudo-parent of w in tree T_j such that none of the internal vertices of the path lie on $\text{PATH}_{T_1}(s, w)$ or $\text{PATH}_{T_2}(s, w)$.

Now let x_1 be the first descendant of f_1 on $\text{PATH}_{T_1}(s, v)$ whose immediate dominator is equal to $idom(v)$. Similarly, let x_2 be the first descendant of f_2 on $\text{PATH}_{T_1}(s, v)$ whose immediate dominator is equal to $idom(v)$. Then the ancestor-detours of x_1, x_2 will not be of any help as they would terminate at either f_1, f_2 or their ancestors. Now as in Section 5, we can argue that ancestor-detours of vertices on $\text{PATH}_{T_1}(\bar{x}_1, v) \cup \text{PATH}_{T_2}(\bar{x}_2, v)$ suffice to answer the reachability query for vertex v. This completes the analysis of the third case.

We thus have the following lemma.

▶ **Lemma 12.** *Let v be a vertex satisfying condition $\mathcal{C}$ such that $f_1 \in \text{PATH}_{T_1}(\overline{idom(v)}, v)$ and $f_2 \in \text{PATH}_{T_1}(\overline{idom(v)}, v)$. Also let x_1 and x_2 be as defined above. Then v is reachable from s in $G \setminus \{f_1, f_2\}$ if and only if either of the following statements holds true.*

(i) [Case 1] *The first vertex of $\text{D}^1(v)$ or $\text{D}^2(v)$ lies in $S_A(v)$.*

(ii) [Case 2] *There exists a vertex $w \in S_B(v)$ for which $idom(w) \in S_A(v) \setminus \{idom(v)\}$.*

(iii) [Case 3] *There exists a vertex $w \in \text{PATH}_{T_1}(\bar{x}_1, v)$ such that $idom(w) = idom(v)$ and the first vertex of either $\text{AD}^1_1(w)$ or $\text{AD}^2_1(w)$ lies in $S_A(v)$.*

(iv) [Case 3] *There exists a vertex $w \in \text{PATH}_{T_2}(\bar{x}_2, v)$ such that $idom(w) = idom(v)$ and the first vertex of either $\text{AD}^1_2(w)$ or $\text{AD}^2_2(w)$ lies in $S_A(v)$.*

6.1 Implementation of the oracle

We now explain the implementation of reachability oracle for general graphs. As in Section 5, we define the following notations.

- $\alpha^i(v)$: $depth_{T_i}(idom(v))$.
- $\beta^i(v)$: $depth_{T_i}(\text{first vertex on } \text{D}^i(v))$.
- $\gamma^i_j(v)$: $depth_{T_i}(\text{first vertex on } \text{AD}^i_j(v))$.

Let f_1, f_2 be a given pair of failed vertices and v be a given query step. We assume that condition $\mathcal{C}$ is satisfied, and failures f_1, f_2 lies respectively on $\text{PATH}_{T_1}(idom(v), v)$ and $\text{PATH}_{T_2}(idom(v), v)$. We first check for $i = 1, 2$, if $D^i(v)$ starts from an ancestor of f_i in T_i or not. This is done by comparing the value of $\beta^i(v)$ with the depth of f_i in T_i.

Next we compute the vertices x_1, x_2 as follows. Recall that x_1 is the highest ancestor of v in $\text{PATH}_{T_1}(\bar{f}_1, v)$ whose immediate dominator is equal to $idom(v)$. So to obtain x_1, we call the range minima query for vertices on $\text{PATH}_{T_1}(\bar{f}_1, v)$ with $\langle \alpha^1(\cdot), depth_{T_1}(\cdot) \rangle$ as the weight function. By comparing the value of $\alpha^1(\cdot)$, it is able to filter out those vertices in

$\textsc{Path}_{T_1}(\bar{f}_1, v)$ whose immediate dominator is at minimum depth in T_1, i.e. it is equal to $idom(v)$. After this it assigns x_1 to be that vertex which has minimum depth in T_1. Vertex x_2 is computed in a similar manner.

Now notice that to find whether there exists a vertex in $S_B(v)$ whose immediate dominator lies in $S_A(v) \setminus \{idom(v)\}$, we only need to restrict ourself to paths $\textsc{Path}_{T_1}(\bar{f}_1, \bar{x}_1)$ and $\textsc{Path}_{T_1}(\bar{f}_1, \bar{x}_1)$. This is because Property 2 implies that immediate dominator of vertices in $\textsc{Path}_{T_1}(x_1, v)$ is either equal to $idom(v)$ or lies in $\textsc{Path}_{T_1}(x_1, v)$ itself. Similarly, for $\textsc{Path}_{T_2}(x_2, v)$. So for $i = 1, 2$, we perform the range minima query to find a vertex, say w, on $\textsc{Path}_{T_i}(\bar{f}_i, \bar{x}_i)$ for which $\alpha^i(w)$ is minimum. If $\alpha^i(w)$ is less than the depth of f_i in T_i, then we report that v is reachable from s.

Finally for $i, j \in \{1, 2\}$, we compute a vertex $w \in \textsc{Path}_{T_j}(\bar{x}_j, v)$ for which $\langle \alpha^i(\cdot), \gamma^i_j(\cdot) \rangle$ is minimum. The term $\alpha^i(\cdot)$ is added in front so that we are able to filter out those vertices whose immediate dominator is equal to $idom(v)$. Now if $\gamma^i_j(w)$ is less than the depth of f_i in T_i, then it implies that $\text{AD}^i_j(w)$ starts from an ancestor of f_i in T_i, so we return True.

If we reach to the end of code, that means we have not been able to find any path for v, so we return False.

Algorithm 2: Oracle for reachability to v in general graphs.

```
1  if β¹(v) < depth_{T1}(f1) or β²(v) < depth_{T2}(f2) then Return True;
2  ;
3  x1 ← a vertex on Path_{T1}(f̄1, v) for which ⟨α¹(·), depth_{T1}(·)⟩ is minimum;
4  x2 ← a vertex on Path_{T2}(f̄2, v) for which ⟨α²(·), depth_{T2}(·)⟩ is minimum;
5  foreach i ∈ {1, 2} do
6  |   w ← a vertex on Path_{Ti}(f̄i, x̄i) for which αⁱ(·) is minimum;
7  |   if αⁱ(w) < depth_{Ti}(fi) then Return True;
8  |   ;
9  end
10 foreach i, j ∈ {1, 2} do
11 |   w ← a vertex on Path_{Tj}(x̄j, v) for which ⟨αⁱ(·), γⁱⱼ(·)⟩ is minimum;
12 |   if γⁱⱼ(w) < depth_{Ti}(fi) then Return True;
13 |   ;
14 end
15 Return False;
```

As in Algorithm 1, we can argue that the Steps 2, 3, 5 and 9, can be implemented in $O(1)$ time. Thus Algorithm 2 takes constant time to answer reachability queries. We thus conclude with the following theorem.

▶ **Theorem 13.** *A directed graph $G = (V, E)$ on n vertices can be preprocessed in polynomial time for a given source vertex $s \in V$ to build a data structure of $O(n)$ size such that for any $f_1, f_2, v \in V$, it takes $O(1)$ time to determine if there exists a path from s to v in $G \setminus \{f_1, f_2\}$.*

Abstract

Given a graph where vertices are partitioned into k terminals and non-terminals, the goal is to compress the graph (i.e., reduce the number of non-terminals) using minor operations while preserving terminal distances approximately. The distortion of a compressed graph is the maximum multiplicative blow-up of distances between all pairs of terminals. We study the trade-off between the number of non-terminals and the distortion. This problem generalizes the Steiner Point Removal (SPR) problem, in which all non-terminals must be removed.

We introduce a novel black-box reduction to convert any lower bound on distortion for the SPR problem into a super-linear lower bound on the number of non-terminals, with the same distortion, for our problem. This allows us to show that there exist graphs such that every minor with distortion less than 2 / 2.5 / 3 must have $\Omega(k^2)$ / $\Omega(k^{5/4})$ / $\Omega(k^{6/5})$ non-terminals, plus more trade-offs in between. The black-box reduction has an interesting consequence: if the tight lower bound on distortion for the SPR problem is super-constant, then allowing any $\mathcal{O}(k)$ non-terminals will *not* help improving the lower bound to a constant.

We also build on the existing results on spanners, distance oracles and connected 0-extensions to show a number of upper bounds for general graphs, planar graphs, graphs that exclude a fixed minor and bounded treewidth graphs. Among others, we show that any graph admits a minor with $\mathcal{O}(\log k)$ distortion and $\mathcal{O}(k^2)$ non-terminals, and any planar graph admits a minor with $1+\varepsilon$ distortion and $\widetilde{\mathcal{O}}((k/\varepsilon)^2)$ non-terminals.

1 Introduction

Graph compression generally describes a transformation of a *large* graph G into a *smaller* graph G' that preserves, either exactly or approximately, certain features (e.g., distance, cut, flow) of G. Its algorithmic value is apparent, since the compressed graph can be computed in

a preprocessing step of an algorithm, so as to reduce subsequent running time and memory. Some notable examples are graph spanners, distance oracles and cut/flow sparsifiers.

In this paper, we study compression using minor operations, which has attracted increasing attention in recent years. Minor operations include vertex/edge deletions and edge contractions. It is naturally motivated since it preserves certain structural properties of the original graph, e.g., any minor of a planar graph remains planar, while reducing the size of the graph. We are interested in *vertex sparsification*, where G has a designated subset T of k vertices called the *terminals*, and the goal is to reduce the number of non-terminals in G' while preserving some feature among the terminals. Recent work in this field studied preserving cuts and flows. Our focus here is on preserving terminal distances approximately in a multiplicative sense, i.e., we want that for any terminals t, t', $d_G(t,t') \leq d_{G'}(t,t') \leq \alpha \cdot d_G(t,t')$, for a small *distortion* α. This problem, called *Approximate Terminal Distance Preservation (ATDP) problem*, has natural applications in multicast routing [6] and network traffic optimization [22]. It was also suggested in [15] that to solve the *subset travelling salesman problem*, one can compute a compressed minor with a small distortion as a preprocessing step for algorithms that solve the travelling salesman problem for planar graphs.

ATDP was initiated by Gupta [11], who introduced the related *Steiner Point Removal (SPR) problem*: Given a tree G with both terminals and non-terminals, output a weighted tree G' *with terminals only* which minimizes the distortion. Gupta gave an algorithm that achieves a distortion of 8. Chan et al. [4] observed that Gupta's algorithm returned always a minor of G. For general graphs, Kamma et al. [13] gave an algorithm to construct a minor with distortion $\mathcal{O}(\log^5 k)$. Krauthgamer et al. [15] studied ATDP and showed that every graph has a minor with $\mathcal{O}(k^4)$ non-terminals and distortion 1. It is then natural to ask, for different classes of graphs, what the trade-off between the distortion and the number of non-terminals is. In this paper, for different classes of graphs, and w.r.t. different allowed distortions, we provide lower and upper bounds on the number of non-terminals needed.

Further Related Work. Basu and Gupta [3] showed that for outer-planar graphs, SPR can be solved with distortion $\mathcal{O}(1)$. When randomization is allowed, Englert et al. [9] showed that for graphs that exclude a fixed minor, one can construct a randomized minor for SPR with $\mathcal{O}(1)$ expected distortion. Krauthgamer et al. [15] proved that solving ATDP with distortion 1 for planar graphs needs $\Omega(k^2)$ non-terminals.

Recently, there has been a growing interest on cut/flow vertex sparsifiers [19, 16, 5, 18, 9, 7, 2, 21]; given a capacitated graph G with terminals $T \subset V$, the goal is to find a sparsifier H with $V(H) = T$ preserving all terminal cuts up to a factor $q \geq 1$, i.e. for all $S \subset T$, $\text{mincut}_G(S, T \setminus S) \leq \text{mincut}_H(S, T \setminus S) \leq q \cdot \text{mincut}_G(S, T \setminus S)$. In this setting, there is an equivalence between the construction of vertex cut/flow and distance sparsifiers [20, 9].

A related graph compression is spanners, where the objective is to reduce the number of edges by edge deletions only. We will use a spanner algorithm (e.g., [1]) to derive our upper bound results for general graphs. Although spanner operation enjoys much less freedom than minor operation, proving a lower bound result for it is notably difficult. Assuming the Erdös girth conjecture [10], there are lower bounds that match the best known upper bounds, but the conjecture seems far from being settled [25]. Woodruff [27] showed a lower bound result bypassing the conjecture, but only for *additive* spanners.

Graph	Upper Bound	Lower Bound
General	$\forall q \in \mathbb{N} \quad (2q-1, \mathcal{O}(k^{2+2/q}))$	$(2-\varepsilon, \Omega(k^2))$
General	–	$(2.5-\varepsilon, \Omega(k^{5/4}))$, $(3-\varepsilon, \Omega(k^{6/5}))$
Bounded-treewidth p	$\forall q \in \mathbb{N} \quad (2q-1, \mathcal{O}(p^{1+2/q}k))$	$(1, \Omega(pk))$ †
Excluded-Fixed-Minor	$(\mathcal{O}(1), \widetilde{\mathcal{O}}(k^2)$	–
Planar	$(3, \widetilde{\mathcal{O}}(k^2))$, $(1+\varepsilon, \widetilde{\mathcal{O}}((k/\varepsilon)^2)$	$(1+o(1), \Omega(k^2))$ †

Our Contributions. For various classes of graphs, we show lower and upper bounds on the number of non-terminals needed in the minor for low distortion. The table above summarizes our results (results with † are from [15]); see the full version for more details.

For our lower bound results, we use a novel black-box reduction to convert any lower bound on distortion for the SPR problem into a super-linear lower bound on the number of non-terminals for ATDP with the same distortion. Precisely, we show that given any graph G^* such that solving its SPR problem leads to a minimum distortion of α, we use G^* to construct a new graph G such that every minor of G with distortion less than α must have at least $\Omega(k^{1+\delta(G^*)})$ non-terminals, for some constant $\delta(G^*) > 0$. The lower bound results in the above table are obtained by using for G^* a complete ternary tree of height 2, which was shown that solving its SPR problem leads to minimum distortion 3 [11]. More trade-offs are shown by using for G^* a complete ternary tree of larger heights.

The black-box reduction has an interesting consequence. For the SPR problem on general graphs, there is a huge gap between the best known lower and upper bounds, which are 8 [4] and $\mathcal{O}(\log^5 k)$ [13]; it is unclear what the asymptotically tight bound would be. Our black-box reduction allows us to prove the following result concerning the tight bound: for general graphs, if the tight bound on distortion for the SPR problem is super-constant, then for any constant $C > 0$, even if Ck non-terminals are allowed in the minor, the lower bound will remain super-constant. See Theorem 15 for a formal statement of this result.

We also build on the existing results on spanners, distance oracles and connected 0-extensions to show a number of upper bound results for general graphs, planar graphs and graphs that exclude a fixed minor. Our techniques, combined with an algorithm in Krauthgamer et al. [15], yield an upper bound result for graphs with bounded treewidth. In particular, our upper bound on planar graphs implies that allowing quadratic number of non-terminals, we can construct a deterministic minor with arbitrarily small distortion.

2 Preliminaries

Let $G = (V, E, \ell)$ denote an undirected graph with terminal set $T \subset V$ of cardinality k, where $\ell : E \to \mathbb{R}^+$ is the length function over edges E. A graph H is a *minor* of G if H can be obtained from G by performing a sequence of vertex/edge deletions and edge contractions, but no terminal can be deleted, and no two terminals can be contracted together. In other words, all terminals in G must be *preserved* in H.

Besides the above standard description of minor operations, there is another equivalent way to construct a minor H from G [13], which will be more convenient for presenting some of our results. A partial partition of $V(G)$ is a collection of pairwise disjoint subsets of $V(G)$ (but their union can be a proper subset of $V(G)$). Let $S_1, \cdots, S_m$ be a partial partition of $V(G)$ such that (1) each induced graph $G[S_i]$ is connected, (2) each terminal belongs to exactly one of these partial partitions, and (3) no two terminals belong to the same partial partition. Contract the vertices in each S_i into one single "super-node" in H. For any vertex $u \in V(G)$, let $S(u)$ denote the partial partition that contains u; for any super-node $u \in V(H)$, let $S(u)$ denote the partial partition that is contracted into u. In H, super-nodes u_1, u_2 are adjacent *only if* there exists an edge in G with one of its endpoints in $S(u_1)$ and the other in $S(u_2)$. We denote the super-node that contains terminal t by t as well.

▶ **Definition 1.** The graph $H = (V', E', \ell')$ is an α-distance approximating minor (abbr. α-DAM) of $G = (V, E, \ell)$ if H is a minor of G and for any $t, t' \in T$, $d_G(t, t') \le d_H(t, t') \le \alpha \cdot d_G(t, t')$. H is an (α, y)-DAM of G if H is an α-DAM of G with at most y non-terminals.

We note that the SPR problem is equivalent to finding an $(\alpha, 0)$-DAM. One can also define a randomized version of distance approximating minor:

▶ **Definition 2.** Let π be a probability distribution over minors of $G = (V, E, \ell)$. We call π an α-randomized distance approximating minor (abbr. α-rDAM) of G if for any $t, t' \in T$, $\mathbb{E}_{H\sim\pi}[d_H(t,t')] \leq \alpha \cdot d_G(t,t')$, and for every minor H in the support of π, $d_H(t,t') \geq d_G(t,t')$. Furthermore, we call π an (α, y)-rDAM if π is an α-rDAM of G, and every minor in the support of π has at most y non-terminals.

3 Deterministic and Randomized Lower Bounds

For all the lower bound results, we use a tool in combinatorial design called *Steiner system* (or alternatively, *balanced incomplete block design*). Let $[k]$ denote the set $\{1, 2, \cdots, k\}$.

▶ **Definition 3.** Given a ground set $T = [k]$, an $(s, 2)$-Steiner system (abbr. $(s, 2)$-SS) of T is a collection of s-subsets of T, denoted by $\mathcal{T} = \{T_1, \cdots, T_r\}$, where $r = \binom{k}{2} / \binom{s}{2}$, such that every 2-subset of T is contained in *exactly* one of the s-subsets.

▶ **Lemma 4** ([26])**.** *For any integer $s \geq 2$, there exists an integer M_s such that for every $q \in \mathbb{N}$, the set $[M_s + qs(s-1)]$ admits an $(s, 2)$-SS.*

Our general strategy is to use the following black-box reduction, which proceeds by taking a *small* connected graph G^* as input, and it outputs a *large* graph G which contains many disjoint embeddings of G^*. Here is how it exactly proceeds:

- Let G^* be a graph with $s \geq 2$ terminals and $q \geq 1$ non-terminals. Let k be an integer, as given in Lemma 4, such that the terminal set $T = [k]$ admits an $(s, 2)$-SS $\mathcal{T}$.
- We construct $\mathcal{T}' \subseteq \mathcal{T}$ that satisfies *certain* property depending on the specific problem. For each s-set in $\mathcal{T}'$, we add q non-terminals to the s-set, which altogether form a *group*. The union of vertices in all groups is the vertex set of our graph G. We note that each terminal may appear in many groups, but each non-terminal appears in one group only.
- *Within* each of the groups, we embed G^* in the natural way.

The following two lemmas describe some basic properties of all minors of G output by the black-box above. Their proofs are deferred to the full version.

▶ **Lemma 5.** *Let H be a minor of G. Then for each edge (u_1, u_2) in H, there exists exactly one group R in G such that $S(u_1) \cap R$ and $S(u_2) \cap R$ are both non-empty.*

The above lemma permits us to legitimately define the notion R-edge: an edge (u_1, u_2) in H is an R-edge if R is the unique group that intersects both $S(u_1)$ and $S(u_2)$.

▶ **Lemma 6.** *Suppose that in a minor H of G, (u_1, u_2) is a R_1-edge and (u_2, u_3) is R_2-edge, where $R_1 \neq R_2$. Then R_1 and R_2 intersect, and $S(u_2)$ contains the terminal in $R_1 \cap R_2$.*

We will show that for any minor H with low distortion, at least one of the non-terminals in each group must be retained, and thus H must have at least $|\mathcal{T}'|$ non-terminals. We first present some of our main theorems on lower bounds and then prove them; two more theorems are given in Section 3.3.

▶ **Theorem 7.** *For infinitely many $k \in \mathbb{N}$, there exists a bipartite graph with k terminals which does not have a $(2 - \epsilon, k^2/7)$-DAM, for all $\epsilon > 0$.*

▶ **Theorem 8.** *There exists a constant $c_1 > 0$, such that for infinitely many $k \in \mathbb{N}$, there exists a quasi-bipartite graph with k terminals which does not have an $(\alpha - \epsilon, c_1 k^\gamma)$-DAM, for all $\epsilon > 0$, where α, γ are given in the table below.*

α	2.5	3	10/3	11/3	4	4.2	4.4
γ	5/4	6/5	10/9	11/10	12/11	21/20	22/21

▶ **Theorem 9.** *For infinitely many $k \in \mathbb{N}$, there exists a bipartite graph with k terminals which does not have a $\left(2 - \epsilon, \epsilon^3 k^2/150\right)$-rDAM, for any $1 \geq \epsilon > 0$.*

3.1 Proof of Theorem 7

We start by reviewing the lower bound for SPR problem on stars due to Gupta [11].

▶ **Lemma 10.** *Let $G^* = (T \cup \{v\}, E)$ be an unweighted star with $k \geq 3$ terminals, in which v is the center of the star. Then, every edge-weighted graph only on the terminals T with fewer than $\binom{k}{2}$ edges has distortion at least 2.*

We construct G using the black-box reduction above. Let $k \in \mathbb{N}$ be such that the terminals $T = [k]$ admits a $(3, 2)$-SS, denoted by $\mathcal{T}$. Here, we set $\mathcal{T}' = \mathcal{T}$ and G^* to be the star with 3 terminals, as described in Lemma 10.

By the definition of Steiner system, the shortest path between every pair of terminal t, t' in G is unique, which is the 2-hop path within the group that contains both terminals, i.e., $d_G(t, t') = 2$ for all $t, t' \in T$. Every other simple path between t, t' must pass through an extra terminal, so the length of such simple path is at least 4.

Let H be a minor of G. Suppose that the number of non-terminals in H is less than r, then there exists a group R in which its non-terminal is not retained (which means that it is either deleted, or contracted into a terminal in that group). By Lemma 10, there exists a pair of terminals in that group such that every simple path within R (which means a path comprising of R-edges only) between the two terminals has length at least 4. And every other simple path must pass through an extra terminal (just as in G), so again it has length at least 4. Thus, the distortion of the two terminals is at least 2.

Therefore, every $(2 - \epsilon)$-DAM of G must have $r > k^2/7$ non-terminals.

3.2 Proof of Theorem 8

We will give the proof for the case $\alpha = 2.5$ here, and discuss how to generalize this proof for other distortions. We will first define the notions of *detouring graph* and *detouring cycle*, and then use them to construct the graph G that allows us to show the lower bound.

Detouring Graph and Detouring Cycle. For any $s \geq 3$, let $k \in \mathbb{N}$ be such that the terminal set $T = [k]$ admits an $(s, 2)$-SS. Let $\mathcal{T} = \{T_1, \cdots, T_r\}$ be such an $(s, 2)$-SS. A *detouring graph* has the vertex set $\mathcal{T}$. By the definition of Steiner system, $|T_i \cap T_j|$ is either zero or one. In the detouring graph, T_i is adjacent to T_j if and only if $|T_i \cap T_j| = 1$. Thus, in the detouring graph, it is legitimate to give each edge (T_i, T_j) a *terminal label*, which is the terminal in $T_i \cap T_j$. A *detouring cycle* is a cycle in the detouring graph such that no two neighbouring edges of the cycle have the same terminal label.

Suppose that two edges in the detouring graph have a common vertex, and their terminal labels are different, denoted by t, t'. Then the common vertex must be an s-set in $\mathcal{T}$ containing both t, t'. By the definition of Steiner system, the s-set is uniquely determined.

▶ **Claim 11.** *In the detouring graph, number of detouring cycles of size $\ell \geq 3$ is at most k^ℓ.*

Our key lemma is: for any $L \geq 3$, we can retain $\Omega_s(k^{L/(L-1)})$ vertices in the detouring graph, such that the induced graph on these vertices has *no* detouring cycle of size L or less.

▶ **Lemma 12.** *For any integer $L \geq 3$, given a detouring graph with vertex set $\mathcal{T} = \{T_1, T_2, \cdots, T_r\}$, there exists a subset $\mathcal{T}' \subset \mathcal{T}$ of cardinality $\Omega_s(k^{L/(L-1)})$ such that the induced graph on $\mathcal{T}'$ has no detouring cycle of size L or less.*

Proof. We choose the subset $\mathcal{T}'$ by the following randomized algorithm:

1. Each vertex is picked into $\mathcal{T}'$ with probability $\delta k^{-(L-2)/(L-1)}$, where $\delta = \delta(s) < 1$ is a positive constant which we will derive explicitly later.
2. While (there is a detouring cycle of size L or less in the induced graph of $\mathcal{T}'$)
   Remove a vertex in the detouring cycle from $\mathcal{T}'$

After Step 1, $\mathbb{E}[|\mathcal{T}'|] = r \cdot \delta k^{-(L-2)/(L-1)} \geq \frac{\delta}{2s(s-1)} k^{L/(L-1)}$. Using Claim 11, the expected number of detouring cycles of size L or less is at most $\sum_{\ell=3}^{L} k^{\ell} \cdot (\delta k^{-(L-2)/(L-1)})^{\ell} \leq 2\delta^3 k^{L/(L-1)}$. Thus, the expected number of vertices removed in Step 2 is at most $2\delta^3 k^{L/(L-1)}$. Now, choose $\delta = 1/\sqrt{8s(s-1)}$. By the end of the algorithm,

$$\mathbb{E}[|\mathcal{T}'|] \geq \frac{\delta}{2s(s-1)} k^{L/(L-1)} - 2\delta^3 k^{L/(L-1)} = \Omega(k^{L/(L-1)}).$$ ◀

Construction of G and the Proof. Recall the black-box reduction. Let k be an integer such that $T = [k]$ admits a $(9, 2)$-SS $\mathcal{T}$. By Lemma 12, we choose $\mathcal{T}'$ to be a subset of $\mathcal{T}$ with $|\mathcal{T}'| = \Omega(k^{5/4})$, such that the induced graph on $\mathcal{T}'$ has no detouring cycle of size 5 or less. We choose G^* to be a complete ternary tree of height 2, in which the 9 leaves are the terminals. For each $T_i \in \mathcal{T}'$, we add four non-terminals to T_i, altogether forming a *group*.

The following lemma is a direct consequence that the induced graph on $\mathcal{T}'$ has no detouring cycle of size 5 or less.

▶ **Lemma 13.** *For any two terminals t, t' in the same group, let R denote the group. Then, in any minor H of G, every simple path from t to t' either comprises of R-edges only, or it comprises of edges from at least 5 groups other than R.*

Proof. Proof of Theorem 8 Let H be a $(2.5 - \epsilon)$-DAM of G, for some $\epsilon > 0$. Suppose that there exists a group such that all its non-terminals are not retained in H. By [11], there exists a pair of terminals t, t' in that group such that every simple path between t and t', which comprises of edges of that group only, has length at least $3 \cdot d_G(t, t')$.

By Lemma 13 and Lemma 6, any other simple path P between t and u passes through at least 4 other terminals, say they are t_a, t_b, t_c, t_d in the order of the direction from t to t'. We denote this path by $P := t \to t_a \to t_b \to t_c \to t_d \to t'$, by ignoring the non-terminals along the path. Between every pair of consecutive terminals in P, the length is at least 2. Thus, the length of P is at least 10. Since $d_G(t, t') \leq 4$, the length of P is at least $2.5 \cdot d_G(t, t')$.

Thus, the length of *every* simple path from t to t' in H is at least $2.5 \cdot d_G(t, t')$, a contradiction. Therefore, at least one non-terminal in each group is retained in H. As there are $\Omega(k^{5/4})$ groups, we are done. ◀

For the other results in Theorem 8, we follow the above proof almost exactly, with the following modifications. Set $s = 3^h$ for some $h \geq 2$, and set G^* to be a complete ternary tree with height h, in which the leaves are the terminals. Let α_h be a lower bound on the distortion for the SPR problem on G^*. Apply Lemma 12 with some integer $h < L \leq \lceil \alpha_h h \rceil$. Following the above proof, attaining a distortion of $\min\left\{\frac{L}{h}, \alpha_h\right\} - \epsilon$ needs $\Omega(k^{L/(L-1)})$ non-terminals.

The last puzzle we need is the values of α_h. Chan et al. [4] proved that for complete binary trees of height h, $\lim_{h\to+\infty} \alpha_h = 8$, but they did not give explicit values of α_h. We apply their ideas to complete ternary tree of height h, to obtain explicit values for $h \leq 5$, which are used to prove all the results in Theorem 8. The explicit values are $\alpha_2 = 3$, $\alpha_3 = \alpha_4 = 4$ and $\alpha_5 = 4.4$. We discuss the details for computing these values in the full version.

3.3 Full Generalization of Theorem 8, and its Interesting Consequence

Indeed, we can set G^* as *any* graph. In our above proofs we used a tree for G^* because the only known lower bounds on distortion for the SPR problem are for trees. If one can find a graph G^* (either by a mathematical proof, or by computer searches) such that its distortion for the SPR problem is at least α, applying the black-box reduction with this G^*, and reusing the above proof show that there exists a graph G with k terminals such that attaining a distortion of $\alpha - \epsilon$ needs $\Omega(k^{1+\delta(G^*)})$ non-terminals, for some $\delta(G^*) > 0$.

▶ **Theorem 14.** *Let G^* be a graph with s terminals, and the distance between any two terminals is between 1 and β. Suppose the distortion for the* SPR *problem on G^* is at least α. Then, for any positive integer $\max\{2, \lceil\beta\rceil\} \leq L \leq \lceil\alpha\beta\rceil$, there exists a constant $c_4 := c_4(s) > 0$, such that for infinitely many $k \in \mathbb{N}$, there exists a graph with k terminals which does not have a $\left(\min\{L/\beta, \alpha\} - \epsilon, c_4 k^{L/(L-1)}\right)$-DAM, for all $\epsilon > 0$.*

The above theorem has an interesting consequence. For the SPR problem on general graphs, the best known lower bound is 8, while the best known upper bound is $\mathcal{O}(\log^5 k)$ [13]. There is a huge gap between the two bounds, and it is not clear where the tight bound locates in between. Suppose that the tight lower bound on SPR is super-constant. Then for any positive constant α, there exists a graph G^*_α with $s(\alpha)$ terminals and some non-terminals, such that the distortion is larger than α. By Theorem 14, G^*_α can be used to construct a family of graphs with k terminals, such that to attain distortion α, the number of non-terminals needed is super-linear in k. Recall that in SPR, no non-terminal can be retained. In other words, Theorem 14 implies that: *if retaining no non-terminal will lead to a super-constant lower bound on distortion, then having the power of retaining any linear number of non-terminals will not improve the lower bound to a constant.*

Formally, we define the following generalization of SPR problem. Let LSPR_y denote the problem that for an input graph with k terminals, find a DAM with at most yk non-terminals so as to minimize the distortion; the SPR problem is equivalent to LSPR_0.

▶ **Theorem 15.** *For general graphs,* SPR *has super-constant lower bound on distortion if and only if for any constant $y \geq 0$, LSPR_y has super-constant lower bound on distortion.*

3.4 Proof of Theorem 9

In this subsection we give a lower bound for rDAM. The strategy we follow will be very similar to that of Theorem 7. In fact, one can view it as a randomized version of that proof. We start with the following lemma, which generalizes the deterministic SPR lower bound of Gupta in Lemma 10 to randomized minors.

▶ **Lemma 16.** *Let $G^* = (T \cup \{v\}, E)$ be an unweighted star with $k \geq 3$ terminals, in which v is the center of the star. Then, for every probability distribution over minors of G^* with vertex set T, there exists a terminal pair with distortion at least $2(1 - 1/k)$.*

We now continue with the construction of our input graph. For some constant $s \geq 3$ and some integer k, we construct a $(s, 2)$-SS of the terminal set T and denote it by

$\mathcal{T} = \{T_1, \ldots, T_r\}$, where $r = \binom{k}{2}/\binom{s}{2} \geq 2\binom{k}{2}/s^2$. Similarly to the proof of Theorem 7, we apply the black-box reduction with $\mathcal{T}' = \mathcal{T}$, and set G^* as a star with c_1 terminals, to generate a bipartite graph G. For any constant $c_1 > 0$, we define the family of minors $\mathcal{L} := \{H : H \text{ is a minor of } G \text{ and } |V(H)| < \binom{k}{2}/c_1\}$.

▶ **Claim 17.** *Let π be any probability distribution over $\mathcal{L}$. There exists a non-terminal of G that is involved in an edge contraction with probability at least $1 - s^2/2c_1$ under π.*

Proof. Proof of Theorem 9 Let v be the non-terminal from Claim 17 and let T_i be its corresponding set of size c_1. Invoking Lemma 16 and using conditional expectations, we get that there exists a terminal pair $(t, t') \in T_i$ such that

$$\frac{\mathbb{E}_\pi[d_H(t,t')]}{d_G(t,t')} \geq \frac{\mathbb{E}_\pi\left[d_H(t,t') \mid v \text{ is contracted}\right] \cdot \mathbb{P}_\pi\left[v \text{ is contracted}\right]}{d_G(t,t')}$$
$$\geq 2\left(1 - \frac{1}{s}\right)\left(1 - \frac{s^2}{2c_1}\right) \geq 2 - \left(\frac{2}{s} + \frac{s^2}{c_1}\right),$$

which can be made arbitrarily close to 2 by setting s and c_1 sufficiently large. To be precise, given any $\epsilon > 0$, by setting $s = 5/\epsilon$ and $c_1 = 2s^2/\epsilon$, the distortion is at least $2 - \epsilon$. ◀

4 Minor Construction for General Graphs

In this section we give minor constructions that present numerous trade-offs between the distortion and size of DAMs. Our results are obtained by combining the work of Coppersmith and Elkin [8] on sourcewise distance preservers with the well-known notion of spanners.

Given an undirected graph $G = (V, E, \ell)$ with terminals T, we let $\Pi_{u,v}$ denote the shortest path between u and v in G. Without loss of generality, we assume that for any pair of vertices (u, v), the shortest path connecting u and v is *unique*. This can be achieved by slightly perturbing the original edge lengths of G (see [8]).

For a graph G, let $N_G(u)$ denote the vertices incident to u in G. We say that two paths Π and Π' branch at a vertex $u \in V(\Pi) \cap V(\Pi')$ iff $|N_{\Pi \cup \Pi'}(u)| > 2$. We call such a vertex u a *branching* vertex. Let $\mathcal{P}$ denote the set of shortest paths corresponding to every pair of vertices in G. We review the following result proved in [8, Lemma 7.5].

▶ **Lemma 18.** *Any pair of shortest paths $\Pi, \Pi' \in \mathcal{P}$ has at most two branching vertices.*

▶ **Definition 19** (Terminal Path Cover)**.** Given $G = (V, E, \ell)$ with terminals T, a set of shortest paths $\mathcal{P}' \subset \mathcal{P}$ is an $(\alpha, f(k))$-terminal path cover (abbr. $(\alpha, f(k))$-TPc) of G if

1. $\mathcal{P}'$ covers the terminals, i.e. $T \subseteq V(H)$, where $H = \bigcup_{\Pi \in \mathcal{P}'} E(\Pi)$,
2. $|\mathcal{P}'| \leq f(k)$ and $\forall t, t' \in T$, $d_G(t,t') \leq d_H(t,t') \leq \alpha \cdot d_G(t,t')$.

We remark that the endpoints of the shortest paths in $\mathcal{P}'$ are not necessarily terminals. Now we give a simple algorithm generalizing the one presented by Krauthgamer et al. [15].

Algorithm 1 MinorSparsifier (graph G, terminals T, $(\alpha, f(k))$-TPc $\mathcal{P}'$ of G)

1: Set $H = \emptyset$. Then add all shortest paths from the path cover $\mathcal{P}'$ to H.
2: **while** there exists a degree two non-terminal v incident to edges (v, u) and (v, w) **do**
3: Contract the edge (u, v), then set the length of edge (u, w) to $d_H(u, w)$.
4: **return** H

▶ **Lemma 20.** *For a given graph $G = (V, E, \ell)$ with terminals $T \subset V$ and an $(\alpha, f(k))$-TPc $\mathcal{P}'$ of G,* MinorSparsifier$(G,T,\mathcal{P}')$ *outputs an $(\alpha, f(k)^2)$-DAM of G.*

A trivial *exact* terminal path cover for any k-terminal graph is to take the union of all terminal shortest paths, which we refer to as the $(1, \mathcal{O}(k^2))$-TPc $\mathcal{P}'$ of G. Krauthgamer et al. [15] used this $(1, \mathcal{O}(k^2))$-TPc to construct an $(1, \mathcal{O}(k^4))$-DAM. Here, we study the question of whether increasing the distortion slightly allows us to obtain a cover of size $o(k^2)$. We answer this question positively, by reducing it to the well-known spanner problem. Let $q \geq 1$ be an integer and let $G = (V, E, \ell)$ be an undirected graph. A q-spanner of G is a subgraph $S = (V, E_S, \ell)$ such that $\forall u, v \in V,\ d_G(u, v) \leq d_S(u, v) \leq q \cdot d_G(u, v)$. We refer to q and $|E_S|$ as the *stretch* and *size* of spanner S, respectively.

▶ **Lemma 21** ([1]). *Let $q \geq 1$ be an integer. Any graph $G = (V, E, \ell)$ admits a $(2q-1)$-spanner S of size $\mathcal{O}(|V|^{1+1/q})$.*

Given a graph $G = (V, E, \ell)$ with terminals T, we compute the complete graph $Q_T = (T, \binom{T}{2}, d_G|T)$, where $d_G|T$ denotes the distance metric of G restricted to the point set T (In other words, for any pair of terminals $t, t' \in T$, the weight of the edge connecting them in Q_T is given by $w_{Q_T}(t, t') = d_G(t, t')$). Recall that all shortest paths in G are unique.

Using Lemma 21, we construct a $(2q-1)$-spanner S of size $\mathcal{O}(k^{1+1/q})$ for Q_T. Observe that each edge of S corresponds to an unique (terminal) shortest path in G since S is a subgraph of Q_T. Thus, the set of shortest paths corresponding to edges of S form a $(2q-1, \mathcal{O}(k^{1+1/q}))$-TPc $\mathcal{P}'$ of G. Using $\mathcal{P}'$ with Lemma 20 gives the following theorem.

▶ **Theorem 22.** *Let $q \geq 1$ an integer. Any graph $G = (V, E, \ell)$ with $T \subset V$ admits a $(2q-1, \mathcal{O}(k^{2+2/q}))$-DAM.*

We mention two trade-offs from the above theorem. When $q = 2$, we get an $(3, \mathcal{O}(k^3))$-DAM. When $q = \log k$, we get an $(\mathcal{O}(\log k), \mathcal{O}(k^2))$-DAM. These are new distortion-size trade-offs.

The above method allows us to have improved guarantees for bounded treewidth graphs.

▶ **Theorem 23.** *Let $q \geq 1$ be an integer. Any graph $G = (V, E, \ell)$ with treewidth at most p, $T \subset V$ and $k \geq p$ admits a $(2q-1, \mathcal{O}(p^{1+2/q}k))$-DAM.*

5 Minor Construction for Graphs that Exclude a Fixed Minor

In this section we give improved guarantees for distance approximating minors for special families of graphs. Specifically, we show that graphs that exclude a fixed minor admit an $(\mathcal{O}(1), \widetilde{\mathcal{O}}(k^2))$-DAM. This family of graphs includes, among others, the planar graphs.

The reduction to spanner in Section 4 does not consider the structure of Q_T, which is inherited from the input graph. We exploit this structure, together with the use of the randomized Steiner Point Removal Problem, which is equivalent to finding an $(\alpha, 0)$-rDAM.

We will make use the following theorem due to Englert et al. [9, Theorem 14].

▶ **Theorem 24** ([9]). *Let $\alpha = \mathcal{O}(1)$. Given a graph that excludes a fixed minor $G = (V, E, \ell)$ with $T \subset V$, there is a probability distribution π over its minors $H = (T, E', \ell')$, such that $\forall\ t, t' \in T,\ \mathbb{E}_{H\sim\pi}[d_H(t, t')] \leq \alpha \cdot d_G(t, t')$ and for all H in support of π, $d_H(t, t') \geq d_G(t, t')$.*

Given a graph G that excludes a fixed minor, any minor H of G only on the terminals also excludes the fixed minor. Thus H has $\mathcal{O}(k)$ edges [23]. This leads to the corollary below.

▶ **Corollary 25.** *Let $\alpha = \mathcal{O}(1)$. Given a graph that excludes a fixed minor $G = (V, E, \ell)$ with $T \subset V$ and Q_T as defined in Section 4, there exists a probability distribution π over subgraphs $H = (T, E', \ell')$ of Q_T, each having at most $\mathcal{O}(k)$ edges, such that for all $t, t' \in T,\ \mathbb{E}_{H\sim\pi}[d_H(t, t')] \leq \alpha \cdot d_{Q_T}(t, t')$.*

Proof. Let π be the distribution over minors of G from Theorem 24, then every minor in its support is clearly a subgraph of Q_T with $\mathcal{O}(k)$ edges. Since during the construction of these minors we may assume that $\forall (t,t') \in E',\ \ell'(t,t') = d_G(t,t')$, the corollary follows. ◀

▶ **Lemma 26.** *Given a graph that excludes a fixed minor $G = (V, E, \ell_G)$ with $T \subset V$, and Q_T as defined in Section 4, there exists an $\mathcal{O}(1)$-spanner S of size $\mathcal{O}(k \log k)$ for Q_T.*

Proof. Let π be the probability distribution over subgraphs H from Corollary 25. Set $S = \emptyset$. First, we sample independently $q = 3 \log k$ subgraphs $H_1, \ldots, H_q$ from π. We then add the edges from all these subgraphs to the graph S, i.e., $E_S = \bigcup_{i=1}^{q} E_{H_i}$. Fix an edge (t,t') from Q_T and a subgraph H_i. By Corollary 25 and the Markov inequality, $\mathbb{P}[d_{H_i}(t,t') \geq 2\alpha \cdot d_{Q_T}(t,t')] \leq 2^{-1}$, and hence

$$\mathbb{P}[d_S(t,t') \geq 2\alpha \cdot d_{Q_T}(t,t')] = \prod_{i=1}^{q} \mathbb{P}[d_{H_i}(t,t') \geq 2\alpha \cdot d_{Q_T}(t,t')] \leq 2^{-q} = k^{-3}.$$

Applying union bound overall all edges from Q_T yields

$$\mathbb{P}[\text{there exists an edge } (t,t') \in Q_T \text{ s.t. } d_S(t,t') \geq 2\alpha \cdot d_{Q_T}(t,t')] \leq k^2 \cdot k^{-3} = k^{-1}.$$

Hence, for all edges (t,t') from Q_T, with probability at least $1 - 1/k$, we preserve the shortest path distance between t and t' up to a factor of $2\alpha = \mathcal{O}(1)$ in S. Since S is a subgraph of Q_T, this implies that there exists a $\mathcal{O}(1)$-spanner S of size $\mathcal{O}(k \log k)$ for Q_T. ◀

Similar to the last section, the set of shortest paths corresponding to edges of S is an $(\mathcal{O}(1), \mathcal{O}(k \log k))$-TPc $\mathcal{P}'$ of G. Using $\mathcal{P}'$ with Lemma 20 gives the following theorem.

▶ **Theorem 27.** *Any graph that excludes a fixed minor $G = (V, E, \ell)$ with $T \subset V$ admits an $(\mathcal{O}(1), \widetilde{\mathcal{O}}(k^2))$-DAM.*

6 Minor Construction for Planar Graphs

In this section, we show that for planar graphs, we can improve the constant guarantee bound on the distortion to 3 and $1 + \varepsilon$, respectively, without affecting the size of the minor. Our work builds on existing techniques used in the context of approximate distance oracles, thereby bypassing our previous spanner reduction. Both results use essentially the same ideas and rely heavily on the fact that planar graphs admit separators with special properties.

We say that a graph $G = (V, E, \ell)$ admits a λ-separator if there exists a set $R \subseteq V$ whose removal partitions G into connected components, each of size at most λn, where $1/2 \leq \lambda < 1$. Lipton and Tarjan [17] showed that every planar graph has a 2/3-separator R of size $\mathcal{O}(\sqrt{n})$. Later on, Gupta et al. [12] and Thorup [24] independently observed that one can modify their construction to obtain a 2/3-separator R, with the additional property that R consists of vertices belonging to shortest paths from G (note that this R is not guaranteed to be small). We briefly review the construction of such *shortest path separators*.

Let $G = (V, E, \ell)$ be a triangulated planar graph (the triangulation is guaranteed by adding infinity edge lengths among the missing edges). Further, let us fix an arbitrary shortest path tree A rooted at some vertex r. Then, it can be inferred from the work of Lipton and Tarjan [17] that there always exists a non-tree edge $e = \{u, v\}$ of A such that the fundamental cycle $\mathcal{C}$ in $A \cup \{e\}$, formed by adding the non-tree edge e to A, gives a 2/3-separator for G. Because A is a tree, the separator will consist of two paths from the $\mathrm{lca}(u, v)$ to u and v. We denote such paths by P_1 and P_2, respectively. Both paths are

shortest paths as they belong to A. We will show how to use such separators to obtain terminal path covers. Before proceeding, we give the following preprocessing step.

Given a planar graph $G = (V, E, \ell)$ with $T \subset V$, the algorithm MinorSparsifier(G, T, $\mathcal{P}'$) with $\mathcal{P}'$ being the $(1, \mathcal{O}(k^2))$-TPc of G, produces an $(1, \mathcal{O}(k^4))$-DAM for G. Thus, without loss of generality, we may assume that G has at most $\mathcal{O}(k^4)$ vertices.

Stretch-3 Guarantee. When solving a graph problem, it is often that the problem can be more easily solved for simpler graph instances, e.g., trees. Driven by this, it is desirable to reduce the problem from arbitrary graphs to one or several tree instances, possibly allowing a small loss in the quality of the solution. Along the lines of such an approach, Gupta et al. [12] gave the following definition in the context of shortest path distances.

▶ **Definition 28** (Forest Cover)**.** Given a graph $G = (V, E, \ell)$, a forest cover (with stretch α) of G is a family $\mathcal{F}$ of subforests $\{F_1, F_2, \ldots, F_k\}$ of G such that for every $u, v \in V$, there is a forest $F_i \in \mathcal{F}$ such that $d_G(u, v) \leq d_{F_i}(u, v) \leq \alpha \cdot d_G(u, v)$.

If we restrict our attention to planar graphs, Gupta et al. [12] used shortest path separators (as described above) to give a divide-and-conquer algorithm for constructing forest covers with small guarantees on the stretch and size. Here, we slightly modify their construction for our purpose. Before proceeding to the algorithm, we give the following useful definition.

▶ **Definition 29.** Let t be a terminal and let P be a shortest path in G. Then $t^P_{\min}$ denotes the vertex of P that minimizes $d_G(t, p)$, for all $p \in P$, breaking ties lexicographically.

Algorithm 2 ForestCover (planar graph G, terminals T)

1: **if** $|V(G)| \leq 1$ **then return** $V(G)$
2: Compute a 2/3-separator $\mathcal{C}$ consisting of shortest paths P_1 and P_2 for G.
3: **for** $i = 1, 2$ **do**
4: Contract P_i to a single vertex p_i and compute a shortest path tree L_i from p_i.
5: Expand back the contracted edges in L_i to get the tree L'_i.
6: **for** every terminal $t \in T$ **do**
7: Add $t^{P_i}_{\min}$ as a terminal in the tree L'_i.
8: Let (G_1, T_1) and (G_2, T_2) be the resulting connected graphs from $G \setminus \mathcal{C}$, where T_1 and T_2 are disjoint subsets of the terminals T induced by $\mathcal{C}$.
`// Note that all distances involving terminals from` $\mathcal{C}$ `are taken care of.`
9: **return** $\bigcup_{i=1}^{2} L'_i \cup \bigcup_{i=1}^{2}$ ForestCover(G_i, T_i).

Algorithm 3 PlanarTPc-1 (planar graph G, terminals T)

1: Set $\mathcal{P}' = \emptyset$. Set $\mathcal{F} =$ ForestCover(G, T).
2: **for** every forest $F_i \in \mathcal{F}$ **do**
3: Let R_i be the terminal set of F_i and let $\mathcal{P}'_i$ be the (trivial) $(1, \mathcal{O}(k^2))$-TPc of F_i;
4: Compute $F'_i =$ MinorSparsifier$(F_i, R_i, \mathcal{P}'_i)$.
5: Add the shortest paths corresponding to the edges of F'_i to $\mathcal{P}'$.
6: **return** $\mathcal{P}'$

▶ **Theorem 30** ([12], Theorem 5.1)**.** *Given a planar graph $G = (V, E, \ell)$ with $T \subset V$,* ForsetCover(G, T) *produces a stretch-3 forest cover with $\mathcal{O}(\log |V|)$ forests.*

We note that the original construction does not consider terminal vertices, but this does not worsen neither the stretch nor the size of the cover. The only difference here is that we need to add at most k new terminals to each forest compared to the original number of terminals in the input graph. This modification affects our bounds only by a constant factor.

▶ **Lemma 31.** *Given a planar graph $G = (V, E, \ell)$ with $T \subset V$,* PlanarTPc-1(G, T) *produces an $(3, \mathcal{O}(k \log k))$-*TPc *$\mathcal{P}'$ for G.*

Proof. We first review the following simple fact, whose proof can be found in [15].

▶ **Fact 32.** *Given a forest $F = (V, E, \ell)$ with terminals $T \subset V$ and $\mathcal{P}'$ being the (trivial) $(1, \mathcal{O}(k^2))$-TPc of F, the procedure* MinorSparsifier$(F, T, \mathcal{P}')$ *outputs an $(1, k)$-DAM.*

Let us proceed with the analysis. Observe that from the Preprocessing Step our input graph G has at most $\mathcal{O}(k^4)$ vertices. Thus, applying Theorem 30 on G gives a stretch-3 forest cover $\mathcal{F}$ of size $\mathcal{O}(\log k)$. In addition, recall that all shortest paths are unique in G.

Next, let F_i by any forest from $\mathcal{F}$. By construction, we note that each tree belonging to F_i has the nice property of being a concatenation of a given shortest path with another shortest path tree. We will exploit this in order to show that every edge of the minor F_i' for F_i corresponds to the (unique) shortest path between its endpoints in G.

To this end, let $e' = (u, v)$ be an edge of F_i' that does not exist in F_i. Since F_i' is a minor of F_i, we can map back e' to the path $\Pi_{u,v}$ connecting u and v in F_i. Because of the additional terminals $u_{\min}^{P_i}$ added to F_i, we claim that $\Pi_{u,v}$ is entirely contained either in some shortest path tree L_j or some shortest path separator P_j. Using the fact that subpaths of shortest paths are shortest paths, we conclude that the length of the path $\Pi_{u,v}$ (or equivalently, the length of edge e') corresponds to the unique shortest path connecting u and v in G. The same argument is repeatedly applied to every such edge of F_i'.

By construction we know that F_i has at most $2k$ terminals. Using Fact 32 we get that F_i' contains at most $4k$ edges. Since there are $\mathcal{O}(\log k)$ forests, we conclude that the terminal path cover $\mathcal{P}'$ consists of $\mathcal{O}(k \log k)$ shortest paths. The stretch guarantee follows directly from that of cover $\mathcal{F}$, since F_i' exactly preserves all distances between terminals in F_i. ◀

▶ **Theorem 33.** *Any planar graph $G = (V, E, \ell)$ with $T \subset V$ admits a $(3, \widetilde{\mathcal{O}}(k^2))$-*DAM.

Indeed, there is another distance oracle that yields better distortion $(1 + \varepsilon)$ (see [24, 14]). Similar to the above, we prove the following theorem; its proof is deferred to the full version.

▶ **Theorem 34.** *Any planar graph $G = (V, E, \ell)$ with $T \subset V$ admits an $(1 + \varepsilon, \widetilde{\mathcal{O}}((k/\varepsilon)^2)$-*DAM.

7 Discussion and Open Problems

We note that there remain gaps between some of the best upper and lower bounds, e.g., for general graphs and distortion $3 - \epsilon$, the lower bound is $\Omega(k^{6/5})$, while for distortion 3, our upper bound is $\mathcal{O}(k^3)$. Improving the bounds is an interesting open problem.

Our techniques for showing upper bounds rely heavily on the spanner reduction. For planar graphs, Krauthgamer et al. [15] showed that to achieve distortion $1 + o(1)$, $\Omega(k^2)$ non-terminals are needed; we bypass the spanner reduction to construct an $(1 + \varepsilon, \widetilde{\mathcal{O}}(k/\varepsilon)^2)$-DAM, which is tight up to a poly-logarithmic factor. It is an interesting open question on whether similar guarantees can be achieved for general graphs.

Abstract

We consider distance labeling schemes for trees: given a tree with n nodes, label the nodes with binary strings such that, given the labels of any two nodes, one can determine, by looking only at the labels, the distance in the tree between the two nodes.

A lower bound by Gavoille et al. [Gavoille et al., J. Alg., 2004] and an upper bound by Peleg [Peleg, J. Graph Theory, 2000] establish that labels must use $\Theta(\log^2 n)$ bits[1]. Gavoille et al. [Gavoille et al., ESA, 2001] show that for very small approximate stretch, labels use $\Theta(\log n \log\log n)$ bits. Several other papers investigate various variants such as, for example, small distances in trees [Alstrup et al., SODA, 2003].

We improve the known upper and lower bounds of exact distance labeling by showing that $\frac{1}{4}\log^2 n$ bits are needed and that $\frac{1}{2}\log^2 n$ bits are sufficient. We also give $(1+\varepsilon)$-stretch labeling schemes using $\Theta(\log n)$ bits for constant $\varepsilon > 0$. $(1+\varepsilon)$-stretch labeling schemes with polylogarithmic label size have previously been established for doubling dimension graphs by Talwar [Talwar, STOC, 2004].

In addition, we present matching upper and lower bounds for distance labeling for caterpillars, showing that labels must have size $2\log n - \Theta(\log\log n)$. For simple paths with k nodes and edge weights in $[1, n]$, we show that labels must have size $(k-1)/k \log n + \Theta(\log k)$.

1 Introduction

A *distance labeling scheme* for a given family of graphs assigns *labels* to the nodes of each graph in the family such that, given the labels of two nodes in the graph and no other information, it is possible to determine the shortest distance between the two nodes. The labels are assumed to be composed of bits, and the goal is to make the worst-case label size as

Table 1 Results presented in this paper. $\varepsilon > 0$ is a constant.

Problem	Lower bound	Upper bound
Exact, general trees	$\frac{1}{4}\log^2 n$	$\frac{1}{2}\log^2 n$
$(1+\varepsilon)$-stretch, general trees	$\Theta(\log n)$	
Caterpillars	$2\log n - \Theta(\log\log n)$	
Weighted paths, k nodes, weights in $[1,n]$	$\frac{k-1}{k}\log n + \Theta(\log k)$	

small as possible. Labeling schemes are also called *implicit representation of graphs* [64, 71]. The problem of finding implicit representations with small labels for specific families of graphs was introduced in the 1960s [16, 17], and efficient labeling schemes were introduced in [44, 57]. Distance labeling for general graphs has been considered since the 1970/80s [40, 72], and later for various restricted classes of graphs and/or approximate distances, often tightly related to distance oracle and routing problems, see e.g. [7]. This paper focuses on distance labels for the well studied case of trees.

Exact distances. In [61] Peleg presented an $O(\log^2 n)$ bits distance labeling scheme for general unweighted trees. In [39] Gavoille et al. proved that distance labels for unweighted binary trees require $\frac{1}{8}\log^2 n - O(\log n)$ bits and presented a scheme with $1/(\log 3 - 1)\log n \approx 1.7\log n$ bits. This paper presents a scheme of size $\frac{1}{2}\log^2 n + O(\log n)$ and further reduces the gap by showing that $\frac{1}{4}\log^2 n - O(\log n)$ bits are needed. Our upper bound is a somewhat straightforward application of a labeling scheme for nearest common ancestors [8, 9].

Approximate distances. Let $\text{dist}_T(x,y)$ denote the shortest distance between nodes x, y in a tree T. An r-additive approximation scheme returns a value $\text{dist}'_T(x,y)$, where $\text{dist}_T(x,y) \leq \text{dist}'_T(x,y) \leq \text{dist}_T(x,y)+r$. An s-stretched approximation scheme returns a value $\text{dist}'_T(x,y)$, where $\text{dist}_T(x,y) \leq \text{dist}'_T(x,y) \leq \text{dist}_T(x,y)\cdot s$. For trees of height h Gavoille et al. [32, theorem 4] gave a 1-additive $O(\log n \log h)$ bit labeling scheme. However, using an extra bit in the label for the node depth modulo 2, it is easy to see that any 1-additive scheme can be made exact. Gavoille et al. [32] also gave upper and lower bounds of $\Theta(\log\log n \log n)$ bits for $(1+1/\log n)$-stretched distance. This paper presents a scheme of size $\Theta(\log n)$ for $(1+\varepsilon)$-stretch for constant $\varepsilon > 0$. Labeling schemes for $(1+\varepsilon)$-stretch with polylogarithmic size label have previously been given for graphs of doubling dimension [65] and planar graphs [67].

Distances in caterpillars and paths. Labeling schemes for caterpillars have been studied for various queries, e.g., adjacency [15]. Here we present upper and lower bounds showing that distance labeling caterpillars requires $2\log n - \Theta(\log\log n)$ bits. The upper bound is constructed by reduction to the case of *weighted paths* with $k > 1$ nodes and positive integer edge weights in $[1,n]$, for which we give upper and lower bounds showing that labels must have size $\frac{k-1}{k}\log n + \Theta(\log k)$.

1.1 Related work

Distances in trees with small height. It is known that, for unweighted trees with bounded height h, labels must have size $\Theta(\log n \log h)$. The upper bound follows from [32, Theorem 2]

and the lower bound from [39, Section 3][2]. In [45] distance labeling for various restricted class of trees, including trees with bounded height, is considered, and in [66] another distance labeling scheme for unweighted trees using $O(\log n \log h)$ bits is given.

Small distances in trees. Distances in a tree between nodes at distance at most k can be computed with labels of size $\log n + O(k\sqrt{\log n})$ [46]. In [5] it is shown that size $\log n + \Theta(\log \log n)$ are needed for labeling schemes supporting both parent and sibling queries. More generally, [5] shows that, using labels of size $\log n + O(\log \log n)$, the distance between two nodes can be determined if it is at most k for some constant k, which is optimal for $k > 1$. In [33, 34] further improvements are given for small distances in trees. For $k = 1$, corresponding to adjacency testing, there is a sequence of papers that improve the second order term, recently ending with [6] which establishes that $\log n + \Theta(1)$ bits are sufficient.

Various other cases for trees. Distance labeling schemes for various other cases have been considered, e.g., for weighted trees [32, 39, 61], dynamic trees [52], and a labeling scheme variation with extra free lookup [50, 51].

Exact and approximate distances in graphs. Distance labeling schemes for general graphs [7, 39, 40, 64, 70, 72] and various restricted graphs exist, e.g., for bounded tree-width, planar and bounded degree [39], distance-hereditary [36], bounded clique-width [22], some non-positively curved plane [19], interval [37] and permutation graphs [14]. Approximate distance labeling schemes, both additive and stretched, are also well studied; see e.g., [18, 26, 32, 35, 39, 41, 42, 53, 61, 69]. An overview of distance labeling schemes can be found in [7].

1.2 Second order terms for labeling schemes are theoretically well studied

Chung's solution in [20] gives labels of size $\log n + O(\log \log n)$ for adjacency labeling in trees, which was improved to $\log n + O(\log^* n)$ in FOCS'02 [13] and in [15, 20, 29, 30, 47] to $\log n + \Theta(1)$ for various special cases. Finally it was improved to $\log n + \Theta(1)$ for general trees in FOCS'15 [6].

A recent STOC'15 paper [11] improves label size for adjacency in general graphs from $n/2 + O(\log n)$ [44, 56] to $n/2 + O(1)$ almost matching an $(n-1)/2$ lower bound [44, 56].

Likewise, the second order term for ancestor relationship is improved in a sequence of STOC/SODA papers [2, 4, 12, 30, 31] (and [1, 47]) to $\Theta(\log \log n)$, giving labels of size $\log n + \Theta(\log \log n)$.

Somewhat related, *succinct data structures* (see, e.g., [24, 27, 28, 58, 59]) focus on the space used in addition to the information theoretic lower bound, which is often a lower order term with respect to the overall space used.

1.3 Labeling schemes in various settings and applications

Using labeling schemes to compute locally and distributed, it is possible to avoid costly access to large global tables. Such properties are used, e.g., in XML search engines [2], network routing and distributed algorithms [23, 25, 68, 69], dynamic and parallel settings [21, 52], graph representations [44], and other applications [48, 49, 60, 61, 62].

[2] We thank Gavoille for pointing this out.

Trees have always been a subject of special interest in the routing literature (see e.g. [3, 10, 55, 73]). As pointed out by Leighton [54], many networks are simply trees, and, moreover, routing in general graphs may be done using only the edges of a spanning tree of the graph. In [68] a $O(\log n)$ labeling routing scheme for tree is given. This e.g. combined with one of the results in this paper makes it possible using labels of size $O(\log n)$ not only to route packets in trees, but also estimate the distance to its destination.

Various computability requirements are sometimes imposed on labeling schemes [2, 44, 48]. This paper assumes the RAM model.

2 Preliminaries

Trees. Given nodes u, v in a rooted tree T, u is an *ancestor* of v and v is a *descendant* of u, if u is on the unique path from v to the root. For a node u of T, denote by T_u be the subtree of T consisting of all the descendants of u (including itself). The *depth* of u is the number of edges on the unique simple path from u to the root of T. The nearest common ancestor (NCA) of two nodes is the unique common ancestor with largest depth. Let $T[u, v]$ denote the nodes on the simple path from u to v in T. The variants $T(u, v]$ and $T[u, v)$ denote the same path without the first and last node, respectively. The distance between u and v is the number $\text{dist}(u, v) = |T(u, v]|$. We set $\text{distroot}(v) = \text{dist}(v, r)$, where r is the root of T. A *caterpillar* is a tree whose non-leaf nodes form a path, called the *spine*.

Heavy-light decomposition (From [63]). Let T be a rooted tree. The nodes of T are classified as either *heavy* or *light* as follows. The root r of T is light. For each non-leaf node v, pick one child w where $|T_w|$ is maximal among the children of v and classify it as heavy; classify the other children of v as light. The *apex* of a node v is the nearest light ancestor of v. By removing the edges between light nodes and their parents, T is divided into a collection of *heavy paths*. Any given node v has at most $\log n$ light ancestors (see [63]), so the path from the root to v goes through at most $\log n$ heavy paths.

Bit strings. A bit string s is a member of the set $\{0, 1\}^*$. We denote the length of a bit string s by $|s|$, the ith bit of s by s_i, and the concatenation of two bit strings s, s' by $s \circ s'$. We say that s_1 is the most significant bit of s and $s_{|s|}$ is the least significant bit.

Labeling schemes. An *distance labeling scheme* for trees of size n consists of an *encoder* e and a *decoder* d. Given a tree T, the encoder computes a mapping $e_T : V(T) \to \{0, 1\}^*$ assigning a *label* to each node $u \in V(T)$. The decoder is a mapping $d : \{0, 1\}^* \times \{0, 1\}^* \to \mathbb{Z}^+$, where $\mathbb{Z}^+$ denotes the positive integers, such that, given any tree T and any pair of nodes $u, v \in V(T)$, $d(e(u), e(v)) = \text{dist}(u, v)$. Note that the decoder does not know T. The *size* of a labeling scheme is defined as the maximum label size $|e_T(u)|$ over all trees T and all nodes $u \in V(T)$. If, for all trees T, the mapping e_T is injective we say that the labeling scheme assigns *unique* labels.

3 Distances on weighted paths

In this section we study the case of paths with k nodes and integral edge weights in $[1, n]$. The solution to this problem will later be used to establish the upper bound for caterpillars.

3.1 Upper Bound

▶ **Theorem 1.** *There exist a distance labeling scheme for paths with k nodes and positive integral edge weights in $[1, n]$ with labels of size $\frac{k-1}{k}\log n + O(\log k)$.*

Proof. We begin by considering the family of paths with k nodes, integral edge weights and diameter $< n$. We shall prove that there exists a distance labeling scheme for this family with labels of size $\frac{k-1}{k}\log n + \log k + \mathrm{O}(\log\log k)$.

So consider such a path, and root it in one of its end nodes, denoted v_0. Denote the nodes on the path $v_0, \ldots, v_{k-1}$ in order. Let $d_i = \mathrm{distroot}(v_i)$ and note that, by assumption, $d_i < n$ for all i. We will let the label for v_i store the number $d_i + x$ for some $x < n$ that allows us to represent $d_i + x$ compactly. Since we use the same x for all nodes, we can easily compute the distance between any pair of nodes v_i, v_j as $|(d_i + x) - (d_j + x)|$.

Since we choose $x < n$, the largest number stored in a label will be $d_k + x < 2n$, which can be represented with *exactly* $L = \lceil \log(2n) \rceil$ bits. Divide those L bits to $k + 1$ segments, whereof k have $\ell = \lfloor L/k \rfloor$ bits and the last segment contains the remaining bits. The first segment, segment 0, will contain the ℓ least significant bits, segment 1 the following ℓ bits and so on. We will choose x such that the representation of $d_i + x$ has 0s in all the bits in the i'th segment. If we manage to do so, we will be able to encode each $d_i + x$ with $L - \ell + \lceil \log k \rceil$ bits. Indeed, we can use exactly $\lceil \log k \rceil$ bits to represent i, and the next $L - \ell$ bits to represent $d_i + x$ where we skip the i'th segment. Prefixing with a string in the form $0^{\lceil \log \lceil \log k \rceil \rceil}1$, we get a string from which we can determine the number of bits needed to write $\lceil \log k \rceil$ and therefrom the numbers i and $d_i + x$. We use this string as the label for v_i. The label length is $L - \ell + \lceil \log k \rceil + \lceil \log \lceil \log k \rceil \rceil + 1 = \frac{k-1}{k}\log n + \log k + O(\log\log k)$.

It remains to show that there exist a number $x < n$ as described. In the following we shall, as in the above, represent numbers $< 2n$ with L bits that are divided into $k + 1$ segments whereof the first k have size ℓ. For $i < k$ and $y < 2n$, let $a(i, y)$ be a function which returns a number z with the following properties:

(i) In z, all bits outside segment i are 0.
(ii) $z + y$ has only 0s in segment i.

This function is constructed as follows. If y only has 0s in segment i, let $a(i, y) = 0$. Otherwise take the representation of y, zero out all bits outside segment i, reverse the bits in segment i and add v to the resulting number, where v has a 1 in the least significant bit of segment i and 0s in all other positions.

Note that from (i) it follows that adding z to any number will not change bits in less significant positions than segment i. We can now scan through the nodes $v_0, \ldots v_{k-1}$, increasing x by adding bits to x in more and more significant positions (in non-overlapping segments), as follows:

- Set $x = 0$.
- For $i = 1 \ldots, k - 1$, set $x = x + a(i, x + d_i)$.

After iteration i we have that $x + d_i$ in segment i only has 0s, and in the following iterations, 1s are only added to x in more significant bit positions, meaning that $d_i + x$ continues to have only 0s in segment i. Since the segments are non-overlapping, we end up with $x < n$.

For the more general family of paths with k nodes and edge weights in $[1, n]$, we simply note that the diameter of any path in this family is at most kn. Using the above result thus immediately gives us a labeling scheme with labels of size $\frac{k-1}{k}\log n + O(\log k)$. ◀

3.2 Lower bound

▶ **Theorem 2.** *Labeling scheme for distances on weighted paths with k nodes and edge weights $[1, n]$ require $\frac{k-1}{k}\log n + \Omega(\log k)$ bits.*

Proof. Let $\mathcal{F}$ denote the family of paths with k nodes and integral edge weights in $[1, n]$. We can construct all the members of $\mathcal{F}$ by selecting $(k-1)$ different edge weights in the range $[1, n]$, skipping the paths which have already been constructed by the reverse sequence of edge weights. With this construction we will at most skip half of the paths, and hence $|\mathcal{F}| \geq \frac{1}{2}n^{k-1}$. Let the worst-case label size of an optimal distance labeling scheme for such paths have length L. The number of different labels with length at most L is $N = 2^{L+1} - 1$. We can uniquely represent each of the paths in $\mathcal{F}$ with the collection of their labels, and hence $|\mathcal{F}| \leq \binom{N}{k}$. Thus, we have found that $\frac{1}{2}n^{k-1} \leq \binom{N}{k}$. Since $\binom{N}{k} \leq (Ne/k)^k$, it follows that $\frac{k-1}{k}\log n \leq \log N - \log k + O(1)$ and hence that $L \geq \frac{k-1}{k}\log n + \log k - O(1)$ as desired. ◀

Combining Theorem 2 with Theorem 1 we see that distance labels for paths of k nodes with integral weights in $[1, n]$ must have length $\frac{k-1}{k}\log n + \Theta(\log k)$.

4 Distances in caterpillars

4.1 Upper bound

▶ **Theorem 3.** *There exist a distance labeling scheme for caterpillars with worst-case label size $2\log n - \log\log n + O(\log\log\log n)$.*

Proof. We will start by giving a simple $2\log n$ bits scheme and then improve it. The simple solution assigns two numbers to each node. The nodes on the spine save distroot and the number 0. The nodes not on the spine save their parent's distroot and a number that is unique among their siblings. The second number is required to distinguish siblings, and hence determine if the distance between two nodes is 0 or 2. The worst-case label size for this solution is $2\log n + O(1)$.

To improve the solution, we split up the nodes on the spine into two groups: (1) nodes with $> \frac{n}{k}$ leaves and (2) nodes with $\leq \frac{n}{k}$ leaves, for some parameter k to be chosen later. We add the root to the first group no matter what. Note that the first group can contain at most k nodes.

As before, all nodes save two numbers: distroot and the number 0 for spine nodes or a number to distinguish siblings. The idea is to reduce label size with $\log k$ bits by using fewer bits for the first number for nodes in the first group and for the second number for nodes in the second group.

The nodes in the first group form a path with at most k nodes and edge weights in $[1, n]$ (where each weight corresponds to the distance between the nodes in the original graph). The algorithm from Theorem 1 will add a number x, which is less than the diameter, which again is less than n, to the numbers representing the root distances of the nodes. Using this technique, we can, as seen in the proof of Theorem 1, encode the (modified) distroots of the nodes in the first group with only $\frac{k-1}{k}\log n + \log k + O(\log\log k)$ bits. This gives labels of size $\frac{2k-1}{k}\log n + \log k + O(\log\log k)$ for non-spine nodes whose parents are in the first group.

We will also add x to the distroots of nodes in the second group, but since $x < n$ this will not change the label size by more than a single bit. For non-spine nodes whose parents are in the second group, we need at most $\log n - \log k + O(1)$ bits for the second number, giving a total label size of $2\log n - \log k + O(1)$.

Finally, since the two numbers that form a label now have different lengths, we need an additional $O(\log\log k)$ bits to determine when one number ends and the next begins. Indeed, it wil be possible to split up labels into their components if we know the number of bits used to write $\lceil \log k \rceil$, and we represent this number with $O(\log\log k)$ bits.

Setting $k = \frac{\log n}{2\log\log n}$, we now see that our worst-case label size is the maximum of

$$2\log n - \log k + O(\log\log k) = 2\log n - \log\log n + O(\log\log\log n)$$

and

$$\begin{aligned}\frac{2k-1}{k}\log n + \log k + O(\log\log k) &= 2\log n - 2\log\log n + \log\log n + O(\log\log\log n)\\ &= 2\log n - \log\log n + O(\log\log\log n).\end{aligned}$$

This proves the theorem. ◀

It is worth noting that the ability to distinguish nodes plays a significant part in the label size. Indeed, if the two nodes given as input to the decoder could always be assumed to be distinct, then a distance labeling scheme for caterpillars with worst-case label size $\log n + O(1)$ would be possible.

4.2 Lower bound

We present a technique that counts tuples of labels that are known to be distinct and compares the result to the number of tuples one can obtain with labels of size L. The technique may have applications to distance labeling for other families of graphs.

▶ **Theorem 4.** *For any $n \geq 4$, any distance labeling scheme for the family of caterpillars with at most n nodes has a worst-case label size of at least $2\lfloor\log n\rfloor - \lfloor\log\lfloor\log n\rfloor\rfloor - 4$.*

Proof. Set $k = \lfloor\log n\rfloor$ and $m = 2^k$. Let $(i_1, \ldots, i_k)$ be a sequence of k numbers from the set $\{1, \ldots, m/2\}$ with the only requirement being that $i_1 = 1$. Now consider, for each such sequence, the caterpillar whose main path has length $m/2$ and where, for $t = 1, \ldots, k$, the node in position i_t has $\lfloor m/2k\rfloor$ leaf children (not on the main path). We shall refer to these children as the *t'th group*. Note that two disjoint groups of children may be children of the same node if $i_t = i_s$ for some s, t. Each of these caterpillars has $m/2 + k\lfloor m/2k\rfloor \leq m \leq n$ nodes.

Suppose that σ is a distance labeling scheme for the family of caterpillars, and consider one of the caterpillars defined above. Given distinct nodes u, v not on the main path, their distance will be $\mathrm{dist}(u, v) = |i_s - i_t| + 2$, where i_s and i_t are the positions on the main path of the parents of u and v, respectively. In particular, if $s = 1$, so that $i_s = 1$, then $\mathrm{dist}(u, v) = i_t + 1$. Thus, if σ has been used to label the nodes of the caterpillar, the number i_t for a child in the t'th group can be uniquely determined from its label together with the label of any of the children from the first group. It follows that any k-tuple of labels $(l_1, \ldots, l_k)$ where l_t is a label of a child in the t'th group uniquely determines the sequence $(i_1, \ldots, i_k)$. In particular, k-tuples of labels from distinct caterpillars must be distinct. Of course, k-tuples of labels from the same caterpillar must also be distinct, since labels are unique in a distance labeling scheme.

Now, there are $(m/2)^{k-1}$ choices for the sequence $(i_1, \ldots, i_k)$, and hence there are $(m/2)^{k-1}$ different caterpillars in this form. For each of these, there are $\lfloor m/2k\rfloor^k$ different choices of k-tuples of labels. Altogether, we therefore have $(m/2)^{k-1}\lfloor m/2k\rfloor^k$ distinct k-tuples of labels. If the worst-case label size of σ is L, then we can create at most $(2^{L+1} - 1)^k$

distinct k-tuples of labels, so we must have $(m/2)^{k-1}\lfloor m/2k \rfloor^k \leq (2^{L+1}-1)^k$. From this it follows that

$$\begin{aligned} L &\geq \lfloor \frac{k-1}{k}(\log m - 1) + \log\lfloor m/2k \rfloor \rfloor \\ &\geq \lfloor \frac{(k-1)^2}{k} + k - \log k \rfloor - 2 \\ &\geq 2k - \lfloor \log k \rfloor - 4 \\ &= 2\lfloor \log n \rfloor - \lfloor \log \lfloor \log n \rfloor \rfloor - 4. \end{aligned}$$

◀

5 Exact distances in trees

5.1 Upper bound

Let u, v be nodes in a tree T and let w be their nearest common ancestor. We then have

$$\operatorname{dist}(u,v) = \operatorname{distroot}(u) - \operatorname{distroot}(v) + 2\operatorname{dist}(w,v)\,. \tag{1}$$

If $w = u$ so that u is an ancestor of v, then the above equation is just a difference of distroots, which can be stored for each node with $\log n$ bits. The same observation clearly holds if $w = v$.

Assume now that $w \notin \{u, v\}$ so that u and v are not ancestors of each other. Consider the heavy-light decomposition [63] described in the preliminaries. At least one of the nodes u and v must have an ancestor which is a light child of w. Assume that it is v. Now, v has at most $\log n$ light ancestors. Saving the distance to all of them together with distroot gives us sufficient information to compute the distance between u and v using equation (1). This is the idea behind Theorem 6 below.

By examining the NCA labeling scheme from [8, 9], we see that it can easily be extended as follows.

▶ **Lemma 5** ([8, 9]). *There exists an NCA labeling scheme of size $O(\log n)$. For any two nodes u, v the scheme returns the label of $w = \operatorname{nca}(u,v)$ as well as:*

- *which of u and v (if any) have a light ancestor that is a child of w; and*
- *the number of light nodes on the path from the root to w and from w to u and v, respectively.*

▶ **Theorem 6.** *There exists a distance labeling scheme for trees with worst-case label size $\frac{1}{2}\log^2 n + O(\log n)$.*

Proof. We use $O(\log n)$ bits for the extended NCA labeling in Lemma 5 and for distroot. Using (1) it now only remains to efficiently represent, for each node, the distance to all its light ancestors.

We consider the light ancestors of a node v encountered on the path from the root to v. The distance from v to the root is at most $n-1$ and can therefore be encoded with *exactly* $\lceil \log n \rceil$ bits (by adding leading zeros if needed). By construction of the heavy-light decomposition, the next light node on the path to v will be the root of a subtree of size at most $n/2$, meaning that the distance from v to that ancestor is at most $n/2 - 1$ and can be encoded with *exactly* $\lceil \log n \rceil - 1$ bits. Continuing this way, we encode the i'th light ancestor on the path from the root to v with exactly $\lceil \log n \rceil - i$ bits. When we run out of light ancestors, we concatenate all the encoded distances, resulting in a string of length at most

$$\lceil \log n \rceil + (\lceil \log n \rceil - 1) + \cdots + 2 + 1 = \frac{1}{2}\lceil \log n \rceil^2 + \frac{1}{2}\lceil \log n \rceil\,.$$

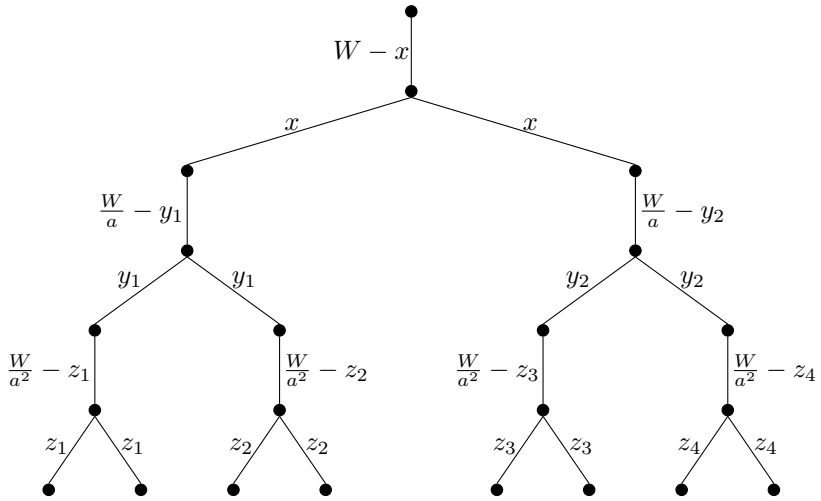

Figure 1 An (h, W, a)-tree, where $h = 3$. We require that $x < W$, $y_1, y_2 < W/a$ and $z_1, \ldots, z_4 < W/a^2$.

We can use $O(\log n)$ extra bits to encode n and to separate all sublabels from each other. The decoder can now determine $\lceil \log n \rceil$ and split up the entries in the list of distances. When applying formula (1), it can then determine the distance between v and w by adding together the relevant distances in the list of light ancestors, using the fact from Lemma 5 that it knows the number of light ancestors from v to w. ◀

5.2 Lower bound

In the case of general trees, Gavoille et al [39] establish a lower bound of $\frac{1}{8}\log^2 n - O(\log n)$ using an ingenious technique where they apply a distance labeling scheme to a special class of trees called (h, M)-trees[3]. The following uses a generalization of (h, M)-trees to improve their ideas and leads to a lower bound of $\frac{1}{4}\log^2 n - O(\log n)$.

(h, W, a)-trees. We begin with some definitions. For integers $h, W \geq 0$ and a number $a \geq 1$ such that W/a^i is integral for all $i = 0, \ldots, h$, an (h, W, a)-*tree* is a rooted binary tree T with edge weights in $[0, W]$ that is constructed recursively as follows. For $h = 0$, T is just a single node. For $h = 1$, T is a claw (i.e. a star with three edges) with edge weights $x, x, W - x$ for some $0 \leq x < W$ rooted at the leaf node of the edge with weight $W - x$. For $h > 1$, T consists of an $(1, W, a)$-tree whose two leaves are the roots of two $(h - 1, W/a, a)$-trees T_0, T_1. We shall denote an (h, W, a)-tree constructed in this way by $T = \langle T_0, T_1, x \rangle$ An example for $h = 3$ can be seen in Figure 1. Note that the case $a = 1$ simply corresponds to the (h, W)-trees defined in [39].

It is easy to see that an (h, W, a)-tree has 2^h leaves and $3 \cdot 2^h - 2$ nodes. Further, it is straightforward to see that, if u, v are leaves in an (h, W, a)-tree $T = \langle T_0, T_1, x \rangle$, then

$$\mathrm{dist}_T(u, v) = \begin{cases} 2W\frac{a^{-1} - a^{-h}}{1 - a^{-1}} + 2x, & \text{if } u \in T_0 \text{ and } v \in T_1, \text{ or vice versa,} \\ \mathrm{dist}_{T_i}(u, v), & \text{if } u, v \in T_i \text{ for some } i = 0, 1. \end{cases} \tag{2}$$

[3] Note that their exposition has some minor errors as pointed out (and corrected) in [43].

Leaf distance labeling schemes. In the following we shall consider *leaf distance labeling schemes* for the family of (h, W, a)-trees: that is, distance labeling schemes where only the leaves in a tree need to be labeled, and where only leaf labels can be given as input to the decoder. Since an ordinary distance labeling scheme obviously can be used only for leaves, any lower bound on worst-case label sizes for a leaf distance labeling scheme is also a lower bound for an ordinary distance labeling scheme. We denote by $g(h, W, a)$ the smallest number of labels needed by an optimal leaf distance labeling scheme to label all (h, W, a)-trees.

▶ **Lemma 7.** *For all $h \geq 1$ and $W \geq 2$, $g(h, W, a)^2 \geq W g(h-1, W^2/a^2, a^2)$.*

Proof. Fix an optimal leaf distance labeling scheme σ which produces exactly $g(h, W, a)$ distinct labels for the family of (h, W, a)-trees. For leaves u and v in an (h, W, a)-tree, denote by $l(u)$ and $l(v)$, respectively, the labels assigned by σ. For $x = 0, \ldots, W-1$, let $S(x)$ be the set consisting of pairs of labels $(l(u), l(v))$ for all leaves $u \in T_0$ and $v \in T_1$ in all (h, W, a)-trees $T = \langle T_0, T_1, x\rangle$.

The sets $S(x)$ and $S(x')$ are disjoint for $x \neq x'$, since every pair of labels in $S(x)$ uniquely determines x due to (2). Letting $S = \bigcup_{x=0}^{W-1} S(x)$, we therefore have $|S| = \sum_{x=0}^{W-1} |S(x)|$. Since S contains pairs of labels produced by σ from leaves in (h, W, a)-trees , we clearly also have $|S| \leq g(h, W, a)^2$, and hence it only remains to prove that $|S| \geq W g(h-1, W^2/a^2, a^2)$, which we shall do by showing that $|S(x)| \geq g(h-1, W^2/a^2, a^2)$ for all x.

The goal for the rest of the proof is therefore to create a leaf distance labeling scheme for $(h-1, W^2/a^2, a^2)$-trees using only labels from the set $S(x)$ for some fixed x. So let x be given and consider an $(h-1, W^2/a^2, a^2)$-tree T'. Let $V = W/a$. From T' we shall construct an $(h-1, V, a)$-tree $\phi_i(T')$ for $i = 0, 1$ such that every leaf node v in T' corresponds to nodes $\phi_i(v)$ in $\phi_i(T')$ for $i = 0, 1$. The trees $\phi_i(T')$ are defined as follows. If $h = 1$, so that T' consists of a single node, then $\phi_i(T') = T'$ for $i = 0, 1$. If $h > 1$, then T' is in the form $T' = \langle T'_0, T'_1, y\rangle$ for some $0 \leq y < V^2$. We can write y in the form $y = y_0 + y_1 V$ for uniquely determined y_0, y_1 with $0 \leq y_0, y_1 < V$. For $i = 0, 1$, we recursively define $\phi_i(T') = \langle \phi_i(T'_0), \phi_i(T'_1), y_i\rangle$. Thus, $\phi_i(T')$ is an $(h-1, V, a)$-tree that is similar to T' but where we replace the top edge weight y by edge weights y_i and, recursively, do the same for all $(h-2, V^2/a^2, a^2)$-subtrees. Note also that the corresponding edge weight $V^2 - y$ in T' automatically is replaced by the edge weight $V - y_i$ in $\phi_i(T')$ in order for $\phi_i(T')$ to be an $(h-1, V, a)$-tree.

Denote by $\phi_i(v)$ the leaf in $\phi_i(T')$ corresponding to the leaf v in T'.

Consider now the (h, W, a)-tree $T = \langle \phi_0(T'), \phi_1(T'), x\rangle$. Every leaf v in T' corresponds to the leaves $\phi_0(v), \phi_1(v)$ in T where $\phi_i(v) \in \phi_i(T')$ for $i = 0, 1$. Using formula (2) for the distances in T', it is straightforward to see that

$$\mathrm{dist}_{T'}(u, v) = \big(\mathrm{dist}_{\phi_0(T')}(\phi_0(u), \phi_0(v)) \bmod (2V)\big) + V\, \mathrm{dist}_{\phi_1(T')}(\phi_1(u), \phi_1(v)). \tag{3}$$

We can now apply the leaf distance labeling scheme σ to T and obtain a label for each leaf node in T. In particular, the pair of leaves $(\phi_0(v), \phi_1(v))$ corresponding to a node v in T' will receive a pair of labels. We use this pair to label v in T', whereby we have obtained a labeling of the leaves in T' with labels from $S(x)$. Using the formula in (3) we can construct a decoder that can compute the distance between two nodes in T' using these labels alone, and hence we have obtained a leaf distance labeling scheme for $(h-1, V^2, a^2)$-trees using only labels from $S(x)$ as desired. ◀

▶ **Lemma 8.** *For all $h \geq 1$ and $W \geq 2$, $g(h, W, a) \geq \frac{W^{h/2}}{a^{h(h-1)/4}}$.*

Proof. The proof is by induction on h. For $h = 1$ we note that an $(0, W, a)$-tree has only one node, so that $g(0, W^2/a^2, a^2) = 1$. Lemma 7 therefore yields $g(1, W, a)^2 \geq W$ from which

it follows that $g(1,W,a) \geq \sqrt{W}$. The lemma therefore holds for $h=1$. Now let $h>1$ and assume that the lemma holds for $h-1$. Lemma 7 and the induction hypothesis now yield

$$g(h,W,a)^2 \;\geq\; Wg(h-1,W^2/a^2,a^2) \;\geq\; W\frac{(W^2/a^2)^{(h-1)/2}}{a^{2(h-1)(h-2)/4}} \;=\; \frac{W^h}{a^{h(h-1)/2}}$$

from which it follows that $g(h,W,a) \geq \frac{W^{h/2}}{a^{h(h-1)/4}}$ as desired. ◀

The previous lemma implies that any (leaf and hence also ordinary) distance labeling scheme for (h,W,a)-trees must have labels with worst-case length at least $\frac{h}{2}(\log W - \frac{h-1}{2}\log a) = \frac{1}{2}h\log W - \frac{1}{4}h^2\log a + \frac{1}{4}h\log a$. Since the number of nodes in such a tree is $n = 3\cdot 2^h - 2$, it follows that $h = \log(n+2) - \log 3$, and hence that $\log n - 2 \leq h \leq \log n$ for sufficiently large n. From this we see that the worst case label length is at least

$$\frac{1}{2}\log n\log W - \frac{1}{4}\log n(\log n - 1)\log a - \log W - \frac{1}{2}\log a.$$

In the case where $a=1$, we retrieve the bound of $\frac{1}{2}\log n\log W - \log W$ obtained in [38]. It seems that larger values of a only makes the above result weaker, but the the real strength of the above becomes apparent when we switch to the unweighted version of (h,W,a)-trees, in which we replace weighted edges by paths of similar lengths. Note that a distance labeling scheme for the family of unweighted (h,W,a)-trees can be used as a distance labeling scheme for the weighted (h,W,a)-trees, and hence any lower bound in the weighted version automatcially becomes a lower bound in the unweighted version.

The number of nodes n in an *unweighted* (h,W,a)-tree is upper bounded by

$$n \leq 2W + 2\cdot 2W/a + 2^2\cdot 2W/a^2 + \cdots + 2^{h-1}\cdot 2W/a^{h-1} + 1$$

In the case $a=2$, we get $n \leq 2Wh+1$.

▶ **Theorem 9.** *Any distance labeling scheme for unweighted $(h,W,2)$-trees, and hence also for general trees, has a worst-case label size of at least $\frac{1}{4}\log^2 n - O(\log n)$.*

Proof. Choose the largest integer h with $2\cdot 2^h h + 1 \leq n$, and note that we must have $h \geq \log n - O(\log\log n)$. Set $W = 2^h$ and consider the family of $(h,W,2)$-trees, which is a subfamily of the family of trees with n nodes. From Lemma 8 it therefore follows that the worst-case label length is

$$\frac{1}{2}h\log W - \frac{1}{4}h^2 + \frac{1}{4}h = \frac{1}{4}h^2 + \frac{1}{4}h = \frac{1}{4}\log^2 n + \frac{1}{4}\log n - O(\log\log n).$$ ◀

6 Approximate distances in trees

In this section we present a $(1+\varepsilon)$-stretch distance labeling schemes with labels of size $O(\log n)$.

▶ **Theorem 10.** *For constant $\varepsilon > 0$, $(1+\varepsilon)$ stretch distance labeling schemes for trees use $\Theta(\log n)$ bits.*

Proof. As in the case of exact distances, we will create labels of size $O(\log n)$ bits that contain the extended NCA labels from Lemma 5 as well as distroot. We will also be using the formula in (1). However we can not afford to store exact distance to each apex ancestor. Even directly storing an 2-approximate distance to each apex ancestor would require $\log n\log\log n$ bits. Instead we show how to compactly represent all the $(1+\varepsilon)$-approximate distances to

light ancestors for a node using a total of $O(\log n)$ bits, and show how to use this to obtain a $(1+2\varepsilon)$-approximation.

Let $w = \text{nca}(u,v)$ and assume $w \notin \{u,v\}$, since otherwise we can compute the exact distance using only distroot. Suppose we know a $(1+\varepsilon)$-approximation α of $\text{dist}(w,v)$ for some $\varepsilon \geq 0$. That is,

$$\text{dist}(w,v) \leq \alpha \leq (1+\varepsilon)\,\text{dist}(w,v). \tag{4}$$

Define $\tilde{d} = \text{distroot}(u) - \text{distroot}(v) + 2\alpha$. First we show that $\tilde{d}$ is a $(1+2\varepsilon)$-approximation of $\text{dist}(u,v)$. Next we show how to represent all the $(1+\varepsilon)$-approximate distances to light ancestors for a node using a total of $O(\log n)$ bits. Together with formula (1), these two facts prove that we can compute $(1+2\varepsilon)$-stretch distances between any pair of nodes with labels of size $O(\log n)$. To prove the theorem, we can then simple replace ε by $\frac{1}{2}\varepsilon$.

To see that $\tilde{d}$ is a $(1+2\varepsilon)$-approximation of $\text{dist}(u,v)$, first note that

$$\tilde{d} = \text{distroot}(u) - \text{distroot}(v) + 2\alpha \geq \text{distroot}(u) - \text{distroot}(v) + 2\,\text{dist}(w,v) = \text{dist}(u,v).$$

For the other inequality, note that

$$\begin{aligned}
\tilde{d} &= \text{distroot}(u) - \text{distroot}(v) + 2\alpha \\
&\leq \text{distroot}(u) - \text{distroot}(v) + 2(1+\epsilon)\,\text{dist}(w,v) \\
&= \text{distroot}(u) - (\text{distroot}(v) - \text{dist}(w,v)) + (1+2\epsilon)\,\text{dist}(w,v) \\
&= \text{distroot}(u) - \text{distroot}(w) + (1+2\epsilon)\,\text{dist}(w,v) \\
&= \text{dist}(u,w) + (1+2\epsilon)\,\text{dist}(w,v) \\
&\leq (1+2\epsilon)\,(\text{dist}(u,w) + \text{dist}(w,v)) \\
&= (1+2\epsilon)\,\text{dist}(u,v)\ .
\end{aligned}$$

It now only remains to show that we can compactly store all the approximate distances α to light ancestors using $O(\log n)$ bits space.

We use a heavy light path decomposition of the tree. For each node v we can save a 2 approximate distance to all its k proper light ancestors as follows. Let S be a binary string initially with k zeros. Before each 0 we now insert 1s such that, if we have j 1s in total from the beginning of S and to the i'th 0, then the distance to the ith light ancestor a of v satisfies that $2^{j-1} \leq \text{dist}(v,a) \leq 2^j$. This is the same as traversing the tree bottom-up from v and, for each light node encountered on the way, adding a 0 and each time the distance doubles adding a 1. The number of 0s equal the number of light nodes which is at most $\log n$, and the number of 1s is also limited by $\log n$ since n is the maximum distance in the tree. In total the length of S is at most $2\log n$.

Using the $O(\log n)$ bits label from Lemma 5 we can tell if one node is an ancestor of another, and if not which one has a light ancestor a that is a child of their nearest common ancestor w. In addition, we can determine the total number i of light ancestors up to a. This means that we can compute j, and hence the 2-approximation $j-1$, as the number of 1's in S until the i'th 0.

We have now obtained a 2-approximation with labels of size $O(\log n)$. We can improve this to a $(1+\varepsilon)$-approximation by setting a 1 in S each time the distance increases with $1+\varepsilon$ rather than 2. This will increase the label size with a constant factor $\frac{1}{\log(1+\varepsilon)}$.

This proves that there is a $(1+\varepsilon)$-stretch distance labeling scheme with $O(\log n)$ bit label length. To complete the proof of the theorem, we note that, given any $(1+\varepsilon)$-stretch distance scheme, we can always distinguish nodes (since identical nodes have distance 0), which means that we always need at least n different labels, and hence labels of size at least $\log n$ bits. ◀

Abstract

An adjacency labeling scheme labels the n nodes of a graph with bit strings in a way that allows, given the labels of two nodes, to determine adjacency based only on those bit strings. Though many graph families have been meticulously studied for this problem, a non-trivial labeling scheme for the important family of power-law graphs has yet to be obtained. This family is particularly useful for social and web networks as their underlying graphs are typically modelled as power-law graphs. Using simple strategies and a careful selection of a parameter, we show upper bounds for such labeling schemes of $\tilde{O}(\sqrt[\alpha]{n})$ for power law graphs with coefficient α, as well as nearly matching lower bounds. We also show two relaxations that allow for a label of logarithmic size, and extend the upper-bound technique to produce an improved distance labeling scheme for power-law graphs.

1 Introduction

A body of work on large, real-world networks deals with the difficulties of storing them and effectively resolving queries on them; examples of techniques are compression [14, 13] and dissemination of the underlying graphs of these networks over several machines [35, 52, 54]. A different approach to storing information about the graph is to disseminate the structural information of the graph to its vertices and store it locally. This *peer-to-peer* strategy allows inferring the graph's local topology using only local information stored in each vertex without using costly access to large, global data structures. In particular, it can be useful to address privacy concerns and ensure a high survivability rate [18].

We posit that a useful tool for such a peer-to-peer strategy is the notion of a *labeling scheme*: an algorithm that assigns a bit string–a *label*–to each vertex so that a query between

any two vertices can be deduced solely from their respective labels. Labeling schemes are extremely well-studied in the algorithmic literature [8, 17, 20, 27, 32, 30, 37, 38, 40, 41, 49]; the main objective is to minimize the *maximum label size*: the maximum number of bits used in a label of any vertex. Among their applications are XML search engines [25], mapping services [1], and internet routing [43].

One class of graphs extensively used for modelling real-world networks is *power-law graphs*: roughly, n-vertex graphs where the number of vertices of degree k is proportional to n/k^α for some positive α. Power-law graphs (also called scale-free graphs in the literature) have been used to model the Internet AS-level graph [50, 4], and many other types of network (see, e.g., [24, 47] for overviews). The adequacy of fit of power-law graph models to actual data, as well as the empirical correctness of the conjectured mechanisms giving rise to power-law behaviour, have been subject to criticism (see, e.g., [2, 24]). In spite of such criticism, and because their degree distribution affords a reasonable approximation of the degree distribution of many networks, the class of power-law graphs remains a popular tool in network modelling. In this paper, we perform the first theoretical and practical study of adjacency labeling schemes for classes of graphs whose statistical properties–in particular their *degree distribution*–more closely resemble that of real-world networks.

1.1 Our contributions

Our contributions are:

A discrete and simple characterisation of power-law graphs

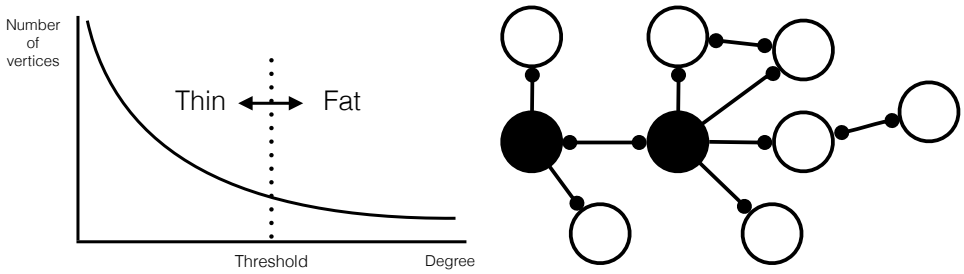
An n-vertex graph is power-law if the number of its vertices of degree k is proportional to n/k^α for some positive α. To solidify this somewhat vague definition, numerous probabilistic and deterministic definitions of power-law graphs are given in the literature. In Sec. 3, we define and prove useful properties for two simple families of graphs, $\mathcal{P}_h$ and $\mathcal{P}_l$, where $\mathcal{P}_h$ contains and $\mathcal{P}_l$ is contained by the standard definitions of power-law graphs in the literature, including recent ones [16]. We use $\mathcal{P}_h$ and $\mathcal{P}_l$ to study upper and lower bounds respectively.

An $O(\sqrt[\alpha]{n}(\log n)^{1-1/\alpha})$ adjacency labeling scheme

In Sec. 4, we describe our labeling scheme, which is based on two ideas: (i) a labeling *strategy* that partitions the vertices of G into high ("fat") and low degree ("thin") vertices based on a threshold degree, and (ii) a threshold *prediction* that depends only on the coefficient α of a power-law curve fitted to the degree distribution of G. These ideas are illustrated in Figure 1. Using the same ideas, we get an asymptotically near-tight $O(\sqrt{n \log n})$ adjacency labeling scheme for sparse graphs. As real-world power-law graphs have $2 \leq \alpha \leq 3$ and rarely exceed 10^{10} vertices, this implies labels of the order of $10^4 - 10^5$ bits. That, and the simplicity of our labeling scheme suggests that our labeling schemes may be appealing in practice. To stress this point, we offer an experimental evaluation of our labeling scheme in the full version of the paper.

A lower bound of $\Omega(\sqrt[\alpha]{n})$ for any adjacency labeling scheme

In Sec. 5, We use our restrictive subclass of power-law graphs and show that it requires label size $\Omega(\sqrt[\alpha]{n})$ for n-vertex graphs. This lower bound shows that our upper bound above is asymptotically optimal, bar a $(\log n)^{1-1/\alpha}$ factor. By the connections between adjacency labeling schemes and universal graphs, we also obtain upper and lower bounds for induced



(a) demonstrates the threshold assignment

(b) demonstrates the label assignment, in which fat (black) nodes do not store adjacency to thin (white) nodes

Figure 1 Two illustrations of the main idea.

universal graphs for power-law graphs. We also show, in Sec. 6, two scenarios in which this lower bound can be bypassed.

A $o(n)$ distance labeling scheme

In Sec. 7, we demonstrate the usefulness of our strategy to arrive at a $o(n)$ distance labeling scheme for power-law graphs. Our labeling scheme is designed to outperform competing labeling schemes for small distances, in accordance with Chung and Lu's findings [22] on the small expected diameter of power-law graphs.

1.2 Related work

Adjacency labeling schemes for key graph families are by now well understood. General graphs require a label size of $n/2 + O(1)$ [48, 8], while trees, planar graphs, and bounded degree graphs enjoy labels of logarithmic size [9, 30, 3]. Adjacency labeling schemes are also tightly coupled with the graph-theoretic concept of induced universal graphs, in which one aims to find the smallest N where there exist a graph of N vertices which contains all graphs of a particular graph family $\mathcal{F}_n$ of n vertices as induced subgraphs. It was shown [36] that an $f(n) \log n$ adjacency labeling scheme for $\mathcal{F}_n$ constructs an induced universal graph for this family of $2^{f(n)}$ vertices. In the context of sparse graphs, a body of work on universal graphs[1] for this family was investigated both by Babai et al. [11] and by Alon and Asodi [5].

Routing labeling schemes for power-law graphs have been investigated by Brady and Cowen [17], and by Chen et al. [21]. Labeling schemes for properties other than adjacency have been investigated for various classes of graphs, e.g., distance [32], and flow [37]. Dynamic labeling schemes were studied by Korman and Peleg [38, 40, 41] and recently by Dahlgaard et. al [27]. Experimental evaluations for some labeling schemes for various properties on general graphs have been performed by Caminiti et. al [20], Fischer [29] and Rotbart et. al [49].

In the context of distributed graph computing systems, a somewhat related paradigm of computation is the vertex centric computing model "think like a vertex". In this model each vertex exchanges messages only with nearby vertices, to improve locality and simplify the design and implementation of such systems. Among the numerous systems proposed are Pregel [45], Power-Graph [35] and GraphLab [44]. For a recent survey on the topic see [46].

[1] A graph that contains each graph from the graph family as a subgraph, not necessarily induced.

2 Preliminaries

Throughout the paper we consider n-vertex, undirected graphs. For a real $c > 0$, a graph is *c-sparse* if it has at most cn edges and *sparse* if it is c-sparse for some constant c. For $0 < c \leq n-1$, the set of c-sparse graphs with n vertices is denoted by $\mathcal{S}_{c,n}$. If $\mathcal{F}$ is a set of graphs, $\mathcal{F}_n$ denotes the subset of graphs in $\mathcal{F}$ having exactly n vertices. The degree of a vertex v in a graph is denoted by $\Delta(v)$, and for non-negative integers k, the set of vertices in a graph G of degree k is denoted by V_k. The length of a binary string $x \in \{0,1\}^*$ is denoted by $|x|$.

Let $\mathcal{F}$ be a set of graphs. An *adjacency labeling scheme* (from hereon just *labeling scheme*) for $\mathcal{F}$ is a pair consisting of an *encoder* and a *decoder*. The encoder is an algorithm that receives $G \in \mathcal{F}$ as input and outputs a bit string $\mathcal{L}(v) \in \{0,1\}^*$, called the *label* of v, for each vertex v in G. The decoder is an algorithm that receives any two labels $\mathcal{L}(v), \mathcal{L}(u)$ as input and outputs `true` if u and v are adjacent in G and `false` otherwise. Note that the graph G is not an input to the decoder. The *size* of a labeling scheme is the map $\text{size} : \mathbb{N} \longrightarrow \mathbb{N}$ such that $\text{size}(n)$ is the maximum length of any label assigned by the encoder to any vertex in any graph $G \in \mathcal{F}_n$. The *degree distribution* of a graph $G = (V, E)$ is the mapping $\text{ddist}_G(k) : \mathbb{N}_0 \longrightarrow \mathbb{Q}$ defined by $\text{ddist}_G(k) := \frac{|V_k|}{n}$.

3 Defining Power-Law Graphs

In the literature *power-law* graphs are usually defined as the class of n vertex graphs G such that $\text{ddist}_G(k)$ is proportional to $k^{-\alpha}$ for some real number $\alpha > 1$. Ideally, and ignoring rounding, $\text{ddist}_G(k) = Ck^{-\alpha}$ for all k for constant C. As the degree distribution of a graph must be a probability distribution, we have $\sum_{k=1}^{\infty} Ck^{-\alpha} = C\sum_{k=1}^{\infty} k^{-\alpha} = 1$, hence $C = 1/\zeta(\alpha)$ where ζ is the Riemann zeta function. However, in the literature, concessions are usually made that relax the restrictions on $\text{ddist}_G(k)$, for example that the power-law property need only hold for high-degree vertices ("above a cutoff"), or that $\text{ddist}_G(k)$ is only *approximately* equal to $Ck^{-\alpha}$, with some approximation error that falls off with n. To ensure that our results hold for all these variations of power-law graphs, we define two families of graphs $\mathcal{P}_h$ and $\mathcal{P}_l$ with $\mathcal{P}_l \subsetneq \mathcal{P}_h$. Family $\mathcal{P}_h$ is rich enough to contain the graphs whose degree distribution is approximately, or perfectly, power-law distributed, and our upper bound on the label size for our labeling scheme holds for any graph in $\mathcal{P}_h$. Family $\mathcal{P}_l$ is used to show our lower bound and is restrictive enough that most definitions of power-law graph occurring in the literature will contain it.

In the following, let $i_1 = \Theta(\sqrt[\alpha]{n})$ be the smallest integer such that $\lfloor Cn/i_1^{\alpha} \rfloor \leq 1$, and let $C' \geq (\frac{C}{\alpha-1} + \frac{i_1}{\sqrt[\alpha]{n}} + 5)^{\alpha} + \frac{C}{\alpha-1}$ be a constant; we shall use C' in the remainder of the paper.

▶ **Definition 1.** Let $\alpha > 1$ be a real number and let $\chi : \mathbb{N} \to \mathbb{N}$ be a function. $\mathcal{P}_{h,\chi,\alpha}$ is the family of graphs G such that if $n = |V(G)|$ then for all integers k between $\chi(n)$ and $n-1$, $\sum_{i=k}^{n-1} |V_i| \leq C'(\frac{n}{k^{\alpha-1}})$. We shall usually suppress χ and α, writing merely $\mathcal{P}_h$.

The function χ captures the notion of a cutoff as defined in [24, Sec. 3.1]; the intuition is that for an n-vertex graph the power-law distribution need only apply for nodes of degree higher than $\chi(n)$, rather than for all degrees. Setting $\chi(n) = 1$ corresponds to the case where the entire range of degrees follows a power-law distribution, hence even for small values of $\chi(n)$, $\mathcal{P}_h$ morally contains all graphs with power-law degree distribution. We will later prove upper bounds that hold for *all* χ bounded from above by some function; in particular for the upper bound for adjacency labeling schemes, the bound holds for $\chi(n)$ as high as $\sqrt[\alpha]{n/\log n}$.

The class $\mathcal{P}_l$ contains graphs where the number of vertices of degree k must be $C\frac{n}{k^\alpha}$ rounded either up or down and the number of vertices of degree k is non-increasing with k. Note that the function $k \mapsto C\frac{1}{k^\alpha}$ is strictly decreasing.

▶ **Definition 2.** Let $\alpha > 1$ be a real number and let $C = 1/\zeta(\alpha)$ where ζ is the Riemann zeta function. $\mathcal{P}_{l,\alpha}$ is the set of graphs $G = (V, E)$ such that

1. $\lfloor Cn \rfloor - i_1 - 1 \leq |V_1| \leq \lceil Cn \rceil$,
2. $\lfloor C\frac{n}{2^\alpha} \rfloor \leq |V_2| \leq \lceil C\frac{n}{2^\alpha} \rceil + 1$,
3. for every i with $3 \leq i \leq n$: $|V_i| \in \{\lfloor C\frac{n}{i^\alpha} \rfloor, \lceil C\frac{n}{i^\alpha} \rceil\}$, and
4. for every i with $2 \leq i \leq n-1$: $|V_i| \geq |V_{i+1}|$.

We usually suppress α, writing just $\mathcal{P}_l$.

Note that we allow slightly more noise in the sizes of V_1 and V_2 than in the remaining sets; without it, it seems tricky to prove a better lower bound than $\Omega(\sqrt[\alpha+1]{n})$ on label sizes.

We show the following properties of $\mathcal{P}_l$.

▶ **Proposition 1.** *The maximum degree in an n-vertex graph in $\mathcal{P}_l$ is at most $\left(\frac{C}{\alpha-1} + 2\right)\sqrt[\alpha]{n} + i_1 + 3 = \Theta(\sqrt[\alpha]{n})$.*

Proof. Let $n > 0$ be an integer and let $k' = \lfloor \sqrt[\alpha]{n} \rfloor$. Furthermore, let $S_{k'} = \sum_{i=1}^{k'} |V_i|$, that is $S_{k'}$ is the number of vertices of degree at most k'. Let $S^-_{k'} = (\sum_{i=1}^{k'} \lfloor Cni^{-\alpha} \rfloor) - i_1 - 1$. Then $S_{k'} \geq S^-_{k'}$. We now bound $S^-_{k'}$ from below. For every i with $1 \leq i \leq k'$,

$$\begin{aligned}
S^-_{k'} + k' &= -i_1 - 1 + \sum_{i=1}^{k'} \left(\lfloor Cni^{-\alpha} \rfloor + 1 \right) \geq -i_1 - 1 + \sum_{i=1}^{k'} Cni^{-\alpha} = -i_1 - 1 + Cn \sum_{i=1}^{k'} i^{-\alpha} \\
&\geq n \left(1 - C \sum_{i=k'+1}^{\infty} i^{-\alpha} \right) - i_1 - 1 \geq n \left(1 - C \int_{k'}^{\infty} x^{-\alpha} dx \right) - i_1 - 1 \\
&= n \left(1 - C \left[\frac{1}{\alpha - 1} x^{-\alpha+1} \right]_{\infty}^{k'} \right) - i_1 - 1 = n \left(1 - \frac{C}{\alpha - 1} \left(\lceil \sqrt[\alpha]{n} \rceil \right)^{-\alpha+1} \right) - i_1 - 1 \\
&\geq n \left(1 - \frac{C}{\alpha - 1} \left(\sqrt[\alpha]{n} \right)^{-\alpha+1} \right) - i_1 - 1 = n - \frac{Cn}{\alpha - 1} n^{-1+\frac{1}{\alpha}} - i_1 - 1 \\
&= n - \frac{C}{\alpha - 1} \sqrt[\alpha]{n} - i_1 - 1,
\end{aligned}$$

giving $S_{k'} \geq S^-_{k'} \geq n - \frac{C}{\alpha-1}\sqrt[\alpha]{n} - \lceil \sqrt[\alpha]{n} \rceil - i_1 - 1$. There are thus at most $\frac{C}{\alpha-1}\sqrt[\alpha]{n} + \lfloor \sqrt[\alpha]{n} \rfloor + i_1 + 1$ vertices of degree strictly more than $k' = \lceil \sqrt[\alpha]{n} \rceil$. Since for every $1 \leq i \leq n-1$: $|V_i| \geq |V_{i+1}|$, it follows that the maximum degree of any graph in $\mathcal{P}_l$ is at most $\left(\frac{C}{\alpha-1} + 2\right)\sqrt[\alpha]{n} + i_1 + 3$. ◀

▶ **Proposition 2.** *For $\alpha > 2$, all graphs in $\mathcal{P}_l$ are sparse.*

Proof. By Proposition 1, the maximum degree of an n-vertex graph in $\mathcal{P}_l$ graph is at most $k' \triangleq \left(\frac{C}{\alpha-1} + 2\right)\sqrt[\alpha]{n} + i_1 + 3$, whence the total number of edges is at most $\frac{1}{2}\sum_{k=1}^{k'} k|V_k|$. By definition, $|V_k| \leq \lceil \frac{Cn}{k^\alpha} \rceil \leq \frac{Cn}{k^\alpha} + 1$ for $k \neq 2$ and $|V_2| \leq \lceil \frac{Cn}{2^\alpha} \rceil + 1$, and thus

$$\begin{aligned}
\frac{1}{2} \sum_{k=1}^{k'} k|V_k| &\leq 1 + \frac{1}{2} \sum_{k=1}^{k'} k \left(\frac{Cn}{k^\alpha} + 1 \right) \leq 1 + \frac{k'(k'+1)}{4} + Cn \sum_{k=1}^{\infty} k^{-\alpha+1} \\
&= O(n^{2/\alpha}) + Cn\zeta(\alpha - 1) = O(n).
\end{aligned}$$

◀

▶ **Proposition 3.** *For any χ and $\alpha > 1$, $\mathcal{P}_{l,\alpha} \subseteq \mathcal{P}_{h,\chi,\alpha}$.*

Proof. Let $d = \lfloor (\frac{C}{\alpha-1} + 2)\sqrt[\alpha]{n} + i_1 + 3 \rfloor$. For any graph in $\mathcal{P}_l$ with n vertices and for any k, $|V_k| \leq Ck^{-\alpha}n + 1$ and by Proposition 1, $|V_k| = 0$ when $k > d$.

Let k be an arbitrary integer between $\chi(n)$ and $n-1$. We need to show that $\sum_{i=k}^{n-1} |V_i| \leq C'(\frac{n}{k^{\alpha-1}})$. It suffices to show this for $k \leq d$. We have:

$$\begin{aligned}
\sum_{i=k}^{n-1} |V_i| &\leq \sum_{i=k}^{d} (Ci^{-\alpha}n + 1) = d - k + 1 + Cn \sum_{i=k}^{d} i^{-\alpha} \\
&\leq \left(\frac{C}{\alpha - 1} + \frac{i_1}{\sqrt[\alpha]{n}} + 5 \right) \sqrt[\alpha]{n} + Cn \int_k^d x^{-\alpha} dx \\
&\leq \left(\frac{C}{\alpha - 1} + \frac{i_1}{\sqrt[\alpha]{n}} + 5 \right) \sqrt[\alpha]{n} + Cn \left[\frac{1}{\alpha - 1} x^{-\alpha+1} \right]_{\infty}^{k} \\
&\leq \left(\left(\frac{C}{\alpha - 1} + \frac{i_1}{\sqrt[\alpha]{n}} + 5 \right) \left(\frac{\sqrt[\alpha]{n} d^{\alpha-1}}{n} \right) + \frac{C}{\alpha - 1} \right) nk^{-\alpha+1} \\
&\leq \left(\frac{C}{\alpha - 1} + \frac{i_1}{\sqrt[\alpha]{n}} + 5 \right) \left(\frac{C}{\alpha - 1} + \frac{i_1}{\sqrt[\alpha]{n}} + 5 \right)^{\alpha-1} nk^{-\alpha+1} + \left(\frac{C}{\alpha - 1} \right) nk^{-\alpha+1} \\
&\leq C' nk^{-\alpha+1},
\end{aligned}$$

as desired. ◀

3.1 Comparison to other deterministic models

Numerous probabilistic and deterministic definitions of power-law graphs are given in the literature. A recent deterministic model, called shifted power-law distribution [28] has recently proven to capture a vast number of such definitions, both in theory and experimentally in [16]. We show that our definition of $\mathcal{P}_h$ contains graphs that adhere to the model, which is defined as follows. Let $c_1 > 0$ be a constant. A graph G is *power-law bounded* for parameters $\alpha > 1$ and $t \geq 0$ if for every integer $d \geq 0$, the number of vertices of G of degree in $[2^d, 2^{d+1})$ is at most

$$c_1 n (t+1)^{\alpha-1} \sum_{i=2^d}^{2^{d+1}-1} (i+t)^{-\alpha}.$$

As experimentally verified in [16], the value of t is typically very small. If $t = O(1)$, the bound above becomes $O(n \sum_{i=2^d}^{2^{d+1}-1} i^{-\alpha})$. In this case, our family $\mathcal{P}_h(\chi, \alpha)$ is rich enough to contain these power-law bounded graphs for sufficiently large C' and any choice of χ and α. This follows since for any power-law bounded graph with n vertices and any integer k between 1 and $n-1$, $\sum_{i=k}^{n-1} |V_i| = O(\sum_{d=\lfloor \lg k \rfloor}^{\lceil \lg(n-1) \rceil} n \sum_{i=2^d}^{2^{d+1}-1} i^{-\alpha}) = O(\frac{n}{k^{\alpha-1}})$. Thus our upper bound also applies to power-law bounded graphs. It is possible to extend our upper bound to super-constant t where the bound is stronger the smaller t is; we omit the details. Conversely, our family $\mathcal{P}_l$ is restrictive enough that $\mathcal{P}_l$ is contained in the family of power-law bounded graphs when $t = O(1)$, and the lower bound we derive thus also holds in that setting.

4 The Labeling Schemes

We now construct algorithms for labeling schemes for c-sparse graphs and for the family $\mathcal{P}_h$. Both labeling schemes partition vertices into *thin* vertices which are of low degree and *fat*

vertices of high degree. The *degree threshold* for the scheme is the lowest possible degree of a fat vertex. We start with c-sparse graphs.

▶ **Theorem 3.** *There is a* $\sqrt{2cn\log n} + 2\log n + 1$ *labeling scheme for* $\mathcal{S}_{c,n}$.

Proof. Let $G = (V, E)$ be an n-vertex c-sparse graph. Let $\tau(n)$ be the degree threshold for n-vertex graphs; we choose $\tau(n)$ below. Let k denote the number of fat vertices of G, and assign each fat vertex a unique identifier between 1 and k. Each thin vertex is given a unique identifier between $k+1$ and n.

For a $v \in V$, the first part of the label $\mathcal{L}(v)$ is a single bit indicating whether v is thin or fat followed by a string of $\log n$ bits representing its identifier. If v is thin, the last part of $\mathcal{L}(v)$ is the concatenation of the identifiers of the neighbors of v. If v is fat, the last part of $\mathcal{L}(v)$ is a *fat bit string* of length k where the ith bit is 1 iff v is incident to the (fat) vertex with identifier i.

Decoding a pair $(\mathcal{L}(u), \mathcal{L}(v))$ is straightforward: if one of the vertices, say u, is thin, u and v are adjacent iff the identifier of v is part of the label of u. If both u and v are fat then they are adjacent iff the ith bit of the fat bit string of $\mathcal{L}(u)$ is 1 where i is the identifier of v. Both decoding processes can be computed in $O(\log n)$ time using standard assumptions.

Since $|E| \leq cn$, we have $k \leq 2cn/\tau(n)$. A fat vertex thus has label size $1 + \log n + k \leq 1 + \log n + 2cn/\tau(n)$ and a thin vertex has label size at most $1 + \log n + \tau(n)\log n$. To minimize the maximum possible label size, we solve $2cn/x = x\log n$. Solving this gives $x = \sqrt{2cn/\log n}$ and setting $\tau(n) = \lceil x \rceil$ gives a label size of at most $1 + \log n + (\sqrt{2cn/\log n} + 1)\log n \leq 1 + 2\log n + \sqrt{2cn\log n}$. ◀

By Proposition 2, graphs in $\mathcal{P}_l$ are sparse for $\alpha > 2$. This gives a label size of $O(\sqrt{n\log n})$ with the labeling scheme in Theorem 3. We now show that this label can be significantly improved, by constructing a labeling scheme for $\mathcal{P}_h$ which contains $\mathcal{P}_l$.

▶ **Theorem 4.** *There is a* $\sqrt[\alpha]{C'n}(\log n)^{1-1/\alpha} + 2\log n + 1$ *labeling scheme for* $\mathcal{P}_h$.

Proof. The proof is very similar to that of Theorem 3. We let $\tau(n)$ denote the degree threshold. If we pick $\tau(n) \geq \sqrt[\alpha]{n/\log n}$ then by Definition 1 there are at most $C'n/\tau(n)^{\alpha-1}$ fat vertices. Defining labels in the same way as in Theorem 3 gives a label size for thin vertices of at most $1 + \log n + \tau(n)\log n$ and a label size for fat vertices of at most $1 + \log n + C'n/\tau(n)^{\alpha-1}$. We minimize by solving $x\log n = C'n/x^{\alpha-1}$, giving $x = \sqrt[\alpha]{C'n/\log n}$. Setting $\tau(n) = \lceil x \rceil$ gives a label size of at most $\sqrt[\alpha]{C'n}(\log n)^{1-1/\alpha} + 2\log n + 1$. ◀

4.1 A labeling scheme for random graphs

There are schemes using randomness to "grow" graphs that, with high probability, have an approximate power-law degree distribution for a range of degrees (see e.g. [23]). For graphs obtained from such models, their degree sequences are instead probability distributions. We now show that applying our labeling scheme for $\mathcal{P}_h$ to random graphs with the power-law distribution results in a small expected worst-case label size.

Using the definition of Mitzenmacher [47], a random variable X is said to have the *power-law* distribution (w.r.t. $\alpha > 1$) if

$$Pr[X \geq x] \sim cx^{-\alpha+1},$$

for a constant $c > 0$, i.e., $\lim_{x\to\infty} Pr[X \geq x]/cx^{-\alpha+1} = 1$.

Let $\epsilon > 0$ be fixed. Consider a graph G picked from a family $\mathcal{F}$ of random graphs whose degree sequences have the power-law distribution. Order the vertices of G arbitrarily

as $v_1, \ldots, v_n$. For $i = 1, \ldots, n$, let indicator variable X_i be 1 iff v_i has degree at least $d = \sqrt[\alpha]{n/\log n}$. There is a constant $N_0 \in \mathbb{N}$ (depending on ϵ) such that if $n \geq N_0$ then for all i,

$$E[X_i] = \Pr[X_i = 1] \leq (1+\epsilon)cd^{-\alpha+1}.$$

With the same labeling scheme as for $\mathcal{P}_h$ with degree threshold $\tau(n) = d$, denote by E_n the expected label size of an n-vertex graph from $\mathcal{F}$. Then for all $n \geq N_0$,

$$\begin{aligned} E_n &= \sum_{x=0}^{n} \Pr\left[\sum_{i=1}^{n} X_i = x\right] O((x + d\log n)) = O\left(d\log n + E\left[\sum_{i=1}^{n} X_i\right]\right) \\ &= O\left(d\log n + \sum_{i=1}^{n} E[X_i]\right) = O\left(d\log n + nd^{-\alpha+1}\right) = O\left(\sqrt[\alpha]{n}(\log n)^{1-1/\alpha}\right). \end{aligned}$$

Thus, we have:

▶ **Theorem 5.** *Let $\mathcal{F}$ be a family of graphs with degree sequences having the power-law distribution w.r.t. $\alpha > 1$. Then there is a labeling scheme for $\mathcal{F}$ such that the expected worst-case label size of any graph $G \in \mathcal{F}$ is $O(\sqrt[\alpha]{n}(\log n)^{1-1/\alpha})$ where n is the number of vertices of G.*

5 Lower Bounds

We now derive lower bounds for the label size of any labeling schemes for both $\mathcal{S}_{c,n}$ and $\mathcal{P}_l$. Our proofs rely on Moon's [48] lower bound of $\lfloor n/2 \rfloor$ bits for labeling scheme for general graphs. We first show that the upper bound achieved for sparse graphs is close to the best possible. The following proposition is essentially a more precise version of the lower bound suggested by Spinrad [51].

▶ **Proposition 4.** *Any labeling scheme for $\mathcal{S}_{c,n}$ requires labels of size at least $\left\lfloor \frac{\sqrt{cn}}{2} \right\rfloor$ bits.*

Proof. Assume for contradiction that there exists a labeling scheme assigning labels of size strictly less than $\lfloor \frac{\sqrt{cn}}{2} \rfloor$. Let G be an n-vertex graph. Let G' be the graph resulting by adding $\left\lfloor \frac{n^2}{c} \right\rfloor - n$ isolated vertices to G, and note that now G' is c-sparse. The graph G is an induced subgraph of G'. It now follows that the vertices of G have labels of size strictly less than $\left\lfloor \frac{\sqrt{c\lfloor n^2/c \rfloor}}{2} \right\rfloor \leq n/2$ bits. As G was arbitrary, we obtain a contradiction. ◀

In the remainder of this section we are assuming that $\alpha > 2$ and prove the following:

▶ **Theorem 6.** *For any n, any labeling scheme for n-vertex graphs of $\mathcal{P}_{h,\chi,\alpha}$ requires label size $\Omega(\sqrt[\alpha]{n})$.*

More precisely, we present a lower bound for $\mathcal{P}_l$ which is contained in $\mathcal{P}_h$. Let $n \in \mathbb{N}$ be given and let $H = (V(H), E(H))$ be an arbitrary graph with i_1 vertices where $i_1 = \Theta(\sqrt[\alpha]{n})$ is defined as in Section 3. We show how to construct a graph $G = (V, E)$ in $\mathcal{P}_l$ with n vertices that contains H as an induced subgraph. Observe that a labeling of G induces a labeling of H. As H was chosen arbitrarily and as any labeling scheme for k-vertex graphs requires $\lfloor i_1/2 \rfloor$ label size in the worst case, Theorem 6 follows if we can show the existence of G.

We construct G incrementally where initially $E = \emptyset$. Partition V into subsets $V_1, \ldots, V_n$ as follows. The set V_1 has size $\lfloor Cn \rfloor - i_1$. For $i = 2, \ldots, i_1 - 1$, V_i has size $\lfloor Cn/i^\alpha \rfloor$. Letting

$n' = \sum_{i=1}^{i_1-1} |V_i|$, we set the size of V_i to 1 for $i = i_1, \ldots, i_1 + n - n' - 1$ and the size of V_i to 0 for $i = i_1 + n - n', \ldots, n$, thereby ensuring that the sum of sizes of all sets is n. Observe that $\sum_{i=1}^{i_1} \lfloor Cn/i^\alpha \rfloor \leq n$ so that $n' \leq n - i_1$, implying that $n - n' \geq i_1$. Hence we have at least i_1 size 1 subsets $V_{i_1}, \ldots, V_{i_1+n-n'-1}$ in each of which the vertex degree allowed by Definition 2 is at least i_1.

Let $v_1, \ldots, v_{i_1}$ be an ordering of $V(H)$, form a set $V_H \subseteq V$ of i_1 arbitrary vertices from the sets $V_{i_1}, \ldots, V_{i_1+n-n'-1}$, and choose an ordering $v'_1, \ldots, v'_{i_1}$ of V_H. For all $i, j \in \{1, \ldots, i_1\}$, add edge (v'_i, v'_j) to E iff $(v_i, v_j) \in E(H)$. Now, H is an induced subgraph of G and since the maximum degree of H is $i_1 - 1$, no vertex of V_i exceeds the degree bound allowed by Definition 2 for $i = 1, \ldots, n$.

We next add additional edges to G in three phases to ensure that it is an element of $\mathcal{P}_l$ while maintaining the property that H is an induced subgraph of G. For $i = 1, \ldots, n$, during the construction of G we say that a vertex $v \in V_i$ is *unprocessed* if its degree in the current graph G is strictly less than i. If the degree of v is exactly i, v is *processed*.

Phase 1

Let $V' = V \setminus (V_1 \cup V_H)$. Phase 1 is as follows: while there exists a pair of unprocessed vertices $(u, v) \in V' \times V_H$, add (u, v) to E.

When Phase 1 terminates, H is clearly still an induced subgraph of G. Furthermore, all vertices of V_H are processed. To see this, note that the sum of degrees of vertices of V_H when they are all processed is $O(i_1^2) = O(n^{2/\alpha})$ which is $o(n)$ since $\alpha > 2$. Furthermore, prior to Phase 1, each of the $\Theta(n)$ vertices of V' have degree 0 and can thus have their degrees increased by at least 1 before being processed.

Phase 2

While there exists a pair of unprocessed vertices $(u, v) \in V' \times V'$, add (u, v) to E. At termination, at most one vertex of V' remains unprocessed. If such a vertex exists we process it by connecting it to $O(\sqrt[c]{n})$ vertices of V_1; as $|V_1| = \Theta(n)$ there are enough vertices of V_1 to accomodate this. Furthermore, prior to adding these edges, all vertices of V_1 have degree 0, and hence the bound allowed for vertices of this set is not exceeded.

Phase 3

We add edges between pairs of unprocessed vertices of V_1 until no such pair exists. If no unprocessed vertices remain we have the desired graph G. Otherwise, let $w \in V_1$ be the unprocessed vertex of degree 0. We add a single edge from w to another vertex w' of V_1, thereby processing w and moving w' from V_1 to V_2. Note that the sizes of V_1 and V_2 are kept in their allowed ranges due to the first two conditions in Definition 2. This proves Theorem 6.

6 $O(\log n)$ adjacency labeling schemes for some power-law graphs

The lower bound presented can be avoided in two interesting cases. The first, for random graphs generated by a popular model, and the second using an extension of the concept of labeling schemes from the literature.

BA model

As discussed in Sec. 4.1, generative models play an important role in the study of power-law graphs. Perhaps the most well-known generative model is the Barabási-Albert (BA) which, roughly, grows a graph in a sequence of time steps by inserting a single vertex at each step and attaching it to m existing vertices with probability weighted by the degree of each existing vertex [12]. The BA model generates graphs that asymptotically have a power-law degree distribution ($\alpha = 3$) for low-degree nodes [15]. However, graphs created by the BA model have low arboricity [2] [34]. We use this fact to devise the following highly efficient labeling scheme for such graphs.

▶ **Proposition 5.** *The family of graphs generated by the BA model has an $O(m \log n)$ adjacency labeling scheme.*

Proof. Let $G = (V, E)$ be an n-vertex graph resulting by the construction by the BA model with some parameter m (starting from some graph $G_0 = (V_0, E_0)$ with $|V_0| \ll n$). While it is not known how to compute the arboricity of a graph efficiently, it is possible in near-linear time to compute a partition of G with at most twice[3] the number of forests in comparison to the optimal [10]. We can thus decompose the graph to $2m$ forests in near linear time and label each forest using the recent $\log n + O(1)$ labeling scheme for trees [6], and achieve a $2m(\log n + O(1))$ labeling scheme for G. ◀

If the encoder operates at the same time as the creation of the graph, Proposition 5 can be tightened to yield a $m \log n$ labeling scheme, by storing the identifiers of the vertices to the node introduced. Theorem 6 and Proposition 5 strongly suggest that local properties of power-law graphs are very different from those of a randomly generated graph using the BA model. In contrast, other generative models such as Waxman's [53], N-level Hierarchical [19]. and Chung and Liu's [23] (Chapter 3) do not seem to have an obvious smaller label size than the one in Proposition 4.

Labeling schemes with a query

The concept of labeling scheme limits the number of nodes participating in a query severely. A relaxed variant thereof, called 1-query labeling scheme [39], assumes that the decoder receives both labels queried, and may access the label of a third node in order to answer the query. If this is allowed, we can construct an $O(\log n)$ 1-query adjacency labeling scheme for sparse (and power-law) graphs as follows: We assign each node v with an identifier $ID(v)$, then produce a classic [26] chaining perfect hash-function[4] from $\{1 \dots cn\}$ to $\{1 \dots n\}$, with the guarantee that the worst case number of collisions is constant. We then compute the hash function for all edges (u, v) and store the tuple $\langle ID(v), ID(u) \rangle$ in the label of the corresponding vertex. The decoder first computes the hash value resulting from $ID(v)$ and $ID(u)$ and proceed to examine if on the label corresponding to the result of the function the tuple appears. The decoder needs only to know the primary and secondary hash functions used, description thereof amount to logarithmic number of bits, which can be concatenated to each label.

---

[2] the arboricity of a graph is the minimum number of spanning forests needed to cover its edges.

[3] More precisely, for any $\epsilon \in (0, 1)$ there exist an $O(|E(G)|/\epsilon)$ algorithm [42] that computes such partition using at most $(1 + \epsilon)$ times more forests than the optimal one.

[4] To this end, we may for example first partition the domain into c parts.

7 A distance labeling scheme

In this section we extend the usefulness of our strategy by showing a labeling scheme for small distances in power-law graphs.

For sparse graphs, Alstrup et al. [7] obtain a distance labeling scheme with maximum label size $O(\frac{n}{D}\log^2 D)$ where $D = (\log n)/(\log \frac{m+n}{n})$ and m is the number of edges in the graph. Gawrychowski et al. obtain an upper bond of [33] $O(\frac{n}{D}\log D)$ with sub-linear decoding time. Few general results on lower bounds exist. The lower bound of $\Omega(\sqrt{n})$ for adjacency given in the present paper is trivially also a lower bound for distance; for total label size, the best known lower bound remains $\Omega(n^{3/2})$ as proved by Gavoille et al. [31].

▶ **Lemma 7.** *For any computable $f : \mathbb{N} \longrightarrow \mathbb{N}$ such that $f(n) \leq n-1$ for all n, and for any $\chi(n) \geq n^{1/(alpha-1+f(n))}$ there is an $f(n)$-distance labeling scheme for $\mathcal{P}_{h,\chi,\alpha}$ that assigns labels of length at most $O(n^{f(n)/(f(n)+1)}\log f(n))$.*

Proof. Let G be a graph in $\mathcal{P}_{h,\chi,\alpha}$. A node of G is *fat* if it has degree at least $n^{1/(\alpha-1+f(n))}$ and *thin* otherwise. The label of each node v contains (i) a table of distances to all fat nodes (if the distance is more than $f(n)$, it is simply ignored), (ii) a table of distances to all thin nodes w that are at most distance $f(n)$ away from v where the shortest path between v and w does not pass through any fat node, and (iii) a single bit signifiying whether the node is fat or thin. Clearly, as $f(n)$ is computable and distances in G are computable, there is a computable encoder assigning labels. A decoder can now compute the distance between any two nodes u, v as follows: If both u or v are fat, the distance can be directly read off part (i) of the label of any node. If at least one of u and v is fat, the distance can be read off part (i) of the label of the thin node. If both nodes are thin, the decoder can check if the distance is in part (ii) of the label of either node; if the distance is not present, either the distance is strictly greater than $f(n)$, or the shortest path between u and v passes through a fat node; in this case, the decoder may brute-force check the distances from u and v to each fat node, and output the smallest sum of these two distances.

Furthermore, as all nodes of G are either thin or fat, it is clearly possible for an encoder to compute all distances less than or equal to $f(n)$ between any pair of nodes. Note that as all distances we care for are bounded above by $f(n)$, each such distance can be stored using at most $\log f(n)$ bits.

As $G = G(V, E)$ is in $\mathcal{P}_{h,\chi,\alpha}$, we have

$$\sum_{i=\chi(n)}^{n-1} |V_i| \leq \sum_{i=n^{\frac{1}{\alpha-1+f(n)}}}^{n-1} |V_i| \leq C'\left(\frac{n}{\left(n^{\frac{1}{\alpha-1+f(n)}}\right)^{\alpha-1}}\right)$$
$$\leq C' n^{1-(\alpha-1)/\alpha-1+f(n)} = C' n^{f(n)/(\alpha-1+f(n))}$$

Thus, a table of distances to all fat nodes takes up at most $O\left(n^{\frac{f(n)}{\alpha-1+f(n)}}\log f(n)\right)$ bits.

Similarly, for each node v there are at most $\left(n^{1/(\alpha-1+f(n))}\right)^{f(n)}$ $= n^{f(n)/(\alpha-1+f(n))}$ nodes at distance at most $f(n)$ away from v where the shortest path consists only of thin nodes. Hence, the associated table of distances takes up at most $O(n^{f(n)/(\alpha-1+f(n))}\log n)$ bits.

In total, each label thus has size at most $O(n^{f(n)/(f(n)+1)}\log n)$ bits. ◀

For $f(n) = \log n$, Lemma 7 yields labels of size $O\left(n^{(\log n)/(\alpha-1+\log n)}\log\log n\right)$. Unsurprisingly, as we are only considering distances up to $f(n)$, this label size is asymptotically

smaller than for the labeling schemes working for all distances in *sparse* graphs, e.g. the largest label sizes of [33] for sparse graphs is $O(n\frac{\log\log n}{\log n})$. For power-law random graphs, Chung and Lu show in [22] that, subject to mild conditions, the diameter of power-law graphs with $\alpha > 2$ is almost surely $\Theta(\log n)$. We thus expect our labeling scheme to have superior performance for such graphs.

8 Conclusion and Future Work

We have devised adjacency and distance labeling schemes for sparse graphs and graphs whose degree distribution approximately follows a power-law distribution. We have proven lower bounds for the class of power-law graphs showing that our strategy for adjacency labeling scheme is almost optimal, and showed two relaxations that allow for logarithmic size labels. In the full version of the paper we also validate experimentally that the labeling scheme for power-law graphs obtains results in practice requiring little space, and that the theoretical threshold we use in our strategy is reasonably close to the optimum threshold.

8.1 Future work

We propose the following directions:

- Our labeling schemes are designed for static networks, and while it seems not difficult to extend our idea to dynamic networks, an analysis is required to account for the communication and number of re-labels incurred by such an extension.
- Labeling schemes for power-law graphs can likely be devised for the realistic case where the scheme only has incomplete knowledge of the graph, for example when the expected frequency of vertices of each degree is known, but not the exact frequency of each vertex.
- Closing the gap of the multiplicative logarithmic factor may be of interest to the theory community. A more interesting gap exists for distance labeling schemes. As we have seen, there is a large gap between labeling schemes for short distance and adjacency for power-law (and sparse) graphs. This gap effectively deemed the distance labels uninteresting for practical applications.
- Finally, while power-law distributions may model the degree distribution of real-world networks, other distributions may fit better (see, e.g., [24]); it is interesting to see whether refinements of our labeling scheme that utilize knowledge about such distributions would result in superior labeling schemes for real-world data.

Abstract

We study the Static-Routing-Resiliency problem, motivated by routing on the Internet: Given a graph G = (V, E), a unique destination vertex d, and an integer constant c > 0, does there exist a static and destination-based routing scheme such that the correct delivery of packets from any source s to the destination d is guaranteed so long as (1) no more than c edges fail and (2) there exists a physical path from s to d? We embark upon a study of this problem by relating the edge-connectivity of a graph, i.e., the minimum number of edges whose deletion partitions G, to its resiliency. Following the success of randomized routing algorithms in dealing with a variety of problems (e.g., Valiant load balancing in the network design problem), we embark upon a study of randomized routing algorithms for the Static-Routing-Resiliency problem. For any k-connected graph, we show a surprisingly simple randomized algorithm that has expected number of hops O(|V|k) if at most k-1 edges fail, which reduces to O(|V|) if only a fraction t of the links fail (where t < 1 is a constant). Furthermore, our algorithm is deterministic if the routing does not encounter any failed link.

1 Introduction

Routing on the Internet (both within an organizational network and between such networks) typically involves computing a set of *destination-based* routing tables (i.e., tables that map the destination IP address of a packet to an outgoing link). Whenever a link or node fails, routing tables are recomputed by invoking the routing protocol to run again (or having it

* Additional details of the results in this note appear in [9].

run periodically, independent of failures). This produces well-formed routing tables, but results in relatively long outages after failures as the protocol is recomputing routes.

As critical applications began to rely on the Internet, such outages became unacceptable. As a result, "fast failover" techniques have been employed to facilitate immediate recovery from failures. The most well-known of these is Fast Reroute in MPLS where, upon a link failure, packets are sent along a precomputed alternate path without waiting for the global recomputation of routes [23]. This, and other similar forms of fast failover thus enable rapid response to failures but are limited to the set of precomputed alternate paths. Most of existing approaches protect only from a single failure, however in many scenarios (e.g. overlay networks [11], highly-connected large datacenter networks [15]) multiple failures at the same time may be a common occurrence.

The goal of this paper is to perform a theoretical study of failover routing. The fundamental question is, how resilient can failover routing be? That is, how many link failures can failover routing schemes tolerate before connectivity is interrupted (i.e., packets are trapped in a forwarding loop, or hit a dead end)? The answer to this question depends on both the structural properties of the graph, and the limitations imposed on the routing scheme.

Clearly, if it is possible to store arbitrary amount of information in the packet header, perfect resiliency can be achieved by collecting information about every failed link that is hit by a packet [19, 26]. Such approaches are not feasibly deployable in modern-day networks as the header of a packet may be too large for today's routing tables. Our focus is thus on failover routing schemes that do not involve any change in the packet headers. Another traditional approach to achieving high resiliency is implementing stateful routing, i.e., storing information at a node every time a packet is seen being received from a different incoming link (see, e.g., link reversal [14] and other approaches [20, 21]). As current routing protocols do not allow network operators to implement such stateful failover routing, our goal is to design protocols that correspond to a stateless, or *static*, failover routing.

Specifically, we consider a particularly simple and practical form of static failover routing: for each incoming link, a router maintains a destination-based routing table that maps the destination address of a packet and the set of non-failed ("active") links, to an output link. The router can locally detect which outgoing links are down and forwards packets accordingly. One should note that maintaining such per-incoming-link destination-based routing tables is necessary; not only is destination-based routing unable to achieve robustness against even a single link failure [18], but it is even computationally hard to devise failover routing schemes that maximize the number of nodes that are protected [2, 5, 18, 24]. We only consider link failures, not router failures (which are not always detectable by neighboring routers, and so such fast failover techniques may not apply).

A failover routing algorithm is responsible for computing, for each node (vertex) of a network (graph), a *routing function* that *matches* an incoming packet to an outgoing edge. A set of such routing functions for each vertex guarantees *reachability* between a pair of vertices, u and v, for which there exists a connecting path in the graph, if any packet directed to node v originated at node u is correctly routed from u to v.

We are interested in routing functions that rely solely on information that is locally available at a node (e.g., the set of non-failed edges, the incoming link along which the packet arrived, and any information stored in the header of the packet).

While it is known that every k-connected network cannot be partitioned by deleting at most $k-1$ links, it is not known whether any static "deterministic" routing (i.e., the outgoing port of each packet is always uniquely determined at a vertex v by its incoming link and the failed edges incident at v) achieves such resiliency.

On the other hand, routing based on random walks, i.e., choosing the outgoing link at random, achieves the best possible resilience as they will eventually deliver a packet to the destination as long as the network is connected. But, it comes with a huge cost. Namely, a random walk might traverse the whole network even when there is no single failed link. In fact, the expected delivery time of a packet would be as large as $\Theta(|V|^3)$ in some network topologies [6]. Furthermore, a random walk almost never reaches the destination following the shortest path. So, although extremely robust, when it comes to the time needed to deliver a packet to the destination, the behaviour of random walks is undesirable.

1.1 Our Results

In this paper, we show how randomness can be used to achieve $k-1$ resilient routing in k-connected networks while significantly outperforming random walks in terms of number of traversed nodes. Namely, we introduce **Randomized failover routing (`RND`)** in which outgoing edge is chosen for packets in a probabilistic manner based on the destination label, the incoming edge, and the set of non-failed edges. The randomized protocol that we present provides bound on the expected delivery time that gracefully grows with the number of actual link failures.

Our randomized routing functions provide delivery in case of any $k-1$ link failures for any k-connected graph. We achieve that by leveraging the standard decomposition of k-connected graphs into k arc-disjoint spanning arborescences $\mathcal{T}$ [10]. We also provide a bound on the expected number of hops that our algorithm performs, which is $O(Hk)$ for any $k-1$ failures and $O(H)$ for αk failures, where H is the length of the longest branch of any arborescence of $\mathcal{T}$ and $\alpha < 1$ is a constant. Furthermore, our routing functions are deterministic as long as the routing does not encounter any failure. Hence, packets belonging to the same logical connection are routed along the same path, minimizing reordering complexity at the receiver side.

Motivated by the fact that one can protect against $k-1$ failures in k-connected graphs using randomness, we make the following general conjecture, whose proof eludes us despite much effort.

- **Conjecture:** For any k-connected graph, one can find deterministic failover routing functions that are robust to any $k-1$ failures.

1.2 Organization

The rest of the paper is organized as follows. Section 2 provides background on existing works. In Section 3, we introduce our routing model and formally state the Static-Routing-Resiliency problem. The summary of our routing techniques that are leveraged throughout the whole paper are presented in Section 4. In Section 5, we focus on studying the relation between arborescences our input graph decomposes into and failed links. Section 6 builds on Section 5 and is devoted to designing an algorithm that, for any k-connected graph, computes randomized routing functions that are robust to $k-1$ edge failures and have bounded expected delivery time.

2 Related Work

Past work [1, 29] (1) designed such routing functions with guaranteed robustness against *only* a single link/node failure [12, 13, 22, 28, 30, 32], (2) achieved robustness against $\lfloor \frac{k}{2} - 1 \rfloor$

edge failures for k-connected graphs [11], and (3) proved that it is impossible to be robust against any set of edge failures that does not partition the network [13].

Thanks to its flexibility and oblivious behavior, another line of study was motivated by randomization. Namely, some of the previous work developed randomized routing schemes, usually to directly or indirectly achieve low congestion and/or balance the network load. In particular, Busch et al. [7] use randomization to adjust packet priorities, which in turn allows them to control deflection of packets.

Valiant [27] proposed a randomized routing algorithm with the goal to balance the load of the underlying network. Since then, that scheme is called *Valiant Load-Balancing* (VLB), whose one of the main ingredients is randomization. VLB was extensively used in designing networks. Zhang-Shen et al. [31] employed VLB to design fault-tolerant networks with guaranteed no congestion under few router or link failures. Greenberg et al. [16] adopt VLB to reduce volatility of traffic and failure pattern of their data centers. In [25], Shepherd et al. extend VLB in order to build cost-effective networks robust to changes in demand patterns.

Beraldi [3] presents a search protocol for mobile networks that is based on modified random walks, i.e. based on biased random walks with look-ahead. Motivated by the success of ant-colonies in their search for food, Günes et al.[17] studied ant algorithms, which in their heart rely on randomization, as an approach to designing on-demand ad-hoc routing algorithms.

Chiesa et al. [8] studied resilience under link failures in k-connected networks. They devise static routing schemes that are resilient under $k-1$ failures in the following regimes: (1) if the routers are allowed to use three bits in the packet header for read/write operation, or (2) if the network supports broadcasting. A building block of those schemes is the result that every k-connected graph contains k arc-disjoint arborescences rooted at the same vertex [10].

3 Model

We represent our network as an undirected multigraph $G = (V(G), E(G))$, where each router in the network is modeled by a vertex in $V(G)$ and each link between two routers is modeled by an undirected edge in the multiset $E(G)$. When it is clear from the context, we simply write V and E instead of $V(G)$ and $E(G)$. We denote an (undirected) edge between x and y by $\{x, y\}$. A graph is *k-edge-connected* if there exist k edge-disjoint paths between any pair of vertices of G.

Each vertex v routes packets according to a *routing function* that matches an incoming packet to a sequence of forwarding actions. Packet *matching* is performed according to the set of active (non-failed) edges incident at v, the incoming edge, and any information stored in the packet header (e.g., destination label, extra bits), which all are *locally* available at a vertex.

Since our focus is on per-destination routing functions, we assume that there exists a unique destination $d \in V$ to which every other vertex wishes to send packets and, therefore, that the destination label is not included in the header of a packet. Forwarding *actions* consist of routing packets through an outgoing edge, rewriting some bits in the packet header, and creating duplicates of a packet.

In this paper we consider *randomized* routing functions, in which a vertex forwards a packet through an outgoing edge with a probability based only on the incoming port and the set of active outgoing edges. We present the formal definitions of the randomized routing model in Section 6.

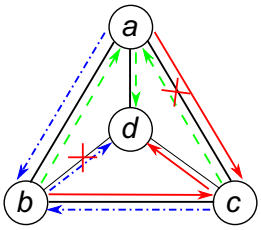

Figure 1 A 3-connected graph with 3 arc-disjoint arborescences colored red, blue, and green.

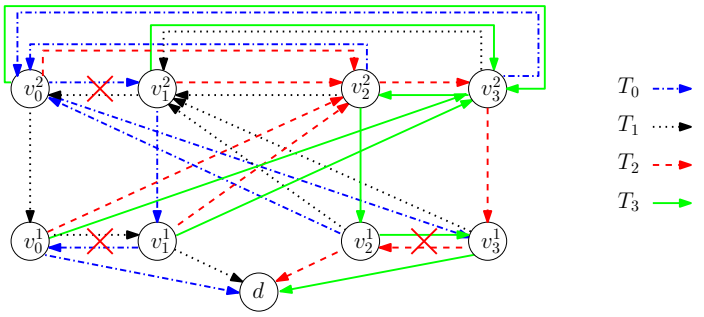

Figure 2 Graph used in the proof of Theorem 7 for $k = 2$.

The Static-Routing-Resiliency (Srr) problem. Given a graph G, a routing function f is *k-resilient* if, for each vertex $v \in V$, a packet originated at v and routed according to f reaches its destination d as long as at most k edges fail and there still exists a path between v and d. The input of the Srr problem is a graph G, a destination $d \in V(G)$, and an integer $k > 0$, and the goal is to compute a set of resilient routing functions that is k-resilient.

4 General Routing Techniques and Randomized Algorithm

Definition and notation. We denote a directed arc from x to y by (x, y) and by $\vec{G}$ the directed copy of G, i.e. a directed graph such that $V(\vec{G}) = V$ and $\{x, y\} \in E$ if and only if $(x, y), (y, x) \in E(\vec{G})$.

A subgraph T of $\vec{G}$ is an *r-rooted arborescence* of $\vec{G}$ if (i) $r \in V$, (ii) $V(T) \subseteq V$, (iii) r is the only vertex without outgoing arcs and (iv), for each $v \in V(T) \setminus \{r\}$, there exists a single directed path from v to r that only traverses vertices in $V(T)$. If $V(T) = V$, we say that T is a r-rooted *spanning* arborescence of $\vec{G}$. When it is clear from the context, we use the word "arborescence" to refer to a d-rooted spanning arborescence, where d is the destination vertex. We say that two arborescences T_1 and T_2 are *arc-disjoint* if $(x, y) \in E(T_1) \implies (x, y) \notin E(T_2)$. A set of l arborescences $\{T_1, \ldots, T_l\}$ is *arc-disjoint* if the arborescences are pairwise arc-disjoint. We say that two arc-disjoint arborescences T_1 and T_2 do not *share* an edge $\{x, y\} \in E$ if $(x, y) \in E(T_1) \implies (y, x) \notin E(T_2)$.

For example, consider Fig. 1, in which each pair of nodes is connected by an edge (ignore the red crosses) and three arc-disjoint (d-rooted spanning) arborescences `Red`, `Green`, and `Blue` are depicted by colored arrows.

Arborescence-based routing. Throughout the paper, unless specified otherwise, we let $\mathcal{T} = \{T_1, \ldots, T_k\}$ denote a set of k d-rooted arc-disjoint spanning arborescences of $\vec{G}$. All our routing techniques are based on a decomposition of $\vec{G}$ into $\mathcal{T}$. The existence of k arc-disjoint arborescences in any k-connected graph was proven in [10], while fast algorithms to compute such arborescences can be found in [4]. We say that a packet is routed in *canonical* mode along an arborescence T if a packet is routed through the unique directed path of T towards the destination. If the packet hits a failed edge at vertex v along T, it is processed by v (e.g., duplication, header-rewriting) according to the capabilities of a specific routing function and it is rerouted along a different arborescence. We call such routing technique *arborescence-based* routing. One crucial decision that must be taken is the next arborescence

to be used after a packet hits a failed edge. In this paper, we propose two natural choices that represent the building blocks of all our routing functions. When a packet is routed along T_i and it hits a failed arc (v, u), we consider the following two possible actions:

- **Reroute along some available arborescence**, e.g., reroute along T', where T' is chosen randomly from distribution that we define in the sequel. Observe that, if the outgoing arc belonging to T' failed, we randomly pick another arborescence T'', and so on.
- **Bounce on the reversed arborescence**, i.e., we reroute along the arborescence T_{next} that contains arc (u, v).

To grasp how bouncing enters in our picture for obtaining $k-1$ resiliency, consider the following case. Assume that in the network there are $k/2$ failed links, such that every single out of k arborescences contains one of the links. (As a reminder, arborescences that we construct might share links, but not arcs.) So, this example might suggest that there are scenarios in which already $k/2$ failed links make all the arborescences not very useful, and that no algorithm can cope with that. But, there is a twist. Let $k = 2$, and T_i and T_j be the two arborescences and let them share the same failed edge a. Furthermore, let a be the only failed edge T_i and T_j contain. If a packet hits a while routed along T_i or T_j, then after bouncing on a the packet will reach d without any further interruption! So, we have just found a way to resolve a case in which every arborescence contains one failed link, and that is not an isolated scenario, as we discuss in the sequel.

From a different point of view, bouncing is a way of recycling arborescences that contain one failed link. This observation is crucial to obtain an efficient and a simple randomized $(k-1)$-resilient routing scheme, which we are now ready to present. The algorithm is parametrized by q that we define later.

Algorithm 1 Definition of Rand-Bouncing-Algo.

Rand-Bouncing-Algo: Given $\mathcal{T} = \{T_1, \ldots, T_k\}$

1. $T :=$ an arborescence from $\mathcal{T}$ sampled uniformly at random (u.a.r.)
2. While d is not reached
   a. Route along T (canonical mode)
   b. If a failed edge is hit then
      i. With probability q, replace T by an arborescence from $\mathcal{T}$ sampled u.a.r.
      ii. Otherwise, bounce the failed edge and update T correspondingly

In the following sections, we first study the connection between arborescences of $\mathcal{T}$ and failed links, and show how a part of their intricate interaction can be represented in a simple and an elegant way via, so-called, *meta-graph*. Afterwards, we show the Rand-Bouncing-Algo is $(k-1)$-resilient and we analyze its efficiency.

5 Meta-graph, Good Arcs, and Good Arborescences

The goal of this section is to provide an understanding of the structural relation between the arborescences of $\mathcal{T}$ when the underlying k-connected network has at most $k-1$ failed edges. The perspective that we are building here drives the construction of our randomized algorithm.

We start by introducing the notion of a *meta-graph*. To that end, we fix an arbitrary set of failed edges F. Throughout the section, we assume $|F| < k$, and define $f := |F|$. Then, we define a meta-graph $H_F = (V_F, E_F)$ as follows:

- $V_F = \{1, \ldots, k\}$, where vertex i is a representative of arborescence T_i.
- For each failed edge $e \in E$ belonging to at least one arborescences of $\mathcal{T}$ we define the corresponding edge e_F in H_F in the following way:
  - $e_F := \{i, j\}$, if e belongs to two different arborescences T_i and T_j;
  - $e_F := \{i, i\}$, i.e. e_F is a self-loop, if e belongs to a single arborescence T_i only.

Note that in our construction H_F might contain parallel edges. Intuitively, the meta-graph represents a relation between arborescences of $\mathcal{T}$ for a fixed set of failed edges. We provide the following lemma as the first step towards understanding the structure of H_F.

▶ **Lemma 1.** *The set of connected components of H_F contains at least $k - f$ trees.*

Proof. We give a proof by contradiction. To that end, assume that the set of connected components of H_F, denoted by $\mathcal{C}$, contains at most $k - f - 1$ trees. Now, if $C \in \mathcal{C}$ is a tree, we have $|E(C)| = |V(C)| - 1$, and $|E(C)| \geq |V(C)|$ otherwise. We also have

$$\begin{aligned} \sum_{C \in \mathcal{C}} |E(C)| &= \sum_{C \in \mathcal{C} \text{ is not a tree}} |E(C)| + \sum_{C \in \mathcal{C} \text{ is a tree}} |E(C)| \\ &\geq \sum_{C \in \mathcal{C} \text{ is not a tree}} |V(C)| + \sum_{C \in \mathcal{C} \text{ is a tree}} (|V(C)| - 1). \end{aligned} \tag{1}$$

Next, following our assumption that $\mathcal{C}$ contains at most $k - f - 1$ trees, from (1) we obtain

$$\sum_{C \in \mathcal{C}} |E(C)| \geq \sum_{C \in \mathcal{C}} |V(C)| - (k - f - 1). \tag{2}$$

Furthermore, as by the construction we have $\sum_{C \in \mathcal{C}} |V(C)| = |V_F| = k$, (2) implies

$$\sum_{C \in \mathcal{C}} |E(C)| \geq |V_F| - (k - f - 1) = f + 1. \tag{3}$$

On the other hand, from the construction of H_F we have

$$\sum_{C \in \mathcal{C}} |E(C)| = f,$$

which leads to a contradiction with (3). ◀

Lemma 1 implies that the fewer failed edges there are, the larger fraction of connected components of the meta-graph H_F are trees. Note that an isolated vertex is a tree as well.

In the sequel, we show that each tree-component of H_F contains at least one vertex corresponding to an arborescence from which any bounce on a failed edge leads to the destination d without hitting any new failed edge. To that end, we introduce the notion of good arcs and good arborescences. We say that an arc (u, v) is a *good arc* of an arborescence T if on the (unique) v-d path in T there is no failed edge. Let $a = (i, j)$, for $i \neq j$, be an arc of $\vec{H_F}$, $\{u, v\}$ be the edge that corresponds to a, and w.l.o.g. assume (u, v) is an arc of T_j. Then, we say a is a *well-bouncing* arc if (u, v) is a good arc of T_j. Intuitively, a well-bouncing arc (i, j) of $\vec{H_F}$ means that by bouncing from T_i to T_j on the failed edge $\{v, u\}$ the packet will reach d via routing along T_j without any further interruption. Finally, we say that an arborescence T_i is a *good arborescence* if every outgoing arc of vertex $i \in V_F$ is well-bouncing.

▶ **Lemma 2.** *Let T be a tree-component of H_F s.t. $|V(T)| > 1$. Then, $\vec{T}$ contains at least $|V(T)|$ well-bouncing arcs.*

Proof. Let T_i be an arborescence of $\mathcal{T}$ such that $i \in V(T)$. Then, by the construction of H_F we have that T_i contains a failed link. Next, a failed link closest to the root of T_i is a good arc of T_i. Therefore, for every $i \in V(T)$, we have that T_i contains an arc which is both good and failed. Furthermore, by the construction of H_F and the definition of well-bouncing arcs, we have that for every good, failed link of T_i there is the corresponding well-bouncing arc of $\vec{T}$. Also, observe that the construction of H_F implies that a well-bouncing arc corresponds to exactly one good-arc.

Now, putting all the observations together, we have that each T_i, for every $i \in V(T)$, has a good failed link which further corresponds to a well-bouncing arc of $\vec{T}$. As all the arborescences are arc-disjoint, and there are $|V(T)|$ many of them represented by the vertices of T, we have that $\vec{T}$ contains at least $|V(T)|$ well-bouncing arcs. ◀

Now, building on Lemma 2, we prove the following.

▶ **Lemma 3.** *Let T be a tree-component of H_F. Then, there is an arborescence T_i such that $i \in V(T)$ and T_i is good.*

Proof. Consider two cases: $|V(T)| = 1$, and $|V(T)| > 1$. In the case $|V(T)| = 1$, T is an isolated vertex which implies that it has no outgoing arcs. Therefore, T represents a good arborescence.

If $|V(T)| > 1$, then from Lemma 2 we have that $\vec{T}$ contains at most $2(|V(T)|-1)-|V(T)| < |V(T)|$ arcs which are not well-bouncing. This implies that there is at least one vertex in T from which every outgoing arc is well-bouncing. ◀

Let us understand what this implies. Consider an arborescence T_i, and a routing of a packet along it. In addition, assume that the routing hits a failed edge e, such that e is shared with some other arborescence T_j. Now, if e corresponds to a well-bouncing arc of $\vec{H_F}$, then by bouncing on e and routing solely along T_j, the packet will reach d without any further interruption. Lemma 3 claims that for each tree-component T of H_F there always exists an arborescence T_i, with $i \in V(T)$, which is good, i.e. every failed edge of T_i corresponds to a well-bouncing arc of $\vec{H_F}$.

We can now state the main lemma of this section.

▶ **Lemma 4.** *If G contains at most $k-1$ failed edges, then $\mathcal{T}$ contains at least one good arborescence.*

Proof. We prove that there exists an arborescence T_i such that if a packet bounces on any failed edge of T_i it will reach d without any further interruption. Let F be the set of failed edges, at most $k-1$ of them. Then, by Lemma 1 we have that H_F contains at least $k-f \geq 1$ tree-components. Let T be one such component.

By Lemma 3, we have that there exists at least an arborescence T_i such that every outgoing arc from i is well-bouncing. Therefore, bouncing on any failed arc of T_i the packet will reach d without any further interruption. ◀

6 Randomized Routing via Good Arborescences

In this section, we show that a set of routing functions for G obtained by Rand-Bouncing-Algo is $(k-1)$-resilient. Note that our routing function (`RND`) maps an incoming edge and the set of active edges incident at v to a set of pairs (e, q), where e is an outgoing edge and q is the probability of forwarding a packet through e. A packet is forwarded through a unique outgoing edge.

The section is structured as follows. As a prelude, we show a simple, yet inefficient, randomized routing algorithm, called Rand-Algo, that although is $(k-1)$-resilient, fails to achieve low expected number of hops in case of $k-1$ failed edges. We then apply our results from Section 5 to show that Rand-Bouncing-Algo is both $(k-1)$-resilient and requires up to an order fewer number of hops, compared to Rand-Algo, to reach the destination.

6.1 A Simple (Inefficient) Randomized Routing

Consider the following naive randomized algorithm Rand-Algo for routing along arborescences. A packet is routed along the same arborescence until it either reaches its destination or hits a failed edge. In the latter case, it is rerouted along another arborescences chosen uniformly at random. We show that there exists a k-connected graph and a set of failed edges such that the expected number of tree switches that Rand-Algo makes is $\Omega(k^2)$. This further implies that the expected number of hops is $\Omega(Hk^2)$ in the worst case, where H is the length of a longest path in any arborescence and assuming that longest path in all the arborescences are up to a constant factor the same.

To prove the promised bound, we start by defining a $2k$ edge connected graph $G=(V,E)$ and its set of $2k$ arc disjoint spanning trees $T_0,\ldots,T_{2k-1}$ as follows.

- Set V consists of a destination vertex d and $4k$ additional vertices arranged into two equal-sized layers $L_1=\{v_0^1,\ldots,v_{2k-1}^1\}$ and $L_2=\{v_0^2,\ldots,v_{2k-1}^2\}$.
- Set E is defined by the following four subgraphs: (1) L_2 is a clique of size $2k$; (2) (L_1,L_2) is a complete bipartite graph; (3) for each $k=0,\ldots,k-1$, there is an edge (v_{2i}^1,v_{2i+1}^1) and (4) vertex d is connected to each vertex of L_1. There is no other edge included in G.

Next, we construct $2k$ arc-disjoint spanning trees $T_0,\ldots,T_{2k-1}$ (see Fig. 2 for an example with $k=2$). We use $[t]_0$ to denote set $\{0,1,2,\ldots,t-1\}$.

- For each $i\in[k]_0$, add the following arcs:
  - (v_{2i+1}^2,v_{2i}^2), (v_{2i}^2,v_{2i}^1), (v_{2i}^1,v_{2i+1}^1), and (v_{2i+1}^1,d) into T_{2i+1};
  - arcs (v_{2i}^2,v_{2i+1}^2), (v_{2i+1}^2,v_{2i+1}^1), (v_{2i+1}^1,v_{2i}^1), and (v_{2i}^1,d) into T_{2i}.
- For each $i\in[k]_0$, and for each $j\in[2k]_0\setminus\{2i,2i+1\}$, add the following arcs:
  - (v_j^2,v_{2i}^2), and (v_j^1,v_{2i}^2) into T_{2i};
  - (v_j^2,v_{2i+1}^2), and (v_j^1,v_{2i+1}^2) into T_{2i+1}.

Finally, consider a scenario in which edges (v_0^2,v_1^2), (v_2^2,v_3^2), $\ldots$, (v_{2k-4}^2,v_{2k-3}^2) and (v_0^1,v_1^1), (v_2^1,v_3^1), $\ldots$, (v_{2k-4}^1,v_{2k-3}^1), (v_{2k-2}^1,v_{2k-1}^1) failed.

We say that a packet is routed *downwards* (*upwards*) if it is routed from a vertex in L_2 (L_1) to a vertex in L_1 (L_2). Let E_d be the expected number, minimized over all the vertices, of tree switches of a packet that is routed downwards, E_u be the expected number of tree switches of a packet that is routed along T_i and is currently located at v_i^2, for some $i\in[2k-2]_0$, and E_2 be the expected number of tree switches of a packet that is originated by a vertex in L_2. Then, we can show.

▶ **Lemma 5.** *It holds* $E_u \geq \frac{3}{2k-1}E_d + \frac{2k-4}{2k-1}E_u + 1$.

Proof. Let p be routed along T_h and located at v_h^2, for some $h\in[2k-2]_0$. W.l.o.g, let $h=0$. By the construction of T_0, from v_0^1 packet p should be forwarded to v_1^2 but (v_0^2,v_1^2) has failed. So, from v_0^2, p is forwarded downwards along T_1, T_{2k-2} or T_{2k-1} with probability $\frac{3}{2k-1}$ and routed along any other tree T_j to a vertex v_j^2 in L_2 with probability at least $\frac{2k-4}{2k-1}$. Hence, the lemma follows. ◀

▶ **Lemma 6.** *We have* $E_d\in\Omega(k^2)$.

Proof. By the construction, a packet routed downwards traverses arc (v_i^2, v_i^1) of T_i. W.l.o.g, let p be routed along (v_{2i}^2, v_{2i}^1) of T_{2i}. As (v_{2i}^1, v_{2i+1}^1), which belongs to T_{2i}, has failed, p is rerouted along T_j for some $j \in [2k]_0 \setminus \{2i\}$. Among them, only T_{2i+1} has a path from v_{2i}^1 to d that does not contain any failed link. T_{2i+1} is chosen with probability $\frac{1}{2k-1}$.

If any other tree T_j is chosen except T_{2k-2} and T_{2k-1}, which happens with probability $\frac{2k-4}{2k-1}$, then p is rerouted through T_j from v_{2i}^1 to a vertex v_j^2 in L_2, and hence

$$E_d \geq \frac{2k-4}{2k-1} E_u + 1. \tag{4}$$

Putting together with (4) and Lemma 5 we obtain $E_d \in \Omega(k^2)$. ◀

We finally observe that any packet originated at a vertex of L_2 is routed downwards at least once before reaching the destination vertex, i.e., $E_2 \geq E_d = \Omega(k^2)$, which proves the following theorem.

▶ **Theorem 7.** *For any $k > 0$, there exists a $2k$ edge-connected graph, a set of $2k$ arc-disjoint spanning trees, and a set of $2k-1$ failed edges, such that the expected number of tree switches with* Rand-Algo *is $\Omega(k^2)$.*[1]

6.2 Correctness of Randomized-Bouncing Routing

In this section we prove that Rand-Bouncing-Algo eventually delivers a packet to d, i.e. it avoids loops, and in the next section we analyze its efficiency.

Assume that we, magically, know whether the arborescence we are routing along is a good one or not. Then, on a failed edge we could bounce if the arborescence is good, or switch to the next arborescence otherwise. And, we would not even need any randomness. However, we do not really know whether an arborescence is good or not since we do not know which edges will fail. To alleviate this lack of information we use a random guess. So, each time we hit a failed edge we take a guess that the arborescence is good, where the parameter q estimates this likelihood. Notice that Rand-Bouncing-Algo implements exactly this approach. As an example, consider Fig. 1. If a packet originated at a is first routed through `Red` and the corresponding outgoing edge $\{a, c\}$ is failed, then the packet is forwarded with probability q to `Blue` or `Green` chosen u.a.r., and with probability $1 - q$ it is bounced to `Green`, which shares the outgoing failed edge $\{a, c\}$ with `Red`. By the following lemma we show that this approach leads to $(k-1)$-resilient routing.

▶ **Lemma 8.** Rand-Bouncing-Algo *produces a set of $(k-1)$-resilient routing functions.*

Proof. By Lemma 4 we have that there exists at least one arborescence T_i of $\mathcal{T}$ such that bouncing on any failed edge of T_i the packet will reach d without any further interruption. Now, as on a failed edge algorithm Rand-Bouncing-Algo will switch to T_i with positive probability, and on a failed edge of T_i the algorithm will bounce with positive probability, we have that the algorithm will eventually reach d. ◀

[1] In the extended version of this paper [9], we show a more involved example for which Rand-Algo makes $\Omega(|V|k^2)$ hops, in expectation, to deliver a packet to d.

6.3 Number of Switches of Rand-Bouncing-Algo

In this subsection we analyze the expected number of times I the packet is rerouted from one arborescence to another one in Rand-Bouncing-Algo. As we are interested in providing an upper bound on I, we make the following assumptions. First, we assume that bouncing from an arborescence which is not good the routing always bounces to an arborescence which is not good as well. Second, we assume that only by bouncing from a good arborescence the routing will reach d without switching to any other arborescence. Third, we assume that there are exactly $k - f$ good arborescences, which is the lower bound provided by Lemma 1 and Lemma 3. Clearly, these assumptions can only lead to an increased number of iterations compared to the real case. Finally, for the sake of brevity we define $t := \frac{f}{k}$.

Now, we are ready to start with the analysis. As the first step we define a random variable, where in the definitions T is the arborescence variable from algorithm Rand-Bouncing-Algo,

$$X := \text{ number of times a failed edge is hit before reaching } d \text{ if routing on } T\,.$$

Let T_{init} be the first arborescence that we consider in Rand-Bouncing-Algo. Then, $\mathbb{E}[I]$ is upper-bounded by

$$\begin{aligned}\mathbb{E}[I] \leq &\Pr[T_{init} \text{ is not good}]\,\mathbb{E}[X|T_{init} \text{ is not good}] + \\ &\Pr[T_{init} \text{ is good}]\,\mathbb{E}[X|T_{init} \text{ is good}]\,,\end{aligned} \tag{5}$$

where from our assumptions we have

$$\Pr[T_{init} \text{ is not good}] = t, \text{ and } \Pr[T_{init} \text{ is good}] = 1 - t.$$

To simplify calculations, let X_P and Y_P be *pessimistic* upper bound on conditional expected values. That is, let X_P be the same as $\mathbb{E}[X|T_{init} \text{ is not good}]$ and Y_P as $\mathbb{E}[X|T_{init} \text{ is good}]$ under assumption that: the packet always hits a failed edge unless it bounces on a good arborescence; and, whenever packet bounces on a non-good arborescence it switches to a non-good one.

Now, let us express X_P and Y_P as functions in X_P, Y_P, q, and t, while following our assumptions. If T is not a good arborescence, then a routing along T will hit a failed edge. If it hits a failed edge, with probability $1 - q$ the routing will bounce and switch to a non good arborescence. With probability qt the routing scheme will set T to be a non good arborescence, and with probability $q(1 - t)$ it will set T to be a good arborescence. Formally, we have

$$X_P = 1 + qtX_P + q(1 - t)Y_P + (1 - q)X_P. \tag{6}$$

Applying an analogous reasoning about Y_P, we obtain

$$Y_P = 1 + qtX_P + q(1 - t)Y_P. \tag{7}$$

Observe that the equations describing X_P and Y_P differ only in the term $(1 - q)X_P$. This comes from the fact that bouncing on a good arborescences the packet will reach d without hitting any other failed edge.

By some simple calculations (see [9]), we obtain

$$\mathbb{E}[I] \leq U(q) := \frac{t}{(1 - q)q(1 - t)} + \frac{1}{1 - q}. \tag{8}$$

Now we can prove the following lemma.

▶ **Lemma 9.** *We have that*

$$\mathbb{E}[I] \leq 2 + 4\frac{t}{1-t} = 2 + 4\frac{f}{k-f}.$$

Proof. From (8) we have $\mathbb{E}[I] \leq U(q)$. Setting $q = 1/2$ we obtain

$$U(1/2) \leq 2 + 4\frac{t}{1-t},$$

and by plugging $t = f/k$ the lemma follows. ◀

Note that if we know f in advance, or have some guarantee in terms of an upper bound on f, we can derive parameter q that improves the running time of Rand-Bouncing-Algo, as provided by the following lemma.

▶ **Lemma 10.** *$U(q)$ is minimized for $q = q^* := 1 - (1 + \sqrt{t})^{-1}$, and equal to*

$$U(q^*) = \frac{1+\sqrt{t}}{1-\sqrt{t}}. \tag{9}$$

Proof. Consider $U(q)'$, which is

$$U(q)' = \frac{t(1-q)^2 - q^2}{(1-q)^2 q^2 (t-1)}.$$

In order to find the value of q that minimizes $U(q)$, denote it by q^*, we find the roots of $U(q)' = 0$ with respect to q. There is only one positive solution of equation $U(q)' = 0$, which is also the minimizer q^*, and is equal to $q^* = 1 - \frac{1}{1+\sqrt{t}}$, as desired.

Finally, substituting q^* into (8) and simplifying the expression we obtain (9). ◀

Observe that

$$U(q^*) \leq \frac{4}{1-\frac{f}{k}}.$$

Therefore, if $f = \alpha k$, i.e., only a fraction of the edges fail, we obtain $U(q^*) \leq \frac{4}{1-\alpha}$. This means that the expected number of arborescence switches does not depend on the number of failed edges but on the ratio between this number and the connectivity of the graph. Otherwise, if $f = k - 1$, we have that the expected number of arborescence switches is bounded by $4k$, which is linear w.r.t. to the connectivity of the graph. Combining these conclusions with Lemma 8, we obtain the following.

▶ **Theorem 11.** *Given a k-connected graph G, destination d and a decomposition of G into k arc-disjoint arborescences $\mathcal{T}$ rooted at d, there exists a $(k-1)$-resilient algorithm that delivers a packet to d after $O\left(\frac{k}{k-f}H\right)$ hops in expectation, where H is the length of a longest path of any arborescence of $\mathcal{T}$ and f the number of failed edges. The algorithm uses randomization only when encounters a failed edge. In particular, if $f = 0$, the algorithm is deterministic.*

6.4 An Extension: Rerouting in a Non-uniform Manner

In this section we briefly study non-uniform choice of arborescence used for rerouting in algorithm Rand-Bouncing-Algo. To motivate that discussion, consider a scenario in which a packet hits a failed edge u, v while routed along arborescence T. Wlog, assume $T = T_k$. Furthermore, assume that path v-d along every other arborescence does not contain any

failed link. Therefore, switching from T_k to any other arborescence the packet will reach d without any further interruption. If the packet is rerouted at step 2.2.(a) of algorithm Rand-Bouncing-Algo but not bounced, then the rerouting tree is chosen uniformly at random. It further means that the expected number of edges the packet will traverse before reaching d from v is

$$E_U = \sum_{i=1}^{k-1} \frac{dist_{T_i}(v)}{k-1} = \frac{\sum_{i=1}^{k-1} dist_{T_i}(v)}{k-1},$$

where $dist_{T_i}(a)$ is the number of the edges on the unique path from a to d along arborescence T_i.[2] However, the distances from v to d along different arborescences might significantly differ. This naturally suggests us to consider a non-uniform distribution of arborescences chosen at step 2.2.(a) of Rand-Bouncing-Algo, as we do in the rest of this section.

For each vertex $v \neq d$ and each arborescence T_i define probability p_v^i as

$$p_v^i := \frac{\frac{1}{dist_{T_i}(v)}}{\sum_{j=1}^{k-1} \frac{1}{dist_{T_j}(v)}}.$$

The expected number of the edges the packet will traverse if each arborescence is chosen with respect to the distribution given by p_v is

$$E_{NU} = \sum_{i=1}^{k-1} p_v^i dist_{T_i}(v) = \sum_{i=1}^{k-1} \frac{1}{\sum_{j=1}^{k-1} \frac{1}{dist_{T_j}(v)}} = \frac{k-1}{\sum_{i=1}^{k-1} \frac{1}{dist_{T_i}(v)}}.$$

Now we would like to show that indeed $E_U \stackrel{?}{\geq} E_{NU}$. But, it is the same as showing that

$$(k-1)^2 \stackrel{?}{\leq} \sum_{i=1}^{k-1} dist_{T_i}(v) \sum_{i=1}^{k-1} \frac{1}{dist_{T_i}(v)}.$$

However, the latter follows from Cauchy–Schwarz inequality as

$$(k-1)^2 = \left(\sum_{i=1}^{k-1} \sqrt{dist_{T_i}(v)} \sqrt{\frac{1}{dist_{T_i}(v)}} \right)^2 \leq \sum_{i=1}^{k-1} dist_{T_i}(v) \sum_{i=1}^{k-1} \frac{1}{dist_{T_i}(v)}.$$

Hence, $E_U \geq E_{NU}$, as advertised.

We note that this example is a potential scenario that might occur. However, and unfortunately, in case of failures we are unable to detect whether the described situation has occurred or not. Nevertheless, we believe that in practical applications the non-uniform choice of arborescences used for rerouting, as described above, would result in a more efficient routing than its uniform counterpart.

Abstract

Let $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ be a 2-party function. For every product distribution μ on $\{0,1\}^n \times \{0,1\}^n$, we show that

$$\mathsf{CC}^{\mu}_{0.49}(f) = O\left(\left(\log \mathsf{prt}_{1/8}(f) \cdot \log\log \mathsf{prt}_{1/8}(f)\right)^2\right),$$

where $\mathsf{CC}^{\mu}_{\varepsilon}(f)$ is the distributional communication complexity of f with error at most ε under the distribution μ and $\mathsf{prt}_{1/8}(f)$ is the *partition bound* of f, as defined by Jain and Klauck [*Proc. 25th CCC*, 2010]. We also prove a similar bound in terms of $\mathsf{IC}_{1/8}(f)$, the *information complexity* of f, namely,

$$\mathsf{CC}^{\mu}_{0.49}(f) = O\left(\left(\mathsf{IC}_{1/8}(f) \cdot \log \mathsf{IC}_{1/8}(f)\right)^2\right).$$

The latter bound was recently and independently established by Kol [*Proc. 48th STOC*, 2016] using a different technique.

We show a similar result for query complexity under product distributions. Let $g : \{0,1\}^n \to \{0,1\}$ be a function. For every bit-wise product distribution μ on $\{0,1\}^n$, we show that

$$\mathsf{QC}^{\mu}_{0.49}(g) = O\left(\left(\log \mathsf{qprt}_{1/8}(g) \cdot \log\log \mathsf{qprt}_{1/8}(g)\right)^2\right),$$

where $\mathsf{QC}^{\mu}_{\varepsilon}(g)$ is the distributional query complexity of f with error at most ε under the distribution μ and $\mathsf{qprt}_{1/8}(g))$ is the *query partition bound* of the function g.

Partition bounds were introduced (in both communication complexity and query complexity models) to provide LP-based lower bounds for randomized communication complexity and randomized query complexity. Our results demonstrate that these lower bounds are polynomially tight for *product* distributions.

1 Introduction

Over the last decade, several lower bound techniques using linear programming formulations and information complexity methods have been developed for problems in communication complexity and query complexity. One of the central questions in communication complexity is to understand the tightness of these lower bound techniques. For instance, over the last few years, considerable effort has gone into understanding the *information complexity* measure. Informally speaking, (internal) information complexity is the amount of information the two parties reveal to each other about their respective inputs while computing the joint function. It is known that for product distributions, the internal information complexity not only lower bounds but also upper bounds the distributional communication complexity (up to logarithmic multiplicative factors in the communication complexity) [1]. On the other hand, recent works due to Ganor, Kol and Raz [3, 4, 5] show that there exist non-product distributions which exhibit exponential separation between internal information complexity and distributional communication complexity[1]. However, it is still open if internal information complexity (or a polynomial of it) upper bounds the public-coin randomized communication complexity (up to logarithmic multiplicative factors in the input size) [2].

Jain and Klauck [9], using tools from linear programming, gave a uniform treatment of several of the existing lower bound techniques and proposed the *partition bound*. This leads to following related (but incomparable) conjecture: does a polynomial of the partition bound yield an upper bound on the communication complexity? We are not aware of any counterexample to this conjecture[2].

We consider these questions when the inputs to Alice and Bob are drawn from a product distribution and show the following.

▶ **Theorem 1.** *Let $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$, and let $\mathsf{IC}_\varepsilon(f)$ and $\mathsf{prt}_\varepsilon(f)$ be the information complexity and partition bound respectively of f with error at most ε. For a product distribution μ on $\{0,1\}^n \times \{0,1\}^n$, the distributional communication complexity of f under distribution μ with error at most 0.49, denoted by $\mathsf{CC}^\mu_{0.49}(f)$, can be bounded above as follows:*

$$\mathsf{CC}^\mu_{0.49}(f) = O\left(\left(\mathsf{IC}_{1/8}(f) \cdot \log \mathsf{IC}_{1/8}(f)\right)^2\right), \tag{1.1}$$

$$\mathsf{CC}^\mu_{0.49}(f) = O\left(\left(\log \mathsf{prt}_{1/8}(f) \cdot \log\log \mathsf{prt}_{1/8}(f)\right)^2\right). \tag{1.2}$$

Our technique yields bounds more general than those stated above (see discussion after Proposition 7 for this generalization). We remark that recently (and independently of this work) Kol [11] obtained the bound (1.1) using very different techniques. Kol's result is stronger in the sense that her bound is in terms of the information complexity $\mathsf{IC}^\mu(f)$ for the product distribution μ, while our result is in terms of the worst case information complexity $\mathsf{IC}(f)$ (note, $\mathsf{IC}_\varepsilon(f) = \max_\mu \mathsf{IC}^\mu_\varepsilon(f)$). In fact, Kol showed that

$$\mathsf{CC}^\mu_{\delta+\varepsilon}(f) = O\left(\mathsf{IC}^\mu_\delta(f)^2 \cdot \operatorname{poly}\log \mathsf{IC}^\mu_\delta(f)/\varepsilon^5\right), \tag{1.3}$$

and concluded that

$$\mathsf{CC}^\mu_{0.49}(f) = O\left(\mathsf{IC}_{1/8}(f)^2 \cdot \operatorname{poly}\log \mathsf{IC}_{1/8}(f)\right). \tag{1.4}$$

[1] The third result of Ganor, Kol and Raz [5] actually demonstrates an exponential separation between external information and communication complexity, albeit not for computing a Boolean function.

[2] The recent work of Göös et al. [6] demonstrates the existence of a total function for which the partition bound is strictly sublinear in the randomized communication complexity. This still does not rule out communication complexity being bound by a polynomial of the partition bound.

Kol's result (1.3) is incomparable to our second result in terms of partition bound (1.2).

We consider a similar question in query complexity and show the following.

▶ **Theorem 2.** *Let $g : \{0,1\}^n \to \{0,1\}$ be a function and μ be a bit-wise product distribution on $\{0,1\}^n$. Let $\mathsf{qprt}_\varepsilon(g)$ be the query partition bound for g with error ε. Then, the distributional query complexity with error at most 0.49 under the distribution μ, denoted by $\mathsf{QC}^\mu_{0.49}(f)$, can be bounded above as follows:*

$$\mathsf{QC}^\mu_{0.49}(g) = O\left(\left(\log \mathsf{qprt}_{1/8}(g) \cdot \log\log \mathsf{qprt}_{1/8}(g)\right)^2\right).$$

A similar quadratic upper bound for query complexity for product distributions in terms of approximate certificate complexity was obtained by Smyth [14]. His proof uses Reimer's inequality while our proof technique is based on Nisan and Wigderson's [13] more elementary approach.

Organization. The communication complexity result is proven in §2 while the query complexity result is deferred to the full version [8] for lack of space.

2 Communication Complexity

2.1 Preliminaries

We work in Yao's two-party communication model [15] (see Kushilevitz and Nisan [12] for an excellent introduction to the area). Let $\mathcal{X}$, $\mathcal{Y}$ and $\mathcal{Z}$ be finite non-empty sets, and let $f : \mathcal{X} \times \mathcal{Y} \to \mathcal{Z}$ be a function. A two-party protocol for computing f consists of two parties, Alice and Bob, who get inputs $x \in \mathcal{X}$ and $y \in \mathcal{Y}$ respectively, and exchange messages in order to compute $f(x,y) \in \mathcal{Z}$ (using shared randomness).

For a distribution μ on $\mathcal{X} \times \mathcal{Y}$, let the ε-error distributional communication complexity of f under μ (denoted by $\mathsf{CC}^\mu_\varepsilon(f)$), be the number of bits communicated (for the worst-case input) by the best deterministic protocol for f with average error at most ε under μ. Let $\mathsf{CC}^{\mathrm{pub}}_\varepsilon(f)$, the public-coin randomized communication complexity of f with worst case error ε, be the number of bits communicated (for the worst-case input) by the best public-coin randomized protocol that for each input (x,y) computes $f(x,y)$ correctly with probability at least $1-\varepsilon$. Randomized and distributional complexity are related by the following special case of von Neumann's minmax principle.

▶ **Theorem 3** (Yao's minmax principle [16])**.** $\mathsf{CC}^{\mathrm{pub}}_\varepsilon(f) = \max_\mu \mathsf{CC}^\mu_\varepsilon(f)$.

We will prove Theorem 1 by first showing an upper bound on communication complexity in terms of the smooth rectangle bound and then observing that the smooth rectangle bound is bounded above by the partition bound.

Smooth rectangle bound

The smooth rectangle bound was introduced by Jain and Klauck [9] as a generalization of the rectangle bound. Just like the rectangle bound, the smooth rectangle bound also provides a lower bound for randomized communication complexity. Informally, the smooth rectangle bound for a function f under a distribution μ, is the maximum over all functions g , which are close to f under the distribution μ, of the rectangle bound of g. However, it will be more convenient for us to work with the following linear programming formulation. (See [9,

Lemma 2] and [10, Lemma 6] for the relations between the LP formulation and the more "natural" formulation in terms of rectangle bound.) It is evident from the LP formulation that the smooth rectangle bound is a further relaxation of the partition bound (defined in the appendix). We will formulate our results in terms of a distributional version of the above smooth rectangle bound. For $\mu : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ and any $z \in \mathcal{Z}$ and rectangle R, let $\mu_z(R) := \mu(R \cap f^{-1}(z))$ and $\mu_{\bar{z}}(R) := \mu(R) - \mu_z(R)$. Furthermore, let $\mu_z := \mu_z(\mathcal{X} \times \mathcal{Y})$ and $\mu_{\bar{z}} := \mu_{\bar{z}}(\mathcal{X} \times \mathcal{Y})$. The smooth rectangle and its distributional version are defined below.

▶ **Definition 4** (Smooth rectangle bound)**.**

- For a function $f : \mathcal{X} \times \mathcal{Y} \to \mathcal{Z}$ and $\varepsilon \in (0,1)$, the (ε,δ)-smooth rectangle bound of f denoted $\mathsf{srec}_{\varepsilon,\delta}(f)$ is defined to be $\max\{\mathsf{srec}^z_{\varepsilon,\delta}(f) : z \in \mathcal{Z}\}$, where $\mathsf{srec}^z_{\varepsilon,\delta}(f)$ is the optimal value of the following linear program.
- For a distribution μ on $\mathcal{X} \times \mathcal{Y}$ and function $f : \mathcal{X} \times \mathcal{Y} \to \mathcal{Z}$, the (ε,δ)-smooth rectangle bound of f with respect to μ denoted $\mathsf{srec}^\mu_{\varepsilon,\delta}(f)$ is defined to be $\max\{\mathsf{srec}^{z,\mu}_{\varepsilon,\delta}(f) : z \in \mathcal{Z}\}$, where $\mathsf{srec}^{z,\mu}_{\varepsilon,\delta}(f)$ is the optimal value of the following linear program.

$\underline{\mathsf{srec}^z_{\varepsilon,\delta}(f)}$

$$\begin{aligned}
\min \quad & \sum_R w_R \\
& \sum_{R \ni (x,y)} w_R \geq 1-\varepsilon, \quad \forall (x,y) \in f^{-1}(z) \\
& \sum_{R \ni (x,y)} w_R \leq \delta, \quad \forall (x,y) \notin f^{-1}(z) \\
& \sum_{R \ni (x,y)} w_R \leq 1, \quad \forall (x,y) \\
& w_R \geq 0, \quad \forall R \ .
\end{aligned}$$

$\underline{\mathsf{srec}^{z,\mu}_{\varepsilon,\delta}(f)}$

$$\begin{aligned}
\min \quad & \sum_R w_R \\
& \sum_{(x,y) \in f^{-1}(z)} \mu_{x,y} \sum_{R \ni (x,y)} w_R \geq (1-\varepsilon) \cdot \mu_z \qquad (2.1) \\
& \sum_{R \ni (x,y)} w_R \leq \delta, \quad \forall (x,y) \notin f^{-1}(z) \qquad (2.2) \\
& \sum_{R \ni (x,y)} w_R \leq 1, \quad \forall (x,y) \qquad (2.3) \\
& w_R \geq 0, \quad \forall R \ .
\end{aligned}$$

We will refer to the constraint in (2.1) as the covering constraint and the ones in (2.2) as the packing constraints. Note that while there is a single covering constraint (averaged over all the inputs (x,y) that satisfy $f(x,y) = z$) there are packing constraints corresponding to each $(x,y) \notin f^{-1}(z)$.

Similar to Yao's minmax principle Theorem 3, we have the following proposition relating the distributional version of the smooth rectangle bound to the smooth rectangle bound.

▶ **Proposition 5.** $\mathsf{srec}_{\varepsilon,\delta}(f) = \max_\mu \mathsf{srec}^\mu_{\varepsilon,\delta}(f)$.

The main result of this section is the following

▶ **Theorem 6.** *For any Boolean function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ and any* product *distribution μ on $\{0,1\}^n \times \{0,1\}^n$, we have the following.*

1. $\mathsf{CC}^\mu_{0.49}(f) = O\left((\log \mathsf{srec}^\mu_{1/n^2,1/n^2}(f))^2 \cdot \log n\right)$.
2. *Furthermore, if there exists $k \geq 20$ such that*

$$\lceil 100 \log \mathsf{srec}^\mu_{\delta,\delta}(f) \rceil \leq k,$$

for $\delta \leq 1/(30 \cdot 100(k+1)^4)$, then

$$\mathsf{CC}^\mu_{0.49}(f) = O(k^2).$$

The above theorem is useful only when we have a upper bound on the smooth rectangle bound for very small δ. The following proposition shows that such upper bounds for smooth rectangle bound for such small δ can be obtained in terms of either the information complexity or the partition bound.

▶ **Proposition 7.** *For any Boolean function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ and any $\delta \in (0,1)$, we have the following bounds on $\mathsf{srec}_{\delta,\delta}(f)$:*

$$\log \mathsf{srec}_{\delta,\delta}(f) \leq O\left(\log \frac{1}{\delta}\right) \cdot \mathsf{IC}_{1/8}(f),$$
$$\log \mathsf{srec}_{\delta,\delta}(f) \leq O\left(\log \frac{1}{\delta}\right) \cdot \log \mathsf{prt}_{1/8}(f).$$

(This proposition depends on the error-reduction properties of information complexity and partition bound; a proof appears in the full version [8].) Using this proposition, we can reduce the error (i.e., δ) to $1/n^2$ and show that $\mathsf{CC}^{\mu}_{0.49}(f) = O\left(\left(\log \mathsf{prt}_{1/8}(f)\right)^2 \cdot (\log n)^3\right)$. However, we can also reduce the error to $1/\mathrm{poly}(\log \mathsf{prt}_{1/8}(f))$ and show that there exists a $k = O\left(\log \mathsf{prt}_{1/8}(f) \cdot \log\log \mathsf{prt}_{1/8}(f)\right)$ that satisfies the hypothesis for the second part of Theorem 6. The bound (1.2) in Theorem 1 now follows by combining Propositions 7 and 5 and Theorem 6. A similar argument yields the bound (1.1).

In particular, the above discussion shows that our techniques apply to any complexity measure (not necessarily partition bound and information complexity) which can be used to bound the smooth rectangle bound for very small δ. An interesting question that arises in this context is if we could bound smooth rectangle bound for small δ in terms of smooth rectangle bound for large δ, say $\delta = 1/3$ (i.e., is error-reduction for srec feasible?). This question was answered in the negative for partial functions by Göös et al. [7] who show that there exists a partial function f that has $\mathsf{srec}_{1/3}(f) = O(\log n)$ and yet $\mathsf{srec}_{1/4}(f) = \Omega(n)$.

2.2 Proof of Theorem 6

In this section, we construct a communication protocol tree with a small number of leaves from the optimal solutions to the LPs corresponding to $\mathsf{srec}^{0,\mu}_{\varepsilon,\delta}$ and $\mathsf{srec}^{1,\mu}_{\varepsilon,\delta}$. The construction of the protocol tree with a small number of leaves is inspired by a construction due to Nisan and Wigderson, in the context of log-rank conjecture [13, Theorem 2] (see also [12, Combinatorial proof of Theorem 2.11]). Unlike the earlier constructions, our protocol works for a distribution and allows for error. As a result, the decomposition into sub-problems needs to be performed more carefully. This step critically uses the product nature of the distribution μ.

The decomposition is accomplished using an inductive argument. We will work with the quantity $\mathsf{srec}^0 + \mathsf{srec}^1$. That is, we will show that if this sum is small, then there is a protocol with few leaves. Suppose $\mathsf{srec}^0 \leq \mathsf{srec}^1$. Since srec^0 is small, we will conclude that there is a large rectangle biased towards 0 (see Lemma 8). Based on this large rectangle, the entire communication matrix is partitioned into three parts: (1) the large biased rectangle itself, (2) a rectangle whose corresponding sub-problem admits an LP solution leading to a smaller srec^1 value (the underlying product nature of the distribution μ is used here) and (3) a rectangle where the total measure with respect to μ drops significantly (see Lemma 9).

We say that a rectangle R is $(1-\alpha)$-biased towards to 0 if $\mu_1(R) \leq \alpha\mu_0(R)$.

▶ **Lemma 8** (large biased rectangle)**.** *Let μ be a product distribution. If $\mathsf{srec}^{0,\mu}_{\varepsilon,\delta}(f) \le D$, then for every $\rho \in (0,1)$ there exists a rectangle S such that S is $(1-\rho)$-biased towards 0 and*

$$\mu(S) \ge \mu_0(S) \ge \frac{1}{D} \cdot \left((1-\varepsilon) \cdot \mu_0 - \left(\frac{\delta}{\rho}\right) \cdot \mu_1 \right).$$

(The proof appears in §2.3.) We will apply the above lemma with $\rho = \sqrt{\delta}$ and conclude that there exists a large rectangle $S = X_0 \times Y_0$ that is $(1-\sqrt{\delta})$-biased towards 0. Let $X_1 = \mathcal{X} \setminus X_0$ and $Y_1 = \mathcal{Y} \setminus Y_0$. For $i,j \in \{0,1\}$, define rectangles $R^{(ij)} := X_i \times Y_j$, $R^{(1*)} := X_1 \times \mathcal{Y}$, and $R^{(*1)} := \mathcal{X} \times Y_1$. (Note, $S = R^{(00)}$.) For $i,j \in \{0,1,*\}$, let $\mu^{(ij)}$ be the restriction of μ to the rectangle $R^{(ij)}$. We show in the lemma below that the function f when restricted to either $R^{(10)}$ or $R^{(01)}$ has the property that the corresponding srec^1 drops by a constant factor. Define

$$\varepsilon(f) := 1 - \frac{\left(\sum_{(x,y)\in f^{-1}(1)} \mu_{x,y} \sum_{R:(x,y)\in R} w_R\right)}{\mu_1},$$

$$\varepsilon^{(ij)}(f) := 1 - \frac{\left(\sum_{(x,y)\in f^{-1}(1)\cap R^{(ij)}} \mu_{x,y} \sum_{R:(x,y)\in R} w_R\right)}{\mu_1(R^{(ij)})}; \qquad \text{for } i,j \in \{0,1\}.$$

It follows from the covering constraint that $\varepsilon(f) \le \varepsilon$. Furthermore, $\varepsilon(f)$ is an average of the $\varepsilon^{(ij)}$'s in the sense that $\varepsilon(f) = \left(\sum_{i,j\in\{0,1\}} \mu_1(R^{(ij)})\varepsilon^{(ij)}\right)/\mu_1$.

▶ **Lemma 9.** *Suppose the product distribution μ and rectangles $R^{(ij)}$ are as above; in particular, $R^{(00)}$ is $(1-\sqrt{\delta})$-biased towards 0. There exists an $(ij) \in \{(01),(10)\}$ such that one of the following holds: (a) $2\mu^{(ij)}(f^{-1}(1)) \le \mu^{(ij)}(f^{-1}(0))$ or (b) $\mathsf{srec}^{1,\mu^{(ij)}}_{\varepsilon^{(ij)}+30\sqrt[4]{\delta},\delta}(f) \le 0.9D$ where $\varepsilon^{(ij)}$ is as defined above.*

We will prove this lemma in §2.3. Let us assume the above lemmas and obtain the low cost communication protocol claimed in Theorem 6.

Suppose $\mu^{(01)}$ satisfies $\mathsf{srec}^{1,\mu^{(01)}}_{\varepsilon^{(01)}+30\sqrt[4]{\delta},\delta}(f) \le 0.9D$ as given by the above lemma. Consider the decomposition of the space $\mathcal{X}\times\mathcal{Y}$ given by $(R^{(00)}, R^{(01)}, R^{(1*)} = R^{(10)} \cup R^{(11)})$. We note that $R^{(00)}$ is a large biased rectangle, $R^{(01)}$ has lower srec^1 value while $R^{(1*)}$ has lower μ value (since $R^{(00)}$ is large) and its srec values are no larger than that of the entire space. In the case when $\mu^{(10)}$ satisfies $\mathsf{srec}^{1,\mu^{(10)}}_{\varepsilon^{(10)}+30\sqrt[4]{\delta},\delta}(f) \le 0.9D$, we similarly have the decomposition $(R^{(00)}, R^{(10)}, R^{(*1)} = R^{(01)} \cup R^{(11)})$.

This suggests a natural inductive protocol Π for f that we formalize in the lemma below.

For our induction it will be convenient to work with μ that are not necessarily normalized. So, we will only assume $\mu : \mathcal{X}\times\mathcal{Y} \to [0,1]$ but not that $|\mu| := \mu(\mathcal{X}\times\mathcal{Y}) = \sum_{(x,y)\in\mathcal{X}\times\mathcal{Y}} \mu(x,y) = 1$. For a protocol Π, let the advantage of Π be defined by

$$\mathsf{adv}_\mu(\Pi) = \sum_{(x,y):f(x,y)=\Pi(x,y)} \mu(x,y) - \sum_{(x,y):f(x,y)\neq\Pi(x,y)} \mu(x,y).$$

Let $L(\Pi)$ be the number of leaves in Π.

We now formulate the induction hypothesis as follows.

▶ **Lemma 10.** *Fix a function $f : \mathcal{X}\times\mathcal{Y} \to \{0,1\}$ and a product distribution (not necessarily normalized) $\mu : \mathcal{X}\times\mathcal{Y} \to [0,1]$ such that $|\mu| \ge 0$. Let $\varepsilon,\delta \in (0,1)$ and $\Delta \in (0,|\mu|)$. Let s,t be*

non-negative integers such that

$$s \geq s(\mu,\varepsilon,\delta) := \left\lceil 100 \cdot \log 2(\mathsf{srec}^{0,\mu}_{\varepsilon,\delta}(f) + \mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f)) \right\rceil;$$
$$t \geq t(\mu,\varepsilon,\delta) := \lceil 100 \cdot 2^s \log(|\mu|/\Delta) \rceil.$$

Then, there is a protocol Π *such that*

$$L(\Pi) \leq 4\binom{s+t}{t} - 1; \tag{2.4}$$
$$\mathsf{adv}_\mu(\Pi) \geq \left(\frac{1}{10} - \varepsilon - 30(s+1)\sqrt[4]{\delta}\right)|\mu| - \Delta \cdot L(\Pi). \tag{2.5}$$

▶ Remark. Since $\varepsilon \leq \frac{1}{2}$, our definitions imply that $\mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f) + \mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f)) \geq \frac{1}{2}$; thus $s \geq 0$. Similarly, since $\Delta \leq |\mu|$, we have $t \geq 0$.

Proof. First, we observe that if $\max\{\mu_0,\mu_1\} \geq 2\min\{\mu_0,\mu_1\}$, then the protocol Π consisting of just one leaf, with the most popular value as label, meets the requirements: for, $\mathsf{adv}_\mu(\Pi) \geq \frac{1}{3}|\mu|$ and $L(\Pi) = 1$, and our claim holds. Also, we may assume that $\varepsilon - 30(s+1)\sqrt[4]{\delta} < \frac{1}{10}$, for otherwise the claim is trivially true.

We now proceed by induction on $s+t$, assuming that μ is balanced: $\max\{\mu_0,\mu_1\} \leq 2\min\{\mu_0,\mu_1\}$.

Base case ($s = 0$)

Since $s = 0$, we have $\log \mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f) \leq \frac{1}{100}$. We will show a protocol Π where Alice sends one bit after which Bob announces the answer. Consider the optimal solution $\langle w_R : R \text{ a rectangle}\rangle$ to the LP corresponding to $\mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f)$; thus, $\mathsf{OPT} := \sum_R w_R = \mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f) \leq 2^{1/100} \leq 2$. Let $R = R_X \times R_Y$ be a random rectangle picked with probability proportional to w_R (using public coins). In the protocol Π, Alice tells Bob if $x \in R_X$, and Bob returns the answer 1 if $(x,y) \in R_Y$ and returns 0 otherwise. Let $p_{xy} := \Pr_R[(x,y) \in R]$. Then, by (2.1) we have $\sum_{(x,y)\in f^{-1}(1)} \mu(x,y)p_{xy} \geq (1-\varepsilon)\mu_1/\mathsf{OPT}$, and by (2.2), we have $\sum_{(x,y)\in f^{-1}(0)} \mu(x,y)p_{xy} \leq \delta\mu_0/\mathsf{OPT}$. Thus,

$$\begin{aligned}
\mathbb{E}_R\left[\sum_{(x,y):\Pi(x,y)\neq f(x,y)} \mu(x,y)\right] &= \sum_{(x,y)\in f^{-1}(1)} \mu(x,y)(1-p_{xy}) + \sum_{(x,y)\in f^{-1}(0)} \mu(x,y)p_{x,y} \\
&\leq \mu_1 - (1-\varepsilon)\mu_1/\mathsf{OPT} + \delta\mu_0/\mathsf{OPT} \\
&\leq \mu_1 - ((1-\varepsilon)\mu_1 - \delta\mu_0)/\mathsf{OPT} \\
&\leq \frac{1}{2}(\mu_1 + \varepsilon\mu_1 + \delta\mu_0) \qquad (\text{since } \mathsf{OPT} \leq 2).
\end{aligned} \tag{2.6}$$

Fix a choice R for which the quantity under the expectation is at most $\frac{1}{2}(\mu_1 + \varepsilon\mu_1 + \delta\mu_0)$. Then,

$$\begin{aligned}
\mathsf{adv}(\Pi) &= |\mu| - 2\sum_{(x,y):\Pi(x,y)\neq f(x,y)} \mu(x,y) \\
&\geq |\mu| - (\mu_1 + \varepsilon\mu_1 + \delta\mu_0) \\
&\geq \left(\frac{1}{3} - \varepsilon - \delta\right)|\mu| \qquad (\text{since } \mu_1 \leq 2\mu_0).
\end{aligned}$$

Base case ($t = 0$)

In this case, $|\mu| = \Delta$, and the protocol Π with a single leaf that gives the most probable answer achieves $\mathsf{adv}(\Pi) \geq 0 \geq |\mu| - \Delta$.

Induction step

We will use Lemma 8 to decompose the communication matrix into a small number of rectangles. After an exchange of a few bits to determine in which rectangle the input lies, Alice and Bob will be left with a problem for which s or t is significantly smaller. Assume $\mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f) \geq \mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f)$; in particular, $\mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f) \leq 2^{s/100}$.

Formally, from Lemma 8 (taking $\rho = \sqrt{\delta}$), we obtain a rectangle $R^{(00)} = X_0 \times Y_0$ such that (a) $R^{(00)}$ is $(1-\sqrt{\delta})$-biased towards 0, and (b) $\mu(R^{(00)}) \geq \frac{1}{2^{s/100}}(1-\varepsilon-2\sqrt{\delta})|\mu_0| \geq \frac{1}{3\cdot 2^{s/100}}(1-\varepsilon-2\sqrt{\delta})|\mu|$. Recall the definitions of the rectangles $R^{(10)}, R^{(01)}, R^{(11)}, R^{(1*)}, R^{(*1)}$ and the corresponding restrictions of μ, namely, $\mu^{(01)}, \mu^{(10)}, \mu^{(11)}, \mu^{(1*)}, \mu^{(*1)}$. Suppose the choice of ij in Lemma 9 for which one of the alternatives holds is $ij = 01$ (the other case $ij = 10$ is symmetric). The protocol Π proceeds as follows. Alice starts by telling Bob if $x \in X_0$.

Alice says $x \in X_0$. Now, Bob tells Alice if $y \in Y_0$.

Bob says $y \in Y_0$. The protocol $\Pi^{(00)}$ in this case has one leaf with answer 0; thus $\mathsf{adv}(\Pi^{(00)}) \geq |\mu^{(00)}| \cdot (1-\sqrt{\delta})$.

Bob says $y \notin Y_0$. Alice and Bob follow the protocol $\Pi^{(01)}$ promised by induction for $R^{(01)}$ under $\mu^{(01)}$. To bound the number of leaves in $\Pi^{(01)}$, we will consider the two alternatives ((a) and (b)) specified in Lemma 9 separately. First (alternative (a)) suppose $2\mu^{(01)}(f^{-1}(1)) \leq \mu^{(01)}(f^{-1}(0))$; then we immediately declare 0 as the response, so that $L(\Pi^{(01)}) = 1$ and $\mathsf{adv}(\Pi^{(01)}) \geq |\mu^{(01)}|/3$. If alternative (b) holds, then we have

$$\mathsf{srec}^{1,\mu^{(01)}}_{\varepsilon^{(01)}+30\sqrt[4]{\delta},\delta}(f) \leq 0.9\mathsf{srec}^{1,\mu}_{\varepsilon,\delta}(f). \tag{2.7}$$

Then, we obtain $\Pi^{(01)}$ by induction. We take $\varepsilon^{(01)} + 30\sqrt[4]{\delta}$ as ε (if this quantity is greater than 1, then we use a trivial protocol with one leaf and zero advantage). With the reduction promised in (2.7), we may use a value of s that is the old s minus 1. Thus, we have

$$L(\Pi^{(01)}) \leq 4\binom{(s-1)+t}{t} - 1;$$
$$\mathsf{adv}(\Pi^{(01)}) \geq |\mu^{(01)}| \cdot \left(\frac{1}{10} - (\varepsilon^{(01)} + 30\sqrt[4]{\delta}) - 30s\sqrt[4]{\delta}\right) - \Delta \cdot L(\Pi^{(01)}).$$

Alice says $x \notin X_0$. Alice and Bob follow the protocol $\Pi^{(1*)}$ obtained by applying the induction hypothesis to the rectangle $R^{(1*)}$ and the associated distribution $\mu^{(1*)}$. Observe that

$$|\mu^{(1*)}| \leq |\mu| - \mu(R^{(00)}) \leq |\mu|\left(1 - \frac{1}{3\cdot 2^{s/100}}(1-\varepsilon-2\sqrt{\delta})\right) \leq |\mu|\left(1-\frac{1}{4\cdot 2^s}\right). \tag{2.8}$$

For the last inequality we used $\varepsilon + 2\sqrt{\delta} \leq \frac{1}{10}$, for otherwise (2.5) holds trivially. Now, (2.8) implies that $\log|\mu^{(1*)}| \leq \log|\mu| - \frac{1}{1002^s}$; so, for our induction we may take $t \leftarrow t-1$. The parameters ε, δ and Δ remain the same. The original LP solutions are still valid for

the subproblem, so we use the same s. The protocol $\Pi^{(1*)}$ obtained by induction satisfies the following inequalities.

$$L(\Pi^{(1*)}) \leq 4\binom{s+(t-1)}{t-1} - 1;$$
$$\mathsf{adv}(\Pi^{(1*)}) \geq |\mu^{(1*)}| \cdot \left(\frac{1}{10} - \varepsilon^{(1*)} - 30(s+1)\sqrt[4]{\delta}\right) - \Delta \cdot L(\Pi^{(1*)}).$$

Putting all the contributions together, we obtain

$$\begin{aligned}
L(\Pi) &= 1 + L(\Pi^{(01)}) + L(\Pi^{(1*)}) \\
&\leq 1 + \left(4\binom{(s-1)+t}{t} - 1\right) + \left(4\binom{s+(t-1)}{t-1} - 1\right) \\
&= 4\binom{s+t}{t} - 1; \\
\mathsf{adv}(\Pi) &\geq |\mu^{(00)}| \cdot (1 - \sqrt{\delta}) \\
&\quad + |\mu^{(01)}| \cdot \left(\frac{1}{10} - (\varepsilon^{(01)} + 30\sqrt[4]{\delta}) - 30s\sqrt[4]{\delta}\right) - \Delta \cdot L(\Pi^{(01)}) \\
&\quad + |\mu^{(1*)}| \cdot \left(\frac{1}{10} - \varepsilon^{(1*)} - 30(s+1)\sqrt[4]{\delta}\right) - \Delta \cdot L(\Pi^{(1*)}) \\
&\geq \left(\frac{1}{10} - \varepsilon - 30(s+1)\sqrt[4]{\delta}\right)|\mu| - \Delta \cdot L(\Pi).
\end{aligned}$$

◀

The above lemma yields a protocol whose protocol tree has a small number of leaves, but not necessarily small depth. We can balance the protocol tree using the following proposition.

▶ **Proposition 11** ([12, Lemma 2.8]). *If f has a deterministic communication protocol tree with ℓ leaves, then f has a protocol tree with depth at most $O(\log \ell)$.*

We are now in a position to complete the proof of the main theorem of this section.

Proof of Theorem 6. To prove the first part of Theorem 6, we invoke Lemma 10 with $\Delta = 1/2^{4n}$ and $\varepsilon = \delta = 1/n^2$ to derive a protocol tree Π with at most

$$L(\Pi) = n^{O\left(\log \mathsf{srec}^{1,\mu}_{1/n^2,1/n^2}(f)\right)^2}$$

leaves and advantage at least $1/20$. The first part now follows from Proposition 11.

To prove the second part of Theorem 6, we invoke Lemma 10 with $s = k$, $\Delta = 1/2^{5k^2}$ and $\varepsilon = \delta = 1/(30 \cdot 100(k+1)^4)$ where k satisfies the hypothesis. With this setting of parameters $t = \lceil 500 \cdot 2^k k^2 \rceil \leq 2^{2k}$ (for $k \geq 20$). Lemma 10 implies a protocol tree Π with at most

$$L(\Pi) \leq (t+s)^s \leq t^{2s} \leq 2^{4k^2}$$

leaves and advantage at most $1/20$. The second claim then follows from Proposition 11. ◀

2.3 Proofs of Lemmas 8–9

Proof of Lemma 8. Fix $z \in \{0,1\}$. In the following we say that a rectangle R is *biased* (towards 0) if $\mu_1(R) \leq \rho \cdot \mu_0(R)$; otherwise, we say it is unbiased. Fix a solution $\langle w_R :$

R is a rectangle$\rangle$ that achieves the optimum $\mathsf{srec}^{0,\mu}_{\varepsilon,\delta}(f) \le D$. It follows

$$\begin{aligned}\sum_{R:\text{unbiased}} w_R \cdot \mu_0(R) &\le \sum_{R:\text{unbiased}} w_R \cdot \frac{\mu_1(R)}{\rho} \\ &\le \frac{1}{\rho} \cdot \sum_R w_R \cdot \mu_1(R) \\ &= \frac{1}{\rho} \sum_{(x,y)\in f^{-1}(1)} \mu(x,y) \sum_{R:(x,y)\in R} w_R \\ &\le \frac{\delta}{\rho} \cdot \mu_1,\end{aligned}$$

where the last inequality follows from the packing constraints (2.2). We now use the covering constraints (2.1) to conclude that

$$\sum_{R:\text{biased}} w_R \cdot \mu_0(R) = \sum_R w_R \cdot \mu_0(R) - \sum_{R:\text{unbiased}} w_r \cdot \mu_0(R) \ge (1-\varepsilon)\cdot\mu_0 - \frac{\delta}{\rho}\cdot\mu_1. \quad (2.9)$$

Define a probability distribution on the rectangles R as follows $p(R) := w_R/\mathsf{srec}^{0,\mu}_{\varepsilon,\delta}(f)$. Then (2.9) can be rewritten as

$$\mathbb{E}_R\left[\mathbb{I}_{\text{biased}}(R)\cdot\mu_0(R)\right] \ge \frac{1}{D}\cdot\left((1-\varepsilon)\cdot\mu_0 - \frac{\delta}{\rho}\cdot\mu_1\right).$$

Hence, there exists a large biased rectangle $S = X_0 \times Y_0$ as claimed. ◀

Proof of Lemma 9. Since $R^{(00)}$ is $(1-\sqrt{\delta})$-biased towards 0, we have from the packing and covering constraints (2.2) and (2.3) that

$$\begin{aligned}&\sum_{(x,y)\in R^{(00)}} \mu_{x,y} \sum_{R\ni(x,y)} w_R \\ &= \sum_{(x,y)\in R^{(00)}\cap f^{-1}(1)} \mu_{x,y} \sum_{R\ni(x,y)} w_R + \sum_{(x,y)\in R^{(00)}\cap f^{-1}(0)} \mu_{x,y} \sum_{R\ni(x,y)} w_R \\ &\le \mu_1(R^{(00)}) + \delta\mu_0(R^{(00)}) \le (\sqrt{\delta}+\delta)\mu_0(R^{(00)}) \le 2\sqrt{\delta}\mu(R^{(00)}).\end{aligned}$$

Hence,

$$\sum_R w_R \cdot \left(\frac{\mu(R^{(00)}\cap R)}{\mu(R^{(00)})}\right) \le 2\sqrt{\delta}. \quad (2.10)$$

Group the rectangles in to subsets as follows:

$$B^{(01)} := \left\{R : \frac{\mu(R^{(01)}\cap R)}{\mu(R^{(01)})} \ge \frac{10\sqrt[4]{\delta}}{D}\right\}, \qquad B^{(10)} := \left\{R : \frac{\mu(R^{(10)}\cap R)}{\mu(R^{(10)})} \ge \frac{10\sqrt[4]{\delta}}{D}\right\},$$
$$B := \left\{R : \frac{\mu(R^{(11)}\cap R)}{\mu(R^{(11)})} \ge \frac{10}{D}\right\}.$$

By (2.3), we have

$$\sum_{(x,y)\in R^{(11)}} \mu_{x,y} \sum_{R\ni(x,y)} w_R \le \sum_{(x,y)\in R^{(11)}} \mu_{x,y} = \mu(R^{(11)}).$$

Or equivalently,

$$\sum_R \frac{w_R}{D} \cdot \frac{\mu(R^{(11)} \cap R)}{\mu(R^{(11)})} \leq \frac{1}{D}.$$

Hence,

$$\sum_{R \in B} w_R \leq 0.1D. \tag{2.11}$$

We will now argue that either $\sum_{R \in B^{(01)}} w_R \leq 0.9D$ or $\sum_{R \in B^{(10)}} w_R \leq 0.9D$. Suppose, for contradiction, that neither is true. Then, by (2.11) we have

$$\sum_{R \in \left(B^{(01)} \cap B^{(10)}\right) \setminus B} w_R \geq 0.7D. \tag{2.12}$$

Since μ is a product distribution we have

$$\frac{\mu(R^{(01)} \cap R)}{\mu(R^{(01)})} \cdot \frac{\mu(R^{(10)} \cap R)}{\mu(R^{(10)})} = \frac{\mu(R^{(00)} \cap R)}{\mu(R^{(00)})} \cdot \frac{\mu(R^{(11)} \cap R)}{\mu(R^{(11)})}.$$

Using the above we have

$$\begin{aligned}
&\sum_R w_R \cdot \left(\frac{\mu(R^{(00)} \cap R)}{\mu(R^{(00)})}\right) \\
&\geq \sum_{R \in \left(B^{(01)} \cap B^{(10)}\right) \setminus B} w_R \cdot \left(\frac{\mu(R^{(00)} \cap R)}{\mu(R^{(00)})}\right) \\
&\geq \sum_{R \in \left(B^{(01)} \cap B^{(10)}\right) \setminus B} w_R \cdot \left(\frac{\mu(R^{(01)} \cap R)}{\mu(R^{(01)})}\right) \cdot \left(\frac{\mu(R^{(10)} \cap R)}{\mu(R^{(10)})}\right) \Bigg/ \left(\frac{\mu(R^{(11)} \cap R)}{\mu(R^{(11)})}\right) \\
&\geq \sum_{R \in \left(B^{(01)} \cap B^{(10)}\right) \setminus B} w_R \cdot \left(\frac{10\sqrt[4]{\delta}}{D}\right) \cdot \left(\frac{10\sqrt[4]{\delta}}{D}\right) \Bigg/ \left(\frac{10}{D}\right) \\
&\geq \frac{10\sqrt{\delta}}{D} \cdot (0.7D) \\
&= 7\sqrt{\delta}.
\end{aligned}$$

This contradicts (2.10). Hence, either $\sum_{R \in B^{(01)}} w_R \leq 0.9D$ or $\sum_{R \in B^{(10)}} w_R \leq 0.9D$. Assume, wlog that $\sum_{R \in B^{(01)}} w_R \leq 0.9D$. If f is 1/2-biased towards 0 with respect to the distribution $\mu^{(01)}$, then the alternative (a) of the lemma holds, and we are done. Otherwise, that is $\mu_0(R^{(01)}) \leq 2\mu_1(R^{(01)})$ or equivalently $\mu(R^{(01)}) \leq 3\mu_1^{(01)}(R^{(01)})$. We will infer from this that $\mathsf{srec}^{1,\mu^{(01)}}_{\varepsilon^{(01)}+30\sqrt[4]{\delta},\delta}(f) \leq 0.9D$. Consider the primal solution given by

$$w'_R = \begin{cases} w_R, & \text{if } R \in B^{(01)} \\ 0, & \text{if } R \notin B^{(01)}. \end{cases}$$

Clearly, w'_R, being a part of the original solution, satisfies (2.2) and (2.3), and has objective value at most $0.9D$. All we need to show is that it satisfies the covering constraint (2.1). For this, we first consider

$$\sum_{R \notin B^{(01)}} w_R \cdot \left(\frac{\mu_1(R^{(01)} \cap R)}{\mu(R^{(01)})}\right) \leq \sum_{R \notin B^{(01)}} w_R \cdot \left(\frac{\mu(R^{(01)} \cap R)}{\mu(R^{(01)})}\right) \leq \frac{10\sqrt[4]{\delta}}{D} \cdot D \leq 10\sqrt[4]{\delta}. \tag{2.13}$$

Now,

$$\begin{aligned}
&\sum_{(x,y)\in f^{-1}(1)\cap R^{(01)}} \mu_{x,y} \sum_{R\in(x,y)} w'_R \\
&= \sum_{(x,y)\in f^{-1}(1)\cap R^{(01)}} \mu_{x,y} \sum_{R\in(x,y),R\in B^{(01)}} w_R \\
&= \sum_{(x,y)\in f^{-1}(1)\cap R^{(01)}} \mu_{x,y} \left(\sum_{R\in(x,y)} w_R - \sum_{R\in(x,y),R\notin B^{(01)}} w_R \right) \\
&= (1-\varepsilon^{(01)})\mu_1(R^{(01)}) - \sum_{(x,y)\in f^{-1}(1)\cap R^{(01)}} \mu_{x,y} \sum_{R\in(x,y),R\notin B^{(01)}} w_R \\
&= (1-\varepsilon^{(01)})\mu_1(R^{(01)}) - \sum_{R\notin B^{(01)}} w_R \mu_1(R^{(01)}\cap R) \\
&\geq (1-\varepsilon^{(01)})\mu_1(R^{(01)}) - 10\sqrt[4]{\delta}\mu(R^{(01)}) && \text{[From (2.13)]} \\
&\geq (1-\varepsilon^{(01)})\mu_1(R^{(01)}) - 30\sqrt[4]{\delta}\mu_1(R^{(01)}) && \text{[Since } \mu(R^{(01)}) \leq 3\mu_1(R^{(01)})\text{]} \\
&= (1-\varepsilon^{(01)} - 30\sqrt[4]{\delta})\mu_1(R^{(01)})
\end{aligned}$$

Thus, (2.1) holds for $R^{(01)}$ with ε replaced by $\varepsilon^{(01)} + 30\sqrt[4]{\delta}$. ◀

Abstract

Plurality consensus considers a network of n nodes, each having one of k opinions. Nodes execute a (randomized) distributed protocol with the goal that all nodes adopt the *plurality* (the opinion initially supported by the most nodes). Communication is realized via the Gossip (or random phone call) model. A major open question has been whether there is a protocol for the complete graph that converges (w.h.p.) in polylogarithmic time and uses only polylogarithmic memory per node (local memory). We answer this question affirmatively.

We propose two protocols that need only mild assumptions on the bias in favor of the plurality. As an example of our results, consider the complete graph and an arbitrarily small constant multiplicative bias in favor of the plurality. Our first protocol achieves plurality consensus in $\mathrm{O}(\log k \cdot \log\log n)$ rounds using $\log k + \Theta(\log\log k)$ bits of local memory. Our second protocol achieves plurality consensus in $\mathrm{O}(\log n \cdot \log\log n)$ rounds using only $\log k + 4$ bits of local memory. This disproves a conjecture by Becchetti et al. (SODA'15) implying that any protocol with local memory $\log k + \mathrm{O}(1)$ has worst-case runtime $\Omega(k)$. We provide similar bounds for much weaker bias assumptions. At the heart of our protocols lies an *undecided state*, an idea introduced by Angluin et al. (Distributed Computing'08).

1 Introduction

Reaching *plurality consensus* is a fundamental problem in distributed computing. We consider this problem in a networked setting, where a graph is given in which each node initially holds one of $k \in \mathbb{N}$ *opinions*. The objective is the design of an efficient distributed protocol that ensures that eventually all nodes agree on the initial *plurality opinion*, which is the opinion that is initially supported by the most nodes. This problem is also referred to as *majority consensus* or *proportionate agreement* [1, 3, 19]. In accordance with [5] and others, we prefer to refer to it as *plurality consensus*, so as to make clear that the opinion eventually to be attained by all nodes need not initially have been absolute majority. One need not stray too far from the core of distributed computing to come across direct applications of plurality consensus: the handling of fault tolerance in parallel computing or the implementation of

majority-based conflict resolution for CRCW PRAMs (and derivative models) are immediate examples.

Natural metrics for plurality consensus protocols are running time and memory overhead. The latter is the additional amount of (local) memory needed by each node above and beyond the bits required to store its current opinion. Results are typically expressed in terms of the number of nodes, the number of initial opinions, and the initial bias (between plurality and remaining opinions). Of particular interest, to us and in general, are fast protocols with small memory overhead. As in [5] we assume a synchronous PULL-based GOSSIP communication model on the underlying graph. Here, in each discrete round, every node may contact one neighbor and query that neighbor's opinion. We mostly assume the complete graph, but using a construction of [5] we can easily extend our results to regular expanders. We define the (relative) plurality gap $\gamma > 1$ as the ratio between the plurality opinion and the second most common opinion. We analyze two protocols in this paper:

- A protocol with running time $\mathrm{O}\big(\log k \cdot \log\log_\gamma n + \log\log n\big)$ and memory overhead $\Theta\left(\log\log k\right)$.
- A protocol with running time $\mathrm{O}\big(\log n \cdot \log\log_\gamma n\big)$ and memory overhead 4.

Plurality consensus is a member of the class of population dynamics, which are of great interest in fields as varied as epidemiology, physics, statistics, biology, chemistry, or sociology. All these have in common an initial population of agents with some initial properties and a protocol (dynamics) that in some manner changes the properties of given agents usually based on those of other agents. Specific models are as varied as the problems themselves; for instance, we may or may not have an underlying graph structure, a prescribed timing model, or restrictions on the amount and nature of communication. Other related dynamics are the lately en vogue voting protocols and Moran-type processes.

1.1 Related Work

In [3], Aspnes et al. consider $k = 2$ initial opinions $\{x, y\}$ and the complete graph as neighborhood structure. They introduce a third state, referred to as *blank*, b, which is a crucial ingredient in their protocol and analysis. Their protocol works such that an activated node u picks another node v at random. Given the opinions of those two nodes, the transition now proceeds as follows: If u has a non-blank opinion and sees in v the other non-blank opinion then it changes to b, if it has a non-blank opinion and sees in v the same non-blank opinion or b then it maintains its opinion, and if it has the blank opinion then it just copies whatever it sees in v. The authors show that with high probability all n nodes reach consensus within $\mathrm{O}\left(n \log n\right)$ many interactions (corresponding to parallel convergence time $\mathrm{O}\left(\log n\right)$), and the consensus value is the plurality value provided its (absolute) initial bias is at least $\omega\left(\sqrt{n}\log n\right)$. Each node needs to be able to store one of three values, x, y, or b.

In the case of two opinions the plurality problem can be solved by calculating the median of the opinions. In [11] the authors present such a protocol that converges in $\mathrm{O}\left(\log n\right)$ rounds and has constant memory overhead, if the initial difference bias $c_1 - c_2$ is at least $\Omega\left(\sqrt{n \log n}\right)$. In [2] the authors consider the plurality problem in a sequential setting where only one node can change its opinion at a time. They present a new protocol called Average and Conquer (AVC) that solves plurality exactly, in sequential time $\mathrm{O}\left(n \log n/(s\epsilon) + \log n \log s\right)$, where ϵn ($\epsilon > 1/2$) is the size of the plurality opinion and s the number of states. In [7] the authors generalize the former result to general networks and k opinions. They introduce protocols that solve the plurality consensus problem that are based on an interesting relationship between plurality consensus and distributed load balancing.

In [5] Becchetti et al. take the model of [3] and generalise it to $k \geq 2$ initial opinions. They still use the blank state, which they however refer to as undecided. The authors express their results in terms of $\mathrm{md}(\bar{\mathbf{c}})$, *the monochromatic distance* of configuration c. Formally, $\mathrm{md}(\bar{\mathbf{c}}) = \sum_{i=1}^{k} c_i/c_1$, where c_i is the number of nodes with opinion i and $c_1 \geq c_2 \cdots \geq c_k$. Note that $\mathrm{md}(\bar{\mathbf{c}})$ is always between $\mathrm{O}(1)$ and $\mathrm{O}(k)$. Then authors show almost-tight bounds on convergence time. Formally, let $k = k(n)$ be any function such that $k = \mathrm{O}\left((n/\log n)^{1/3}\right)$, and consider any initial configuration with $c_1 \geq (1+\alpha) \cdot c_2$, where $\alpha \geq 0$ is any arbitrarily-small constant. Their protocol converges in $\mathrm{O}(\mathrm{md}(\bar{\mathbf{c}}) \cdot \log n)$, rounds (w.h.p.) and it has only constant memory overhead. They also show that for $k = \mathrm{O}\left((n/\log n)^{1/6}\right)$ and any initial configuration the convergence time of their protocol is (w.h.p.) linear in the monochromatic distance. Finally, they show how to adapt their results to regular expanders using random walks to sample the opinion of nodes. As with [3], they require one state more than is necessary to store the actual opinion values. They conjecture that any protocol using $\log k + \mathrm{O}(1)$ bits of memory has runtime at least linear in k in the worst case — as discussed later, we partially refute this conjecture. In [6] the authors consider the 3-majority dynamics. They show that for $k \leq n^{\alpha}$ (with constant α) the 3-majority dynamics converges to an *almost-consensus* state in time $\mathrm{O}\left((k^2\sqrt{\log n} + kl\log n)(k+\log n)\right)$. An almost-consensus state is defined as a state where all but a subset of size $\mathrm{O}(n^{\gamma})$ (for constant $\gamma < 1$) of the nodes support the same opinion. In [4] the authors consider the undecided dynamics in complete graphs in an asynchronous setting. They derive the time of convergence and an upper bound for the probability of error.

A line of research which is related to the plurality consensus problem is the voting problem. The setting is the same, a network with n nodes is given and initially every node has one of k opinions. Here the goal is that all nodes agree on one opinion, which is not necessarily the plurality opinion. A sequential version of the voter model was introduced in [16]. The parallel voter model was first analyzed in [15]. The authors of [15] bound the expected consensus time in terms of the expected meeting time T_m of two random walks and show a bound of $\mathrm{O}(T_m \cdot \log n) = \mathrm{O}\left(n^3 \log n\right)$. The authors of [8] provide an improved upper bound of $O\big(1/(1-\lambda_2) \cdot \log^4 n + \rho\big)$ on the expected consensus time for any graph G, where λ_2 is the second eigenvalue of the transition matrix of a random walk on G, and $\rho = \big(\sum_{u \in V(G)} d(u)\big)^2 / \sum_{u \in V(G)} d^2(u)$ is the ratio of the square of the sum of node degrees over the sum of the squared degrees. The authors of [9, 10] consider a modification of the standard voter model with two opinions, which they call *two-sample voting*. In every round, each node chooses two of its neighbors randomly and adopts their opinion only if they both agree. For regular graphs and random regular graphs, it is shown that two-sample voting has a consensus time of $\mathrm{O}(\log n)$ if the initial imbalance between the nodes having the two opinions is large enough. In [13] the authors consider a 2-choice voting protocol for k opinions in the complete graph. Their protocol converges to the majority opinion in time $\mathrm{O}(k \cdot \log n)$, with high probability, if k=$\mathrm{O}(n^{\epsilon})$ for some small $\epsilon > 0$, and the initial absolute gap between largest and second-largest opinion is $\Omega\left(\sqrt{n \log n}\right)$. They also show that there exist initial configurations where the $\Theta(k)$ bound on the run time is matched. Independently, they also give a protocol which is similar to our simple, first protocol (cf. Section 3) and has roughly the same voting time. Other related papers from literature about sensor networks include [12] (which considers *binary interval consensus*, which can be used to solve majorization) and [17] (which considers the plurality problem in a different distributed model and for constant k).

1.2 Our Contribution

In Section 3 we present and analyze protocol RepeatedCleanup, which in a complete graph of n nodes and k opinions works in $\mathrm{O}\left(\log k \cdot \log\log_{\gamma} n + \log\log n\right)$ rounds and has a memory

overhead of $O(\log\log k)$ bits. The protocol is a synchronized version of the protocol from [6], in which the nodes "lose" their opinion and adopt the state "undecided" whenever they sample a node with a different opinion. Then they will adopt the "real" opinion of the next (i.e., not undecided) node they sample. The nodes keep changing their opinion until all nodes agree on the plurality opinion. In contrast, our protocol works in $O\left(\log\log_\gamma n\right)$ many phases, each of length $\Theta(\log k)$. In the first round of every phase the nodes sample a node and lose the opinion if the sampled node has a different opinion. They then use the rest of the phase to find a new "real" opinion. In [5] the authors show that for $k = O\left((n/\log n)^{1/6}\right)$ and any initial configuration the convergence time of their protocol is linear in the monochromatic distance, which can be as large as $O(k)$. Hence, our protocol outperforms the lower bound for the protocol of [5]. Interestingly, the speed-up is reached by synchronizing the protocol, which can also be regarded as slowing it down. In our protocol a node that just found a real opinion again waits until the beginning of the next round to sample another node, instead of doing that immediately.

The drawback of our first protocol is that it uses a counter to determine the end of a phase. In Section 4 we present a protocol that works in $O\left(\log n \cdot \log\log_\gamma n\right)$ rounds and has a memory overhead of only 4 bits. The main idea of the protocol is to slow down the progress in the individual phases by having nodes toss a biased coin with success probability $1/n$, basically replacing the deterministic counter by a probabilistic counterpart. Our result shows that a conjecture by Becchetti et al. [5], implying that any protocol with constant memory overhead has worst-case runtime $\Omega(k)$, does not hold if nodes have access to such a coin. Note that the coin toss is not necessary if nodes can decide whether they sampled themselves (or a marked node/leader).

A very recent, independent result by Ghaffari and Parter [14] suggests a protocol for plurality consensus with similar time and memory bounds as ours. They employ the same basic idea of cleanup and decision-accumulation rounds (cf. Section 3), which they name selection and recovery steps. Their final protocol differs in that they use some of the undecided nodes as *clock nodes* (which use the $\log k$ bits normally used to store the opinion to count time) to help synchronize other nodes.

2 Model & Notation

We consider protocols in the complete graph with $n \in \mathbb{N}$ nodes. Each node u has one of $k \in \mathbb{N}$ opinions $\mathrm{op}_u \in \{1, 2, \ldots, k\}$. We write $\mathrm{op}_u = \perp$ to indicate that node u is undecided. Time is modelled in synchronous, discrete and parallel rounds and we assume a PULL-based GOSSIP model for communication (nodes can request information from one other node chosen uniformly at random). Note that each node needs at least $\lceil \log k \rceil$ bits of local memory (to store its current opinion). Any additional number of bits per node needed by a given protocol is called the protocol's *memory overhead*.

Notation. In the following, $\|\cdot\|_1$ and $\|\cdot\|_2$ denote the L^1 and L^2 norms, respectively, that is, $\|\boldsymbol{x}\|_1 = \sum_{i=1}^n |x_i|$ and $\|\boldsymbol{x}\|_2 = \sqrt{\sum_{i=1}^n |x_i|^2}$ for an n-dimensional vector $\boldsymbol{x}$. For a real value $x > 0$, its binary logarithm is denoted by $\log x$ and its natural logarithm by $\ln x$. For an integer i, the shorthand $[i] \coloneqq \{1, 2, \ldots, i\}$ denotes the set of the first i integers. The phrase *with high probability* (w.h.p.) refers to probabilities of the form $1 - n^{-\Omega(1)}$.

At any point in time, the system can be described by a k-dimensional vector $\boldsymbol{x} = (x_1, x_2, \ldots, x_k) \in \{0/n, 1/n, \ldots, 1\}^k \subseteq [0,1]^k$, where the i-th entry $x_i \in [0,1]$ denotes the current fraction of nodes with opinion i. We call such a vector $\boldsymbol{x}$ a *configuration*. Note

that $1 - \|\boldsymbol{x}\|_1 \in [0,1]$ is the fraction of undecided nodes. $X_i(t)$ is defined as the random variable that takes as its values the configuration produced by the protocol at the end of round $t \in \mathbb{N}_0$. We use $\bar{\boldsymbol{x}} \coloneqq \boldsymbol{X}(0)$ to denote the initial (fixed) configuration. The random variable $Y(t) \coloneqq 1 - \|\boldsymbol{X}(t)\|_1$ with values in $\in [0,1]$ denotes the fraction of undecided nodes at the end of round t.

To measure how far we are from plurality consensus, we define two *plurality gap* notions: Assuming (w.l.o.g.) that 1 is a most common opinion, let $\psi(\boldsymbol{x}) \coloneqq x_1 - \max_{i \neq 1} x_i \in [0,1]$ be the *absolute* plurality gap. Similarly, $\gamma(\boldsymbol{x}) \coloneqq x_1 / \max_{i \neq 1} x_i \geq 1$ is the *relative* plurality gap.

Assumptions. In order to guarantee convergence, we need some (mild) bias assumptions. Given the initial configuration $\bar{\boldsymbol{x}}$, without loss of generality (w.l.o.g.), we assume $\bar{x}_1 \geq \bar{x}_i$ for all $i \in [k]$ and refer to (the initially most common) opinion 1 as the *plurality opinion*. For most of the analysis we assume

$$\psi(\bar{\boldsymbol{x}}) = \omega\left(\frac{(\log n)^2}{\sqrt{n}}\right) \tag{1}$$

and

$$k = \mathrm{o}\left(\frac{\sqrt{n}}{(\log n)^2}\right). \tag{2}$$

While Condition (1) is essential[1], Condition (2) is without loss of generality (it can be achieved by merging small opinions). We define $\rho = \rho(n) \coloneqq (\log n)^2/\sqrt{n}$ and call a configuration $\boldsymbol{x}$ *biased* if $\psi(\boldsymbol{x}) = \omega(\rho)$. Our analysis assumes n to be at least some sufficiently large constant.

3 Plurality Consensus with $\log k + \Theta(\log\log k)$ Bits

We divide time into *phases*, each consisting of $T \coloneqq 5 + 2\log k$ rounds. In each round, every node u uses a Pull operation to sample a random node v and checks its opinion op_v. We distinguish two types of rounds:

- *Cleanup* rounds represent the first round of each phase. Here, u becomes undecided if op_v differs from u's own opinion op_u (and keeps its opinion otherwise).
- *Decision-accumulation* rounds make up the remaining $T - 1$ rounds of a phase. Here, only undecided nodes act and simply adopt the pulled opinion op_v.

The synchronization of the steps in which nodes lose their opinion and adopt opinions of sampled nodes is key to the fast convergence. As we will see in the analysis they ensure that each phase increases the relative plurality gap exponentially. We call this protocol RepeatedCleanup. See Listing 1 for a formal description. In the remainder of this section we prove the following theorem.

▶ **Theorem 1.** RepeatedCleanup *has a local memory overhead of* $\Theta(\log\log k)$ *bits. If started on a biased configuration* $\bar{\boldsymbol{x}}$ *with relative plurality gap* $\gamma \coloneqq \gamma(\bar{\boldsymbol{x}})$*, then (w.h.p.) plurality consensus is achieved in* $\mathrm{O}\big(\log(k) \cdot \log\log_\gamma n + \log\log n\big)$ *rounds.*

We use the shorthand $\boldsymbol{X}(\tau, t) \coloneqq \boldsymbol{X}((\tau - 1) \cdot T + t)$ to denote the configuration at the end of round t in phase τ. Similarly, $X_i(\tau, t)$ and $Y(\tau, t)$ denote the corresponding fractions

[1] Our results hold also under the slightly weaker condition $\psi(\bar{\boldsymbol{x}}) = \omega\big(\sqrt{\log(n)/n}\big)$. However, Condition (1) significantly simplifies some parts of the analysis.

```
1  sample a random node v
2  if t ≡ 0 (mod T):                                   {cleanup}
3      if op_v ≠ op_u:   op_u ← ⊥
4  else:                                               {decision−accumulation}
5      if op_u = ⊥:      op_u ← op_v
```

Listing 1 Protocol RepeatedCleanup as executed by node u in round $t \in \mathbb{N}$. It works in phases of length $T = \Theta(\log k)$ and has memory overhead $\Theta(\log\log k)$.

of nodes. The following definition identifies opinions that are supported by only a small fraction of nodes (and, thus, are likely to vanish in a cleanup round), and configurations that do not have too many undecided nodes.

- An opinion i in configuration $\boldsymbol{x}$ is *negligible* if $x_i \le \rho$ (recall that $\rho = (\log n)^2/\sqrt{n}$).
- A configuration $\boldsymbol{x}$ is *alive* if $\|\boldsymbol{x}\|_1 \ge 1 - e^{-1}$.

The following simple observation already hints at the basic change of configurations during a phase: in expectation, the cleanup round squares the relative plurality gap (but reduces the absolute support of each opinion), while the decision-accumulation rounds increase the absolute support of each opinion (not changing the relative plurality gap).

▶ **Observation 2.** *Consider a configuration $\boldsymbol{x}$ with $y \coloneqq 1 - \|\boldsymbol{x}\|_1$. If the configuration $\boldsymbol{X}$ results from a cleanup round on $\boldsymbol{x}$ and $Y = 1 - \|\boldsymbol{X}\|_1$, then*

$$\mathbb{E}[X_i] = x_i^2, \qquad \mathbb{E}[\|\boldsymbol{X}\|_1] = \|\boldsymbol{x}\|_2^2, \qquad \text{and} \qquad \mathbb{E}[Y] = 2y - y^2. \tag{3}$$

Similarly, if $\boldsymbol{X}$ results from a decision-accumulation round, then

$$\mathbb{E}[X_i] = (1+y)\cdot x_i, \qquad \mathbb{E}[\|\boldsymbol{X}\|_1] = 2\|\boldsymbol{x}\|_1 - \|\boldsymbol{x}\|_1^2, \qquad \text{and} \qquad \mathbb{E}[Y] = y^2\,. \tag{4}$$

Analysis Overview. The bound on the memory overhead in Theorem 1 immediately follows from the protocol description. The runtime bound is proven in three steps: Lemma 7 shows that all non-plurality opinions become negligible during the first $O\big(\log\log_{\gamma(\bar{\boldsymbol{x}})} n\big)$ phases. Lemma 8 proves that all these negligible opinions vanish within an additional constant number of phases. Lemma 9 shows that any remaining undecided nodes vanish in another $O(\log\log n)$ phases. Before we prove these key lemmas (Section 3.3), we show how configurations evolve during single rounds (Section 3.1) and single phases (Section 3.2).

3.1 Change During a Single Round

Our first two claims show concentration for the expected configuration change in cleanup and decision-accumulation rounds we saw in Observation 2. They follow by standard Chernoff bounds.

▶ **Claim 3** (Cleanup Round). *Consider a configuration $\boldsymbol{x}$ at the beginning of phase τ. Let $a > 0$ be a constant.*

(a) *Let $i \in [k]$ and $\delta \coloneqq \sqrt{3a\cdot\log(n)/n}\cdot x_i^{-1}$. Then*

$$\Pr\left[X_i(\tau,1) \ge \max\left(\rho^2, (1+\delta)\cdot x_i^2\right) \,\middle|\, \boldsymbol{X}(\tau,0) = \boldsymbol{x}\right] \le n^{-a} \qquad \text{and} \tag{5}$$

$$\Pr\left[X_i(\tau,1) \le (1-\delta)\cdot x_i^2 \,\middle|\, \boldsymbol{X}(\tau,0) = \boldsymbol{x}\right] \le n^{-a}. \tag{6}$$

(b) *Let $\delta \coloneqq \sqrt{3a\cdot\log(n)/n}\cdot\|\boldsymbol{x}\|_2^{-1}$. Then* $\Pr\left[\|\boldsymbol{X}(\tau,1)\|_1 \le (1-\delta)\cdot\|\boldsymbol{x}\|_2^2 \,\middle|\, \boldsymbol{X}(\tau,0) = \boldsymbol{x}\right] \le n^{-a}$.

▶ **Claim 4** (Decision-accumulation Round). *Consider a configuration $\boldsymbol{x}$ at the beginning of round $t+1>1$ in phase τ. Let $a>0$ be a constant and $y \coloneqq 1-\|\boldsymbol{x}\|_1$ the fraction of undecided nodes.*

(a) *Let $i \in [k]$, $\delta' \coloneqq \sqrt{13a \cdot \log n/(x_i y \cdot n)}$, and $\delta \coloneqq \max(\delta', \delta'^2)$. Then*

$$\Pr\left[X_i(\tau,t+1) \geq (1+\delta y)\cdot x_i \cdot (1+y) \mid \boldsymbol{X}(\tau,t)=\boldsymbol{x}\right] \leq n^{-a} \qquad \text{and} \tag{7}$$

$$\Pr\left[X_i(\tau,t+1) \leq (1-\delta' y)\cdot x_i \cdot (1+y) \mid \boldsymbol{X}(\tau,t)=\boldsymbol{x}\right] \leq n^{-a}\,. \tag{8}$$

(b) *Assume $y \leq 1-\rho$. Then* $\Pr\left[Y(\tau,t+1) \geq \max\left(\rho^2, y^{3/2}\right) \mid \boldsymbol{X}(\tau,t)=\boldsymbol{x}\right] \leq n^{-a}$.

3.2 Change During a Single Phase

Next, we use the effects of single rounds to show that (a) the property of being alive is (w.h.p.) invariant from phase to phase (Claim 5) and (b) the relative plurality gap of a biased configuration increases (w.h.p.) exponentially during a phase (Claim 6).

▶ **Claim 5.** *Consider a configuration $\boldsymbol{x}$ at the beginning of phase τ. Let $a>0$ be a constant. Assume $\|\boldsymbol{x}\|_1 \geq 1-e^{-1}$ and $\|\boldsymbol{x}\|_2^2 = \omega(\rho)$. Then*

$$\Pr\left[\|\boldsymbol{X}(\tau+1,0)\|_1 < 1-e^{-1} \;\middle|\; \boldsymbol{X}(\tau,0)=\boldsymbol{x}\right] = n^{-a}\,. \tag{9}$$

Proof. Let us first consider the effect of the cleanup round. Claim 3(b) gives

$$\Pr\left[\|\boldsymbol{X}(\tau,1)\|_1 \leq \|\boldsymbol{x}\|_2^2/2 \;\middle|\; \boldsymbol{X}(\tau,0)=\boldsymbol{x}\right] \leq n^{-a-1}\,, \tag{10}$$

where we used $\|\boldsymbol{x}\|_2^2 = \omega(\rho) = \omega\big(\sqrt{\log(n)/n}\big)$, such that the involved δ-term becomes $\mathrm{o}(1)$. Next, fix the configuration $\tilde{\boldsymbol{x}} = X(\tau,1)$ after the cleanup round. Let $\tilde{y} \coloneqq 1-\|\tilde{\boldsymbol{x}}\|_1$ and assume $\tilde{y} \leq 1-\|\boldsymbol{x}\|_2^2/2$ (this holds with probability at least $1-n^{-a-1}$ due to Equation (10)). With the claim's assumption $\|\boldsymbol{x}\|_2^2 = \omega(\rho)$, this implies $\tilde{y} \leq 1-\rho$ and we can apply Claim 4(b) to get

$$\Pr\left[Y(\tau,t+1) \geq \max(\rho^2, \tilde{y}^{3/2}) \;\middle|\; \boldsymbol{X}(\tau,1)=\tilde{\boldsymbol{x}}\right] \leq n^{-a-1} \tag{11}$$

for a decision-accumulation round $t+1>1$. A union bound over the $T-1=\mathrm{O}\big(\log n\big)$ decision-accumulation rounds, combined with Equation (10) via the law of total probability, gives

$$\Pr\left[Y(\tau,T) \geq \max\left(\rho^2, \left(1-\|\boldsymbol{x}\|_2^2/2\right)^{(3/2)^{T-1}}\right) \;\middle|\; \boldsymbol{X}(\tau,0)=\boldsymbol{x}\right] \leq n^{-a}\,. \tag{12}$$

The second term of the maximum is at most $\exp\big(-(3/2)^{T-1}\cdot\|\boldsymbol{x}\|_2^2/2\big)$. For this to be at most some value $z>0$, we need $T-1 \geq \log_{3/2}\big(2\ln(1/z)/\|\boldsymbol{x}\|_2^2\big)$. Choosing $z \coloneqq \exp\big(-k\cdot\|\boldsymbol{x}\|_2^2/\|\boldsymbol{x}\|_1^2\big)$ and remembering our choice of T (see beginning of Section 3), we calculate

$$\log_{3/2}\left(\frac{2\ln(1/z)}{\|\boldsymbol{x}\|_2^2}\right) = \log_{3/2}\left(2/\|\boldsymbol{x}\|_1^2\right) + \log_{3/2}(k) \leq 4+2\log(k) = T-1\,, \tag{13}$$

where we used the claim's assumption $\|\boldsymbol{x}\|_1 \geq 1-e^{-1}$ to bound $\log_{3/2}\big(2/\|\boldsymbol{x}\|_1^2\big) \leq 4$. Thus, Equation (12) implies that with probability at least $1-n^{-a}$ we have $Y(\tau,T) \leq \max(\rho^2,z) \leq e^{-1}$, where we used $\rho^2=\mathrm{o}(1)$ and the Cauchy-Schwarz inequality to get $z=\exp(-k\cdot\|\boldsymbol{x}\|_2^2/\|\boldsymbol{x}\|_1^2) \leq e^{-1}$. The claim follows with this from $\|\boldsymbol{X}(\tau+1,0)\|_1 = \|\boldsymbol{X}(\tau,T)\|_1 = 1-Y(\tau,T)$. ◀

▶ **Claim 6.** *Consider a configuration $\boldsymbol{x}$ at the beginning of phase τ. Let $a > 0$ be a constant. For an opinion $i \neq 1$ assume $x_1 - x_i = \omega(\rho)$ and let $\gamma_i \coloneqq \min(x_1/\rho, x_1/x_i)$. Then*

$$\Pr\left[\frac{X_1(\tau+1,0)}{X_i(\tau+1,0)} \leq \gamma_i^{3/2} \;\middle|\; \boldsymbol{X}(\tau,0) = \boldsymbol{x}\right] \leq n^{-a}\,. \tag{14}$$

Proof. For a configuration $\boldsymbol{x'}$ define the shorthands $\gamma_i(\boldsymbol{x'}) \coloneqq x'_1/x'_i$ and $\psi_i(\boldsymbol{x'}) \coloneqq x'_1 - x'_i$. We make an inductive argument over γ_i during the phase (using ψ_i as an auxiliary tool for the induction). Applying Claim 3(a) to both opinions (once the upper and once the lower bound) yields

$$\Pr\left[X_1(\tau,1) \leq (1-\delta_1)\cdot x_1^2 \;\middle|\; \boldsymbol{X}(\tau,0) = \boldsymbol{x}\right] \leq n^{-a-1} \qquad \text{and} \tag{15}$$

$$\Pr\left[X_i(\tau,1) \geq \max\left(\rho^2, (1+\delta_i)\cdot x_i^2\right) \;\middle|\; \boldsymbol{X}(\tau,0) = \boldsymbol{x}\right] \leq n^{-a-1}\,, \tag{16}$$

where $\delta_j \coloneqq \sqrt{3a\cdot\log(n)/n}\cdot x_j^{-1}$ for $j \in \{1, i\}$. Let $\delta_\rho \coloneqq \sqrt{3a\cdot\ln(n)/n}\cdot\rho^{-1}$ and $\delta \coloneqq \min(\delta_i, \delta_\rho)$. Note that $\delta_1 \leq \delta$, since $x_1 \geq x_i + \omega(\rho)$ by the claim's assumption. With this, we bound the right-hand side in the probability of Equation (15) by $(1-\delta)\cdot x_1^2$ and, similarly, the right-hand side in the probability of Equation (16) by $(1+\delta)\cdot\max(\rho^2, x_i^2)$. Using a union bound and the inequality $(1-x)/(1+x) \geq (1-2x)$ for $x \in [0,1]$, with probability at least $1 - 2n^{-a-1}$ we have $\gamma_i(\boldsymbol{X}(\tau,1)) \geq (1-2\delta)\cdot\gamma_i^2$. Similarly, we also have $\psi_i(\boldsymbol{X}(\tau,1)) = \omega\left(\rho^2\right)$. For $x_i \leq \rho$, this follows immediately from Equations (15) and (16) (since $x_1^2 = \omega\left(\rho^2\right)$ and $x_i^2 = \mathrm{O}\left(\rho^2\right)$). For $x_i > \rho$, we calculate

$$\begin{aligned}
\psi_i(\boldsymbol{X}(\tau,1)) &= X_1(\tau,1) - X_i(\tau,1) \geq (1-\delta_1)\cdot x_1^2 - (1+\delta_i)\cdot x_i^2 \\
&= \left(x_1^2 - x_i^2 - x_1\cdot\sqrt{\frac{3a\cdot\log n}{n}} - x_i\cdot\sqrt{\frac{3a\cdot\log n}{n}}\right) \\
&= (x_1+x_i)\cdot\left(x_1 - x_i - 2\sqrt{\frac{3a\cdot\log n}{n}}\right) = \omega(\rho)\cdot(\omega(\rho) - \mathrm{o}(\rho)) = \omega\left(\rho^2\right)\,.
\end{aligned} \tag{17}$$

Next, fix the configuration $\tilde{\boldsymbol{x}} = X(\tau,t)$ and let $\tilde{y} \coloneqq 1 - \|\tilde{\boldsymbol{x}}\|_1$. Assume $\psi_i(\tilde{\boldsymbol{x}}) = \omega\left(\rho^2\right)$ and $\tilde{x}_i \geq \rho^2$. Applying Claim 4(a) to both opinions (once the upper and once the lower bound) yields

$$\Pr\left[X_1(\tau,t+1) \leq (1-\tilde{\delta}'_1\tilde{y})\cdot\tilde{x}_1\cdot(1+\tilde{y}) \;\middle|\; \boldsymbol{X}(\tau,t) = \tilde{\boldsymbol{x}}\right] \leq n^{-a-1} \qquad \text{and} \tag{18}$$

$$\Pr\left[X_i(\tau,t+1) \geq (1+\tilde{\delta}_i\tilde{y})\cdot\tilde{x}_i\cdot(1+\tilde{y}) \;\middle|\; \boldsymbol{X}(\tau,t) = \tilde{\boldsymbol{x}}\right] \leq n^{-a-1}\,, \tag{19}$$

where $\tilde{\delta}'_j \coloneqq \sqrt{13a\cdot\log n/(\tilde{x}_j\tilde{y}\cdot n)}$ and $\tilde{\delta}_j \coloneqq \max(\tilde{\delta}'_j, \tilde{\delta}'^2_j)$ for $j \in \{1, i\}$. Note that $\tilde{\delta}'_1 \leq \tilde{\delta}_i$, since $\tilde{x}_1 \geq \tilde{x}_i + \omega\left(\rho^2\right)$ by our assumption. Thus, as before we can combine Equations (18) and (19) via a union bound to get that with probability at least $1 - 2n^{-a-1}$ we have $\gamma_i(\boldsymbol{X}(\tau,t+1)) \geq (1-2\tilde{\delta}_i\tilde{y})\cdot\gamma_i(\tilde{\boldsymbol{x}})$ and – analogous to the calculation in Equation (17) – $\psi_i(\boldsymbol{X}(\tau,t+1)) = \omega\left(\rho^2\right)$. Now, define the error $\tilde{\delta} \coloneqq 2\tilde{\delta}_i\tilde{y}$ and note that

$$\tilde{\delta} = \max\left(\sqrt{\frac{13a\cdot\log n}{\tilde{x}_i n}}\cdot\sqrt{\tilde{y}}, \frac{13a\cdot\log n}{\tilde{x}_i n}\right) \leq \sqrt{\frac{13a\cdot\log n}{\tilde{x}_i n}} = \mathrm{O}\left((\log n)^{-3/2}\right)\,, \tag{20}$$

where we used the assumption $\tilde{x}_i \geq \rho^2 = \omega(\log(n)/n)$. In particular, this implies that (w.h.p.) we have $\gamma_i(\boldsymbol{X}(\tau,t+1)) \geq (1-\tilde{\delta})\cdot\gamma_i(\tilde{\boldsymbol{x}})$, $\psi_i(\boldsymbol{X}(\tau,t+1)) = \omega\left(\rho^2\right)$, and $X_i(\tau,t+1) \geq X_i(\tau,t) = \tilde{x} \geq \rho^2$. Moreover, the error $\tilde{\delta}$ is non-increasing in t (since $\tilde{x}_i$ is non-decreasing in

t), such that we get the largest error for $t = 1$, such that we can apply the above recursively. Applying this via the chain rule to the $T - 1 = \mathrm{O}(\log n)$ decision accumulation rounds yields

$$\Pr\left[\gamma_i(\boldsymbol{X}(\tau,T)) \geq (1-\tilde{\delta})^{T-1} \cdot \frac{\tilde{x}_1}{\max(\rho^2, \tilde{x}_i)} \;\middle|\; \boldsymbol{X}(\tau,1) = \tilde{\boldsymbol{x}}\right] \geq 1 - \mathrm{O}(\log n) \cdot 2n^{-a-1}\,. \quad (21)$$

Since $\tilde{\delta} = \mathrm{O}\big((\log n)^{-3/2}\big)$, we can bound the error term $(1-\tilde{\delta})^{T-1} \geq \exp(-(T-1)\cdot 2\tilde{\delta}) \geq 1 - 2T\cdot\tilde{\delta}$. That is, the error due to the decision-accumulation rounds is $1-\delta'$ for $\delta' \coloneqq 2T\cdot\tilde{\delta} = \mathrm{O}\big((\log n)^{-1/2}\big)$. We now combine our result for the cleanup round and the decision-accumulation rounds via the law of total probability to get that with probability at least $1-n^{-a}$ we have $\gamma_i(\boldsymbol{X}(\tau,T)) \geq (1-2\delta)(1-\delta')\cdot\gamma_i^2$.

Using $\check{\delta} \coloneqq 2\max(2\delta,\delta') = \mathrm{O}\big(\log(n)\cdot\sqrt{\log(n)/n}\big)\cdot\min(x_i^{-1},\rho^{-1})$, we get $\gamma_i(\boldsymbol{X}(\tau,T)) \geq (1-\check{\delta})\cdot\gamma_i^2$. It merely remains to verify that $1-\check{\delta} \geq \gamma_i^{-1/2}$. This is equivalent to $\check{\delta} \leq 1-\gamma_i^{-1/2}$. If $\gamma_i = \Omega(1)$, this holds trivially since $\check{\delta} = \mathrm{o}(1)$. So assume $\gamma_i = 1+\varepsilon$ for a suitable $\varepsilon \in (0,1]$. For this range, we have $1-\gamma_i^{-1/2} \geq \varepsilon/4$, such that it is sufficient to show $\check{\delta} \leq \varepsilon/4$. By the claim's assumption $x_1 - x_i = \omega(\rho)$, we get $\varepsilon = \gamma_i - 1 = x_1/x_i - 1 = \omega(\rho)\cdot x_i^{-1}$. On the other hand, we have $\check{\delta} = \mathrm{O}\big(\log(n)\cdot\sqrt{\log(n)/n}\big)\cdot\min(x_i^{-1},\rho^{-1}) \leq \mathrm{O}\big(\sqrt{(\log n)^3/n}\big)\cdot x_i^{-1} = \mathrm{O}(\rho)\cdot x_i^{-1}$. This finishes the proof. ◀

3.3 Wrapping up the Analysis

We now have the tools to prove the three key lemmas mentioned before (which immediately imply Theorem 1). We first show that after $\mathrm{O}\big(\log\log_{\gamma(\bar{\boldsymbol{x}})} n\big)$ phases, (w.h.p.) all opinions $i \geq 2$ are negligible and the configuration is still alive.

▶ **Lemma 7.** *Consider an initial configuration $\bar{\boldsymbol{x}}$ that is alive and for which $\psi(\bar{\boldsymbol{x}}) = \omega(\rho)$. Define $\tau_1 \coloneqq \log_{3/2}\log_{\gamma(\bar{\boldsymbol{x}})} n$. Then*

$$\Pr\left[\bigcap_{i=2}^{k}\big(X_i(\tau_1,0) \leq \rho\big) \wedge \|\boldsymbol{X}(\tau_1,0)\|_1 \geq 1-e^{-1} \;\middle|\; \boldsymbol{X}(1,0) = \bar{\boldsymbol{x}}\right] \geq 1 - n^{-2}\,.$$

Proof. Fix a phase $\tau \in \mathbb{N}$ and let $\boldsymbol{x}$ denote the configuration at the beginning of phase τ. Assume $\boldsymbol{x}$ to be alive, biased, and 1 to be the plurality opinion. Let $\gamma \coloneqq \min(x_1/\rho, \gamma(\boldsymbol{x}))$. By Claim 5, with probability at least $1-n^{-3}$ we have $\|\boldsymbol{X}(\tau+1,0)\|_1 \geq 1-e^{-1}$. Combined with Claim 6 via a union bound over all opinions we get

$$\Pr\left[\gamma(\boldsymbol{X}(\tau+1,0)) \leq \gamma^{3/2} \vee \|\boldsymbol{X}(\tau+1,0)\|_1 < 1-e^{-1} \;\middle|\; \boldsymbol{X}(\tau,0) = \boldsymbol{x}\right] \leq 2n^{-3}\,. \quad (22)$$

Thus, as long as there is at least one non-negligible opinion $i \geq 2$, (w.h.p.) the relative plurality gap increases exponentially and the configuration stays alive. Moreover, note that $\boldsymbol{X}(\tau+1,0)$ being alive and the increased relative gap between x_1 and $\max(\rho, x_i)$ for *any* other opinion i implies $\psi(\boldsymbol{X}(\tau+1,0)) = \omega(\rho)$. Thus, we can iterate this argument. To this end, for any $\tau \in \mathbb{N}$ define the event

$$\mathcal{E}_{\tau+1} \coloneqq \Big(\gamma(\boldsymbol{X}(\tau+1,0)) > \gamma_\tau^{3/2}\Big) \wedge (\|\boldsymbol{X}(\tau+1,0)\|_1 \geq 1-e^{-1}) \wedge \psi(\boldsymbol{X}(\tau+1,0)) = \omega(\rho)\,, \quad (23)$$

where $\gamma_\tau \coloneqq \min(X_1(\tau,0)/\rho, \gamma(\boldsymbol{X}(\tau,0)))$. Above we proved $\Pr[\mathcal{E}_{\tau+1} \mid \mathcal{E}_\tau, \boldsymbol{X}(\tau,0) = \boldsymbol{x}] \geq 1-2n^{-3}$. Using the definition of conditional probability, we get $\Pr[\bigcap_{\tau\leq\tau_1}\mathcal{E}_\tau] \geq \big(1-2n^{-3}\big)^{\tau_1} \geq 1-n^{-2}$, where we used (by Assumption (1)) $\tau_1 \leq 2\log\frac{\log n}{\log\gamma(\bar{\boldsymbol{x}})} \leq 2\log\frac{\log n}{\log(1+\psi(\bar{\boldsymbol{x}}))} \leq 2\log\frac{2\log n}{\psi(\bar{\boldsymbol{x}})} = \mathrm{o}(\log n)$. Finally, our choice of τ_1 guarantees $\gamma(\bar{\boldsymbol{x}})^{(3/2)^{\tau_1}} = n \geq \rho^{-1}$, such that all opinions are negligible at the start of phase τ_1. ◀

The next lemma shows that once we are in a configuration that is alive and where all opinions $i \geq 2$ are negligible, (w.h.p.) all these negligible opinions vanish within a constant number of additional phases.

▶ **Lemma 8.** *Consider a configuration $\boldsymbol{x}$ that is alive and for which $x_i \leq \rho$ for all $i \neq 1$. Define $\tau_2 \coloneqq \tau_1 + 3$. Then* $\Pr\left[\sum_{i=2}^{k} X_i(\tau_2, 0) = 0 \wedge \|\boldsymbol{X}(\tau_2, 0)\|_1 \geq 1 - e^{-1} \;\middle|\; \boldsymbol{X}(\tau_1, 0) = \boldsymbol{x}\right] \geq 1 - n^{-2}$.

Proof. Applying Claim 6 yields $\Pr\left[\bigcup_{i\neq 1}\left(\frac{X_1(\tau_1+1,0)}{X_i(\tau_1+1,0)} \leq \gamma_\rho^{3/2}\right) \;\middle|\; \boldsymbol{X}(\tau_1, 0) = \boldsymbol{x}\right] \leq n^{-3}$, where $\gamma_\rho = x_1/\rho$ as in Claim 6. Since $\|\boldsymbol{x}\|_1 \geq 1 - e^{-1}$ but $x_i \leq \rho$ for all $i \geq 2$, we must have $x_1 = \Omega(1)$ (or $\|\boldsymbol{x}\|_1 \leq k \cdot \rho + \mathrm{o}(1) = \mathrm{o}(1)$ would contradict $\boldsymbol{x}$ being alive). In particular, we get $\gamma_\rho = \Omega(1/\rho)$. Combining this with Claim 5 via a union bound, with probability at least $1 - 2n^{-3}$ configuration $\boldsymbol{X}(\tau_1 + 1, 0)$ is alive and $X_i(\tau_1 + 1, 0) < \gamma_\rho^{-3/2} = \mathrm{O}(\rho^{3/2})$ for all $i \geq 2$. Now consider the cleanup round of phase $\tau_1 + 1$ for an opinion $i \geq 2$ with $X_i(\tau_1 + 1, 0) = \mathrm{O}(\rho^{3/2})$. The probability that even one node of such an opinion remains decided after the cleanup round is at most $X_i(\tau_1+1, 0) \cdot n \cdot X_i(\tau_1+1, 0) = \mathrm{O}(\rho^3 n)$. Repeating this for a constant number of phases (note that we can use our high probability bounds to guarantee that the configuration stays alive and the plurality gap high enough) and applying the geometric distribution, we get that the probability for an opinion $i \geq 2$ to survive c more phases is at most $\mathrm{O}(\rho^{3c} n)$. The probability that even one of the $k - 1 \leq \sqrt{n}$ negligible opinions survives these c phases is $\mathrm{O}(\rho^{3c} \cdot n^{3/2}) = \mathrm{o}(n^{-(c-1)\cdot 5/4})$. The claim's statement follows for $c = 2$. ◀

Our last lemma shows that once we reached a configuration that is alive and only the plurality opinion is left, (w.h.p.) all nodes adopt the plurality in $\mathrm{O}(\log \log n)$ phases.

▶ **Lemma 9.** *For $\boldsymbol{x}$ with $\sum_{i\geq 2} x_i = 0$ and $\|\boldsymbol{x}\|_1 = x_1 \geq 1 - e^{-1}$ let $\tau_3 \coloneqq \tau_2 + \ln \log n + 1 = \tau_2 + \mathrm{O}(\log \log n)$. Then* $\Pr[X_1(\tau_3, 0) = 1 \mid \boldsymbol{X}(\tau_2, 0) = \boldsymbol{x}] \geq 1 - n^{-2}$.

Proof. We will show that the number of undecided nodes decreases exponentially from phase to phase, until their number is so low that (w.h.p.) they vanish within a constant number of decision-accumulation rounds. To this end, we use two basic high probability bounds: for cleanup rounds of a phase τ on any configuration $\boldsymbol{x'}$ with $\sum_{i\geq 2} x'_i = 0$ and $\|\boldsymbol{x'}\|_1 = x'_1 \geq 2/3$, we use

$$\Pr\left[Y(\tau, 1) \geq \max(\rho^2, 2.05 \cdot y') \;\middle|\; \boldsymbol{X}(\tau, 0) = \boldsymbol{x'}\right] \leq n^{-a}. \tag{24}$$

To see this, first note that[2] we have $\Pr[Y(\tau, 1) \geq (1 + \delta x'_1) \cdot y' \cdot (1 + x'_1) \mid \boldsymbol{X}(\tau, 0) = \boldsymbol{x'}] \leq n^{-a}$ for $\delta' \coloneqq \sqrt{13a \cdot \log n/(x'_1 y' \cdot n)}$ and $\delta \coloneqq \max(\delta', \delta'^2)$. Equation (24) then follows by distinguishing whether $y' \geq \rho^2/4$ or not.

To show the exponential decrease of the undecided nodes, assume we are given a configuration $\boldsymbol{x''}$ with $y'' < \max(\rho^2, 2.05 \cdot y')$ after the cleanup round of a phase τ. We apply Claim 4(b) to the first $t_* \coloneqq 5 \leq T - 1$ decision-accumulation rounds of phase τ and use a union bound to get $\Pr\left[Y(\tau, 1 + t_*) \geq \max\left(\rho^2, y''^{(3/2)^{t_*}}\right) \;\middle|\; \boldsymbol{X}(\tau, 1) = \boldsymbol{x''}\right] \leq t_* \cdot n^{-a}$. Since $y' \leq e^{-1}$, we get $(2.05 \cdot y')^{(3/2)^5} \leq y'^2$. Combining these observations with Equation (24)

[2] This follows exactly like Claim 4(a) when switching x_i for y' and y for x'_1. If only one opinion is left, undecided nodes in cleanup rounds increase exactly as decided nodes in decision-accumulation rounds.

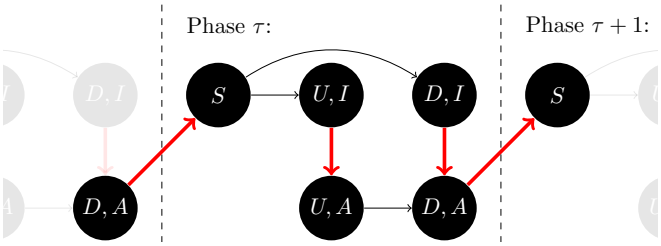

Figure 1 Illustration how nodes transition through phases. Red (thick) state transitions highlight slow transitions that ensure that nodes do not get out of sync too much.

we get $\Pr\left[Y(\tau+1,0) \geq \max\left(\rho^2, y'^2\right) \mid \boldsymbol{X}(\tau,0) = \boldsymbol{x'}\right] \leq 6n^{-a}$. In particular, the resulting configuration is still alive at the start of phase $\tau+1$, so we can iterate to get

$$\Pr\left[Y(\tau_2+t,0) \geq \max\left(\rho^2, y^{2^t}\right) \mid \boldsymbol{X}(\tau_2,0) = \boldsymbol{x}\right] \leq 6t \cdot n^{-a}\,. \tag{25}$$

Since $y \leq e^{-1}$, for $t = \ln\ln n$ we get $\max\left(\rho^2, y^{2^t}\right) = \rho^2$. Now, consider a configuration $\boldsymbol{x'}$ with $y' < \rho^2$. Equation (24) yields $\Pr\left[Y(\tau_2+t,1) \geq 2.05\rho^2 \mid \boldsymbol{X}(\tau_2+t,0) = \boldsymbol{x'}\right] \leq n^{-a}$. If $Y(\tau_2+t,1) < 2.05\rho^2$, then the probability that even one undecided node remains undecided after the first decision-accumulation round is at most $Y(\tau_2+t,1)n \cdot Y(\tau_2+t,1) \leq 5\rho^4 n \leq n^{-3/4}$. Similar to the proof of Lemma 8, we boost this probability using a geometric random variable by considering the first $4 \leq T-1$ consecutive decision-accumulation rounds, such that $\Pr\left[Y(\tau_2+t,5) \geq 0 \mid \boldsymbol{X}(\tau_2+t,0) = \boldsymbol{x'}\right] \leq n^{-a} + n^{-3}$. Combined with Equation (25), we get the desired statement. ◀

4 Plurality Consensus with $\log k + 4$ Bits

The non-constant memory overhead of RepeatedCleanup is due to the round counter used to synchronize phases. We now present a protocol that avoids this counter. Each node u stores its opinion $\mathrm{op}_u \in [k]$, a *phase counter* $\mathrm{p}_u \in \mathbb{N}$, and a *state variable* $\mathrm{s}_u \in \{S, (U,I), (D,I), (U,A), (D,A)\}$. Our description and analysis assume p_u to be an arbitrary integer. While this would result in a non-constant memory overhead, we will prove that (w.h.p.) $|\mathrm{p}_u - \mathrm{p}_v| \leq 1$ for any two nodes u, v and any round. Thus, the actual implementation can restrict p_u to $\{0,1,2\}$, such that we get a memory overhead of $\log(3 \cdot 5) \leq 4$ bits. We call this protocol ConstOverhead. Our main result is the following theorem:

▶ **Theorem 10.** ConstOverhead *has a local memory overhead of* 4 *bits (15 states). If started on a biased configuration* $\bar{\boldsymbol{x}}$ *with relative plurality gap* $\gamma := \gamma(\bar{\boldsymbol{x}})$*, then (w.h.p.) plurality consensus is achieved in* $\mathrm{O}\left(\log n \cdot \log\log_\gamma n\right)$ *rounds.*

The rest of this section describes the protocol as well as the underlying idea and gives a sketch of the analysis. More details can be found in the full version.

Protocol Overview. Initially, each node u starts with $\mathrm{p}_u = 1$ and $\mathrm{s}_u = S$. We call u *undecided* if $\mathrm{s}_u = (U,\cdot)$, *decided* if $\mathrm{s}_u = (D,\cdot)$, *inactive* if $\mathrm{s}_u = (\cdot,I)$, and *active* if $\mathrm{s}_u = (\cdot,A)$. At the start of a round, each node u samples a random node v and uses v's data to transition through its phase. Listing 2 gives the formal protocol description and Figure 1 an illustration.

We start with a high level description of the protocol which we gradually refine. Basically, ConstOverhead mimics the synchronized behavior of RepeatedCleanup. As in our first protocol, there are two ways to transition through a phase: if a node u samples another

```
1  sample a random node v
2  if s_u = S:                                                    {cleanup}
3      if p_v ≥ p_u or (p_v = p_u − 1 and s_v = (D, A)):
4          if op_v = op_u:   s_u ← (D, I)
5          else:             s_u ← (U, I)
6  elseif s_u ∈ { (U, I), (D, I) }:                               {slow transition}
7      if (p_v = p_u and v active) or p_v > p_u or Ber(1/n) = 1:
8          become active
9  elseif s_u = (U, A):                                           {decision−accumulation}
10     if (p_v = p_u and v decided) or p_v > p_u:
11         op_u ← op_v and become decided
12 elseif s_u = (D, A):                                           {slow transition}
13     if p_v > p_u or Ber(1/n) = 1:   (p_u, s_u) ← (p_u + 1, S)
```

Listing 2 Protocol ConstOverhead as executed by node u in round $t \in \mathbb{N}$. This description assumes p_u to be an arbitrary integer.

node v of the same opinion, it keeps its opinion and has to wait for the other nodes to catch up. While RepeatedCleanup implemented this waiting via a counter, ConstOverhead uses *slow transitions* (highlighted red/thick in Figure 1). Otherwise, if u samples a node v of a different opinion, it becomes undecided and keeps sampling nodes until it finds a new opinion.

Becoming decided or undecided is modeled by entering the *inactive decided* state (D, I) or *inactive undecided* state (U, I), respectively. This transition from S to one of these inactive states corresponds to cleanup rounds of RepeatedCleanup. Now, there is a slow transition to the *active decided* state (D, A) and *active undecided* state (U, A). This transition from inactive to active ensures that (a) decided nodes do not enter the next phase too early (which could require a large phase counter) and (b) undecided nodes do not sample decided nodes too early (which could result in a skewed distribution, since the number of decided nodes might be too small). Once an undecided node u becomes active, it keeps sampling nodes until it finds a new opinion. This corresponds to decision-accumulation rounds of RepeatedCleanup. Note that the transition from (D, A) to S (at which the phase counter is increased) is slow. This ensures that not too many nodes enter the next phase before all undecided nodes found a new opinion (which could, as before, require a large phase counter).

Some Subtleties. While the above reflects the basic behavior of our protocol, we omitted some details. Let us make a few important and useful observations:

- A node u always checks whether the sampled node v is not too far behind.
- Nodes do not explicitly forget their opinion when becoming undecided but simply overwrite their old opinion when they find a new opinion. In particular, if a node from an earlier state asks for u's opinion while u is undecided, u answers with its most recent opinion (the provision of which does not cost us extra in terms of memory as we simply retain the information where it was; the undecided state is seperately encoded in the already accounted-for $\Theta(1)$ additional bits).
- Slow transitions $s \to s'$ between two states s and s' basically simulate Pull-rumor spreading [18]: Nodes in state s' or later are "informed", while all other nodes are "uninformed". When u samples an informed node (a node in s' or beyond), it can cross the slow transition (independent of the sampled opinion). The Bernoulli trial $\mathrm{Ber}(1/n)$ in slow transitions ensures that, eventually, at least one node is "informed". Without it, no node could cross such a transition.

Analysis Overview. Given that ConstOverhead is based on the same principle as RepeatedCleanup, namely employing synchronized cleanup rounds to increase the relative plurality gap exponentially from phase to phase, it is natural to use a similar analysis. The major difficulty stems from the fact that our synchronization primitive is now probabilistic (slow transitions) instead of deterministic (counter). In particular, in the case of ConstOverhead there is no guarantee that nodes wait at slow transitions for other nodes to catch up; in fact, there will typically be a few nodes that proceed early on over slow transitions. This might disturb our analysis in two ways: (a) if nodes could proceed arbitrarily far ahead, their phase counter could become arbitrarily high, resulting in a non-constant memory overhead, and (b) if a small group of nodes with a non-plurality opinion were "lucky" and proceeded fast, these nodes might cause more and more latecomers to adopt a non-plurality opinion.

The major tool to address both of these issues are two probabilistic synchronization results. The first shows that (w.h.p.) there is a period/stage of $\mathrm{O}(\log n)$ consecutive rounds such that:

- If $n - \mathrm{polylog}(n)$ nodes are in state (D, A) of phase $\tau - 1$ or state S of phase τ, and all remaining nodes are in one of the two inactive states $(\cdot, I)$ of phase τ,
- then at the end of this period, $n - \mathrm{polylog}(n)$ nodes are in one of the two inactive states $(\cdot, I)$ of phase τ, and all remaining nodes are in one of the two active states $(\cdot, A)$ of phase τ.

The second result shows that (w.h.p.) there is a period/stage of $\mathrm{O}(\log n)$ consecutive rounds such that:

- If $n - \mathrm{polylog}(n)$ nodes are in one of the two inactive states $(\cdot, I)$ of phase τ, and all remaining nodes are in one of the two active states $(\cdot, A)$ of phase τ,
- then at the end of this period, $n - \mathrm{polylog}(n)$ nodes are in state (D, A) of phase τ or state S of phase $\tau + 1$, and all remaining nodes are in one of the two inactive states $(\cdot, I)$ of phase τ.

Note that the final condition of the first stage fits perfectly into the assumption of the second stage and vice versa. We call the first stage the *cleanup stage* and the second stage the *decision-accumulation stage* (in the style of the corresponding round in RepeatedCleanup). Since these stages are well-sparated, we can prove an analogue of Claim 3 and an analogue of Claim 4. Equipped with these, the remainder of the proof is basically identical to the proof of RepeatedCleanup (which was completely based on these concentration bounds).

Abstract

We introduce a new class of distributed algorithms for the approximate consensus problem in dynamic rooted networks, which we call *amortized averaging algorithms*. They are deduced from ordinary averaging algorithms by adding a value-gathering phase before each value update. This results in a drastic drop in decision times, from being exponential in the number n of processes to being polynomial under the assumption that each process knows n. In particular, the *amortized midpoint algorithm* is the first algorithm that achieves a linear decision time in dynamic rooted networks with an optimal contraction rate of $1/2$ at each update step.

We then show robustness of the amortized midpoint algorithm under violation of network assumptions: it gracefully degrades if communication graphs from time to time are non rooted, or under a wrong estimate of the number of processes. Finally, we prove that the amortized midpoint algorithm behaves well if processes can store and send only quantized values, rendering it well-suited for the design of dynamic networked systems. As a corollary we obtain that the 2-set consensus problem is solvable in linear time in any dynamic rooted network model.

1 Introduction

This paper studies the problem of *approximate consensus*: given a set of processes, each of them with an initial real value, for any positive real number ε, every process has to achieve ε*-consensus*, i.e., decides on one value that lies in the range of the initial values and that differs from the other decision values by at most ε. This problem, which is a weakening of *exact* ($\varepsilon = 0$) *consensus*, has a large variety of applications in distributed computing or multi-agent control (e.g., clock synchronization or geometric coordination tasks) and often has to be solved in the context of dynamic networks, using local information, and under adverse constraints.

In recent work [8], we proved that approximate consensus is solvable in a dynamic network model if and only if the directed time-varying communication graph is always rooted, i.e.,

contains a rooted spanning tree. The spanning tree can change completely from time to time. Hence no stability condition is required to solve approximate consensus.

In fact, we showed that when addressing the solvability issue of approximate consensus, it suffices to consider the class of *averaging algorithms* where each process maintains a single scalar state variable and repeatedly updates to a weighted average of the values it has just received. Indeed, the problem is solvable if and only if it can be solved by an averaging algorithm.

We proved that, if there is a positive lower bound ϱ on the weights used in averaging steps, then the averaging algorithm achieves ε-agreement in $O\big(n\varrho^{-n}\log\frac{1}{\varepsilon}\big)$ rounds where n is the number of processes. Moreover, we showed that the classical averaging algorithm, called the *equal-neighbor* algorithm, exhibits an exponentially large decision time in the case of the *Butterfly network model*.

Contribution. In this work we present a new approximate consensus algorithm that we show to be *fast*, being the first algorithm in highly dynamic networks with linear time complexity in the number of processes, *robust* to violation of network assumptions, and allowing for *quantization* of its variables – leading to a space efficient algorithm.

We list the main contributions in detail in the following:

(i) We consider the property of *ϱ-safety* for averaging algorithms originally introduced by Chazelle [12], which is a generalization of the lower bound condition on positive weights. This property focuses on the set of transmitted *values* and not on the linear *functions* (stochastic matrices) applied in the averaging steps, as done classically. It thus captures the essential properties needed for contracting the range of current values in the system. Using a graph-theoretic reduction that already played a key role in [8], we first give simple proofs of correctness and of upper bounds on the contraction rate of ϱ-safe averaging algorithms.
More importantly, this approach allows us to propose a new averaging algorithm for approximate consensus in dynamic rooted networks, that we call the *midpoint algorithm*, with an optimal contraction rate of $1/2$.

(ii) We introduce the notion of *amortization* of averaging algorithms, which consists in inserting a value-gathering phase before each averaging step. This additional phase transforms ϱ-safe averaging algorithms into "turbo versions" of themselves in that decision times pass from being exponential [8] to being polynomial in the number n of processes.
Amortization assumes that each process knows the size n of the network. Furthermore, processes ought to be able to accumulate and to relay values from the past, as opposed to averaging algorithms that are memoryless in the sense that processes deal only with fresh values. More precisely, we show that the amortized version of a ϱ-safe averaging algorithm solves approximate consensus with polynomial decision times in any dynamic rooted network, and *a priori* under the conditions that each process knows the size of the network, and can store and transmit in every message up to $n(n-1)$ scalar values. Then we combine the two above ideas in the design of the *amortized midpoint algorithm*, which achieves ε-agreement in $O\big(n\log\frac{1}{\varepsilon}\big)$ rounds. Apart its linear decision times, the positive features of this amortized averaging algorithm are that it works in anonymous networks (without process identifier) and that processes are required to store and to transmit in each message only *two* scalar values, whatever the size of the network is.

(iii) The correctness proof of amortized averaging algorithms relies on two fundamental hypotheses: common knowledge of the number n of processes and rootedness of all

occurring communication graphs. However we show that, even with an erroneous estimate on n or when communication graphs sometimes fail to be rooted, the amortized version of a ϱ-safe averaging algorithm still solves approximate consensus, albeit with larger decision time. This graceful degradation property demonstrates that the robustness of a ϱ-safe averaging algorithm carries over to some extent to its amortized versions.

(iv) Finally we show that if processes can only use variables with finite precision, then the amortized midpoint algorithm achieves ε-consensus in linear time whenever possible, i.e., when ε is larger than the variables' precision. The decision time with quantization does not degrade and remains in the same order as without quantization. The robustness to rounding errors seems to be specific to the amortized midpoint algorithm as our proof does not work for general amortized ϱ-safe averaging algorithms.

As a corollary, we get that the 2-*set consensus problem* – another weakening of exact consensus where disagreement is limited to at most two different decision values – is solvable in linear time in all dynamic rooted network models.

While the practical implications of a versatile approximate consensus algorithm which is both fast and robust are clearly appealing for the design of man-made dynamic networked systems, our results go even beyond that and are interesting also from a different, more analytic, perspective.

Many natural phenomena, like bird flocking [11], synchronization of coupled oscillators [27, 20], opinion dynamics [16], or firefly synchronization [19], can be modeled with agents that execute averaging algorithms. However, there is a large mismatch between the fast agreement times observed in nature and the theoretical worst-case times, which may be exponential [11]. In this sense, our results provide a step towards closing this gap, suggesting that the agents in these natural systems in fact operate on a different, slower, time scale than their environments, and that this inertia actually contributes positively to faster consensus.

Related work. The time complexity of approximate consensus has been extensively studied in the past. Several papers (e.g., [20, 6, 1, 5, 2]) handle the case of time-varying communication graphs and consider averaging algorithms with decision times which are exponential in the number of processes.

The first algorithm with polynomial decision times has been proposed by Olshevsky and Tsitsiklis [24], based on ideas from load balancing. They proved that their algorithm achieves ε-consensus in $O\big(n^3 \log \frac{1}{\varepsilon}\big)$ rounds with a time-varying *bidirectional* topology under the quite strong stability condition that graphs do not change during each 3 round slot $3k$, $3k+1$, $3k+2$. A refined analysis of this algorithm [22] results in an improved quadratic bound. In the meantime, Chazelle [12] proposed a remarkable averaging algorithm with cubic decision times, which works in any bidirectional connected network model.

Another approach to speed up decision times – also developed in the context of load balancing – consists in considering *second-order* algorithms where the update rule for process p at round $k+1$ involves the old value held by p at round $k-1$, in addition to the values at round k of p's neighbors; see [21]. Following this approach, Olshevsky [23] has recently proposed a linear decision time algorithm that requires each process to know n, and to be able to store and to transmit in every message two scalar values, like the amortized midpoint algorithm. Unfortunately Olshevsky's algorithm works only under the assumption of a *fixed bidirectional* communication graph. Another linear approximate consensus algorithm has been proposed in [28] in the case of a fixed topology, possibly non-bidirectional, but it assumes processes with strong computational power and large memory (processes ought to store all values of the past). The sum of these efforts makes the time-linearity of the

relatively simple amortized midpoint algorithm in arbitrarily dynamic directed anonymous networks all the more so striking.

As for the effects of quantization, they have been studied in a number of papers, but most of them assume a fixed topology to bound the time complexity; see [18, 15]. In their seminal paper [22], Nedić et al. analyzed the quantized version of their quadratic averaging algorithm for a time-varying bidirectional topology and proved that decision times with quantized values are of the same order as with continuous values.

2 Approximate consensus and averaging algorithms

We assume a distributed, round-based computational model in the spirit of the Heard-Of model [9]. A system consists in a set of processes $[n] = \{1, \dots, n\}$. Computation proceeds in *rounds*: In a round, each process sends its state to its outgoing neighbors, receives values from its incoming neighbors, and finally updates its state based. The value of the updated state is determined by a deterministic algorithm, i.e., a transition function that maps the values in the incoming messages to a new state value. Rounds are communication closed in the sense that no process receives values in round k that are sent in a round different from k.

Communications that occur in a round are modeled by a directed graph $G = ([n], E(G))$ with a self-loop at each node. The latter requirement is quite natural as a process can obviously communicate with itself instantaneously. Such a directed graph is called a *communication graph*. We denote by $\mathrm{In}_p(G)$ and $\mathrm{Out}_p(G)$ the sets of incoming and outgoing neighbors of p, respectively.

The *product* of two communication graphs G and H, denoted $G \circ H$, is the directed graph with an edge from (p, q) if there exists $r \in [n]$ such that $(p, r) \in E(G)$ and $(r, q) \in E(H)$. We easily see that $G \circ H$ is a communication graph and, because of the self-loops, $E(G) \cup E(H) \subseteq E(G \circ H)$.

A *communication pattern* is a sequence $(G(k))_{k \geqslant 1}$ of communication graphs. For a given communication pattern, $\mathrm{In}_p(k)$ and $\mathrm{Out}_p(k)$ stand for $\mathrm{In}_p(G(k))$ and $\mathrm{Out}_p(G(k))$, respectively.

Each process p has a *local state* s_p the value of which at the end of round $k \geqslant 1$ is denoted by $s_p(k)$. Process p's initial state, i.e., its state at the beginning of round 1, is denoted by $s_p(0)$. Let the *global state* at the end of round k be the collection $s(k) = (s_p(k))_{p \in [n]}$. The *execution* of an algorithm from global initial state $s(0)$, with communication pattern $(G(k))_{k \geqslant 1}$ is the unique sequence $(s(k))_{k \geqslant 0}$ of global states defined as follows: for each round $k \geqslant 1$, process p sends $s_p(k-1)$ to all the processes in $\mathrm{Out}_p(k)$, receives $s_q(k-1)$ from each process q in $\mathrm{In}_p(k)$, and computes $s_p(k)$ from the incoming messages, according to the algorithm's transition function.

When the structure of states allows each process to record and to relay information it has received during any period of K rounds for some positive integer K, we may be led to modify time-scale and to consider blocks of K consecutive rounds, called *macro-rounds*: macro-round ℓ is the sequence of rounds $(\ell - 1)K + 1, \dots, \ell K$ and the corresponding information flow graph, called *communication graph at macro-round* ℓ, is the product of the communication graphs $G((\ell - 1)K + 1) \circ \dots \circ G(\ell K)$.

2.1 Approximate consensus

A crucial problem in distributed systems is to achieve agreement among local process states from arbitrary initial local states. It is a well-known fact that this goal is not easily achievable in the context of dynamic network changes [26, 8], and restrictions on communication patterns

are required for that. We define a *network model* as a non-empty set $\mathcal{N}$ of communication graphs, those that may occur in communication patterns.

We now consider the above round-based algorithms in which the local state of process p contains two variables x_p and dec_p. Initially the range of x_p is $[0,1]$ and $\mathrm{dec}_p = \perp$ (which informally means that p has not decided yet).[1] Process p is allowed to set dec_p to the current value of x_p, and so to a value v different from $\perp$, only once; in that case we say that p *decides* v.

For any $\varepsilon \geqslant 0$, an algorithm *achieves ε-agreement with communication pattern* $(G(k))_{k\geqslant 1}$ if each execution from a global initial state as specified above and with the communication pattern $(G(k))_{k\geqslant 1}$ fulfills the following three conditions:

ε-Agreement. The decision values of any two processes are within ε.

Validity. All decided values are in the range of the initial values of processes.

Termination. All processes eventually decide.

An algorithm *solves approximate consensus* in a network model $\mathcal{N}$ if for any $\varepsilon > 0$, it achieves ε-agreement with each communication pattern formed with graphs all in $\mathcal{N}$. It *solves exact consensus* in $\mathcal{N}$ if f it achieves 0-agreement with each communication pattern with graphs in $\mathcal{N}$.

In a previous paper [8], we proved the following characterization of network models in which approximate consensus is solvable:

▶ **Theorem 1** ([8]). *The approximate consensus problem is solvable in a network model $\mathcal{N}$ if and only if each graph in $\mathcal{N}$ has a rooted spanning tree.*

2.2 Averaging algorithms

We focus on *averaging algorithms* in which at each round k, every process p updates x_p to some weighted average of the values it has just received: formally, if $m_p(k-1)$ is the minimum of the values $\{x_q(k-1) \mid q \in \mathrm{In}_p(k)\}$ received by p in round k and $M_p(k-1)$ is its maximum, then

$$m_p(k-1) \leqslant x_p(k) \leqslant M_p(k-1)\,.$$

In other words, at each round k, every process adopts a new value within the interval formed by the values of its incoming neighbors in the communication graph $G(k)$.

Since we strive for distributed implementations of averaging algorithms, weights in the average update rule of process p are required to be locally computable by p. They may depend only on the set of values received by p at round k, as is the case, for instance, with the update rule of the *mean-value algorithm*:

$$x_p(k) = \frac{1}{|V_p(k)|} \sum_{v\in V_p(k)} v \tag{1}$$

where $V_p(k) = \{x_q(k-1) \mid q \in \mathrm{In}_p(k)\}$. In contrast, even in anonymous networks, weights in the update rule for p may depend on the *multiset* of values received by p at round k counted with their multiplicities: as an example, p's update rule in the *equal-neighbor algorithm* is given by:

$$x_p(k) = \frac{1}{|\,\mathrm{In}_p(k)|} \sum_{q\in \mathrm{In}_p(k)} x_q(k-1)\,. \tag{2}$$

[1] In the case of *binary consensus*, x_p is restricted to be initially from $\{0,1\}$.

Observe that the decision rule is not specified in the above definition of averaging algorithms: the decision time immediately follows from the number of rounds that is proven to be sufficient to reach ε-agreement.

Let $\varrho \in]0, 1/2]$; an averaging algorithm is *ϱ-safe in $\mathcal{N}$* if at any round k of each of its executions with communication patterns in $\mathcal{N}$, each process adopts a new value within the interval formed by its neighbors in $G(k)$ not too close to the boundary:

$$\varrho M_p(k-1) + (1-\varrho)m_p(k-1) \leqslant x_p(k) \leqslant (1-\varrho)M_p(k-1) + \varrho\, m_p(k-1)\,.$$

Clearly if an averaging algorithm is ϱ-safe, then it is ϱ'-safe for any $\varrho' \leqslant \varrho$. We also easily check the following property of the equal-neighbor and mean-value algorithms.

▶ **Proposition 2.** *In any network model with n processes, the equal-neighbor algorithm and the mean-value algorithm are both $(1/n)$-safe.*

Finally, an averaging algorithm is *α-contracting in $\mathcal{N}$* if at each round k of any of its executions with communication patterns in $\mathcal{N}$, we have

$$\delta\big(x(k)\big) \leqslant \alpha\, \delta\big(x(k-1)\big)$$

where δ is the seminorm on $\mathbb{R}^n$ defined by $\delta(x) = \max_p(x_p) - \min_p(x_p)$.

▶ **Proposition 3.** *In any network model, every α-contracting averaging algorithm with $\alpha \in [0, 1[$ solves approximate consensus and achieves ε-agreement in $\left\lceil \log_{\frac{1}{\alpha}} \left(\frac{1}{\varepsilon}\right)\right\rceil$ rounds.*

3 Averaging algorithms, nonsplitness, and contraction rates

In a previous paper [8], we proved solvability of approximate consensus in rooted network models by a reduction to *nonsplit* network models: a directed graph is *nonsplit* if any two nodes have a common incoming neighbor. The crucial point of nonsplitness lies in the following result:

▶ **Theorem 4.** *In a nonsplit network model, a ϱ-safe averaging algorithm is $(1-\varrho)$-contracting. Thus it solves approximate consensus and achieves ε-agreement in $\left\lceil \log_{\frac{1}{1-\varrho}} \left(\frac{1}{\varepsilon}\right)\right\rceil$ rounds.*

Combined with Proposition 2, we obtain an elementary proof of the classical result [4, 7] that approximate consensus is solvable in rooted network models, which does not make use anymore of Dobrushin's coefficients of scrambling matrices [14], which can be defined as $\delta(A) = \sup_{\delta(x)\neq 0} \delta(Ax)/\delta(x)$.

As an immediate consequence of Theorem 4, we deduce that any ϱ-safe algorithm is at best $(1/2)$-contracting since by definition the safety coefficient ϱ cannot be larger than $1/2$. Indeed, in Section 4 we shall present an averaging algorithm that is $(1/2)$-safe in any nonsplit network model. But do there exist other averaging algorithms with a contraction rate less than $1/2$? As stated in the following theorem, the answer is no in the network model of nonsplit communication graphs, except in the case of two processes for which the best contraction rate is $1/3$.

▶ **Theorem 5.** *In the network model of nonsplit communication graphs with n processes, there is no averaging algorithm that is α-contracting for any $\alpha > 1/3$ if $n = 2$ and for any $\alpha > 1/2$ if $n \geqslant 3$.*

Both lower bounds in Theorem 5 are tight. Indeed the *midpoint algorithm* that we will introduce in Section 4.3 is $(1/2)$-safe, and so $(1/2)$-contracting in the network model of nonsplit communication graphs. For a two process network, we check that Algorithm 1 has a contraction rate of $1/3$.

Algorithm 1 Averaging algorithm for two processes with contraction rate 1/3

4 Speedup by amortization

In [8] we proved the following reduction from rooted to nonsplit network models to show that averaging algorithms solve approximate consensus in exponential time.

▶ **Proposition 6** ([8]). *Every product of $n-1$ rooted graphs with n nodes and self-loops at all nodes is nonsplit.*

We next show that one can in fact push this reduction to the extreme, obtaining significantly faster algorithms: Proposition 6 and Theorem 4 suggest to consider a new type of distributed algorithms, which we call *amortized averaging algorithms*, in which each process repeatedly first collects values during $n-1$ rounds, and then computes a weighted average of values it has just collected. In other words, an amortized averaging algorithm is an averaging algorithm with the granularity of macro-rounds consisting in blocks of $n-1$ consecutive rounds.

We now make this notion more precise. First let us fix some notation. Macro-round ℓ is the sequence of rounds $(\ell-1)(n-1)+1,\dots,\ell(n-1)$. We consider algorithms for which every variable x_p is updated only at the end of macro-rounds; $x_p(\ell)$ will denote the value of x_p at the end of round $\ell(n-1)$, as no confusion can arise. Given some communication pattern $(G(k))_{k\geqslant 1}$, the communication graph at macro-round ℓ is equal to:

$$\hat{G}(\ell) = G((\ell-1)(n-1)+1) \circ \dots \circ G(\ell(n-1))\,.$$

Each process p can record the set of values it has received during macro-round ℓ, namely the set $V_p(\ell) = \{x_q(\ell-1) \mid q \in \mathrm{In}_p\left(\hat{G}(\ell)\right)\}$, but in anonymous networks, p cannot determine the set of its incoming neighbors in $\hat{G}(\ell)$. This is in contrast to networks with unique process identifiers where each process p can determine the membership of $\mathrm{In}_p\left(\hat{G}(\ell)\right)$ by piggybacking the name of the sender onto every message, and so can compute the set $W_p(\ell) = \{\left(q, x_q(\ell-1)\right) \mid q \in \mathrm{In}_p\left(\hat{G}(\ell)\right)\}$. Each process can then determine the multiset of values that it has received during a macro-round, counted with their multiplicities.

In consequence in any anonymous network, we can define the *amortized version of* an averaging algorithm $\mathcal{A}$ with weights in update rules that depend only on the sets of received values: at the end of every macro-round ℓ, each process p adopts a new value by applying the same update rule as in $\mathcal{A}$ with the macro-set $V_p(\ell)$. Based on the above discussion, this definition can be extended to averaging algorithms with update rules involving the sets of incoming neighbors when processes have unique identifiers. For instance, the amortized version of the mean-value algorithm is defined in any anonymous network while the amortized equal-neighbor algorithm requires to have unique process identifiers.

In both cases, the new value adopted by process p at the end of macro-round ℓ lies within the interval formed by the values of its incoming neighbors in the communication graph $\hat{G}(\ell)$: if $\hat{m}_p(\ell-1)$ is the minimum of the values in $V_p(\ell)$ and $\hat{M}_p(\ell-1)$ is the maximum, then

$$\hat{m}_p(\ell-1) \leqslant x_p(\ell) \leqslant \hat{M}_p(\ell-1)\,.$$

Algorithm 2 Amortized equal-neighbor algorithm

Initialization:

1: $x_p \in [0,1]$ and $W_p \leftarrow \{(p, x_p)\}$

In round $k \geqslant 1$ **do:**

2: send W_p to all processes in $\mathrm{Out}_p(k)$ and receive W_q from all processes q in $\mathrm{In}_p(k)$

3: $W_p \leftarrow \bigcup_{q \in \mathrm{In}_p(k)} W_q$

4: **if** $k \equiv 0 \mod n-1$ **then**

5: $\quad x_p \leftarrow \frac{1}{|W_p|} \sum_{(q,v) \in W_p} v$

6: $\quad W_p \leftarrow \{(p, x_p)\}$

7: **end if**

If the original averaging algorithm is ϱ-safe, then we have the additional guarantee that

$$\varrho \hat{M}_p(\ell-1) + (1-\varrho)\hat{m}_p(\ell-1) \leqslant x_p(\ell) \leqslant (1-\varrho)\hat{M}_p(\ell-1) + \varrho\, \hat{m}_p(\ell-1)\,.$$

We can then combine Proposition 6 and Theorem 4 to derive the following central result for amortized averaging algorithms.

▶ **Theorem 7.** *In any rooted network model, the amortized version of a ϱ-safe averaging algorithm solves approximate consensus and achieves ε-agreement in $(n-1)\left\lceil \log_{\frac{1}{1-\varrho}} \left(\frac{1}{\varepsilon}\right)\right\rceil$ rounds.*

In order to fix decision times, we have assumed from the beginning that each process knows the number n of processes or at least a common upper bound on n. However, regarding the *asymptotic consensus* problem, obtained by substituting limit values for decision values in the specification of approximate consensus, this common knowledge on n is actually useless for averaging algorithms.

In contrast, update rules in amortized averaging algorithms require that the number of processes in the network is known to all processes. In other words, amortized averaging algorithms are defined only under the assumption of this common knowledge in the network, even for solving asymptotic consensus. In fact, we can adapt the definition of amortized averaging algorithms to the case where n is a fixed parameter and then, because of the self-loops, obtain that Theorem 7 still holds when n is only an upper bound on the number of processes.

4.1 A quadratic-time algorithm in rooted networks with process identifiers

In [8], we proposed an approximate consensus algorithm with a quadratic decision time. The algorithm (cf. Algorithm 2) does not work in anonymous networks as it uses process identifiers so that each process can determine whether some value that it has received several times during a macro-round is originated from the same process or not.

The update rule (line 5) rewrites as:

$$x_p(\ell) = \frac{1}{\left|\mathrm{In}_p\left(\hat{G}(\ell)\right)\right\}\!\right|} \sum_{q \in \mathrm{In}_p\left(\hat{G}(\ell)\right)} x_q(\ell-1)\,.$$

Hence Algorithm 2 is actually the amortized version of the equal-neighbor algorithm.

From Proposition 2 and Theorem 7, it follows that Algorithm 2 solves approximate consensus. Moreover, because of the inequality $\log(1-a) \leqslant -a$ when $0 \leqslant a$ and because $\delta\left(x(0)\right) \leqslant 1$, it follows that if $\ell \geqslant n \log \frac{1}{\varepsilon}$, then $\delta\left(x(\ell)\right) \leqslant \varepsilon$. Hence Algorithm 2 achieves ε-agreement in $O\left(n^2 \log \frac{1}{\varepsilon}\right)$ rounds.

4.2 A quadratic-time algorithm in anonymous rooted networks

Interestingly, Algorithm 2 still works when processes just collect values without taking into account processes from which they originate.

Algorithm 3 Amortized mean-value algorithm

Initialization:

1: $x_p \in [0,1]$
2: $V_p \subseteq V$, initially $\emptyset$
In round $k \geqslant 1$ **do:**
3: send V_p to all processes in $\mathrm{Out}_p(k)$ and receive V_q from all processes q in $\mathrm{In}_p(k)$
4: $V_p \leftarrow \bigcup_{q \in \mathrm{In}_p(k)} V_q$
5: **if** $k \equiv 0 \mod n-1$ **then**
6: $\quad x_p \leftarrow \frac{1}{|V_p|} \sum_{v \in V_p} v$
7: $\quad V_p \leftarrow \emptyset$
8: **end if**

At each macro-round ℓ, the update rule in the resulting algorithm for anonymous networks (cf. Algorithm 3, line 6) coincides with the update rule in the mean-value algorithm. In other words, Algorithm 3 is the amortized version of the mean-value algorithm. Since the latter algorithm is a $(1/n)$-safe averaging algorithm (Proposition 2), we may apply Theorem 7 and obtain the following result.

▶ **Theorem 8.** *In a rooted network model of n processes, the amortized mean-value algorithm solves approximate consensus and achieves ε-agreement in $O(n^2 \log \frac{1}{\varepsilon})$ rounds.*

4.3 A linear-time algorithm in anonymous rooted networks

We improve the above quadratic upper bound on decision times with a linear amortized averaging algorithm which differs from our previous algorithm in the update rule: each process adopts the midpoint of the range of values it has received during a macro-round (cf. Algorithm 4).

Algorithm 4 Amortized midpoint algorithm

Initialization:

1: $x_p \in [0,1]$
2: $m_p \in [0,1]$, initially x_p
3: $M_p \in [0,1]$, initially x_p
In round $k \geqslant 1$ **do:**
4: send (m_p, M_p) to all processes in $\mathrm{Out}_p(k)$ and receive (m_q, M_q) from all processes q in $\mathrm{In}_p(k)$
5: $m_p \leftarrow \min\{m_q \mid q \in \mathrm{In}_p(k)\}$
6: $M_p \leftarrow \max\{M_q \mid q \in \mathrm{In}_p(k)\}$
7: **if** $k \equiv 0 \mod n-1$ **then**
8: $\quad x_p \leftarrow (m_p + M_p)/2$
9: $\quad m_p \leftarrow x_p$
10: $\quad M_p \leftarrow x_p$
11: **end if**

Let us now consider the *midpoint algorithm* that is the simple averaging algorithm with the midpoint update rule. In other words, Algorithm 4 is the amortized version of the midpoint algorithm.

By definition, the midpoint algorithm is $(1/2)$-safe. By Theorem 4, it follows that this algorithm is a $(1/2)$-contracting approximate consensus algorithm in any nonsplit network

model, with a constant decision time. This improves the linear time complexity of the equal neighbor averaging algorithm [8] for this type of network models and demonstrates that the $1/2$ lower bound in Theorem 5 for networks with $n \geqslant 3$ processes is tight.

Furthermore Theorem 7 implies that Algorithm 4 solves approximate consensus in any rooted network model with a decision time in $O(n \log \frac{1}{\varepsilon})$ rounds.

▶ **Theorem 9.** *In a rooted network model of n processes, the amortized midpoint algorithm solves approximate consensus and achieves ε-agreement in $(n-1)\lceil \log_2 \frac{1}{\varepsilon} \rceil$ rounds.*

Hence the amortized mean-value algorithm and the amortized midpoint algorithm both work in any anonymous network model, under the assumption that the number of processes is known to all processes. However while the first algorithm has quadratic decision times and requires each process to store n values per round and to transmit n values per message, the amortized midpoint algorithm solves approximate consensus in linear-time and with only a constant number of (namely, two) values per process and per message.

5 Robustness of amortized averaging algorithms

In this section, we discuss the resiliency of our amortized averaging algorithms against a wrong estimate of the number of processes or against a partial failure of the assumption that communication graphs are permanently rooted.

Firstly consider some communication pattern in which only part of communication graphs are rooted: suppose that $N-1$ communication graphs in any macro-round of $n-1$ consecutive rounds are guaranteed to be rooted. Then there are at least $n-1$ rooted communication graphs in any sequence of $L = \left\lceil \frac{n-1}{N-1} \right\rceil$ macro-rounds of length $n-1$, and every product of L communication graphs of macro-rounds is nonsplit.

Secondly suppose that the network model is indeed rooted but processes do not know the exact number n of processes and only knows an estimate N on n. Macro-rounds in the amortized averaging algorithms then consist of $N-1$ rounds (instead of $n-1$), and so the cumulative communication graphs in such macro-rounds may be not nonsplit when $N < n$. However the communication graph over any block of $L = \left\lceil \frac{n-1}{N-1} \right\rceil$ macro-rounds of length $N-1$ is nonsplit.

In both cases, the above discussion leads to introduce the notion of K-*nonsplit* network model defined as any network model $\mathcal{N}$ such that every product of K communication graphs from $\mathcal{N}$ is nonsplit. Theorem 4 can then be extended as follows:

▶ **Theorem 10.** *In a K-nonsplit network model, a ϱ-safe averaging algorithm is $(1-\varrho^K)$-contracting over each block of K consecutive rounds, i.e., for every non negative integer k, we have*

$$\delta\big(x(k+K)\big) \leqslant (1-\varrho^K)\,\delta\big(x(k)\big)\,.$$

As an immediate corollary of Theorem 10, we obtain that the amortized version of a ϱ-safe averaging algorithm is resilient against a wrong estimate of the number of processes or against a partial failure of the assumption of a rooted network model, and its decision times are multiplied by a factor in $O\big(L\varrho^{-L}\big)$. Note that the theorem measures the number of macro-rounds, and not the number of rounds.

▶ **Theorem 11.** *The amortized version of a ϱ-safe averaging algorithm solves approximate consensus even with an erroneous number of processes or with a communication pattern*

where only part of communication graphs are rooted. Moreover it achieves ε-agreement in $O\left(L\varrho^{-L} \cdot \log\left(\frac{1}{\varepsilon}\right)\right)$ macro-rounds if N denotes the estimate on process number or if only $N-1$ rounds in each block of $n-1$ consecutive rounds are guaranteed to have a rooted communication graph and where $L = \left\lceil \frac{n-1}{N-1} \right\rceil$.

6 Quantization

In this section, we take into account the additional constraint that processes can only store and transmit quantized values. This model provides a good approximation for networks with storage constraints or with finite bandwidth channels.

We include this constraint by quantizing each averaging update rule. For that, we fix some positive integer Q and choose a rounding function, denoted $[\,.\,]$, which rounds down (or rounds up) to the nearest multiple of $1/Q$. Then the quantized update rule for process p at round k writes

$$x_p(k) = \left[\sum_{q \in \mathrm{In}_p(k)} w_{qp}(k)\, x_q(k-1) \right] \tag{3}$$

where the $w_{qp}(k)$ denote the weights in the average of the original algorithm. Besides we assume that all initial values are multiples of $1/Q$.

6.1 Quantization and midpoint

Nedić et al. [22] proved that in any strongly connected network model, every quantized averaging algorithm with the update rule (3) solves exact consensus (and so approximate consensus). Because of the impossibility result for exact consensus [8], their result does not hold if the strong connectivity assumption is weakened into the one of rooted network models.

For the same reason, if $\varepsilon < 1/Q$, then ε-consensus cannot be generally achieved in a rooted network model by a quantized averaging algorithm or its amortized version. In this section, we prove that the quantization of the amortized midpoint algorithm indeed achieves $1/Q$-agreement in any rooted network model.

▶ **Theorem 12.** *In a rooted network model, quantization of the amortized midpoint algorithm achieves $1/Q$-agreement by round $(n-1)\left(\lfloor \log_2(Q-2) \rfloor + 2\right)$. Moreover in every execution, the sequence of values of every process p converges to a limit x_p^* that is a multiple of $1/Q$ in finite time, and for every pair of processes p, q, we have either $x_p^* = x_q^*$ or $\left|x_p^* - x_q^*\right| = 1/Q$.*

We see that the decision times of the quantized and the non-quantized versions of the amortized midpoint algorithm are in the same order for $\varepsilon = 1/Q$. Further, one can show that for $\varepsilon > 2/Q$, ε-agreement is achieved earlier, namely in round $(n-1)\left(\left\lfloor \log_2 \frac{Q-2}{Q\varepsilon-2} \right\rfloor + 1\right)$. When increasing precision, i.e., for $Q \to \infty$, this reduces to $O(n \log \frac{1}{\varepsilon})$.

6.2 Approximate consensus versus 2-set consensus

We now consider the *2-set consensus problem* which is another natural generalization of the consensus problem. Instead of requiring that processes agree to within any positive real-valued tolerance ε, processes have to decide on at most 2 different values:

Agreement. There are at most two different decision values.

Formally, each process starts with an input value from the set V of multiples of $1/Q$ and has to output a decision value from V in such a way that the termination and validity conditions in the consensus specification as well as the above agreement condition are satisfied.

The 2-set consensus problem naturally reduces to approximate consensus: processes round off their $1/Q$-agreement output values. Unfortunately, the use of averaging procedures to solve approximate consensus leads processes to exchange values out of the set V in the resulting 2-set consensus algorithms. The quantized amortized midpoint algorithm allows us to overcome this problem, and Theorem 12 shows that in any rooted network model, this algorithm achieves 2-set consensus in $(n-1)\left(\lfloor \log_2(Q-2) \rfloor + 2\right)$ rounds.

The above discussion shows that the 2-set consensus problem is solvable in a dynamic network model if all the communication graphs are rooted. In particular, 2-set consensus is solvable in a asynchronous complete network with a minority of faulty senders since nonsplit rounds can be implemented in this model. Combined with the impossibility result in [13] in the case of a strict majority of faulty processes, we obtain an exact characterization of the sender faulty models for which 2-set consensus is solvable in asynchronous systems if the number of processes n is odd and a small gap (namely $n/2$ faulty processes) when n is even.

Our positive result can be interestingly compared with the 2 faulty processes boundary [3, 17, 25] between possibility and impossibility of the original (and stronger) 2-set consensus problem [10] where decision values ought to be initial values, instead of being in the range of the initial values. That points out the crucial role of the validity condition on the solvability of 2-set consensus.

7 Conclusion

This paper presented a linear-time approximate consensus algorithm in rooted dynamic network models. For that, we introduced the amortization technique to speed up classical averaging algorithms from exponential to polynomial time, while preserving their inherent robustness. Careful study of the properties that make averaging algorithms contracting lead us to identify the midpoint algorithm as having the optimal contraction rate of $1/2$. Central to our analysis of the amortized midpoint algorithm was the switch from the commonly employed matrix-based to a value-based view. An important property of the amortized midpoint algorithm is that it can be used almost unaltered with quantized values, which allows to decide on at most two neighboring values, thereby a fortiori solving 2-set consensus. Interestingly, it only needs to store and send two values in each round, which makes it space-efficient and viable for implementation.

Abstract

The *dual graph* model describes a radio network that contains both reliable and unreliable links. In recent years, this model has received significant attention by the distributed algorithms community [12, 4, 8, 10, 9, 16, 1, 14]. Due to results in [10], it is known that leader election plays a key role in enabling efficient computation in this difficult setting: a leader can synchronize the network in such a manner that most problems can be subsequently solved in time similar to the classical radio network model that lacks unreliable links. The *feasibility* of efficient leader election in the dual graph model, however, was left as an important open question. In this paper, we answer this question. In more detail, we prove new upper and lower bound results that characterize the complexity of leader election in this setting. By doing so, we reveal a surprising dichotomy: (1) under the assumption that the network size n is in the range 1 to N, where N is a large upper bound on the maximum possible network size (e.g., the ID space), leader election is fundamentally hard, requiring $\tilde{\Omega}(\sqrt{N})$ rounds to solve in the worst-case; (2) under the assumption that n is in the range 2 to N, however, the problem can be solved in only $\tilde{O}(D)$ rounds, for network diameter D, matching the lower bound for leader election in the standard radio network model (within log factors) [7].

1 Introduction

The *dual graph* model is a generalization of the classical radio network model [5, 3] that augments a connected network topology of *reliable* links with an additional set of *unreliable* links. These latter links can come and go on a round-by-round basis as determined links. These latter links can come and go on a round-by-round basis as determined by an unknown adversarial process. The model is motivated by the observation that in real radio networks link quality can change unpredictably due to many different factors (e.g., [17]). Upper bounds proved in this general model are therefore more robust in real world deployments, while lower bounds help formalize the complexity induced by link unreliability.

The dual graph model was introduced in [11] and has since been well-studied in the distributed algorithms community [12, 4, 8, 10, 9, 16, 1, 14]. In this paper, we present new upper and lower bounds for the problem of leader election in this setting. As we elaborate below, by doing so we resolve an important open question from [10] and provide a primitive that enables efficient solutions to many problems in this difficult model.

The Power of Rerandomization. In more detail, the dual graph model describes a radio network consisting of n processes connected by two network topology graphs $G = (V, E)$

43rd International Colloquium on Automata, Languages, and Programming (ICALP 2016).

and $G' = (V, E')$, where the nodes in V correspond to the n processes, E describes reliable links, and E' describes unreliable links. We assume G is connected and use D to describe its diameter. We consider randomized algorithms executing in synchronous rounds. In each round, the network topology is fixed to include all edges in E and some subset of the edges in E', where the latter decision is made by an unknown adversary. Once the topology is fixed, communication follows the standard multi-hop multiple access channel rules (see Section 2).

An important assumption in the dual graph model is the strength of the adversary that selects the unreliable links to include in each round. Early work on this model assumed the adversary was *strongly adaptive* (i.e., it knows the processes' random bits), which led, not surprisingly, to pessimistic lower bounds [11, 12, 4, 8, 16]. In response to these negative results, we argued in [10] that it makes more sense to assume an *oblivious* adversary, as this still allows for unpredictable link behavior, but it removes the unrealistic assumption that link quality can somehow adapt to the processes' private bits.

To validate the claim that the oblivious dual graph model is tractable, we demonstrated that *if* you can synchronize a group of processes with new random bits generated after the execution begins (and therefore unknown to the adversary), these processes can then efficiently communicate. The high-level idea is that transmitters use the shared bits to randomly permute the broadcast probabilities used by the standard *Decay* contention management routine [3] in a manner that is hard for the adversary to predict and therefore is hard for the adversary to impede with its selection of unreliable links.

The key to enabling efficient communication in the dual graph model, therefore, is to efficiently spread shared random bits among the processes in the network. In [10], we took a first step toward this goal by showing that if you are provided a single leader in the network, this leader can generate the bits itself, and then efficiently disseminate them to all processes in $O(D \log n + \log^2(n))$ rounds (with high probability in n)—nearly matching the lower bound of $\Omega(D \log (n/D) + \log^2 n)$ for one-to-all broadcast in the standard radio network model [2, 13, 15]. The high-level idea is that as the new bits spread, the processes that learn them are synchronized and can therefore run the efficient *Decay* variation to efficiently spread them to the next hop.

This strategy reduces the challenge of efficient communication in the dual graph model to electing a single leader. *Whether or not it is possible to efficiently solve leader election in this setting, however, was left as key open question in [10].* In this paper, we answer it.

Our Results. We prove lower and upper bounds that characterize the complexity of leader election in the dual graph model with an oblivious adversary. In doing so, we reveal a surprising dichotomy: (1) under the assumption that the network size n is in the range 1 to N, where N is a large upper bound on the maximum possible network size (e.g., the ID space), leader election is fundamentally *hard*, requiring $\tilde{\Omega}(\sqrt{N})$ rounds to solve in the worst-case; (2) under the assumption that n is in the range 2 to N, however, the problem can be solved in only $\tilde{O}(D)$ rounds, matching the lower bound for leader election in the standard radio network model (within log factors) [7].

Put another way: the promise that you are not alone in the world renders the problem of leader election vastly more tractable. We are unaware of other similar settings for which the split between $n \geq 1$ and $n \geq 2$ holds such significance. In the standard radio network model, for example, the best known leader election algorithms (which nearly match the relevant lower bounds) work equally well for all network sizes [7].

Our lower bound focuses on the easier problem of *loneliness detection*, in which the goal is for each process in a network to correctly determine whether or not it is alone. We construct

a network of maximum size N that consists of $\approx \sqrt{N}$ *outsider* processes each connected to an *insider* process in G. We then connect the insider processes to satisfy the model requirement that G is connected. The graph G' describing unreliable links is fully connected. We then demonstrate how an oblivious adversary can construct a schedule for adding and removing G' edges between insider and outsider processes that delays some outsider processes from receiving messages for a long period. During this period, these outsiders cannot distinguish this execution from those in networks where they are alone. The challenge in constructing this schedule is that the insider processes might coordinate after the execution begins, creating correlated behavior that is hard to predict when constructing our G' schedule. To sidestep this problem we connect each insider process to a line of length $\approx \sqrt{N}$ such that all these lines connect at their far ends. This allows us to keep insider behavior independent for the $\Omega(\sqrt{N})$ rounds that pass before any two insider processes can learn common information.

Our upper bound, by contrast, leverages a novel strategy that necessitates that $n \geq 2$. In particular, the algorithm works in phases. In each phase, it attempts to elect a single leader by having each process flip a weighted coin and become a candidate leader if it comes up heads. For each weight tried, the processes run a series of *experiments* to detect whether they succeeded in electing a single leader.

At a high-level, in these experiments, each candidate leader begins to grow a *territory* of processes that it synchronizes with new random bits. These bits allow them to communicate efficiently using the rerandomization strategy from [10] described above. For territory A to detect if it neighbors some different territory B (indicating the election failed), processes within each territory watch the success rate of their internal communication. If the collision rate is higher than expected, this is evidence that another territory, using different random bits, exists nearby. This strategy requires that each candidate leader has at least one neighbor to recruit for this testing—generating our requirement that $n \geq 2$. We emphasize that this cooperative approach to interference detection is new in the dual graph literature.

Related Work. A close predecessor to the dual graph model of unreliable radio communication was introduced by Clementi et al. [6]. The model in its current form was identified by Kuhn et al. [11]. It has since been well-studied by the distributed algorithms community [12, 4, 8, 10, 9, 16, 1, 14]. Under the pessimistic assumption of a strongly adaptive adversary controlling the unreliable links, results are known for global broadcast [11, 12], local broadcast [8], and graph structuring algorithms [4, 16]. In [10], we suggested the assumption of an oblivious adversary and produced near optimal bounds for global broadcast. We also proved that local broadcast *could not* be solved in $o(D)$ rounds—establishing the $\tilde{O}(D)$ round strategy for enabling efficient communication presented in this paper as optimal with respect to its dependence on D. Recent work by Lynch and Newport [14] explored a different route to efficient communication in this setting by describing how to enable efficient communication in $o(D)$ time under the *additional assumption* that G and G' satisfy strong geographic constraints. The algorithm described here makes no assumption on the network topologies and the graphs used in our lower bound do not satisfy the constraints of [14].

2 Model and Problem Statement

Model. We study the dual graph model of unreliable networks with an oblivious adversary. In more detail, we model a network consisting of n processes connected by a topology consisting of both *reliable* and *unreliable* links. We describe the reliable links with a connected graph $G = (V, E)$, and the unreliable links with a graph $G' = (V, E')$. We use

D to describe the diameter of G. An algorithm in our setting assigns one computational process to each node in V, and we assume processes are provided no advance information about G or G'. In the following, we will use the terms *node* and *process* interchangeably.

Executions are divided into synchronous rounds. At the beginning of an execution, an oblivious adversary determines which edges from G' to include in the network topology for all upcoming rounds (e.g., it generates an infinite sequence of graphs, $G_1, G_2, ...$, where each $G_i = (V, E_i)$, where E_i includes every edge in E and a subset of edges from E'). The adversary does not have access to the nodes' private random bits in generating this sequence. In each round r, we call the edges in G_r the active edges for the round. At the beginning of the round, each node decides to listen or transmit. A node u receives a message m in r if and only if: (a) u decides to listen; and (b) exactly one neighbor of u in the active edges (i.e., neighbor in G_r) transmits in r and it transmits m. In this case, u learns whether the message came from a reliable neighbor. Put another way, if two or more neighbors transmit, all messages are lost at u due to collision. We assume that collisions cannot be distinguished from silence (i.e., no collision detection).

Problem Statements. The problem of *leader election* requires each node v to output a binary value b_v such that, with high probability, exactly one node outputs 1. This node is called the leader. This problem specification suffices for our lower bound. For our algorithmic result, we strengthen the problem by also requiring that each node other than the leader receive at least one message from the leader. The problem of *loneliness detection* requires that each node v outputs a binary value b'_v such that, with high probability, if v is not alone in the network, $b'_v = 0$, and if v is alone, then $b'_v = 1$.

3 The Loneliness Detection Lower Bound

Here, we show that detecting whether a node is alone in the network or not requires $\tilde{\Omega}(\sqrt{N})$ rounds, where N is the best known upper bound on n, e.g., the size of the ID space. That is, if all that nodes know about the current number n of nodes in the network is that $n \in [1, N]$, then leader election in the dual graph model requires much more than its analogue in the reliable model, where $\tilde{O}(D)$ round suffices. Note that in the reliable model, detecting loneliness can be solved easily in $O(\log^2 N)$ rounds, with high probability, using the classical Decay protocol. In contrast, as we show here, the same problem in the unreliable model requires $\tilde{\Omega}(\sqrt{N})$ rounds. Formally, we prove the following result:

▶ **Theorem 1.** *Loneliness detection in the oblivious-adversary dual graph model requires $\tilde{\Omega}(\sqrt{n})$ rounds. More specifically, there is a dual graph radio network (G, G') with at most N nodes in which, for any execution of any distributed algorithm $\mathcal{A}$, some nodes cannot distinguish this execution from one in which they are alone.*

We first start with describing the structure of the dual graph radio network (G, G') that proves this lower bound. We then provide intuitive discussions about the adversary's oblivious strategy for each given algorithm $\mathcal{A}$. At the end, we provide the formal attack strategy and prove that it ensures that some of the nodes in the network experience an execution identical to one in the setting where they are alone in the network.

The Lower Bound Network. We first explain the reliable graph G. We have $\lfloor\sqrt{N}\rfloor$ paths, each consisting of $\lfloor\frac{N-1}{\sqrt{N}}\rfloor \approx \sqrt{N}$ nodes. We call these support lines, and we label them 1, 2, ..., $\lfloor\sqrt{N}\rfloor$. For each line, we call one endpoint "right" and the other "left". We connect all

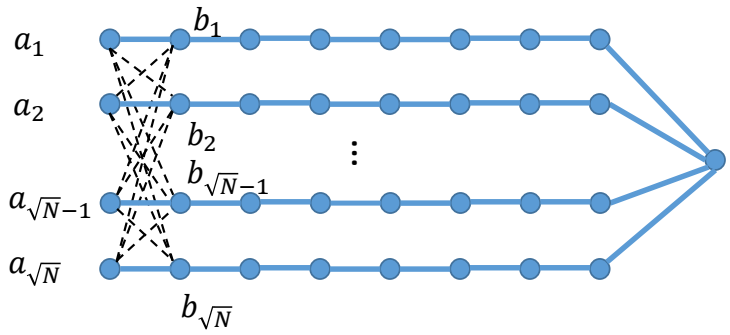

Figure 1 An illustration of the lower bound network. The reliable G-edges are depicted as solid blue lines, and the dashed black lines indicate the unreliable G'-edges.

the right endpoints to one node t. For each line i, we call the first node a_i and the second node b_i. The unreliable graph G' is then defined as a complete bipartite graph between $A = \{a_i | i \in [\lfloor\sqrt{N}\rfloor]\}$ and $B = \{b_i | i \in [\lfloor\sqrt{N}\rfloor]\}$, except for the first path edges a_i–b_i, for each path i, which are reliable and in G. For each i, we refer to a_i and b_i as pairs of each other. Figure 1 shows an illustration of this network.

3.1 Intuitive Discussions about the Adversary's Strategy

The adversary's plan is to ensure that by round $O(\sqrt{N}/\log N)$, with high probability, there are still at least half of the nodes of A which have not received any message from any other node. Thus, for each of them, the execution is identical to one in which the node is alone.

The Adversarial Strategy – Take 1. We start with an insufficient but instructive strategy. For the moment, think of b_i nodes as detached from the rest of their respective lines and let us focus on just the bipartite graph $A \times B$. Let us call a node $v \in A \cup B$ *compromised* if it has received at least one message from some other node of $A \cup B$ or some node in $A \cup B$ has received a message of v. Otherwise, we call v uncompromised.

The adversary uses its knowledge of the algorithm $\mathcal{A}$ to calculate the expected number of nodes in $A \cup B$ that will transmit in each given round. If this expectation is greater than $\Omega(\log N)$, then the adversary will aim for creating a collision for all nodes, by making all edges of G' active. The idea is that, if we have independence between the random decision of nodes in $A \cup B$ transmitting in this round, then due to this high expectation, with high probability, two or more nodes transmit. That would mean all nodes in $A \cup B$ experience collisions and none of them receives a message. Thus, in these high-expectation rounds, no nodes gets compromised, with high probability. On the other hand, if the expected number of transmitting nodes in $A \cup B$ is at most $O(\log N)$, then the adversary will work in the other extreme, and it does not activate any of the unreliable G' edges. Assuming independence between different nodes in $A \cup B$ transmitting, with high probability, at most $O(\log N)$ nodes transmit. This means, with high probability, there are at most $O(\log N)$ many a_i–b_i pairs for which some message exchange happens between a_i and b_i. Hence, in these low-expectation rounds, at most $O(\log N)$ nodes get compromised. Therefore, per round, $O(\log N)$ nodes get compromised, with high probability. That means, even after $O(\sqrt{N}/\log N)$ rounds—for small enough constants—at least half of A remain uncompromised.

The Problem in the Take 1 Strategy. The key difficulty with the above strategy is that, whether different nodes of $A \cup B$ transmit or not in a given round are not independent. This creates a challenge for concentration arguments around the expectation. For instance, there can be dependency between nodes that are compromised as there might be some communication that happened between them. Furthermore, note that the adversary cannot know which nodes are compromised in each round, as that depend on the random decisions of nodes with respect to transmitting or not.

The Adversarial Strategy – Take 2. The adversary will base its decision on the expected number X^r of uncompromised nodes that transmit, in each given round. Notice that the adversary does not know which nodes are compromised. Hence, in this expectation, whether a node is compromised or not is also a random event. Note that $X^r = \sum_i x^r_{a_i} + x^r_{b_i}$ where, for instance, $x^r_{a_i}$ is an indicator random variable for the event of a_i remaining uncompromised up to round r and then transmitting in round r.

The reason that we can focus the attack on only uncompromised nodes is that the behavior of compromised nodes will not impact the new nodes that get compromised, with high probability. Particularly, if $X^r = \Omega(\log N)$ and we have independence, then with high probability, two or more uncompromised nodes transmit. Thus activating all G' edges makes every node in $A \cup B$ experience collision. On the other hand, if $X^r = O(\log N)$ and we have independence, then with high probability, at most $O(\log N)$ uncompromised nodes transmit. Hence, if no G'-edge is activated, only nodes which their pair transmitted can be compromised. Thus, per round, at most $O(\log N)$ new nodes get compromised. Hence, even after $O(\sqrt{N}/\log N)$ rounds, at least half of the nodes in A remain uncompromised.

The Problem in the Take 2 Strategy. It remains to explain how the adversary computes the probabilities of the indicator random variables $x^r_{a_i}$ and $x^r_{b_j}$. Furthermore, the events of these variables are not precisely independent, because there is dependency between different nodes becoming compromised. For instance, if a node transmits alone in a high-expectation round in $A \cup B$, all nodes are compromised. Also, if a node gets compromised in a low-expectation round, so does its pair. We need to explain that we have sufficient independence between the random variables to use concentration arguments.

3.2 The Formal Adversarial Strategy and its Analysis

We now describe our exact adversarial strategy for determining the active edges of G' per round. We describe this process algorithmically. We later prove that for any loneliness detection algorithm $\mathcal{A}$, under this oblivious adversarial strategy, at least half of the A-nodes remain uncompromised. the schedule produced by this process works well.

In more detail, let $T = c\sqrt{n}/\log n$, for a sufficiently small constant $c > 0$, to be fixed later. As mentioned before, the adversary uses only two choices regarding which edges of G' are active: The first option is include no extra G'-edges. We call these rounds *sparse*. The second option is to include all G' edges. We call these rounds *dense*. We can, therefore, describe the adversary's behavior with a binary array S of size T, where $S[r] = 0$ indicates round r will be sparse and $S[r] = 1$ indicates it will be dense.

Oblivious Link Schedule Generation for Duration T

// `Initialization`
α is a positive constant that we use in defining our sparse/dense threshold
A is binary array of size T initialized to 0 in all positions
$N(u)$, for $u \in A \cup B$, is a real value initialized to 1
$P_r(u)$, for $u \in A \cup B$ and $r \in [T]$, is the probability node u transmits in r if it is still uncompromised at r (this depends on the definition of $\mathcal{A}$)
// `Assigning Values to Array` S
for $r = 1$ to T:
  $x \leftarrow \sum_{u \in A \cup B} N(u) \cdot P_r(u)$
  if $x \geq \alpha \log n$ **then**
    $S[r] \leftarrow 1$ // `round` r `is dense` (so we assume no compromises)
  else
    $S[r] \leftarrow 0$ // `round` r `is sparse`
    foreach $u \in A \cup B$
      $N(u) \leftarrow N(u) \cdot [(1 - P_r(u)) \cdot (1 - P_r(v)) + P_r(u) \cdot P_r(v)]$
        // `updating the probability that` u `is compromised, where` v `is the pair of` u `in the respective path.`

We must first verify that the above schedule can be generated by the oblivious adversary prior to the execution. The only non-trivial information in this effort is how the adversary generates $P_r(u)$ in advance, which we discuss next.

Computing Transmission Probabilities of Uncompromised Nodes in $A \cup B$. For $u \in A$, this follows directly from the definition of the algorithm: given the algorithm and a single node u, it is straightforward to calculate the probability that the algorithm broadcasts in any round r, given that node u is isolated.

For $u \in B$, where $u = b_i$ the adversary computes $P_r(u)$ by recursively simulating the following modified graph under a fixed pattern of delivering messages. The graph is simply the line starting from b_i and ending with the left endpoint of the path. The simulation is done (recursively, round by round) under the setting that whenever $S[r] = 1$, node b_i does not receive any message even if it is listening and its left neighbor transmits, whenever $S[r] = 0$, the reception of b_i is the same as it when this detached path is running alone. Simulating this detached line under this fixed reception strategy to b_i allows us to compute the $P_r(b_i)$ for each round $r \leq T$. This is because, if b_i is not compromised, the only difference between this simulated ditached line and the line in our network would be the connection to node t at the far right end. However, that connection cannot affect the behavior of b_i in the first $T = c\sqrt{N}/\log N$ rounds, as it is $\sqrt{N}$ hops away from b_i and due to the synchronous rounds, the causal dependency propagates with a speed of one hop per round at most.

Analysis. Next we analyze the performance of any algorithm $\mathcal{A}$ when executed in our network with the G' edges following the adversarial strategy captured by the array S as generated above.

▶ **Lemma 2.** *With high probability, in each of the first $T = c\sqrt{N}/\log N$ rounds, at most $O(\sqrt{N})$ new nodes get compromised.*

Proof. By induction on r, we show that with high probability, (1) in each dense round, all nodes in $A \cup B$ experience collision and thus no new node gets compromised, and (2) in each sparse round, at most $O(\log N)$ nodes get compromised. This directly proves the lemma.

The claim is trivially correct for round $r = 1$ because in this round, all nodes are uncompromised and $N(u) = 1$ for all of them. So, the parameter x in the adversary's calculations is the correct expectation of the number of transmitting nodes in $A \cup B$ in this round. Since we have independence between these events in the first round, Chernoff bound gives that with high probability, dense rounds are in collision for all nodes in $A \cup B$, and sparse rounds compromise at most $O(\log N)$ nodes.

Next, we prove the inductive step. Suppose that the claim is true for all rounds $r' \leq r-1$. Note that the claim implies that, modulo an inverse-polynomially small term (for the negligible change of the claim being broken), in round r, the variable $N(u)$ in the pseudo-code correctly captures the probability of node u remaining uncompromised. This is because, the calculation ignores the dense rounds, in which we know the u would not get compromised there, and it takes the transmission probability of the node and its pair into account in sparse rounds, as only the transmission of exactly one of these two nodes can compromise u.

Define N_r be random variable indicating the set of uncompromised nodes in r. Also, define the random variable X_r to be the number of uncompromised nodes in $A \cup B$ that transmit in r. Let $Y_r(u)$ be the indicator variable that is 1 if and only if u is uncompromised and transmits in r. We clearly have $E[X_r] = \sum_{u \in A \cup B} Y_r(u) = \sum_{u \in A \cup B} P_r(u) \cdot \Pr[u \in N_r]$.

In the following, we use the notation x_r to refer to the value of x in the pseudo-code run by our oblivious scheduler algorithm in round r. By the argument above, and thanks to the hypothesis of induction, we know that the computations of $N(u)$ for the probability of not being compromised was correct up to round $r-1$.

▶ **Claim 3.** *By way of induction, assume that in every dense round $r' \leq r-1$, all nodes of $A \cup B$ experience collision and thus, none of them receives a message. It follows that for each $v, u \in A \cup B$ where $(u, v) \notin G$, and each $r \leq T$, the events $Y_r(u)$ and $Y_r(v)$ are independent.*

Claim Proof. Given the inductive assumption that collisions are enforced in dense rounds $r' \leq r-1$, for each $u \in A \cup B$, we have the following: If it is in A, until u is compromised, it sees an execution identical to those in which it is alone. Also, if it is in B, until u is compromised, it experiences an execution identical to those in which the related detached line is under the reception adversary discussed above when computing $P_r(u)$. Particularly, u has received no information from outside its support line, and therefore its transmission decisions are independent of nodes in other lines.

Hence, the only way for a node to be compromised for the first time is if the node u or its pair transmit during a sparse round, in the past. However, these transmissions (prior to being compromised) are independent events between nodes of different pairs (i.e., lines). ◀

By the independence provided by the above claim, we can prove that the inductive assumption of having collisions in dense rounds is correct also for the next round r. This is because, under the inductive assumption that dense rounds prior to round r were all in collisions, the calculations $N(u)$ in the pseudo-code correctly captures the probability of a node u being uncompromised up to and including round r. This is equal to the probability of remaining uncompromised up to round $r-1$, which we know was correctly computed by indcution, and then having either none of u and its pair v transmit, or both transmit. Now, given that these events $Y_r(u)$ for different $u \in A \cup B$ are independent, except for each depending on one other event in the same set, we can finish the argument as follows: we use the standard extensions of Chernoff bound to settings with bounded (constant) dependency-graph degree and conclude the following: if the expectation $E[X_r]$ is $\Omega(\log N)$, then with high probability, $X_r \geq 2$. Hence, with high probability, the dense round r also is in collision. Similarly, if the expectation $E[X_r]$ is $O(\log N)$, then with high probability

$X_r \leq O(\log N)$ and thus, in round r, at most $O(\log N)$ new nodes get compromised. This finishes the proof of the inductive proof and thus also the proof of the lemma. ◀

4 The Algorithm

Here, we explain a distributed algorithm that computes a leader in $\tilde{O}(D)$ rounds, in the dual graph model with an oblivious adversary, when nodes are given the promise that $n \geq 2$.

▶ **Theorem 4.** *There is a distributed algorithm that in any dual graph network (G, G') with an oblivious adversary, and where $n \geq 2$ and G has diameter D, elects a leader in at most $O(D \log^4 N)$ rounds, with probability at least $1 - 1/N^c$, for any desired constant $c \geq 2$.*

4.1 Outline

Suppose that all nodes know an upper bound D on the diameter of the reliable graph G, that is within a constant factor of the diameter. We will explain how to remove this assumption using the standard doubling technique, at the end of this section.

We will try $O(\log N)$ estimates of the form $\eta = 2^i$ for n, where $i \in [1, \log N]$. For each of these, we run $O(\log N)$ experiments, where in each experiment each node is marked with probability $1/\eta = 2^{-i}$. Each marked node is considered as a candidate for leadership and an experiment is *successful* if and only if there is exactly one candidate. It is easy to see that, with high probability, there is at least one experiment in which there is exactly one marked node. The challenge is to identify experiments with exactly one candidate.

We run the $O(\log^2 N)$ experiments in parallel. Particularly, we divide time into epochs of length $O(\log^2 N)$ and the j^{th} round of each epoch belongs to the j^{th} experiment. Let us focus on one experiment. The problem we need to solve in a single experiment is to detect whether in this experiment, there is exactly one candidate or not, in $\tilde{O}(D)$ rounds.

For now, we focus on one fixed arbitrary experiment. In this experiment, we perform a special broadcast procedure starting from each of the candidates. At any point in time, we call the set of nodes that receive (only) the identifier of a candidate v the *territory* of v. Nodes that have received two or more candidate identifiers in this experiment are called *in conflict*, and nodes that have not received any candidate identifier in this experiment are called *leaderless*. We define the *conflict* and *leaderless* territories accordingly.

We first explain in Section 4.2 the simple broadcast scheme that starts from each candidate and tries to grow its territory. The guarantee will be that, if the candidate is alone, the message reaches all nodes in $O(D \log^2 N)$ rounds. In Section 4.3, we then explain how to detect whether the broadcast has already reached all nodes or not. The guarantee will be that an experiment terminates if and only if there is exactly one candidate, and in that case, it terminates in $\Theta(D \log^2 N)$ rounds. Hence, once an experiment terminates, if we wait for a (sufficiently large) constant factor more time, all those experiment that can terminate do so. At the end, among these successful experiments, the one with the smallest experiment-number wins. That means the single candidate of that experiment is elected as the leader.

4.2 Growing Territories

Each candidate v initiates a special single-message broadcast procedure. Included in this message is the identifier of the candidate v, as well as $O(\log^2 N \log \log N)$ bits of randomness. The broadcast procedure then proceeds in D phases, where in each phase, we perform the following procedure:

Rerandomized Decay Protocol. Each phase consists of $L = \alpha \log^2 N$ consecutive rounds, for a large enough constant α. In each round of the phase, all nodes that have received the message of a candidate by the start of the phase use the randomness shared in the message to pick a shared random number $j \in_{\mathcal{U}} [1, 2 \log N]$. The details of this part will be discussed shortly. Then, each node decides to transmit with probability 2^{-j}, using its own private randomness, and remains silent otherwise. At the end of the phase, each node only keeps the messages that it received from its reliable neighbors, or those that it had before. Note that the former uses the assumption that each node is able to distinguish successful receptions from reliable and unreliable neighbors. This will later simplify the process of removing the assumption of knowing an upper bound on the diameter D.

We note that the above is an adaptation of the classical Decay procedure[3], with the key change being in the publicly random choice of the transmission probability. This property helps crucially in defeating the oblivious adversary.

We show that if we have a single candidate, after $O(D \log^2 N)$ rounds, its message reaches all nodes, w.h.p. This follows immediately from the following simple lemma, which particularly implies that if there is only one candidate, its broadcast grows at a speed of one G-hop per round, thus reaching all nodes in $O(D \log^2 N)$ rounds.

▶ **Lemma 5.** *Suppose that node w has at least one G-neighbor that had received the message of a candidate v by the start of the phase. Furthermore, assume that no G'-neighbor of w has received a message from any candidate other than v. Then, regardless of the behavior of the adversary, w.h.p., node w receives the message of candidate v during this phase.*

Proof. Consider each round r of the phase and let G^r be the graph fixed by the adversary for round r. Let d^r be the number of active neighbors of w in round r that have received the message of candidate v, by the start of the phase. Notice that all potentially-active neighbors of w that transmit have received the message of candidate v and act according to the randomness bits received in the related message. Particularly, this shared randomness, they pick a common $j \in_{\mathcal{U}} [1, 2 \log N]$ for this round r. With probability $\frac{1}{2 \log N}$, the random value $j \in_{\mathcal{U}} [1, 2 \log N]$ will be such that $j = \lceil \log d^r \rceil$. If that happens, the probability that exactly one active neighbor of w transmit in round r is at least $\frac{d^r}{2^j}(1 - \frac{1}{2^j})^{d^r - 1} \geq 1/5$. Thus, per round, the probability that node w receives the message of candidate v from one of its active neighbors is at least $\frac{1}{10 \log N}$. By a simple Chernoff bound, this means that during the $\alpha \log^2 N$ rounds of the phase, node w receives the message of v with high probability. ◀

4.3 Detecting Loneliness for Candidates

Note that if in an experiment, we have two or more candidates, their territories will grow and eventually reach each other. At that point, the territories can obstruct each other from growing and covering all nodes. The key task will be to determine if the broadcast of a candidate has reached all nodes or not.

We call a node u in the territory of candidate v a *boundary node* of this territory if u has at least one G-neighbor outside the territory of v. Notice that, if the broadcast of v has not reached all nodes, then there is at least one boundary node in the territory of node v. On the other hand, if v was the only candidate, once the broadcast reaches all nodes, there will not be any boundary nodes.

The boundary nodes have the responsibility for detecting whether the broadcast has reached all nodes or not. They will deliver their indications to the candidate, which then decides whether the experiment was successful or not. The existence of boundary nodes will

be taken as an indication that the territory does not cover all nodes. Let us first explain the key idea for detecting boundary nodes.

Boundary Detection. As the lower bound from the previous section suggests, even the rudimentary problem of each node receiving a single message from any nearby node can be hard. Thus we cannot rely on the boundary nodes receiving a message from a node outside their territory. We turn the problem around. Instead of insisting on actually receiving a message from outside the territory, we take lack of a frequent receptions from the node's own territory as an indication for collisions, implying that the node is potentially a boundary node. More concretely, the following two are indications for the bound w being boundary and thus that the related broadcast has not reached all nodes: (1) if w receives a message from the territory of a different leader, or more cruicially (2) if w *does not receive* messages from its own territory frequently enough. Let us make this formal.

The boundary detection algorithm consists of a single phase—i.e., $L = \alpha \log^2 N$ rounds. Each node that has received a message from exactly one candidate v performs one phase of its Rerandomized Decay Protocol, exactly as explained above. On the other hand, all other nodes (those in conflict or leaderless) transmits a special NOISE message in all of the rounds of the phase. A node will consider itself boundary if it receives messages from its own territory in less than $\frac{\alpha \log N}{15}$ of the rounds of this phase. The next two lemmas, the second of which is the key lemma in this whole approach, explain why this criterion correctly identifies the boundary nodes:

▶ **Lemma 6.** *If a node w is not alone in its territory and it does not have a G'-neighbor out of its territory, then throughout the phase, it will receive at least $\frac{\alpha \log N}{15}$ messages from its own territory.*

Proof. The proof is similar to Lemma 5. We easily see that per round, w receives a message from its own territory with probability at least $\frac{\log N}{10}$. Thus, by a Chernoff bound, node w receives messages from its own territory in at least $\frac{\alpha \log N}{15}$ rounds, with high probability. ◀

▶ **Lemma 7.** *[Key Lemma] If w has at least one G-neighbor out of its territory, then w.h.p., it will either receive a message from a different territory, or it receives less than $\frac{\alpha \log N}{25}$ messages from its own territory.*

Proof. First note that if w has a G-neighbor in the conflict or leaderless territory, it will not receive any message from its own territory and hence it detects that it is a boundary. Next, suppose that each G-neighbor of w has received a message from exactly one marked node.

Consider a given round r of the phase, and fix the edges incident on w made active for this round by the adversary. Let A_r be the set of active neighbors of w in its own territory, and let B_r be the set of active neighbors of w in other territories. Note that by the assumption that w has at least one G-neighbor out of its territory, B_r is nonempty. Suppose that the set B_r is composed of nodes of t territories, $B_r = B_r^1 \cup B_r^2 \cup \ldots B_r^t$, where without loss of generality, B_r^t is not the conflict or leaderless territory. Define p_r to be the probability of the event that no node in B_r^1 to B_r^{t-1} transmits. We have the following simple observations regarding the transmission probabilities in these sets:

(1) The probability that no node in A_r transmits is at least $1/(2e)$.
(2) The probability that exactly one node of A_r transmits is in at most $\frac{5}{\log N}$.
(3) The probability that no node in any of B_r^1 to B_r^t transmits is at most p_r.
(4) The probability that exactly one node of B_r transmits, and it is in B_r^t, is at least $\frac{p_r}{10 \log N}$.

Note that the events of different territories are independent. Hence, by (2) and (3), we have that the probability that w receives a message from its own territory is at most $\frac{5p_r}{\log N}$. Also, by (1) and (4), we have that the probability that w receives a message from another territory is at least $\frac{p_r}{20e \log N}$.

Therefore, over all the L rounds of the phase, the expected number of messages that w receives from other territories is at least $\sum_{r=1}^{L} \frac{p_r}{20e \log N}$. If $\sum_{r=1}^{L} \frac{p_r}{20e \log N} \geq 5 \log N$, then with high probability, w receives a message from another territory. On the other hand, if $\sum_{r=1}^{L} \frac{p_r}{20e \log N} \leq 5 \log N$, the expected number of messages that w receives from its own territory is at most $\sum_{r=1}^{L} \frac{5p_r}{\log N} \ll \frac{\alpha \log N}{30}$, as the constant α is chosen to be large enough. Thus, in this case, with high probability, the number of rounds in which w receives a message from its own territory is less than $\frac{\alpha \log N}{25}$. This completes the proof. ◀

Delivering the Boundary Signal to the Candidate. If for a candidate v, there is a node u in the territory of v for which the condition of Lemma 7 is satisfied, then v knows that its experiment was not successful. We next describe how to let the candidate v know whether there is such a "boundary" node u in its territory. The basis for this again will be mimicking *collision detection*, where lack of frequent receptions from a node's own territory is regarded as a collision.

We now explain how we deliver the indicator about the existence of boundaries to the candidate, and how they react. Note that the broadcast algorithm, explained in Section 4.2, grows the territory at a speed of one G-hop per phase, when there is a single candidate, and at a (potentially) slower speed, when there are two or more. Hence, all nodes of the territory of a candidate v are within its $O(D)$ hops in G. After one phase of boundary detection, if the territory of v does not include all nodes, there will be at least one node u in this territory that satisfies the condition of Lemma 7. Thus, this node provides an excuse for not announcing the experiment successful, and potentially continuing the broadcast.

To deliver this information to the candidate, we run $O(D)$ additional phases of broadcast. Here, if a node has noticed a boundary (or is in conflict or leaderless), it constantly transmits NOISE in all the rounds of the phase. Otherwise, the node broadcasts simply according to its rerandomized decay protocol, using the shared randomness provided in the candidate's message. At the end of each phase, each node w believes that there is a boundary node in its territory if it believed so before or if receives a message from outside territory or a NOISE message, or more critically, if it does not receive messages from the node's own territory frequently enough (less than $\frac{\alpha \log N}{25}$ times). If this happens, node w constantly transmits NOISE in the rounds of the next phases. The following lemma follows by straightforward application of Lemma 7.

▶ **Lemma 8.** *If there is at least one boundary in the territory of candidate v, then by the end of these $O(D)$ phases, candidate v will be informed about it. Moreover, if the territory includes all nodes, then v will not receive such an indication.*

Finally, if after all these $\Theta(D)$ phases, a candidate v received no indication of a boundary, it considers this experiment successful. It then initiates a "*successful experiment*" announcement. Other candidate do not initiate any announcement. We run a broadcast from the candidates, in $\tilde{O}(D)$ rounds, spreading this success announcement. If the experiment was successful, then with high probability, the candidate is alone and thus, this success announcement gets delivered to all nodes of the network.

Removing the knowledge of diameter. Recall that above, we assumed that nodes know a constant factor upper bound D on the diameter of graph G. Here, we remove this assumption using a standard doubling method.

Effectively, we try 2-factor estimates of diameter. We divide the time into $\log N$ scales, where the k^{th} is made of $\tilde{O}(2^k)$ consecutive rounds. In the k^{th} scale, we imagine 2^k to be the upper bound on diameter. We thus grow the territories up to a radius of 2^k by running the broadcast (from scratch) for 2^k phases. Then we have one boundary detection phase, and then we spend 2^k additional phases to deliver the indicator about existence of boundaries to the candidate. A final set of 2^k spreads the potential announcements of successful experiments. Note that since the length of the scales form a geometric sum, and as when 2^k reaches D we will have the first successful experiment, we will observe the first successful experiment in $O(D)$ phases, considering all the scales. In the other experiments prior to this scale, the broadcasts will not be able to reach all nodes, as it spreads at a speed of one G-hop per round. Hence, those experiments will not be announced successful.

Consider the first scale for which some candidate announces a successful experiment. In this scale, we take the candidate of these successful experiments that has the smallest experiment number as the global leader.

Abstract

In this paper we improve the deterministic complexity of two fundamental communication primitives in the classical model of ad-hoc radio networks with unknown topology: broadcasting and wake-up. We consider an unknown radio network, in which all nodes have no prior knowledge about network topology, and know only the size of the network n, the maximum in-degree of any node Δ, and the eccentricity of the network D.

For such networks, we first give an algorithm for wake-up, in both directed and undirected networks, based on the existence of small universal synchronizers. This algorithm runs in $O(\frac{\min\{n, D\Delta\} \log n \log \Delta}{\log \log \Delta})$ time, improving over the previous best $O(n \log^2 n)$-time result across all ranges of parameters, but particularly when maximum in-degree is small.

Next, we introduce a new combinatorial framework of block synchronizers and prove the existence of such objects of low size. Using this framework, we design a new deterministic algorithm for the fundamental problem of *broadcasting*, running in $O(n \log D \log \log \frac{D\Delta}{n})$ time. This is the fastest known algorithm for this problems, improving upon the $O(n \log n \log \log n)$-time algorithm of De Marco (2010) and the $O(n \log^2 D)$-time algorithm due to Czumaj and Rytter (2003), the previous fastest results for directed networks, and is the first to come within a log-logarithmic factor of the $\Omega(n \log D)$ lower bound due to Clementi et al. (2003).

Our results have also direct implications on the fastest *deterministic leader election* and *clock synchronization* algorithms in both directed and undirected radio networks, tasks which are commonly used as building blocks for more complex procedures.

1 Introduction

1.1 Model of communication networks

We consider the classical model of *directed ad-hoc radio networks* with *unknown structure*. A *radio network* is modeled by a *directed* network $\mathfrak{N} = (V, E)$, where the set of nodes

corresponds to the set of transmitter-receiver stations. The nodes of the network are assigned different identifiers (IDs), and throughout this paper we assume that all IDs are distinct numbers in $\{1, \ldots, |V|\}$. A directed edge $(v, u) \in E$ means that node v can send a message directly to node u. To make propagation of information feasible, we assume that every node in V is reachable in $\mathfrak{N}$ from any other.

In accordance with the standard model of unknown (ad-hoc) radio networks (for more elaborate discussion about the model, see, e.g., [1, 2, 5, 9, 10, 12, 17, 19, 22]), we make the assumption that a node does not have any prior knowledge about the topology of the network, its in-degree and out-degree, or the set of its neighbors. We assume that the only knowledge of each node is the *size* of the network n, the *maximum in-degree* of any node Δ, and the *eccentricity* of the network D, which is the maximum distance from the source node to any node in $\mathfrak{N}$. For a discussion of these assumptions, see the full version of this paper.

Nodes operate in discrete, synchronous time steps, but we do not need to assume knowledge of a global clock. When we refer to the "running time" of an algorithm, we mean the number of time steps which elapse before completion (i.e., we are not concerned with the number of calculations nodes perform within time steps). In each time step a node can either *transmit* a message to all of its out-neighbors at once or can remain silent and *listen* to the messages from its in-neighbors. We do not make any restriction on the size of messages.

The distinguishing feature of radio networks is the interfering behavior of transmissions. In the most standard radio networks model, the *model without collision detection* (see, e.g., [1, 2, 10, 22]), which is studied in this paper, if a node v listens in a given round and precisely one of its in-neighbors transmits, then v receives the message. In all other cases v receives nothing; in particular, the lack of collision detection means that v is unable to distinguish between zero of its in-neighbors transmitting and more than one.

The model without collision detection describes the most restrictive interfering behavior of transmissions; also considered in the literature is a less restrictive variant, the model with collision detection, where a node listening in a given round can distinguish between zero of its in-neighbors transmitting and more than one (see, e.g., [12, 22]).

1.2 Communications primitives: broadcasting and wake-up

In this paper we consider two fundamental communications primitives, namely *broadcasting* and *wake-up*, and consider *deterministic protocols* for each of these tasks.

1.2.1 Broadcasting

Broadcasting is one of the most fundamental problems in communication networks and has been extensively studied for many decades (see, e.g., [22] and the references therein).

The premise of the broadcasting task is that one particular node, called the *source*, has a message which must become known to all other nodes. We assume that all other nodes start in a dormant state and do not participate until they are "woken up" by receiving the source message (this is referred to in some works as the "no spontaneous transmissions" rule). As a result, while the model does not assume knowledge of a global clock, we can make this assumption in practice, since the current time can be appended to the source message as it propagates, and therefore will be known be all active nodes. This is important since it allows us to synchronize node behavior into fixed-length *blocks*.

1.2.2 Wake-up

The *wake-up problem* (see, e.g., [15]) is a related fundamental communication problem that arises in networks where there is no designated "source" node, and no synchronized time-step at which all nodes begin communicating. The goal is for all nodes to become "active" by receiving some transmission. Rather than a single source node which begins active, we instead assume that some subset of nodes spontaneously become active at arbitrary time-steps. The task can be seen as a variant of broadcast, with possibly multiple sources, and without the ability to assume a global clock. This last point is important, and results in wake-up protocols being slower than those for broadcast, since nodes cannot co-ordinate their behavior.

1.3 Related work

As a fundamental communications primitive, the task of *broadcasting* has been extensively studied for various network models for many decades.

For the model studied in this paper, directed radio networks with unknown structure and without collision detection, the first sub-quadratic deterministic broadcasting algorithm was proposed by Chlebus et al. [5], who gave an $O(n^{11/6})$-time broadcasting algorithm. After several small improvements (cf. [6, 21]), Chrobak et al. [9] designed an almost optimal algorithm that completes the task in $O(n \log^2 n)$ time, the first to be only a poly-logarithmic factor away from linear dependency. Kowalski and Pelc [17] improved this bound to obtain an algorithm of complexity $O(n \log n \log D)$ and Czumaj and Rytter [11] gave a broadcasting algorithm running in time $O(n \log^2 D)$. Finally, De Marco [20] designed an algorithm that completes broadcasting in $O(n \log n \log \log n)$ time steps. Thus, in summary, the state of the art result for deterministic broadcasting in directed radio networks with unknown structure (without collision detection) is the complexity of $O(n \min\{\log n \log \log n, \log^2 D\})$ [11, 20]. The best known lower bound is $\Omega(n \log D)$ due to Clementi et al. [10].

Broadcasting has been also studied in various related models, including undirected networks, randomized broadcasting protocols, models with collision detection, and models in which the entire network structure is known. For example, if the underlying network is undirected, then Kowalski [16] gave a deterministic broadcasting algorithm running in time $O(n \log D)$. If spontaneous transmissions are allowed and a global clock available, then deterministic broadcast can be performed in $O(n)$ time in undirected networks [5]. Randomized broadcasting has been also extensively studied, and in a seminal paper, Bar-Yehuda et al. [2] designed an almost optimal broadcasting algorithm achieving the running time of $O((D + \log n) \cdot \log n)$. This bound has been later improved by Czumaj and Rytter [11], and independently Kowalski and Pelc [18], who gave optimal randomized broadcasting algorithms that complete the task in $O(D \log \frac{n}{D} + \log^2 n)$ time with high probability, matching a known lower bound from [19]. In the model with collision detection, an $O(D + \log^6 n)$-time randomized algorithm due to Ghaffari et al. [12] is the first to exploit collisions and surpass the algorithms (and lower bound) for broadcasting without collision detection.

For more details, see e.g., [22] and the references therein.

The *wake-up problem* (see, e.g., [15]) is a related communication problem that arises in networks where there is no designated "source" node, and no synchronized time-step at which all nodes begin communicating. Before any more complex communication can take place, we must first require all nodes to be "active," i.e., aware that they should be communicating. This is the goal of wake-up, and it is a fundamental starting point for most other tasks in this setting, for example leader election and clock synchronization [8].

The first sub-quadratic deterministic wake-up protocol was given in by Chrobak et al. [8], who introduced the concept of *radio synchronizers* to abstract the essence of the problem.

They give an $O(n^{5/3} \log n)$-time protocol. Since then, there have been two improvements in running time, both making use of the radio synchronizer machinery: firstly to $O(n^{3/2} \log n)$ [4], and then to $O(n \log^2 n)$ [3]. Unlike for the problem of broadcast, the fastest known protocol for directed networks is also the fastest for undirected networks. A recent survey of the current state of research on the wake-up problem is given in [15].

1.4 Our results

In this paper we present a *new construction of universal radio synchronizers* and introduce and analyze a *new concept of block synchronizers* to improve the deterministic complexity of two fundamental communication primitives in the model of ad-hoc radio networks with unknown topology: broadcasting and wake-up.

By applying the analysis of block synchronizers, we present a new deterministic broadcasting algorithm (**Algorithm 1**) in directed ad-hoc radio networks with unknown structure, without collision detection, that for any directed network $\mathfrak{N}$ with n nodes, with eccentricity D, and maximum in-degree Δ, completes broadcasting in $O(n \log D \log\log \frac{D\Delta}{n})$ time-steps. This result almost matches a lower bound of $\Omega(n \log D)$ due to Clementi et al. [10], and improves upon the previous fastest algorithms due to De Marco [20] and due to Czumaj and Rytter [11], which require $O(n \log n \log\log n)$ and $O(n \log^2 D)$ time-steps, respectively.

Our result reveals that a non-trivial speed-up can be achieved for a broad spectrum of network parameters. Since $\Delta \leq n$, our algorithm has the complexity at most $O(n \log D \log\log D)$. Therefore, in particular, it significantly improves the complexity of broadcasting for shallow networks, where $D \ll n^{O(1)}$. Furthermore, the dependency on Δ reduces the complexity even further for networks where the product $D\Delta$ is near linear in n including sparse networks which can appear in many natural scenarios.

Our broadcasting result has also direct implications on the fastest *deterministic leader election algorithm* in directed and undirected radio networks. It is known that leader election can be completed in $O(\log n)$ times broadcasting time (see, e.g., [9, 13]) (assuming the broadcast algorithm extends to multiple sources, which is the case here as long as we have a global clock), and so our result improves the bound to achieve a deterministic leader election algorithm running in $O(n \log n \log D \log\log \frac{D\Delta}{n})$ time. For undirected networks the best result is $O(n \log^{3/2} n \sqrt{\log\log n})$ time [7] (we note that the $O(n \log D)$ broadcast protocol of [16] cannot be used at a $\log n$ slowdown for leader election, since it relies on token traversal and does not extend to multiple sources). Our result therefore favorably compares for shallow networks (for small D) even in undirected networks.

We also present a deterministic algorithm (**Algorithm 2**) for the related task of wake-up. We show the existence of universal radio synchronizers of delay $g(k) = O(\frac{n \log n \log k}{\log\log k})$, and demonstrate that this yields a wake-up protocol taking time $O(\frac{\min\{n, D\Delta\} \log n \log \Delta}{\log\log \Delta})$. This improves over the previous best result, the $O(n \log^2 n)$-time protocol of [3]; the improvement is largest when Δ is small, but even when it is polynomial in n, our algorithm is a $\log\log n$-factor faster.

Our improved result for wake-up has direct applications to communication algorithms in networks that do not have access to a global clock, where wake-up is an essential starting point for most more complex communication tasks. For example, wake-up is used as a subroutine in the fastest known protocols for fundamental tasks of *leader election* and *clock synchronization* (cf. [8]). These are two fundamental tasks in networks without global clocks, since they allow initially unsynchronized networks to be brought to a state in which synchronization can be assumed, and results from the better-understood setting with a global

clock can then be applied. Our wake-up protocol yields $O(\frac{\min\{n,D\Delta\}\log^2 n\log\Delta}{\log\log\Delta})$-time leader election and clock synchronization algorithms, which are the fastest known in both directed and undirected networks.

1.5 Previous approaches

Almost all deterministic broadcasting protocols with sub-quadratic complexity (that is, since [5]) have made use of the concept of *selective families* (or some similar variant thereof, such as selectors). These are families of sets for which one can guarantee that any subset of $[n] := \{1, 2, \ldots, n\}$ below a certain size has an intersection of size exactly 1 with some member of the family. They are useful in the context of radio networks because if the members of the family are interpreted to be the set of nodes which are allowed to transmit in a particular time-step, then after going through each member, any node with an active in-neighbor and an in-neighborhood smaller than the size threshold will be informed. Most of the recent improvements in broadcasting time have been due to a combination of proving smaller selective families exist, and finding more efficient ways to apply them (i.e., choosing which size of family to apply at which time).

One of the drawbacks of selective-family based algorithms is that applying them requires coordination between nodes. For the problem of broadcast, this means that some time may be wasted waiting for the current selective family to finish, and also that nodes cannot alter their behavior based on the time since they were informed, which might be desirable. For the problem of wake-up, this is even more of a difficulty; since we cannot assume a global clock, we cannot synchronize node behavior and hence cannot use selective families at all.

To tackle this issue, Chrobak et al. [8] introduced the concept of *radio synchronizers*. These are a development of selective families which allow nodes to begin their behavior at different times. A further extension to *universal synchronizers* in [4] allowed effectiveness across all in-neighborhood sizes. However, the adaptability to different node start times comes at a cost of increased size, meaning that synchronizer-based wake-up algorithms were slightly slower than selective family-based broadcasting algorithms .

The proofs of existence for selective families and synchronizers follow similar lines: a probabilistic candidate object is generated by deciding on each element independently at random with certain carefully chosen probabilities, and then it is proven that the candidate satisfies the desired properties with positive probability, and so such an object must exist. The proofs are all non-constructive (and therefore all resulting algorithms non-explicit; cf. Indyk [14] for an explicit construction of selective families).

Returning to the problem of broadcasting, a breakthrough came in 2010 with a paper by De Marco [20] which took a new approach. Rather than having all nodes synchronize their behavior, it instead had them begin their own unique pattern, starting immediately upon being informed. These behavior patterns were collated into a transmission matrix. The existence of a transition matrix with appropriate selective properties was then proven probabilistically. The ability for a node to transmit with a frequency which decayed over time allowed De Marco's method to inform nodes with a very large in-neighborhood faster, and this in turn reduced total broadcasting time from $O(n\log^2 D)$ [11] to $O(n\log n\log\log n)$.

A downside of this new approach is that having nodes begin immediately, rather than wait until the beginning of the next selector, gives rise to a far greater number of possible starting-time scenarios that have be accounted for during the probabilistic proof. This caused the logarithmic factor in running time to be $\log n$ rather than $\log D$. Further, the method was comparatively slow to inform nodes of low in-degree, compared to a selective family of appropriate size. These are the difficulties that our approach will have to overcome.

1.6 Overview of our approach

Our wake-up result follows a similar line to the previous works; we prove the existence of smaller universal synchronizers than previously known, using the probabilistic method. Our improvement stems from new techniques in analysis rather than method, which allow us to gain a log-logarithmic factor by choosing what we believe are the optimal probabilities by which to construct a randomized candidate.

Our broadcasting result takes a new direction, some elements of which are new and some of which can be seen as a compromise between selective family-type objects and the transmission schedules of De Marco [20]. We first note that nodes of small in-degree can be quickly dealt with by repeatedly applying $(n, \frac{n}{D})$-selective families "in the background" of the algorithm. This allows us to tailor the more novel part of the approach to nodes of large in-degree. We have nodes perform their own behavior patterns with decaying transmission frequency over time, but they are semi-synchronized to "blocks" of length roughly $\frac{n}{D}$, in order to cut down the number of circumstances we must consider. This idea is formalized by the concept of *block synchronizers,* combinatorial objects which can be seen as an extension of the radio synchronizers used for wake-up.

An important new concept used in our analysis of block synchronizers (and also in our proof of small universal synchronizers) is that of *cores*. Cores reduce a set of nodes and starting times to a (usually smaller) set of nodes which are active during a critical period. In this way we can combine many different circumstances into a single case, and demonstrate that for our purposes they all behave in the same way.

The most technically involved part of both of the proofs is the selection of the probabilities with which we generate a randomized candidate object (universal synchronizer or block synchronizer). Intuitively, when thinking about radio networks, a node in our network is aiming to inform its out-neighbors, and it should assume that as time goes on, only those with large in-neighborhoods will remain uninformed (because these nodes are harder to inform quickly). Therefore a node should transmit with ever-decreasing frequency, roughly inversely proportional to how large it estimates remaining uninformed neighbors' in-neighborhoods must be. However, these in-neighborhoods cannot be estimated exactly, and so we must tweak the probabilities slightly to cover the possible range. In block synchronizers we do this using phases of length $O(\log\log\frac{D\Delta}{n})$ during which nodes halve their transmission probability every step, but since behavior must be synchronized to achieve this we cannot do the same for radio synchronizers. Instead, we allow our estimate to be further from the true value, and require more time-steps around the same value to compensate.

As with previous results based on selective families, synchronizers, or similar combinatorial structures, the proofs of the structures we give are non-constructive, and therefore the algorithms are non-explicit.

2 Combinatorial tools

Our communications protocols rely upon the existence of objects with certain combinatorial properties, and we will separate these more abstract results from their applications to radio networks. In this section, we will define the combinatorial objects we will need to make use of, and prove their existence. Next, in Sections 3–4, we will demonstrate in details how these combinatorial objects can be used to obtain fast algorithms for broadcasting and wake-up.

2.1 Selective families

We begin with a brief discussion about *selective families*, whose importance in the context of broadcasting was first observed by Chlebus et al. [5]. A selective family is a family of subsets of $[n] := \{1, \ldots, n\}$ such that every subset of $[n]$ below a certain size has intersection of size exactly 1 with a member of the family. For the sake of consistency with successive definitions, rather than defining the family of subsets S_i, we will instead use the equivalent definition of a set of binary sequences S^v (that is, $S^v_i = 1$ if and only if $v \in S_i$).

For some $m \in \mathbb{N}$, let each $v \in [n]$ have its own length-m binary sequence $S^v = S^v_0 S^v_1 S^v_2 \ldots S^v_{m-1}$.

▶ **Definition 1.** $S = \{S^v\}_{v\in[n]}$ is an (n, k)-**selective family** if for any $X \subseteq [n]$ with $1 \leq |X| \leq k$, there exists $j \in [0, m)$ such that $\sum_{v\in X} S^v_j = 1$. (We say that such j *hits* X.)

2.1.1 Application to radio networks

During the course of radio network protocols we can "apply" a selective family S on an n-node network by having each node v transmit in time-step j if and only if v has a message it wishes to transmit and $S^v_j = 1$ (see, e.g., [5, 10]). Some previous protocols involved nodes starting to transmit immediately if they were informed of a message during the application of a selective family (or a variant called a selector designed for such a purpose), but here we will require nodes to wait until the current selective family is completed before they start participating. That is, nodes only attempt to transmit their message if they knew it at the beginning of the current application.

The result of applying an (n, k)-selective family is that any node u which has between 1 and k active neighbors before the application will be informed of a message upon its conclusion. This is because there must be some time-step j which hits the set of u's active neighbors, and therefore exactly one transmits in that time-step, so u receives a message. This method of selective family application in radio networks was first used in [5].

2.1.2 Existence of small selective families

The following standard lemma (see, e.g., [10]) posits the existence of (n, k)-selective families of size $O(k \log \frac{n}{k})$. This has been shown to be asymptotically optimal [10].

▶ **Lemma 2 (Small selective families).** *For some constant c and for any $1 \leq k \leq n$ there exists an (n, k)-selective family of size at most $m = ck \log \frac{n}{k}$.*

2.2 Radio synchronizers

Radio synchronizers are an extension of selective families designed to account for nodes in a radio network starting their behavior patterns at different times, and without access to a global clock. They were first introduced in [8] and used in an algorithm for performing wake-up, and this is also the purpose for which we will apply them.

To define radio synchronizers, we first define the concept of *activation schedule*.

▶ **Definition 3.** An n-**activation schedule** is a function $\omega : [n] \to \mathbb{N}$.

We will extend the definition to subsets $X \subseteq [n]$ by setting $\omega(X) = \min_{v\in X} \omega(v)$.

As for selective families, let each $v \in [n]$ have its own length-m binary sequence $S^v = S^v_0 S^v_1 S^v_2 \ldots S^v_{m-1}$. We then define radio synchronizers as follows:

▶ **Definition 4.** $S = \{S^v\}_{v\in[n]}$ is an (n, k, m)-**radio synchronizer** if for any activation schedule ω and for any $X \subseteq [n]$ with $1 \leq |X| \leq k$, there exists $j \in [\omega(X), \omega(X) + m)$ such that $\sum_{v\in X} S^v_{j-\omega(v)} = 1$.

One can see that the definition is very similar to that of selective families (Definition 1), except that now each v's sequence is offset by the value $\omega(v)$. To keep track of this shift in expressions such as the sum in the definition, we will call such values j *columns*. As with selective families, we say that any column j satisfying the condition in Definition 4 *hits* X.

In [4], this concept was extended to universal radio synchronizers which cover the whole range of k from 1 to n. Let $g : [n] \to \mathbb{N}$ be a non-decreasing function, which we will call the *delay* function.

▶ **Definition 5.** $S = \{S^v\}_{v\in[n]}$ is an (n, g)-**universal radio synchronizer** if for any activation schedule ω, and for any $X \subseteq [n]$, there exists column $j \in [\omega(X), \omega(X) + g(|X|))$ such that $\sum_{v\in X} S^v_{j-\omega(v)} = 1$.

2.2.1 Application of universal radio synchronizers to radio networks

One can apply universal radio synchronizers to the problem of wake-up in radio networks by having $\omega(v)$ represent the time-step in which node v becomes active during the course of a protocol (either spontaneously or by receiving a transmission). Subsequently, v interprets S^v as the pattern in which it should transmit, starting immediately from time-step $\omega(v)$. That is, in each time-step j after activation, v checks the next value in S^v (i.e., $S^v_{j-\omega(v)}$), transmits if it is **1** and stays silent otherwise. Then, the selective property specified by the definition guarantees that any node u with an in-neighborhood of size q hears a transmission within at most $g(q)$ steps of its first in-neighbor becoming active.

2.2.2 Existence of small universal radio synchronizers

We will prove existence of small universal synchronizers.

▶ **Theorem 6.** *For some constant c and for any $n \in \mathbb{N}$ there exists an (n, g)-**universal radio synchronizer** with $g(q) = \frac{cq \log q \log n}{\log \log q}$.*

The proof of Theorem 6 is deferred to the full version, but here we present its main ideas.

Our universal synchronizer must hit any set X within $g(X)$ columns of the set's start column $\omega(X)$. Our first step is to narrow down the amount of sets and activation schedules we must consider by defining the *core* of a set. The core removes elements of X which only become active after we must already have hit X (i.e. after column $\omega(X) + g(X)$), and then shifts all values of ω so that $\omega(X) = 0$. Multiple different sets X under multiple different activation schedules can have the same core, and therefore behave the same way during the critical period. So, by considering cores instead of the original sets and activation schedules, we can reduce the amount of cases we must account for.

We then probabilistically generate a candidate universal synchronizer, and prove that it does indeed satisfy the required property with positive probability. The crucial part of this method is our choice of probabilities with which we include each element in the candidate.

We expect to be able to hit a core of size q within $\frac{cq \log q \log n}{\log \log q}$ columns. Therefore, for a particular element v and for columns greater than $\omega(v) + \frac{cq \log q \log n}{\log \log q}$, all remaining cores containing v that we have left to hit should be larger than q. If we want to hit a set of size roughly q by randomly selecting each element of $[n]$, then we optimize our probability of doing so by selecting each element with probability roughly $\frac{1}{q}$. This translates to setting

$S^v_{\frac{cq\log q\log n}{\log\log q}} = 1$ with probability roughly $\frac{1}{q}$. Substituting $j = \frac{cq\log q\log n}{\log\log q}$, this works out to give the probability of $S^v_j = 1$ to be roughly $\frac{\log j\log n}{j\log\log j}$. However, as it transpires, this is not quite the optimal choice.

To see what we should choose instead, we must first examine how we analyze our candidate. We define the *load* $f_C(j)$ of a column j with respect to a core C; this is the expected number of elements of the core selected in that column. We show that the probability of hitting the core on j is at least $f_C(j)2^{-f_C(j)}$. Ideally, we want $f_C(j)$ to be constant for cores of roughly the size we should currently be hitting, and then this hitting probability is also constant. However, if we use the probabilities $\mathbf{P}[S^v_j = 1] = \frac{\log j\log n}{j\log\log j}$, we in fact find that $f_C(j)$ can be between $\Omega(1)$ and $O(\log j)$, depending upon the times at which its elements became active. This $\log j$-sized gap cannot be closed, since we can easily find cores which do indeed have loads at either end of the range. What we can do, however, is tweak the probabilities to shift this range down and maximize hitting probability over it.

Specifically, if we shift probabilities down by a factor of $\frac{\log j}{\log\log j}$, i.e. to $\mathbf{P}[S^v_j = 1] \approx \frac{\log n}{j}$, we shift the range of possible loads to be between $\Omega(\frac{\log\log j}{\log j})$ and $O(\log\log j)$, ensuring that the hitting probability is $\Omega(\frac{\log\log j}{\log j})$. This is as close to constant as we can get; the gap is what necessitates the $\frac{\log q}{\log\log q}$ factor in our delay function g.

With this bound on the probability of hitting a particular core at a particular column, we can use independence to obtain an lower bound for hitting a core over the whole range of valid columns, and then use a union bound to show that we can hit all cores with positive probability.

2.3 Block synchronizers

Next, we introduce *block synchronizers*, which are a new type of combinatorial object designed for use in a fast broadcasting algorithm. They can be seen as an extension of both radio synchronizers and the transmission matrix formulation of De Marco [20].

Let each $v \in [n]$ have its own length-m binary sequence $S^v = S^v_0 S^v_1 S^v_2 \dots S^v_{m-1}$. Define a function $\mu_B : \mathbb{N} \to \mathbb{N}$, for some fixed B, which rounds its input up to the next multiple of B, that is, $\mu_B(x) = \min\{pB : p \geq \frac{x}{B}, p \in \mathbb{N}\}$; we will call $s(v) := \mu_B(\omega(v))$ the *start column* of v. We extend s to subsets of $[n]$ in the obvious way, $s(X) = \mu_B(\omega(X))$.

▶ **Definition 7.** $S = \{S^v\}_{v\in[n]}$ is an (n, Δ, r, B)-**block synchronizer** if for any activation schedule ω and any set $X \subseteq [n]$ with $|X| \leq \Delta$, there exists column $j \in [s(X), s(X) + B\lceil\frac{|X|}{r}\rceil)$ such that $\sum_{v\in X} S^v_{j-s(v)} = 1$.

Block synchronizers differ from radio synchronizers in two ways: Firstly, on top of the offsetting effect of the activation schedule, there is also the function μ_B that effectively "snaps" behavior patterns to blocks of size B, hence the name block synchronizer. Secondly, the size of the range in which we must hit X is linearly dependent on $|X|$ rather than being fixed. The parameter r is the increment by which each block increases the size of sets we can hit.

2.3.1 Application of block synchronizers to radio networks

The idea of our broadcasting algorithm will be that any node v waits until the start of the first block after its activation time $\omega(v)$, and then begins its transmission pattern S^v. The definition of block synchronizer aims to model this scenario. The hitting condition ensures that any node with an in-neighborhood of size $q \leq \Delta$ will be informed within $B\lceil\frac{q}{r}\rceil$ time-steps of the start of the block in which its first in-neighbor begins transmitting.

2.3.2 Existence of small block synchronizers

We prove the following theorem.

▶ **Theorem 8.** *For some constant c and for any $n, D, \Delta \in \mathbb{N}$ with D, $\Delta \leq n < D\Delta$, there exists an $(n, \Delta, \frac{n}{D}, c\frac{n}{D} \log D \log\log \frac{D\Delta}{n})$-**block synchronizer**.*

The proof of this theorem is deferred to the full version, but we outline its main ideas.

We begin in a similar way to that of Theorem 6, in that we define the concept of a core to narrow down the range of possibilities we must consider. The difference is that now elements v have their behavior patterns snapped to blocks, so the core need only store the number of the first block v becomes active, rather than the exact column. This significantly reduces the number of possible cores, and is essential for obtaining the $\log D$ factor in size, rather than $\log n$. As before, cores also shift the activation schedule to begin at 0.

We wish to proceed in a similar manner as in the proof of small universal synchronizers, generating a candidate probabilistically and then proving that it satisfies the desired property with positive probability. While we could do this directly for block synchronizers using the same method, we would obtain a size of $\Theta(n \log D \log\log \Delta)$. Our improved bound of $O(n \log D \log\log \frac{D\Delta}{n})$ results from noting that we can afford to hit cores smaller than $\frac{n}{D}$ using selective families, leaving a narrower range of cores to be hit by our randomized candidate object. Therefore, we define an *upper block synchronizer* which need only hit cores above a certain size threshold (in our case, $\frac{n}{D}$), and this is the object we prove the existence of with the probabilistic method.

Once again, the most technical aspect of the proof lies in the probabilities with which we choose elements in our candidate object. Again, we define the load of a column $f_{\mathcal{C}}(j)$ to be the expected number of elements in a core $\mathcal{C}$ which are selected in column j, and show that the probability of hitting the core at j is at least $f_{\mathcal{C}}(j)2^{-f_{\mathcal{C}}(j)}$. By choosing our probabilities to be roughly inversely proportional to the size of cores we expect to remain un-hit, we can guarantee that on a constant fraction of columns we have $f_{\mathcal{C}}(j) = \Omega(1)$ and $f_{\mathcal{C}}(j) = O(\log \frac{Dj}{n}) = O(\log \frac{D\Delta}{n})$. However, the way in which we deal with this range differs from the case of universal synchronizers.

Since our elements' behavior is snapped to blocks, we can synchronize changes in probability of selection between all elements. Specifically, we have $O(\log\log \frac{D\Delta}{n})$-length phases in which the selection probability of all elements halves every consecutive column (in addition to the slight decrease that occurs between columns naturally). This means that $f_{\mathcal{C}}(j)$ also roughly halves every column within phases, and so there is at least one column within each phase in which it is within some constant range (we use the interval $(\frac{1}{3}, 1)$). Then, the probability of hitting the core at that column is also at least some constant.

With this bound, we can again use independence of columns and a union bound to show that our candidate upper block synchronizer hits all cores larger than $\frac{n}{D}$ with positive probability. Then, it remains only to insert a $(n, \frac{n}{D})$-selective family at the start of every block in order to hit smaller cores, and we meet the conditions of a block synchronizer.

3 Algorithms for broadcasting and wake-up

In this section we present our algorithms for broadcasting and wake-up in radio networks.

3.1 Broadcasting

We will assume that $D\Delta > n$, otherwise an earlier $O(D\Delta \log \frac{n}{\Delta})$-time protocol from [10] can be used to achieve $O(D\Delta \log \frac{n}{\Delta}) = O(n \log D)$ time.

Let $\mathcal{S}$ be an $(n, \Delta, \frac{n}{D}, \mathcal{B})$-block synchronizer, with $\mathcal{B} = c\frac{n}{D}\log D \log\log \frac{D\Delta}{n}$, and recall that $\mu_{\mathcal{B}}(x) = \min\{p\mathcal{B} : p \geq \frac{x}{\mathcal{B}}, p \in \mathbb{N}\}$. We will say that the source node becomes active at time-step 0, and any other node v becomes active in a time-step i if it received its first transmission at time-step $i-1$. Our broadcasting algorithm is the following (Algorithm 1):

Algorithm 1 Broadcast at a node v

Let i be the time-step in which v becomes active
for j from 0 to $DB-1$, in time-step $\mu_{\mathcal{B}}(i)+j$ **do** v transmits source message iff $\mathcal{S}^v_j = 1$
end for

3.2 Wake-up

Let S be an (n, g)-universal radio synchronizer with $g(q) = \frac{cq\log q \log n}{\log\log q}$. We will say that a node v becomes active in a time-step i if it either spontaneous wakes up at i, or received its first transmission at time-step $i-1$. Our wake-up algorithm is the following (Algorithm 2):

Algorithm 2 Wake-up at a node v

Let i be the time-step in which v becomes active
for j from 0 to $g(n)-1$, in time-step $i+j$ **do** v transmits source message iff $S^v_j = 1$
end for

4 Analysis of broadcasting and wake-up algorithms

In this section we show that our algorithms for broadcasting and wake-up have the claimed running times. We begin with the analysis of the broadcasting algorithm.

▶ **Theorem 9.** *Algorithm 1 performs broadcast in $O(n\log D\log\log\frac{D\Delta}{n})$ time-steps.*

To begin the analysis, fix some arbitrary node v and let P be a shortest path from the source (or first informed node) x to v. Number the nodes in this path consecutively, e.g., $P_0 = x$ and $P_{dist(x,v)} = v$. Classify all other nodes into *layers* dependent upon the furthest node along the path P to which they are an in-neighbor (some nodes may not be an in-neighbor to any node in P; these can be discounted from the analysis). That is, layer $L_\ell = \{u \in V : \max_{u \text{ in-neighbour to } P_i} i = \ell\}$ for $\ell \leq dist(x,v)$. We separately define layer $L_{dist(x,v)+1}$ to be $\{v\}$.

At any time step, we call a layer *leading* if it is the foremost layer containing an active node, and our goal is to progress through the network until the final layer is leading, i.e., v is active. The use of layers allows us to restrict to the set of nodes of our main interest: if we focus on the path node whose in-neighborhood contains the leading layer, we cannot have interference from earlier layers since they contain no in-neighbors of this path node, and we cannot have interference from later layers since they are not yet active.

▶ **Lemma 10.** *Let $h : [\Delta] \to \mathbb{N}$ be a non-decreasing function, and define $T(n, D, \Delta, h)$ to be the supremum of the function $\sum_{i=1}^{D} h(q_i)$, where integers $1 \leq q_i \leq \Delta$ satisfy the additional constraint $\sum_{i=1}^{D} q_i \leq n$. If a broadcast or wake-up protocol ensures that any layer (under any choice of v) of size q remains leading for no more than $h(q)$ time-steps, then all nodes become active within $T(n, D, \Delta, h)$ time-steps.*

Proof. Let $q_i = |L_i|$. Layer $L_{dist(x,v)+1}$ must be leading (and thus node v active) once no other layers are leading, and so this occurs $\sum_{i=1}^{dist(x,v)} h(q_i)$ time-steps after layer L_1

becomes leading. Since $\sum_{i=1}^{dist(x,v)} h(q_i) \leq \sum_{i=1}^{D} h(q_i)$ and $\sum_{i=1}^{D} q_i \leq n$, this is no more than $T(n, D, \Delta, h)$ time-steps. Since v was chosen arbitrarily, all nodes must be active within $T(n, D, \Delta, h)$ time-steps of x becoming active. ◀

We make use of Lemma 10 to give bounds on the running times of our algorithms:

▶ **Lemma 11.** *Algorithm 1 ensures that any layer of size q remains leading for fewer than $\mathcal{B}\lceil\frac{q+r}{r}\rceil$ time-steps.*

Proof. For all nodes w, let $\omega(w)$ be the time-step that w becomes active during the course of the algorithm. By definition of a block selector, for any layer L_i of size q_i there is a time-step $j < s(L_i) + B\lceil\frac{q_i}{r}\rceil$ in which exactly one element of L_i transmits. Then, either path node P_i hears the transmission (and so layer L_i is no longer leading in time-step $j+1$), or P_i has active in-neighbors not in L_i, in which case these must be in a later layer so L_i is not leading. Thus, L_i can remain leading for no more than $s(L_i) + \mathcal{B}\lceil\frac{q_i}{r}\rceil - \omega(L_i) < \mathcal{B}\lceil\frac{q_i+r}{r}\rceil$ time-steps. ◀

With these tools, we are now ready to complete the proof of Theorem 9.

Proof. Proof of Theorem 9 By Lemma 10, Algorithm 1 ensures that all nodes are active (and have therefore heard the source message) within $T(n, D, \Delta, h)$ time-steps, where $h(q) = \mathcal{B}\lceil\frac{q+r}{r}\rceil$. We will use an upper bound $T(n, D, \Delta, h')$, where $h'(q) = \mathcal{B}\frac{q+2r}{r}$. Since h' is linear and increasing, $\sum_{i=1}^{D} h'(q_i)$ subject to $\sum_{i=1}^{D} q_i \leq n$ is maximized whenever $\sum_{i=1}^{D} q_i = n$, for example at $q_i = \frac{n}{D}$ for all $i \in [D]$. So, the algorithm completes broadcast within

$$\sum_{i=1}^{D} h'(\frac{n}{D}) = \sum_{i=1}^{D} \mathcal{B}\frac{\frac{n}{D}+2r}{r} = 3\mathcal{B}D = 3c'n\log D\log\log\frac{D\Delta}{n}$$

time-steps. ◀

In a similar way, we can analyze Algorithm 2.

▶ **Theorem 12.** *Algorithm 2 performs wake-up in $O(\frac{\min(n,D\Delta)\log n\log\Delta}{\log\log\Delta})$ time-steps.*

5 Conclusions

The task of broadcasting in radio networks is a longstanding, fundamental problem in communication networks. Our result for deterministic broadcasting in directed networks combines elements from several of the previous works with some new techniques, and, in doing so, makes a significant improvement to the fastest known running time. Our algorithm for wake-up also improves over the previous best running time, and relies on a proof of smaller universal synchronizers, a combinatorial object first defined in [4].

Neither of these algorithms are known to be optimal. The best known lower bound for both broadcasting and wake-up is $\Omega(\min(n\log D, D\Delta\log\frac{n}{\Delta}))$ [10]; our broadcasting algorithm therefore comes within a log-logarithmic factor, but our wake-up algorithm remains a logarithmic factor away.

As well as the obvious problems of closing these gaps, there are several other open questions regarding deterministic broadcasting in radio networks. Firstly, the lower bound for undirected networks is weaker than that for directed networks [18], and so one avenue of research would be to find an $O(n\log D)$ lower bound in undirected networks, matching the broadcasting time of [16]. Secondly, the algorithms given here, along with almost all

previous work, are non-explicit, and therefore it remains an important challenge to develop explicit algorithms that can come close to the existential upper bound. The best constructive algorithm known to date is by Indyk [14], but it is a long way from optimality.

Some variants of the model also merit interest, in particular the model with collision detection. It is unknown whether the capacity for collision detection improves deterministic broadcast time, as it does for randomized algorithms [12]. Collision detection does remove the requirement of spontaneous transmissions for the use of the $O(n)$ algorithm of [5], but a synchronized global clock would still be required. It should be noted that collision detection renders the wake-up problem trivial, since if every active node transmits in every time-step, collisions will wake up the entire network within D time-steps.

Abstract

We consider a network of sellers, each selling a single product, where the graph structure represents pair-wise complementarities between products. We study how the network structure affects revenue and social welfare of equilibria of the pricing game between the sellers. We prove positive and negative results, both of "Price of Anarchy" and of "Price of Stability" type, for special families of graphs (paths, cycles) as well as more general ones (trees, graphs). We describe best-reply dynamics that converge to non-trivial equilibrium in several families of graphs, and we use these dynamics to prove the existence of approximately-efficient equilibria.

1 Introduction

Sellers typically do not operate in isolated markets but in conjunction with other sellers and buyers. In particular, sellers need to take into account the fact that buyers may value the goods they sell as substitutes or complements to goods sold by others. This has a tremendous impact on how sellers compete with each other. Indeed, in Cournot's [8] famous paper from 1838 about sellers who compete through quantities, Cournot also describes a model of a duopoly selling perfect complements, zinc and copper. In Cournot's example, a manufacturer of zinc may observe that some of her major customers produce brass (made of zinc and copper); Therefore, zinc manufacturers compete not only with other zinc sellers, but they also indirectly compete with manufacturers of copper, as both target the money of brass producers. We are interested in a more complicated competition structure, where as zinc can be also used for Galvanization of iron, zinc sellers compete at the same time with sellers of iron. In a similar way, iron is also demanded by car manufacturers that need to purchase glass from other sellers, and so on.

Another classic example is by Ellet [10], who studied how owners of two consecutive segments of a canal determine the tolls for shippers; Clearly, every shipper must purchase a permit from both owners for being granted the right to cross the canal. Another, more contemporary, example might be a high-tech or pharmaceutical firm that must use two

registered patents to manufacture its product; The owners of the two patents quote prices for the usage rights, and these patents can be viewed as perfect complements for the firm. As a final example, consider an international trader who wishes to export goods from country X to country Y, and needs to pay license fees to both countries. In the last two examples, one can see how licenses have a network structure, as each patent may be needed for the production of several different products, and trade may occur between country X and country Y, but also between country X and another country Z, etc.

In this paper, we study markets where goods are complementary to several other goods, but not substitutes. Price discrimination is impossible, and sellers need to offer the same price in all markets. This situation creates a global price competition between sellers, which raises interesting questions we aim to explore: What kinds of equilibria exist in these games? How efficient are the equilibria in this game? Will natural dynamics reach highly efficient equilibria?

The structure of the market plays a central role in our analysis. We model the market using a weighted undirected graph, where each vertex represents a seller of a certain good. An edge with weight v between vertices i and j indicates that there is a buyer that is willing to pay an amount v for the bundle of goods $\{i, j\}$.[1] In the above example, a market with sellers of copper, zinc, iron and glass can be represented as a path-graph with 4 vertices (See Figure 1), where edges connect copper and zinc, zinc and iron, and iron and glass.

We study the following simultaneous full-information pricing game between sellers on a graph: the sellers observe the values of the buyers, which are common knowledge; each seller then posts a single price to all buyers; a buyer on an edge buys the two goods on this edge if the total price (the sum of the prices of the two goods) is no larger than her value. Sellers have zero manufacturing costs and unlimited supply, and the profit of each seller is the price she posted times the number of buyers that accepted this price. In a (pure) Nash equilibrium, no seller would benefit from changing its price given the prices offered by the other sellers.

There are two natural benchmarks for measuring the quality of equilibria in such games. The first is the *maximum welfare*, which is the sum of values of all buyers.[2] This is the welfare that would be achieved with zero prices for all goods. The second benchmark is the *optimal monopolist revenue*, which is the optimal total revenue achievable by a monopolist that owns all the goods in the network. (Clearly, the optimal monopolist revenue is always at most the maximum welfare.) Several papers studied the problem of computing the optimal pricing for a monopolist in our setting. The problem was proposed by [12] which showed that it is APX-hard and presented an approximation algorithm that is logarithmic in the number of buyers. A 1/4-approximation algorithm was later presented by [3] when buyers are interested in bundles of size 2, and recently [19] showed that this bound is tight under some computational assumptions. A similar algorithm for this problem was suggested by [20] in the context of setting up peering connections in networks. [18] provided an improved bound for monopolist revenue maximization with buyers having the same value but interested in one or two items. Unlike these papers which focus on the monopolist's algorithmic problem, we focus on analyzing equilibria in the game between competing sellers and on how the welfare and revenue of these equilibria approximate the above benchmarks.

---

[1] Throughout this paper, for the simplicity of presentation, we consider buyers that demand bundles of size 2 which we can model using graphs; Buyers that demand bundles of arbitrary sizes can be modeled as hyper-edges on a hyper-graph. We show how some of our results extend to hyper-graphs in the full paper.

[2] Assuming 0 production costs for sellers, and payments cancel out.

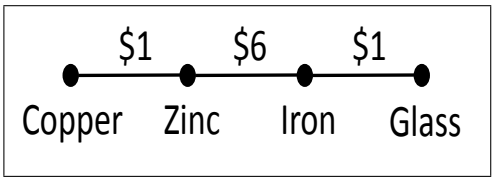

Figure 1 A market with 4 sellers and 3 buyers. The weight on each edges is the amount this buyer is willing to pay for the bundle of the two adjacent goods. For example, the middle edge represents a buyer that is willing to pay \$6 for a bundle of zinc and iron, but has value 0 for each good alone.

It is straightforward to see that some equilibria in these games demonstrate a complete market failure. For example, a vector of prices of ∞ posted by all sellers forms a Nash equilibrium that yields zero welfare and revenue. Yet, there might be multiple equilibria in these games, and one may hope that other equilibria perform better. Indeed, we prove that for some families of graphs the best equilibria ("price of stability") have high revenue and welfare. Observe that we cannot hope for full efficiency as even for path graphs, the most efficient equilibria are sometimes not fully efficient: For example, in Figure 1, if either the seller of zinc or of iron offer a price above 1, then one of its edges will not be sold. However, there is no equilibrium in which these two sellers offer prices at most 1: if this occurs, each seller gains at most 2 (from selling to its two edges) but they can get revenue of at least 5 by offering 5 and selling to the middle edge only.

Another way to alleviate the problem of low welfare and revenue of some equilibria is by restricting attention to equilibria with natural properties. For instance, it may be unreasonable for a seller that does not sell any good to insist on a very high price despite having zero costs; Such behavior might be considered as a malicious behavior towards his neighboring sellers. We therefore sometimes restrict attention to *non-malicious* equilibria, where all sellers that are not selling at all offer a price of 0. Non-malicious equilibria serve as a main tool for proving the existence of approximately-optimal equilibria: we show that the revenue of every such equilibrium approximates the maximum welfare, and we show cases where such equilibria exist.

Our Results

Our main goal is to understand how the network structure affects various properties of equilibria in markets. We aim to understand how well can the welfare and revenue in equilibrium approximate the maximum welfare and the optimal revenue. We explore whether best-response dynamics can lead to approximately-optimal equilibria, and we prove the existence of such equilibria in several settings. We study graphs of different complexities, like paths, cycles, trees and general graphs.

We start by considering some special families of graphs (paths and cycles) and show that there is a natural best response dynamics that reaches equilibria with a constant fraction of the optimal welfare as revenue. For path graphs, we consider a dynamics starting with all sellers pricing at infinity. Then, we change the price of a seller on one side of the path to zero, and let each seller in turn best reply to current prices. We show that when this best-reply process reaches the other end of the path, it ends up in an equilibrium. Moreover, for at least one of the end points, the revenue when starting from that point is at least half the maximum welfare. An extension of this dynamics for cycles converges to an equilibrium with revenue of at least one quarter of the optimal welfare.

After we prove that for some families of graphs there exist Nash equilibria with good revenue guarantees, the immediate question is whether this generalizes to more complex graphs. It turns out that non-maliciousness of equilibria can be used to prove bounds on the revenue. In particular, we show that for any tree, every non malicious equilibrium has revenue that is at most $O(\log d)$ factor smaller than the optimal welfare, where d is the maximum degree. One might hope that such a result can be achieved for general graphs as well, but unfortunately this is not the case. For a clique of degree d, the loss can be linear in d,[3] and therefore we cannot hope for a logarithmic fraction for general graphs. Our main positive result presents a refined bound that depends not only on the maximum degree, but also on the *arboricity* of the graph (see, e.g., [22]). This additional parameter nicely captures the difference between trees and cliques (and other graphs). The arboricity of an undirected graph is the minimum number of forests into which its edges can be partitioned. (For example, a tree has arboricity 1, a cycle has arboricity 2, and a clique of n nodes has arboricity $n/2$.) We prove the following bound on the revenue of any non-malicious equilibrium:[4]

▶ **Theorem.** *In every graph with maximum degree d and arboricity w and every non-malicious equilibrium in it, the total revenue of all sellers is at least $\Omega(\frac{1}{w+\log d})$ of the maximum welfare.*

The above theorem does not claim anything about the existence of non-malicious equilibria, but only bounds the revenue obtained by such equilibria if they exist. For this result to imply a bound on the "price of stability" in such games,[5] one needs to show that non-malicious equilibria actually exist. We prove the existence of non-malicious equilibria via the natural heuristic of repeated best-reply dynamics. Such a dynamics starts with arbitrary prices; At each step, a seller who is not best replying is chosen, and he updates his price to a best reply (breaking ties non-maliciously - towards 0 price). Our main result in this context shows that in tree graphs, a specific sequence of best replies does stop at a non-malicious equilibrium.

▶ **Theorem.** *In every tree, for every initial profile of prices, there exists a sequence of best replies that terminates in a non-malicious Nash equilibrium.*

In particular, this result implies the existence of non-malicious equilibria in trees, and together with the approximation theorem above, we conclude that the price of stability in trees (i.e., the approximation achieved by the best equilibrium in every tree) is at least $\Omega(\frac{1}{\log d})$. Of course, it would be interesting to strengthen this result and show that for any graph such dynamics terminate in a (non-malicious) equilibrium. Based on simulations we have executed, we conjecture that this is indeed the case.

▶ **Conjecture.** *In every graph any non-malicious best response dynamics starting from any price vector converges to an equilibrium in polynomial number of steps.*

This is the strongest version of our conjecture. One can also try to prove weaker versions of the conjecture by restricting the graph structure, order of plays, and relaxing the required time to convergence.

---

[3] Consider a clique of degree d with all edges with the same value of 1. Such a clique has a non-malicious equilibrium in which one seller prices at 0 while all others price at 1. The welfare in this non-malicious equilibrium is only linear in d, while the optimal welfare is quadratic in d, and thus there is a linear loss in d.

[4] We note that the theorem holds also for non-simple graphs that have parallel edges.

[5] Our result above also has a "price-of-anarchy" flavor, as we prove that all non-malicious equilibria (when exist) exhibit the approximation guarantee.

We also prove several impossibility results. We first show that the $\Omega(\frac{1}{\log d})$ approximation for trees is tight, by presenting trees in which the welfare of every non-malicious equilibrium is at most an $\Omega(\frac{1}{\log d})$ fraction of the monopolist revenue (and thus of the optimal welfare). However, this bound is proved using constructions for which there are other ("malicious") equilibria that achieve a constant approximation. We therefore strengthen this impossibility result and show instances where *all* equilibria, malicious or not, achieve bad results. In particular, we would like to find out whether the revenue of the best equilibrium is always a constant fraction of the monopolist's revenue. Our main lower bounds show that the answer is negative, even for trees.

▶ **Theorem.** *For graphs with maximum degree d:*

- *There are* graphs *for which the welfare in every Nash equilibrium is at most $O(\frac{1}{\sqrt{\log d}})$ fraction of the monopolist's revenue.*
- *There are* trees *for which the welfare in every Nash equilibrium is at most $O(\frac{1}{\log \log d})$ fraction of the monopolist's revenue.*

Note that the fact that the revenue in every equilibrium is low compared to the monopolist revenue, implies that it is also low compared to the maximum welfare. Moreover, our bounds are actually stronger, showing that not only the revenue in equilibrium is low, but also the welfare.

Related Literature

The analysis of price competition goes back to Cournot [8] and Bertrand [4]. The famous competition model of [8] describes producers who compete through quantities, but in the same work he also described a model of a duopoly selling perfect complements.

[21] consider buyers interested in perfect complements, where each bidder is interested in one specific bundle (single-minded bidders); They study mechanism design for a single seller and buyers with private information, where our focus is on competition between multiple sellers with complete information. Auctions for networks of buyers and sellers with private information were studied in [17].

There is a line of literature studying interactions of sellers and buyers over networks. Among them, [16] considered bargaining in networks, where agents can choose whom they want to negotiate with and the solution implies matching of buyers and sellers. In our model, neighbouring sellers also "negotiate" on dividing the value of the buyer on the edge between them, but unlike [16], a seller can serve several neighbouring buyers simultaneously (with the constraint of non-discriminatory pricing). Sub-game perfect equilibria in bargaining games were studied in [7]. [13] studied general equilibrium models on networks with linear utilities of buyers.

[2] considered a similar model of sellers that compete in prices, and a trade network that is modeled as graph, with one main difference from this paper: items are substitutes for the buyers. Namely, a buyer is interested in buying *either* from one seller or from the other seller on the edge, while here we consider buyers that are interested in *both*. This difference implies significant differences in results. For example, there, unlike our paper, pure Nash equilibria hardly ever exist. For trees, equilibrium utilities of the sellers are uniquely defined, while here they are not.[6]

[6] Our framework can be also viewed as a variant of graphical games [15]. There are several known algorithms for computing equilibria in graphical games (see survey [14]). Another related family of

2 Model

We study trade networks which are modeled as weighted undirected graphs, where sellers are represented by nodes and buyers by weighted edges. The set of edges is denoted by E, let N be the set of nodes and let $i, j \in N$ denote generic sellers. Sellers have no costs and can supply any number of items. The sellers are the players in the game, interested in maximizing revenue. Each buyer is single minded and is interested in the bundle of items sold by both sellers that lie on that edge. The weight $v_{i,j}$ on the edge represents the value of this buyer for buying the bundle $\{i, j\}$. In particular, buyers gain zero value from buying each item alone. A seller i posts a single price $p_i \geq 0$ that will be available to all incident edges (cannot price discriminate between buyers). A buyer of bundle $\{i, j\}$ buys if and only if $v_{i,j} \geq p_i + p_j$.

For a given price vector p we denote the set of sold edges by $S(p)$. The edge (i, j) is *tight* if $p_i + p_j = v_{i,j}$ (the sum of prices of the sellers on the edge equals the value of the edge). We say that *an edge* (i, j) *has slack* if $p_i + p_j < v_{i,j}$. For a given seller i and an edge (i, j), *the slack of seller* i *on that edge* is $v_{i,j} - p_j$ (that is, it equals to the difference between the value of the edge and the price of the *other* seller on that edge).

For a given price vector p, the *revenue* r_i of seller i with price p_i is $p_i \cdot |\{j|(i, j) \in S(p)\}|$, that is, p_i for every adjacent edge that is sold. The *total revenue* is $\sum_i r_i$ and the *welfare* is $\sum_{(i,j)\in S(p)} v_{i,j}$.

The sellers compete in a game in which they simultaneously post prices. These prices form a *(pure) Nash equilibrium (NE)* if each seller maximizes his revenue given the prices of all other sellers. In this paper we only consider pure Nash equilibria.

For a given network, the *revenue of the monopolist* is the supremum of the total revenue over all price vectors for the sellers. The *maximum welfare* is simply the sum of values of all edges (this can be obtained when every seller prices at 0). We study the ratio between the revenue in equilibrium and either the revenue of the monopolist or the maximum welfare (whichever bound is harder to prove): For our positive results we show that the equilibrium revenue is some fraction of the maximum welfare (which clearly implies approximation to the monopolist revenue), while for our negative results we prove inapproximability of the monopolist revenue (which implies the same result with respect to the maximum welfare).

Non Malicious Equilibria. We have already observed that the welfare of the worst equilibrium is arbitrarily low. Thus, we sometimes study an equilibrium refinement in which sellers with 0 utility price at 0. We say that a losing seller (seller with 0 utility) is *non malicious* if she prices at 0. A price vector for the sellers is called *non malicious* if every losing seller is non malicious. This, in particular, implies that every seller's revenue is at least as high as the price he sets. We use the concept of non-malicious NE when proving our main result: we first show that such equilibria always approximate the optimal welfare, and we then show that they always exist in trees. This implies a positive result on the price-of-stability in trees.

games is Polymatrix games (see [5, 9, 6]), where an action of a player is played in several simultaneous bimatrix games (the games in our paper have continuous action spaces); This class of games played an important role in showing hardness of equilibrium computation results. Our goal in this paper is to find equilibria with good economic properties, and compare their properties to the optimal non-strategic solution. Our paper shows that allowing losing sellers to price "maliciously" might be beneficial to society as a whole, this phenomenon was termed the "Windfall of Malice" by [1].

3 Special Families of Graphs: Paths and Cycles

In this section, we present positive results for special cases of graphs and algorithms that compute Nash equilibria with high revenue for those cases. These algorithms consist of a particular sequence of best responses of the sellers. We present a linear time algorithm for path graphs that finds an equilibrium that obtains revenue that is at least half of the maximum welfare. We use it to present a linear time algorithm for cycles that computes an equilibrium with revenue at least a quarter of the maximum welfare.

3.1 Path Graphs

We first consider the simplest non-trivial graphs: path graphs. Our algorithm (Algorithm 1) assumes that sellers are indexed from left to right, with the leftmost seller indexed by 1. The algorithm starts with all sellers pricing at ∞ and then changes the price of the leftmost seller to 0. Then, it goes over the sellers from left to right, letting each seller to choose a best response. If the seller cannot get positive utility, he prices at the value of the previous edge (not at 0 - and thus the equilibrium might be malicious). The way we break ties for sellers with 0 utility ensures that after seller i best responds, all previous sellers are still best responding (as seller i leaves no slack to the previous seller). Our algorithm may achieve terrible revenue when executed in a certain direction on the path (for example, when the weights of the edges are monotonically decreasing), but in such cases we show that running it from for the opposite direction will perform well. This is essentially since every time the value of the edge is larger than the previous edge, it is sold tightly. The algorithm thus picks the better equilibrium out of executing the above procedure starting from one end, or from the other.[7]

Algorithm 1 A $\frac{1}{2}$-Approximation for path graphs.

1. Initialize all prices to infinity, and the price of the first (leftmost) seller to 0.
2. Starting from the second seller, go over the sellers from left to right and let each seller best respond to the current prices. If every price of the current seller i gets him 0 utility, set his price to the value of edge $(i-1, i)$ (the value of the previous edge).
3. Mirror the path left to right (mapping node i to become node $n+1-i$) and repeat the above algorithm. Output one of these two price vectors with the higher total revenue.

This algorithm terminates in a NE with revenue of at least half the maximum welfare (proof appears in the full paper):

▶ **Proposition 1.** *For any path graph, Algorithm 1 terminates in a NE after a linear number of steps. The total revenue in this equilibrium is at least half of the maximum welfare.*

3.2 Cycles

Our next result shows that in any cycle graph there is always a NE with high revenue. Moreover, we show how to compute such a NE in linear time; The algorithm runs the above

[7] We illustrate the algorithm for the path graph of Figure 1: The algorithm chooses a price of 0 for the copper seller, then a price of 1 for the zinc seller, a price of 5 for iron and a price of 1 for glass. This is a NE with revenue 7 (out of maximum welfare of 8). By symmetry, the revenue starting from the other end would be the same.

path-graph algorithm for one full round on all sellers, and then initiates a best-response dynamic that will end up in such an equilibrium.

Fix an arbitrary seller and mark him as seller 1. Going clockwise along the cycle starting from seller 1, number the other sellers 2 to n. We present the algorithm as Algorithm 2.

Algorithm 2 A $\frac{1}{4}$-Approximation for Cycles

1. Initialize all prices to be infinity, initialize the price of seller 1 to 0.
2. Going clockwise: Starting from the second seller till the first seller (inclusive), go over the sellers clockwise and let each seller best response to the current prices. If every price of the considered seller i gets him 0 utility, set his price to the value of edge $(i-1, i)$ (the value of the previous edge in the cycle, with edge $(n, 1)$ being the edge prior to 1).
3. Run a best response dynamics (by iteratively letting a seller that is not best responding to update his price) till it stops.
4. Mirror the cycle and repeat the above algorithm (i.e. the new order after seller 1 is $n, n-1, \ldots, 2, 1$). Output one of these two price vectors with the higher total revenue.

▶ **Theorem 2.** *For any cycle, Algorithm 2 terminates in a Nash equilibrium after linear number of steps. The total revenue in this equilibrium is at least one quarter of the maximum welfare.*

The details of the proof can be found in the full paper. We next present an informal description of the algorithm together with an outline of the proof. First, the algorithm essentially runs Algorithm 1 in one direction, starting with a price of 0 for seller 1 and going clockwise, letting each seller best respond (pricing at the value of the prior edge if his utility is 0) including the first seller as the last seller to change his price. We note that the first seller is now best responding (as the edge to the second seller had no slack, so he could not get any utility out of it). After that cycle completes, we argue that there is at most one seller (the second seller) that is not best responding. From this point on, the algorithm runs a best response dynamics till it stops. We argue that at each point, the only seller that might not be best responding is the next seller, and once he best responds, either the sellers are in a NE or the edge with the previous seller is tight. As we show, it follows that this dynamics will stop after a linear number of steps. We also show that the algorithm running either clockwise or counter-clockwise gets revenue that is at least one quarter of the maximum welfare: the path-graph algorithm gets at least half, and from then edges are only added (and sold tightly), except the edge following the last seller to update his price that might be dropped. We show that the revenue of the dropped edge is no larger than the remaining revenue, thus we lose at most half the revenue obtained by the path algorithm.

4 A Positive Result

We start by presenting our main positive result, showing that the revenue in some NE is at least some fraction of the maximum welfare (and thus also some fraction of the monopolist revenue). We prove this claim by showing that this is true for any non-malicious NE. For any network for which a non-malicious equilibrium exists (like in trees, see Theorem 9), this implies that at least the same fraction can be obtained in the highest revenue equilibrium.[8]

[8] This result actually holds for a more general graph model, where some buyers are interested in a single good, not a pair, and also for graphs that contain parallel edges (that is, there might be multiple buyers

The bound we present is in terms of the maximum degree and the arboricity of the graph. The *maximum degree* is the largest degree of any node: the maximal number of buyers that demand an item from the same seller. The *arboricity* of an undirected graph is the minimum number of forests into which its edges can be partitioned. Equivalently, it is the minimum number of spanning forests needed to cover all the edges of the graph.

To gain some intuition for the notion of arboricity, here are some simple examples. A forest (and a tree) has arboricity 1. A cycle has arboricity 2 as it clearly cannot be spanned by a single forest, but it can be partitioned into two trees, a spanning tree and the missing edge. A clique of size n has arboricity $\lceil n/2 \rceil$: the arboricity is at least $n/2$ as any tree has at most $n-1$ edges and the clique has $n(n-1)/2$ edges, and it is at most $\lceil n/2 \rceil$ as it can be covered by $\lfloor n/2 \rfloor$ Hamiltonian paths, plus a star for odd n.

▶ **Theorem 3.** *In every graph with maximum degree d and arboricity w and every non-malicious NE in it, the total revenue of all sellers is at least $\frac{1}{2(w+1+\ln d)}$ fraction of the maximum welfare.*

Proof. Fix a graph and a non malicious Nash equilibrium in it. We will say that a vertex u is *low for the edge* (v,u) if u's price in the equilibrium is at most half of the value of the edge (v,u). We will say that an edge is *all-high* if both of the vertices on it are not low for the edge (in this case clearly the edge does not buy). Let E^H denote the set of all-high edges. For a vertex v let E^v denote the set of edges (v,u) (edges adjacent to v) such that u is low for (v,u). Observe that since every edge is either all-high or low for some node, the set of all edges E is covered as follows: $E = E^H \cup (\cup_v E^v)$. Thus

$$\sum_{(v,u)\in E} v_{(v,u)} \leq \sum_{(v,u)\in E^H} v_{(v,u)} + \sum_v \sum_{(v,u)\in E^v} v_{(v,u)} \,.$$

Denote the total revenue by r. To complete the proof we bound each of the two terms separately, the first by $2w \cdot r$ and the second by $2(\ln d + 1) \cdot r$, together proving the theorem.

We start by bounding the edges that are not all-high. Let r_v denote the revenue of v. This claim is well known (e.g., [11]) and we present the proof for completeness in the full paper.[9]

▶ **Claim 4.** *For every node v it holds that $\sum_{(v,u)\in E^v} v_{(v,u)} \leq r_v \cdot 2(\ln d + 1)$*

By the claim we derive that

$$\sum_v \sum_{(v,u)\in E^v} v_{(v,u)} \leq \sum_v r_v \cdot 2(\ln d + 1) = 2(\ln d + 1) \cdot r \,.$$

We next bound the total value of the all-high edges. To take care of the total weight of the all-high edges we will use the fact that in a graph of arboricity w there exists a mapping from edges to vertices such that every edge is mapped to one of its two vertices and no vertex has more than w edges mapped to it (this is true as we can just root each tree and map every edge to its child node). Since the edge is all-high and the equilibrium is non malicious, the price – and thus also the revenue – of each of the two vertices on the edge is at least half the value of the edge. Summing, again, over all vertices, we get that the total weight of all

interested in each pair of goods).

[9] The claim essentially says that a single price can gain revenue of at least a logarithmic fraction of the total demand (in our case, it is the residual demand given the prices of the neighbours- which is at least half the value of each edge as these edges are not all-high.).

all-high edges is at most $2w$ the total revenue of all vertices. Stated formally, consider the mapping M from E^H to the set of nodes N that maps each edge to an adjacent node and never maps more than w edges to the same node. For every node v that incident at least one high edge, define $u^*(v)$ to be a vertex such that for all u such that $(v,u) \in E^H$ we have $v_{(v,u^*(v))} \geq v_{(v,u)}$. Then, it holds that

$$\sum_{(v,u)\in E^H} v_{(v,u)} \leq \sum_{v} \sum_{u|M(v,u)=v} v_{(v,u)} \leq \sum_{v|\exists u} \sum_{M(v,u)=v} w \cdot v_{(v,u^*(v))} \tag{1}$$

$$\leq w \cdot \sum_{v} 2 \cdot r_v \leq 2w \cdot r \tag{2}$$

◀

For any network for which a non-malicious equilibrium exists, the theorem ensures that some Nash equilibrium has high revenue. Thus, it can be viewed as a "Price of Stability" result for such networks. In particular, it bounds the price-of-stability for trees, as for any tree a non-malicious equilibrium exists by Theorem 9. It also ensures that every non-malicious equilibrium has high revenue, thus can be viewed as a "Price of Anarchy" result for non-malicious equilibria.

The theorem implies a bound on trees that is only logarithmic in the maximum degree.

▶ **Corollary 5.** *In any tree with maximum degree d and every non-malicious equilibrium in it, the total revenue of all sellers is $\Omega(1/\ln d)$ fraction of the maximum welfare.*

5 Impossibility Results

Theorem 3 gives a positive result, ensuring that the revenue in equilibrium is some fraction of the welfare. Yet, it might be possible that an improved bound can be shown. Specifically, we would like to answer the following question: Is the revenue of best equilibrium always a constant fraction of the revenue of the monopolist? Unfortunately, the answer is no, even for trees. We first present a lower bound for general graphs. This bound is slightly weaker than the logarithmic bound (in the maximum degree) of Theorem 3. We then present a lower bound for trees, showing that the best equilibrium revenue is not necessarily a constant fraction of the monopolist revenue. For missing proofs see the full paper.

5.1 General Graphs

We start with the lower bound for general graphs. For proving the theorem, we construct graphs with arboricity that is much smaller than their maximum degree.

▶ **Theorem 6.** *There exists a family of graphs with maximum degree d and arboricity w for which $w^2 = O(\ln d)$ and the revenue that a monopolist seller can get is factor $\Omega(w)$ larger than the revenue (and welfare) in any Nash equilibrium. It terms of d, the factor can be as large as $\Omega(\sqrt{\ln d})$ when $w^2 = \Theta(\ln d)$.*

The bound is proven using the following construction (see Figure 2). There is a clique of size $w+1$ and any node in the clique is connected to an "harmonic gadget": d edges with values $1, 1/2, 1/3, \ldots, 1/d$. The value of an edge connecting two nodes in the clique is 4. We first claim that for these parameters, a monopolist would price all the clique nodes at 0 and get full revenue from all the harmonic gadgets. In any NE, however, at most one seller prices below $1/w$, thus not much revenue is gained from the harmonic gadgets.

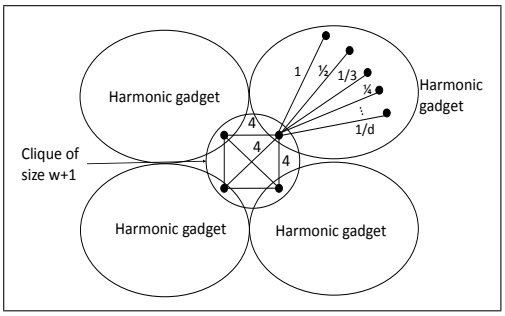

Figure 2 The construction of Theorem 6. A clique of $w+1$ sellers, each edge in it is of value 4. Each node in the clique is connected to an "harmonic gadget".

5.2 Trees

For trees, the above bound (when $w = 1$) is a constant. We next present a different construction that shows that for some trees, the revenue of a monopolist can be factor $\Omega(\ln \ln d)$ larger than the revenue of the best equilibrium. In particular, it show that a constant upper bound is impossible.

▶ **Theorem 7.** *There exists a family of trees with maximum degree d for which the revenue that a monopolist seller gets is factor $\Omega(\ln \ln d)$ larger than the revenue (and welfare) in any NE.*

For proving this impossibility result we construct the following graph, fixing an integer m (to be determined later). Consider a path with $2m+1$ edges. The first edge has value 5. For any $j = 1, 2, \ldots m$, given that edge $2j-1$ has value v, set the value of the edge $2j$ to be $2v+2$ and the value of edge $2j+1$ to be $2v+6$. Any node of even index is additionally connected to an "harmonic gadget" with $d-2$ spikes: $d-2$ edges with values $1, 1/2, 1/3, 1/4, \ldots, 1/(d-2)$.

We first argue that in any Nash equilibrium there is at most a single seller of even index on the path with price that is at most 1. We then argue that a monopolist seller can get revenue of at least $m \ln(d-2)$ by pricing every seller on the path at 0 and gaining all the revenue from the m harmonic gadgets. We conclude that the ratio of the monopolist revenue to equilibrium revenue (and welfare) is at least $\frac{\max\{m \ln(d-2), 2^m\}}{3+\ln d+2^{m+4}}$. For $m = \Theta(\ln \ln d)$ this ratio tends to $\Omega(m)$ as we aimed to prove. Full details appear in the full paper.

For trees, there is still a gap between this $\Omega(\ln \ln d)$ bound and the upper bound of $O(\ln d)$ for non-malicious NE as implied by Corollary 5. Closing this gap is left as an open problem.

5.3 Non malicious Nash equilibrium

We have observed that the worst Nash equilibrium might have zero revenue, even for a single edge. In this section, we consider non-malicious NE and present two simple examples that show that the upper bound of Theorem 3 is tight in both parameters for the non-malicious NE with the worst revenue ("Price of Anarchy").

▶ **Proposition 8.** *The following holds:*

- *For any $w \geq 2$ there exists a graph (symmetric clique) with $2w$ nodes and arboricity w for which the revenue in some non-malicious equilibrium is smaller than the monopolist revenue by a factor of at least w. Moreover, for that graph, every best-response dynamics starting at zero prices converges to such an equilibrium.*

- *For any $d \geq 2$ there exists a tree (star) with maximum degree d for which the revenue in some non-malicious NE is smaller than the monopolist revenue by a factor of at least* $\ln d$.

The two claims directly follow from the following simple examples. Consider first the clique graph of $n = 2w$ nodes with all weights being 1. Note that such a clique has arboricity w. Here is a non-malicious Nash equilibrium: one of the sellers prices at 0 and all others price at 1. The total revenue (and total welfare in this NE) is exactly $(n-1)$. Note that there exists a fully-efficient fully-revenue-extracting non-malicious equilibrium where each seller prices at $1/2$. In this NE the revenue (and welfare) is exactly $n(n-1)/2$. Thus, the ratio between the best non-malicious equilibrium revenue and the worst non-malicious equilibrium revenue is $n/2 = w$. Finally, observe that in any best response dynamics starting at 0, sellers keep increasing prices from 0 to 1, except when there is only one seller pricing at 0, and the others at 1. Thus, any best response dynamics starting at 0 prices will end at a non-malicious NE in which one seller prices at 0 and all others price at 1.

Consider now a star with d spikes, with edge i of value $1/i$. There is a non-malicious NE with revenue of 1: the center prices at 1 and all other price at 0. Revenue (and welfare) of $\sum_{i=1}^{d} 1/i \geq \ln d$ can be achieved by pricing the center at 0 and any other seller at the price of its edge. The second claim follows.

6 Best Reply Dynamics

Our main positive result (Theorem 3) ensures that for any graph for which a non-malicious equilibrium exists, there is an equilibrium with high revenue. Thus, one naturally wonders if all graphs admit a non-malicious equilibrium. If so, can one find such an equilibrium in polynomial time? Is there a natural dynamics that ends in such an equilibrium?

A natural procedure for converging to an equilibrium is repeated best-reply dynamics, and one might hope that such dynamics will indeed always converge to a non-malicious equilibrium in polynomial time. Such a dynamics starts with arbitrary prices, and at each step a seller that is not best replying is chosen, and he updates his price to a best reply. If the goal is finding a non malicious equilibrium, then one needs to consider a seller with 0 utility that is not pricing at 0 as a seller that is not best replying. We conjecture that for any graph, such a process terminates in an equilibrium (which is clearly non malicious). A stronger conjecture is that such an equilibrium will be reached in polynomial time.[10]

In this section, we prove the existence of non-malicious equilibria in *trees* by presenting some best-reply dynamic that converges to equilibrium in a finite number of iterations.[11]

▶ **Theorem 9.** *In every tree, for every initial profile of prices, there exists a sequence of player best replies that terminates in a non-malicious Nash equilibrium.*

The full proof appears in the full paper. We now present a sketch of the proof, and recursively define the sequence of best responses. We pick a leaf u of the tree that is connected to the rest of the tree via vertex v. Let x_0 be the initial price of u and y_0 be the initial price of v. Our best reply dynamics will proceed by repeatedly, for $i = 1 \ldots$, let x_i be u's reply to y_{i-1}, and then recursively use a best reply sequence that updates the rest of the tree, assuming that u's price is set to x_i. Note that this recursive best-reply sequence starts with

[10] We remark that we have simulated best response dynamics on general graphs with arbitrary order, and they always terminated in equilibrium very fast.

[11] Our proof only ensures that the dynamics will stop, but does not ensure terminating in polynomial time.

v updating his price (since all the other vertices are already best-replying from the previous recursive call, but then other vertices may update their price and v may update again, and so on). The v's price at the end of the recursive call is called y_i. The recursive call on the sub-tree terminates due to an inductive use of the theorem (i.e., the theorem is proved by induction on the number of vertices in the tree). To ensure that the induction hypothesis applies to the recursive call which is applied not just to a subtree, but rather to a subtree to which an extra leaf u with a *fixed* value x_i is attached, we prove the theorem (inductively) also for trees in which each vertex may have an arbitrary number of leaves with a fixed value attached to them.

Abstract

Classical online bipartite matching problem and its generalizations are central algorithmic optimization problems. The second related line of research is in the area of algorithmic mechanism design, referring to the broad class of house allocation or assignment problems. We introduce a single framework that unifies and generalizes these two streams of models. Our generalizations allow for arbitrary matroid constraints or knapsack constraints at every object in the allocation problem. We design and analyze approximation algorithms and truthful mechanisms for this framework. Our algorithms have best possible approximation guarantees for most of the special instantiations of this framework, and are strong generalizations of the previous known results.

1 Introduction

Classic online bipartite matching is one of the central algorithmic optimization problems. Since the seminal paper of Karp, Vazirani and Vazirani [21], there have been new developments and generalizations of this model [4, 14, 20]. A related line of research is within algorithmic mechanism design for a broad class of house allocation/assignment problems [1, 7, 18, 19, 27]. House Allocation (HA) problem is a model of assigning indivisible objects to agents, where each agent with a preference order over a subset of objects requires at most one object and payments are not allowed. HA and its generalizations have wide real life applications such as Campus Housing Allocation [12], Student-project Allocation [2], Machine-job Assignment [9]. Our goal is to unify these two streams of models into a single algorithmic framework.

In classic HA, agents' preferences over objects are strict. In many situations, it is more suitable to allow the agent to express indifferences or ties among objects [25]. For example, in Campus Housing Allocation, each student may provide some features (e.g., separate bathroom) of dormitories, and he is indifferent between dormitories with same features. Besides, other optimality criteria for the allocation are also desired, like Pareto optimality. An allocation μ is Pareto optimal if there is no other allocation μ' such that no agent is worse off in μ' and at least one agent is strictly better in μ' compared to μ. Moreover, the agents

are strategic (selfish) players who may not reveal their preference orders truthfully unless they can not get better by misreports. Thus, designing truthful mechanisms is a central issue in mechanism design for HA. A mechanism is truthful (in dominant strategies) if no agent can get better off by misreporting his preference, independent from other agents' reports.

In real world applications, not all the agents can be guaranteed to be matched since the set of their acceptable objects is a subset of all the objects and there may not be enough objects. Thus, designing algorithms to match as many agents as possible is also a much desired objective. This can be quantified by the approximation ratio between the sizes of the optimal matching and the matching obtained by the algorithm, preserving truthfulness and Pareto optimality. In addition, different agents may have different weights or priorities, and in this case, the ratio is between the weights of the optimal weighted matching and the output matching. Krysta et al. [22] initiated the study of designing truthful and Pareto optimal mechanisms for HA with good approximation ratios. They present a tight deterministic 2-approximation, truthful and Pareto optimal mechanism, and a randomized $\frac{e}{e-1}$-approximate, universally truthful and Pareto optimal mechanism. In their setting, each object can be allocated to at most one agent. Can we generalize their results to more general settings?

A simple generalization, called generalized HA, allows each object a to be allocated to at most a given number, $b_a \in \mathbb{N}$, of agents. We observe that all the results in [22] can easily be applied to this generalization. Let us create b_a copies of each object a, and replace a in each agent's preference order by these b_a copies in the same indifference class as a. By this modification, called modified HA, each copy of each object is allowed to be allocated to at most one agent. Each feasible allocation of the generalized HA can be modified to a feasible solution to the modified HA, and vice versa. The mechanism in [22], which is Pareto optimal and truthful for the modified HA, is also Pareto optimal and truthful for the generalized HA.

We study here as our framework, two further natural generalizations of the HA problem: Matroid House Allocation Problem (MHA) and Knapsack House Allocation Problem (KHA). Consider the following more realistic application of HA to the Campus Housing Allocation problem. A university has many dormitories, and each student submits a preference order over dormitories to the university. Besides this, some students may have further requirements about their dormitories which should be fulfilled, e.g., one may require that the room should have an independent bathroom or be far from the kitchen. Thus, for each dormitory a, viewed as an object, and each student i, the rooms in a satisfying the requirements of i are a subset of all the rooms in a. Hence, all the feasible sets of students allocated to a form a transversal matroid (see definition in Section 2) of dormitory a. Our first generalization of HA is based on this application, where each object in HA is associated with a (possibly different) matroid and can be allocated to any number of agents in the ground set (which is the set of agents) of the matroid. The set of agents allocated to each object forms an independent set of its matroid. We call this generalization the Matroid House Allocation Problem (MHA). We can show that MHA includes as special cases all the online bipartite matching models [4, 14, 20, 21] ([20] if fixed vertices are used at most once) mentioned earlier.

The second generalization is as follows: each agent (or job) i is associated with a capacity c_{ia} for each object (machine) a, and each object a is associated with a capacity C_a. As before, each object can be allocated to multiple agents, but the total capacity of the agents allocated to a does not exceed its capacity (i.e., $\sum_i c_{ia} \leq C_a$). We call this generalization the Knapsack House Allocation Problem (KHA). An interesting application of KHA is Job Scheduling Markets [9]. Our main results are the following:

1. We present a tight, deterministic, truthful and Pareto optimal mechanism (TMHA) for MHA with the approximation ratio of 2, where agents have weights and ties.

2. Based on TMHA, a randomized, universally truthful and Pareto optimal mechanism (RTMHA) is presented. We prove that RTMHA is an $\frac{e}{e-1}$-approximation mechanism for MHA where agents have weights and ties. Note, truthful $O(1)$-approximation is impossible if each agent has different weights over objects [17, 3]. 1. and 2. are strong generalizations of the results in [22], and are obtained with completely new techniques.
3. A universally truthful, Pareto optimal mechanism for KHA with a $(4, 2)$-approximation (4-approximation ratio, violating each knapsack constraint by a factor 2) for parallel machines (objects) ($c_{ia} = c_i$, for any object a) when weights and ties are allowed ($(4, 1)$-approximation without ties). For general KHA with weights and ties, we observe that [11] implies a universally truthful $O(1)$-approximate mechanism (but not Pareto optimal).
4. Our mechanism RTMHA applied to the online weighted matroid bipartite matching problem and the online matroid job recruitment problem, implies tight $\frac{e}{e-1}$-approximations.

Technical Contributions. We present a generic approach to design deterministic truthful and Pareto optimal mechanisms for MHA and KHA when agents' preferences include ties, by reducing mechanism design to algorithm design of the underlying graph (i.e., calling the algorithm of finding maximum cardinality matching on an auxiliary graph as a black box). The mechanism RTMHA for MHA shares in spirit the same idea as Random SDMT mechanism in [22]. The main difficulty lies in the analysis of its $\frac{e}{e-1}$-approximation. Our new setting is much more general than [22], thus a completely different analysis is needed. We split the analysis of RTMHA into three parts, and its starting point is based on the charging map method (extended to matroid constraints), widely used for matching problems [4, 10].

First, for unweighted agents without ties, we show that the symmetric difference between a matching μ^τ output by TMHA under an order τ of all agents and the matching $\mu^{\tau_{-i}}$ output by TMHA under order τ_{-i} with agent i absent, is an alternating path starting from i. This characterization implies that, for each object $a \in A$, the agents $S_a(\tau)$ matched to a under μ^τ and agents $S_a(\tau_{-i})$ matched to a under $\mu^{\tau_{-i}}$ satisfy a nice exchange property: if some agent can be added to $S_a(\tau)$ then he can also be added to $S_a(\tau_{-i})$ obeying the matroid constraint.

When preferences have ties, we say that two matchings are equivalent if the matched agents are the same and the matched objects of the same agent are in the same indifference class of that agent. The second part of our analysis, for unweighted agents with ties, shows a similar characterization between the equivalence class $\mathrm{CL}(\mu^\tau)$ (all matchings equivalent to matching μ^τ) and the class $\mathrm{CL}(\mu^{\tau_{-i}})$. That is, there exists an injective map from $\mathrm{CL}(\mu^\tau)$ to $\mathrm{CL}(\mu^{\tau_{-i}})$ such that the symmetric difference of each matching in $\mathrm{CL}(\mu^\tau)$ with its image in $\mathrm{CL}(\mu^{\tau_{-i}})$ is an alternating path. This lets us reduce the problem for agents with ties to that with agents without ties. We believe this technique will find further applications to analyze mechanisms for agents with ties in ordinal settings, which may simplify the proofs. For example, with this technique, we greatly simplify the proof for weighted agents with ties and objects with uniform matroid constraints in [22], where they use a different technique based on trading graphs. Based on this characterization we prove the important Injectivity Lemma; it can be used to show the $\frac{e}{e-1}$-approximation for unweighted agents with ties directly.

Thirdly, for the most general setting of weighted agents with ties, we carefully utilize the previous injectivity lemma, proving a strengthened version of such a lemma (see Lemma 13). Based on this lemma, we show that there exists an injective map from marginal 'bad' events to 'good' events, which suffices for the analysis of the final approximation ratio.

Related Work. Random Serial Dictator (RSD) [1] and Probabilistic Serial (PS) [7] are two paradigmatic randomized mechanisms for HA. Krysta et al. [22] generalize RSD mechanism

to HA with ties and obtain a tight 2-approximate deterministic truthful and Pareto optimal mechanism for weighted agents and an $\frac{e}{e-1}$-approximate universally truthful, Pareto optimal mechanism. They show that no universally truthful, Pareto optimal mechanism can have approximation better than $\frac{18}{13}$, and if the mechanism is additionally non-bossy, the lower bound on the approximation ratio is $\frac{e}{e-1}$. Our random mechanism is non-bossy for agents with strict preferences and thus has best possible approximation ratio in this sense. Bogomolnaia and Moulin [8] show the same ratio $\frac{e}{e-1}$ also for PS. Recently, [17, 3] establish an $O(\sqrt{n})$ bound of RSD (w.r.t. the optimal social welfare) when agents have cardinal values (with arbitrary weights on the objects) over all the objects and show that no truthful in expectation mechanism can have approximation better than $\Omega(\sqrt{n})$. We obtain constant approximation ratios when the agents are weighted. This lower bound $\Omega(\sqrt{n})$ implies that we cannot obtain similar results when agents have different weights over objects. Tight deterministic truthful mechanisms for weighted matching markets were proposed by Dughmi and Ghosh [15].

(M)HA is related to online bipartite matching problem (OBM) as follows. If each agent in HA ranks his desired objects in the order that precisely follows the arrival order of objects in the OBM, the two problems are equivalent, as emphasized in [6, 22]. Karp et al. [21] initialize the study of OBM and provide a RANKING algorithm with a tight approximation ratio $\frac{e}{e-1}$. Aggarwal et al. [4] are the first to study the weighted version of OBM (WOBM) when the fixed vertices have weights (or priorities). They use the charging map approach and prove that the ratio $\frac{e}{e-1}$ also holds. Recently, the analysis of WOBM has been unified into the primal-dual framework by Devanur et al. [14]. There are further generalizations of the online bipartite matching model, e.g., [10, 23, 24]. Matroid HA has an online interpretation, which is loosely related to the Matroid Secretary Problem introduced by Babaioff et al. [5].

Organization. Section 2 contains preliminaries, and Section 3 presents our deterministic mechanism for MHA. We develop a randomized mechanism for MHA in Section 4. Its analysis is divided into three subsections: 4.1 for unweighted agents without ties, 4.2 for unweighted agents with ties, 4.3 for weighted agents with ties. Applications of our mechanisms for MHA and our results for KHA will be published in the the full version of the paper.

2 Preliminaries

Let $N = \{1, 2, \cdots, n_1\}$ be a set of n_1 *agents* and A a set of n_2 *objects*; $n = n_1 + n_2$. Let $[i] = \{1, 2, \cdots, i\}$. Each agent $i \in N$ finds a subset of objects acceptable and has a preference ordering, not necessarily strict, over these objects.

We write $a_t \succ_i a_s$ if agent i *strictly prefers* object a_t to object a_s, and $a_t \simeq_i a_s$ if i is *indifferent between* a_t and a_s. We use $a_t \succeq_i a_s$ to denote that i *weakly prefers* a_t to a_s, i.e., either $a_t \succ_i a_s$ or $a_t \simeq_i a_s$. In some cases a weight w_i is associated with each agent i, representing i's priority or importance; let $W = (w_1, w_2, \ldots, w_{n_1})$. If we are in an unweighted setting then $w_i = 1$ for each i.

Each agent's acceptable objects are divided into *indifference classes*: he is indifferent between the objects in the same class and has a strict preference ordering over these classes. For each agent i, let C_k^i, $1 \le k \le n_2$, be the kth indifference class (*tie*), of i; assume that $C_q^i = \emptyset$, $\forall q, l \le q \le n_2$, if $C_l^i = \emptyset$ for some $l \in [n_2]$. Let $L(i) = (C_1^i \succ_i C_2^i \succ_i \cdots \succ_i C_{n_2}^i)$ be the preference list of i. We write $a \in L(i)$ if a appears in $L(i)$ (i finds a acceptable). Let $L = (L(1), L(2), \cdots, L(n_1))$ and $L(-i) = (L(1), \ldots, L(i-1), L(i+1), \ldots, L(n_1))$.

A matroid is a pair $\mathcal{M} = (X, \mathcal{I})$, where X is a ground set and $\mathcal{I} \subseteq 2^X$ (each $Y \in \mathcal{I}$ is called independent set) satisfying properties: (1) [**non-emptiness**] $\emptyset \in \mathcal{I}$; (2) [**heredity**]

If $Y \in \mathcal{I}$ and $Z \subseteq Y$, then $Z \in \mathcal{I}$; (3) [**exchange**] If $Z, Y \in \mathcal{I}$ and $|Z| > |Y|$, then there is $z \in Z \backslash Y$ such that $Y \cup \{z\} \in \mathcal{I}$. A base of $\mathcal{M}$ is an independent set with maximum size. By (3), any maximal independent set is a base. For any $S \subseteq X$, let $r_{\mathcal{M}}(S)$ be the maximum size of an independent set contained in S; $r_{\mathcal{M}}(X)$ is called the rank of $\mathcal{M}$. A matroid $\mathcal{M} = (X, \mathcal{I})$ is called an ℓ-uniform matroid if $Y \subseteq X$ is independent if and only if $|Y| \leq \ell$. A direct sum of uniform matroids (not necessarily with the same rank) is called a partition matroid. Given a set X and a family $\mathcal{F} = \{X_i\}_{i=1}^{s}$ of subsets of X, a set $T \subseteq X$ is called a transversal set of X if there is an injective map f: $T \to \mathcal{F}$ s.t. $x \in f(x)$, for any $x \in T$. The matroid $(X, \mathcal{I})$, with $\mathcal{I} = \{T \,|\, T \text{ is a transversal set of } X\}$, is called a transversal matroid.

In Matroid HA (MHA), we have a matroid $\mathcal{M}_a = (N, \mathcal{I}_a)$ on agent set N, for each object $a \in [n_2]$. A (feasible) *matching* (or *b-matching*) μ is an allocation (subset of $N \times A$) assigning at most one object to each agent i[1] such that, for each object a, the set of agents who are assigned a is an independent set of $\mathcal{M}_a$ (multiple agents may be allocated the same object). If $(i, a) \in \mu$, agent i and object a are *matched together*. If $(i, a) \in \mu$ for some a, we say that i is *matched*, and *unmatched* otherwise. The definitions of *matched* (*unmatched*) for an object are analogous. If $i \in N$ is matched, $\mu(i)$ denotes the object matched to i. If object a is matched, $\mu^{-1}(a)$ denotes the set of agents matched to a. Two matchings μ, μ' are *equivalent* (denoted $\mu \simeq \mu'$) if in these two matchings, the matched agents are the same and the matched objects for each agent are in the same indifference class of this agent, i.e., $\mu(i) \simeq_i \mu'(i)$, allowing $\emptyset \simeq_i \emptyset$, for any $i \in N$. Let $\mathrm{CL}(\mu)$ be the class of all matchings equivalent to μ. For two sets B and C, we sometimes use $B + C$ ($B - C$, resp.) to denote $B \cup C$ ($B \backslash C$, resp.), and sometimes write a set $\{x\}$ simply as x. Let Π denote the set of all permutations of agents.

In what follows, we will consider the undirected graph $G = (V, E)$ where $V = (N \cup A)$ and $E = \{(i, a), i \in N, a \in L(i)\}$. We also use μ to denote a matching (a feasible matching for MHA) in G. The *size* of a matching μ is equal to the number of agents matched under μ. In the presence of weights, the *weight* of a matching is equal to the sum of the weights of the matched agents. For any subset $E' \subseteq E$, define $E'_v = \{u \,|\, (u, v) \in E'\}$, for any $v \in V$. An instance of MHA is denoted by $I = (N, A, L, (\mathcal{M}_a)_a, W)$. We drop W and $(\mathcal{M}_a)_a$ and write $I = (N, A, L, \mathcal{M})$ if agents are unweighted. Let $\mathcal{I}^{MHA}$ denote the set of all possible instances of MHA. For two given matchings μ_1, μ_2, we will use $\mu_1 \oplus \mu_2$ to denote the symmetric difference with respect to their sets of edges. An *alternating path* in G, w.r.t. a matching μ_1, is a path that consists of edges that alternately belong to μ_1 and do not belong to μ_1.

A matching μ is *Pareto optimal* if there is no other matching under which some agent is strictly better off while none is worse off, w.r.t. their preferences. Formally, μ is *Pareto optimal* if there is no other matching μ' such that (i) $\mu'(i) \succeq_i \mu(i)$ for all $i \in N$, and (ii) $\mu'(i') \succ_{i'} \mu(i')$ for some $i' \in N$. Given an order $\sigma \in \Pi$, a matching μ is strictly lexicographically σ-better than a matching μ' if there exists a $k \in [n_1]$ such that $\mu(\sigma(i)) \simeq_{\sigma(i)} \mu'(\sigma(i))$, $i \in [k-1]$ and $\mu(\sigma(k)) \succ_{\sigma(k)} \mu'(\sigma(k))$. A matching μ is called a lexicographically σ-maximal matching if there does not exist a matching μ' such that μ' is strictly lexicographically σ-better than matching μ. Note, if μ is lexicographically σ-maximal, then μ must be Pareto optimal.

Let $\mathcal{M}^{MHA}$ denote the set of all possible matchings. A *deterministic mechanism* ϕ maps an instance of MHA to a matching, i.e., $\phi : \mathcal{I}^{MHA} \to \mathcal{M}^{MHA}$. Let $R : \mathcal{M}^{MHA} \to [0, 1]$ be a probability distribution over possible matchings (a *random matching*), i.e., $\sum_{\mu \in \mathcal{M}^{MHA}} R(\mu) = 1$. A *randomized mechanism* ϕ is a mapping from $\mathcal{I}^{MHA}$ to a distribution over possible matchings, i.e., $\phi : \mathcal{I}^{MHA} \to Rand(\mathcal{M}^{MHA})$, where $Rand(\mathcal{M}^{MHA})$ is the set of all random

[1] Note that if agents are allowed to receive more than one object, the model becomes a many-to-many matching and the preference spaces of agents are much more complicated, which is not studied here.

matchings. A deterministic (randomized, resp.) mechanism is Pareto optimal if it returns a Pareto optimal matching (a distribution over Pareto optimal matchings, resp.).

Agents' preferences are private knowledge and they may prefer not to reveal their preferences truthfully if it is not in their best interests, for a given mechanism. A *deterministic* mechanism is *truthful* (*in dominant strategies*) if agents always find it in their best interests to declare their preferences truthfully, no matter what other agents declare, i.e., for every i and every possible declared list $L'(i)$ for i, $\phi(L(i), L(-i)) \succeq_i \phi(L'(i), L(-i))$, $\forall L(i), L(-i)$. A randomized mechanism ϕ is *universally truthful* if it is a probability distribution over deterministic truthful mechanisms. Let $w(\phi(I))$ be the (expected) weight of the (random) matching output by ϕ on instance $I \in \mathcal{I}^{MHA}$, and $w(I)$ be the weight of a maximum weight Pareto optimal matching in I. The *approximation ratio* of ϕ is defined as $\max_{I \in \mathcal{I}^{MHA}} \frac{w(I)}{w(\phi(I))}$.

For any agent i, define a matroid on agent i as $\mathcal{M}_i = (A, \mathcal{I}_i)$, with $\mathcal{I}_i = \{S \,|\, S \subseteq A \text{ and } |S| \leq 1\}$. We define two useful matroids on edge set E. Let $\mathcal{M} = (E, \mathcal{I})$, where, for any $E' \subseteq E$, $E' \in \mathcal{I}$ if and only if $E'_a \in \mathcal{I}_a$, for any $a \in A$. Let $\mathcal{M}' = (E, \mathcal{I}')$, where, for any $E' \subseteq E$, $E' \in \mathcal{I}'$ if and only if $E'_i \in \mathcal{I}_i$, for any $i \in N$. Note, $\mathcal{M}'$ is a partition matroid. Also, an allocation $E' \subseteq E$ is feasible for MHA if and only if $E' \in \mathcal{I} \cap \mathcal{I}'$, meaning that E' is an independent set in both $\mathcal{M}'$ and $\mathcal{M}$. Hence, our objective is to design (universally) truthful, Pareto optimal mechanisms to find an edge set that is independent in both $\mathcal{M}'$ and $\mathcal{M}$, such that its size (or weight for weighted agents) is maximized. Edmonds [16] provides an algorithm to compute a maximum independent set that is independent for two matroids.

▶ **Proposition 1** ([16, 13]). *Given two matroids $\mathcal{M}^1 = (X, \mathcal{I}^1)$ and $\mathcal{M}^2 = (X, \mathcal{I}^2)$, there is a matroid intersection algorithm $\mathcal{A}^{MI}$ for computing a maximum cardinality common independent set $S \in \mathcal{I}^1 \cap \mathcal{I}^2$, terminating in polynomial time $\Gamma(|X|) \leq O(|S|^{\frac{3}{2}}|X|Q^{test})$, where Q^{test} is the time needed to test if a given set is independent.*

We assume for simplicity that the test time $Q^{test} = O(1)$, and we omit it in the rest of the paper. We also need a fact from exchange theory between two bases of a matroid.

▶ **Proposition 2** (Corollary 39.12a [26]). *For a matroid $\mathcal{M} = (X, \mathcal{I})$ and $B_1, B_2 \in \mathcal{I}$ with $|B_1| = |B_2|$, there exists a bijection f: $B_1 - B_2 \to B_2 - B_1$ s.t. $\forall x \in B_1 - B_2$, $B_1 - x + f(x) \in \mathcal{I}$.*

3 Deterministic Mechanism for MHA

We introduce TMHA, a truthful and Pareto optimal mechanism, that generalizes SDMT-1 [22] to the case where sets allocated to the objects are independent sets of matroids. Let $I = (N, A, L, \mathcal{M})$ be an instance of MHA, and $\sigma \in \Pi$ (w.l.o.g., $\sigma(i) = i$ for $i \in N$). TMHA, given in Algorithm 1, proceeds in n_1 phases, each phase corresponds to one iteration of the for loop. Notice, at any stage of TMHA, $(i, a) \in E$ if and only if either agent i is matched in μ and $a \simeq_i \mu(i)$ or TMHA is at phase i, examining the indifference class that contains a.

▶ **Observation 3.** *At the end of phase i of TMHA, if agent i is assigned no object then he will be assigned no object when TMHA terminates. If i is provisionally assigned an object a, then he will be allocated an object in the same indifference class as a in the final matching.*

By Observation 3, different tie breaking rules lead to equivalent produced matchings.

▶ **Theorem 4.** *Given an order $\sigma \in \Pi$ of agents, the matching generated by TMHA is a lexicographically σ-maximal matching, thus, also Pareto optimal.*

TMHA is truthful, no matter which matching is selected in each phase of the mechanism:

Algorithm 1: Truthful Mechanism for MHA (TMHA)

Input: Agents N; Objects A; Preference list profile L; Matroids $(\mathcal{M}_a)_a$; Order σ
Output: Matching μ

Let $G = (N \cup A, E)$, $E \leftarrow \emptyset$, $\mu \leftarrow \emptyset$.
for *each agent* $i \in N$ *in the order of* σ **do**
  Let $\ell \leftarrow 1$
  Step (*): **if** $C_\ell^i \neq \emptyset$ **then**
    $E \leftarrow E \cup \{(i,a) : a \in C_\ell^i\}$; // all new edges are non-matching edges
    Run $\mathcal{A}^{MI}$ on G and obtain a maximum cardinality matching μ'
    if $|\mu'| = |\mu| + 1$ **then**
      modify μ to μ'; // i must be provisionally allocated some $a \in C_\ell^i$ and (i,a) is now a matching edge
    else
      $E \leftarrow E \setminus \{(i,a) : a \in C_\ell^i\}$; $\ell \leftarrow \ell + 1$; Go to Step (*)
Return μ; //each matched agent is allocated his matched object

▶ **Theorem 5.** *The mechanism TMHA is truthful.*

We now show a bound on the time complexity of TMHA. Let γ denote the size of the largest indifference class for a given instance I.

▶ **Theorem 6.** *TMHA terminates in time* $O(n_1^3\gamma)$.

Any Pareto optimal matching is at least half the size of a maximum size such matching [9]. Thus, TMHA achieves approximation ratio 2 with respect to the maximum cardinality matching. We show that, when agents are assigned arbitrary weights, TMHA is 2-approximate (w.r.t. maximum weight Pareto optimal matching) if the order σ is by non-increasing agents' weights, breaking ties arbitrarily. The bound is tight since no deterministic truthful mechanism can achieve an approximation ratio better than 2 even if $r_{\mathcal{M}_a} = 1$, for any $a \in A$, see [22].

▶ **Theorem 7.** *TMHA achieves a 2-approximation w.r.t. the size of a maximum weight Pareto optimal matching, if agents are ordered in* σ *by non-increasing order of their weights.*

4 Randomized Mechanism for MHA

We now present a universally truthful, Pareto optimal mechanism for Matroid House Allocation Problem (see Algorithm 2, where $g(y) = e^{y-1}$). When the matroid for each object is a uniform matroid with rank one, Algorithm 2 reduces to SDMT-1 from [22]. The analysis of RTMHA will be gradually developed in the following three subsections for various settings. We will start with the simplest setting of unweighted agents without ties (Subsection 4.1), then proceed to the setting of unweighted agents with ties (Subsection 4.2), and, finally, weighted agents with ties (Subsection 4.3). The next subsection builds on the previous one.

If the weights are agents' private data with no over-bidding assumption, Algorithm 2 is universally truthful (w.r.t. preferences and weights) and Pareto optimal as well [22].

4.1 Unweighted Agents without Ties

We will show now that RTMHA achieves $\frac{e}{e-1}$-approximation for unweighted agents without ties. Note that the order of RTMHA for unweighted agents is just the uniform random order

Algorithm 2: Random Truthful Mechanism for MHA (RTMHA)

Input: Agents N; Objects A; Preference list profile L; Matroids $(\mathcal{M}_a)_a$; Weights W
Output: Matching

```
for each agent i ∈ N do
    Pick Y_i ∈ [0,1] uniformly at random;
Sort agents in decreasing order of w_i(1 − g(Y_i)) (break ties in favor of smaller index);
Run TMHA according to above order;
Return the matching;
```

of agents. Our technique is based on a charging map method (extended by us to matroids), which is widely used in analyzing the approximation ratio for matching problems [4, 10].

We assume here that agents' preferences are strict: $|C_j^i| \leq 1$, for $i \in [n_1]$, $j \in [n_2]$. Recall, each object a is associated with a matroid $\mathcal{M}_a = (N, \mathcal{I}_a)$. We present a characterization of $\mu^\tau \oplus \mu^{\tau_{-i}}$, where μ^τ and $\mu^{\tau_{-i}}$ are the matchings obtained by TMHA under the order τ of agents and τ_{-i} (τ with i absent), respectively. We first prove a useful lemma.

Lemma 8 shows exchange properties between two independent sets of a matroid and their switching sets. Let $T_0 = \{i'_1, i'_2, \cdots, i'_k\}$ and $T_k = \{i_1, i_2, \cdots, i_k\}$ be two sets of size k with different elements (orders of elements in T_0 and T_k are fixed). We define the *switching sets* T_ℓ, $\ell \in [k-1]$ between T_0 and T_k, as $T_\ell = \{i_1, i_2, \cdots, i_\ell, i'_{\ell+1}, \cdots, i'_k\}$, $\ell \in [k-1]$. (Lemma 8 is used in the proof of Lemma 10 with elements being agents.)

▶ **Lemma 8.** *Let $\mathcal{M} = (X, \mathcal{I})$ be a matroid and $S \in \mathcal{I}$. Let $T_0 = \{i'_1, i'_2, , \cdots, i'_k\} \subseteq X$ and $T_k = \{i_1, i_2, \cdots, i_k\} \subseteq X$ and their switching sets $T_\ell = \{i_1, i_2, \cdots, i_\ell, i'_{\ell+1}, \cdots, i'_k\} \in \mathcal{I}$, $\ell \in [k-1]$. Suppose $S + T_\ell \in \mathcal{I}$, for any $\ell = 0, 1, \cdots, k$. We also have $S + \{i_1, \cdots, i_\ell, i'_\ell\} \notin \mathcal{I}$, for any $\ell \in [k]$. Then, for any element j (which is not in $S + T_0 + T_k$),*

(i) *if $S + T_k + j \in \mathcal{I}$ then $S + T_0 + j \in \mathcal{I}$;*

(ii) *if $S + T_0 + j \notin \mathcal{I}$ then $S + T_k + j \notin \mathcal{I}$ (contrapositive proposition of* (i)*).*

Proof. For (i), by the exchange property of matroids, there exists a $y \in T_k + j$ such that $S + T_0 + y \in \mathcal{I}$. If $y \neq j$, suppose $y = i_\ell$ for some $\ell \in [k]$. Then we have $T = S + \{i_1, \cdots, i_\ell\} \in \mathcal{I}$ (from $S + T_k \in \mathcal{I}$) and $T' = S + \{i'_1, \cdots, i'_\ell, i_\ell\} \in \mathcal{I}$ (from $S + T_0 + y \in \mathcal{I}$). Then by the exchange property of matroids, there exists $y' \in T' - T$ such that $T + y' \in \mathcal{I}$. Let $y' = i'_{\ell'}$ for some $\ell' \leq \ell$. Consequently, $S + \{i_1, i_2, \cdots, i_{\ell'}, i'_{\ell'}\} \in \mathcal{I}$, which leads to a contradiction. ◀

▶ Remark. Although in Lemma 8 we require two initial sets with the same cardinality, we can relax the requirement to allow them to have different cardinalities. Namely, let $T_0 = \{i'_1, i'_2, \cdots, i'_{k'}\}$ and $T_k = \{i_1, i_2, \cdots, i_k\}$ with $k' \leq k$ (the orders of elements in two sets are fixed). The switching sets T_ℓ, $\ell \in [k']$ between T_0 and T_k are defined as: $T_\ell = \{i_1, i_2, \cdots, i_\ell, i'_{\ell+1}, \cdots, i'_{k'}\}$, $\ell \in [k'-1]$, and $T_{k'} = T_k$. Lemma 8 still holds.

Given $\tau \in \Pi$, let μ^τ be the matching obtained by TMHA under τ, and let $S_a(\tau)$ be the set of agents matched to $a \in A$ by TMHA. Let, for any $t \in [n_1]$, $S_a^t(\tau) \subseteq S_a(\tau)$ be the top t agents in $S_a(\tau)$, i.e., $S_a^t(\tau) = \{i \in S_a(\tau) \,|\, \tau^{-1}(i) \leq t\}$. Then $S_a(\tau) = S_a^{n_1}(\tau)$. Let τ_{-i} be order τ after removing agent i from τ. Similarly, define $S_a^t(\tau_{-i})$ and $S_a(\tau_{-i}) = S_a^{n_1-1}(\tau_{-i})$. When we say "*under* τ", we mean the process of running TMHA under order τ. For any $a \in A$, let $F_a^t = S_a^t(\tau_{-i}) \cap S_a^t(\tau)$. $T_0^t = S_a^t(\tau_{-i}) - S_a^t(\tau) = \{i'_1, i'_2, \cdots, i'_\ell, i'_{\ell+1}, \cdots, i'_{k'}\}$, $k' = |T_0^t|$. Let $T_k^t = S_a^t(\tau) - S_a^t(\tau_{-i}) = \{i_1, i_2, \cdots, i_\ell, i_{\ell+1}, \cdots, i_k\}$, $k = |T_k^t|$. We will show in the next lemma that $k \in \{k', k'+1\}$, for any $t \in [n_1]$ and $a \in [n_2]$. Note that this includes the case $k' = 0$ (in a sense that Property $\mathcal{P}$ (i)-(iv) below trivially holds). The orders in T_0^t and T_k^t

both follow order τ. We have the switching sets $T^t_\ell = \{i_1, i_2, \cdots, i_\ell, i'_{\ell+1}, \cdots, i'_{k'}\}$ between T^t_0 and T^t_k, $\ell \in [k'-1]$, and $T^t_{k'} = T^t_k$. We finally define Property $\mathcal{P}$ as follows.

▶ **Definition 9.** Let $E' = \{(i', \mu^\tau(i')), (i', \mu^{\tau_{-i}}(i')) : i' \in N, i'$ matched by μ^τ and $\mu^{\tau_{-i}}\}$. We say that Property $\mathcal{P}$ holds for μ^τ and $\mu^{\tau_{-i}}$ if: $C = ((\mu^\tau \oplus \mu^{\tau_{-i}}) \cap E') \cup \{(i, \mu^\tau(i))\}$ is an alternating path starting from agent i if it is non-empty, and for any $a \in A$, and $t \in [n_1]$:

- **(i)** $F^{n_1}_a + T^t_\ell \in \mathcal{I}_a$, for any $\ell \in [k']$;
- **(ii)** $F^t_a + \{i_1, \cdots, i_\ell, i'_\ell\} \notin \mathcal{I}_a$, $\ell \in [k']$;
- **(iii)** For any agent s, if $S^t_a(\tau) + s \in \mathcal{I}_a$, then $S^t_a(\tau_{-i}) + s \in \mathcal{I}_a$ (or equivalently, $S^t_a(\tau_{-i}) + s \notin \mathcal{I}_a$ implies that $S^t_a(\tau) + s \notin \mathcal{I}_a$).
- **(iv)** $\tau^{-1}(i_1) < \tau^{-1}(i'_1) < \tau^{-1}(i_2) < \tau^{-1}(i'_2) < \cdots < \tau^{-1}(i_{k'}) < \tau^{-1}(i'_{k'})$

We are ready to give our characterization lemma in the following.

▶ **Lemma 10.** *Property $\mathcal{P}$ holds for unweighted agents with strict preference orders.*

Lemma 10 can be used to directly prove that RTMHA is $\frac{e}{e-1} + o(1)$-approximate for unweighted agents without ties. Analysis in Subsection 4.2 builds on developments in this section.

4.2 Unweighted Agents with Ties

When agents have ties without weights, we will present a similar characterization in Lemma 11 (by alternating path) of symmetric differences between the matching obtained by TMHA under some order τ of all agents and the matching obtained by TMHA under τ_{-i} when an agent i is absent. We will prove that in any step of the two processes of TMHA under τ and under τ_{-i}, there is an injective map from the equivalence class of matchings generated by TMHA under τ to the class generated by TMHA under τ_{-i}. This injective map is such that each pair of the corresponding matchings from these two classes satisfies Property $\mathcal{P}$.

For any $t \in [n_1]$, let $\mathrm{CL}^t(\mu^\tau)$ denote the equivalence class of matchings equivalent to the matching found by TMHA under τ until tth iteration. Precisely, if $\mu^\tau_{\leq t} = \{(i, \mu^\tau(i)) : \tau^{-1}(i) \leq t\}$ is the matching μ^τ restricted to the first t agents of τ, then: $\mathrm{CL}^t(\mu^\tau) = \{\mu \in G \,|\, \mu \simeq \mu^\tau_{\leq t}\}$. Let $\mathrm{CL}(\mu^\tau) = \mathrm{CL}^{n_1}(\mu^\tau)$. When we consider the process of running TMHA under τ_{-i}, to simplify the notation, we consider an equivalent process that runs TMHA under τ while imposing the condition that agent i is unmatched. Hence, in the following we suppose TMHA running on τ_{-i} is such an equivalent process. Thus, we have $\mathrm{CL}^t(\mu^{\tau_{-i}})$, for any $t \in [n_1]$.

▶ **Lemma 11.** *For any t, there exists an injective map f from $\mathrm{CL}^t(\mu^\tau)$ to $\mathrm{CL}^t(\mu^{\tau_{-i}})$ such that for any $\mu \in \mathrm{CL}^t(\mu^\tau)$, μ and $f(\mu)$ satisfy Property $\mathcal{P}$.*

Proof. The proof is by induction on the iterations of the two processes of TMHA run under τ and under τ_{-i}. First, note that $\mathrm{CL}^s(\mu^\tau) = \mathrm{CL}^s(\mu^{\tau_{-i}})$, for any $s < \tau^{-1}(i)$. Thus each matching from $\mathrm{CL}^s(\mu^\tau)$ can be mapped to itself. This shows that if i is unmatched under τ, the lemma trivially holds. Hence, w.l.o.g., suppose agent i is matched under τ.

Second, for any matching $\mu^{s+1} \in \mathrm{CL}^{s+1}(\mu^\tau)$, there exists a unique matching $\mu^s \in \mathrm{CL}^s(\mu^\tau)$ such that $\mu^{s+1} = \mu^s \cup \{(\tau(s+1), \mu^{s+1}(\tau(s+1)))\}$, for any $s \leq n_1 - 1$.

We now prove the induction base case for $s = \tau^{-1}(i)$. For any matching $\mu^s \in \mathrm{CL}^s(\mu^\tau)$, we define f as $f(\mu^s) = \mu^s_{<s} \in \mathrm{CL}^s(\mu^{\tau_{-i}})$. Now we can see that the symmetric difference of μ^s and $f(\mu^s)$ is a single edge and all parts of Property $\mathcal{P}$ hold. Hence, the base case is true.

Now suppose the lemma holds for $s = k-1$, where $k - 1 \geq \tau^{-1}(i)$, i.e., we have an injective function f: $\mathrm{CL}^{k-1}(\mu^\tau) \to \mathrm{CL}^{k-1}(\mu^{\tau_{-i}})$ such that for any $\mu \in \mathrm{CL}^{k-1}(\mu^\tau)$, μ and

$f(\mu)$ satisfy Property $\mathcal{P}$. Let's see the case $s = k \leq t$. Let $j = \tau(k)$ be the kth agent of τ. Consider this new agent j, and any $\mu \in \mathrm{CL}^k(\mu^{\tau_{-i}})$. Since for any a which is strictly better than $\mu(j)$, i.e., $a \succ_j \mu(j)$, agent j will not be matched to a under μ, which means $j + S_a^{k-1}(\mu) \notin \mathcal{I}_a$, by part (iii) of Property $\mathcal{P}$, $j + S_a^{k-1}(f^{-1}(\mu_{<k})) \notin \mathcal{I}_a$ if $f^{-1}(\mu_{<k})$ exists. Therefore, for any $\mu^{k,\tau} \in \mathrm{CL}^k(\mu^\tau)$ and $\mu^{k,\tau_{-i}} \in \mathrm{CL}^k(\mu^{\tau_{-i}})$, we will have $\mu^{k,\tau}(j) \preceq_j \mu^{k,\tau_{-i}}(j)$. Let $b = \mu^{k,\tau}(j)$ and $c = \mu^{k,\tau_{-i}}(j)$. Note that for each matching $\mu^{k,\tau} \in \mathrm{CL}^k(\mu^\tau)$, we have $\mu^{k,\tau}_{\leq k-1} \in \mathrm{CL}^{k-1}(\mu^\tau)$; similar property holds for $\mathrm{CL}^k(\mu^{\tau_{-i}})$. Hence, we consider two cases:
Case(i). If $b \simeq_j c$, we define $f(\mu^{k,\tau}) = f(\mu^{k,\tau}_{<k}) \cup (j, b)$. We can see that f is well defined since j can be added into $S_b(\mu^{k,\tau}_{<k})$, it also can be added into $S_b(f(\mu^{k,\tau}_{<k}))$ by Property $\mathcal{P}$ (iii). Second, there is no change for alternating path after j is considered. Third, j will be added into the set $S_b(\mu^{k,\tau}) \cap f(S_b(\mu^{k,\tau}))$ and the matched object of the other agents will not change when compared their matchings under τ and under τ_{-i}. Thus, Property $\mathcal{P}$ holds.
Case (ii). If $b \prec_j c$, by induction hypothesis, Property $\mathcal{P}$ (ii), there exists an object $b' \simeq_j c$ such that $j + S_{b'}(\mu^{k,\tau}_{<k}) \notin \mathcal{I}_{b'}$ and $j + S_{b'}(f(\mu^{k,\tau}_{<k})) \in \mathcal{I}_{b'}$. We know the current alternating path (up-to iteration $k-1$) must be with b' as its another end point. Hence, b' is unique. Otherwise, let $d \neq b'$ be the end point of the alternating path. Then the switching agent, i.e., i'_ℓ in Property $\mathcal{P}$ (ii) for object b' is not j, and by Property $\mathcal{P}$ (i), $j + S_{b'}(\mu^{k,\tau}_{<k}) \in \mathcal{I}_{b'}$, a contradiction. Define $f(\mu^{k,\tau}) = f(\mu^{k,\tau}_{<k}) \cup (j, b')$. Now we see that two edges $(j, b') \in \mu^{k,\tau_{-i}}$ and $(j, b) \in \mu^{k,\tau}$ will be added to the alternating path; thus, Property $\mathcal{P}$ holds. The end point of the alternating path is now object b. The last part of the proof of the induction step (omitted here) is to show that sets of agents matched to objects b and b' satisfy Property $\mathcal{P}$ (note that sets of agents matched to other objects do not change). ◀

By Lemma 11, we can suppose w.l.o.g. that there exists a matching in the graph G such that all the agents are matched. (Otherwise, we can find a maximum matching in graph G and remove the unmatched agents in this matching and their adjacent edges. After this, Lemma 11 implies that the expected matching size of RTMHA can not increase (because $|\mu| \geq |f(\mu)|$) and the graph has a matching with all agents matched.) Let μ^* denote this matching in G. Given τ, let τ_i^t denote the order obtained from τ by first removing agent i from τ and then inserting him into the tth position of τ_{-i}, i.e., $\tau_i^t(i) = t$. Now fix $t \in [n_1]$. For any $\tau \in \Pi$, $a \in A$, let $U_a^t(\tau)$ be defined as $U_a^t(\tau) = \{i \in S_a(\mu^*) \mid i \text{ is not matched by TMHA under } \tau_i^t\}$.

▶ **Lemma 12** (INJECTIVITY LEMMA). $|U_a^t(\tau)| \leq |S_a^t(\tau)|$.

Proof. Suppose that $|U_a^t(\tau)| > |S_a^t(\tau)|$. Then by matroid exchange property, there is an agent $i \in U_a^t(\tau)$ such that $S_a^t(\tau) + i \in \mathcal{I}_a$. Suppose i is unmatched by TMHA under τ. Since i is unmatched under τ_i^t, $S_a^t(\tau) = S^t(\tau_i^t)$. However $S_a^t(\tau_i^t) + i = S_a^t(\tau) + i \in \mathcal{I}_a$, implying agent i will be matched to an object at least as good as a by TMHA under τ_i^t, a contradiction.
Suppose now that agent i is matched by TMHA under τ. Removing agent i from τ, we get τ_{-i}. Then inserting i into the tth position of τ_{-i} we get τ_i^t. Since agent i is unmatched by TMHA under τ_i^t, the processes of TMHA under τ_i^t and under τ_{-i} is the same. Let f be the injective function from $\mathrm{CL}^t(\mu^\tau)$ to $\mathrm{CL}^t(\mu^{\tau_{-i}})$ in Lemma 11. By Property $\mathcal{P}$ (iii), $S_a^t(\tau) + i \in \mathcal{I}_a$, then $S_a^t(f(\tau)) + i \in \mathcal{I}_a$. That is $S_a^t(\tau_i^t) + i \in \mathcal{I}_a$, implying agent i will be matched to an object at least as good as a by TMHA under τ_i^t. This leads to a contradiction. ◀

Lemma 12 can be used to directly prove that RTMHA is $\frac{e}{e-1} + o(1)$-approximate for unweighted agents with ties. Analysis in Subsection 4.3 builds on developments in this section.

4.3 Weighted Agents with Ties

Building on Subsection 4.1 and 4.2 we give the proof of the $\frac{e}{e-1}$-approximation for weighted agents with ties. A careful utilization of Lemmas 11 and 12 is needed to obtain a strengthened version of injectivity lemma (Lemma 13). This lemma helps define an injective function from marginal 'bad' events to 'good' events, allowing to prove the ratio. Interestingly, Lemma 11 and primal-dual analysis [22], leads to a significantly simpler proof (compared to [22]) of the ratio $\frac{e}{e-1}$ when each associated matroid is uniform. The main technical ingredient of the proof is a strong version of the injectivity lemma similar to Lemma 12 to define an injective map from marginal set $\bigcup_{t\geq 1} M_t$ (defined later) to the set $2^{\bigcup_{t\geq 1} Q_t}$.

Because of weights, we consider the discrete version of the function $1-g(y)=1-e^{y-1}$ used in the sampling. For every $i\in N$, we will choose an integer $t=\tau(i)$ uniformly at random from $\{1,\cdots,\kappa\}$, where $\kappa\in\mathbb{N}_+$ is a parameter. Let $\psi(t)=1-(1-\frac{1}{\kappa})^{\kappa-t+1}$. The random order of agents follows the decreasing order of $w_i\psi(\tau(i))$, for any $i\in[n_1]$. Note, $\tau\in[\kappa]^{n_1}$ is different from previous subsections (where $\tau\in\Pi$), but we still call it a permutation and the discrete process is the same as RTMHA when $\kappa\to\infty$. For each $\tau\in[\kappa]^{n_1}$, there is a corresponding order of agents defined above. Hence, when we say 'under τ', we mean to run the above discrete RTMHA (called DRTMHA) under decreasing order of $w_i\psi(\tau(i))$, $i\in[n_1]$.

Let $\tau_i^t\in[\kappa]^{n_1}$ denote the same order of agents except we set i's τ value to t, i.e., $\tau_i^t(i)=t$ and $\tau_i^t(k)=\tau(k)$, for any agent $k\neq i$. The other notions have the same meaning as before unless explicitly redefined. Let μ^* be the maximum weighted matching on G, i.e., the optimal matching to our problem. Recall, $S_a(\mu^*)$ is the set of agents matched to a under μ^*. Let Q_t be the set of all the triples among permutations, τ values and agents such that the agent with τ value t at the current order is matched by TMHA. Precisely,

$$Q_t=\{(\tau,t,i)\,|\,i \text{ is matched by TMHA under } \tau \text{ and } \tau(i)=t,\ i\in N,\tau\in[\kappa]^{n_1}\}.$$

Let R_t be the set of all the triples among permutations, t values and agents such that the agent matched in μ^* with τ value at the current order is unmatched. That is:

$$R_t=\{(\tau,t,i)\,|\,i \text{ is unmatched under } \tau \text{ and } \tau(i)=t, \text{ and } i \text{ is matched in } \mu^*,\tau\in[\kappa]^{n_1}\}.$$

Our goal now is to define an injective map from R_t to $2^{\bigcup_{s\leq t} Q_t}$. Towards this aim, we define the marginal (loss) set M_t, which is a subset of R_t with marginal property, i.e., an agent in M_t will be matched after decreasing his τ value by one: $M_t=\{(\tau,t,i)\in R_t\,|\,i \text{ is matched under } \tau_i^{t-1}\}$. Let $M_0=\emptyset$. Let $OPT=w(\mu^*)$ be the optimal weight and $B=\frac{OPT}{\kappa}$. Let $w(Q_t)$ denote the total weights of agents for triples in Q_t: $w(Q_t)=\sum_{(\tau,t,i)\in Q_t} w_i$. Similarly, define $w(R_t)$ and $w(M_t)$. Let $x_t=\frac{w(Q_t)}{\kappa^{n_1}}$ be the expected weights gained by DRTMHA on all agents with τ value t, and $y_t=\frac{w(M_t)}{\kappa^{n_1}}$ the expected marginal loss of all agents with τ value t. Since each agent appears with τ equal to $t\in[\kappa]$ in DRTMHA with equal probability $\frac{1}{\kappa}$, if $Q_t'\subseteq Q^t$ is the set of triples with agents matched in μ^*, then $\frac{w(Q_t')}{\kappa^{n_1}}+\frac{w(R_t)}{\kappa^{n_1}}=B$, for any $t\in[\kappa]$. Therefore,

$$x_t+\frac{w(R_t)}{\kappa^{n_1}}\geq B. \tag{1}$$

So the expected weight of matching obtained by DRTMHA is $\sum_{t\in[n_1]} x_t$. There is a bijection $h: R_t\to\bigcup_{s\leq t} M_s$. Note, for any $(\tau,t,i)\in R_t$, if there is $s\in[t-1]$ s.t. $(\tau_i^s,s,i)\in Q_s$, then there is such s that is a unique maximal one. Note, in this case $(\tau_i^{s+1},s+1,i)\in M_{s+1}$. Define $h(\tau,t,i)=(\tau_i^{s+1},s+1,i)$. Otherwise, define $h(\tau,t,i)=(\tau_i^1,1,i)\in M_1$; note that

$M_0 = \emptyset$. (h is well defined.) For any $(\tau, s, i) \in M_s$, and some $s \leq t$, agent i will not be matched under τ_i^t since it is unmatched under τ, by Lemma 11 (Property $\mathcal{P}$ (iii)). Then $(\tau_i^t, t, i) \in R_t$, which means h is surjective, i.e., $h(\tau_i^t, t, i) = (\tau, s, i)$. If $h(\tau, t, i) = h(\tau', t, i') = (\sigma, s, i'') \in M_s$, by definition $i = i' = i''$ and $\tau = \tau' = \sigma_{i''}^t$. Then h is also injective. Hence,

$$w(R_t) = \sum_{s \leq t} w(M_s) \tag{2}$$

For any $\tau \in [\kappa]^{n_1}$, $a \in A$, let $S_a(\tau)$ be the set of agents matched to a by DRTMHA under τ. Let $U_a(\tau)$ be the set of agents in $S_a(\mu^*)$ such that changing the τ of any one of them, e.g., agent $i \in S_a(\mu^*)$ to some t_i, the new triple of τ together with his new value t_i and himself belongs to M_{t_i} (Note that for any agent $i \in S_a(\mu^*)$, if there exists a t_i such that $(\tau_i^{t_i}, t_i, i) \in M_{t_i}$, then t_i is unique for agent i). Precisely, $U_a(\tau) = \{i \in S_a(\mu^*) \,|\, (\tau_i^{t_i}, t_i, i) \in M_{t_i}\}$.

▶ **Lemma 13** (INJECTIVITY LEMMA). *There exists an injective function $g_{a\tau}$: $U_a(\tau) \to S_a(\tau)$ such that $w_i\psi(t_i) \leq w_{i'}\psi(\tau(i'))$, for any $i \in U_a(\tau)$ and $i' = g_{a\tau}(i)$.*

Proof (Sketch). From map h: $R_t \to \bigcup_{s \leq t} M_s$, we know $U_a^t(\tau)$ is well defined. Now, for any $i \in U_a^t(\tau)$, by definition, i is unmatched under $\tau_i^{t_i}$. Let ℓ_i denote the position where agent i sits in the order of agents of DRTMHA under $\tau_i^{t_i}$ (we call it a position value). We can partition $U_a^t(\tau)$ into different groups such that different groups have different position values ℓ_i's, and agents in the same group have the same position value. That is, partition set $U_a^t(\tau)$ into n_3 such groups $\{T_s\}_{s \in [n_3]}$, where T_s has position value ℓ_s.

Note that if i is unmatched when his position value is ℓ_i, then he will remain unmatched when he is in any position $\ell > \ell_i$, by Lemma 11 (part (iii) of Property $\mathcal{P}$). We now use Lemma 12 iteratively on set $\bigcup_{j \leq s} T_j$, $s \in [n_3]$ to prove Lemma 13 as follows: suppose we have constructed a map $g_{a\tau}$ on set $\bigcup_{j \leq s} T_j$ satisfying the property of Lemma 13. Then by Lemma 12, there exists an injective map $f_{a\tau}^{\ell_{s+1}}$: $\bigcup_{j \leq s+1} T_j \to S_a^{\ell_{s+1}}(\tau)$, satisfying the property of the lemma. Combining the two maps $g_{a\tau}$ and $f_{a\tau}^{\ell_{s+1}}$, we obtain the map on $\bigcup_{j \leq s+1} T_j$. ◀

Next we define a map H from $\bigcup_{t \in [\kappa]} M_t$ to $2^{\bigcup_{t \in [\kappa]} Q_t}$ to bound the marginal 'bad' events $\bigcup_{t \in [\kappa]} M_t$ by 'good' events $\bigcup_{t \in [\kappa]} Q_t$ as follows: For any $t \in [\kappa]$, $(\tau, t, i) \in M_t$,

$$H(\tau, t, i) = \{(\tau_i^s, p_i^s, g_{a\tau_i^s}(i)) \,|\, a = \mu^*(i) \text{ and } p_i^s = \tau_i^s(g_{a\tau_i^s}(i)) \text{ and } s \in [\kappa]\}.$$

Note that for any $(\tau, t, i) \in M_t$, $|H(\tau, t, i)| = \kappa$. Due to the injectivity of $g_{a\tau}$ (Lemma 13), we will show that the image sets of H are disjoint.

▶ **Lemma 14.** *For any $(\tau, t, i) \in M_t$ and $(\tau', t', i') \in M_{t'}$, if $(\tau, t, i) \neq (\tau', t', i')$, then $H(\tau, t, i) \cap H(\tau', t', i') = \emptyset$.*

Proof. Suppose there is a triple $(\sigma, s, \ell) \in H(\tau, t, i) \cap H(\tau', t', i')$. Then there exists $a \in A$ s.t. $\mu^*(i) = \mu^*(i') = a$, by the definition of $g_{a\sigma}$ (since $S_a(\sigma) \cap S_b(\sigma) = \emptyset$, for any $a \neq b$). By the definition of H, we know that $\tau = \sigma_i^t$ and $\tau' = \sigma_{i'}^{t'}$. Hence, $i, i' \in U_a(\sigma)$ since $(\tau, t, i) \in M_t$, $(\tau', t', i') \in M_{t'}$. As $g_{a\sigma}$ is an injective function from $U_a(\sigma)$ to $S_a(\sigma)$, $g_{a\sigma}(i) = g_{a\sigma}(i')$, implies $i = i'$. As $\tau = \sigma_i^t$, $\tau' = \sigma_i^{t'}$, there exists a unique t such that $(\sigma_i^t, t, i) \in M_t$, which gives that $t = t'$ and $\tau = \sigma_i^t = \sigma_i^{t'} = \tau'$. This shows $(\tau, t, i) = (\tau', t', i')$, and thus a contradiction. ◀

By Lemmas 13 and 14, we have for any $(\tau, t, i) \in M_t$, $t \in [k]$, and any $(\sigma, s, i') \in H(\tau, t, i)$, $w_i\psi(t) \leq w_{i'}\psi(s)$ and $(\sigma, s, i') \in \bigcup_{\ell \leq k} Q_\ell$. Summing over M_t: $\psi(t)w(M_t) =$

$\sum_{(\tau,t,i)\in M_t} w_i\psi(t) \leq \frac{\sum_{(\sigma,s,i')\in H(M_t)} w_{i'}\psi(s)}{\kappa}$. Therefore:

$$\begin{aligned}
\sum_{t\leq\kappa} \psi(t)w(M_t) &= \sum_{t\leq\kappa} \sum_{(\tau,t,i)\in M_t} w_i\psi(t) \\
&\leq \frac{\sum_{t\leq\kappa}\sum_{(\sigma,s,i')\in H(M_t)} w_{i'}\psi(s)}{\kappa} \\
&= \frac{\sum_{(\sigma,s,i')\in\bigcup_{t\leq\kappa} H(M_t)} w_{i'}\psi(s)}{\kappa} \\
&\leq \frac{\sum_{(\sigma,s,i')\in\bigcup_{t\leq\kappa} Q_t} w_{i'}\psi(s)}{\kappa} \\
&= \frac{\sum_{t\leq\kappa}\sum_{(\tau,t,i)\in Q_t} w_i\psi(t)}{\kappa} \\
&= \frac{\sum_{t\leq\kappa}\psi(t)w(Q_t)}{\kappa}.
\end{aligned}$$

Dividing both sides of this inequality by κ^{n_1} implies $\sum_{t\leq\kappa}\psi(t)y_t \leq \frac{\sum_{t\leq\kappa} x_t\psi(t)}{\kappa}$. Combining this inequality with (1) and (2), and following a step in the analysis from [4] implies.

▶ **Theorem 15.** *DRTMHA is universally truthful and has an approximation ratio* $\frac{e}{e-1}+O(\frac{1}{\kappa})$ *for weighted agents with ties and terminates in* $O(n_1^4\gamma\log\kappa)$ *time, for any* $\kappa\in\mathbb{N}_+$.

Abstract

Internet display advertising industry follows two main business models. One model is based on *direct deals* between publishers and advertisers where they sign legal contracts containing terms of fulfillment for a future inventory. The second model is a spot market based on auctioning page views in real-time on advertising exchange (AdX) platforms such as DoubleClick's Ad Exchange, RightMedia, or AppNexus. These exchanges play the role of intermediaries who sell items (e.g. page-views) on behalf of a seller (e.g. a publisher) to buyers (e.g., advertisers) on the opposite side of the market. The computational and economics issues arising in this second model have been extensively investigated in recent times.

In this work, we consider a third emerging model called *reservation exchange market*. A reservation exchange is a two-sided market between buyer orders for blocks of advertisers' impressions and seller orders for blocks of publishers' page views. The goal is to match seller orders to buyer orders while providing the right incentives to both sides. In this work we first describe the important features of mechanisms for efficient reservation exchange markets. We then address the algorithmic problems of designing revenue sharing schemes to provide a fair division between sellers of the revenue collected from buyers.

A major conceptual contribution of this work is in showing that even though both clinching ascending auctions and VCG mechanisms achieve the same outcome from a buyer perspective, however, from the perspective of revenue sharing among sellers, clinching ascending auctions are much more informative than VCG auctions.

1 Introduction

The universe of internet advertisement is divided in two big worlds: *search ads* and *display ads*. At first glance, they look very similar: both sell impressions using variants of the second

price auction with reserves. A closer look, however, reveals that they are very different: in *search ads*, the platform (Google or Bing, for example) is both the *auctioneer* and the *seller*, i.e., it sells inventory in their own properties. This makes it a one-sided market design problem, or in other words, the designer needs to reason only about the incentives of the buyers. In *display ads*, the platform is auctioning inventory not owned by them, turning it into a two-sided market design problem, where incentives for buyers (advertisers) and sellers (publishers, such as websites, blogs and news portals) need to be balanced.

Designing practical markets for display ads is challenging, since the theory of market design is much more developed for one-sided markets (there are tools like VCG, Myerson's optimal auction, ...) while for two-sided markets, what classic auction theory offers are mainly impossibility results, such as the Myerson-Satterthwaite Impossibility Theorem [23].

One complicating factor in display ads is that while we are used to think of internet advertisement in the form of auctions, auctions are only the tip of the iceberg. The most premium inventory is sold via the *reservations market* (also called *direct deals* or *guaranteed contracts*.) In this method, a publisher and an advertiser make a deal to allocate a certain number of impressions over a certain period, for a pre-specified price per impression. This deal is made offline in advance for a future inventory. Direct deals are known to suffer from inefficiencies for two reasons: first is the manual nature of formation of these contracts which allows a publisher to sign deals with a small number of advertisers, thus creating allocation inefficiencies. The second reason is the manual negotiation between buyers and publishers which incurs a huge cost and lowers the overall efficiency.

Auctions are fully automated and don't suffer from any of these inefficiencies. On the other hand, they can't guarantee to buyers and sellers the certainty that reservations can. For example, a brand launching a large campaign to advertise a new product certainly benefits from the certainty (both in terms of cost and volume of impressions) provided by reservation contracts.

The idea of *automated reservation market* is to overcome the shortcomings of both auctions (real-time spot market) and traditional reservations (offline negotiation). Such markets would allow sellers and buyers to transact for a bulk inventory in advance. This is inspired by a number of recent two-sided markets for online advertising, e.g., an exchange for future contracts[1]. In particular, we study a two-sided market, which we call a *reservation market*, where publishers can post offers for blocks of ad slots characterized by parameters like supply level, reserve price, and their preference for a set of advertisers. Advertisers post requests for ad slots defined by parameters like valuation, demand, and targeting constraints specifying where and when they want to show their ads. The role of the reservation mechanism is to match the seller and buyer orders that attain some economic objectives.

Note that, unlike ad exchange markets that offer impressions available on the spot, the reservation market offers guaranteed deals for an inventory available in the future. Moreover, the reservation market brings together multiple publishers and advertisers with the goal of reducing the intermediation costs and the underlying inefficiencies of one-to-one deals, also by selling bundles of inventories from different publishers.

In this work, we start the investigation of the economics and algorithmic principles that are central to these reservation markets. The major questions we address in this work are: What features and incentive properties form the basis of a successful reservation market? What are the economic objectives of a reservation market? What are the revenue sharing policies that we can employ? What are the algorithmic problems we need to address in the design of reservation mechanisms?

[1] `http://www.massexchange.com/`

1.1 Our contribution

Our main contribution is to propose a formal model of reservation exchange market and discuss what are desirable properties (referred to as *axioms*) for this market. Secondly, we propose two specific mechanisms that help us understand the extent to which some of the aforementioned properties can be simultaneously achieved. We also provide several algorithmic results for the two mechanisms that we study.

Axioms for a reservation exchange market. In Section 2, we provide a simple and clean abstraction of reservation exchange markets for display ads as a two-sided matching market with buyer orders on one side and seller orders on the other side and in Section 3 we identify a list of axioms that we wish any mechanism for these markets to approximately satisfy.

The first axiom for the reservation mechanism that we discuss is the *efficiency of the market,* i.e., the social welfare of all agents of the market. The agents of the market are sellers and buyers, both with quasi-linear utilities. Buyers aim at maximizing their utility, i.e., the total value of the inventory received minus price. Sellers aim at maximizing revenue minus reservation price. The mechanism decides on the allocation to buyer orders of the inventory supplied from each seller, a payment to be charged to each buyer and a distribution of the revenue among sellers.

Individual rationality (IR) requires that participating in the mechanism is beneficial to all agents. *Incentive compatibility* (IC) requires that truthfully reporting one's preferences to the mechanism is the best strategy for each agent, independently from what the other agents report.

Budget Balance (BB) states the payments of the advertisers must entirely and exclusively be transferred to the publishers, i.e., the buyers and the sellers are allowed to trade without leaving to the mechanism any share of the payments, and without the mechanism adding money into the market. This axiom might appear strange at first glance, but it reflects a business practice common to most exchanges, which is of the exchange to get a fixed cut (typically called *revenue sharing margin*) of the seller's revenue. The reasoning behind this rule is that sellers have the option to send their inventory to different exchanges and keeping the revenue sharing margin fixed helps the exchange to be perceived as fair and hence attract more seller's inventory. Since fixed margins are an industrial standard in the ads world, any practical mechanism must implement some of that. Fixed margins are equivalent to budget-balance applied to bids rescaled by the revenue sharing margin up to rescaling bids.

An ideal goal in a reservation exchange is to design IR, IC, BB mechanisms that maximize the social welfare of all agents in the market. Unfortunately, Myerson and Satterthwaite [23] proved impossibility for an IR, IC, and BB mechanism that maximizes social welfare in such a market. The direction we pursue in this work is to ensure full efficiency and incentive compatibility for buyers as the most desirable goal for advertiser. This can be achieved for one-side markets by the family of Vickrey-Clarke-Groves (VCG) mechanisms [6, 29]. As extensively discussed in this work, the main problem with the vanilla VCG allocation is that it does not offer any good incentives to sellers, e.g., VCG can match fungible inventories from different sellers to buyers that offer very different payments thus producing the feeling that revenue is unfairly distributed among sellers.

An alternative to enforcing incentive compatibility for sellers is to design a mechanism that leads to a fair distribution of mechanism's revenue among sellers. Envy-free allocations [28] and other notions of market equilibria have often been considered in markets that cannot achieve full efficiency with truthful allocations. This leads to our third axiom as follows: sellers should not envy each other with respect to the revenue that is received from the mechanism.

Most of the first part of the paper will be devoted to the discussion of which definition of *envy-freeness among sellers* is meaningful for reservation exchange markets. Our conclusion is that such a definition should crucially rely on the buyer-seller transactions that can arise in an efficient allocation, while it should disregard revenue that can only be obtained from allocations with suboptimal social welfare. With this aim, when introducing our notion of envy-freeness between sellers, we define the concept of *clinching graph* as the collection of buyer-seller transactions that can arise in a VCG allocation. We conveniently define and compute the clinching graph by resorting to the implementation of VCG through an ascending clinching auction.

A major insight of this paper is that while the usual description of VCG payments as externalities imposed by agents on others offers little clue on how to split the proceeds of the auction among the sellers, the alternative description of VCG as an ascending auction (Ausubel's clinching framework [1]) provides additional structure obtained from the execution of the auction that can be exploited to design revenue sharing schemes. The clinching auction returns not only bundle prices, but the order in which each item was sold and the price at which the sale occurred. In an ideal case, whenever a *clinch* happens, if the clinching auction points to a unique item to be clinched, then there is a unique way to split the revenue among the sellers (and in this case clinching auctions capture the full information in how to split the revenue). However, sometimes, when a clinch happens, there are multiple items that can be used for that clinch. This is precisely the case when the clinching auction, even though it provides more information than VCG, it doesn't lead to a unique revenue sharing scheme, and we rely on a notion of envy-freeness for the revenue sharing scheme.

Finally, we discuss further desirable properties of reservation markets as additional axioms, and study our proposed mechanisms for their satisfaction of these axioms. These axioms are stability properties that prevent the market to be manipulated from buyers or sellers. We define the concept of *buyer monotonicity (BM)* as the property that the revenue of all sellers does not decrease when new buyer orders are presented. A second property called *seller monotonicity (SM)* states that the increase of the reservation price of a seller is not responsible of the decrease of the revenue of another seller.

Algorithmic results. We restrict our attention to buyer incentive-compatible efficient mechanisms based on VCG allocations. For all these mechanisms truth-telling is a dominant strategy for buyers. The major issue we face is to complement the VCG mechanism with a suitable envy-free revenue sharing scheme between sellers. Our first result is actually a negative result:

- There exists no efficient revenue sharing scheme that is both envy-free and budget balance. We actually demonstrate that any envy-free revenue sharing scheme cannot distribute more than a $\sqrt{3}-1+\delta$ share of the total revenue, for any $\delta > 0$.

Given the impossibility result above, we investigate the possibility of finding good trade-offs between budget balance or envy freeness. Relaxing one of these two constraints imply that either the mechanism is able to distribute a guaranteed share of the total revenue or that any seller has only limited envy of any other seller. With this goal in mind, we propose two revenue sharing schemes: (i) a *revenue sharing by the clinching auction (CA)*, and (ii) a *revenue sharing by the eating mechanism (EM)*.

For the CA revenue sharing scheme, we prove the following desirable properties:

- CA is budget balance.
- CA is 1/2-envy free and this bound is tight.
- CA is budget monotone and seller monotone.

Finally, for the EM revenue sharing scheme, we prove that following three results:

- EM is envy-free.
- EM is at most $\frac{11+\epsilon}{12+\epsilon}$ budget balance, for any $\epsilon > 0$.
- EM is at least $\frac{e-1}{e}$-budget balance.

Most of the technical proofs are given in the full version of the paper.

1.2 Related work

Double Auctions. Double auctions are special cases of two-sided markets with unit-supply buyers and sellers. Myerson and Satterthwaite [23] proved that it is impossible to obtain an IR, Bayesian IC[2], and weak BB [3] mechanism to maximize social welfare in double auctions. Since then, much of the literature has focused on trading off social welfare for buyers and sellers, incentive compatibility and budget balance for double auctions [21, 25, 26, 11, 7]. The seminal work on double auctions [21] shows that efficiency for both buyers and sellers can actually be achieved asymptotically in large markets. In the context of one-shot auctions, optimal auctions for two-sided settings has been studied by [23], following the Nobel-prize winning work of [22]. The problem of finding the right trade-offs between social welfare, IC and BB is largely open for two-sided markets that model reservation exchanges. In this work we investigate two-sided markets that achieve IC for buyers and envy-freeness for sellers. This follows a line of work that looks at envy-freeness and other market equilibria if social welfare cannot be optimized truthfully [14, 19, 28]. Recently, this literature has also been adopted to design the optimal revenue sharing double auctions in the context of advertising exchanges [18]. In this paper, we focus on two-sided markets where multiple buyers are allocated to multiple sellers and the allocation and pricing are done differently. Other than online advertising systems, optimal two-sided markets can be applied to online and offline retailers and e-commerce websites like Amazon and eBay. A very recent paper by [20] studies EBay's double auction problem, but their setting is different from this paper as they consider one buyer and multiple sellers, and explore approximately optimal pricing schemes for this setting.

Clinching Ascending Auctions. One fundamental component of this work is the use of the structure that can be obtained from the execution of Ausubel's clinching auction [1] in designing revenue sharing schemes for the sellers. The clinching auction has been very successful in a variety of scenarios: designing auctions with budget constraints [10, 13, 8, 16], designing online auctions [17], extracting revenue in settings with budgets [3, 9]. The current paper adds to this line of work by showcasing another application of the clinching framework.

Cooperative games. Cooperative game theory may provide insights for modeling the fair sharing of revenue in the ad reservation exchange market. Shapley value [27] is a widely adopted notion of fair division between agents of the value of a game. It is however hard to extend this concept to our model since a crucial axiom of Shapley value (summability) does not hold in our case. Similar difficulties can also be found while trying to design a revenue sharing scheme that results in an attribution that lies in the core of a game [15]. On the positive side, we mention that the revenue sharing scheme by the clinching auction we

[2] Bayesian incentive compatibility is a less restrictive form of incentive compatibility.
[3] Weak budget balance allows the mechanism to retain a share of the payments while not subsidizing the market.

present resembles Shapley values since it is defined as the expected revenue obtained over all possible seller permutations.

Market Equilibria. Several notions of equilibrium in markets have been studied. In a Walrasian equilibrium, we have item prices such that every agent receives a bundle of items that maximizes her utility, the market clears, and the corresponding outcome is efficient. However, except from very special cases (e.g. unit demand buyers), it can't be converted to a mechanism that is incentive-compatible for the buyer [19, 12]. Envy-freeness for buyers is also a concept widely used to characterize the stability of allocations. We do not survey here the extensive literature on this topic. However, we notice that we instead adopt the notion of envy-freeness to characterize fair revenue sharing schemes between sellers.

Reservation-based Internet advertising has also previously considered with more optimization-related questions than mechanism design questions. Examples of this line of work that is quite unrelated to the scope of this paper can be found in [30, 4, 24]. Markets that combine characteristics of the spot market and of direct deals between publishers and sellers have been also considered in [5] with the goal of maximizing the revenue of one single publisher.

2 Preliminaries

We consider a two-sided market, referred to as a *reservation exchange market*, consisting of a set B of buyers and a set S of sellers. Each seller $s_i \in S$ holds a supply of ℓ_i units of an *indivisible* good and has a reserve price ρ_i for each unit of those goods. Each buyer is interested in purchasing at most d_i units and has a value v_i per unit. The structure of the matching market is captured by a bipartite graph $G = (B \cup S, F)$ which indicates which buyer is interested in buying goods from which seller.

For example, in the case of internet advertisement, each buyer $b_j \in B$ corresponds to an advertiser and a seller $s_i \in S$ corresponds to a publisher. An edge $(b_j, s_i) \in F$ indicates that buyer b_j is interested in purchasing inventory from the publisher s_i's website. We define $B_i = \{b_j \in B; (b_j, s_i) \in F\}$ as the set of buyers who target seller s_i inventory. Similarly, we define $S_j = \{s_i \in S; (b_j, s_i) \in F\}$ as the set of sellers that are targeted by buyer b_j.

We are interested in designing *reservation exchange mechanisms* (or simply reservation mechanisms) which associate for any given matching market described by (B, S, v, d, ℓ, ρ) an outcome composed of:

- an allocation $x_i[j] \in \mathbb{Z}$, indicating how many goods from seller s_i are sold to buyer b_j, respecting demands $a_j := \sum_i x_i[j] \leq d_j$ and supply $c_i := \sum_j x_i[j] \leq \ell_i$.
- a total amount P_j paid by each buyer b_j, such that the payment per unit doesn't exceed buyer j's value per unit: $P_j \leq a_j \cdot v_j$
- a revenue sharing scheme which allocates for each buyer b_j and seller s_i, a portion $R_i[j]$ of the buyer's payment P_j to seller s_i, such that $\sum_i R_i[j] \leq P_j$. We define $R_i := \sum_j R_i[j]$ to be the total revenue obtained by seller i.

An outcome satisfying the properties above is said to be a *feasible outcome*. Given a feasible outcome, the utility of involved agents are as follows:

- buyers have quasi-linear utilities, i.e, $u_j = v_j \cdot a_j - P_j$.
- sellers have the revenue minus the reservation price $R_i - \rho_i \cdot c_i$ as their utility.

In the next section, we discuss a set of desirable properties for a reservation mechanism and discuss which subsets of those properties can be simultaneously satisfied.

3 Axioms for Reservation Exchange Markets

In this section, we develop an axiomatic approach to reservation markets. First, we define a set of desirable properties, referred to axioms, for a well-designed market. As it is the case with axiomatic approaches, some seemingly innocuous axioms might generate impossibility results and some seemingly powerful axioms might not prevent the pitfalls we intended. Here, we define a family of axioms (many with different variations) and discuss, using examples, their strengths and weaknesses.

3.1 Fundamental Axioms: efficiency and budget-balance

We establish as our first and most important goal the maximization of market efficiency, which is the sum of the utilities of all agents involved:

- **Efficiency [Eff]:** The implemented outcome maximizes $SW(B \cup S) = \sum_{j \in B} v_j \cdot a_j + \sum_{i \in S} \rho_i \cdot (\ell_i - c_i)$ among all feasible outcomes, assuming the seller derives utility ρ_i for unsold items.

In order to simplify notation, for each seller that has a reserve price $\rho_i > 0$ we add a *proxy buyer* $j(i)$ with demand $d_{j(i)} = \ell_i$ and value $v_{j(i)} = \rho_i$. Let also $j(i)$ be the endpoint of a single edge connecting it to seller i. Notice that there is a social-welfare-preserving one-to-one map between outcomes for sellers with reserve prices and sellers without reserves but with proxy buyers. This reduction allows us to ignore from this point on the reserve prices ρ_i and focus on maximizing $\sum_i v_j \cdot a_j$ as the [Eff] goal.

A second goal of the mechanism is to distribute the revenue between sellers. A budget balance mechanism should distribute the entire revenue collected from the buyers to the sellers. A β-budget balance mechanism should distribute at least a β-fraction of the revenue.

- **β-Budget Balance [β-BB]:** The implemented outcome is β-budget balance for a constant $\beta \in [0, 1]$ if $\sum_{i \in S} R_i \geq \beta \sum_{j \in B} P_j$. We say that the reservation mechanism is exact budget balance if $\beta = 1$.

3.2 Stability properties

A second set of properties describes the stability of the allocation and resilience to manipulation via adding or removing buyers or sellers:

- **Buyer Monotonicity [BM]**: If a new buyer order b_j is added, the revenue of all sellers in S_j does not decrease.
- **Seller monotonicity [SM]**: If a seller increases his reserve price, the revenue of all other sellers does not decrease.

3.3 Incentive compatibility

We next define a set of desirable incentives properties for buyers and sellers.

- **[B-IC] Buyer incentive compatibility:** Buyers maximize their utility by reporting their true valuations to the mechanism.
- **[S-IC] Seller incentive compatibility:** Sellers maximize their utility by declaring true reserve prices and supply levels.

Unfortunately, [B-IC] and [S-IC] cannot be simultaneously achieved in a two-sided market [23, 21] if not at the expense of efficiency. Here, we choose to relax seller incentive

compatibility and instead, enforce a fairness constraint among sellers while keeping buyer incentive compatibility.

If we enforce [Eff] and [B-IC], the only mechanism available to decide on the allocation and buyer payments is the VCG mechanism. VCG, however, treats all the sellers as one and therefore doesn't prescribe how the revenue of the auctions should be distributed among the sellers. The central issue in the design of reservation exchange mechanisms is how to distribute the revenue from the VCG auction in a manner that is fair to the sellers. As we will see next, defining a precise notion of fairness that matches our intuition is a quite non-trivial task. First, we show how the most natural definitions fail to capture important situations.

3.4 Seller Fairness and Envy-Freeness

We start by identifying a set of properties that we believe a fair revenue sharing scheme should satisfy. The challenge here is in identifying, when a buyer gets some item at price p, if a seller can stake a claim on this revenue or not. Firstly, a seller s_i can claim revenue only from buyers that are interested in the inventory owned by seller s_i, i.e., $R_i[j] = 0$ for $j \notin B_i$. Also, if a certain buyer b_j never receives goods from seller s_i under any efficient allocation, seller s_i shouldn't be able to claim stake on the revenue of buyer b_j. This is so because even if this seller drops this connection to the buyer, it won't change the set of efficient outcomes. Moreover, the seller may end up getting a lower revenue because of the reduced competition after dropping such a connection.

In order to capture the above notions, we define for each seller s_i, the set $A_i \subseteq B_i$ as the set of buyers that are allocated at least one good from s_i in *some* efficient allocation. We are now able to define the concept of envy-free revenue sharing: roughly speaking, we say that a revenue sharing scheme is envy-free if each seller s_i extracts from A_i more revenue then any other seller with at most the same supply and proportionally more revenue than any seller with higher supply. More specifically, this concept is defined as follows:

- **Envy-free Revenue Sharing [ERS]**: $\forall s_i, s_{i'}$, $\sum_{j \in A_i} R_i[j] \geq \min(1, \frac{\ell_{s_i}}{\ell_{s_{i'}}}) \cdot \sum_{j \in A_i} R_{i'}[j]$.

If all sellers have the same supply, this boils down to $\sum_{j \in A_i} R_i[j] \geq \sum_{j \in A_i} R_{i'}[j]$. We note that if one is able to design an envy-free mechanism for sellers with unit-supply, this automatically extends to sellers with non-unit supply by the following reduction: transform each seller of supply ℓ_i in ℓ_i unit supply sellers. An envy free allocation in the transformed setting naturally translates to an envy-free allocation in the original setting. For this reason we will assume for the remainder of the paper that sellers are unit supply.

However, as shown in the following example, the above notion of envy-freeness doesn't fully capture the notion of a fair allocation among the sellers:

▶ **Example 1.** Consider two buyers with valuation $v_1 = 2$, $v_2 = 1$, and demands $d_1 = 2$, $d_2 = 1$. There are two unit supply sellers s_1, s_2 with preference constraints shown in Figure 1. For any mechanism satisfying [Eff], [B-IC] and [ERS], the allocation and payments charged to the buyers must be the one of the VCG mechanism. So, the mechanism sells both items to buyer b_1 at total price 1.

Since $A_1 = A_2 = \{b_1\}$, ERS imposes to share the revenue equally between s_1 and s_2. This way to partition of the revenue can be hardly called fair, since the 1 dollar in revenue is caused by the competition with buyer b_2 that is brought to the market by seller s_2. So a natural intuition is that a 'fair' scheme should attribute the 1 dollar in revenue to seller 2.

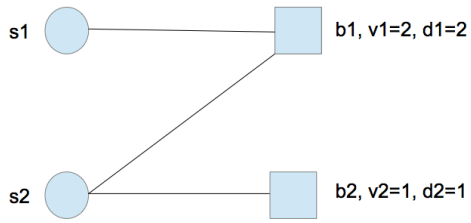

Figure 1 The two sellers receive different revenue.

The above example implies the need to refine the envy-freeness property to incorporate some notion of *which buyers are responsible for putting the price pressure*. To get a handle on such a notion, we consider ascending auctions to refine our envy-freeness property.

3.5 Fairness via ascending auction

The traditional definition of the VCG mechanism is that it allocates according to an efficient allocation and charges each agent according to the externality it imposes on other agents. One problem with this way of defining VCG is that it returns a bundle of items to each agent and a total price but does not specify how much of the payment is attributed to each item. An alternative way to define VCG is via an ascending auction [2, 1], in which there is a price clock p that gradually ascends, and as the price increases items are allocated to buyers. The total payment of the buyer in such a case is the sum over the prices of all individual items, where the price of each item is the value of the price clock when the buyer acquired the item.

The ascending auction description of VCG returns for each buyer b_j his allocation, say $x_j \in \mathbb{Z}_+$ together with x_j prices $p_1 \leq p_2 \leq \ldots \leq p_{x_j}$ corresponding to the value of the price clock when he acquires each of those items. In other words, we can describe the outcome of VCG as an ascending auction as a set of n *buying events*, where $n = \sum_i \ell_i$ and each buying event is a pair (b_j, p) indicating that one item was sold to buyer b_j at price p. Note that we assume all items are sold by VCG, which is always the case when we consider proxy buyers as discussed in Section 3.1.

Let E be the set of buying events that represents the outcome of the auction. During its execution, the ascending auction maintains in each step a tentative assignment of buying events to sellers. This allows us to define a bipartite graph between sellers and buying events called the *clinching graph*. We say that a seller s_i is connected to buying event e_j if this seller is tentatively allocated to that buying event in some point of the auction execution. If the auction execution is not unique (because of ties, caused for example by two identical sellers) we consider an edge to be in the clinching graph if for some execution of the auction its corresponding buying event is connected to the corresponding seller.

We refer to [1, 10, 13, 16] and to the full version of the paper for a formal definition of the ascending auction, but we illustrate its execution for the instance in Example 1. The price clock starts at zero, and at that price the auction is already able to allocate the item in s_1 to buyer b_1, since he faces no competition on that item. This generates a buying event $(b_1, 0)$ that is associated with seller s_1. For prices between 0 and 1, both buyers compete for the remaining item. When the price clock reaches 1, buyer b_2 is no longer interested in the remaining item and buyer b_1 can acquire it at price 1, generating a buying event $(b_1, 1)$, which is associated with seller s_2. There are no ties, so this is the unique execution of the auction, which generates the clinching graph represented in Figure 2.

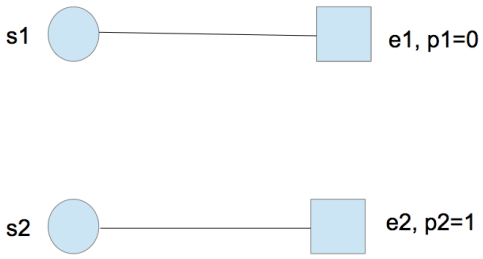

Figure 2 Each seller is linked in the clinching graph to only one buying event.

Given the clinching graph, we are now able to define a stronger notion of envy-freeness based on it. We denote by E_i the set of buying events associated to buyer b_i and by $r_i[j]$ the revenue obtained by seller s_i from buying event $e_j \in E_i$. Let us denote the revenue of unit supply seller s_i by $r_i = \sum_{j \in E_i} r_i[j]$. We now state a new version of Envy-free Revenue Sharing, that we denote by ERSCG, as follows:

- **Envy-free Revenue Sharing from Clinching Graph [ERSCG]**: $\forall s_i, s_{i'}$, $\sum_{j \in E_i} r_i[j] \geq \sum_{j \in E_i} r_{i'}[j]$.

According to the definition of clinching graph, we obtain for the example of Figure 2 that $E_1 = \{e_1\}$ and $E_2 = \{e_2\}$. The revenue sharing scheme that attributes $r_1[1] = 0$, $r_1[2] = 0$, $r_2[1] = 0$ and $r_2[2] = 1$ is therefore ERSCG. We conclude that the new definition of envy-freeness is able to characterize a fair sharing of the revenue between sellers.

We also define an approximate version of the previous property:

- **α-Envy-free Revenue Sharing from Clinching Graph[α-ERSCG]:** $\forall s_i, s_{i'}$, $\sum_{j \in E_i} r_i[j] \geq \alpha \sum_{j \in E_i} r_{i'}[j]$.

We conclude by observing that the notion of envy-freeness we introduce can easily be adapted to the original non-unit supply sellers.

4 Impossibility of Envy-freeness and Budget Balance

Before presenting two revenue sharing schemes based on the definition of clinching graph in Sections 5 and 6, we show that envy-freeness and budget balance are indeed contradicting objectives for any revenue sharing scheme based on an efficient allocation.

▶ **Theorem 2.** *There does not exist any revenue sharing efficient mechanism for the reservation exchange market which is BB and α-ERSCG for $\alpha \geq \sqrt{3} - 1 + \delta \approx 0.732$, for an arbitrary small value $\delta > 0$.*

5 Revenue sharing by the Clinching Ascending Auction.

The first revenue sharing scheme is based on the allocations computed by the clinching ascending auction (CA). We denote by CA this revenue sharing scheme.

A detailed description of the use of the clinching ascending auction [2, 1] to compute efficient VCG allocations is given in the full version of the paper. We specifically use a version for matching markets given in [13].

Crucial to the definition of revenue sharing scheme is the notion of *priority order* among sellers that is used in the execution of the CA. Whenever the CA is indifferent about buying between a set of sellers, it decides in "favor" of the seller with lower priority in the precedence

order. Intuitively, the seller of higher priority will enjoy a payment that is at least as good as the lower priority seller since the price in the ascending auction is non-decreasing. A priority order between sellers is simply represented by a permutation $\pi \in \Pi(S)$ where $\Pi(S)$ defines the set of all permutations of set S.

We set $r_i^\pi[j] = p_j$ if the execution of CA on permutation π matches e_j to s_i.

Revenue share of seller s_i from buying event e_j is defined as

$$r_i[j] = \mathbb{E}_{\pi \in \Pi(S)}[r_i^\pi[j]]. \tag{1}$$

The revenue of seller s_i is defined as $r_i = \sum_{e_j \in E_i} r_i[j]$. Since the total revenue of the mechanism $REV = \sum_{j \in E} p_j$ is shared between sellers, we state a first property of the revenue sharing scheme CA:

▶ **Claim 3.** *The revenue sharing scheme CA is BB.*

We next prove that the revenue sharing scheme CA is not exact ERSCG.

▶ **Theorem 4.** *The revenue sharing scheme CA is at most* $1/2$*-ERSCG.*

We next prove the approximate envy-freeness of revenue sharing scheme CA.

▶ **Theorem 5.** *The revenue sharing scheme CA is* $1/2$*-ERSCG.*

We conclude with the properties of buyer monotonicity and seller monotonicity for revenue sharing scheme CA.

▶ **Theorem 6.** *BM and SM hold for revenue sharing scheme CA.*

6 Revenue sharing by the Eating mechanism.

The eating mechanism is defined as a fractional process in time on the clinching graph $CG = (E \cup S, H), H = \{(e_j, s_i) : e_j \in E_i\}$. At each time $x \in [0, 1]$, the unit supply seller s_i "eats" from the the non-exhausted buying event $e_j \in E_i$ of highest payment p_j. Each seller will eat at most up to a fraction of 1. A buying event is exhausted when it has been eaten for 1 unit. The result of the eating mechanism is a fractional assignment $x_i[j] \in [0, 1]$ such that $\sum_{j \in E_i} x_i[j] \leq 1$ for each seller $s_i \in S$ and $\sum_{s_i : e_j \in E_i} x_i[j] \leq 1$ for each buying event $e_j \in E$.

Revenue share of seller s_i from buying event e_j is defined as

$$r_i[j] = x_i[j] \times p_j. \tag{2}$$

The total revenue of seller s_i is also equal to $r_i = \sum_{j \in E_i} r_i[j]$.

It is easy to observe that the revenue shares by the eating mechanism can be computed in polynomial time. We first show that revenue share mechanism EM is envy-free.

▶ **Theorem 7.** *The revenue sharing scheme EM is ERSCG.*

Proof. Consider any two sellers s_i and $s_{i'}$. At any time $x \in [0, 1]$ of execution of the eating mechanism, seller s_i eats from the non-exhausted buying event $e_j \in E_i$ of highest payment p_j. At the same time x, $s_{i'}$ eats from a buying event $e_{j'}$. Buying event $e_{j'}$ is either outside E_i or it offers payment $p_{j'} \leq p_j$. When s_i stops eating, all $e_j \in E_i$ are exhausted. We conclude that the revenue of s_i on E_i is higher than the revenue of $s_{i'}$ on E_i. ◀

It is not clear that in the EM sharing scheme all sellers eat up to 1. We show in the following that EM is not exact budget balance.

▶ **Theorem 8.** *For any* $\epsilon > 0$*, the revenue sharing scheme EM is at most* $\frac{11+\epsilon}{12+\epsilon}$*-BB.*

▶ **Theorem 9.** *The revenue sharing scheme EM is* $1 - 1/e$*-BB.*

7 Conclusions

The reservation exchange market is an emerging model for internet advertising that brings together multiple publishers and advertisers interested in trading inventories of impressions available in the future. In this work, we present the axioms and the design principles at the basis of mechanisms for reservation exchange markets. The goal we define for these markets is the design of mechanisms that are incentive compatible for buyers, envy-free for sellers, efficient and budget balance. We show that this is possible if one of the requirements of budget balance or envy-freeness is slightly relaxed. Our efficient revenue sharing mechanisms are based on the notion of clinching graph that is a convenient representation of the trades of efficient VCG allocations.

We leave several open problems in the context of reservation exchange markets. First of all, it would be interesting to close some of the gaps on approximate envy-freeness and budget balance of the revenue sharing mechanisms we propose. It is also unknown whether the eating mechanism holds some of the monotonicity properties we define in this paper. Moreover, since the clinching graph seems to provide fundamental insights for designing fair revenue sharing mechanisms, it would be helpful to derive its structure from basic properties of VCG mechanisms.

Acknowledgements. We thank Marek Adamczyk for suggesting the analysis of budget balance of the eating mechanism.

Abstract

We consider the classical problem of constrained queueing (or switched networks): There is a set of N queues to which unit sized packets arrive. The queues are interdependent, so that at any time step, only a subset of the queues can be activated. One packet from each activated queue can be transmitted, and leaves the system. The set of feasible subsets that can be activated, denoted $\mathcal{S}$, is downward closed and is known in advance. The goal is to find a scheduling policy that minimizes average delay (or flow time) of the packets. The constrained queueing problem models several practical settings including packet transmission in wireless networks and scheduling cross-bar switches.

In this paper, we study this problem using the the competitive analysis: The packet arrivals can be adversarial and the scheduling policy only uses information about packets currently queued in the system. We present an online algorithm, that for any $\epsilon > 0$, has average flow time at most $O\left(\frac{R^2}{\epsilon^3}OPT + NR\right)$ when given $(1+\epsilon)$ speed, *i.e.*, the ability to schedule $(1+\epsilon)$ packets on average per time step. Here, R is the maximum number of queues that can be simultaneously scheduled, and OPT is the average flow time of the optimal policy. This asymptotic competitive ratio $O(\frac{R^2}{\epsilon^3})$ improves upon the previous $O(\frac{N}{\epsilon^2})$ which was obtained in the context of multi-dimensional scheduling [6]. In the full general model where N can be exponentially larger than R, this is an exponential improvement. The algorithm presented in this paper is based on Makespan estimates which is very different from that in [6], a variation of the Max-Weight algorithm. Further, our policy is myopic, meaning that scheduling decisions at any step are based only on the current composition of the queues. We finally show that speed augmentation is necessary to achieve any bounded competitive ratio.

1 Introduction

Stochastic processing networks [16] capture a wide range of resource allocation scenarios. In the general setting, there are a set of N queues, $Q_1, Q_2, \ldots, Q_N$. Packets of unit size arrive at these queues according to some arrival process. Time is discrete, and at each time step, at most one packet from each queue can be served (or scheduled), each packet requiring unit amount of service. The queues use shared resources for scheduling, leading to constraints on the subsets of queues that can be simultaneously scheduled. Let $\mathcal{S} = \{S_1, S_2, \ldots, S_m\}$ denote the set of feasible subsets of queues that can be simultaneously scheduled at any time slot; we assume the system $\mathcal{S}$ is downward closed so that if $S \in \mathcal{S}$, then any subset of S also belongs to $\mathcal{S}$. [1] For such a system let $R = \max_{S \in \mathcal{S}} |S|$ denote the maximum number of packets that can be simultaneously be scheduled.

Such a general model was first formulated in the seminal work of Tassiulas and Ephremides [16]. We first discuss some applications. First consider a $n \times n$ packet switch with crossbar architecture [11, 12, 4]. Packets arrive at each of the n input ports, with each packet specifying an output port to which it must be scheduled. The crossbar architecture enforces the constraint that at most one packet can be scheduled per input or output port per time slot. There are therefore $N = n^2$ queues $\{Q_{ij}\}$, one per input-output pair (i, j). Queue Q_{ij} queues packets arriving at input i for output j. A feasible subset of queues in $\mathcal{S}$ is a matching of input to output ports, so that $\mathcal{S}$ is the set of all matchings between inputs and outputs. A generalization of this setting arises in wireless networking, where there is a queue Q_{ij} between every pair of locations i and j that are within communication radius; a feasible subset of queues is any set of pairs (i, j) that can simultaneously communicate without interference.

A similar problem arises in *multicast* switch scheduling [14], where packets arriving at an input port of a crossbar switch need to be simultaneously transmitted to multiple output ports.

We now present the formal model. Packets arrive into the queues according to an adversarially chosen process during a *finite* time interval $[0, T]$. We do not constrain the number of packets that can arrive into any queue at any time step. We assume each packet suffers a delay of at least one time slot. The main objective considered in this setting is the average flow time. Let n_t denote the number of packets awaiting service at time t; this is the queue size at time t. Let n denote the total (finite) number of packets arriving in the system. Let T' be a sufficiently large time, for example, $T' = T + n$, by which any 'non-idle' algorithm can complete all packets.

$$\text{Average Flow Time } = \frac{1}{n} \sum_{t=0}^{T'} n_t \,. \tag{1}$$

A scheduling policy is an algorithm that decides (at every time slot) the set of queues to schedule. In an *online* policy, this decision is based on the number of packets in each queue, but not on the knowledge of future arrivals. Policies whose decisions are based only on queue sizes (or current system state) are termed *Markovian* in queueing theory. In this paper, we will call such policies *myopic*. Our focus will be on designing myopic policies.

Integral vs. Fractional Schedules. We make a distinction between *integral* and *fractional* schedules. The definition above assumes time is slotted into unit length slots, and we execute

[1] Such a set system is often called an independence system, and a set $S \in \mathcal{S}$ is said to be independent.

one schedule $\sigma \in \mathcal{S}$ per time slot. Using the notation in [15], let

$$\langle \mathcal{S} \rangle = \left\{ \sum_{\sigma \in \mathcal{S}} \alpha_\sigma \sigma \;\; | \;\; \sum_{\sigma \in \mathcal{S}} \alpha_\sigma \leq 1, \;\; \alpha_\sigma \geq 0 \;\; \forall \sigma \in \mathcal{S} \right\} \tag{2}$$

For each $S \in \mathcal{S}$, we let $\sigma(S)$ denote a binary vector in $2^{[N]}$ that encodes the subset of queues activated in S, and for notational convenience, we let $\sigma \in \mathcal{S}$, omitting S. The set $\langle \mathcal{S} \rangle$ therefore represents collections of schedules, each executed to a fraction, so that the total fraction is one unit. A fractional schedule executes one schedule from $\langle \mathcal{S} \rangle$ per time slot. In other words, a fractional schedule assumes time is continuous, and that packets are divisible. When α amount of schedule σ is executed, α amount of the corresponding packets leave the system. Note that an integral schedule is a special case of a fractional schedule where $\alpha_\sigma \in \{0, 1\}$ for all $\sigma \in \mathcal{S}$.

In fractional schedule, an alternative but equivalent definition of average flow time will be useful: we assume that packets are processed in first-in-first-out manner in each queue, and a packet j's completion time C_j is the earliest time when the whole packet leaves the queue. An individual packet's flow time is defined as its completion time C_j minus its arrival time at the queue, and the average flow time is the total flow time of all packets divided by the total number of packets. It is easy to see this definition of average flow time coincides with the above definition (1).

Let OPT denote the average flow time of the fractional policy that makes optimal scheduling decisions with knowledge of all future arrivals. This is a valid relaxation since allowing the optimal scheduler/the adversary to be fractional can only decrease its average flow time. Our goal is to design an online *integral* scheduling policy whose average flow time, for all input sequences, is at most $c \times OPT$. We call c as the *competitive ratio* of the policy. We will achieve this by first developing a fractional online schedule and then converting it into an integral schedule online.

1.1 Resource Augmentation Analysis and Scalable Policies

A simple example shows that no online algorithm can have bounded competitive ratio. To see this, consider a simple 2×2 crossbar switch with two input ports and two output ports. For some large L, at time $t = 0$, L packets arrive at both inputs destined for output 1. From time $t = L$ to $t = 2L - 1$, where one packet arrives per time step destined for output 2; the algorithm is not told which input port these packets arrive at. (Suppose these arrive at input 1.) Beyond this time, there is one packet per time slot arriving at input 1 for output 1 and input 2 for output 2. The optimal algorithm which knows the future, spends the first L steps serving the L packets queued at input 1. From time $t = L$ to $t = 2L - 1$, it schedules the matching of input port 1 to output 2 and input port 2 to output 1. Beyond this time, it has no queued packets, and can schedule each incoming packet in the same time slot. In the limit as $T \to \infty$, $OPT = 1$. Any online algorithm has to guess the behavior of OPT between time $t = L$ and $t = 2L - 1$. Suppose it keeps $x \leq L$ packets on input port 1 at time $t = L$, then it has x packets queued for all time $t \geq L$, leading to average flow time of x. This shows an unbounded competitive ratio even for randomized strategies.

The above example is typical of several scheduling problems when the input is adversarial [8, 7, 1], and motivates the need for *resource augmentation analysis*, a framework introduced by Kalyanasundaram and Pruhs [8]. We say that an online algorithm is given $(1 + \epsilon)$ speed for any $\epsilon > 0$, if in the integral case, the algorithm is allowed to perform an extra round of scheduling every $\lfloor \frac{1}{\epsilon} \rfloor$ time steps; or is allowed to execute schedules at rate

$(1+\epsilon)$ in the fractional case. Equivalently, the online algorithm, given no extra speed, is compared against the optimal scheduler with $(1-\epsilon)$-speed. This view is more natural since we simply constrain the space of feasible schedules used by the optimal policy to have $(1-\epsilon)$ rate, *i.e.*, use $\sum_{\sigma\in\mathcal{S}} \alpha_\sigma \leq 1-\epsilon$ in (2), and give a speed 1 to the online algorithm. This also highlights the fact that resource augmentation is purely an analysis tool – the algorithms we design are oblivious to such resource augmentation, using only the current queue sizes to make scheduling decisions. We call an algorithm *scalable* if for every $\epsilon > 0$, the competitive ratio of the algorithm is $f\left(N, \frac{1}{\epsilon}\right)$ for some function f.

We note that even with resource augmentation, the design of scalable scheduling policies is non-trivial. Consider the *stochastic* setting where packets arrive in each queue according to a Bernoulli process with known rate. This arguably benign setting is widely studied in networks [16, 12, 13, 15]. Consider an 3×3 crossbar switch, and the natural policy that maximizes instantaneous throughput: Consider the pairs of inputs and outputs such that there is at least one packet queued for that input/output pair. Find a maximum size matching of these input/output pairs and schedule this matching, choosing a matching at random if there are multiple maximum matchings. It is known [12] that for Bernoulli traffic where the arrival rates for all inputs and outputs are strictly smaller than one packet per time step, the expected queue size (and hence expected flow time) of this policy can be unbounded. However, for such input, there are other policies with bounded expected queue size (see below for more details). This directly shows that there exists some $\epsilon > 0$ for which the maximum throughput policy, even with $(1+\epsilon)$-speed has unbounded competitive ratio, and is hence not scalable.

1.2 Our Results

Our main result is a myopic scheduling policy for *arbitrary* scheduling constraints $\mathcal{S}$ whose asymptotic competitive ratio only depends on R. Recall that $R = \max_{S\in\mathcal{S}} |S|$ is the maximum number of packets that can be feasibly scheduled any time slot. We first develop a fractional online scheduler, and then convert it into a feasible integral policy.

▶ **Theorem 1.** *There is an online fractional policy, which we name* Sampling Independent Set from Min-Makespan (SISM)*, that is myopic, and is $O(\frac{R^2}{\epsilon^3}+N)$-competitive when compared to the optimal scheduler with $(1-\epsilon)$-speed. More precisely, the online policy has an average flow time $O(\frac{R^2}{\epsilon^3}\mathrm{OPT}+N)$ where* OPT *is the optimal algorithm's average flow time. If the online algorithm does not have to be myopic, the competitive ratio can be improved to $O(\frac{R^2}{\epsilon^4})$.*

We note that if OPT is large, then the competitive ratio depends only on $R = \max_{S\in\mathcal{S}} |S|$, which could be much smaller than N, and is a more robust measure of the complexity of the scheduling constraints $\mathcal{S}$. On the other hand, N can be made larger by simply splitting one queue into several "virtual queues". (A related notion to R, called *rank*, is used in [15] as a measure of the complexity of $\mathcal{S}$.) In fact, N can be exponentially larger than R. As mentioned before, the best known competitive ratio prior to this work was $O(\frac{N}{\epsilon^2})$ [6] which was found in the context of multi-dimensional scheduling. Further, our algorithm is very different from [6] which can't avoid a linear dependency on N; this previous work will be discussed in detail in Section 1.4.

Fractional Scheduling Policy. Our scheduling policy SISM is quite natural. At time step t, let n_{it} denote the (possibly fractional) number of packets queued at queue Q_i. At time t,

assuming no more packets arrive in the future, solve the makespan minimization problem: Find a fractional cover $\{\lambda(S)\}_{S\in\mathcal{S}}$ such that if these schedules are executed (in arbitrary order), then all queues Q_i are emptied, i.e. $\sum_{S:i\in S}\lambda(S) = n_{it}$. We process each independence set S at a rate in proportion to its weight $\{\lambda(S)\}$. An equivalent view which explains the algorithm's name is that each cover (independent set) S exists in $\lambda(S)$ copies, and we sample a cover uniformly, and process it by an infinitesimal amount.

We first show that our algorithm is $O(R^2/\epsilon^3)$-competitive for the fractional average flow time. Roughly speaking, the algorithm incurs a cost equal to the total remaining size of packets for the fractional flow – the discrepancy between the total remaining size and the total number of packets is at most N, hence the N appears in the competitive ratio. Alternatively, by using a standard method of converting fractional flow to integral flow, we can get a competitive ratio with no dependency on N, but the resulting algorithm is no longer myopic.

We note that the SISM has running time poly($|\mathcal{S}|$). However, for several applications, $|\mathcal{S}|$ itself may be exponential in N, the number of queues, leading to an exponential time algorithm. This dependence is unavoidable given the generality of the problem statement: For myopic policies that can not store past scheduling decisions, it is easy to check that maximizing instantaneous throughput encodes computing independent set of a general graph, a problem whose solution cannot be approximated to any constant factor unless $P = NP$. Assuming $P \neq NP$, this implies there is no myopic policy with poly(N) computation per time slot, which has bounded competitive ratio even with constant speed. Nevertheless, for the case of scheduling crossbar switches, our policy has poly(N) computation time per step using the Birkhoff-von Neumann theorem (see for instance [13]). Furthermore, as mentioned above, for settings such as scheduling jobs in data centers where the number of resources in contention is constant, we can assume $\mathcal{S}$ to have constant size.

Integral Policy. As mentioned above, we convert our fractional policy SISM into an integral scheduler on the fly using an emulation technique from [15]. For comparison, best previous policies [4] required speed of at least 2, and were specific to crossbar switches.

▶ **Theorem 2.** *There is an online integral policy that is myopic, and is $O(\frac{R^2}{\epsilon^3} + NR)$-competitive when compared to the optimal scheduler with $(1-\epsilon)$-speed. More precisely, the online policy has an average flow time $O(\frac{R^2}{\epsilon^3}\mathrm{OPT} + NR)$ where OPT is the optimal scheduler's average flow time.*

1.3 Technical Contributions

Our analysis proceeds via establishing amortized local competitiveness [7], a framework first introduced in [2]. Potential functions are often very useful when local competitiveness analysis fails. As one can deduce from (1), we can perform a strictly local competitiveness analysis if we can upper bound the number of packets alive in SISM's queues at any time by the analogous number for the optimal scheduler. However, this approach fails since the optimal scheduler can cleverly group packets and complete them more quickly than our algorithm. Intuitively, in the presence of an arbitrary independence set system $\mathcal{S}$, the number of queued packets can change very dynamically. In such settings, potential functions allow us to compare the online algorithm to the optimal scheduler more robustly over time.

As illustrated in [7], the standard approach to designing a potential function is to establish a rough estimate of the algorithm's flow time assuming that no more packets arrive. We use the minimum makespan needed to complete all queued packets as our estimate. A standard

way of converting this quantity into a potential function is to now replace each packet's remaining size with the *lag* that measures how much the algorithm is behind the optimal scheduler in processing that packet. This conversion makes the potential resilient to discrete events such as new packets arriving, and allows us to focus on how the potential changes as packets are continuously processed. However, the analysis is still complicated since SISM's schedule can be very different from OPT's schedule, which means the algorithm's processing may not change the potential in the right direction when needed.

As mentioned above, the potential we use is based on the minimum makespan when each packet's remaining size replaced with its lag, which can be very different from the minimum makespan schedule constructed by SISM. We therefore need to relate these two schedules, which is not at all obvious. It becomes crucial that SISM sample an independent set uniformly at random from its min-makespan schedule. This ensures two nice properties. First, it decreases the makespan of SISM uniformly with time. More importantly, due to the uniform sampling nature, it processes packets in proportion to their respective remaining sizes. Using these two properties, we show that if the optimal scheduler has very few packets left (and these are exactly the times when the algorithm needs the potential), the min-makepsan schedule for the packet lags (*i.e.*, the potential) mostly consists of independent sets where all packet's size decrease almost uniformly. Hence the potential decreases in the desired direction.

We finally note that we do not know how to use popular linear programming approaches, such as dual fitting [5] for this problem. We do note that it is relatively straightforward to obtain a $O(1)$-competitive algorithm with R-speed using these methods, and the hard part is to obtain a scalable algorithm.

1.4 Related Work

Constrained queueing systems are among the most widely studied settings in scheduling theory. Existing work falls in the realm of queueing theory, and has mostly focused on the stochastic case where packet arrivals are *i.i.d.* according to some stochastic process (most commonly Bernoulli or Poisson). In this context, the key assumption is that the arrival rates into the queues are feasible (in a certain natural sense), and the focus is on designing policies that are *stable*, meaning that the expected flow time is finite. The seminal result of [16] shows that the *maximum weight* policy is stable: This policy defines the weight of a queue as the number of packets waiting at the queue, and at each time step, finds a feasible schedule in $\mathcal{S}$ such that the sum of the weights of the queues in the schedule is maximized. When specialized to a $n \times n$ crossbar switch, this policy finds a maximum weight matching between inputs and outputs [12], where the weight of an input/output pair is the number of packets queued at that input for that output. In this context, for Bernoulli arrivals, this policy has expected queue size (or average flow time) $O(n^2)$ [15].

Most theoretical work on constrained queueing has focused on improving delay bounds in the stochastic setting. The work of [13] constructs a policy with average flow time $O(n \log n)$ for an $n \times n$ crossbar switch. Their algorithm considers a batch of L packets per input and output, finds a makespan minimizing schedule over L time steps for this batch, and runs this schedule for the next L steps. Such a policy is clearly not myopic since the policy is computed in batches; in addition, they set L carefully based on the input arrival rates, making the policy specific to the stochastic setting. Our policy Min-Makespan can be thought of as an online, myopic analog of this policy. Finally, the work of [15] presents a policy with expected flow time $O(n)$, which can be generalized to arbitrary constraints $\mathcal{S}$; their policy is based on modeling the constrained system $\mathcal{S}$ as a network of queues, and using

a proportional fairness type queueing policy called Store and Forward Allocation (SFA) [3, 10] on this queueing network. The SFA policy is a fractional scheduling policy that is specific to stochastic arrivals, and we need new ideas for the adversarial setting. The main contribution of [15] is an emulation of fractional scheduling policies by integral policies, and we use this same technique for converting our fractional schedules to integral ones.

We emphasize that the hard part of our problem is to obtain a *scalable* algorithm, *i.e.*, algorithms that have bounded competitive ratio for any ϵ extra speed, in addition to being myopic. It is relatively simple to obtain competitive algorithms that use speed that depends on $\mathcal{S}$. In particular, for scheduling a crossbar switch, any greedy maximal matching algorithm is 1-competitive with speed 2. In fact, in this same setting, the work of Chuang *et al.* [4] shows something far stronger: With speedup 2, suitably designed stable marriage algorithms are 1-competitive on *any* QoS property of delays (such as weighted flow time, l_k-norms of flow time, etc). However, these algorithms are specific to switch scheduling; furthermore, they have unbounded competitive ratio with speed less than 2, and are hence not scalable.

The constrained queueing problem (fractional version) is a special case of the polytope scheduling problem (PSP) formulated in [5]. The authors show that the proportional fairness (PF) algorithm [9] can be adapted to derive a competitive scheduling algorithm for this general setting. The objective considered is the sum of completion times of the jobs. Using the KKT conditions combined with dual fitting, the authors show that the PF algorithm is constant competitive on this objective even when jobs have arbitrary lengths and weights. The flow time objective we consider corresponds to the difference between completion time and release date of a job, and is typically a more difficult objective to optimize even in simpler settings.

In [6], PSP was reformulated with queues. In PSP-Q, the polytope is defined over queues. This constrains how much each queue can be processed. Then, any two jobs arriving into the same queue are interchangeable in the sense that one job can be replaced with the other job, preserving how much the queue is processed. In [6], it was shown that the Normalized Max-Weight algorithm is $(1+\epsilon)$-speed $O(N/\epsilon^2)$-competitive – roughly speaking, the maximum weight independence set is scheduled assuming that each queue's weight is equal to the number of jobs in the queue. The work in [6] can handle weighted jobs, but the linear dependency on N was unavoidable due to the nature of the algorithm. On the other hand, this paper can only handle packets of the same size, but the competitive ratio only depends on R.

2 Fractional Scheduling Policy: SISM

In this section, we present our fractional scheduling policy Sampling Independent Set from Min-Makespan (SISM), and analyze its performance for the average flow time objective. For convenience, we abuse the notation slightly to let $Q_i(t)$ denote the (possibly fractional) number of packets (or workload) waiting at queue Q_i. See Figure 1 for the description of the algorithm.

To compute a desired fractional cover, we can simply solve a linear programming over the variables $\{\lambda(S)\}_{S\in\mathcal{S}}$. Then, the running time will be a polynomial in $|\mathcal{S}|$. Note that this computation needs to be done only when new packets arrive since otherwise the optimal cover remains the same. As mentioned earlier, for the special case of switch scheduling, such an optimal cover can be computed in polynomial time in N by using the Birkhoff-von Neumann theorem; we can represent the current workload as a square matrix; and obtain a doubly stochastic matrix by adding dummy quantities so that the entries in each row and

Sampling Independent Set from Min-Makespan (SISM)
At each time t,
Compute a fractional cover $\{\lambda(S)\}_{S\in\mathcal{S}}$ that completes the workload $\{Q_i(t)\}_{i\in[N]}$ with the minimum makespan $L_Q(t)$.
(i.e., $L_Q(t) = \min \sum_{S\in\mathcal{S}} \lambda(S)$ s.t. $\sum_{S\in\mathcal{S}:i\in S} \lambda(S) = Q_i(t)$).
Schedule each independent set S at a rate of $\lambda(S)/L_Q(t)$.

Figure 1 The SISM Procedure.

column add up to $\max_i Q_i(t)$ and normalizing the matrix; and decompose it into permutation matrices.

Our scheduling policy has the following nice property.

▶ **Proposition 3.** *The policy* SISM *decreases each $Q_i(t)$ at a rate of $\frac{Q_i(t)}{L_Q(t)}$ at all times when no packets arrive or are completed by* SISM *or the optimal scheduler.*

The proof easily follows by viewing the policy as sampling an independence set uniformly from a multi-set of independent sets where each independence set S exists in $\lambda(S)$ copies, and observing each queue Q_i appears in exactly $Q_i(t)$ independent sets in the multi-set.

2.1 Potential Function

Throughout the analysis, we assume that the optimal scheduler (OPT) is restricted to $(1-10\epsilon)$-speed for $\epsilon \le 1/10$. Our analysis is based on a potential function. To formally define the potential function, we need more notation. Let $Q_i^*(t)$ denote the workload waiting at Q_i at time t in the optimal schedule. Define $Z_i(t) := \max\{Q_i(t) - Q_i^*(t), 0\}$ to be the algorithm's lag on queue Q_i compared to the optimal scheduler. Define $L_Z(t)$ to be the minimum makespan achievable assuming that each queue Q_i has $Z_i(t)$ workload. More precisely,

$$L_Z(t) := \min_{\lambda_Z} \sum_{S\in\mathcal{S}} \lambda_Z(S) \quad \text{s.t.} \quad \sum_{S\in\mathcal{S}:i\in S} \lambda_Z(S) = Z_i(t) \quad \forall i \in [N] \tag{3}$$

The potential function $\Phi(t)$ is defined as follows.

$$\Phi(t) = \frac{R}{\epsilon}(L_Z(t))^2 \tag{4}$$

2.2 High Level Idea

We first give a high-level overview of the analysis. For notational convenience, let time ∞ refer to a sufficiently large time step by which all packets are completed by our policy and the optimal scheduler. This is well-defined since the total number of packets arriving into queues is finite. Our final goal is to show

$$\int_0^\infty V(t)dt \le \frac{2R^2}{\epsilon^3} \int_0^\infty V^*(t)dt, \tag{5}$$

where $V(t) := \sum_i Q_i(t)$ denotes the total workload waiting in our algorithm's queues. Likewise, $V^*(t)$ is analogously defined for the optimal scheduler. The left-hand-side quantity is the algorithm's total fractional flow time, and the right-hand-side quantity is the optimal scheduler's total fractional flow time, which is at most the optimal scheduler's total integral

flow time. Once we establish the bound (5), using the fact that the number of packets alive at each time t is at most $V(t) + N$, we will be able to complete the analysis.

To show (5), it suffices to show that the following standard conditions are satisfied.

1. Boundary condition: $\Phi(0) = \Phi(\infty) = 0$.
2. Discontinue changes: $\Phi(t)$ does not change when a packet arrives, or is completed by the online algorithm or the optimal scheduler.
3. Continuous changes: For every time t when no job arrives or completes, $V(t) + \frac{d}{dt}\Phi(t) \leq \frac{2R^2}{\epsilon^3} V^*(t)$.

The first condition is easy to check since the potential is clearly 0 when no jobs are waiting in the algorithm's or in the optimal scheduler's queues. When a new packet arrives into Q_i, $Q_i(t)$ and $Q_i^*(t)$ both increase by 1, hence $Z_i(t)$ and $L_Z(t)$ remain the same. Completion of packets does not affect the potential since $Z_i(t)$ and $L_Z(t)$ are defined in the continuous time domain. Hence the second condition follows. Note that there are only a finite number of time steps when discontinuous changes occur.

2.3 Competitive Analysis of Queue Size

In view of the above discussion, we will focus on proving the third condition concerning continuous changes. Throughout this section, we will consider an infinitesimal time interval $[t, t + \mathrm{dt}]$ during which no discontinuous changes occur. We will consider two cases. In the first case where the algorithm has a workload comparable to that of the optimal solution, we charge the algorithm's workload plus the possible potential increase to the optimal solution's workload. In the other case, the algorithm's workload in each queue Q_i is very similar to $Z_i(t)$ which is always non-negative and measures how much the algorithm is behind the optimal solution in terms of the workload in queue Q_i. This is the case where the potential helps the algorithm in need. In this case, the algorithm will effectively decrease the makespan $L_Z(t)$ based on lags $\{Z_i(t)\}$ in the potential function, which will cancel off the potential increase due to the optimal solution's processing and give enough credits to pay for the algorithm's workload due to the extra speed the algorithm is given.

We begin with a couple of definitions.

▶ **Definition 4.** A queue Q_i is said to be tight at time t if $Z_i(t) \geq (1 - \epsilon)Q_i(t)$, otherwise loose. An independent set $S \in \mathcal{S}$ is said to be tight at time t if *all* queues in S are tight. Otherwise, S is said to be loose.

The following simple observation will be used throughout the analysis.

▶ **Proposition 5.** $L_Q(t) \leq V(t) \leq R \cdot L_Q(t)$.

To study the continuous changes of $\Phi(t)$, we will first take a close look at the optimal scheduler's effect on $\Phi(t)$, freezing the algorithm's effect. Let $\frac{d}{dt}\Phi(t)\big|_{\mathrm{OPT}}$ denote the continuous change of $\Phi(t)$ due to the optimal scheduler's processing.

▶ **Lemma 6.** $\frac{d}{dt}\Phi(t)\big|_{\mathrm{OPT}} \leq 2(1 - 10\epsilon)\frac{R}{\epsilon} L_Z(t)$.

Proof. Fix a time t and consider an infinitesimal time interval $[t_1 = t, t_2]$ where *no discontinuous changes* occur. Let $L_{Z,1}$ denote the minimum makespan for queues with workload $\{Z_i(t_1)\}_{i\in[N]}$. Let $L'_{Z,2}$ the minimum makespan for queues with workload $\{Z'_i(t_2)\}$ where $Z'_i(t_2) := \max\{Q_i(t_1) - Q_i^*(t_2), 0\} \leq \max\{Q_i(t_1) - Q_i^*(t_1), 0\} + (Q_i^*(t_1) - Q_i^*(t_2))$. Note that $(Q_i^*(t_1) - Q_i^*(t_2))$ is non-negative, and refers to the amount of work that the optimal scheduler

does for queue Q_i during $[t_1, t_2]$. Observe that $L'_{Z,2} \le L_{Z,1} + (1-10\epsilon)(t_2 - t_1)$. This is because one can empty all queues with sizes $Z_i(t_1) + (Q^*_i(t_1) - Q^*_i(t_2))$ by following the schedule that achieves the makespan $L_{Z,1}$ for workload $\{Z_i(t_1)\}$, and the optimal schedule during $[t_1, t_2]$ with 1-speed; recall that the optimal scheduler has $(1-10\epsilon)$-speed. Such a schedule only does more work than the required workload, $\{Z'_i(t_2)\}_{i\in[N]}$. Hence due to downward closedness of $\mathcal{S}$, we have $\frac{d}{dt}L_Z(t)\big|_{\mathrm{OPT}} \le 1-10\epsilon$, which completes the proof. ◀

We now study the more interesting case of continuous changes of $\Phi(t)$ due to the algorithm's processing freezing the optimal scheduler's processing. We consider two cases depending on the magnitude of the volume of loose queues. Let $V_{loose}(t)$ denote the total sum of $Q_i(t)$ over all loose queues Q_i. $V_{tight}(t)$ is similarly defined for tight queues.

Case (i): $V_{loose}(t) \ge (\epsilon/R)V(t)$, i.e. $V_{tight}(t) \le (1-\epsilon/R)V(t)$. By definition, for any loose queue Q_i, we have $Z_i(t) := \max\{Q_i(t) - Q^*_i(t), 0\} \le (1-\epsilon)Q_i(t)$, hence $Q^*_i(t) \ge \epsilon Q_i(t)$. Thus $V^*(t) \ge \sum_{i:loose} Q^*_i(t) \ge \sum_{i:loose} \epsilon Q_i(t) = (\epsilon^2/R)V(t)$. We directly charge $V(t)$ to $V^*(t)$. We also charge $\frac{d}{dt}\Phi(t)\big|_{\mathrm{OPT}}$ to $V^*(t)$. Towards this end, we use Lemma 6 together with the following simple observation which immediately follows from $Z_i(t) \le Q_i(t)$ for all i, and downward closedness of $\mathcal{S}$.

▶ **Proposition 7.** *$L_Z(t) \le L_Q(t)$.*

Hence $\frac{d}{dt}\Phi(t)\big|_{\mathrm{OPT}} \le \frac{2R}{\epsilon}L_Z(t) \le \frac{2R}{\epsilon}L_Q(t) \le \frac{2R}{\epsilon}V(t) \le \frac{2R^2}{\epsilon^3}V^*(t)$.

The algorithm's processing can only decrease $\Phi(t)$, i.e. $\frac{d}{dt}\Phi(t)\big|_{algo} \le 0$, but we do not need it in this case; in the other case, we will need a stronger bound which is stated in Lemma 10. Combining these, the desired third condition easily follows.

Case (ii): Otherwise. This is the more interesting case where the potential plays a crucial role. We begin with showing the following lemma. Intuitively, since $Z_i(t)$ is very close to $Q_i(t)$ over most queues, the makespan for workload $\{Z_i(t)\}$ should be almost as large as the makespan for workload $\{Q_i(t)\}$.

▶ **Lemma 8.** *$L_Z(t) \ge (1-3\epsilon)L_Q(t)$.*

Proof. It is easy to see that the total weight of tight independent sets in $\{\lambda_Q(S)\}$ is at least $L_Q(t) - \frac{\epsilon}{R}V(t) \ge (1-\epsilon)L_Q(t)$, since one unit of loose workload in a queue can make at most one unit of independent sets loose. In other words, among independent sets of total weight $L_Q(t)$, tight independent sets have total weight at least $(1-\epsilon)L_Q(t)$, which lower bounds how much tight independent sets contribute to the makespan. Now for the sake of contradiction, suppose that $L_Z(t) < (1-3\epsilon)L_Q(t)$. This implies that there is a way of scheduling tight queues Q_i with workload $Z_i(t) \ge (1-\epsilon)Q_i(t)$ within $(1-3\epsilon)L_Q(t)$ time steps, so all tight queues Q_i with workload $Q_i(t)$ within $(1-3\epsilon)L_Q(t)/(1-\epsilon) < (1-\epsilon)L_Q(t)$ time steps. Hence we can complete all workload appearing in the tight independent sets more quickly than $(1-\epsilon)L_Q(t)$ time steps, which is a contraction to the minimality of $L_Q(t)$. ◀

For notational convenience, let $\{\lambda_Z(S)\}$ be an optimal fractional cover that achieves the minimum makespan for workload $\{Z_i(t)\}$ as illustrated in (3). We now take a close look at $\{\lambda_Z(S)\}$ focusing on tight independent sets.

▶ **Lemma 9.** *The total weight of tight independent sets in $\{\lambda_Z(S)\}$ is at least $(1-3\epsilon)L_Z(t)$.*

Proof. Recall that the total workload of loose queues is at most $(\epsilon/R)V(t) \le \epsilon L_Q(t)$. The total weight of tight independent sets in $\{\lambda_Z(S)\}$ is then at least $L_Z(t) - \epsilon L_Q(t) \ge L_Z(t) - \epsilon L_Z(t)/(1-3\epsilon) \ge (1-3\epsilon)L_Z(t)$. The first inequality is due to Lemma 8. ◀

Let $y_i(t)$ denote the total weight of tight independent sets in $\{\lambda_Z(S)\}$ that contain queue Q_i. Since our goal is to lower bound the potential's decrease due to A's processing, we can assume that Q_i is processed at a rate of $\frac{y_i(t)}{L_Q(t)} \leq \frac{Z_i(t)}{L_Q(t)} \leq \frac{Q_i(t)}{L_Q(t)}$ due to Proposition 3 and downward closeness of $\mathcal{S}$. For each tight independent set S, imagine that we process queue Q_i in S at a rate of $\frac{\lambda_Z(S)}{L_Q(t)}$ – here note that each Q_i is processed exactly at a rate of $\frac{y_i(t)}{L_Q(t)}$ in total. Hence the weight of tight indepedent set S decreases at a rate of $\frac{\lambda_Z(S)}{L_Q(t)}$, and the total weight of tight independent sets decreases at a rate of $\frac{(1-3\epsilon)L_Z(t)}{L_Q(t)} \geq (1-3\epsilon)^2 \geq 1-6\epsilon$ by summing over all tight independent sets, and subsequently by applying Lemma 9 and 8. Hence we derive the following lemma.

▶ **Lemma 10.** $\frac{d}{dt}L_Z(t)\Big|_{algo} \leq -(1-6\epsilon)$, *and* $\frac{d}{dt}\Phi(t)\Big|_{algo} \leq -2\frac{R}{\epsilon}(1-6\epsilon)L_Z(t)$.

We are now ready to complete the analysis. By Lemma 6, 10, 8, we have $\frac{d}{dt}\Phi(t) = -8R \cdot L_Z(t) \leq -4R \cdot L_Q(t) \leq -4V(t)$. In either of the two cases, we have shown the third condition on $\Phi(t)$ concerning the continuous changes.

2.4 From Queue Size to Flow Time

So far we have shown (5). By processing packets in each queue in first-in-first-out order, we have that $0 \leq A_i(t) - Q_i(t) < 1$ for all i, where $A_i(t)$ denotes the number of packets in queue Q_i at time t. Let $A(t) := \sum_i A_i(t)$. Let $\mathcal{T}$ be the collection of maximal intervals such that $V(t) > 0$ at all times t during T, for each time interval $T \in \mathcal{T}$. Note that $A(t) = 0$ if $V(t) = 0$. Hence the algorithm's total flow time is

$$\sum_{T\in\mathcal{T}}\sum_{t\in T} A(t) \leq \sum_{T\in\mathcal{T}}\sum_{t\in T}\int_{\tau=t}^{t+1}\Big(V(t)+N\Big)d\tau \leq O(\frac{R^2}{\epsilon^3})\int_0^\infty V^*(t)dt + N\sum_{T\in\mathcal{T}}|T|$$

Since our algorithm processes at least one unit of workload at each time if it exists, it is easy to observe that $\sum_{T\in\mathcal{T}}|T|$ is at least $\Omega(1)$ times the total number of packets. Knowing that each packet has flow time at least one, we can upper bound $N\sum_{T\in\mathcal{T}}|T|$ by N times the total number of packets. By dividing both sides of the inequality by the total number of packets, we derive the first part of Theorem 1.

The second part follows by a standard method of converting an algorithm good for fractional flow time into one for integral flow time. In fact, the quantity $\int_0^\infty V(t)dt$ in Equation (5) is the algorithm's total fractional flow time, where each packet incurs a penalty equal to its remaining size. In general, one can translate an online algorithm that is c-competitive with s speed for the average fractional flow time objective online into one that is $O(c/\epsilon)$-competitive with $s(1+\epsilon)$-speed for the average integral flow objective, for any $0 \leq \epsilon < 1$. For example, see [7]. However, after this conversion, the algorithm is no longer myopic.

3 Emulation by Integral Schedules

Once we have a fractional algorithm we can convert it into an integral algorithm with a small loss in the competitive algorithm. We remind the reader that an integral algorithm must schedule exactly one independent set S out of $\mathcal{S}$ at each time t. In contrast, a fractional algorithm schedules an independent set S for any infinitesimal time step dt, and reduces each queue in S by dt. Shah et al. [15] show that given an fractional schedule B, one can obtain an integral schedule on the fly that has an $O(RN)$ upper bound on the algorithm's total lag at each time as opposed to the optimal schedule.

Let $Q_i^B(t)$ be the number of packets waiting in queue Q_i at time t in the integral algorithm B's schedule. The quantity $Q_i^A(t)$ is analogously defined for a given fractional online algorithm A – however, $Q_i^A(t)$ does not have to be integral at an integer time point. Define B's lag as opposed to A as $\Delta_i(t) := \max\{Q_i^B(t) - Q_i^A(t), 0\}$. The integral algorithm B has the following description at any time t.

- Compute a (fractional) min-makespan schedule on $\{\Delta_i(t), i = 1, 2, \ldots, N\}$.
- In the above solution, if some independent set is scheduled to an amount at least 1, schedule this independent set.
- Otherwise, let $W(t) = \{i|\Delta_i(t) \geq 1\}$. Find an independent set that schedules the most number of packets from $W(t)$, and schedule this set.

The following lemma restates Lemma 5.7 and 5.8 in [15].

▶ **Lemma 11.** *For the algorithm B as described above, we have $\sum_i \Delta_i(t) \leq R(N+2)$.*

Note that the above lemma is only concerned with the difference between the queues of the two algorithms A and B. However, we can now use an idea similar to the one we used in Section 2.4. The crucial observation is that the discrepancy $\sum_i \Delta_i(t)$ can occur only at the times where the algorithm B has at least one packet at time t; the number of such times is at least the total number of packets arriving at queues. Theorem 2 easily follows from Theorem 1 and this observation.

4 Conclusions

In this paper, we studied competitive algorithms for constrained queueing systems, which have been extensively studied in stochastic queueing theory. In queueing theory, the goal is to obtain a stable algorithm when the load reaches the inherent "system threshold". A parameter is often used to measure the proximity of the system load to the threshold. For example, in the special case of switch scheduling, the expected load arriving at queues is assumed to have a makespan at most $1 - \epsilon$ for $\epsilon > 0$. The work of [15] shows an expected total queue size of $O(R/\epsilon + RN)$, and the additive term RN is ignored assuming that ϵ is arbitrarily small. In contrast, we give an $O(R^2/\epsilon^3 + RN)$-competitive algorithm for the average flow time objective when compared to the optimal scheduler with $(1 - \epsilon)$-speed. As illustrated in the seminal paper [8] that introduced the resource augmentation analysis model, a slightly weaker adversary/benchmark is also motivated by the system threshold. The goal is to design an online algorithm whose objective is comparable to the optimal offline solution with the least possible speed augmentation for all adversarial inputs. As mentioned before, such an algorithm is said to be scalable. Despite the seemingly similar goals and motivations as well as the seemingly similar analytic bounds, the relation between queueing theory (stability) and competitive analysis (scalability) remains unclear. Our work suggests the possibility of making a rigorous connection between the two concepts.

An open problem is to get tighter upper or lower bounds on the competitive ratio, even in the special case of switch scheduling. The lower bounds in [5, 6] do not hold since it requires packets having varying sizes. The only known negative resultis that the problem does not admit a (bounded) competitive algorithm without speed augmentation. However, we cannot even rule out the existence of $O(\text{poly}(1/\epsilon))$-competitive algorithms with $(1 + \epsilon)$-speed.

Abstract

We study voting models on graphs. In the beginning, the vertices of a given graph have some initial opinion. Over time, the opinions on the vertices change by interactions between graph neighbours. Under suitable conditions the system evolves to a state in which all vertices have the same opinion. In this work, we consider a new model of voting, called the Linear Voting Model. This model can be seen as a generalization of several models of voting, including among others, pull voting and push voting. One advantage of our model is that, even though it is very general, it has a rich structure making the analysis tractable. In particular we are able to solve the basic question about voting, the probability that certain opinion wins the poll, and furthermore, given appropriate conditions, we are able to bound the expected time until some opinion wins.

1 Introduction

Graphs are very popular as a simple model of the complex environment in which individuals interact. In this paper we focus in voting models on finite graphs, in which vertices of a given graph have opinions and by interacting with their neighbours they change such opinions. Voting models can be used to mimic real-life situations such as the spread of opinions or infections in a society, the evolution of species or models of particle interaction in physics.

While many models has been proposed in the literature, we do not aim to propose a new particular model, but to unify some of the existing models in a tractable way. With this in mind, we propose a general model of voting, called the Linear Voting Model. This model subsumes several models proposed in the past, including, for example, the push model and the very popular pull model.

Even though the voter model has been widely studied in the case of infinite structures, one of the first rigorous studies on finite structures was made by Donnelly and Welsh [4]. In that work, the authors studied a continuous-time version of the pull voting model and, under the name of infection model, the push voting model. In the continuous time version, each vertex has an exponential clock and when it rings, the vertex selects a random neighbour and pulls its opinion (in the case of pull voting) or pushes its opinion on the neighbour (in the

case of push voting). On the other hand, Hassin and Peleg [6] and Nakata et al. [8] studied the discrete time version of pull voting, in which vertices do not have a clock but at each round each vertex synchronously pulls an opinion. Both papers considered the two-party model and studied its possible application to distributing computing, in particular to the agreement problem. The focus of [6] and [8] is on the probability that all vertices eventually adopt the opinion which was initially held by a given subset of vertices. They proved that the probability that opinion A wins is $d(A)/d(V)$, where $d(X)$ is the sum of the degrees of the vertices of $X \subseteq V$ and A is the set of vertices whose initial opinion was A.

The consensus time of G, i.e., the time needed for the vertices of a graph G to agree on an opinion during voting, has attracted a lot of attention, especially because a low consensus time implies a better distributed algorithm for the agreement problem. In the continuous-time setting, Oliveira [9] shows that the expected consensus time is $\mathcal{O}(H_{\max})$, where $H_{\max} = \max_{v,u \in V} H(v,u)$ and $H(v,u)$ is the hitting time of u of a random walk starting at vertex v. Furthermore, in a later work [10], Olivera proved that under certain conditions on the underlying graph G, the consensus time is concentrated around $2m(G)$, where $m(G)$ is the meeting time of two independent random walk starting in stationary distribution. It is however, not clear whether the continuous-time results apply to the discrete-time setting. Hassin and Peleg [6] using a dual process, the coalescing random walk, proved that the expected consensus time is $\mathcal{O}(m(G)\log(n))$, where $m(G)$ is the meeting time of independent discrete-time random walks, thus giving $\mathcal{O}(n^3 \log(n))$ in the worst case. By using the same approach, Cooper et al. [2] improved the previous result and proved that the consensus time is $\mathcal{O}(n/(\nu(1-\lambda_2)))$, where n is the number of vertices of G and ν is a parameter that measures the regularity of the degree sequence, ranging from 1 for regular graphs to $\Theta(n)$ for the star graph. The result of Cooper et al. achieves an upper bound of $\mathcal{O}(n^3)$ in the worst case. Berenbrink et al. [1] used a more ad hoc approach and proved that the consensus time is $\mathcal{O}((d_{\text{ave}}/d_{\min})(n/\Phi))$ where Φ is the conductance of the graph, and d_{ave}, $d_{\min}$ are the average and minimum degrees respectively.

The consensus time for the push model has not been so widely studied. Push voting is a particular class of the so-called Moran process. Díaz et al. [3] proved that the the consensus time is $\mathcal{O}(n^4 q)$ where q is the square of the sum of the inverses of the degree sequence of G, giving a consensus time of $\mathcal{O}(n^6)$ in the worst case.

1.1 Our model and results

Let $G = (V, E)$ be a graph with $|V| = n$. Define a configuration of opinions as a $n \times 1$ vector $\xi \in Q^V$, where $Q = \{0, 1\}$ for the two party model, or $Q = \{1, \ldots, n\}$ if we want to allow more parties.

Let $\mathcal{M}(V)$ be the set of all $n \times n$ matrices indexed by the elements of V, with exactly one 1 entry per row and all other elements 0. Also, define $\Pi(V)$ as the set of probability measures on $\mathcal{M}(V)$. If no confusion arises, we will just write $\mathcal{M}$ instead of $\mathcal{M}(V)$ and Π instead $\Pi(V)$.

Let $l \in \Pi$ be a distribution over matrices in $\mathcal{M}$. Given an initial configuration ξ, we define the process $(\xi_t)_{t \geq 0}$, with t running over the non-negative integers, as

$$\xi_t = \begin{cases} \xi, & \text{if } t = 0, \\ M_{t-1}\xi_{t-1}, & \text{if } t > 0, \end{cases} \tag{1}$$

where M_t are i.i.d matrices sampled from l, and $M\xi$ is the standard matrix-vector multiplication. The above process is called a **linear voting model** with parameters (l, ξ) and it

is denoted by $(\xi_t) \sim \mathcal{LVM}(l, \xi)$. Clearly, $\xi_t(v)$ represents the opinion of vertex v at round t. Consider $M \in \mathcal{M}$ and $\xi' = M\xi$, then if al vertices have different opinions, we have that $\xi'(v) = \xi(w)$ if and only if $M(v, w) = 1$. Since M has only one 1 in each row, the voting is well-defined in the sense at every round each vertex adopts the opinion of only one vertex (including itself). Examples of linear voting models include the pull voting (asynchronous or synchronous) and the push voting model.

We proceed to present our contribution. Theorem 1 of this paper gives the probability a particular opinion wins. This generalises the approach used in [6]. Theorem 2 gives an upper bound to the expected consensus time. Our technique is qualitatively different from the approach of previous authors which depended on a detailed dualisation of the voting process, indeed, we follow an approach similar to Levin et al. [7, chapter 17] or Berenbrink [1].

Let $l \in \Pi$ and define the mean matrix H of l as

$$H = H(l) = \sum_{M \in \mathcal{M}} l(M)M.$$

From Lemma 4 we have that H is the transition Matrix of a Markov Chain with state space V. We denote by μ the stationary distribution of H (if any). Define the consensus time τ_{cons} as the first time all the opinions are the same, i.e, there exists c such that $\xi_{\tau_{\text{cons}}}(v) = c$ for all $v \in V$. Observe τ_{cons} is a stopping time and that c is the final opinion of the vertices. We have the following theorem about the winning probability.

▶ **Theorem 1.** *Let $(\xi_t) \sim \mathcal{LVM}(l, \xi)$ be a linear voting model with mean matrix H with $\xi \in \{0, 1\}^V$. Assume that H has a unique stationary distribution μ and that $\tau_{\text{cons}} < \infty$, then*

$$\mathbb{P}(\textit{opinion } 1 \textit{ wins} | \xi_0 = \xi) = \sum_{v \in V} \mu(v)\xi(v).$$

The above theorem solves the winning probability problem under reasonable conditions, so we focus on the consensus time problem.

Consider the two party model and let S_t be the set of vertices with opinion 1 at the beginning of round t. Denote $\mu(S_t) = \sum_{v \in S_t} \mu(v)$, where μ is the stationary distribution of H, and $Z_t = \mu(S_{t+1}) - \mu(S_t)$. Let $\mu^* = \min_{v \in V} \mu(v)$. Define the quantity Ψ as

$$\Psi = \mu^* \min_{\substack{S \subseteq V \\ S \neq \emptyset, V}} \frac{\mathbb{E}(|Z_0||S_0 = S)}{\min\{\mu(S), 1 - \mu(S)\}}, \tag{2}$$

where the minimum is over all $S \subseteq V$ except $S = \emptyset$ and $S = V$. Using the above definitions we prove the following theorem.

▶ **Theorem 2.** *Let $(\xi_t)_{t \geq 0} \sim \mathcal{LVM}(l, \xi)$ with $\xi \in \{0, 1\}^V$ be a voting model with $\Psi > 0$ then*

$$\mathbb{E}(\tau_{\text{cons}}) \leq 64/\Psi.$$

The structure of the paper is as follows. In Section 2 we introduce the model and give some examples to gain some intuition and demonstrate the flexibility of the model. In Section 3, we introduce the necessary notation to prove Theorem 1. In Section 4 we prove Theorem 2.

Notation. $G = (V, E)$ stands for a simple graph. We assume $|V| = n$. For $v \in V$ we denote by $N(v)$ the neighbourhood of v and define $d(v) = |N(v)|$. Moreover, given $X \subseteq V$, we define $d(X)$ as the sum of the degrees of the vertices in X. We use the notation $v \sim w$ to say that v and w are adjacent vertices. Q stands for the set of possible opinions, in general

$Q = \{0, 1\}$ or $Q = \{1, \dots, n\}$. We denote by $\mathcal{M}$ the set of $n \times n$ matrices with exactly one 1 in each row and 0 in the other positions. Let Π be the set of probability distribution on $\mathcal{M}$, and $l \in \Pi$ be a given probability distribution over matrices in $\mathcal{M}$. $M^\top$ denotes the transpose of the matrix M.

2 The linear voting model.

Recall the definition of a linear voting model. Given $l \in \Pi$ and $\xi \in Q^V$ we say $(\xi_t)_{t\geq 0} \sim \mathcal{LVM}(l, \xi)$ if $\xi_0 = \xi$ and $\xi_{t+1} = M_t\xi_t$, $t \geq 0$, where the M_t are i.i.d. samples from l. The following models are examples of linear voting.

(a) Synchronous pull model. At each round each vertex samples a random neighbour and adopts the opinion of such neighbour.

(b) Asynchronous pull model. At each round one vertex v is selected at random, then it samples a random neighbour and v adopts the opinion of this neighbour.

(c) Asynchronous push model. At each round a vertex v is selected at random, then it samples a random neighbour and the neighbour adopts the opinion of v.

(d) Abusive push model. At each round one vertex v is selected at random and the whole neighbourhood adopts the opinion of v.

(e) Pull-push model. At each round one vertex v is selected at random, and two neighbours u_1, u_2 are selected randomly (with replacement). Then at the same time, u_1 adopts the opinion of v while v adopts the opinion of u_2.

▶ Remark. To be precise, the changes in the opinions happen at the end of a round t, prior to round $t + 1$. In particular if v adopts the opinion of w at round t, it means that at round $t + 1$, vertex v has the opinion of w at round t.

▶ **Lemma 3.** *The five models defined above are linear voting models.*

Proof Sketch. We just prove it for the first and second model. For the other models the proof is similar. Let ξ_t be the configuration of opinions at round t. In the synchronous pull voting at each round each vertex v samples a random neighbour $w(v)$ and then v adopts the opinion of $w(v)$. Call ξ_{t+1} the new configuration of opinion. We check that $\xi_{t+1} = M\xi_t$ where the (random) matrix M is given by $M(v, w(v)) = 1$ for all $v \in V$, and 0 for the others entries. It is straightforward to check that $M\xi_t(v) = M(v, w(v))\xi(w(v)) = \xi_t(w(v)) = \xi_{t+1}(v)$ and also that M has only one 1 in each row and thus $M \in \mathcal{M}$.

For the asynchronous pull model, observe that only one vertex v is selected and then v adopts the opinion of a random vertex $w(v)$, while all other vertices keep their opinions unchanged. Call ξ_{t+1} the new configuration. Define M as $M(v, w(v)) = 1$, $M(u, u) = 1$ for all $u \neq v$ and 0 for all other entries (M is like the identity matrix, except in the column of v). It is not hard to check that the random matrix M mimics the asynchronous pull model, i.e. $\xi_{t+1} = M\xi_t$, and that $M \in \mathcal{M}$. ◀

Remember we define the mean matrix of $l \in \Pi$ as $H = H(l) = \sum_{M\in\mathcal{M}} l(M)M$. Since most of the models are described by rules rather than by giving the explicit distribution l, it might be hard to compute $H(l)$. Nevertheless, the following lemma helps us to compute H without exhibiting l explicitly.

▶ **Lemma 4.** *For any distribution l over matrices in $\mathcal{M}$, the matrix $H = H(l)$ is the transition matrix of a Markov chain. Moreover, for every $t \geq 0$, and $v, w \in V$,*

$$H(v, w) = \mathbb{P}(v \text{ adopts the opinion of } w \text{ at round } t)\,. \tag{3}$$

Proof. Note that, as each element of M is a transition matrix (the rows sum up to 1), H is the convex combination of transition matrices and thus is a transition matrix. To prove the second part note that by conditioning on the configuration ξ_t we have that

$$\mathbb{E}(\xi_{t+1}|\xi_t) = \sum_{M\in\mathcal{M}} l(M)(M\xi_t) = \left(\sum_{M\in\mathcal{M}} l(M)M\right)\xi_t = H\xi_t. \tag{4}$$

Choose ξ_t such that the opinion of w is 1 and all other opinions are 0. Then the event $\{v$ adopts the opinion of w at round $t\}$ is equal to $\{\xi_{t+1}(v) = 1\}$. Thus, from equation (4)

$$\mathbb{P}(\xi_{t+1}(v) = 1|\xi_t) = \mathbb{E}(\xi_{t+1}(v)|\xi_t) = (H\xi_t)(v) = \sum_{w\in V} H(v,w)\xi_t(w) = H(v,w). \quad \blacktriangleleft$$

Let P be the transition matrix of a simple random walk on G, A the adjacency matrix of G and let I denote the identity matrix. Let $L = D - A$ be the combinatorial Laplacian where D is the diagonal matrix containing the degree sequence of G. Moreover, let F be the diagonal matrix defined by $F(v,v) = \sum_{w:w\sim v} 1/d(w)$. The next theorem gives the matrix H for the linear voting models used in our examples.

▶ **Theorem 5.** *The mean matrix of the synchronous pull, asynchronous pull, push, abusive push, pull-push models are, respectively,* $H_a = P$ *[6] and*

$$H_b = \frac{n-1}{n}I + \frac{1}{n}P, \quad H_c = I + \frac{1}{n}P^\top - \frac{1}{n}F, \quad H_d = I - \frac{1}{n}L, \quad H_e = \frac{1}{n}(P+P^\top) + \frac{n-1}{n}I - \frac{1}{n}F.$$

Proof Sketch. We compute H_a. Observe that $H_a(v,w)$ is the probability that v adopts the opinion of w. That happens only if the random neighbour selected for v is w. Then $H_a(v,w) = \frac{1}{d(v)}\mathbb{1}_{v\sim w}$, concluding that $H_a = P$. For H_b, remember that in asynchronous pull we select a random vertex v and then v adopts the opinion of a random neighbour $w(v)$. Observe that for a vertex u we have $H_b(u,u)$ is the probability that u adopts the opinion of u, i.e. the probability that u does not change the opinion. That happen with probability $(n-1)/n$, On the other hand if $w \sim v$ then we have $H_b(v,w) = 1/nd(v)$ because v has to be initially selected and then v has to select w from its neighbourhood. We conclude that $H_b = ((n-1)/n)I + (1/n)P$. The other cases are similar. ◀

3 Winning probability

The most basic question in any voting model is, 'who wins?'. In order to answer this question we use some martingale arguments. Assume the two-party model, $Q = \{0,1\}$. Since the mean matrix H of a linear voting model is a transition matrix, then all its eigenvalues lie in $[-1,1]$. We order the eigenvalues in decreasing order, i.e. $1 = \lambda_1 \geq \lambda_2 \ldots, \geq \lambda_n$. Let λ be an eigenvalue of $H^\top$ (H and $H^\top$ have the same eigenvalues) with corresponding eigenvector f, that is $H^\top f = \lambda f$. Given $f, g \in \mathbb{R}^V$, we denote $\langle f, g\rangle = \sum_{v\in V} f(v)g(v)$ the standard inner product. Observe that $Q \subseteq \mathbb{R}$, so if $\xi \in Q^V$ and $f \in \mathbb{R}^V$, the inner product $\langle f, \xi\rangle = \sum_{v\in V} f(v)\xi(v)$ is well-defined.

▶ **Lemma 6.** *The process* $(\langle f, \xi_t\rangle/\lambda^t)_{t\geq 0}$ *is a martingale with respect to* $(\xi_t)_{t\geq 0}$

Proof. Since $\langle f, \xi_t\rangle$ is bounded, we can check that $\mathbb{E}(\langle f, \xi_{t+1}\rangle|\xi_t) = \lambda\langle f, \xi_t\rangle$ and divide both sides by λ^{t+1}. By linearity of (conditional) expectation and equation (4) we have

$$\mathbb{E}(\langle f, \xi_{t+1}\rangle|\xi_t) = \langle f, H\xi_t\rangle = \langle H^\top f, \xi_t\rangle = \lambda\langle f, \xi_t\rangle . \quad \blacktriangleleft$$

Since H is a transition matrix, if the associated Markov chain is recurrent and aperiodic then the Markov chain has a unique stationary distribution. Denote this stationary distribution by μ. It is a classic result of the theory of finite Markov chains that μ, interpreted as a vector, is the unique eigenvector of $H^\top$ with eigenvalue 1. We assume the vector μ is scaled so that $\sum_{v\in V}\mu(v)=1$. Since, among all eigenvectors, μ is the most important we denote by $m_t=\langle\mu,\xi_t\rangle$ the martingale associated with the eigenvalue 1, and we call this martingale the **voting martingale**.

Proof of Theorem 1. Denote by $\mathbf{1}$ and $\mathbf{0}$ the vector where all components are 1 and 0 respectively. Since $(\xi_t)_{t\geq 0}$ always reaches consensus, it converges to $\mathbf{1}$ or $\mathbf{0}$ and thus $(m_t)_{t\geq 0}$ converges to 1 or 0. Moreover, $0\leq m_t=\sum_{v\in V}\mu(v)\xi_t(v)\leq 1$ for every $\xi_t\in\{0,1\}^V$, so $(m_t)_{t\geq 0}$ is a bounded martingale. These two properties of $(m_t)_{t\geq 0}$, together with the fact that τ_{cons} is a stopping time, allows us to apply the optional stopping theorem [5] to conclude $\mathbb{E}(m_0)=\mathbb{E}(m_{\tau_{\text{cons}}})$. Since $\xi_0=\xi$ is a deterministic quantity then $\mathbb{E}(m_0)=m_0$. Moreover

$$\mathbb{E}(m_{\tau_{\text{cons}}})=\langle\mu,\mathbf{1}\rangle\mathbb{P}(\xi_{\tau_{\text{cons}}}=\mathbf{1}|\xi_0=\xi)+\langle\mu,\mathbf{0}\rangle\mathbb{P}(\xi_{\tau_{\text{cons}}}=\mathbf{0}|\xi_0=\xi)=\mathbb{P}(\xi_{\tau_{\text{cons}}}=\mathbf{1}|\xi_0=\xi).$$

Hence $\mathbb{P}(\xi_{\tau_{\text{cons}}}=\mathbf{1}|\xi_0=\xi)=m_0=\langle\mu,\xi\rangle$, therefore

$$\mathbb{P}(\text{opinion 1 wins}|\xi_0=\xi)=\sum_{v\in V}\mu(v)\xi(v).$$ ◀

▶ **Corollary 7.** *Assume the same conditions of Theorem 1 but consider $Q=\{1\ldots,,n\}$. Suppose that $\xi\in Q^V$. Then the probability that $k\in Q$ wins is*

$$\mathbb{P}(\xi_{\tau_{\text{cons}}}=k\mathbf{1}|\xi_0=\xi)=\sum_{v\in V:\xi(v)=k}\mu(v).$$

Proof. Replace opinion k by opinion 1 and all other opinions by opinion 0, and then use Theorem 1 ◀

▶ **Theorem 8.** *Let G be a connected graph. Let A be the set of vertices whose initial opinion is 1. Then, given that the models reach consensus, the probability p that opinion 1 wins is*

(a) *synchronous pull model: $p_a=d(A)/d(V)$*
(b) *asynchronous pull model: $p_b=d(A)/d(V)$*
(c) *push model: $p_c=(\sum_{v\in A}d(v)^{-1})/(\sum_{v\in V}d(v)^{-1})$*
(d) *abusive pushing model: $p_d=|A|/n$*
(e) *pull-push model : $p_e=|A|/n$.*

Proof. We apply Theorem 1. For that we need to find the stationary distribution of the above models. The stationary distribution of P is $\pi(v)=d(v)/d(V)$, that gives us the result for synchronous pull. Observe that $(n-1)/nI+(1/n)P$ is a lazy version of the random walk of P, then it has the same stationary distribution, giving us the result for the asynchronous pull model. For the push model we just guess the stationary distribution and check it. Let $C=1/(\sum_{v\in V}d(v)^{-1})$ and let $\pi'(v)=C/d(v)$, then as $F=F^\top$

$$\begin{aligned}(H_c^\top\pi)(v) &= ((I+\frac{1}{n}P-\frac{1}{n}F)\pi')(v)=\pi'(v)+\frac{1}{n}\sum_{w\in V}P(v,w)\pi'(w)-\frac{1}{n}F(v,v)\pi'(v)\\ &= \pi'(v)+\frac{1}{n}\sum_{w:w\sim v}\frac{1}{d(v)}\frac{C}{d(w)}-\frac{C}{d(v)n}\sum_{w:w\sim v}\frac{1}{d(w)}=\pi'(v)\end{aligned}$$

proving that π' is the stationary distribution of the mean matrix of the push model. For the abusive pushing model observe that as $I-(1/n)L$ is a symmetric matrix, its stationary distribution is uniform. H_e is also symmetric, giving the result for the push-pull model. ◀

4 Consensus Time

In this section we assume the two-party model with opinions $Q = \{0, 1\}$. Let $(\xi_t)_{t\geq 0} \sim \mathcal{LVM}(l, \xi)$ be a linear voting model. Assume $H = H(l)$ has a unique stationary distribution and let $(m_t)_{t\geq 0}$ be the voting martingale defined in Section 3. We use the following convenient notation. Let S_t be the set of vertices with opinion 1 at the beginning of round t, let $\mu(S_t) = m_t = \langle \mu, \xi_t \rangle$, and let $Z_t = \mu(S_{t+1}) - \mu(S_t)$. Note that, since $\mu(S_t)$ is a martingale, $\mathbb{E}(Z_t | S_t = S) = 0$. The random variable Z_t gives us information about the change in the measure of the set S_t. A larger value of $|Z_t|$ implies voting finishes faster.

Let $\eta(S) = \min\{\mu(S), \mu(S^c)\}$, where $\mu(S^c) = 1 - \mu(S)$. Denote by η_t the process $\eta(S_t)$. Since $\mu(S_t) \in [0, 1]$ we have $\eta_t \in [0, 1/2]$. Recall that $\mu(V) = 1$ and $\mu(\emptyset) = 0$. Note that $\eta_{t+1} = \min\{\mu(S_t) + Z_t, \mu(S_t^c) - Z_t\}$. Noting that if $\eta_t = \mu(S_t)$, i.e. $\mu(S_t) \leq \mu(S_t^c)$, then

$$\eta_{t+1} \leq \mu(S_{t+1}) = \mu(S_t) + Z_t = \eta_t + Z_t,$$

and if $\eta_t = \mu(S_t^c)$, the same applies by noticing that $\mu(S_{t+1}^c) - \mu(S_t^c) = -Z_t$, i.e.

$$\eta_{t+1} \leq \mu(S_{t+1}^c) = \mu(S_t^c) - Z_t = \eta_t - Z_t,$$

then in both cases we get

$$\eta_{t+1} \leq \eta_t + \rho_t Z_t, \tag{5}$$

where $\rho_t = \rho(S_t) = 2\mathbb{1}_{\{\mu(S_t) \leq \mu(S_t^c)\}} - 1$. Observe $\rho_t \in \{-1, +1\}$. We are going to study the process $\sqrt{\eta_t}$, in particular, $\mathbb{E}(\sqrt{\eta_t})$. Define $\Upsilon(S)$ by

$$\Upsilon(S) = \mathbb{E}\left(Z_t^2 \mathbb{1}_{\{\rho_t Z_t < 0\}} \middle| S_t = S\right) \tag{6}$$

and define $\Upsilon = \min \frac{\Upsilon(S)}{\eta(S)}$, where the minimum is over all $S \subseteq V$ but $S \neq \emptyset$ and $S \neq V$. With these ingredients we are ready to prove a technical lemma, which is fundamental for the proof of Theorem 2.

▶ **Lemma 9.** *Let $(\xi_t)_{t\geq 0} \sim \mathcal{LVM}(l, \xi)$ with $\xi \in \{0, 1\}^V$ be a voting model with $\Upsilon > 0$ then*

$$\mathbb{E}(\tau_{\text{cons}}) \leq 32/\Upsilon.$$

Proof. We borrow part of the argument from [1]. Let $S \subseteq V$ but $S \neq \emptyset$ and $S \neq V$. By conditioning on $S_t = S$, from equation (5) we have $\eta_{t+1} \leq \eta_t + \rho_t Z_t = \eta(S) + \rho_t Z_t$ (we replace η_t by $\eta(S)$ as $S_t = S$ is fixed). Then, by taking expectations

$$\begin{aligned}
\mathbb{E}(\sqrt{\eta_{t+1}} | S_t = S) &\leq \sqrt{\eta(S)}\mathbb{E}\left(\sqrt{1 + \frac{\rho_t Z_t}{\eta_t}} \middle| S_t = S\right) \\
&= \sqrt{\eta(S)}\mathbb{E}\left(\left(\sqrt{1 + \frac{\rho_t Z_t}{\eta_t}}\right) \mathbb{1}_{\{\rho_t Z_t \geq 0\}} \middle| S_t = S\right) \qquad (7) \\
&\quad + \sqrt{\eta(S)}\mathbb{E}\left(\left(\sqrt{1 + \frac{\rho_t Z_t}{\eta_t}}\right) \mathbb{1}_{\{\rho_t Z_t < 0\}} \middle| S_t = S\right). \qquad (8)
\end{aligned}$$

Let $x = \rho_t Z_t / \eta_t$. It can be checked that $x \geq -1$. Indeed, from equation (5) we have $\rho_t Z_t \geq \eta_{t+1} - \eta_t \geq -\eta_t$, concluding $x \geq -1$.

For $x \geq -1$ the following partial Taylor expansions are valid,

$$\sqrt{1+x} \leq 1 + \frac{x}{2}, \tag{9}$$

$$\sqrt{1+x} \leq 1 + \frac{x}{2} - \frac{x^2}{8} + \frac{x^3}{16}. \tag{10}$$

To upper bound (7) use (9), and for (8) use (10). Recall that, since $\mu(S_t)$ is a martingale, then $\mathbb{E}(Z_t|S_t = S) = 0$. After some rearrangement, we obtain

$$\begin{aligned}
\mathbb{E}(\sqrt{\eta_{t+1}}|S_t = S) &\leq \sqrt{\eta(S)} - \sqrt{\eta(S)}\mathbb{E}\left(\left(\frac{(\rho_t Z_t)^2}{8\eta_t^2} - \frac{(\rho_t Z_t)^3}{16\eta_t^3}\right)\mathbb{1}_{\{\rho_t Z_t<0\}}\middle| S_t = S\right) \\
&\leq \sqrt{\eta(S)} - \sqrt{\eta(S)}\mathbb{E}\left(\frac{Z_t^2}{8\eta_t^2}\mathbb{1}_{\{\rho_t Z_t<0\}}\middle| S_t = S\right) \\
&= \sqrt{\eta(S)} - \frac{\Upsilon(S)}{8\eta(S)^{3/2}} \leq \sqrt{\eta(S)} - \frac{\Upsilon}{8\eta(S)^{1/2}}
\end{aligned} \tag{11}$$

In the second inequality we used the fact that we are working in $\{\rho_t Z_t < 0\}$ and after that we used the definition of $\Upsilon(S)$ from (6) and $\Upsilon = \min(\Upsilon(S)/\eta(S))$. Remember that $\eta(\emptyset) = \eta(V) = 0$, then

$$\begin{aligned}
\mathbb{E}(\sqrt{\eta_{t+1}}) &= \sum_{S\subseteq V} \mathbb{E}(\sqrt{\eta_{t+1}}|S_t = S)\mathbb{P}(S_t = S) = \sum_{S:S\neq\emptyset,V} \mathbb{E}(\sqrt{\eta_{t+1}}|S_t = S)\mathbb{P}(S_t = S) \\
&\leq \sum_{S:S\neq\emptyset,V} \left(\sqrt{\eta(S)} - \frac{\Upsilon}{8\eta(S)^{1/2}}\right)\mathbb{P}(S_t = S) \qquad (12) \\
&= \mathbb{E}(\sqrt{\eta_t}) - \sum_{S:S\neq\emptyset,V} \left(\frac{\Upsilon}{8\eta(S)^{1/2}}\right)\mathbb{P}(S_t = S|\tau_{\text{cons}} > t)\mathbb{P}(\tau_{\text{cons}} > t) \\
&= \mathbb{E}(\sqrt{\eta_t}) - \frac{\Upsilon}{8}\mathbb{E}\left(\frac{1}{\sqrt{\eta_t}}\middle|\tau_{\text{cons}} > t\right)\mathbb{P}(\tau_{\text{cons}} > t), \qquad (13)
\end{aligned}$$

where (12) follows using equation (11). As $1/x$ is convex for $x > 0$, apply Jensen's inequality to the random variable $x = \sqrt{\eta_t}$, to obtain

$$\mathbb{E}\left(\frac{1}{\sqrt{\eta_t}}\middle|\tau_{\text{cons}} > t\right) \geq \frac{1}{\mathbb{E}\left(\sqrt{\eta_t}\middle|\tau_{\text{cons}} > t\right)} = \frac{\mathbb{P}(\tau_{\text{cons}} > t)}{\mathbb{E}\left(\sqrt{\eta_t}\right)}. \tag{14}$$

The last equality holds because the event $\{\tau_{\text{cons}} \leq t\}$ implies that the vertices reached consensus, then $S_t = \emptyset$ or $S_t = V$, hence $\eta_t = 0$, and then

$$\begin{aligned}
\mathbb{E}(\sqrt{\eta_t}) &= \mathbb{E}(\sqrt{\eta_t}|\tau_{\text{cons}} > t)\mathbb{P}(\tau_{\text{cons}} > t) + \mathbb{E}(\sqrt{\eta_t}|\tau_{\text{cons}} \leq t)\mathbb{P}(\tau_{\text{cons}} \leq t) \\
&= \mathbb{E}(\sqrt{\eta_t}|\tau_{\text{cons}} > t)\mathbb{P}(\tau_{\text{cons}} > t).
\end{aligned}$$

By substituting (14) into (13) we obtain

$$\mathbb{E}(\sqrt{\eta_{t+1}}) \leq \mathbb{E}(\sqrt{\eta_t}) - \frac{\Upsilon}{8}\frac{\mathbb{P}(\tau_{\text{cons}} > t)^2}{\mathbb{E}\left(\sqrt{\eta_t}\right)},$$

then as $\eta_t \in [0, 1/2]$

$$\frac{\Upsilon}{8}\mathbb{P}(\tau_{\text{cons}} > t)^2 \leq \mathbb{E}(\sqrt{\eta_t})(\mathbb{E}(\sqrt{\eta_t}) - \mathbb{E}(\sqrt{\eta_{t+1}})) \leq \frac{\mathbb{E}(\sqrt{\eta_t}) - \mathbb{E}(\sqrt{\eta_{t+1}})}{\sqrt{2}}.$$

Summing from $t = 0$ up to a time $T - 1$ we have

$$\Upsilon \sum_{t=0}^{T-1} \mathbb{P}(\tau_{\text{cons}} > t)^2 \leq 8 \frac{\mathbb{E}(\sqrt{\eta_0}) - \mathbb{E}(\sqrt{\eta_T})}{\sqrt{2}} \leq 4. \tag{15}$$

Let T be the minimum time t such that $\mathbb{P}(\tau_{\text{cons}} > t) < 1/2$, then for every $t < T$ we have $\mathbb{P}(\tau_{\text{cons}} > t) \geq 1/2$. Therefore, from equation (15), it holds that

$$T \leq 16/\Upsilon.$$

Note that our bound for T is independent of the initial position, so we assume the worst case. We compute $\mathbb{E}(\tau_{\text{cons}})$ by looking at the process every T steps. If at round T the process finished then $\tau_{\text{cons}} \leq T$, otherwise, we restart the process and look again after T steps until we reach consensus. As the probability the process does not finish in T steps is at most $1/2$, we conclude that

$$\mathbb{E}(\tau_{\text{cons}}) \leq \sum_{k=1}^{\infty} kT \left(\frac{1}{2}\right)^k \leq 2T \leq \frac{32}{\Upsilon}. \qquad \blacktriangleleft$$

We need the following simple lemma.

▶ **Lemma 10.** *Let X be an integrable random variable with mean 0 then*

$$\mathbb{E}(|X|\mathbb{1}_{\{X<0\}}) = \mathbb{E}(|X|)/2.$$

Proof. Let $X^+ = X\mathbb{1}_{\{X>0\}}$ and $X^- = |X|\mathbb{1}_{\{X<0\}}$. Clearly $X = X^+ - X^-$ and $|X| = X^+ + X^-$. Then we have the system of equations

$$\begin{aligned} \mathbb{E}(X^+) - \mathbb{E}(X^-) &= \mathbb{E}(X) = 0, \\ \mathbb{E}(X^+) + \mathbb{E}(X^-) &= \mathbb{E}(|X|). \end{aligned}$$

Then $\mathbb{E}(X^-) = \mathbb{E}(X^+) = \mathbb{E}(|X|)/2$. ◀

We proceed with the proof of Theorem 2

Proof of Theorem 2. From Lemma 9 we have

$$\mathbb{E}(\tau_{\text{cons}}) \leq 32/\Upsilon,$$

where $\Upsilon = \min \frac{\Upsilon(S)}{\eta(S)}$ and the minimum is over all $S \subseteq V$ other than $S = \emptyset$ and $S = V$. Observe that if $|Z_t| > 0$, it means that at least one vertex changes its opinion, thus $|Z_t| \geq \mu^* = \min_{v \in V} \mu(v)$. From there

$$\begin{aligned} \Upsilon(S) &= \mathbb{E}\left(Z_t^2 \mathbb{1}_{\{\rho_t Z_t < 0\}} \middle| S_t = S\right) = \mathbb{E}\left((\rho_t Z_t \mathbb{1}_{\{\rho_t Z_t < 0\}})^2 \middle| S_t = S\right) \\ &\geq \mu^* \mathbb{E}\left(|\rho_t Z_t \mathbb{1}_{\{\rho_t Z_t < 0\}}| \middle| S_t = S\right) \end{aligned} \tag{16}$$

Note that $\mathbb{E}(\rho_t Z_t | S_t = S) = \rho(S)\mathbb{E}(Z_t|S_t) = 0$ because $\mu(S_t)$ is a martingale. Using Lemma 10 in equation (16), gives $\Upsilon(S) \geq \mu^* \mathbb{E}(|Z_t||S_t)/2$. Hence $\Upsilon \geq \mu^* \min \frac{1}{2} \frac{\mathbb{E}(|Z_t||S_t)}{\eta(S)}$. Recalling the definition of Ψ in equation 2, we conclude $\Upsilon \geq \Psi/2$ and therefore

$$\mathbb{E}(\tau_{\text{cons}}) \leq \frac{64}{\Psi}. \qquad \blacktriangleleft$$

We apply the above theorems to our examples. We use the following notation. Given $S \subseteq V$, denote by $E(S : S^c)$ the number of edges going from S to S^c. Denote by $d_S(v)$ the number of vertices of S adjacent to v. Observe that $E(S : S^c) = \sum_{v \in S} d_{S^c}(v) = \sum_{v \in S^c} d_S(v)$. We denote the graph conductance by $\Phi(G) = \min_{S \subseteq V} \frac{E(S:S^c)}{\min\{d(S), d(S^c)\}}$ where $0/0 = \infty$.

▶ **Example 11.** Consider the asynchronous pulling model on a graph G.

$$\mathbb{E}(|Z_t||S_t = S) = \sum_{v\in S} \frac{d(v)}{d(V)} \frac{1}{n} \frac{d_{S^c}(v)}{d(v)} + \sum_{v\in S^c} \frac{d(v)}{d(V)} \frac{1}{n} \frac{d_S(v)}{d(v)}.$$

Why? With probability $1/n$ we select vertex v and this vertex selects a random neighbour w with probability $1/d(v)$, and adopts its opinion. The stationary distribution of v is $\mu(v) = d(v)/d(V)$. If w has the same opinion as v, then $Z_t = 0$, but if w has the opposite opinion then $|Z_t| = d(v)/d(V)$. Then

$$\mathbb{E}(|Z_t||S_t = S) = \frac{1}{nd(V)} \left(\sum_{v\in S} d_{S^c}(v) + \sum_{v\in S^c} d_S(v) \right) = \frac{2E(S : S^c)}{nd(V)} \tag{17}$$

therefore from (2)

$$\Psi = \frac{d_{\min}}{d(V)} \frac{2}{n} \min_S \frac{E(S : S^c)}{\min\{d(S), d(S^c)\}} \tag{18}$$

Hence we conclude that $\mathbb{E}(\tau_{con}) = \mathcal{O}(nd(V)/d_{\min}\Phi)$. This gives a consensus time of $\mathcal{O}(n^2)$ for expanders, which is optimal up to a constant. For the cycle, $\mathcal{O}(n^3)$ optimal as well.

▶ **Example 12.** Consider the push model on a graph G. Let $C = (\sum_{v\in V} d(v)^{-1})^{-1}$.

$$\mathbb{E}(|Z_t||S_t = S) = \sum_{v\in S} \frac{C}{d(v)} \sum_{w:w\sim v, w\in S^c} \frac{1}{nd(w)} + \sum_{v\in S^c} \frac{C}{d(v)} \sum_{w:w\sim v, w\in S} \frac{1}{nd(w)}.$$

The above equation holds because to change the opinion of a vertex $v \in S$, the push model needs to select a vertex $w \in S^c$ adjacent to v and then w needs to push its opinion on v. That happens with probability $1/(nd(w))$. In such case, the change in $|Z_t|$ is $\mu(v) = C/d(v)$. The same applies if $v \in S^c$. Then

$$\mathbb{E}(|Z_t||S_t = S) = 2\frac{C}{n} \sum_{v\in S} \sum_{w\in S^c} \frac{\mathbb{1}_{v\sim w}}{d(v)d(w)}. \tag{19}$$

By using the notation $J(S) = \sum_{v\in S} d(v)^{-1}$ and that the stationary distribution is $\mu(v) = C/d(v)$ we have

$$\Psi = \frac{2C}{nd_{\max}} \min_S \frac{\sum_{v\in S} \sum_{w\in S^c} \frac{\mathbb{1}_{v\sim w}}{d(v)d(w)}}{\min\{J(S), J(S^c)\}}.$$

The parameter Ψ does not seem related to the classical graph parameters.

▶ **Example 13.** We continue with the abusive push model on a graph G.

$$\mathbb{E}(|Z_t||S_t = S) = \sum_{v\in S} \frac{1}{n} \frac{d_{S^c}(v)}{n} + \sum_{v\in S} \frac{1}{n} \frac{d_S(v)}{n}.$$

The above equation holds because with probability $1/n$ we sample a vertex v. Then v pushes its opinion on all its neighbours. Since the stationary distribution for this model is $\mu(v) = 1/n$, then the change in $|Z_t|$ is $d_{S^c}(v)/n$ if $v \in S$ and $d_S(v)/n$ if $v \in S^c$. Then $\mathbb{E}(|Z_t||S_t) = \frac{2}{n^2} E(S : S^c)$. Then it holds that

$$\Psi = \frac{2}{n^2} \min_S \frac{E(S : S^c)}{\min\{|S|, |S^c|\}} \tag{20}$$

The parameter $\min_S \frac{E(S:S^c)}{\min\{|S|,|S^c|\}}$ is very similar to the graph conductance, indeed, for d-regular graphs $\min_S \frac{E(S:S^c)}{\min\{|S|,|S^c|\}} = d\Phi(G)$. In such case we have that

$$\mathbb{E}(\tau_{\text{cons}}) = \mathcal{O}\left(\frac{n^2}{d\Phi}\right).$$

That gives us a $\mathcal{O}(n^2/d)$ time for regular expanders, which is optimal when the degree is constant. For the complete graph it gives us $\mathcal{O}(n)$, which is far from optimal, since the abusive push model finishes in just one round on the complete graph. For a cycle it gives us a $\mathcal{O}(n^3)$ time which is optimal.

▶ **Example 14.** Our final example is for the pull-push model. In this model the stationary distribution is uniform. Then the only way to produce a positive change in $|Z_t|$ is that when the random vertex v is chosen to pull and push, it selects one neighbour in S and the other in S^c. In that case, the change in $|Z_t|$ will be of $1/n$, then

$$\mathbb{E}(|Z_t||S_t = S) \quad = \quad \sum_{v\in V} \frac{1}{n^2} \frac{d_{S^c}(v) d_S(v)}{d(v)^2}.$$

Then

$$\Psi = \frac{1}{n^2} \min_S \sum_{v\in V} \frac{d_{S^c}(v) d_S(v)}{d(v)^2} \Big/ \min\{|S|, |S^c|\}.$$

Once again Ψ does not seem related to the classical graph parameters.

5 Discussion

In this paper we introduced and studied the linear voting model. The model can be seen as a generalisation of many models of voting. Despite its generality, the process is tractable and we can compute the probability that a given opinion wins. Moreover, by using a suitable potential function we were able to provide a bound for the expected consensus time. Furthermore, applying this bound in specific cases led to classical graph parameters, such as conductance, as well to other less familiar, or even new, parameters.

Future work includes the study of particular models on interesting graph families, like expanders, transitive graphs or random graphs, as well as the development of new techniques to analyse the model.

Abstract

We consider an asynchronous voting process on graphs which we call discordant voting, and which can be described as follows. Initially each vertex holds one of two opinions, red or blue say. Neighbouring vertices with different opinions interact pairwise. After an interaction both vertices have the same colour. The quantity of interest is T, the time to reach consensus, i.e. the number of interactions needed for all vertices have the same colour.

An edge whose endpoint colours differ (i.e. one vertex is coloured red and the other one blue) is said to be discordant. A vertex is discordant if its is incident with a discordant edge. In discordant voting, all interactions are based on discordant edges. Because the voting process is asynchronous there are several ways to update the colours of the interacting vertices.

- *Push:* Pick a random discordant vertex and push its colour to a random discordant neighbour.
- *Pull:* Pick a random discordant vertex and pull the colour of a random discordant neighbour.
- *Oblivious:* Pick a random endpoint of a random discordant edge and push the colour to the other end point.

We show that $\mathbf{E}T$, the expected time to reach consensus, depends strongly on the underlying graph and the update rule. For connected graphs on n vertices, and an initial half red, half blue colouring the following hold. For oblivious voting, $\mathbf{E}T = n^2/4$ independent of the underlying graph. For the complete graph K_n, the push protocol has $\mathbf{E}T = \Theta(n \log n)$, whereas the pull protocol has $\mathbf{E}T = \Theta(2^n)$. For the cycle C_n all three protocols have $\mathbf{E}T = \Theta(n^2)$. For the star graph however, the pull protocol has $\mathbf{E}T = O(n^2)$, whereas the push protocol is slower with $\mathbf{E}T = \Theta(n^2 \log n)$.

The wide variation in $\mathbf{E}T$ for the pull protocol is to be contrasted with the well known model of synchronous pull voting, for which $\mathbf{E}T = O(n)$ on many classes of expanders.

1 Introduction

We consider a type of asynchronous distributed voting process on graphs which we call discordant voting, and which can be described as follows. Initially each vertex holds one of two opinions, red or blue say. Neighbouring vertices of different colours, i.e. whose opinions differ, interact pairwise. After an interaction both vertices have the same colour. If, at some step, all vertices have the same colour, we say that a consensus has been reached.

The problem of reaching consensus in graph by means of local interactions is an abstraction of the behavior of both human society and computer networks. As a consequence the process of voting on graphs has been widely studied. Distributed voting finds application in various fields of computing including consensus and leader election in large networks [4, 12], serialisation of read and write in replicated data-bases [10], and the analysis of social behavior in game theory [21]. Voting algorithms are usually simple, fault-tolerant, and easy to implement [12, 14]. Recently, there has been considerable interest in *population protocols*. In this model the interacting vertices can make limited computations using a finite state machine to address a wide range of problems in distributed computing, see e.g. [2].

The classical model, synchronous pull voting, is reasonably well understood. If the colours of the vertices are initially distinct, the randomized process takes $\Theta(n)$ expected steps to reach consensus on many classes of expander graphs on n vertices. This holds for the complete graph K_n (Aldous [1]), and almost all r-regular random graphs [7]. For general results based on the eigenvalue gap and variance of the degree sequence see [6]. Hassin and Peleg [12] and Nakata *et al.* [17] considered the two-party pull voting model on connected graphs, and discussed its application to consensus problems in distributed systems.

In contrast to the case of synchronous voting, where only the pull protocol is well defined, for asynchronous voting, there are at least three ways to update the colours of the interacting vertices.

- *Push:* Pick a random vertex and push its colour to a random neighbour.
- *Pull:* Pick a random vertex and pull the colour of a random neighbour.
- *Oblivious:* Pick a random endpoint of a random edge and push the colour to the other end point.

Discordant voting originated in the complex networks community as a model of social evolution (see e.g. [11], [18]). The general version of the model allows *rewiring*. The interacting vertices can break edges joining them and reconnect elsewhere. This serves as a model of social interaction in which vertices will either change their opinion or their friends.

Holme and Newman [13] investigated discordant voting as a model of a self-organizing network which restructures based on the acceptance or rejection of differing opinions among social groups. At each step, a random discordant edge uv is selected, and an endpoint $x \in \{u, v\}$ chosen with probability $1/2$. With probability $1 - \alpha$ the opinion of x is pushed to the other endpoint y, and with probability α, y breaks the edge and rewires to a random vertex with the same opinion as itself. Simulations suggested the existence of threshold behavior in α. This was investigated further by Durrett et al. [8] for sparse random graphs of constant average degree 4. The paper studies two rewiring strategies, rewire-to-random, and rewire-to-same, and finds experimental evidence of a phase transition in both cases. Basu and Sly [3] made a formal analysis of rewiring for Erdos-Renyi graphs $G(n, 1/2)$ with $1 - \alpha = \beta/n$, $\beta > 0$ constant. They found that for either strategy, if β is sufficiently small the network quickly disconnects maintaining the initial proportions. As β increases the minority proportion decreases, and in rewire-to-random a positive fraction of both opinions survive.

Although discordant voting seems a natural model of local interaction, its behavior, is

not well understood even in the simplest cases. The aim of this paper is a fundamental study of expected time to consensus in the absence of rewiring. As discordant voting always chooses an edge between the red and blue sets, it should be more efficient, and thus finish faster than an asynchronous pull voting process which ignores this information, and takes $\Omega(n^2)$ steps on many classes of sparse graphs (see [5]). However, we find the performance of discordant voting protocols vary considerably with the structure of the underlying graph, and sometimes in a quite counter-intuitive way.

We suppose that the initial vertex colours in the two-party voting model are red and blue, and let $R(t), B(t)$ denote the sets of vertices with the given colours at any step t. For the oblivious protocol, the expected time to completion is the same for any connected graph on n vertices and is independent of graph structure or the number of edges. It depends only on the initial number of vertices of each colour ($R(0)$, $B(0)$). Whenever a discordant edge is chosen, the number of blue vertices in the graph increases (resp. decreases) by one with probability $1/2$. This is equivalent to an unbiased random walk on the line $(0, 1, ..., n)$ with absorbing barriers, starting from $R(0) = r$ red vertices. Thus $\mathbf{E}T = r(n - r)$ (see Feller [9, XIV.3]).

▶ Remark. *Oblivious protocol.* Let T be the time to consensus in the two-party asynchronous discordant voting process starting from any initial coloring with an equal number of red and blue vertices $R = r, B = n - r$. For any connected n vertex graph, $\mathbf{E}T(\text{Oblivious}) = r(n - r)$.

In stark contrast to the oblivious protocol, the discordant push and pull protocols can exhibit very different expected times to consensus, and which depend strongly on the underlying graph in question.

▶ **Theorem 1.** *Let T be the time to consensus of the asynchronous discordant voting process starting from any initial coloring with an equal number of red and blue vertices $R = B = n/2$. For the complete graph K_n, and for random graphs $G_{n,p}$, $np \geq \log n\sqrt{n}$, $\mathbf{E}T(Push) = \Theta(n \log n)$, and $\mathbf{E}T(Pull) = \Theta(2^n)$.*

For reasons of brevity we do not reproduce the proof for $G_{n,p}$ here, but will make it available in the full version of this paper. The interesting point is that for the complete graph K_n and random graphs $G_{n,p}$ the different protocols give very different expected completion times, which vary from $\Theta(n \log n)$ for push, to $\Theta(n^2)$ for oblivious to $\Theta(2^n)$ for pull. On the basis of this evidence, our initial view was that there should be a meta-theorem of the "push is faster than oblivious, oblivious is faster than pull" type. Intuitively, this is supported by the following argument. Suppose red (R) is the larger colour class. Choosing a discordant vertex uniformly at random, favors the selection of the larger class. In the push process, red vertices push their opinion more often, which tends to increase the size of R. Conversely, the pull process tends to re-balance the set sizes. If R is larger, it is recoloured more often.

If the graph has limited expansion, the behavior of discordant voting differs considerably from the above examples. For the cycle C_n, all three protocols are similar.

▶ **Theorem 2.** *Let T be the time to consensus of the asynchronous discordant voting process starting from any initial coloring with an equal number of red and blue vertices $R = B = n/2$. For any of the Push, Pull or Oblivious protocols on the cycle C_n, $\mathbf{E}T = \Theta(n^2)$.*

At this point we were left with a difficult choice. Either to produce evidence for a relationship of the form $\mathbf{E}T(\text{Push}) = O(\mathbf{E}T(\text{Pull}))$, or to refute it. Mossel and Roch [16] found slow convergence of the iterated prisoners dialemma problem (IPD) on caterpillar trees. Intuitively push voting is aggressive, whereas pull voting is altruistic, and thus similar to cooperation in IPD. Motivated by this, we found the star graph S_n as a counter example.

▶ **Theorem 3.** *Let T be the time to consensus in the two-party asynchronous discordant voting process starting from any initial coloring with an equal number of red and blue vertices $R = B = n/2$. For the star graph S_n, $\mathbf{E}T(Push) = \Theta(n^2 \log n)$, and $\mathbf{E}T(Pull) = O(n^2)$.*

For stars, experiments show a clear difference in $\mathbf{E}T$ for three protocols. For cycles the difference is smaller and depends on the initial colouring. See Fig. 4 of Section 5.1.

A major problem in analysing discordant voting, is that the effect of recolouring a vertex is not always monotone. For each of the graphs studied, the way to bound $\mathbf{E}T$ differs. The proof of the pull voting result for the cycle C_n in particular, is somewhat delicate, and requires an analysis of the optimum of a linear program based on a potential function.

Asynchronous discordant voting model

We next give a formal definition of the discordant voting process. Given a graph $G = (V, E)$, with $n = |V|$. Each vertex $v \in V$ is labelled with an *opinion* $X(v) \in \{0, 1\}$. We call X a *configuration* of opinions. We can think of the opinions as having colours; e.g. red (0) and blue (1), or black (0) and white (1) (see e.g. Figure 2). An edge $e = uv \in E$ is *discordant* if $X(u) \neq X(v)$. Let $K(X)$ denote the set of discordant edges at time t. A vertex v is discordant if it is incident with any discordant edge, and $D(X)$ will denote the set of discordant vertices in X. We consider three random update rules for opinions X_t at time t.

Push: Choose $v_t \in D(X_t)$, uniformly at random, and a discordant neighbour u_t of v_t uniformly at random. Let $X_{t+1}(u_t) \leftarrow X_t(v_t)$, and $X_{t+1}(w) \leftarrow X_t(w)$ otherwise.

Pull: Choose $v_t \in D(X_t)$, uniformly at random, and a discordant neighbour u_t of v_t uniformly at random. Let $X_{t+1}(v_t) \leftarrow X_t(u_t)$, and $X_{t+1}(w) \leftarrow X_t(w)$ otherwise.

Oblivious: Choose $\{u_t, v_t\} \in K(X_t)$ uniformly at random. With probability $1/2$, $X_{t+1}(v_t) \leftarrow X_t(u_t)$, with probability $1/2$, $X_{t+1}(u_t) \leftarrow X_t(v_t)$, and $X_{t+1}(w) \leftarrow X_t(w)$ otherwise.

These three processes are Markov chains on the configurations in G, in which the opinion of exactly one vertex is changed at each step. Assuming G is connected, there are two absorbing states, when $X(v) = 0$ for all $v \in V$, or $X(v) = 1$ for all $v \in V$, where no discordant vertices exist. When the process reaches either of these states, we say that is has converged. Let T be the step at which convergence occurs. Our object of study is $\mathbf{E}T$.

Structure of the paper. In Section 2 we prove results for a Birth-and-Death chain which we call the Push chain. This chain can be coupled with many aspects of the discordant voting process. We then prove Theorems 1, 2 and 3 in that order.

2 Birth-and-Death chains

A Markov chain $(X_t)_{t\geq 0}$ is said to be a Birth-and-Death chain on state space $S = \{0, \ldots, N\}$ if given $X_t = i$ then the possible values of X_{t+1} are $i + 1, i$ or $i - 1$ with probability p_i and q_i respectively. We assume that $q_0 = p_N = 0$, and $p_0 = 1$, $q_N = 1$, and $p_i > 0$, $q_i > 0$ otherwise. Denote by $\mathbf{E}_i T_j$ the expected hitting time of state j starting from state i, i.e. $T_j = \min\{t \geq 0 : X_t = j,\ X_0 = i\}$. We summarize the results we require on Birth-and-Death chains (see Peres, Levin and Wilmer [15, 2.5]).

A probability distribution π satisfies the detailed balance condition, if

$$\pi(i)P(i, j) = \pi(j)P(j, i), \text{ for all } i, j \in S. \tag{1}$$

Birth-and-Death chains with $p_i = P(i, i+1), q_i = P(i, i-1)$ can be shown to satisfy the detailed balance equations. It follows from this, (see e.g. [15]) that

$$\mathbf{E}_{i-1}T_i = \frac{1}{q_i\pi(i)}\sum_{k=0}^{i-1}\pi(k) \tag{2}$$

An equivalent formulation (see [15]) is $\mathbf{E}_0T_1 = 1/p_0 = 1$ and in general

$$E_{i-1}T_i = \sum_{k=0}^{i-1}\frac{1}{p_k}\frac{q_{k+1}\cdots q_{i-1}}{p_{k+1}\cdots p_{i-1}}, \qquad \text{for } i \in \{1,\ldots,N\}. \tag{3}$$

In writing this expression we follow the convention that if $k = i-1$ then $\frac{q_{k+1}\cdots q_{i-1}}{p_{k+1}\cdots p_{i-1}} = 1$ so that the last term is $1/p_{i-1}$. Note also that the final index k on p_k is $k = N-1$, i.e. we never divide by $p_N = 0$.

Starting from state 0, let T_M be the number of transitions needed to reach state M for the first time. For any $M \le N$, we have that $\mathbf{E}_0T_M = \sum_{i=1}^{M}\mathbf{E}_{i-1}T_i$. For example, $\mathbf{E}_0T_1 = \frac{1}{p_0} = 1$ and $\mathbf{E}_0T_2 = 1 + \frac{1}{p_1} + \frac{q_1}{p_0p_1}$ etc. Thus, for $M \ge 1$

$$\mathbf{E}_0T_M = \sum_{i=1}^{M}\mathbf{E}_{i-1}T_i = \sum_{i=1}^{M}\sum_{k=0}^{i-1}\frac{1}{p_k}\prod_{j=k+1}^{i-1}\frac{q_j}{p_j}. \tag{4}$$

We next define a Birth-and-Death chain, the push chain, which features in our analysis. The chain has states $\{0, 1, ..., i, ..., N\}$ where $N = n/2$ (assume $n \ge 2$ even). The transition probabilities from state i given by $P(i, i+1)$, $Q(i, i+1) = 1 - P(i, i+1)$.

Let Z_t be the state occupied by the push chain at step $t \ge 0$. Let $\delta \in \{-1, 0, +1\}$ be fixed. When applying results for the push chain in our proofs, we will state the value of δ we use. The transition probability $p_i = P(i, i+1)$ from $Z_t = i$, is given by

$$p_i = \begin{cases} 1, & \text{if } i = 0 \\ 1/2 + i/n + \delta/n, & \text{if } i \in \{1,\ldots,n/2-1\} \\ 0, & \text{if } i = n/2 \end{cases}. \tag{5}$$

For a proof of the following lemma see [5].

▶ **Lemma 4.** *Let $\mathbf{E}_0T_M$ be the expected hitting time of M in the push chain Z_t starting from state 0. For any $M \le N$,*

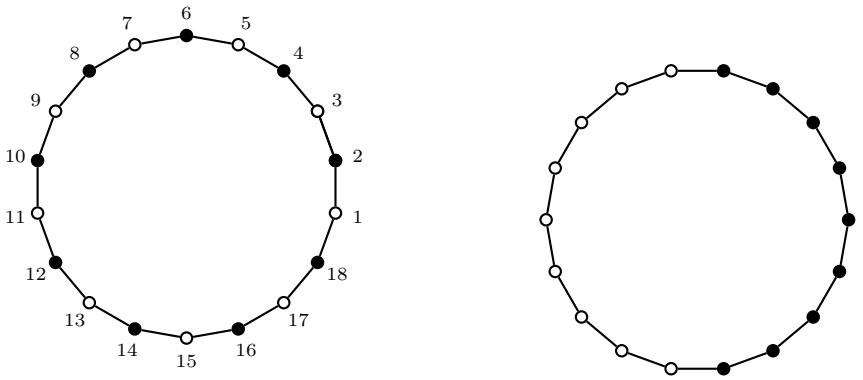
$$\mathbf{E}_0T_M \le 2N\log M + O(1). \tag{6}$$

For any $\sqrt{N} \le M = o(N^{3/4})$, there exists a constant $C > 0$ such that

$$\mathbf{E}_0T_M \ge C(N\log(M/\sqrt{N}) + \sqrt{N}). \tag{7}$$

3 Voting on the complete graph K_n

For the complete graph K_n, the probability B increases at a given step is $B(t)/n$, whereas in the pull process it is $R(t)/n = 1 - B(t)/n$. The chain defined by $Y_t = \max\{R(t), B(t)\} - n/2$ is a Birth-and-Death chain. We study the time that takes Y_t to reach $N = n/2$ starting from 0.



(a) All $X(i) = i \bmod 2$ **(b)** Lower bound configuration

Figure 1 A cycle with $n = 18$. Example colourings.

Push process. For the push model, the process Y_t is identical to the push chain Z_t with transitions p_i given by (5), with $\delta = 0$. The result of Theorem 1 that $\mathbf{E}T(\text{Push}) = \Theta(n \log n)$ follows from Lemma 4.

Pull process. As pull is the opposite of push, the pull process Y_t has transitions given by $\overline{p}_i = 1 - p_i$, i.e. . Thus $\overline{p}_0 = 1$, $\overline{p}_i = 1/2 - i/n$ if $i \in \{1, \dots, N-1\}$, and $\overline{p}_N = 0$.

Let $w_k = \binom{n}{N+k}, k = 0, 1, \dots, N$. Then w_k satisfies the detailed balance equation (1). Hence we have $\pi(k) = w_k/W$, where $W = w_0 + w_1 + \cdots + w_N$. It follows from (2) that

$$\mathbf{E}_{i-1}T_i = \frac{2n}{n+2i} \cdot \frac{1}{\binom{n}{N+i}} \cdot \sum_{k=0}^{i-1} \binom{n}{N+k}.$$

Putting $i = N$ we have

$$\mathbf{E}_{N-1}T_N = \sum_{k=0}^{N-1} \binom{n}{N+k} = \frac{1}{2}\left(2^n - 2 + \binom{n}{N}\right) = \Omega(2^n).$$

On the other hand, an upper bound

$$\sum_{i=1}^{N} \mathbf{E}_{i-1}T_i \le 2 \cdot 2^n \cdot \sum_{i=1}^{N} \frac{1}{\binom{n}{N+i}} = O(2^n),$$

follows from a result of Sury [19], that

$$\sum_{i=1}^{N} \frac{1}{\binom{n}{N+k}} = \frac{n+1}{2^n} \sum_{i=0}^{n} \frac{2^i}{i+1} = O(1).$$

4 Voting on the cycle

An n-cycle G, with $V = [n]$, has $E = \{(i, i+1) : i \in [n]\}$, where we identify vertex $n+i$ with vertex i. See Fig. 1(i).

If $X(i) \neq X(i+1) = X(i+2) = \cdots = X(j) \neq X(j+1)$, we say $i+1, i+2, \dots, j$ is a *run* of vertices of length $(j-i)$ $(1 \le j - i < n)$. Note that the number of runs is equal to the number of discordant edges $k(X)$. Also k is even, since red and blue runs must alternate,

so we can write $r(X) = \frac{1}{2}k(X)$, and $k_0 = 2r_0 = k(X_0)$. Thus $r(X)$ is the number of paths of a given colour. A *singleton* is a run of length 1. Since they lie in two discordant edges, singletons require special treatment. Let $s(X)$ denote the number of singletons. There are $\kappa = 2k - s$ discordant vertices, so $k \le \kappa \le 2k$.

We wish to determine the convergence time T for an arbitrary configuration X_0 of the push or pull process to reach an absorbing state X_T with $X_T(i) = X_T(1)$ $(i \in [n])$. In this process, the run lengths behave rather like symmetric random walks on the line. However, an analysis using classical random walk techniques [9] seems problematic. There are two main difficulties. Firstly, the k "walks" (run lengths) are correlated. If a run is long, the adjacent runs are likely to be shorter, and vice versa. Secondly, when the recoloured vertex is a singleton, the three adjacent runs are combined, so three walks suddenly merge into one. One of the three runs is a singleton, but the other two may have arbitrary lengths. We use the random walk view only for a lower bound on the convergence time.

▶ **Lemma 5.** *Let G is an n-cycle, with $n = 2N$ even, and suppose the process starts with $X_0(i) = 0$ $(i = 1, \ldots, N)$, $X_0(i) = 1$ $(i = N+1, \ldots, n)$, then $\mathbf{E}[T] = \Omega(n^2)$.*

Let L_t be the length of (say) the red run at step t, so $L_0 = N$, (see Fig. 1(ii)), and $L_T \in \{0, n\}$. The number of runs $k(X_t)$ can only be reduced from two to zero if either $L_t = 1$ or $L_t = n-1$, when one of the runs is a singleton. Up to this point, L_t is a symmetric simple random walk and the push and pull processes proceed identically. Thus $\mathbf{E}[T]$ is bounded below by the expected time for a symmetric simple random walk started at N to reach either 1 or $(n-1)$. By Remark 1, $\mathbf{E}[T] \ge (N-1)^2 = \Omega(n^2)$.

4.1 Upper bound for push voting: Proof that $\mathbf{E}[T] = O(n^2)$

Let the k runs in X have lengths $\ell_1, \ell_2, \ldots, \ell_k$ respectively, thus $\sum_{i=1}^{k} \ell_i = n$. Thus T is the first t for which $k(X_t) = r(X_t) = 0$, (a cycle is not a path). For an upper bound on $\mathbf{E}[T]$, we define a *potential function*

$$\psi(X) \;=\; \sum_{i=1}^{k} \sqrt{\ell_i}\,,$$

where $\psi(X) = 0$ if and only if $k(X) = 0$. The important feature of ψ is that it is a separable and strictly concave function of the ℓ_i $(i \in [k])$.

▶ **Lemma 6.** *For any configuration X on the n-cycle with k runs, $\psi(X) \le \sqrt{kn}$.*

Proof. If $k = 0$, this is clearly true. Otherwise, if $k \ge 2$, by concavity we have $\psi(X)/k = \frac{1}{k}\sum_{i=1}^{k}\sqrt{\ell_i} \le \sqrt{\frac{1}{k}\sum_{i=1}^{k}\ell_i} = \sqrt{n/k}$, so $\psi(X) \le \sqrt{kn}$. ◀

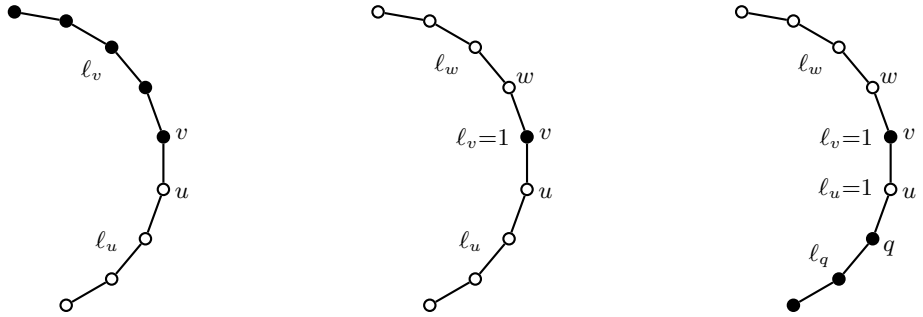
Observe that $k(X_{t+1}) = k(X_t)$ at step t of either the push or pull process, unless the recoloured vertex is a singleton, in which case we may have $k(X_{t+1}) = k(X_t) - 2$. Thus $\{t : k(X_t) = 2r\}$ is an interval $[t_r, t_{r-1})$, which we will call *phase* r of the process.

Let $v_t = v \in D(X_t)$ be the active vertex, i.e. the vertex selected to push in the push rule, or pull in the pull rule. Let δ_v be the expected change in ψ, i.e.

$$\delta_v \;=\; \mathbf{E}[\,\psi(X_{t+1}) - \psi(X_t) \mid v_t = v\,].$$

If there are $\kappa = 2k - s$ discordant vertices, the total expected change δ in ψ is

$$\delta \;=\; \mathbf{E}[\psi(X_{t+1}) - \psi(X_t)] \;=\; \frac{1}{\kappa}\sum_{v \in D} \delta_v. \tag{8}$$



(A) u and v not singleton **(B)** u not singleton, v singleton **(C)** u and v both singleton

Figure 2 Cases for discordant edge uv.

We will show that δ is negative, so $\psi(X_t)$ is monotonically decreasing with t, in expectation. Unfortunately we cannot simply bound δ_v for each $v \in D$, since it is possible to have $\delta_v > 0$. Thus we will consider discordant *edges*. We partition the set K of discordant edges uv into three subsets, Note that k can change only if $uv \in B \cup C$.

(A) $A = \{uv : u \text{ and } v \text{ not singleton}\}$;
(B) $B = \{uv : u \text{ not singleton, } v \text{ singleton}\}$;
(C) $C = \{uv : u \text{ and } v \text{ both singleton}\}$.

See Fig. 2. Let ℓ_z be the length of the run containing discordant vertex z, for $z \in \{u, v, w, q\}$.

Now let

$$\lambda_{uv} = \begin{cases} \sqrt{\ell_u} + \sqrt{\ell_v}, & uv \in A\,; \\ \sqrt{\ell_u} + \frac{1}{2}\sqrt{\ell_v}, & uv \in B\,; \\ \frac{1}{2}\sqrt{\ell_u} + \frac{1}{2}\sqrt{\ell_v}, & uv \in C\,. \end{cases} \qquad \delta_{uv} = \begin{cases} \delta_u + \delta_v, & uv \in A\,; \\ \delta_u + \frac{1}{2}\delta_v, & uv \in B\,; \\ \frac{1}{2}\delta_u + \frac{1}{2}\delta_v, & uv \in C\,. \end{cases}$$

Each singleton is in two discordant edges, all other discordant vertices in one, and each run is bounded by two discordant vertices. Therefore

$$\psi = \tfrac{1}{2}\sum_{v\in D}\sqrt{\ell_v} = \sum_{uv\in K}\lambda_{uv}\,, \qquad \delta = \frac{1}{\kappa}\sum_{v\in D}\delta_v = \frac{1}{\kappa}\sum_{uv\in K}\delta_{uv}\,.$$

We will show that $\delta_{uv} < 0$ for all $uv \in K$. For the proof of the following lemma see [5].

▶ **Lemma 7.** *For all three cases (A)–(C), and for all $uv \in K$,*
For push voting, $\delta_{uv} < -\frac{1}{5}(\ell_v^{-3/2} + \ell_u^{-3/2})$. For pull voting, $\delta_{uv} < -\frac{1}{10}(\ell_v^{-3/2} + \ell_u^{-3/2})$.

The following proof that $\mathbf{E}[T] = O(n^2)$ is for push voting. The upper bound on $\mathbf{E}[T]$ for pull voting is at most twice that for push. Using Lemma 7 we evaluate δ in (8).

$$\delta = \frac{1}{\kappa}\sum_{v\in D}\delta_v = \frac{1}{\kappa}\sum_{uv\in K}\delta_{uv} \le -\frac{1}{5\kappa}\sum_{uv\in K}(\ell_v^{-3/2} + \ell_u^{-3/2}) < -\frac{1}{5\kappa}\sum_{v\in D}\ell_v^{-3/2}\,.$$

Thus

$$\mathbf{E}[\psi(X_{t+1})] < \psi(X_t) - \frac{1}{5\kappa}\sum_{v\in D}\ell_v^{-3/2}\,.$$

Since $f(x) = x^{-3}$ is a convex function, $\mathbf{E}[f(X)] \ge f(\mathbf{E}[X])$ by Jensen's inequality [20, 6.6], so

$$\frac{1}{\kappa}\sum_{v\in D}\ell_v^{-3/2} \ge \Big(\frac{1}{\kappa}\sum_{v\in D}\sqrt{\ell_v}\Big)^{-3} = \Big(\frac{\kappa}{2\psi(X_t)}\Big)^3 \ge \Big(\frac{k}{2\psi(X_t)}\Big)^3,$$

Therefore,

$$\mathbf{E}[\psi(X_{t+1})] \;<\; \psi(X_t) - \frac{1}{5}\Big(\frac{k}{2\psi(X_t)}\Big)^3 \;=\; \psi(X_t) - \frac{k^3}{40\psi(X_t)^3}\,. \tag{9}$$

Recall that for $r \in [r_0]$, phase r of the process, during which the number of runs is $k = 2r$, is the interval $[t_r, t_{r-1})$. During phase r, by Lemma 6, $\psi(X_t) \le \sqrt{kn}$. Using this in (9) gives

$$\mathbf{E}[\psi(X_{t+1})] - \psi(X_t) \;\le\; -\tfrac{1}{40}k^3/(kn)^{3/2} \;=\; -\tfrac{1}{40}(k/n)^{3/2}\,. \tag{10}$$

Let $\gamma_r = \frac{1}{40}(2r/n)^{3/2}$. Then (10) implies that $Y_t = \psi(X_t) + (t - t_r)\gamma_r$ is a supermartingale [20, 10.3] during phase r, and t_{r-1} is a stopping time. Let $\varphi_r = \mathbf{E}[\psi(X_{t_r})]$, and let $m_r = \mathbf{E}[t_{r-1} - t_r]$. The optional stopping theorem [20, 10.10] implies that

$$\varphi_{r-1} + \gamma_r m_r \;=\; \mathbf{E}[\psi(X_{t_{r-1}}) + \gamma_r(t_{r-1} - t_r)] \;\le\; \mathbf{E}[\psi(X_{t_r})] \;=\; \varphi_r\,,$$

which implies

$$\varphi_r - \varphi_{r-1} \;\ge\; \gamma_r m_r \;=\; \tfrac{1}{40}m_r(2r/n)^{3/2} \qquad (r \in [r_0])\,. \tag{11}$$

Note, in particular, that $\varphi_r \ge \varphi_{r-1}$ for all $r \in [r_0]$. When $r_0 = \frac{1}{2}k(X_0)$, $t_{r_0} = 0$ and, since $r(X_T) = k(X_T) = 0$, when $t_0 = T$ then $\varphi_0 = 0$.

Let $x_r = \varphi_r - \varphi_{r-1} \ge 0$, for $r \in [r_0]$, so $\varphi_r = \sum_{i=1}^{r} x_j \le \sqrt{2rn}$. Also, from (11), we have $m_r \le 40x_r(n/2r)^{3/2} = 10\sqrt{2}\,n^{3/2}x_r/r^{3/2}$, so $\mathbf{E}[T] = \sum_{j=1}^{r_0} m_j < 10\sqrt{2}\,n^{3/2}\sum_{j=1}^{r_0} x_r/r^{3/2}$.

Thus $E[T]$ is bounded above by $T^\star$, the optimal value of the following linear program.

$$\begin{aligned} T^\star \;&=\; \max\; 10\sqrt{2}\,n^{3/2}\textstyle\sum_{r=1}^{r_0} x_r/r^{3/2} \\ \text{such that}\;\; \textstyle\sum_{j=1}^{r} x_j \;&\le\; \sqrt{2rn} && (r \in [r_0]) \\ x_j \;&\ge\; 0 && (j \in [r_0])\,. \end{aligned} \tag{12}$$

This linear program can be solved by a greedy procedure.

▶ **Lemma 8.** *Let $0 < b_1 < b_2 < \cdots < b_\nu$ and $c_1 > c_2 > \cdots > c_\nu > 0$. Then the linear program $\max \sum_{j=1}^{\nu} c_j x_j$ subject to $\sum_{j=1}^{r} x_j \le b_r$, $x_r \ge 0$ $(r \in [\nu])$ has optimal solution $x_1 = b_1$, $x_j = b_j - b_{j-1}$ $(j = 2, 3, \ldots, \nu)$.*

Proof. This solution has objective function value $c_1b_1 + c_2(b_2 - b_1) + \cdots + c_\nu(b_\nu - b_{\nu-1})$. The dual linear program is $\min \sum_{i=1}^{\nu} b_i y_i$ subject to $\sum_{i=j}^{\nu} y_i \ge c_j$, $y_j \ge 0$ $(j \in [\nu])$, and has feasible solution $y_\nu = c_\nu$, $y_j = c_j - c_{j+1}$ $(j \in [\nu - 1])$. Then the dual objective function has value $b_\nu c_\nu + b_{\nu-1}(c_{\nu-1} - c_\nu) + \cdots + b_1(c_1 - c_2)$. However,

$$c_1b_1 + c_2(b_2 - b_1) + \cdots + c_\nu(b_\nu - b_{\nu-1}) \;=\; b_\nu c_\nu + b_{\nu-1}(c_{\nu-1} - c_\nu) + \cdots + b_1(c_1 - c_2)\,.$$

Since the objective function values are equal, it follows that the two solutions are optimal in the primal and dual respectively. ◀

Thus, the optimal solution to (12) is $x_r = \sqrt{2nr} - \sqrt{2n(r-1)} = \sqrt{2nr}(1 - \sqrt{1 - 1/r}) \le \sqrt{2n/r}$, for $r \in [r_0]$, since $1 - y \le \sqrt{1-y}$ for $0 \le y \le 1$. Thus

$$T^\star \;\le\; 10\sqrt{2}\,n^{3/2}\sum_{j=1}^{r_0} x_r/r^{3/2} \;\le\; 10\sqrt{2}\,n^{3/2}\sum_{j=1}^{r_0}\sqrt{2n}/\big(\sqrt{r}\,r^{3/2}\big) \;=\; 20n^2\sum_{r=1}^{r_0} 1/r^2 \;<\; (10\pi^2/3)n^2\,,$$

since $\sum_{r=1}^{\infty} 1/r^2 = \pi^2/6$. Thus we have an absolute bound of $\mathbf{E}[T] = O(n^2)$.

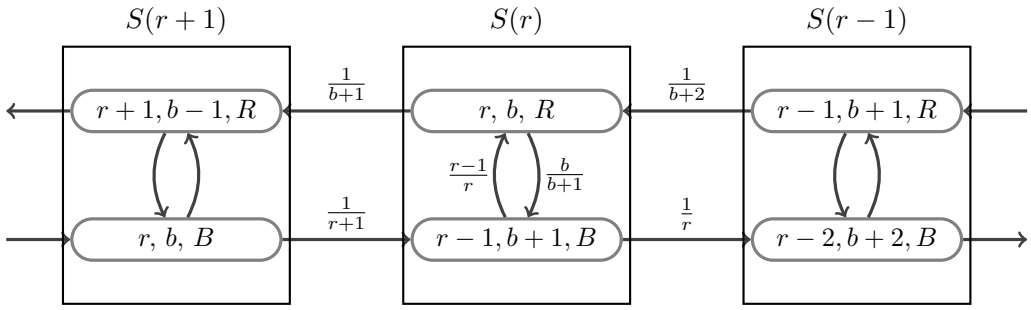


Figure 3 Star graph: Pseudo-states for the push process.

5 Theorem 3: Voting on the star graph S_n

In this section we prove $\mathbf{E}T(\text{Push}) = \Theta(n^2 \log n)$. The result that $\mathbf{E}T(\text{Pull}) = O(n^2)$ is given in [5].

Let (r, b, X) denote the coloring of the star graph S_n on n vertices in which there are r red vertices $b = n - r$ blue vertices. The central vertex has colour $X \in \{R, B\}$. In the case of the push process, the transitions from state (r, b, R) are to state $(r+1, b-1, R)$ with probability $1/(b+1)$ and to state $(r-1, b+1, B)$ with probability $b/(b+1)$. The transitions from state $(r-1, b+1, B)$ are to (r, b, R) with probability $(r-1)/r$ and to $(r-2, b+2, B)$ with probability $1/r$. For the purposes of discussion we group the states $(r, R) = (r, b, R)$ and $(r-1, B) = (r-1, b+1, B)$ into a single pseudo-state $S(r)$.

The transitions probabilities within or between $S(r+1)$ or $S(r-1)$ are shown in Figure 3, and are derived as follows. Let $X, Y \in \{R, B\}$. For a particle occupying a state (of colour) X in $S(r)$ let $P_X(Y, r)$ be the probability of exit from $S(r)$ via state Y. For example $P_R(R, r)$ is the probability that a particle starting at (r, R) eventually exits from $S(r)$ via state (r, R) to state $(r+1, R)$ in $S(r+1)$. Thus

$$P_R(R, r) = \frac{1}{b+1}\left(1 + \frac{b}{b+1}\frac{r-1}{r} + \cdots + \left(\frac{b}{b+1}\frac{r-1}{r}\right)^k + \cdots\right),$$

so that

$$P_R(R, r) = \frac{1}{b+1}\frac{1}{1 - [b(r-1)/(b+1)r]} = \frac{r}{n}.$$

Similarly let $P_B(R, r)$ be the probability that a particle currently at $(r-1, B)$ in $S(r)$ moves from $S(r)$ to $(r+1, R)$ in $S(r+1)$. Then

$$P_B(R, r) = \frac{r-1}{r}P_R(R, r) = \frac{r-1}{n}.$$

In summary, starting from state $X \in \{R, B\}$ of $S(r)$, for $1 \le r \le n-1$ the transition probability $p_X(r)$ from $S(r)$ to $S(r+1)$ (resp. transition probability $p_X(b)$ from $S(r)$ to $S(r-1)$) is given by

$$p_X(r) = \frac{r - 1_{(X=B)}}{n}, \qquad p_X(b) = \frac{b + 1_{(X=B)}}{n}. \tag{13}$$

States $(0, B)$ (i.e. $S(0)$) and (n, R) (i.e. $S(n)$) are absorbing.

Let $i = \max(r, b) - n/2$. To obtain lower and upper bounds on the number of transitions *between pseudo-states* $S(r)$ *before absorption*, we can couple the process with a biassed

random walk on the line $L = \{0, 1, ..., n/2\}$ with a reflecting barrier at 0 and an absorbing barrier at $n/2$. We assume n is even here. For $0 < i < n/2$, let p_i be the probability of a transition from i to $i+1$ on L, and let $q_i = 1 - p_i$ be the probability of a transition from i to $i-1$. It follows from (13) that to obtain bounds on the number of transitions between pseudo-states $S(r)$ before absorption we can use a value of p_i given by

$$p_i = 1/2 + (i+1)/n \quad \text{Lower bound}, \qquad p_i = 1/2 + (i-1)/n \quad \text{Upper bound}. \tag{14}$$

We next consider the number of loops, for example $(r, R) \to (r-1, B) \to (r, R)$, made within $S(r)$ before exit. For a particle starting from state X of $S(r)$ let $C_{XY} = C_{XY}(r)$ be the number of loops before exit at state Y. Let $\lambda = \frac{b}{b+1}\frac{r-1}{r}$ and $\rho = \lambda/(1-\lambda)^2$, then

$$\mathbf{E}C_{RR} = \sum_{k\geq 0} \frac{1}{b+1} k\lambda^k = \frac{1}{b+1}\frac{\lambda}{(1-\lambda)^2} = \rho\frac{1}{b+1}.$$

Similarly,

$$\mathbf{E}C_{BR} = \rho\frac{r-1}{r(b+1)}, \qquad \mathbf{E}C_{RB} = \rho\frac{b}{r(b+1)}, \qquad \mathbf{E}C_{BB} = \rho\frac{1}{r}.$$

The conditional expectations $\mu_{XY}(r) = \mathbf{E}C_{XY}(r)/P_X(Y, r)$ are given by

$$\mu_{XY}(r) = \begin{cases} \rho\frac{n}{r}\frac{1}{b+1}, & XY = RR \\ \rho\frac{n}{r}\frac{1}{b+1}, & XY = BR \\ \rho\frac{n}{n-r}\frac{b}{r(b+1)}, & XY = RB \\ \rho\frac{n}{n-r+1}\frac{1}{r}, & XY = BB \end{cases}. \tag{15}$$

The value of $\rho = (rb(r-1)(b+1))/n^2$. In particular if $b, r = (1 + o(1))n/2$ then, whatever colours X, Y

$$\mu_{XY}(r) = (1 + o(1))\frac{n}{4}. \tag{16}$$

Let $N = n/2$. Starting from $r = b = N$ let T'_N be the number of transitions between states $S(r)$ to reach $\max(r, b) = N + n/2$. Referring to (14), we consider a biassed random walk with transition probabilities of $Z = \max\{r, b\} - n/2$ given by

$$p_i = \begin{cases} 1, & \text{if } i = 0 \\ 1/2 + i/n + \delta/n, & \text{if } i \in \{1, \ldots, n/2 - 1\} \\ 0, & \text{if } i = n/2 \end{cases}, \tag{17}$$

where we set $\delta = 1$ for a lower bound on the number of steps T' to absorption, and $\delta = -1$ for an upper bound. The walk in (17) is the push chain Z_t with transitions given by (5) as analysed Section 2. Referring to (5) and (4) we set $\delta = 0$ for a lower bound on $\mathbf{E}_0 T_M$. For $M = N^{3/4}$, from Lemma 4,

$$\mathbf{E}_0 T_M \geq \Theta(1) \sum_{i=\sqrt{N}}^{M} \frac{N}{i} \geq \Theta(N) \log \frac{M}{\sqrt{N}} = \Theta(n \log n).$$

For all states $i = \sqrt{N}, ..., N^{3/4}$, the corresponding value of $r = (1 + o(1))n/2$. Referring to (16), whatever the type of transition XY between $S(r)$ and neighbouring states, $\mu_{XY}(r) = (1 + o(1))n/4$. Let $\mu = \min_{X,Y}(\mu_{XY}(r) : n/2 \leq r \leq M)$, then $\mu \geq n/5$. As $\mathbf{E}_0 T_N \geq \mathbf{E}_0 T_M = \Theta(n \log n)$ we have that

$$\mathbf{E}T(Push) \geq \mu\, \mathbf{E}_0 T_M = \Omega(n^2 \log n).$$

The upper bound follows by a similar argument. Put $\delta = -1$ in (5), and use Lemma 4.

Abstract

In the *voter model*, each node of a graph has an opinion, and in every round each node chooses independently a random neighbour and adopts its opinion. We are interested in the *consensus time*, which is the first point in time where all nodes have the same opinion. We consider dynamic graphs in which the edges are rewired in every round (by an adversary) giving rise to the graph sequence $G_1, G_2, \ldots$, where we assume that G_i has conductance at least ϕ_i. We assume that the degrees of nodes don't change over time as one can show that the consensus time can become super-exponential otherwise. In the case of a sequence of d-regular graphs, we obtain asymptotically tight results. Even for some static graphs, such as the cycle, our results improve the state of the art. Here we show that the expected number of rounds until all nodes have the same opinion is bounded by $O(m/(d_{min} \cdot \phi))$, for any graph with m edges, conductance ϕ, and degrees at least d_{min}. In addition, we consider a *biased* dynamic voter model, where each opinion i is associated with a probability P_i, and when a node chooses a neighbour with that opinion, it adopts opinion i with probability P_i (otherwise the node keeps its current opinion). We show for any regular dynamic graph, that if there is an $\epsilon > 0$ difference between the highest and second highest opinion probabilities, and at least $\Omega(\log n)$ nodes have initially the opinion with the highest probability, then all nodes adopt w.h.p. that opinion. We obtain a bound on the convergence time, which becomes $O(\log n/\phi)$ for static graphs.

1 Introduction

In this paper, we investigate the spread of opinions in a connected and undirected graph using the *voter model*. The standard voter model works in synchronous rounds and is defined as follows. At the beginning, every node has one opinion from the set $\{0, \ldots, n-1\}$, and

in every round, each node chooses one of its neighbours uniformly at random and adopts its opinion. In this model, one is usually interested in the *consensus time* and the *fixation probability*. The consensus time is the number of rounds it takes until all nodes have the same opinion. The fixation probability of opinion i is the probability that this opinion prevails, meaning that all other opinions vanish. This probability is known to be proportional to the sum of the degrees of the nodes starting with opinion i [13, 22].

The voter model is the dual of the *coalescing random walk model* which can be described as follows. Initially, there is a pebble on every node of the graph. In every round, every pebble chooses a neighbour uniformly at random and moves to that node. Whenever two or more pebbles meet at the same node, they are merged into a single pebble which continues performing a random walk. The process terminates when only one pebble remains. The time it takes until only one pebble remains is called *coalescing time*. It is known that the coalescing time for a graph G equals the consensus time of the voter model on G when initially each node has a distinct opinion [2, 19].

In this paper we consider the voter model and a *biased* variant where the opinions have different popularity. We express the consensus time as a function of the graph *conductance* ϕ.

We assume a dynamic graph model where the edges of the graph can be rewired by an adversary in every round, as long as the adversary respects the given degree sequence and the given conductance for all generated graphs. We show that consensus is reached with constant probability after τ rounds, where τ is the first round such that the sum of conductances up to round τ is at least m/d_{min}, where m is the number of edges. For static graphs the above bound simplifies to $O(m/(d_{min} \cdot \phi))$, where d_{min} is the minimum degree.

For the biased model we assume a *regular* dynamic graph G. Similar to [19, 16] the opinions have a *popularity*, which is expressed as a probability with which nodes adopt opinions. Again, every node chooses one of its neighbours uniformly at random, but this time it adopts the neighbour's opinion with a probability that equals the popularity of this opinion (otherwise the node keeps its current opinion). We assume that the popularity of the most popular opinion is 1, and every other opinion has a popularity of at most $1 - \epsilon$ (for an arbitrarily small but constant $\epsilon > 0$). We also assume that at least $\Omega(\log n)$ nodes start with the most popular opinion. Then we show that the most popular opinion prevails w.h.p.[1] after τ rounds, where τ is the first round such that the sum of conductances up to round τ is of order $O(\log n)$. For static graphs the above bound simplifies as follows: the most popular opinion prevails w.h.p. in $O(\log n/\phi)$ rounds, if at least $\Omega(\log n)$ nodes start with that opinion.

1.1 Related work

A sequential version of the voter model was introduced in [14] and can be described as follows. In every round, a single node is chosen uniformly at random and this node changes its opinion to that of a random neighbour. The authors of [14] study infinite grid graphs. This was generalised to arbitrary graphs in [9] where it is shown among other things that the probability for opinion i to prevail is proportional to the sum of the degrees of the nodes having opinion i at the beginning of the process.

The standard voter model was first analysed in [13]. The authors of [13] bound the expected coalescing time (and thus the expected consensus time) in terms of the expected meeting time t_{meet} of two random walks and show a bound of $O(t_{meet} \cdot \log n) = O(n^3 \log n)$.

[1] An event happens *with high probability (w.h.p.)* if its probability is at least $1 - 1/n$.

Note that the meeting time is an obvious lower bound on the coalescing time, and thus a lower bound on the consensus time when all nodes have distinct opinions initially. The authors of [4] provide an improved upper bound of $O\big(\frac{1}{1-\lambda_2}(\log^4 n + \rho)\big)$ on the expected coalescing time for any graph G, where λ_2 is the second eigenvalue of the transition matrix of a random walk on G, and $\rho = \big(\sum_{u\in V(G)} d(u)\big)^2 / \sum_{u\in V(G)} d^2(u)$ is the ratio of the square of the sum of node degrees over the sum of the squared degrees. The value of ρ ranges from $\Theta(1)$, for the star graph, to n, for regular graphs.

The authors of [20, 2, 19] investigate coalescing random walks in a continuous setting where the movement of the pebbles are modelled by independent Poisson processes with a rate of 1. In [2], it is shown a lower bound of $\Omega(m/d_{max})$ and an upper bound of $O(t_{hit}\cdot\log n)$ for the expected coalescing time. Here m is the number of edges in the graph, d_{max} is the maximum degree, and t_{hit} is the (expected) hitting time. In [23], it is shown that the expected coalescing time is bounded by $O(t_{hit})$.

In[19] the authors consider the biased voter model in the continuous setting and two opinions. They show that for d-dimensional lattices the probability for the less popular opinion to prevail is exponentially small. In [16], it is shown that in this setting the expected consensus time is exponential for the line.

The authors of [5] consider a modification of the standard voter model with two opinions, which they call *two-sample voting*. In every round, each node chooses two of its neighbours randomly and adopts their opinion only if they both agree. For regular graphs and random regular graphs, it is shown that two-sample voting has a consensus time of $O(\log n)$ if the initial imbalance between the nodes having the two opinions is large enough. There are several other works on the setting where every node contacts in every round two or more neighbours before adapting its opinion [1, 7, 6, 10].

There are several other models which are related to the voter model, most notably the *Moran process* and *rumor spreading* in the phone call model. In the case of the Moran process, a population resides on the vertices of a graph. The initial population consists of one mutant with fitness r and the rest of the nodes are non-mutants with fitness 1. In every round, a node is chosen at random with probability proportional to its fitness. This node then reproduces by placing a copy of itself on a randomly chosen neighbour, replacing the individual that was there. The main quantities of interest are the probability that the mutant occupies the whole graph (fixation) or vanishes (extinction), together with the time before either of the two states is reached (absorption time). There are several publications considering the fixation probabilities [15, 21, 8].

Rumor spreading in the phone call model works as follows. Every node v opens a channel to a randomly chosen neighbour u. The channel can be used for transmissions in both directions. A transmission from v to u is called *push* transmission and a transmission from u to v is called *pull*. There is a vast amount of papers analysing rumor spreading on different graphs. The result that is most relevant to ours is that broadcasting of a message in the whole network is completed in $O(\log n/\phi)$ rounds w.h.p, where ϕ is the conductance (see Section 1.2 for a definition) of the network. In [12], the authors study rumor spreading in dynamic networks, where the edges in every round are distributed by an adaptive adversary. They show that broadcasting terminates w.h.p. in a round t if the sum of conductances up to round t is of order $\log n$. Here, the sequence of graphs $G_1, G_2, \ldots$ have the same vertex set of size n, but possibly distinct edge sets. The authors assume that the degrees and the conductance may change over time. We refer the reader to the next section for a discussion of the differences. Dynamic graphs have received ample attention in various areas [3, 17, 24, 18].

1.2 Model and New Results

In this paper we show results for the standard voter model and biased voter model in dynamic graphs. Our protocols work in synchronous steps. The consensus time T is defined at the first time step at which all nodes have the same opinion.

Standard Voter Model

Our first result concerns the standard voter model in dynamic graphs. Our protocol works as follows. In every synchronous time step every node chooses a neighbour u.a.r. and adopts its opinion with probability $1/2$.[2]

We assume that the dynamic graphs $\mathscr{G} = G_1, G_2, \ldots$ are generated by an adversary. We assume that each graph has n nodes and the nodes are numbered from 1 to n. The sequence of conductances $\phi_1, \phi_2, \ldots$ is given in advance, as well as a degree sequence $d_1, d_2, \ldots, d_n$. The adversary is now allowed to create every graph G_i by redistributing the edges of the graph. The constraints are that each graph G_i has to have conductance ϕ_i and node j has to have degree d_j (the degrees of the nodes do not change over time). Note that the sequence of the conductances is fixed and, hence, cannot be regarded as a random variable in the following. For the redistribution of the edges we assume that the adversary knows the distribution of all opinions during all previous rounds.

Note that our model for dynamic graphs is motivated by the model presented in [12]. They allow the adversary to determine the edge set at every round, without having to respect the node degrees and conductances.

We show (Observation 1) that, allowing the adversary to change the node degrees over time can results in super-exponential voting time. Since this changes the behaviour significantly, we assume that the degrees of nodes are fixed. Furthermore, in contrary to [12], we assume that (bounds on) the conductance of (the graph at any time step) are fixed/given beforehand. Whether one can obtain the same results, if the conductance of the graph is determined by an adaptive adversary remains an open question. The reason we consider an adversarial dynamic graph model is in order to understand how the voting time can be influenced in the worst-case. Another interesting model would be to assume that in every round the nodes are connected to random neighbours. One obstacle to such a model seems to be to guarantee that neighbours are chosen u.a.r. and the degrees of nodes do not change. For the case of regular random dynamic graphs our techniques easily carry over since the graph will have constant conductance w.h.p. in any such round since the graph is essentially a random regular graph in every round.

For the (adversarial) dynamic model we show the following result bounding the consensus time T.

▶ **Theorem 1** (upper bound). *Consider the Standard Voter model and in the dynamic graph model. Assume $\kappa \leq n$ opinions are arbitrarily distributed over the nodes of G_1. Let ϕ_t be a lower bound on the conductance at time step t. Let $b > 0$ be a suitable chosen constant. Then, with a probability of $1/2$ we have that $T \leq \min\{\tau, \tau'\}$, where*

(i) *τ is the first round so that $\sum_{t=1}^{\tau} \phi_t \geq b \cdot m/d_{min}$.* (part 1)

(ii) *τ' is the first round so that $\sum_{t=1}^{\tau'} \phi_t^2 \geq b \cdot n \log n$.* (part 2)

For static graphs ($G_{i+1} = G_i$ for all i), we have $T \leq \min\{m/(d_{min} \cdot \phi), n \log n/\phi^2\}$.

[2] The factor of $1/2$ ensures that the process converges on bipartite graphs.

For *static* d-regular graphs, where the graph doesn't change over time, the above bound becomes $O(n/\phi)$, which is tight when either ϕ or d are constants (see Observation 2). Theorem 1 gives the first tight bounds for cycles and circulant graphs C_n^k (node i is adjacent to the nodes $i \pm 1, \ldots, i \pm k \mod n$) with degree $2k$ (k constant). For these graphs the consensus time is $\Theta(n^2)$, which matches our upper bound from Theorem 1.[3] For a comparison with the results of [4] note that $\phi^2 \leq 1 - \lambda_2 \leq 2\phi$. In particular, for the cycle $\phi = 1/n$ and $1/(1-\lambda_2) = \Theta(1/n^2)$. Hence, for this graph, our bound is by a factor of n smaller. Note that, due to the duality between the voter model and coalescing random walks, the result also holds for the coalescing time. In contrast to [4, 5], the above result is shown using a potential function argument, whereas the authors of [4, 5] show their results for coalescing random walks and fixed graphs. The advantage of analysing the process directly is, that our techniques allow us to obtain the results for the dynamic setting.

The next result shows that the bound of Theorem 1 is asymptotically tight if the adversary is allowed to change the node degrees over time.

▶ **Theorem 2** (lower bound). *Consider the Standard Voter model in the dynamic graph model. Assume that $\kappa \leq n$ opinions are arbitrarily distributed over the nodes of G_1. Let ϕ_t be an upper bound on the conductance at time step t. Let $b > 0$ be a suitable constant and assume τ'' is the first round such that $\sum_{t=1}^{\tau''} \phi_t \geq bn$. Then, with a probability of at least $1/2$, there are still nodes with different opinions in $G_{\tau''}$.*

Biased Voter Model

In the *biased* voter model we again assume that there are $\kappa \leq n$ distinct opinions initially. For $0 \leq i \leq \kappa - 1$, opinion i has popularity α_i and we assume that $\alpha_0 = 1 > \alpha_1 \geq \alpha_2 \geq \ldots \geq \alpha_{\kappa-1}$. We call opinion 0 the *preferred opinion*. The process works as follows. In every round, every node chooses a neighbour uniformly at random and adopts its opinion i with probability α_i.

We assume that the dynamic d-regular graphs $\mathscr{G} = G_1, G_2, \ldots$ are generated by an adversary. We assume that the sequence of ϕ_t is given in advance, where ϕ_i is a lower bound on the conductance of G_i. The adversary is now allowed to create the sequence of graphs by redistributing the edges of the graph in every step. The constraints are that each graph G_i has n nodes and has to have conductance at least ϕ_i. Note that we assume that the sequence of the conductances is fixed and, hence, it is not a random variable in the following.

The following result shows that consensus is reached considerably faster in the biased voter model, as long as the bias $1 - \alpha_1$ is bounded away from 0, and at least a logarithmic number of nodes have the preferred opinion initially.

▶ **Theorem 3.** *Consider the Biased Voter model in the dynamic regular graph model. Assume $\kappa \leq n$ opinions are arbitrarily distributed over the nodes of G_1. Let ϕ_t be a lower bound on the conductance at time step t. Assume that $\alpha_1 \leq 1 - \epsilon$, for an arbitrary small constant $\epsilon > 0$. Assume the initial number of nodes with the preferred opinion is at least $c \log n$, for some constant $c = c(\alpha_1)$. Then the preferred opinion prevails w.h.p. in at most τ''' steps, where τ''' is the first round so that $\sum_{t=1}^{\tau'''} \phi_t \geq b \log n$, for some constant b. For static graphs ($G_{i+1} = G_i$ for all i), we have w.h.p. $T = O(\log n/\phi)$.*

[3] The lower bound of $\Omega(n^2)$ follows from the fact that two coalescing random walks starting on opposite sites of a cycle require in expectation time $\Omega(n^2)$ to meet.

The assumption on the initial size of the preferred opinion is crucial for the time bound $T = O(\log n/\phi)$, in the sense that there are instances where the expected consensus time is at least $T = \Omega(n/\phi)$ if the size of the preferred opinion is small.[4]

The rumor spreading process can be viewed as an instance of the biased voter model with two opinions having popularity 1 and 0, respectively. However, the techniques used for the analysis of rumor spreading do not extend to the voter model. This is due to the fact that rumor spreading is a progressive process, where nodes can change their opinion only once, from "uninformed" to "informed", whereas they can change their opinions over and over again in the case of the voter model. Note that the above bound is the same as the bound for rumor spreading of [11] (although the latter bound holds for general graphs, rather than just for regular ones). Hence, our above bound is tight for regular graphs with conductance ϕ, since the rumor spreading lower bound of $\Omega(\log n/\phi)$ is also a lower bound for biased voting in our model.

2 Analysis of the Voter Model

In this section we show the upper and lower bound for the standard voter model. We begin with some definitions. Let $G = (V, E)$. For a fixed set $S \subseteq V$ we define $cut(S, V \setminus S)$ to be the set of edges between the sets $S \subseteq V$ and $V \setminus S$ and let λ_u be the number of neighbours of u in $V \setminus S$. Let $\mathrm{vol}(S) = \sum_{u \in S} d_u$. The *conductance* of G is defined as

$$\phi = \phi(G) = \min \left\{ \frac{\sum_{u \in U} \lambda_u}{\mathrm{vol}(U)} : U \subset V \text{ with } 0 < \mathrm{vol}(U) \leq m \right\}.$$

We note $1/n^2 \leq \phi \leq 1$. We denote by $v_t^{(i)}$ the set of nodes that have opinion i after the first t rounds and $t \geq 0$. If we refer to the random variable we use $V_t^{(i)}$ instead.

First we show Theorem 1 for $\kappa = 2$ (two opinions), which we call 0 and 1 in the following. Then we generalise the result to an arbitrary number of opinions. We model the system with a Markov chain $M_{t \geq 0} = (V_t^{(0)}, V_t^{(1)})_{t \geq 0}$.

Let s_t denote the set having the smaller volume, i.e., $s_t = v_t^{(0)}$ if $\mathrm{vol}(v_t^{(0)}) \leq \mathrm{vol}(v_t^{(1)})$, and $s_t = v_t^{(1)}$ otherwise. Note that we use $s_t, v_t^{(0)}$ and $v_t^{(1)}$ whenever the state at time t is fixed, and $S_t, V_t^{(0)}$ and $V_t^{(1)}$ for the corresponding random variables. For $u \in v_t^{(0)}$, $\lambda_{u,t}$ is the number of neighbours of u in $V \setminus v^1(t)$ and for $u \in v_t^{(1)}$, $\lambda_{u,t}$ is the number of neighbours of u in $V \setminus v_t^{(0)}$; d_u is the degree of u (the degrees do not change over time).

To analyse the process we use a potential function. Simply using the volume of nodes sharing the same opinion as the potential function will not work. It is easy to calculate that the expected volume of nodes with a given opinion does not change in one step. Instead, we use a convex function on the number of nodes with the minority opinion. We define

$$\Psi(S_t) = \sqrt{\mathrm{vol}(S_t)}.$$

In Lemma 4 we first calculate the one-step potential drop of $\Psi(S_t)$. Then we show that every opinion either prevails or vanishes once the sum of conductances is proportional to the volume of nodes having that opinion (see Lemma 5), which we use later to prove Part 1 of Theorem 1. Additionally, Lemma 4 is used to prove Lemma 7 which allows us to prove Part 2 of Theorem 1.

[4] Consider a 3-regular graph and n opinions where all other $\alpha_1 = \alpha_2 = \cdots = \alpha_{n-1} = 1/2$. The preferred opinion vanishes with constant probability and the bound for the standard voter model of Observation 2 applies.

▶ **Lemma 4.** *Assume $s_t \neq \emptyset$ and $\kappa = 2$. Then*

$$\mathbf{E}[\Psi(S_{t+1}) \mid S_t = s_t] \leq \Psi(s_t) - \frac{\sum_{u \in V} \lambda_{u,t} \cdot d_u}{32 \cdot (\Psi(s_t))^3}.$$

Proof. W.l.o.g. we assume that opinion 0 is the minority opinion, i.e. $0 < \mathrm{vol}(V_t^{(0)}) \leq \mathrm{vol}(V_t^{(1)})$. To simplify the notation we omit the index t in this proof and write $v^{(0)}$ instead of $v_t(0)$, $v^{(1)}$ for $V \setminus v_t^{(0)}$, and λ_u instead of $\lambda_{u,t}$. Hence, $s_t = v^{(0)}$ and $\Psi(s_t) = \sqrt{\mathrm{vol}(v^{(0)})}$. Note that for $t = 0$ we have $\mathrm{vol}(v^{(0)}) = \Psi(s_t)^2$. Furthermore, we fix $S_t = s_t$ in the following (and condition on it). We define m as the number of edges. Then we have

$$\begin{aligned}
\mathbf{E}[\Psi(S_{t+1}) - \Psi(s_t) \mid S_t = s_t] &= \mathbf{E}[\sqrt{\mathrm{vol}(S_{t+1})} - \sqrt{\mathrm{vol}(s_t)}] \\
&= \mathbf{E}\left[\sqrt{\min\left\{\mathrm{vol}(V_{t+1}^{(0)}), m - \mathrm{vol}(V_{t+1}^{(0)})\right\}} - \sqrt{\mathrm{vol}(s_t)}\right] \\
&\leq \mathbf{E}\left[\sqrt{\mathrm{vol}(V_{t+1}^{(0)})} - \sqrt{\mathrm{vol}(v^{(0)})}\right] \qquad (1)
\end{aligned}$$

Now we define

$$X_u = \begin{cases} d_u & w.p.\ \frac{\lambda_u}{2 \cdot d_u}\ if\ u \in v^{(1)} \\ -d_u & w.p.\ \frac{\lambda_u}{2 \cdot d_u}\ if\ u \in v^{(0)} \\ 0 & otherwise \end{cases}$$

and $\Delta = \sum_{u \in V} X_u$. Note that we have $\Delta = \mathrm{vol}(V_{t+1}^{(0)}) - \mathrm{vol}(v^{(0)})$ and

$$\begin{aligned}
\mathbf{E}\left[\sqrt{\mathrm{vol}(V_{t+1}^{(0)})} - \sqrt{\mathrm{vol}(v^{(0)})}\right] &= \mathbf{E}\left[\sqrt{\mathrm{vol}(v^{(0)}) + \Delta} - \sqrt{\mathrm{vol}(v^{(0)})}\right] \\
&= \mathbf{E}\left[\sqrt{\mathrm{vol}(v^{(0)})}\left(\sqrt{1 + \tfrac{\Delta}{\mathrm{vol}(v^{(0)})}} - 1\right)\right] \\
&= \Psi(s_t) \cdot \mathbf{E}[\sqrt{1 + \Delta/\Psi(s_t)^2} - 1].
\end{aligned}$$

Unfortunately we cannot bound $\Psi(s_t) \cdot \mathbf{E}[\sqrt{1 + \Delta/\Psi(s_t)^2} - 1]$ directly. Instead, we define a family of random variables which is closely related to X_u.

$$Y_u = \begin{cases} \lambda_u & w.p.\ \frac{1}{2} \quad if\ u \in v^{(1)} \\ -d_u & w.p.\ \frac{\lambda_u}{2 \cdot d_u} \quad if\ u \in v^{(0)} \\ 0 & otherwise \end{cases}$$

Similarly, we define $\Delta' = \sum_{u \in V} Y(u)$. Note that $|E[Y_u]| = \lambda_u/2$ for both $u \in v^{(1)}$ and $u \in v^{(0)}$. In the full version we show that $\mathbf{E}[\sqrt{1 + \Delta/\Psi(s_t)^2}] \leq \mathbf{E}[\sqrt{1 + \Delta'/\Psi(s_t)^2}]$, which results in $\mathbf{E}[\Psi(S_{t+1}) - \Psi(s_t) \mid S_t = s_t] \leq \Psi(s_t) \cdot \mathbf{E}[\sqrt{1 + \Delta'/\Psi(s_t)^2} - 1]$ From the Taylor expansion $\sqrt{1+x} \leq 1 + \frac{x}{2} - \frac{x^2}{8} + \frac{x^3}{16}$, $x \geq -1$ it follows that

$$\mathbf{E}[\Psi(S_{t+1}) - \Psi(s_t) \mid S_t = s_t] \quad \leq \quad \Psi(s_t) \cdot \mathbf{E}\left[\tfrac{\Delta'}{2\Psi(s_t)^2} - \tfrac{(\Delta')^2}{8\Psi(s_t)^4} + \tfrac{(\Delta')^3}{16\Psi(s_t)^6}\right].$$

It remains to bound $\mathbf{E}[\Delta']$, $\mathbf{E}[(\Delta')^2]$, and $\mathbf{E}[(\Delta')^3]$.

- $\mathbf{E}[\Delta']$: We have $\mathbf{E}[\Delta'] = \sum_{u \in V} E[Y_u] = \sum_{u \in v^{(1)}} \frac{\lambda_u}{2} - \sum_{v \in v^{(0)}} \frac{\lambda_v}{2} = 0$, where the last equality holds since $\sum_{u \in v^{(1)}} \lambda_u$ and $\sum_{u \in v^{(1)}} \lambda_u$ both count the number of edges crossing the cut between $v^{(0)}$ and $v^{(1)}$.

- $\mathbf{E}[(\Delta')^2]$: since $E[(Y_u)^2] = (\lambda_u)^2/2$ for $u \in v^{(1)}$ and $E[(Y_u)^2] = -d_u \cdot \lambda_u/2$ for $u \in v^{(0)}$ we have

$$\begin{aligned}\mathbf{E}[(\Delta')^2] &= \sum_{u\in V} \mathbf{Var}[Y_u] + (\mathbf{E}[Y_u])^2 = \sum_{u\in V} \mathbf{Var}[Y_u] + 0 = \sum_{u\in V} (\mathbf{E}[(Y_u)^2] - (\mathbf{E}[Y_u])^2) \\ &= \sum_{u\in v^{(0)}} (\mathbf{E}[(Y_u)^2] - (\mathbf{E}[Y_u])^2) + \sum_{u\in v^{(1)}} (\mathbf{E}[(Y_u)^2] - (\mathbf{E}[Y_u])^2) \\ &= \sum_{u\in v^{(0)}} \frac{\lambda_u d_u}{2} - \sum_{u\in v^{(0)}} \frac{\lambda_u^2}{4} + \sum_{u\in v^{(1)}} \frac{\lambda_u^2}{4} \geq \sum_{u\in v^{(0)}} \frac{\lambda_u d_u}{4}. \end{aligned} \tag{2}$$

- $\mathbf{E}[\Delta'^3]$: In the full version we show that $\mathbf{E}[\Delta'^3] = \sum_{u\in V} \left(\mathbf{E}[(Y_u)^3] - 3\,\mathbf{E}[(Y_u)^2] \cdot \mathbf{E}[Y_u] + 2\,\mathbf{E}[Y_u]^3\right)$. Note that $E[(Y_u)^3] = \frac{1}{2}(\lambda_u)^3$ for $u \in v^{(1)}$ and $E[(Y_u)^3] = -\frac{1}{2}\lambda_u \cdot (d_u)^2$ for $u \in v^{(0)}$. Hence,

$$\begin{aligned}\mathbf{E}[\Delta'^3] = &\sum_{u\in v^{(0)}} \left(-\frac{1}{2}\lambda_u \cdot (d_u)^2 + \frac{3}{4}(\lambda_u)^2 \cdot d_u - \frac{1}{4}\lambda_u^3\right) \\ &+ \sum_{u\in v^{(1)}} \left(\frac{1}{2}(\lambda_u)^3 - \frac{3}{4}(\lambda_u)^3 + \frac{1}{4}(\lambda_u)^3\right) \leq 0, \end{aligned} \tag{3}$$

  where the first sum is bounded by 0 because $\lambda_u \leq d_u$.

  Combining all the above estimations we get

$$\begin{aligned}\mathbf{E}[\Psi(S_{t+1}) - \Psi(s_t) \mid S_t = s_t] &\leq \Psi(s_t) \cdot \mathbf{E}\left[\frac{\Delta'}{2\Psi(s_t)^2} - \frac{\Delta'^2}{8\Psi(s_t)^4} + \frac{\Delta'^3}{16\Psi(s_t)^6}\right] \\ &\leq -\frac{\sum_{u\in v^{(0)}} \lambda_u d_u}{32\Psi(s_t)^3}.\end{aligned}$$

This completes the proof of Lemma 4. ◀

2.1 Part 1 of Theorem 1.

Using Lemma 4 we show that a given opinion either prevails or vanishes with constant probability as soon as the sum of ϕ_t is proportional to the volume of the nodes having that opinion.

▶ **Lemma 5.** *Assume that $s_{\hat{t}}$ is fixed for an arbitrary $(\hat{t} \geq 0)$ and $\kappa = 2$.*
Let $\tau^* = \min\left\{t' : \sum_{i=\hat{t}}^{t'} \phi_i \geq 129 \cdot vol(s_{\hat{t}})/d_{min}\right\}$. Then $\Pr\left(T \leq \tau^* + \hat{t}\right) \geq 1/2$.

In particular, if the graph is static with conductance ϕ, then $\Pr\left(T \leq \frac{129 \cdot vol(s_{\hat{t}})}{\phi \cdot d_{min}} + \hat{t}\right) \geq 1/2$.

Proof. From the definition of $\Psi(s_t)$ and ϕ_t it follows for all t that $\Psi(s_t)^2 = \sum_{u\in v^{(0)}} d_u = \mathrm{vol}(v^{(0)})$ and $\phi_t \leq \sum_{u\in v^{(0)}} \lambda_{u,t}/\mathrm{vol}(v^{(0)})$. Hence, $\Psi(s_t)^2 \cdot \phi_t \cdot d_{min} \leq \sum_{u\in v^{(0)}} \lambda_{u,t} \cdot d_u$. Together with Lemma 4 we derive for $s_t \neq \emptyset$

$$\mathbf{E}[\Psi(S_{t+1}) \mid S_t = s_t] \leq \Psi(s_t) - \frac{\sum_{u\in V} \lambda_{u,t} \cdot d_u}{32 \cdot (\Psi(s_t))^3} \leq \Psi(s_t) - \frac{d_{min} \cdot \phi_t}{32 \cdot \Psi(s_t)}. \tag{4}$$

Recall that $T = \min_t\{S_t = \emptyset\}$. In the following we use the expression $T > t$ to denote the event $s_t \neq \emptyset$. Using the law of total probability we get

$$\mathbf{E}[\Psi(S_{t+1}) | T > t] = \mathbf{E}\left[\Psi(S_t) - \frac{d_{min} \cdot \phi_t}{32 \cdot \Psi(S_t)} \Big| T > t\right]$$

and using Jensen's inequality we get

$$\begin{aligned}\mathbf{E}[\Psi(S_{t+1}) \mid T > t] &= \mathbf{E}[\Psi(S_t) \mid T > t] - \mathbf{E}\left[\frac{d_{min} \cdot \phi_t}{32 \cdot \Psi(S_t)} \mid T > t\right] \\ &\leq \mathbf{E}[\Psi(S_t) \mid T > t] - \frac{d_{min} \cdot \phi_t}{32 \cdot \mathbf{E}[\Psi(S_t) \cdot \mid T > t]}.\end{aligned}$$

Since $\mathbf{E}[\Psi(S_t) \mid T \leq t] = 0$ we have

$$\begin{aligned}\mathbf{E}[\Psi(S_t)] &= \mathbf{E}[\Psi(S_t) \mid T > t] \cdot \Pr[T > t] + \mathbf{E}[\Psi(S_t) \mid T \leq t] \cdot \Pr[T \leq t] \\ &= \mathbf{E}[\Psi(S_t) \mid T > t] \cdot \Pr[T > t] + 0.\end{aligned}$$

Hence,

$$\frac{\mathbf{E}[\Psi(S_{t+1})]}{\Pr(T > t)} \leq \frac{\mathbf{E}[\Psi(S_t)]}{\Pr(T > t)} - \frac{d_{min} \cdot \phi_t \cdot \Pr(T > t)}{32\,\mathbf{E}[\Psi(S_t)]}$$

and

$$\mathbf{E}[\Psi(S_{t+1})] \leq \mathbf{E}[\Psi(S_t)] - \frac{d_{min} \cdot \phi_t \cdot (\Pr(T > t))^2}{32\,\mathbf{E}[\Psi(S_t)]}.$$

Let $t^* = \min\{t\colon \Pr(T > t) < 1/2\}$. In the following we use contradiction to show

$$t^* \leq \max\{t : \sum_{\hat{t} \leq t < t^*} \phi_t \leq 128 \cdot \mathrm{vol}(s_{\hat{t}})/d_{min}\}.$$

Assume the inequality is not satisfied. With $t = t^* - 1$ we get

$$\mathbf{E}[\Psi(S_{t^*})] \leq \mathbf{E}[\Psi(S_{t^*-1})] - \frac{d_{min} \cdot \phi_t \cdot (\Pr(T > t^* - 1))^2}{32\,\mathbf{E}[\Psi(S_{t^*-1})]} \leq \mathbf{E}[\Psi(S_{t^*-1})] - \frac{d_{min} \cdot \phi_{t^*} \cdot (1/4)}{32\,\mathbf{E}[\Psi(S_{t^*-1})]}.$$

Applying this equation iteratively, we obtain

$$\mathbf{E}[\Psi(S_{t^*})] \leq \mathbf{E}[\Psi(S_{\hat{t}})] - \sum_{\hat{t} \leq t < t^*} \frac{d_{min} \cdot \phi_t \cdot 1/4}{32\,\mathbf{E}[\Psi(S_t)]} \leq \mathbf{E}[\Psi(S_{\hat{t}})] - \frac{d_{min} \cdot \sum_{\hat{t} \leq t < t^*} \phi_t}{128\,\mathbf{E}[\Psi(S_{\hat{t}})]}. \tag{5}$$

Using the definition of $\mathbf{E}[\Psi(S_{\hat{t}})] = \sqrt{\mathrm{vol}(s_{\hat{t}})}$ and the definition of t^* we get

$$\mathbf{E}[\Psi(S_{t^*})] < \sqrt{\mathrm{vol}(s_{\hat{t}})} - \frac{d_{min} \cdot 128 \cdot \mathrm{vol}(s_{\hat{t}})}{128 \cdot d_{min} \cdot \sqrt{\mathrm{vol}(s_{\hat{t}})}} = \sqrt{\mathrm{vol}(s_{\hat{t}})} - \frac{\mathrm{vol}(s_{\hat{t}})}{\sqrt{\mathrm{vol}(s_{\hat{t}})}} = 0.$$

This is a contradiction since $\mathbf{E}[\Psi(S_{t^*})]$ is non-negative.

From the definition of t^*, we obtain $\Pr\left(T > \tau^* + \hat{t}\right) < 1/2$, completing the proof of Lemma 5. ◀

Now we are ready to show the first part of the theorem.

Proof of Part 1 of Theorem 1. We divide the τ rounds into phases. Phase i starts at time $\tau_i = \min\{t : \sum_{j=1}^{t} \phi_j \geq 2i\}$ for $i \geq 0$ and ends at $\tau_{i+1} - 1$. Since $\phi_j \leq 1$ for all $j \geq 0$ we have $\tau_0 < \tau_1 < \ldots$ and $\sum_{j=\tau_i}^{\tau_{i+1}} \phi_j \geq 1$ for $i \geq 0$. Let ℓ_t be the number of distinct opinions at the beginning of phase t. Hence, $\ell_0 = \kappa$.

We show in Lemma 6 below that the expected number of phases before the number of opinions drops by a factor of 5/6 is bounded by $6c \cdot \mathrm{vol}(V)/(\ell_t \cdot d_{min})$. For $i \geq 1$ let T_i be the number of phases needed so that the number of opinions drops to $(5/6)^i \cdot \ell_0$. Then only

one opinion remains after $\log_{6/5}\kappa$ many of these meta-phases. Then, for a suitably chosen constant b,

$$\mathbf{E}[T] \quad = \quad \sum_{j=1}^{\log_{6/5}\kappa} E[T_j] \leq \sum_{j=1}^{\log_{6/5}\kappa - 1} \frac{6c \cdot \mathrm{vol}(V)}{\ell_j \cdot d_{min}} \leq \sum_{j=1}^{\log_{6/5}\kappa} \frac{6c\,\mathrm{vol}(V)}{(5/6)^j \cdot \ell_0 \cdot d_{min}} = \frac{b \cdot m}{4 \cdot d_{min}}.$$

By Markov inequality, consensus is reached w.p. at least $1/2$ after $b \cdot m/(2d_{min})$ phases. By definition of τ and the definition of the phases, we have that the number of phases up to time step τ is at least $b \cdot m/(2d_{min})$. Thus, consensus is reached w.p. at least $1/2$ after τ time steps, which finishes the proof. ◀

▶ **Lemma 6.** *Fix a phase t and assume $c = 129$ and $\ell_t > 1$. The expected number of phases before the number of opinions drops to $5/6 \cdot \ell_t$ is bounded by $6c \cdot vol(V)/(\ell_t \cdot d_{min})$.*

Proof. Consider a point when there are ℓ' opinions left, with $5/6 \cdot \ell < \ell' \leq \ell$. Among those ℓ' opinions, there are at least $\ell' - \ell/3$ opinions i such that the volume of nodes with opinion i is at most $3 \cdot \mathrm{vol}(V)/\ell$. Let S denote the set of these opinions and let Z_i be an indicator variable which is 1 if opinion $i \in S$ vanished after $s = 3c \cdot \mathrm{vol}(V)/(\ell \cdot d_{min})$ phases and $Z_i = 0$ if it prevails. To estimate Z_i we consider the process where we have two opinions only. All nodes with opinion i retain their opinion and all other nodes have opinion 0. It is easy to see that in both processes the set of nodes with opinion i remains exactly the same. Hence, we can use Lemma 5 to show that with probability at least $1/2$, after s phases opinion i either vanishes or prevails. Hence,

$$\mathbf{E}\left[\Sigma_{j \in S} Z_j\right] = \Sigma_{j \in S}\, \mathbf{E}[Z_j] \geq |S|/2 \geq (\ell' - \ell/3)/2.$$

Using Markov's inequality we get that with probability $1/2$ at least $(\ell' - \ell/3)/4$ opinions vanish within s phases, and the number of opinions remaining is at most $\ell' - (\ell' - \ell/3)/4 = 3/4 \cdot \ell' + \ell/12 \leq 5/6 \cdot \ell$. The expected number of phases until $5/6 \cdot \ell$ opinions can be bounded by $\sum_{i=1}^{\infty} 2^{-i} \cdot s \leq 2s = \frac{6c \cdot \mathrm{vol}(V)}{\ell \cdot d_{min}}$. ◀

2.2 Part 2 of Theorem 1

We first bound the expected potential drop in round $t+1$, i.e., we bound $\mathbf{E}[\Psi(S_{t+1}) - \Psi(s_t) \mid S_t = s_t]$. This time however, we express the drop as a function which is linear in $\Psi(s_t)$. This allows us to bound the expected size of the potential at time τ', i.e., $\mathbf{E}[\Psi(S_{\tau'})]$, directly. From the expected size of the potential at time τ' we derive the desired bound on $Pr\,(T \leq \tau')$. The proof can be found in the full version.

▶ **Lemma 7.** *Assume $\kappa = 2$. We have $\Pr(T \leq \tau') \geq 1/n^2$. In particular, if the graph is static with conductance ϕ, then $\Pr\left(T \leq \frac{96 \cdot n \log n}{\phi^2}\right) \geq 1 - 1/n^2$.*

We now prove Part 2 of Theorem 1 which generalises to $\kappa > 2$.

Proof of Part 2 of Theorem 1. We define a parameterized version of the consensus time T. We define $T(\kappa) = \min\{t \colon \Psi(S_t) = 0 : \text{the number of different opinions at time } t \text{ is } \kappa\}$ for $\kappa \leq n$. We want to show that $\Pr(T(\kappa) \leq \tau') \geq 1 - 1/n$. From Lemma 7 we have that, that $\Pr(T(2) \leq \tau') \geq 1 - 1/n^2$. We define the 0/1 random variable Z_i to be one if opinion i vanishes or is the only remaining opinion after τ' rounds and $Z_i = 0$ otherwise. We have that $\Pr(Z_i = 1) \geq 1 - 1/n^2$ for all $i \leq \kappa$. We derive $\Pr(T(\kappa) \leq \tau') = \Pr(\wedge_{i \leq \kappa} Z_i) \geq 1 - 1/n$, by union bound. This yields the claim. ◀

2.3 Lower Bounds

In this section, we give the intuition behind the proof of Theorem 2 and state two additional observations. Recall that Theorem 2 states that our bound for regular graphs is tight for the adaptive adversary, even for $k = 2$. The first observation shows that the expected consensus time can be super-exponential if the adversary is allowed to change the degree sequence. The second observation can be regarded as a (weaker) counter part of Theorem 2 showing a lower bound of $\Omega(n/\phi)$ for static graphs, assuming that either d or ϕ is constant.

We now give the intuition behind the proof of Theorem 2 and refer the reader to the full version for the actual proof. The high level approach is as follows. For every step t we define an adaptive adversary that chooses G_{t+1} after observing $V_t^{(0)}$ and $V_t^{(1)}$. The adversary chooses G_{t+1} such that the cut between $V_t^{(0)}$ and $V_t^{(1)}$ is of order of $\Theta(\phi_t \cdot dn)$. We show that such a graph exists when the number of nodes in both $V_t^{(0)}$ and $V_t^{(1)}$ is at least of linear size (in n). By this choice the adversary ensures that the expected potential drop of $\Psi(S_{t+1})$ at most $-c\phi_t d/\Psi(s_t)$ for some constant c. Then we use the expected potential drop, together with the optional stopping theorem, to derive our lower bound.

In the following we observe that if the adversary is allowed to change the degrees, then the expected consensus time is super-exponential. A proof sketch can be found in the full version.

▶ **Observation 1.** *There is a sequence $G_1 = (V, E_1)$, $G_2 = (V, E_2)$, ... be a sequence of graphs with n nodes, where the edges $E_1, E_2, \ldots$ are distributed by an adaptive adversary, such that the expected consensus time is at least $\Omega((n/c)^{n/c})$ for some constant c.*

The bound of Theorem 1 for static regular graphs of $O(n/\phi)$ is tight for regular graphs if either the degree or the conductance is constant. A proof sketch can be found in the full version.

▶ **Observation 2.** *For every n, $d \geq 3$, and constant ϕ, there exists a d-regular graph G with n nodes and a constant conductance such that the expected consensus time on G is $\Omega(n)$. Furthermore, for every even n, $\phi > 1/n$, and constant d, there exists a (static) d-regular graph G with $\Theta(n)$ nodes and a conductance of $\Theta(\phi)$ such that the expected consensus time on G is $\Omega(n/\phi)$.*

3 Analysis of the Biased Voter Model

In this section, we prove Theorem 3. We show that the set S_t of nodes with the preferred opinion grows roughly at a rate of $1 + \Theta(\phi_t)$, as long as S_t has at least logarithmic size. For the analysis we break each round down into several steps, where exactly one node which has at least one neighbour in the opposite set is considered. Instead of analysing the growth of S_t for every round we consider larger time *intervals* consisting of a suitably chosen number of steps. We change the process slightly by assuming that there is always one node with the preferred opinion to allow for an easier analysis. If all other opinions vanish, then node 1 is set to opinion 1. Note that this will only increase the runtime of the process. We also assume that if the preferred opinion vanishes totally, node 1 is set back to the preferred opinion. This alters the process, but as we show later, this event does not happen w.h.p.

The proof unfolds in the following way. First, we define formally the *step sequence* $\mathscr{S}$. Second, we define (Definition 8) a step sequence $\mathscr{S}$ to be *good* if, intuitively speaking, the preferred opinion grows quickly enough in any sufficiently large subsequence of $\mathscr{S}$. Afterward, we show that if $\mathscr{S}$ is a good step sequence, then the preferred opinion prevails in at most

τ''' rounds (Lemma 10). Finally, we show that $\mathscr{S}$ is indeed a good step sequence w.h.p. (Lemma 11).

We now give some definitions. Again, we denote by S_t the random set of nodes that have the preferred opinion right after the first t rounds, and let $S'_t = V \setminus S_t$. For a fixed time step t we write s_t and s'_t. We define the *boundary* ∂s_t as the subset of nodes in s'_t which are adjacent to at least one node from s_t. We use the symmetric definition for $\partial s'_t$. For each $u \in V$, let $\lambda_{u,t}$ be the number of edges incident with u crossing the cut $cut(s_t, s'_t)$, or equivalently, the number of u's neighbours that have a different opinion than u's before round t.

We divide each round t into $|s_t| + |s'_t|$ *steps*, in every step a single node v from either ∂s_t or $\partial s'_t$ randomly chooses a neighbour u and adopts its opinion with the corresponding bias. Note that we assume that v sees u's opinion referring to the *beginning* of the round, even if u was considered before v and changed its opinion in the meantime. It is convenient to label the steps independently of the round in which they take place. Hence, step i denotes the i-th step counted from the *beginning* of the first round. Also u_i refers to the node considered in step i and $\lambda_i = \lambda_{u_i,t}$. We define the indicator variable o_i with $o_i = 1$ if u_i has the preferred opinion and $o_i = 0$ otherwise. Let

$$\Lambda(i) = \sum_{j=1}^{i} (1 - o_i) \cdot \lambda_i \qquad \text{and} \qquad \Lambda'(i) = \sum_{j=1}^{i} o_i \cdot \lambda_i \,.$$

Unfortunately, the order in which the nodes are considered in a round is important for our analysis and cannot be arbitrary. Note that such an ordering does not affect the outcome of the process since the probabilities for a node to switch its opinion only depends on the distribution of opinions at the beginning of the round.

Intuitively, we order the nodes in s_t and s'_t such that the sum of the degrees of nodes which are already considered from s_t and the sum of the degrees of nodes already considered from s'_t differs by at most d, i.e.,

$$|\Lambda_i - \Lambda'_i| \leq d. \tag{6}$$

The following rule determines the node to be considered in step $j+1$: if $\Lambda(j) \leq \Lambda'(j)$, then the (not yet considered) node $v \in \partial s_t$ is with smallest identifier is considered. Otherwise the node $v \in \partial s'_t$ with the smallest identifier is considered. Note that at the first step i of any round we have $\Lambda_i = \Lambda'_i$. This guarantees that (6) holds. The *step sequence* $\mathscr{S}$ is now defined as a sequence of tuples, i.e., $\mathscr{S} = (u_1, Z_1),\ (u_2, Z_2),\ \ldots$, where $Z_j = 1$ if u_j changed its opinion in step j and $Z_j = 0$ otherwise for all $j \geq 1$. Observe that when given the initial assignment and the sequence up to step i, then we know the *configuration* $\mathscr{C}_i$ of the system, i.e., the opinions of all nodes at step i and in which round step i occurred.

In our analysis we consider the increase in the number of nodes with the preferred opinion in time intervals which contain a sufficiently large number of steps, instead of considering one round after the other. The following definitions identify these intervals.

For all $i, k \geq 0$ where $\mathscr{C}_i$ is fixed, we define the random variable $S_{i,k} := \min\{j \colon \Lambda_j - \Lambda_i \geq k\}$, which is the first time step such that nodes with a degree-sum of at least k were considered. Let $I_{i,k} = [i+1, S_{i,k}]$ be the corresponding interval where we note that the length is a random variable. We proceed by showing an easy observation proven in the full version.

▶ **Observation 3.** *The number of steps in the interval $I_{i,k}$ is at most $2k + 2d$, i.e., $|I_{i,k}| \leq 2k + 2d$. Furthermore, $\Lambda'(S_{i,k}) - \Lambda'(i) \leq k + 2d$.*

Fix $\mathscr{C}_i$ and let $X_{i,k}$ be the total number of times during interval $I_{i,k}$ that a switch from a non-preferred opinion to the preferred one occurs; and define $X'_{i,k}$ similarly for the reverse switches. Finally, we define $Y_{i,k} = X_{i,k} - X'_{i,k}$; thus $Y_{i,k}$ is the increase in number of nodes that have the preferred opinion during the time interval $I_{i,k}$.

Define $\ell = \frac{132\beta \log n}{(1-\alpha_1)^2}$ and $\beta' = \frac{600d}{\alpha_1 \cdot (1-\alpha_1)^2}$. In the following we define a *good* sequence.

▶ **Definition 8.** We call the sequence $\mathscr{S}$ of steps *good* if it has all of the following properties for all $i \leq T' = 2\beta' \cdot n$. Consider the first T' steps of $\mathscr{S}$ (fix $\mathscr{C}_{T'}$). Then,

(a) $Y_{0,T'} \geq 2n$ (the preferred opinion prevails in at most T' steps).
(b) $Y_{0,i} + |S_0| > 1$ (the preferred opinion never vanishes).
(c) For any $1 \leq k \leq T'$, $Y_{i,k} \geq -\ell$ (the number of nodes with the preferred opinion never drops by ℓ).
(d) For any $\ell \leq \gamma \leq T'$, $Y_{i,k} > \gamma$, where $k = \gamma \cdot \beta'$ (the nodes with the preferred opinion increase).

This definition allows us to prove in a convenient way that a step sequence $\mathscr{S}$ is w.h.p. good: For each property, we simply consider each (sufficiently large) subsequence S separately and we show that w.h.p. S has the desired property. We achieve this by using a concentration bound on $Y_{i,k}$ which we establish in Lemma 9. Afterward, we take a union bound over all of these subsequences and properties. Using the union bound allows us to show the desired properties in all subsequences in spite of the emerging dependencies. This is done in Lemma 10.

We now show the concentration bounds on $Y_{i,k}$. These bounds rely on the Chernoff-type bound established in the full version. This Chernoff-type bound shows concentration for variables having the property that the sum of the conditional probabilities of the variables, given all previous variables, is always bounded (from above or below) by some b. The bound might be of general interest and its proof can be found in the full version.

▶ **Lemma 9.** *Fix configuration $\mathscr{C}_i$. Then,*

(a) *For $k = \gamma \frac{256d}{\alpha_1 \cdot (1-\alpha_1)^2}$ with $\gamma \geq 1$ it holds that* $\Pr\left(Y_{i,k} < \gamma\right) \leq \exp\left(-\gamma\right)$.
(b) *For $k \geq 0$, any $b' = \alpha_1 \cdot (k + 2d)/d$, and any $\delta > 0$ it holds that*

$$\Pr\left(Y_{i,k} < -(1+\delta)b'\right) \leq \exp\left(\frac{e^\delta}{(1+\delta)^{1+\delta}}\right)^{b'}.$$

The following two lemmas are proven in the full version.

▶ **Lemma 10.** *Let $\mathscr{S}$ be a step sequence. Then $\mathscr{S}$ is good with high probability.*

▶ **Lemma 11.** *If $\mathscr{S}$ is a good step sequence, then in at most T' time steps, the preferred opinion prevails and the T' time steps occur before round τ'''.*

Proof of Theorem 3. The claim follows from Lemma 10 together with Lemma 11. ◀

Abstract

Geometric inhomogeneous random graphs (GIRGs) are a model for scale-free networks with underlying geometry. We study bootstrap percolation on these graphs, which is a process modelling the spread of an infection of vertices starting within a (small) local region. We show that the process exhibits a phase transition in terms of the initial infection rate in this region. We determine the speed of the process in the supercritical case, up to lower order terms, and show that its evolution is fundamentally influenced by the underlying geometry. For vertices with given position and expected degree, we determine the infection time up to lower order terms. Finally, we show how this knowledge can be used to contain the infection locally by removing relatively few edges from the graph. This is the first time that the role of geometry on bootstrap percolation is analysed mathematically for geometric scale-free networks.

1 Introduction

One of the most challenging and intriguing questions about large real-world networks is how activity spreads through the network. "Activity" in this context can mean many things, including infections in a population network, opinions and rumours in social networks, viruses in computer networks, action potentials in neural networks, and many more. While all these networks seem very different, in the last two decades there was growing evidence that most of them share fundamental properties [4, 24]. The most famous property is that the networks are *scale-free*, i.e. the degrees follow a power-law distribution $\Pr[\deg(v) \geq d] \approx d^{1-\beta}$, typically for some $2 < \beta < 3$. Other properties include a large connected component which is a small world (poly-logarithmic diameter) and an ultra-small world (constant or poly-loglog average distance), that the networks have small separators and a large clustering coefficient. We refer the reader to [15] for more detailed discussions.

Classical models for random graphs fail to have these common properties. For example, Erdős-Rényi graphs or Watts-Strogatz graphs do not have power-law degrees, while Chung-Lu

graphs and preferential attachment (PA) graphs fail to have large clustering coefficients or small separators. The latter properties typically arise in real-world networks from an underlying geometry, either spatial or more abstract, e.g., two nodes in a social networks might be considered "close" if they share similar professions or hobbies. It is well-known that in real-world networks the spread of activity (of the flu, of viral marketing, ...) is crucially governed by the underlying spatial or abstract geometry [41]. For this reason, the explanatory power of classical models is limited in this context.

In recent years models have been developed which overcome the previously mentioned limitations, most notably *hyperbolic random graphs* (HypRGs) [13, 12, 10, 44] and their generalisation[1] *geometric inhomogeneous random graphs* (GIRGs) [15][2], and *spatial preferential attachment* (SPA) models [2, 22, 35]. Apart from the power-law exponent β, these models come with a second parameter $\alpha > 1$, which models how strongly the edges are predicted by their distance. Due to their novelty, there are only very few theoretical results on how the geometry impacts the spreading of activity through these networks.

In this paper we make a first step by analysing a specific process, *bootstrap percolation* [20], on the recent and very general GIRG model. In this process, an initial set of *infected* (or *active*) vertices iteratively infects all vertices which have at least k infected neighbours, where $k \geq 2$ is a parameter. It was originally developed to model various physical phenomena (see [1] for a short review), but has by now also become an established model for the spreading of activity in networks, for example for the spreading of beliefs [32, 25, 48, 45], behaviour [30, 31], or viral marketing [38] in social networks (see also [19]), of contagion in economic networks [6], of failures in physical networks of infrastructure [52] or compute architecture [39, 28], of action potentials in neuronal networks (e.g, [47, 49, 5, 21, 50, 43, 26, 27], see also [40] for a review), and of infections in life networks [25].

1.1 Our contribution

We investigate bootstrap percolation on GIRGs with an expected number of n vertices. We fix a ball B in the underlying geometric space, and we initially infect each vertex in B independently with probability ρ. In this way, we model that an infection (a rumour, an opinion, ...) often starts in some local region, and from there spreads to larger parts of the network. In Theorem 1 we determine a threshold ρ_c such that in the *supercritical case* $\rho \gg \rho_c$ whp[3] a linear fraction of the graph is infected eventually, and in the *subcritical case* $\rho \ll \rho_c$ infection ceases immediately. In the *critical case* $\rho = \Theta(\rho_c)$ both options occur with non-vanishing probability. If there are enough (at least k) "local hubs" in the starting region, i.e. vertices of relatively large expected degree, then they become infected and facilitate the process. On the other hand, without such local hubs the initial infection is not dense enough, and comes to a halt.

For the supercritical case, we show that it only takes $O(\log\log n)$ rounds until a constant fraction of all vertices is infected, and we determine the number of rounds until this happens up to a factor $1 \pm o(1)$ in Theorem 2. For the matching lower bound in this result, we need the technical condition $\alpha > \beta - 1$, i.e. edge-formation may not depend too weakly on the

[1] It is non-obvious that GIRGs are a generalization of HypRGs, see [15, Theorem 6.3].

[2] Other than in [15] we do not condition on the number of vertices to be exactly n, which leads to slightly less technical proofs.

[3] with high probability, i.e. with probability tending to 1 as $n \to \infty$. All unspecified limits and asymptotics will be with respect to $n \to \infty$. For example, for a function $f = f(n)$ the notation $f = O(1)$ means that there is $n_0 > 0$ and an absolute constant $C > 0$ that depends only the constant parameters $\alpha, \beta, d, w_{\min}, k$ of the model, such that $f(n) \leq C$ for all $n \geq n_0$. Similarly, $f = \omega(1)$ means $\lim_{n\to\infty} f(n) = \infty$ etc.

geometry. Notably, if the starting region B is sufficiently small then the number of rounds agrees (up to minor terms) with the average distance in the network. In particular, it does not depend on the infection rate ρ, as long as ρ is supercritical.

Finally we demonstrate that the way the infection spreads is strongly governed by the geometry of the process, again under the assumption $\alpha > \beta - 1$. Starting from B, the infection is carried most quickly by local hubs. Once the local hubs in a region are infected, they pass on their infection **a)** to other hubs that are even further away, and **b)** locally to nodes of increasingly lower degree, until a constant fraction of all vertices the region is infected. Indeed, given a vertex v (i.e. given its expected degree and its distance from B), and assuming that v is not too close to B, we can predict whp (Theorem 4) in which round it will become infected, again up to a factor $1 \pm o(1)$. In real applications such knowledge is invaluable: for example, assume that a policy-maker only knows initial time and place of the infection, i.e. she knows the region B and the current round i. In particular, she does not know ρ, she does not know the graph, and she has no detailed knowledge about who is infected. Then we show that she is able to identify a region B' in which the infection can be quarantined. In other words, by removing (from round i onwards) all edges crossing the boundary of B' whp the infection remains contained in B'. The number of edges to be deleted is relatively small: it can be much smaller than n (in fact, any function $f = f(n)$ satisfying $f = \omega(1)$ can be an upper bound, if i and $\mathrm{Vol}(B)$ are sufficiently small), and it is even much smaller than the number of edges *inside* of B', as was already noted in [15].

1.2 Related work

The GIRG model was introduced in [15], and we rely on many results from this paper. The average distance of a GIRG (which, as we show, agrees with the time until the bootstrap percolation process has infected a constant portion of all vertices) was determined in [16] in a much more general setup.

Bootstrap percolation has been intensively studied theoretically and experimentally on a multitude of networks, including trees [20, 9], lattices [3, 8], Erdős-Rényi graphs [36], various geometric graphs [49, 42, 14, 29], and scale-free networks [23, 11, 7, 38]. On geometric scale-free networks there are some experimental results [18], but little is known theoretically. Recently, Candellero and Fountoulakis [17] determined the threshold for bootstrap percolation on HypRGs (in the threshold case $\alpha = \infty$, cf. below), but they assumed that the initial infection takes place *globally*, i.e. whether any vertex is infected initially is independent of its position, and not *locally* as in our paper, where no vertex outside of a certain geometric region is infected initially. This has two major consequences. Firstly, in the global setting, the (expected) number of initially infected vertices needs to be polynomial in n in order for the infection to start spreading significantly; while in our setting every ball containing an expected number of $\omega(1)$ vertices can initiate a large infection whp. Secondly, using our knowledge about how the process evolves in time with respect to the geometry, we show that the infection time of any vertex is mainly governed by its geometric position and its weight. On the other hand, with a global initial infection the infection times only depend on the expected degrees. Note that we do not encode these expected degrees as geometric information (in contrast to [17]), but rather in the weights. Similarly, the questions studied in this paper do not apply for non-geometric random graph models.

While there is plenty of experimental literature and also some mean-field heuristics on other activity spreading processes on geometric scale-free networks (e.g., [51, 53, 34, 54, 33, 46]), rigorous mathematical treatments are non-existent with the notable exception of [37], where rumour spreading is analysed in an SPA model with a push and a push&pull protocol.

2 Model and notation

Graph model

A GIRG is a graph $G = (V, E)$ where both the vertex set V and the edge set E are random. Each vertex v is represented by a pair (x_v, w_v) consisting of a *position* x_v (in some *ground space*) and a *weight* $w_v \in \mathbb{R}_{>0}$.

Ground space and positions. We fix a (constant) dimension $d \geq 1$ and consider the d-dimensional torus $\mathbb{T}^d = \mathbb{R}^d/\mathbb{Z}^d$ as the ground space. We usually think of it as the d-dimensional cube $[0,1]^d$ where opposite boundaries are identified and measure distances by the ∞-norm on $\mathbb{T}^d$, i.e. for $x, y \in [0,1]^d$ set $\|x - y\| := \max_{1 \leq i \leq d} \min\{|x_i - y_i|, 1 - |x_i - y_i|\}$.

The set of vertices and their positions are given by a homogeneous Poisson point process on $\mathbb{T}^d$ with intensity $n \in \mathbb{N}$. More formally, for any (Lebesgue-)measurable set $B \subseteq \mathbb{T}^d$, let $V \cap B$ denote (with slight abuse of notation) the set of vertices with positions in B. Then $|V \cap B|$ is Poisson distributed with mean $n\mathrm{Vol}(B)$, i.e. for any integer $m \geq 0$ we have

$$\Pr\left[|V \cap B| = m\right] = \Pr[\mathrm{Po}\left(n\mathrm{Vol}(B)\right) = m] = \frac{(n\mathrm{Vol}(B))^m \exp(-n\mathrm{Vol}(B))}{m!},$$

and if B and B' are disjoint measurable subsets of $\mathbb{T}^d$ then $|V \cap B|$ and $|V \cap B'|$ are independent. Note in particular that the total number of vertices $|V|$ is Poisson distributed with mean n, i.e. it is also random. An important property of this process is the following: Given a random vertex[4] $v = (x_v, w_v)$, if we condition on $x_v \in B$, where B is some measurable subset of $[0,1]^d$, then the position x_v is uniformly distributed in B.

Weights. For each vertex, we draw independently a weight from some distribution $\mathcal{D}$ on $\mathbb{R}_{>0}$. We say that the weights follow a *weak power-law* for some exponent $\beta \in (2,3)$ if a $\mathcal{D}$-distributed random variable D satisfies the following two conditions: There is a constant $w_{\min} \in \mathbb{R}_{>0}$ such that $\Pr\left[D \geq w_{\min}\right] = 1$, and for every constant $\gamma > 0$ there are constants $0 < c_1 \leq c_2$ such that

$$c_1 w^{1-\beta-\gamma} \leq \Pr\left[D \geq w\right] \leq c_2 w^{1-\beta+\gamma} \tag{1}$$

for all $w \geq w_{\min}$. If this condition is also satisfied for $\gamma = 0$, then we say that the weights follow a *strong power-law*.

Edges. Next we fix a constant $\alpha \in \mathbb{R}_{>1} \cup \{\infty\}$. Then (conditional on the Poisson point process) two distinct vertices $u = (x_u, w_u)$ and $v = (x_v, w_v)$ form an edge independently of all other pairs with probability $p(x_u, x_v, w_u, w_v)$, where the function p satisfies

$$p(x_u, x_v, w_u, w_v) = \Theta(1) \min\left\{\left(\frac{w_u w_v}{\|x_u - x_v\|^d n}\right)^\alpha, 1\right\},$$

if $\alpha < \infty$. In the *threshold model* $\alpha = \infty$ we instead require that p satisfies

$$p(x_u, x_v, w_u, w_v) = \begin{cases} \Omega(1) & \text{if } \|x_u - x_v\| \leq C_1 \left(\frac{w_u w_v}{n}\right)^{1/d} \\ 0 & \text{if } \|x_u - x_v\| > C_2 \left(\frac{w_u w_v}{n}\right)^{1/d} \end{cases}$$

for some constants $0 < C_1 \leq C_2$. Note that for $C_1 \neq C_2$ the edge probability may be arbitrary in the interval $\left(C_1 \left(\frac{w_u w_v}{n}\right)^{1/d}, C_2 \left(\frac{w_u w_v}{n}\right)^{1/d}\right)$.

[4] By abuse of notation, x_v and w_v may either denote random variables or values.

Bootstrap percolation

Let $k \geq 2$ be a constant, let $B_0 \subseteq \mathbb{T}^d$ be measurable, and let $0 \leq \rho \leq 1$. Then the bootstrap percolation process with *threshold* k, *starting region* B_0, and *initial infection rate* ρ is the following process. For every integer $i \geq 0$ there is a set $V^i \subseteq V$ of vertices which are *infected* (or *active*) at time i. The process starts with a random set $V^0 \subseteq V$ which contains each vertex in $V \cap B_0$ independently with probability ρ, and which contains no other vertices. For all integers $i \geq 0$ we then define the set V^{i+1} iteratively by

$$V^{i+1} := V^i \cup \left\{ v \in V \;\middle|\; v \text{ has at least } k \text{ neighbours in } V^i \right\}.$$

Moreover, we set $V^\infty := \bigcup_{i \in \mathbb{N}} V^i$, and for convenience of notation we extend this definition to real parameters $i \in \mathbb{R}_{>0}$ by setting $V^i := V^{\lceil i \rceil}$. For a vertex $v \in V$, we define its *infection time* as $L_v := \inf \left\{ i \geq 0 \;\middle|\; v \in V^i \right\}$ and $L_v := \infty$ if the infimum does not exist.

We denote by $\nu = \nu(n) := n\mathrm{Vol}(B_0)$ the expected number of vertices in B_0. Throughout the paper we will assume that B_0 is a ball, which is – without loss of generality due to symmetry of $\mathbb{T}^d$ – centred at 0. Moreover, we will assume that $\nu = \omega(1)$.

Further notation

We denote the neighbourhood of a vertex $v \in V$ by $N(v) := \{u \in V \mid \{u, v\} \in E\}$. Furthermore, for any two sets of vertices U_1 and U_2, we denote the set of edges between them by $E(U_1, U_2) := \{e = \{u_1, u_2\} \mid u_1 \in U_1, u_2 \in U_2\}$. For any $\lambda \geq 0$ and any closed ball $B \subseteq \mathbb{T}^d$ of radius $r \geq 0$ centred at 0 we denote by λB the closed ball of radius λr around 0. By abuse of notation, if $S \subset V$ and $B \subseteq \mathbb{T}^d$ then $S \cap B := \{v \in S \mid x_v \in B\}$.

3 Main results

First of all we show that bootstrap percolation on a *GIRG* has a threshold with respect to the initial infection rate ρ. Since HypRGs are a special instance of GIRGs, this contains in particular the result of [17] on (threshold) HypRGs, where the case $\nu = n$ was studied.

▶ **Theorem 1.** *Consider a bootstrap percolation process on a GIRG $G = (V, E)$ with constant parameters $\alpha, \beta, d, w_{min}, k$, initial infection rate $\rho = \rho(n) \in [0, 1]$, and initial infection region B_0 with volume ν/n, where $\nu = \nu(n) = \omega(1)$. We set*

$$\rho_c = \rho_c(n) := \nu^{-\frac{1}{\beta - 1}}.$$

If the weights follow a strong power-law, then as $n \to \infty$ we have:

- **(i)** *If $\rho = \omega(\rho_c)$, then $|V^\infty| = \Theta(n)$ whp.*
- **(ii)** *If $\rho = \Theta(\rho_c)$, then $|V^\infty| = \Theta(n)$ with probability $\Omega(1)$, but also $V^\infty = V^0$ with probability $\Omega(1)$.*
- **(iii)** *If $\rho = o(\rho_c)$, then $V^\infty = V^0$ whp.*

If the weights follow a weak power-law, then as $n \to \infty$ we have:

- **(iv)** *If there is a constant $\delta > 0$ such that $\rho \geq \rho_c^{1+\delta}$, then $|V^\infty| = \Theta(n)$ whp.*
- **(v)** *If there is a constant $\delta > 0$ such that $\rho \leq \rho_c^{1-\delta}$, then $V^\infty = V^0$ whp.*

Whenever we refer to the *supercritical* regime we mean case (i) and (iv). Similarly, (iii) and (v) form the *subcritical* regime and (ii) is the *critical* regime. Note in particular that there is a supercritical regime regardless of how small the expected number ν of vertices in the starting region is, provided that $\nu = \omega(1)$. This is in sharp contrast to non-geometric

graphs like Chung-Lu graphs, where the expected number of initially infected vertices must be polynomial in n (if the set of initially infected vertices is chosen at random).

Indeed the proof of Theorem 1 will grant a deeper insight into the evolution of the process. Since the process whp stops immediately in the subcritical regime, we may restrict ourselves to the other cases. We show a doubly logarithmic upper bound on the number of rounds until a constant fraction of all vertices are infected. Furthermore, we prove that this bound is tight up to minor order terms if the influence of the underlying geometry on the random graphs is sufficiently strong ($\alpha > \beta - 1$). Remarkably, the bounds do not depend on the initial infection rate ρ, as long as ρ is supercritical. Moreover, if the expected number ν of vertices in the starting region is sufficiently small (if $\log\log\nu = o(\log\log n)$), then the bound coincides with the average distance in the graph, again up to minor order terms.

▶ **Theorem 2.** *In the situation of Theorem 1, let $\varepsilon > 0$ be constant and set*

$$i_\infty := \frac{\log\log_\nu n + \log\log n}{|\log(\beta-2)|}.$$

Then in the supercritical regime whp, and in the critical regime with probability $\Omega(1)$ we have $|V^{(1+\varepsilon)i_\infty}| = \Theta(n)$, as $n \to \infty$.
If furthermore $\alpha > \beta - 1$ and $\nu = n^{o(1)}$ then in all regimes we have whp $|V^{(1-\varepsilon)i_\infty}| = o(n)$, as $n \to \infty$.

In fact, we can still refine the statement of Theorem 2 tremendously, at least in the case $\alpha > \beta - 1$. In the following, we determine for every fixed vertex v its infection time L_v, up to minor order terms (with the restriction that v may not be too close to the starting region). We will show that it is given by the following expression (see also Remark 6 below).

▶ **Definition 3.** For any $x \in \mathbb{T}^d \setminus B_0$ and $w \in \mathbb{R}_{>0}$ we define

$$\Lambda(x,w) := \begin{cases} \max\left\{0,\ \frac{\log\log_\nu\left(\|x\|^d n/w\right)}{|\log(\beta-2)|}\right\}, & \text{if } w > (\|x\|^d n)^{1/(\beta-1)}, \\ \frac{2\log\log_\nu(\|x\|^d n) - \log\log_\nu w}{|\log(\beta-2)|}, & \text{if } w \le (\|x\|^d n)^{1/(\beta-1)}. \end{cases} \tag{2}$$

In the first case we use the convention that the second term is $-\infty$ if $\|x\|^d n/w < 1$, and thus does not contribute to the maximum.

Note that in the second case, the sign of $\log\log_\nu w$ may be either positive or negative. However, then we have the lower bound $\Lambda(x,w) \ge \log\log_\nu(\|x\|^d n)/|\log(\beta-2)| + O(1)$ due to the upper bound of w and thus, in particular $\Lambda(x,w) \ge 0$, since $x \in \mathbb{T}^d \setminus B_0$.

▶ **Theorem 4.** *Assume we are in the situation of Theorem 1 in the supercritical regime. Let $v = (x_v, w_v)$ be any fixed vertex such that $x_v \in \mathbb{T}^d \setminus B_0$, $w_v = \omega(1)$ and $\Lambda(x_v, w_v) \le \log_2(\|x_v\|^d n/\nu^{2/(\beta-2)})$. Then, as $n \to \infty$, the infection time L_v satisfies whp*

$$L_v \le (1 + o(1))\Lambda(x_v, w_v) + O(1).$$

If additionally $\alpha > \beta - 1$ then, as $n \to \infty$ we also have whp

$$L_v \ge (1 - o(1))\Lambda(x_v, w_v) - O(1).$$

As in Theorem 2, the bounds do not depend on the initial infection rate ρ, as long as it is supercritical.

▶ Remark 5. The technical restrictions in Theorem 4 are necessary: if a vertex v has weight $w_v = O(1)$ then the number of neighbours is Poisson distributed with mean $\Theta(w_v)$ (see Lemma 8), so v is even isolated with probability $\Omega(1)$. In particular, we cannot expected that whp v is ever infected.

The restriction $\Lambda(x_v, w_v) \leq \log_2(\|x_v\|^d n/\nu^{2/(\beta-2)})$ ensures that v is not too close to the starting region. If v is too close, then it may have neighbours inside of B_0, and in this case it does depend on ρ when they are infected. (And of course, this process iterates.) The term $\log_2(\|x_v\|^d n/\nu^{2/(\beta-2)})$ is not tight and could be improved at the cost of more technical proofs. However, there are already rather few vertices that violate the condition $\Lambda(x_v, w_v) \leq \log_2(\|x_v\|^d n/\nu^{2/(\beta-2)})$. For example, recall that it only takes $O(\log\log n)$ steps until a constant fraction of all vertices are infected. At this time, we only exclude vertices which satisfy $\|x_v\|^d n \leq \nu^{2/(\beta-2)} \cdot (\log n)^{O(1)}$, so the expected number of affected vertices is also at most $\nu^{2/(\beta-2)} \cdot (\log n)^{O(1)}$. Even this is a gross overestimate, since the vertices close to the origin have much smaller infection times L_v, and thus only very few of them are affected by the condition.

▶ Remark 6. The first case in Definition 3 is not needed if we restrict ourselves to vertices as they typically appear in GIRGs. More precisely, as we will see in Lemma 10, whp all vertices $v = (x_v, w_v) \in V \cap (\mathbb{T}^d \setminus B_0)$ satisfy $w_v \leq (\|x_v\|^d n)^{1/(\beta-1-\eta)}$ where $\eta > 0$ is an arbitrary constant. In the border case $(\|x_v\|^d n)^{1/(\beta-1)} \leq w_v \leq (\|x_v\|^d n)^{1/(\beta-1-\eta)}$ both expressions in (2) agree up to additive constants, i.e.

$$\Lambda(x_v, w_v) = \frac{2\log\log_\nu(\|x_v\|^d n) - \log\log_\nu w_v}{|\log(\beta-2)|} \pm O(1). \tag{3}$$

Therefore, we could also use (3) as definition for Λ if we would exclude vertices which are unlikely to exist in Theorem 4 .

Finally, we give a strategy how to contain the infection within a certain region when only the starting set and the current round are known, but not the set of infected vertices. Note that the number of edges that need to be removed is substantially smaller than the expected number $\widetilde{\nu}_i$ of vertices in a containment area $\widetilde{B}_i$, see Definition 11.

▶ **Theorem 7.** *Assume that we are in the situation of Theorem 1, and that $\alpha > \beta - 1$. If the starting region B_0 is known, then by removing all edges crossing the boundary of $\widetilde{B}_i$ before round $i+1$, whp (as $n \to \infty$) the infection is contained in $\widetilde{B}_i$. The expected number of edges crossing the boundary of $\widetilde{B}_i$ is $\widetilde{\nu}_i^{\max\{3-\beta, 1-1/d\}+o(1)}$.*

4 Basic properties of GIRGs

In this section we list briefly some basic properties of GIRGs (without proofs). The first lemma, based on [16, Lemma 4.4 and Theorem 7.3], tells us that the expected degree of a vertex equals its weight, up to constant factors. Moreover, it gives the marginal probability that two vertices u, v of fixed weights but random positions in $\mathbb{T}^d$ are adjacent. This probability remains the same if the position of one (but not both) of the vertices is fixed.

▶ **Lemma 8.** *Let $v = (x_v, w_v)$ be a vertex with fixed weight and position. Then $\deg(v)$ is Poisson distributed with mean $\Theta(w_v)$. Moreover, if $u = (x_u, w_u)$ is a vertex with fixed weight, but with random position $x_u \in \mathbb{T}^d$, then*

$$\Pr[\{u,v\} \in E \mid w_u, w_v, x_v] = \Theta\left(\min\left\{\frac{w_u w_v}{n}, 1\right\}\right). \tag{4}$$

Note in particular that the right hand side of (4) *is independent of* x_v*, so the same formula still applies if also the position* x_v *of* v *is randomised.*

We often need to bound the expected number of neighbours of a given vertex in some geometric region, which we may do by the following lemma.

▶ **Lemma 9.** *Let* $\eta > 0$ *and* $C > 1$ *be constants, define* $m := \min\{\alpha, \beta - 1 - \eta\}$ *and consider a closed ball* $B \subseteq \mathbb{T}^d$ *of radius* $r > 0$ *centred at* 0*. Let* $v = (x_v, w_v)$ *be a vertex with fixed weight and position. Then*

$$\mathbb{E}\left[|N(v) \cap B|\right] = O(n\mathrm{Vol}(B)) \cdot \begin{cases} \min\left\{\frac{w_v}{n\mathrm{Vol}(B)}, 1\right\}, & \text{if } \|x_v\| \le Cr, \\ \min\left\{\left(\frac{w_v}{\|x_v\|^d n}\right)^m, 1\right\} & \text{if } \|x_v\| \ge Cr. \end{cases}$$

The last lemma states that whp there are no vertices whose weight is much larger than their distance from the origin.

▶ **Lemma 10.** *Let* $\eta > 0$ *be a constant and consider a closed ball* $B \subseteq \mathbb{T}^d$ *of radius* $r > 0$ *centred at* 0*, satisfying* $n\mathrm{Vol}(B) = \Theta(r^d n) = \omega(1)$*. Then with probability* $1 - (r^d n)^{-\Omega(\eta)}$ *there is no vertex* $v = (x_v, w_v)$ *with* $x_v \in \mathbb{T}^d \setminus B$ *and* $w_v \ge (\|x_v\|^d n)^{1/(\beta-1-\eta)}$*.*

5 Proof outline

5.1 Intuition

Due to space limitations we can only give a very rough sketch of the main ideas. We warn the reader that the statements as they are formulated in this section are not literally true, but they are only true if appropriate error margins (slightly smaller/larger weights or regions) are taken into account. The same holds for definitions within this section. The rigorous definitions and statements with full technical details can be found in Section 5.2 and 5.3.

For the subcritical regime, we distinguish between high-weight vertices ($w_v = \omega(w_0)$, where $w_0 := \nu^{1/(\beta-1)}$) and low-weight vertices ($w_v = O(w_0)$). By an easy computation, the expected number of low-weight vertices in B_0 that are infected in round 1 is $o(1)$, so by Markov's inequality no low-weight vertex becomes infected whp. On the other hand, whp no high-weight vertex exists in B_0, and the expected number of infected vertices outside of B_0 is also $o(1)$ because they are too far away from infected vertices. In order words, whp no vertex is infected in round 1.

In the critical regime, the calculation is similar, but if there exist vertices of weight $\Theta(w_0)$ then these vertices are infected with probability $\Omega(1)$. The number of vertices of weight $\Theta(w_0)$ is Poisson distributed with mean $\Theta(1)$, so it may happen (both with probability $\Omega(1)$) that either no such vertex exists (so percolation stops) or that there are at least k such vertices, and all of them are infected. In the supercritical regime, whp k vertices of weight (slightly less than) w_0 are infected. Whp, these k vertices infect all other vertices of similar weight in two more rounds. This is sufficient to start an avalanche of infection, and for the rest of this section we will restrict ourselves to this case.

If the infection gets started, then it evolves as follows. Let $\zeta := 1/(\beta - 2) > 1$, and consider the sequence B_i of nested balls of volume ν_i/n centred at 0, where $\nu_i := \nu^{\zeta^i}$. Then in the i-th round, all vertices of weight roughly $w_i := \nu_i^{1/(\beta-1)}$ in B_i are infected. In the next round, whp the vertices of weight w_i in B_i infect all vertices of weight w_{i+1} in B_{i+1}, thus spreading the infection to new regions. Note that this statement is easy to prove inductively since we assumed that *all* vertices of weight w_i in B_i are infected, so for the vertices in B_{i+1}

it suffices to count the number of neighbours of a certain weight in B_i, which is a Poisson distributed random variable. This gives a lower bound on how fast the infection spreads geometrically. It can not spread faster since whp there are no edges from B_i to $\mathbb{T}^d \setminus B_{i+1}$. This latter fact already allows us to execute a containment strategy.

On the other hand, if in round j every vertex of weight w in some region has a large probability to be infected, then in round $j+1$ every vertex of weight at least $w^{1/\zeta}$ in this region has a large (though slightly smaller) probability to be infected. To prove this formally, we consider a vertex of weight $w^{1/\zeta}$. Such a vertex (but not vertices of smaller weight) has at least w^δ neighbours of weight w, with probability at least $1 - \exp[-w^\delta]$. So we pick k such neighbours, and bound the probability that at least one of them is *not* infected by a union bound. In this way, we lose a factor of k in each round, but by going through the proof details it turns out that this factor is still negligible compared to the error term $\exp[-w^{\delta/\zeta}]$.

Complementing this infection pathway by a matching upper bound is the most challenging and technical part of the proof. In round $i-1$ there is no infected vertex in B_i, so it is not hard to argue that in round i only vertices of large weight in $\mathbb{T}^d \setminus B_{i-1}$ are infected. However, in subsequent rounds it does happen that vertices of very small weight in $\mathbb{T}^d \setminus B_{i-1}$ become infected. Fortunately, this only happens with rather small probability, which we can explicitly bound (Theorem 13 (f)) as a function of the weight. Once we have such a bound in some round, we use that whp no vertex in $\mathbb{T}^d \setminus B_{i-1}$ (not too close to the boundary) has strictly more than one neighbour in B_{i-1}. Therefore, in order to be infected, at least one of its neighbours in $\mathbb{T}^d \setminus B_{i-1}$ must have been infected in the previous round, and we can bound the probability of this event by the expected number of previously infected neighbours in $\mathbb{T}^d \setminus B_{i-1}$. It turns out that this simple bound is sufficient to provide the desired matching upper bound, safe quite some technical details which we omit.

We remark that it is in this last step where we use the assumption $\alpha > \beta - 1$ since otherwise there do exist vertices in $\mathbb{T}^d \setminus B_{i-1}$ that have several neighbours in B_{i-1}, and these vertices exist in a substantial part of B_i. Even worse, in some (large) subregion of B_i, the number of infections in round $i+1$ that come from neighbours in B_{i-1} dominates the number of infections that come from neighbours in B_i. For investigating the case $\alpha \le \beta - 1$ (which we don't in this paper), it will no longer be possible to use a bound on the infection probability that is uniform within $\mathbb{T}^d \setminus B_{i-1}$, or within $B_i \setminus B_{i-1}$.

Once the claims outlined above are proven (Theorem 13 and 14) we have almost complete control over the process. In particular, for a each vertex v with fixed weight and position (outside of the starting region B_0), and for each round j we have lower and upper bounds for the probability that v has already become infected by round j. We can thus compute rounds j_1, j_2 for which the probability is at most $o(1)$ and at least $1 - o(1)$, respectively, and we find that these rounds coincide up to lower order terms. It is still rather complicated to actually perform the calculations of j_1 and j_2 due to the many technical details which we omitted in this outline, but no further knowledge about the infection process is required.

5.2 Formal statements and sketch of proofs

In this section we will give two theorems which describe the geometrical evolution of the process in detail, and which make the intuitions from Section 5.1 precise. Theorem 13 states that **a)** certain regions cannot be reached too early by the infection, and **b)** within an infected region, vertices of too low weight have a small probability to be infected early. Hence, the theorem gives an *upper bound on the speed* of the infection process. Note that this already gives the quarantine statement (Theorem 7), see Section 5.3 for details. Afterwards, Theorem 14 gives lower bounds on the probability that a vertex in a given region is infected

at a given time, in the supercritical case. In particular, a vertex of weight $w_v = \omega(1)$ will eventually be infected whp. Thus the theorem provides a *lower bound on the speed* of the process. This lower bound also applies in the critical regime if in the first step sufficiently many heavy vertices became infected, an event which holds with at least constant probability.

In Section 5.1 we introduced balls B_i which essentially correspond to the region of infected vertices in round i. For the formal statements we need slightly smaller and larger balls, which we now define formally. In general, $\tilde{\nu}_i, \tilde{B}_i$ etc. will denote the upper bound variants.

▶ **Definition 11.** For all $0 < \varepsilon < \zeta = 1/(\beta-2)$ and all $i \geq 0$, we set

$$\nu_0 := \nu \qquad \text{and} \qquad \nu_i = \nu_i(\varepsilon) := \nu_0^{(\zeta-\varepsilon)^i},$$
$$\widetilde{\nu}_0 = \widetilde{\nu}_0(\varepsilon) := \nu^{(\beta-1)/(\beta-2)+\varepsilon} \qquad \text{and} \qquad \widetilde{\nu}_i = \widetilde{\nu}_i(\varepsilon) := \widetilde{\nu}_0^{(\zeta+\varepsilon)^i}$$

We define $B_i := B_i(\varepsilon)$ and $\widetilde{B}_i := \widetilde{B}_i(\varepsilon)$ to be the closed ball centred around 0 of volume $\min\{\nu_i(\varepsilon)/n, 1\}$ and $\min\{\widetilde{\nu}_i(\varepsilon)/n, 1\}$, respectively. Note that $B_i(\varepsilon) \subseteq \widetilde{B}_i(\varepsilon')$ for all $i \geq 0$ and all $0 < \varepsilon, \varepsilon' < \zeta$.

First we give an upper bound on the speed of the process. For a formal statement, we define the following families of "good" events.

▶ **Definition 12.** Let $\varepsilon > 0$ be a constant and let $\eta = \eta(\varepsilon) > 0$ be a constant which is sufficiently small compared to ε. Moreover, let $h = h(n)$ be a function satisfying $h(n) = \omega(1)$, $h(n) = o(\log n)$, and $h(n) = \nu^{o(1)}$. Then for all $i, \ell, j \geq 0$ we define the following families of events:

- $\mathcal{E}(i) := \{V^i \cap (\mathbb{T}^d \setminus \widetilde{B}_i) = \emptyset\}$;
- For all $w \geq w_{\min}$ let $S(w,\ell) := \{v \in V^{\leq \ell} \mid w_v \geq w\}$. We set

$$\mathcal{F}(\ell, w) = \mathcal{F}_{\varepsilon,\eta,h}(\ell, w) := \left\{ |S(w,\ell)| \leq h^\ell w^{2-\beta+\eta} \widetilde{\nu}_0^{1-(\zeta+\varepsilon)^{-\ell}(\beta-1)^{-1}} \right\},$$

  and $\mathcal{F}(\ell) = \mathcal{F}_{\varepsilon,\eta,h}(\ell) := \bigcap_{w' \geq w_{\min}} \mathcal{F}(\ell, w')$;
- $\mathcal{G}(j) = \mathcal{G}_{\varepsilon,\eta,h}(j) := \bigcap_{j'=0}^{j} (\mathcal{E}(j') \cap \mathcal{F}(j'))$.

In other words, $\mathcal{E}(i)$ means that no vertex outside of $\widetilde{B}_i$ is infected at time i, and $\mathcal{F}(\ell)$ is the event that there are not "too many" vertices which have small weight, are close to the starting region, and are infected at time ℓ. Finally, $\mathcal{G}(j)$ is the event that all "good" events hold up to time j.

▶ **Theorem 13.** *Let ε, η, h be given as in Definition 12 and assume $\alpha > \beta - 1$. Then, for sufficiently large n,*

(a) *$\mathcal{E}(0)$ is always satisfied;*
(b) *$\Pr[\mathcal{F}(0)] \geq 1 - O(h^{-1})$;*
(c) *For all $i \geq 1$ we have $\Pr[\mathcal{E}(i) \mid \mathcal{G}(i-1)] \geq 1 - h^{-\Omega(i)}$;*
(d) *For all $\ell \geq 1$ we have $\Pr[\mathcal{F}(\ell) \mid \mathcal{G}(\ell-1)] \geq 1 - h^{-\Omega(\ell)}$;*
(e) *Whp, the events $\mathcal{G}(j)$ hold for all $j \geq 0$;*
(f) *For all $i \geq 1$ and $\ell \geq 0$, and for every fixed vertex $v = (x_v, w_v)$ such that $x_v \in \mathbb{T}^d \setminus 2^{\ell+1}\widetilde{B}_{i-1}$ and $w_v \geq w_{min}$ we have*

$$\Pr\left[v \in V^{i+\ell} \,\middle|\, \mathcal{G}(i+\ell-1)\right] \leq w_v 2^{\ell d} \widetilde{\nu}_i^{-(\zeta+\varepsilon)^{-\ell-2}/(\beta-1)}.$$

The theorem can be proven by induction on $i + \ell$, with the strategies from Section 5.1, and using the lemmas from Section 4. We next state the complementary lower bound.

For all $i, \ell \geq 0$, let $w_{i,\ell} = w_{i,\ell}(\varepsilon) := \nu^{(\zeta-\varepsilon)^{i-\ell}/(\beta-2)}$, and let U_i be the set of vertices in B_i of weight at least $w_{i,0}$. Furthermore, we denote by $\mathcal{H}(i)$ the event that in round $i+3$ all vertices in U_i are infected.

▶ **Theorem 14.** *Let $0 < \varepsilon < \zeta$ and $\eta = \eta(\varepsilon) > 0$ be sufficiently small. Assume that we are in the supercritical case, or instead that $|U_i \cap V^1| \geq k$. Then the following is true:*

(a) *Whp $|U_i| = \nu_i^{\Omega(\eta)}$ and $|U_i| = O(\nu_i)$ uniformly for all $i \geq 0$.*

(b) *Whp all the events $\mathcal{H}(i)$ occur.*

(c) *There exist constants $C_0, C_1, C_2 > 0$ such that the following holds: Let $v = (x_v, w_v)$ be any vertex with fixed position and weight and let $i, \ell \geq 0$ be such that $x_v \in B_i$ and $w_v \geq \max\{w_{i,\ell}, C_0\}$. Then for sufficiently large $n \in \mathbb{N}$,*

$$\Pr[v \in V^{i+3+\ell} \mid \mathcal{H}(0), \dots, \mathcal{H}(i)] \geq 1 - \exp\left[-C_1 \nu_i^{C_2(\zeta-\varepsilon)^{-\ell}}\right].$$

Again, the theorem can be proven inductively, with the strategies from Section 5.1.

5.3 Proof sketches for main results

In this section we highlight the main steps used to deduce the results from Section 3 from Theorem 13 and Theorem 14.

Threshold and speed of the process: Theorem 1 and Theorem 2

We split the (combined) proof into six claims:

We first show the second statement of Theorem 2, so let $0 < \varepsilon < \zeta$ be a constant.

▶ **Claim 15.** *Assume that $\alpha > \beta - 1$ and $\nu = n^{o(1)}$, then $|V^{(1-\varepsilon)i_\infty}| = o(n)$ whp.*

We define integers $i \geq 0$ and $\ell \geq 0$ such that $i + \ell \geq (1-\varepsilon)i_\infty$ and $\widetilde{\nu}_i = n^{1-o(1)}$ but $2^i \widetilde{\nu}_i = o(n)$. Then whp there are only $o(n)$ vertices inside of $2^\ell \widetilde{B}_i$, by Markov's inequality, and for vertices outside we obtain the corresponding bound from Theorem 14 (f).

In the subcritical regime, (iii) or (v), we will indeed show that whp the process does not infect any vertices in the first step and therefore terminates immediately.

▶ **Claim 16.** *$V^1 = V^0$ whp.*

Since the initial infection occurs only within B_0 and all vertices have the same probability of being infected, the number of neighbours of a given vertex is Poisson distributed, and we can bound the mean by Lemma 9. Thus we can compute the expected number of vertices in $V^{=1}$, which is $o(1)$, and this proves the claim by Markov's inequality.

Next we show that in the critical regime, (ii), with constant probability no further vertices ever become infected.

▶ **Claim 17.** *$V^1 = V^0$ with probability $\Omega(1)$.*

The number of "heavy" vertices of weight $\Theta(w_0)$ is Poisson distributed with expectation $\Theta(1)$. Thus, with probability $\Omega(1)$ there are no heavy vertices. Conditioned on this event, the calculations of the subcritical regime carry over.

On the other hand, also with probability $\Omega(1)$, at least k heavy vertices exist. Each such vertex is infected in the first round with probability $\Omega(1)$ by vertices very close to it, and all these events are positively associated. This proves the following claim.

▶ **Claim 18.** *$V^1 \cap B_0$ contains at least k heavy vertices with probability $\Omega(1)$.*

Next we assume that we are in the supercritical regime (i) or (iv), or in the critical regime (ii) where we also assume that at least k heavy vertices are infected in the first round. Then we need to show the following claim.

▶ **Claim 19.** $|V^{(1+\varepsilon)i_\infty}| = \Omega(n)$ *in expectation and whp.*

We (carefully) choose $i \geq 0$ and $\ell \geq 0$ such that $i+\ell \leq (1+\varepsilon)\, B_i = \mathbb{T}^d$ and $w_{i,l} = O(1)$. Then Theorem 14 (c) tells us immediately that every vertex of weight at least C has probability $\Omega(1)$ to be infected by time $i + \ell + 3$, and since the expected number of such vertices is $\Omega(n)$, thus proving the claim for the expectation. The whp statement follows from a small technical alteration of the previous argument, which we omit for space limitations.

Now Theorem 1 follows from Claims 16, 17, 18 and 19, while Theorem 2 is proven by Claims 15 and 19.

Infection times: Theorem 4

With our previous results, the idea is very simple: given a v vertex which satisfies the assumptions of Theorem 4 we show an lower bound on its infection time L_v by Theorem 14 and an upper bound by Theorem 13, respectively. The details become quite long and technical, and are therefore omitted.

Quarantine strategies: Theorem 7

By Theorem 13, whp there is no vertex outside of $\widetilde{B}_i$ which is infected in round i. Therefore, it suffices to (permanently) remove by the end of round i all edges that cross the boundary of $\widetilde{B}_i$, i.e. all edges in $E(\widetilde{B}_i, \mathbb{T}^d \setminus \widetilde{B}_i)$. Using an argument very similar to the one used in [15, Lemma 7.1 and Theorem 7.2], where the number of edges cutting a grid is considered, we can bound $|E(\widetilde{B}_i, 2\widetilde{B}_i)|$ the expected number of close-range edges by $\widetilde{\nu}_i^{\max\{3-\beta,1-1/d\}+o(1)}$. On the other hand using Lemma 9, we can estimate the expected number $|E(\widetilde{B}_i, \mathbb{T}^d \setminus 2\widetilde{B}_i)|$ of long-range edges by $\widetilde{\nu}_i^{3-\beta}$ and the result follows. We omit the details.

6 Concluding remarks

We have shown that in the GIRG model for scale-free networks with underlying geometry, even a small region can cause an infection that spreads through a linear part of the population. We have analysed the process in great detail, and we have determined its metastability threshold, its speed, and the time at which individual vertices becomes infected. Moreover, we have shown how a policy-maker can utilise this knowledge to enforce a successful quarantine strategy. We want to emphasise that the latter result is only a proof of concept, intended to illustrate the possibilities that come from a thorough understanding of the role of the underlying geometry in infection processes. In particular, we want to remind the reader that bootstrap percolation is not a perfect model for viral infections (though it has been used to this end), but is more adequate for processes in which the probability of transmission grows more than proportional if more than one neighbours is active, like believes spreading through a social network ("What I tell you three times is true."), or action potential spreading through a neuronal network.

Therefore, this paper is only a first step. There are many other models for the spread of an infection, most notably SIR and SIRS models for epidemiological applications, and we have much yet to learn from analysing these models in geometric power-law networks like GIRGs. From a technical point of view, it is unsatisfactory that our analysis does not include the case $\alpha \leq \beta - 1$. We believe that also in this case, the bootstrap percolation process is essentially governed by the geometry of the underlying space, only in a more complex way. Understanding this case would probably also add to our toolbox for analysing less "clear-cut" processes.

Abstract

Due to the sheer size of real-world networks, delay and space become quite relevant measures for the cost of enumeration in network analytics. This paper presents efficient algorithms for listing maximum cliques in networks, providing the first sublinear-space bounds with guaranteed delay per enumerated clique, thus comparing favorably with the known literature.

1 Introduction

The design of efficient algorithms for enumerating all possible solutions of a given problem dates back to the 1950s [5, 19, 35]. Enumeration algorithms have the purpose of either counting the number of solutions or listing the solutions one by one. Their study originated in the area of complexity and optimization [17, 23, 39], and then spread over several other application domains, including bioinformatics, machine learning, network analytics, and social analysis [1, 26, 33]. For instance, a number of papers described how to enumerate triangles [6, 3, 22, 31] and their generalizations such as cliques or other dense subgraphs [7, 9, 11, 12, 14, 15, 21, 25, 29, 34, 38]. Among the first problems attacked is the enumeration of maximal cliques [2, 5, 7, 18, 24, 28], where a maximal clique is a subset of pairwise connected vertices that is maximal under inclusion.

This paper focuses on two worst-case efficiency measures, namely, delay and space, that become relevant for enumeration in massive networks. The delay is the maximum latency between any two consecutively reported solutions. The space is the maximum amount of extra memory that should be allocated to enumerate all the solutions, besides the amount required by the input graph.

Motivation. Let $G(V, E)$ be an undirected connected graph, represented with ordered adjacency lists, where $n = |V|$ is the number of vertices and $m = |E|$ is the number of edges. Although it is known that the number α of maximal cliques in real-world networks is much smaller than the exponentially many possible subsets of vertices [32], it happens that α is still large for massive networks. In this scenario the notion of delay provides a guarantee on the maximum time that a postprocessing algorithm has to wait before the next enumerated maximal clique is produced: letting $t(n, m)$ be the delay, we observe that not only the total time is output-sensitive, i.e. $O(\alpha\, t(n, m))$ plus the setup cost, but we also guarantee that listing the next solution takes $O(t(n, m))$ time in the worst case. This is a stronger notion than average throughput (e.g., number of cliques per second), which is obtained by dividing α by the total time. The former implies the latter, but not vice versa. We observe that the delay has been already used in many papers, e.g. [9, 11, 12, 23, 25, 36], as a worst-case measure.

Space is another measure that has been considered when enumerating solutions, e.g. [13, 10, 41]. Modern CPUs have multiple cores, where each core has a very fast – but small – private cache, with a shared last-level cache and a shared slow random access memory. Consider multiple enumeration threads running simultaneously on the same massive graph in the shared memory: modern machines have very large shared memory compared to the private cores, so massive graphs can be stored in shared memory but not in the private cores. If the memory footprint of each thread is small and fits the private cache of a core, the shared memory access bottleneck is only caused by accessing the graph itself, and not the private data. To make a concrete example, the private cache for CPUs in today's commodity desktops is few hundreds of kilobytes while the random access memory can host several terabytes and networks contain millions of vertices and edges. For example, network EU-2005 (Section 7) contains $n = 850$ thousand vertices, $m = 16.1$ million edges, and $\alpha = 5.7$ million cliques: here, the space of known algorithms ranges from 3 to 164 megabytes, so their working set does not fit the private cache (Table 2).

We remark that delay and space are somehow related measures. An algorithm with good overall time can accumulate solutions in the shared memory or store them temporarily in a file for a subsequent phase of postprocessing. If space is limited (especially in fast memory), this approach cannot be taken into account.

Furthermore, as most current output-sensitive approaches have a recursive nature, they can easily reach $\Theta(n)$ nesting levels in the worst case even for sparse graphs, thus using the stack should be avoided: indeed, just storing one memory word per recursion level kills sublinearity. This motivates the search for enumeration algorithms that provably use sublinear space and have good delay bounds. Some space-efficient algorithms [13, 10, 41] work well in practice for real-world networks but cannot guarantee sublinear space.

We remark that this paper does not address cache-efficient or cache-oblivious algorithms in the parallel or distributed setting, which is worth investigating in future work. What is emphasized here is that small footprint enumeration algorithms have more chances to reduce memory contention and memory bandwidth issues when run on modern processors.

Our results. We provide the first algorithms with sublinear space and bounded delay for enumerating the maximal cliques when the vertices of G are provided in degeneracy order. This means that there exists an integer d, as small as possible, such that each vertex has d or fewer neighbors appearing later in the ordering: d is called the degeneracy of G, a well-known sparsity measure [13, 15, 40, 41], and is equivalently defined as the smallest integer such that every nonempty subgraph of G has at least one vertex of degree $\leq d$. The degeneracy

Table 1 Bounds for maximal clique enumeration, where $q-1 \leq d \leq \Delta \leq n-1 \leq m$, $d = O(\sqrt{m})$. †: it does not list cliques, but outputs a compressed representation. $^{+}$: h is the smallest integer such that $|\{v \in V : |N(v)| \geq h\}| \leq h$, where $d \leq h \leq \Delta$. *: it uses matrix multiplication. A lower bound in the column for the delay means that there exists a family of graphs with that delay.

ordering can be computed in $O(n+m)$ time by repeatedly removing the vertex of minimum degree from G. Also, it can be proved that $d = O(\sqrt{m})$, and that the size q of the maximum clique in G and the maximum degree in the graph Δ satisfy $q-1 \leq d \leq \Delta \leq n-1$.

The last two rows in Table 1 report our bounds in terms of the above parameters, where the $\tilde{O}()$ notation ignores $\log^{O(1)}(n+m)$ factors. We observe that our bounds are expressed in terms of the parameters q, d, Δ instead of m, n, whenever possible, as they are actually smaller than m or n. For example, network EU-2005 has $q = 387$, $d = 388$ and $\Delta = 68\,963$. Also, since both q and d are always $O(\sqrt{m})$, our space is provably sublinear (around 20 kilobytes for EU-2005!). Note that Δ is not always sublinear in the graph size as real-world networks are sparse and could have $\Delta = \Theta(n)$, as shown in Table 2 (see also [13]). Also, our $O(q)$ space is close to optimal as we have to single out a subset of q vertices from G.

The other rows in Table 1 report the bounds for the main results in the state of the art (see below for a discussion). The setup time is the preprocessing cost before starting to list the solutions, and ours is comparable to that of previous results. As for the delay, the cost in the last row is asymptotically smaller in many cases, except for dense graphs, where matrix multiplication based algorithms [12, 25] are preferable (but massive networks can hardly be processed by quadratic space algorithms). As for the overall time, we have a similar improvement for output-sensitive bounds where the α term appears. Moreover, we observe that [16] has great time performance in practice (see Section 7) but it is not output-sensitive as α does not appear in the complexity, and cannot guarantee sublinear space. Summing up, our algorithms can compete with the state of the art when suitably implemented, with the additional bonus of guaranteeing small space and bounded delay.

Related work. The idea of using small space in enumeration algorithms is not new, as witnessed by the notion of "compactness" introduced in Fukuda [17]: however, his goal is not sublinear space as in our paper, but polynomially bounded space in terms of the input size and the maximum output size of a solution. It is also worth mentioning that the class of CAT (constant amortized time) enumeration algorithms described in Ruskey's book [30] seems to be very promising but our algorithms cannot fall within this class as their amortized cost per solution is non-constant.

Our algorithms are based on the reverse search paradigm introduced by Avis and Fukuda [4] as it has been conceived to be space-efficient by its authors. Also, we reuse some of the machinery introduced by Tsukiyama et al. [36] and Makino and Uno [25]. In the reverse search the solutions are the nodes of a virtual digraph, for which a "successor" function is defined to jump from one solution to the other. (Gély et al. [20] study new combinatorial properties of this virtual digraph.) A spanning tree represents all the solutions, where the depth corresponds to the number of nested levels of the corresponding recursion. To achieve sublinear space, our algorithms employ the stateless reverse search to avoid using the stack, plus other properties that exploit the structure of the maximal clique enumeration problem.

Turning to the state of the art for the maximal clique enumeration problem, Table 1 summarizes the main results. The papers by Bron and Kerbosch [7] and Tsukiyama et al. [36] have defined the main lines of research for algorithms using polynomial space, and they are currently at the heart of many other algorithms. The Bron-Kerbosch algorithm relies on a backtracking scheme that is adopted in several efficient algorithms [16, 34, 41]. The algorithm by Tsukiyama et al. has been originally conceived for the enumeration of maximal independent sets, which is a problem equivalent to that of maximal cliques, and inspired at least in part the algorithm by Johnson et al. [23], which produces solutions in lexicographic order but requires exponential space (see also [20]). The approach has been subsequently adapted to clique enumeration by Chiba-Nishizeki [11], and Makino-Uno [25] has reinterpreted [36] in the paradigm of reverse search.

Bron-Kerbosch scheme. The Bron-Kerbosch based algorithms are a popular choice for enumerating cliques due to their simplicity and good performance in practice. The original version [7] does not provide any guarantee. The version in [34] guarantees a total running time of $O(3^{n/3})$, which is optimal for Moon-Moser graphs as they have $3^{n/3}$ cliques [8, 27]. The version in [16] further refines and improves the work for sparse graphs, which may have up to $(n-d)3^{d/3}$ cliques, by producing an algorithm with $O(d(n-d)3^{d/3})$ time. All of these approaches use $O(n+q\Delta)$ space to store sets of candidates and visited vertices. It is possible to modify these algorithms to decrease their space usage (e.g. by modifying the data structure in [16]) but, to the best of our knowledge, with state of the art techniques they would still require $\Omega(\Delta)$, which is not sublinear as Δ can be $\Theta(n)$ in sparse graphs. Algorithms that follow this scheme are characterized by their complexity being related to the worst-case number of cliques in a graph (instead of α), and give no guarantees on the cost per solution nor the delay: these can be shown to be both $\Omega(n^3)$ for [34], while [16] can have a delay of $\Omega(3^{n/6})$ for some families of graphs.

Tsukiyama et al. scheme. The motivation behind algorithms in this class is to achieve an output-sensitive cost that is proportional to the number α of maximal cliques times a function that depends on the graph parameters. The original algorithm by Tsukiyama et al. [36] is a backtracking procedure that enumerates maximal independent sets in $O(mn)$ time per solution. As a maximal independent set is a maximal clique in the complementary

graph, this gives an algorithm for enumerating maximal cliques in $O((n^2 - m)n)$ time per solution. The adaptation of the algorithm to maximal cliques has been improved by Chiba and Nishizeki [11], who bring the delay down to $O(md)$:[1] this algorithm is still based on a stateful backtracking procedure in which the recursion tree has depth $\Omega(n)$, making the required space $\Omega(n)$. Makino and Uno [25] take a step towards statelessness by adapting [36] and [23] to the paradigm of reverse search. The algorithm is still a stateful recursive approach, which takes $\Omega(n)$ space (the depth of the recursion tree). Differently from its predecessors, each node of the tree corresponds to a unique maximal clique whose children can be computed as a function of the graph and the clique itself. The Makino-Uno algorithm is provided in two versions, one combinatorial with delay $O(\Delta^4)$ and one based on matrix multiplication with delay $O(n^{2.37})$. The former has been improved to $O(\Delta h^3)$ by Chang et al. [9], where h is the smallest integer such that $|\{v \in V : |N(v)| \geq h\}| \leq h$: since the reverse search is not stateless, here the space remains $\Omega(n)$. The latter has been improved to $O(n^{2.09})$ by Comin and Rizzi [12] using matrix multiplication but requiring higher space usage and setup time.

2 Preliminaries

Let $G(V, E)$ be an undirected graph with $|V| = n$ and $|E| = m$. We assume that G is connected and represented using ordered adjacency lists. A clique is a subset $K \subseteq V$ of pairwise connected vertices: we will use K to denote both this subset of vertices and the subgraph induced by them. Given G, let Δ be the maximum vertex degree, d the degeneracy, and q be the maximum clique size, where $q - 1 \leq d \leq \Delta \leq n - 1 \leq m$ and $d = O(\sqrt{m})$; also, let $v_1 \dots v_n$ be the vertices of V labelled in a degeneracy ordering (see the introduction). We denote by $V_{\leq i}$ the set of vertices $v_1 \dots v_i$. Let us define $N(v)$ as the set of neighbors of v and $N_>(v)$ as $\{x \in N(v) : x > v\}$. We define $N_<(v)$ analogously. Note that $|N_>(v)| \leq d$ as the graph is labelled in degeneracy ordering. Given a set of vertices $A \subset V$, we define $N(A) = \bigcap_{v \in A} N(v)$ as the set of neighbors common to all the vertices in A. We call *heads* the vertices v such that $N_<(v) = \emptyset$. Moreover, for any $v \in V$, $A_{\leq v} = A \cap V_{\leq v}$ and $A_{<v} = A_{\leq v} \setminus \{v\}$. Given two set of vertices A and B, we say that $A < B$ if A is lexicographically smaller than B. Given a set $X \subseteq V$, we define $\textsc{complete}(X)$ as the lexicographically smallest maximal clique that contains X.

▶ **Lemma 1.** *If $X_1 \subseteq X_2$, then $\textsc{complete}(X_1) \leq \textsc{complete}(X_2)$.*

Proof. Let $\mathcal{C}_1$ and $\mathcal{C}_2$ be the set of maximal cliques containing respectively X_1 and X_2. Clearly $\mathcal{C}_1 \supseteq \mathcal{C}_2$, and as $\textsc{complete}(X)$ returns the lexicographically smallest maximal clique that contains X we have $\textsc{complete}(X_1) = \min(\mathcal{C}_1) \leq \min(\mathcal{C}_2) = \textsc{complete}(X_2)$. ◀

3 Reverse Search Revisited

We sketch a reverse search algorithm for the maximal clique enumeration that revises and simplifies the algorithm by Makino and Uno [25], which is itself a reinterpretation of the works of Tsukiyama et al. in [36] and Johnson et al. in [23] for maximal independent sets.

The rationale of the algorithm can be summarized as follows. Suppose we iteratively add the vertices of G to a graph G', which is initially empty. Each time a vertex v is added, the new maximal cliques can be computed by looking at the maximal cliques of G': an existing clique $K \subseteq G'$ can be extended partially or totally by v. Of course computing all

[1] The work actually exploits the arboricity, but we use d for simplicity as the arboricity is $\Theta(d)$.

Algorithm 1: Enumerate all maximal cliques (a.k.a. revisited Makino-Uno)

Input : Graph $G(V, E)$ where vertices are labeled in degeneracy ordering
Output : Maximal cliques in G

Let $v_1, v_2, \dots v_n \in V$ be the vertices labeled in degeneracy ordering, such that $v_1, \dots, v_j$ are heads, where j is the number of heads ($1 \leq j \leq n$).

```
for i ∈ {1, ..., j} do
    R_i ← COMPLETE({v_i})
    SPAWN(R_i)
Function COMPLETE(K)
    choose any v ∈ K
    foreach increasing w ∈ N(v) do
        if K ⊆ N(w) then
            K ← K ∪ {w}
    return K
Function SPAWN(K)
    CAND ← { w ∈ ⋃_{u∈K} N_>(u) \ K : w > PI(K) }
    foreach v ∈ CAND do
        K'_v ← K_<v ∩ N(v)
        D ← COMPLETE(K'_v ∪ {v})
        if COMPLETE(K'_v) = K and D_<v = K'_v then
            SPAWN(D)
```

the cliques of G in this way requires keeping most of the cliques of the graph in memory (as for independent sets in [23]), which takes exponential space. In order to avoid to store the cliques, we address the following question: given the clique K, maximal for G', which vertices in $G \setminus G'$ expand K and which cliques do they produce in G? This "production" relationship gives us the "successor" function of the reverse search paradigm. Technicalities are needed to avoid expanding K with candidates leading to the same clique more than once.

It is worth observing that, differently from [25], our algorithm assumes that the vertices of G are given in degeneracy ordering and begins the recursion from a set of root cliques (instead of the lexicographically minimum one), where each root R_i corresponds to COMPLETE run on the head v_i. Moreover, we alter the given degeneracy ordering in such a way that the heads are at the beginning. This is always possible: as heads have no backward edges, when moved backwards they will not change the number of forward edges of any vertex (see Section 6).

The pseudocode is shown in Algorithm 1. The function SPAWN makes use of the notion of parent index, borrowed from [25]:

▶ **Definition 2** (Parent Index). Given a maximal clique K, $\text{PI}(K)$ is the smallest x such that $\text{COMPLETE}(K_{\leq x}) = K$.

The CAND set contains the vertices that partially extend K and that are greater than $\text{PI}(K)$. For each vertex in CAND we try to generate a child clique; the check in SPAWN corresponds to conditions (c) and (d) from Lemma 2 in [25], which guarantees that each child clique is only generated once. We remark that each call of SPAWN returns at least a clique.

Space usage and delay. Referring to Algorithm 1, we observe that the COMPLETE function only needs to store the set K, whose size is $O(q)$, and performs $O(\Delta)$ iterations that take $\tilde{O}(q)$ time each. The cost of an iteration on vertex w is also bounded by $\tilde{O}(|N(w)|)$, so the cost of all the iterations is bounded by $\tilde{O}(m)$. Since PI can be computed by running COMPLETE q times, we can conclude the following:

▶ **Lemma 3.** *Function* COMPLETE *in Algorithm 1 takes $O(q)$ space and $\tilde{O}(\min\{q\Delta, m\})$ time. Moreover, computing* PI *takes $O(q)$ space and $\tilde{O}(q \min\{q\Delta, m\})$ time.*

For the sake of clarity, we will refer to the *vertices* in G and to the *nodes* in the recursive tree induced by our approach. The space requirement of each recursive node is bounded by

the size of CAND, as all other lines take $O(q)$ space. As CAND $\subseteq V$ is the union of up to q sets of vertices each of size at most d, we have $|\text{CAND}| \leq \min\{qd, n\}$. The recursion depth of Algorithm 1 is $O(n)$, for a total space requirement of $O(n \min\{qd, n\})$.

Consider now the delay of Algorithm 1. Note that selecting the next head takes constant time as heads are contiguous. By making use of alternative output [37], as we have no dead ends, the delay of the algorithm is bounded by the cost of $O(1)$ recursive nodes. The function SPAWN performs $|\text{CAND}|$ iterations, whose cost is dominated by COMPLETE. The total cost of the loop is thus $\tilde{O}(\min\{qd, n\} \min\{q\Delta, m\})$, which corresponds to the total cost of the recursion node as it dominates the cost of computing CAND. As a consequence we have some new interesting bounds shown in Lemma 4, which we improve in the rest of the paper.

▶ **Lemma 4.** *Algorithm 1 uses $O(n \min\{qd, n\})$ space and has $\tilde{O}(\min\{qd, n\} \min\{q\Delta, m\})$ delay.*

4 Improved Algorithm

Algorithm 1 does not meet our space requirements; still, it is the starting point to build our space efficient scheme. The first issue is its recursive nature: in function SPAWN, each time a recursive call is performed the *status* of the current call needs to be saved. As a result, we require the space needed by each recursive node multiplied by the height of the recursion tree. Note that the standard stack-based transformation of recursive programs into iterative ones, as done in [9], does not solve the issue, as the stack size would be $\Omega(n)$. We will therefore navigate implicitly the recursion tree induced by the reverse search, without using a stack. The other important issue to achieve sublinear space is the CAND set, whose size can be $\min\{qd, n\}$. Hence, we need to traverse CAND without materializing it.

To address the first issue, we represent the state of the computation with the pair:

- the current clique K
- the "bookmark" vertex v in CAND for K (where initially $v = \text{PI}(K)$).

We remark that the bookmark vertex allows us to resume the computation in the parent without the need of storing information for each recursive level.

▶ **Fact 1.** *The state $\langle K, v\rangle$ requires $O(q)$ space.*

Furthermore, we implicitly traverse the recursion tree using these navigation primitives:

- IS-ROOT(K) checks if K is the root of current recursion tree.
- PARENT-STATE(K) returns the state for the parent node of K in the recursion tree.
- GET-NEXT-CAND(K, v) finds the candidate following v in CAND for the current K.
- CHILD-EXISTS(K, v) checks whether the current state will lead to a child maximal clique.

Algorithm 2 shows how to implement and use the above primitives, and Lemmas 5, 6, 7, 10 prove their correctness.

▶ **Lemma 5.** *Let K be any maximal clique examined in Algorithm 1: K is a root iff $\text{PI}(K) = \min(K)$. As a corollary, roots have no parent.*

Proof. Let v_i be the head of the recursion tree containing K and $R_i = \text{COMPLETE}(v_i)$ the relative root. By definition we have that v_i is a head iff $N_<(v_i) = \emptyset$, so a head must be the smallest vertex of any clique. We then have $v_i = \min(R_i)$, and since $\min(D) \in K$ for any child D of K, there cannot be heads other than v_i in the current recursion tree. From this it immediately follows that no other roots are found in the subtree of the root R_i, and hence roots have no parent.

Algorithm 2: Improved enumeration of maximal cliques

Assume $\min(\emptyset) = \texttt{null}$, and adopt the following shorthands for maximal clique K: sub-clique $K'_v \equiv K_{<v} \cap N(v)$ and vertex set $B_K \equiv \{u \in V \setminus K : K_{<u} \subseteq N(u)\}$.

```
Function IMPROVED-SPAWN(K)
    v ← PI(K)
    while true do
        childless ← true
        while v ← GET-NEXT-CAND(K, v) ≠null do
            if CHILD-EXISTS(K, v) then
                K ← COMPLETE(K'_v ∪ {v})
                childless ← false
                break
        if childless then
            if IS-ROOT(K) then return
            else
                ⟨K, v⟩ ← PARENT-STATE(K)

Function IS-ROOT(K)
    return PI(K) = min(K)
Function CHILD-EXISTS(K, v)
    return N(K'_v) ∩ (B_K ∪ N_<(v)) = ∅
Function GET-NEXT-CAND(K,v)
    return min{w ∈ ⋃_{u∈K} N_>(u) \ K :
                w > v}
Function PARENT-STATE(K)
    v ← PI(K)
    return ⟨COMPLETE(K_<v), v⟩
```

We now show that $N_<(\min(K)) = \emptyset$ and $K = \text{COMPLETE}(\{\min(K)\})$ iff $\text{PI}(K) = \min(K)$. This concludes the proof as the first condition correspond to the definition of a root ($\min(K)$ being the corresponding head). Since $\{\min(K)\} = K_{\leq \min(K)}$, we have $\text{PI}(K) = \min(K)$ iff $K = \text{COMPLETE}(\{\min(K)\})$ by definition of PI. Moreover, $K = \text{COMPLETE}(\{\min(K)\})$ implies $N_<(\min(K)) = \emptyset$: indeed, if there was $w \in N_<(\min(K))$, COMPLETE would add w to $\{\min(K)\}$, making it different from K. ◀

The next lemma states that given a clique D, the parent index allows us to identify the clique that generated D and the vertex in CAND used to produce D.

▶ **Lemma 6.** *Let K, D, and v be defined as in* SPAWN *when the recursive call is performed on D. Then* $\text{PARENT-STATE}(D) = \langle K, v\rangle$ *in* IMPROVED-SPAWN.

Proof. We prove that, given a maximal clique D which is not a root, the parent of D in the computational tree is $\text{COMPLETE}(D_{<\text{PI}(D)})$ and the vertex used by the algorithm SPAWN to produce D is $\text{PI}(D)$. Since K is the parent of D, we have $D = \text{COMPLETE}(K'_v \cup \{v\})$. From the conditions tested on K'_v and D, we have $\text{COMPLETE}(D_{<v}) = \text{COMPLETE}(K'_v) = K$. Now we only need to prove that $v = \text{PI}(D)$. We have that $D = \text{COMPLETE}(K'_v \cup \{v\}) = \text{COMPLETE}(D_{\leq v}) > \text{COMPLETE}(D_{<v}) = K$, applying Lemma 1. From this it follows that for any $w < v$, $\text{COMPLETE}(D_{\leq w}) \leq \text{COMPLETE}(D_{<v}) = K < D$, thus $v = \text{PI}(D)$. ◀

Since the candidates are examined in increasing order, when returning from the current child of K, we are able to provide all the remaining children of K. Indeed let v be $\text{PI}(D)$: as a consequence of Lemma 6 we know that D was generated from K using candidate v and that $K = \text{COMPLETE}(D_{<v})$. By using the next lemma, we can provide and test all the remaining candidates, i.e. the ones greater than v.

▶ **Lemma 7.** *For a given maximal clique K, let* $\text{CAND} = \{w \in \bigcup_{x\in K} N_>(x) \setminus K : w > \text{PI}(K)\}$ *in* SPAWN *and let $z_1, \ldots, z_r$ be the sequence of vertices generated by* GET-NEXT-CAND *in* IMPROVED-SPAWN. *Then* $\text{CAND} = \{z_1, \ldots, z_r\}$.

Proof. We give the proof by induction. The first time GET-NEXT-CAND is invoked v is $\text{PI}(K)$, meaning that z_1 is the minimum element of CAND. Let z_j be the last vertex generated by

GET-NEXT-CAND and let us assume that $z_1, \ldots, z_j$ are the first j vertices of CAND. Then $\min\{w \in \bigcup_{u \in K} N_>(u) \setminus K \ : \ w > z_j\}$ is the the $(j+1)$-th element of CAND if $|\text{CAND}| > j$, `null` otherwise. ◀

The check done in CHILD-EXISTS(K, v) is equivalent to the check done in SPAWN. We will prove this in Lemma 10 using Lemmas 8 and 9.

▶ **Lemma 8.** *$N(K'_v) \cap B_K = \emptyset$ is equivalent to* COMPLETE$(K'_v) = K$*, where* $B_K = \{u \in V \setminus K : K_{<u} \subseteq N(u)\}$.

Proof. Let us first prove that if $\exists w \in N(K'_v) \cap B_K$ then COMPLETE$(K'_v) \neq K$. Note that w is adjacent to all the vertices in $K_{<w}$ and in K'_v. COMPLETE(K'_v) will iteratively add to K'_v the smallest vertex z that is a neighbor of all the vertices in K'_v, so clearly $z \leq w$. If $z \notin K$ we have COMPLETE$(K'_v) \neq K$; if $z \in K$ then $z \in K_{<w}$, thus $z \in N(w)$ and w is still a candidate for the COMPLETE procedure. As w remains a candidate when $z \in K$, the process will eventually add either w or another $z \notin K$. Hence, COMPLETE$(K'_v) \neq K$.

We now prove that if COMPLETE$(K'_v) \neq K$ then $N(K'_v) \cap B_K \neq \emptyset$. Let z be the first vertex not in K selected by COMPLETE(K'_v). Since all vertices in $K_{<z}$ were added to K'_v before z, we have $K_{<z} \subseteq N(z)$ and hence $z \in B_K$. Moreover, since z has been selected by the COMPLETE procedure, $K'_v \subseteq N(z)$, which implies $z \in N(K'_v)$. It follows that $N(K'_v) \cap B \supseteq \{z\} \neq \emptyset$. ◀

▶ **Lemma 9.** *$N(K'_v) \cap N_<(v) = \emptyset$ is equivalent to* COMPLETE$(K'_v \cup \{v\})_{<v} = K'_v$.

Proof. We prove that if $N(K'_v) \cap N_<(v) \neq \emptyset$ then COMPLETE$(K'_v \cup \{v\})_{<v} \neq K'_v$. Let z be the smallest vertex in $N(K'_v) \cap N_<(v)$. Note that $z \notin K'_v$, since $z \in N(K'_v)$. The first iteration of COMPLETE$(K'_v \cup \{v\})$ selects the smallest vertex in $N(K'_v \cup \{v\})$, which is z, since $N(K'_v \cup \{v\}) = N(K'_v) \cap N(v)$. Since $z < v$, we have $z \in$ COMPLETE$(K'_v \cup \{v\})_{<v}$, which implies COMPLETE$(K'_v \cup \{v\})_{<v} \neq K'_v$.

We now prove that if COMPLETE$(K'_v \cup \{v\})_{<v} \neq K'_v$ then $N(K'_v) \cap N_<(v) \neq \emptyset$. Note that $K'_v \subseteq$ COMPLETE$(K'_v \cup \{v\})_{<v}$ since $K'_v \subseteq V_{<v}$. Let $z = \min(\text{COMPLETE}(K'_v \cup \{v\})_{<v} \setminus K'_v)$. Since z has been selected by function COMPLETE, we have $z \in N(K'_v \cup \{v\})$, that is $z \in N(K'_v) \cap N(v)$. Since $z < v$, we have $N(K'_v) \cap N_<(v) \supseteq \{z\} \neq \emptyset$. ◀

▶ **Lemma 10.** *$N(K'_v) \cap (B_K \cup N_<(v)) = \emptyset$ iff* COMPLETE$(K'_v) = K$ *and* COMPLETE$(K'_v \cup \{v\})_{<v} = K'_v$

Using Lemmas 5, 6, 7 and 10, we finally obtain the following result:

▶ **Lemma 11.** *Function* SPAWN *in Algorithm 1 and function* IMPROVED-SPAWN *in Algorithm 2 are equivalent.*

Proof. Setting $D =$ COMPLETE$(K'_v \cup \{v\})$ we observe that IMPROVED-SPAWN(K) simulates the preorder traversal of the recursion tree induced by SPAWN(K). When all the children of the current clique K have been explored during the traversal, *childless* is set to true. In this case, if K is the root of the current tree there are no more maximal cliques to be generated with the given head v_i; otherwise, the state of the parent is restored. ◀

5 Analysis

Analogously to Section 3, the delay of Algorithm 2 is the sum of the running times of all the iterations corresponding to the same K. Specifically, the number of iterations of the while loop is $|\text{CAND}| \leq \min\{qd, n\}$ (see Lemma 7). The space usage of IMPROVED-SPAWN, thanks

to its statelessness, corresponds to that of a single iteration. In order to give space and time bounds, let us analyze the costs of our navigation primitives.

Since computing $\text{PI}(K)$ dominates the space and time costs of functions IS-ROOT and PARENT-STATE, we use the bounds in Lemma 3. The next candidate can be obtained from K and the bookmark v as follows: for each element $x \in K$, perform a binary search in $N(x)$ to obtain the smallest vertex greater than v; the minimum of these vertices is the next candidate. Thus we obtain the bounds below:

▶ **Lemma 12.** IS-ROOT(K) *and* PARENT-STATE(K) *take* $\tilde{O}(q \min\{q\Delta, m\})$ *time and* $O(q)$ *space.* GET-NEXT-CAND *uses* $\tilde{O}(q)$ *time and constant space.*

Next we give a careful analysis of CHILD-EXISTS, the dominating cost of IMPROVED-SPAWN.

Cost of testing if a child exists. Function CHILD-EXISTS makes use of the sets B_K and $N(K'_v)$. Due to our memory constraints, we cannot store $N(K'_v)$ explicitly, since it would take $\Omega(\Delta)$ space. For this reason, we need to iterate over $N(K'_v)$ without materializing it.

Analogously, we cannot store $B_K = \{v \in V \setminus K : K_{<v} \subseteq N(v)\}$, whose size can be $\Omega(n)$. The following lemma will allow us to overcome this issue:

▶ **Lemma 13.** *The set* B_K *is equal to* $V_{<\min(K)} \cup \{u \in N_>(\min(K)) \setminus K : K_{<u} \subseteq N(u)\}$.

Proof. vertices in $V_{<\min(K)}$ are in B_K as $K_{<\min(K)} = \emptyset$, thus they can be stored implicitly. All other vertices must clearly be forward neighbors of $\min(K)$. ◀

We denote the non-trivial part of B_K, i.e. $\{u \in N_>(\min(K)) \setminus K : K_{<u} \subseteq N(u)\}$, as B'_K. We can compute it by testing $|N_>(\min(K))| \leq d$ candidates in $O(|K|) = O(q)$ time.

▶ **Lemma 14.** *Computing (or iterating over)* B'_K *can be done in* $\tilde{O}(qd)$ *time.*

We will now analyze the cost of iterating over $N(K'_v)$, and two possible ways of managing B_K (storing it or iterating it implicitly) leading to two different bounds.

Iterating over $N(K'_v)$. Iterating over $N(K'_v)$ using constant space can be done as follows. Let w be the vertex of K'_v with lowest degree: iterate over the vertices $z \in N(w)$ and for each check whether $K'_v \subseteq N(z)$. This costs $\tilde{O}(|N(w)||K'_v|) = \tilde{O}(\sum_{y \in K'_v} |N(y)|)$, since w is the lowest degree element of K'_v.

▶ **Lemma 15.** *The total cost of iterating over all of the sets* $N(K'_v)$ *for* v *in* $\bigcup_{x \in K} N_>(x)$ *is* $\tilde{O}(d \min\{q\Delta, m\})$ *time.*

Proof. Let $C_K = \bigcup_{x \in K} N_>(x)$. Since the cost of iterating over a given $N(K'_v)$ is bounded by $\tilde{O}(\sum_{y \in K'_v} |N(y)|)$, the following steps prove the lemma:

$$\begin{aligned}
\sum_{v \in C_K} \sum_{y \in K \cap N_<(v)} |N(y)| &= \sum_{v \in C_K} \sum_{y \in K} |N(y)| I_{\{y \in N_<(v)\}} \\
&= \sum_{y \in K} \sum_{v \in C_K} |N(y)| I_{\{v \in N_>(y)\}} \\
&= \sum_{y \in K} \sum_{v \in N_>(y)} |N(y)| \\
&= \sum_{y \in K} |N_>(y)| \cdot |N(y)| \\
&\leq d \sum_{y \in K} |N(y)| \leq d \min\{q\Delta, m\}
\end{aligned}$$

◀

Algorithm 3: In-place algorithm for moving heads to the beginning of V

Input : $G(V, E)$, with V in degeneracy ordering and E as ordered adjacency lists $L_1 \dots L_n$.
Output : $G(V, E)$ with V relabeled in degeneracy ordering so that the j heads are $v_1, \dots, v_j$.

```
1 s, e ← n + 1
2 foreach s in decreasing order from n to 1 do                    // Reorder, relabel N_>(v)
3     if s is not a head then
4         e ← e − 1
5         foreach v < s in L_s do replace s with e in L_v
6         replace all v < s with 0 in L_s
7         swap L_s and L_e
8 foreach v in decreasing order from n to 1 do                    // Relabel N_<(v)
9     foreach x ≠ 0 in L_v do replace the rightmost 0 in L_x with v
```

Storing B_K. By applying Lemma 13, since we can check in constant time whether a vertex is in $V_{<\min(K)}$, we only need to store B'_K, whose size is $O(d)$ by definition. The computation of B'_K, which costs $\tilde{O}(qd)$ time applying Lemma 14, is done once for K and once for each child. Hence its cost is payed at most twice for each clique.

Observe that the cost of CHILD-EXISTS is dominated by that of the computation of $N(K'_v)$, since testing $N(K'_v) \cap B_K = \emptyset$ and $N(K'_v) \cap N_<(v) = \emptyset$ can be done in $\tilde{O}(1)$ time for each element of $N(K'_v)$. Applying Lemma 15, we can conclude that:

▶ **Lemma 16.** *Function* CHILD-EXISTS *can be implemented such that the cumulative cost of all the calls to* CHILD-EXISTS(K, v) *for a fixed K is $O(d)$ space and $\tilde{O}(d \min\{q\Delta, m\})$ time.*

Iterating over B_K. In order to avoid storing B'_K, we can compute the intersection between $N(K'_v)$ and B_K iterating over both sets. The iterator for B'_K works as described in Lemma 14. Since the elements of both $N(K'_v)$ and B'_K are iterated in increasing order, the cost of computing their intersection for each call of CHILD-EXISTS is the sum of the costs of the two iterations. Consider the sum of these costs over all the calls of CHILD-EXISTS: applying Lemma 14 and Lemma 15, we obtain a total cost of $\tilde{O}(d \min\{q\Delta, m\} + qd \min\{qd, n\})$, since $|\text{CAND}| \leq \min\{qd, n\}$. As a result, we have the following lemma:

▶ **Lemma 17.** *Function* CHILD-EXISTS *can be implemented such that the cumulative cost of all the calls to* CHILD-EXISTS(K, v) *for a fixed K is $O(q)$ space and $\tilde{O}(d \min\{q\Delta, m\} + qd \min\{qd, n\})$ time.*

The final algorithm corresponds to plugging Algorithm 2 into Algorithm 1, i.e. replacing SPAWN with IMPROVED-SPAWN. In order to show that the final algorithm takes $O(q)$ or $O(d)$ space as well, we should also perform the setup described in Section 6. Using Algorithm 3 as setup, and applying Fact 1 and Lemmas 12, 16, and 17, we obtain our final result (recall that $q - 1 \leq d \leq \Delta \leq n - 1 \leq m$ and $d = O(\sqrt{m})$).

▶ **Theorem 18.** *Let G be an undirected connected graph with n vertices and m edges, whose adjacency lists are ordered and whose vertices are labeled in degeneracy ordering. Let Δ be the maximum degree of its vertices, q the size of its largest clique, and d its degeneracy. Then there exists an algorithm that lists all the maximal cliques in G that has $\tilde{O}(m)$ setup time, $O(q)$ space usage, and $\tilde{O}(qd(\Delta + qd))$ delay. The latter bound improves to $\tilde{O}(qd\Delta)$ if space usage is increased to $O(d)$. Space is always sublinear in the size of G.*

Table 2 Experimental results of our comparison with output-sensitive algorithms in the state of the art. For the graph statistics (upper part), we refer to Table 1. For the comparison (lower part) we have considered the total time (TIME), the delay (DELAY), and the space (MEM).

6 Setup

Algorithm 3 gives some details on how to modify the degeneracy ordering of the vertices so as to place the heads at the beginning in $\tilde{O}(m)$ time and $O(1)$ space. As already noted, the resulting order is still a degeneracy ordering. The main idea is to maintain a *sliding window* over the list of adjacency lists. The window incrementally collects the heads while moving from the last vertex to the first one in the ordering, so that its final position is the beginning of the ordering. The window is moved by swapping the greatest vertex before the window, which is called s and the greatest vertex in the window, which is called e. In case s is a head, the window is not shifted but simply enlarged to include s. While moving the window, the occurrences of the labels of the swapped vertices s and e must be updated accordingly. To this aim just the occurrences of s in $N_>(v)$ are relabeled, for each v neighbor of s. At the end, the backward neighborhoods can be updated by looking at the forward ones.

It is straightforward to see that the time needed by Algorithm 3 is $\tilde{O}(m)$. Indeed, in the loop in line 2, each adjacency list is iterated at most once. The loop in line 8 has the same time bound, i.e. $\tilde{O}(m)$: it traverses the adjacency lists of all vertices performing replace operations, which can be done in logarithmic time on ordered lists. The constant space usage follows from the fact that just $O(1)$ variables are stored.

7 Experimental Evaluation

In this section, we report some preliminary experiments on some large real-world networks that have been taken from LASAGNE (`lasagne-unifi.sourceforge.net/`). Our computing platform is a 24-core machine with Intel(R) Xeon(R) CPU E5-2620 v3 at 2.40GHz, with 128GB of shared memory. The operating system is a Ubuntu 14.04.2 LTS, with Linux kernel version 3.16.0-30. The code has been written in `C++` and forced to run on a single core.

Table 2 reports the results of the comparison between our algorithm and existing algorithms which use at most linear space and are output-sensitive, i.e. the ones providing a bounded delay or cost per solution, namely CN, MU, and CXQ (see Table 1). We limited the running time to two hours. The algorithm RALG2 refers to a recursive version of Algorithm 2. ALG2 refers to Algorithm 2 which takes $O(q)$ memory by using Lemma 17 (similar results

can be found for the iterative version which uses Lemma 16). For each algorithm and for each graph, we report the total time, the maximum delay found while running, and the memory usage (excluding the input size). Note that both RALG2 and ALG2 are significantly faster than CN, MU, and CXQ. It is worth observing that the results highlight how the delay of RALG2 and ALG2 depends on d and q as shown in Theorem 18.

The running times of ALG2 are in general higher than RALG2, even though its performance is competitive. On the other hand, ALG2 uses the smallest amount of memory, namely always less than 0.03 MiB even when these graphs have hundreds of thousands of vertices and millions of edges. The most striking result is for EU-2005, having more than 850 thousands of vertices and more than 16 millions of edges, where our algorithm uses just 0.02 MiB. Finally, observe that the memory seems to be proportional to d and q, since IN-2004 and EU-2005 have relatively higher memory consumption.

For the sake of completeness, we also considered the state of the art for Bron-Kerbosch based algorithms. In particular, we ran the algorithm in [15, 16] using the code provided by the authors (we are grateful to them). Even though its cost per solution can be higher than ours and its delay can be exponential, this algorithm is on the average 3.7 times faster than ALG2. On the other hand, as this algorithm uses linear memory, its memory consumption is on the average 878.9 times larger than the memory of ALG2.

Abstract

We consider *temporal graphs* with discrete time labels and investigate the size and the approximability of minimum temporally connected spanning subgraphs. We present a family of minimally connected temporal graphs with n vertices and $\Omega(n^2)$ edges, thus resolving an open question of (Kempe, Kleinberg, Kumar, JCSS 64, 2002) about the existence of sparse temporal connectivity certificates. Next, we consider the problem of computing a minimum weight subset of temporal edges that preserve connectivity of a given temporal graph either from a given vertex r (r-MTC problem) or among all vertex pairs (MTC problem). We show that the approximability of r-MTC is closely related to the approximability of Directed Steiner Tree and that r-MTC can be solved in polynomial time if the underlying graph has bounded treewidth. We also show that the best approximation ratio for MTC is at least $O(2^{\log^{1-\varepsilon} n})$ and at most $O(\min\{n^{1+\varepsilon}, (\Delta M)^{2/3+\varepsilon}\})$, for any constant $\varepsilon > 0$, where M is the number of temporal edges and Δ is the maximum degree of the underlying graph. Furthermore, we prove that the unweighted version of MTC is APX-hard and that MTC is efficiently solvable in trees and 2-approximable in cycles.

1 Introduction

Graphs and networks are ubiquitous in Computer Science, as they provide a natural and useful abstraction of many complex systems (e.g., transportation and communication networks) and processes (e.g., information spreading, epidemics, routing), and also of the interaction between individual entities or particles (e.g., social networks, chemical and biological networks). Traditional graph theoretic models assume that the structure of the network and the strength of interaction are time-invariant. However, as observed in e.g., [3, 19], in many applications of graph theoretic models, the availability and the weights of the edges are actually time-dependent. For instance, one may think of information spreading and distributed computation in dynamic networks (see e.g., [6, 12, 19, 20]), of mobile adhoc and sensor networks (see e.g.,

[22]), of transportation networks and route planning (see e.g., [3, 15]), of epidemics, biological and ecological networks (see e.g., [17, 19]), and of influence systems and coevolutionary opinion formation (see e.g., [5, 9]).

Several variants of time-dependent graphs have been suggested as abstractions of such settings and computational problems (see e.g., [6] and the references therein). No matter the particular variant, the main research questions are usually related either to optimizing or exploiting temporal connectivity or to computing short time-respecting paths (see e.g., [1, 2, 3, 13, 15, 19, 21]). In this work, we adopt the simple and natural model of temporal graphs with discrete time labels [19] (and its extension with multiple labels per edge [21]), and study the existence of dense minimally connected temporal graphs and the approximability of temporally connected spanning subgraphs with minimum total weight.

Temporal Graphs and Temporal Connectivity. A *temporal graph* is defined on a time-invariant set of n vertices. Each (undirected) edge e is associated with a set of discrete time labels denoting when e is available. If every edge is associated with a single time label, as in [19], the temporal graph is *simple*. An edge e available at time t comprises a temporal edge (e, t) and there is a positive weight $w(e, t)$ associated with it. A (resp. strict) *temporal* (or *time-respecting*) path is a sequence of temporal edges with non-decreasing (resp. increasing) time labels. So, temporal paths respect the time availability constraints of the edges.

Given a source vertex r, a temporal graph is (temporally) *r-connected* if there is a temporal path from r to any other vertex. A temporal graph is (temporally) *connected* if there exists a temporal path from any vertex to any other vertex. We study the existence of dense minimally connected temporal graphs and the optimization problems of computing a minimum weight subset of temporal edges that preserve either r-connectivity or connectivity. We refer to these optimization problems as (Minimum) Single-Source Temporal Connectivity (or r-MTC, in short) and (Minimum) All-Pairs Temporal Connectivity (or MTC, in short). They arise as natural generalizations of Minimum Arborescence and Minimum Spanning Tree in temporal networks, and to the best of our knowledge, their approximability has not been determined so far (but see [1, 18] for some results on variants or special cases).

Previous Work and Motivation. The model of simple temporal graphs with discrete time labels was introduced in [19]. It is essentially equivalent to the model of scheduled networks [3], where each edge is available in a time interval. [3, 19] investigated how time availability restrictions on the edges affect certain graph properties. Berman [3] presented an algorithm for reachability by temporal paths and proved that an analogue of the max-flow-min-cut theorem holds for temporal graphs. Kempe et al. [19] focused on vertex-disjoint temporal paths and showed that Menger's theorem does not generalize to temporal graphs. They also identified a simple forbidden topological minor for Menger's theorem in temporal graphs. Mertzios at al. [21] introduced multiple labels per edge and studied the number of temporal edges required for a temporal design to guarantee certain graph properties. Interestingly, they proved that a variant of Menger's theorem, which also takes time into account, holds in all temporal graphs. A key technical tool in [3, 19, 21] is the time-expanded version of a temporal graph, which reduces reachability, edge-disjoint path and vertex-disjoint path questions in temporal graphs to similar questions in standard directed graphs.

Our motivation comes from a natural open question in [19, Section 6]. Attempting an analogy between spanning trees of (standard undirected) graphs and connectivity certificates of temporal graphs, Kempe et al. asked whether any simple temporal graph admits a sparse connectivity certificate. They observed that any r-connected temporal graph has a time-

respecting arborescence with $n-1$ edges that serves as a sparse r-connectivity certificate. For all-pairs temporal connectivity, however, minimum temporal connectivity certificates may have different sizes. Kempe et al. observed that an allocation of time labels to the edges of the hypercube makes it minimally temporally connected. Hence, there are temporal graphs on n vertices with temporal connectivity certificates of $\Omega(n \log n)$ edges. An open question in [19, Section 6] was to determine the tightest function $c(n)$ for which any temporally connected graph on n vertices has a temporal connectivity certificate with at most $c(n)$ edges. A trivial upper bound on $c(n)$ is $O(n^2)$, since taking n time-respecting arborescences, each rooted at a different vertex, results in a temporally connected subgraph. Kempe et al. observed that if we consider strict temporal paths and allow for the same time label at different edges, $c(n) = \Omega(n^2)$ (e.g., consider K_n with the same time label on all edges). Nevertheless, for connectivity with strict temporal paths and distinct time labels, the best known lower bound on $c(n)$ is $\Omega(n \log n)$ ([1], again by a labeling of the hypercube).

Contribution. In this work, we resolve the open question of [19] and derive upper and lower bounds on the approximability of Single-Source and All-Pairs Temporal Connectivity.

In Section 3, we construct a family of simple temporal graphs with $3n$ vertices and roughly $n(n+9)/2$ edges which are almost minimally temporally connected, in the sense that the removal of any subset of $5n$ edges results in a disconnected temporal graph [1] (Theorem 1). Hence, we show that $c(n) = \Theta(n^2)$ (i.e., there are graphs with dense minimum temporal connectivity certificates), thus resolving the open question of [19]. Our construction is essentially best possible and can be easily extended to connectivity by strict temporal paths (with distinct time labels on the edges). An interesting feature of our construction (and an indication of its tightness) is that slightly increasing the time label of a single temporal edge results in a temporal connectivity certificate with $O(n)$ edges!

Given the huge gap on the size of temporal connectivity certificates, it is natural to ask about the complexity and the approximability of Single-Source and All-Pairs Temporal Connectivity. Previous work shows that we can decide if a temporal graph is connected in polynomial time (see e.g., [1, 3, 19]) and that Single-Source Temporal Connectivity can be solved in polynomial time in the unweighted case. Another interesting observation is that if we use the time-expanded version of a temporal graph for Minimum Temporal Connectivity, the resulting optimization problems are quite similar to Group Steiner Tree problems. In fact, this observation serves as the main intuition behind several of our results.

In Section 4, we show that the polynomial-time approximability of Single-Source Temporal Connectivity (r-MTC) is closely related to the approximability of the classical Directed Steiner Tree problem. Using a transformation from Directed Steiner Tree to r-MTC (Theorem 2) and [16, Theorem 1.2], we show that r-MTC cannot be approximated within a ratio of $O(\log^{2-\varepsilon} n)$, for any constant $\varepsilon > 0$, unless NP $\subseteq$ ZTIME$(n^{\text{poly}\log n})$. Our transformation also implies that any $o(n^{\varepsilon})$-approximation for r-MTC would improve the best known approximation ratio of Directed Steiner Tree. On the positive side, using a transformation from r-MTC to Directed Steiner Tree and the algorithm of [7], we obtain a polynomial-time $O(n^{\varepsilon})$-approximation, for any constant $\varepsilon > 0$, and a quasipolynomial-time $O(\log^3 n)$-approximation for r-MTC (Theorem 3). We also show that r-MTC can be solved in polynomial time if the underlying graph has bounded treewidth (Theorem 4).

[1] Based on Theorem 1, we can easily obtain a family of minimally connected temporal graphs with $\Omega(n^2)$ edges (e.g., we remove temporal edges from the graph, as long as connectivity is preserved). For simplicity and clarity, we avoid presenting a tight (but more complicated) construction of dense minimally connected temporal graphs, and stick to almost minimal graphs in the proof of Theorem 1.

In Section 5, we consider the approximability of All-Pairs Temporal Connectivity (MTC). Theorem 3 implies an $O(n^{1+\varepsilon})$-approximation for MTC (Corollary 5). An approximation-preserving reduction to Directed Steiner Forest and [14, Theorem 1.1] imply a polynomial-time $O((\Delta M)^{2/3+\varepsilon})$-approximation for MTC, where M is the number of temporal edges and Δ is the maximum degree of the underlying graph (Theorem 6). If M is quasilinear and Δ is polylogarithmic, we obtain an $O(n^{2/3+\varepsilon})$-approximation. On the negative side, a reduction from Symmetric Label Cover implies that MTC cannot be approximated within a factor of $O(2^{\log^{1-\varepsilon} n})$ unless NP $\subseteq$ DTIME$(n^{\text{poly}\log n})$ (Theorem 7, see also [10, Section 4]). We also show that the unweighted version of MTC is APX-hard (Theorem 8).

In Section 6, we show that MTC can be solved optimally, in polynomial time, if the underlying graph is a tree (Theorem 9), and that MTC is 2-approximable if the underlying graph is a cycle (Theorem 10, but it is open whether MTC remains NP-hard for cycles).

For clarity, we focus on connectivity by (non-strict) temporal paths. However, all our results can be extended (with small changes in the proofs and with the same approximation guarantees and running times) to the case of connectivity by strict temporal paths.

Comparison to Previous Work. Akrida et al. [1] study connectivity by strict temporal paths. Allocating distinct time labels to the hypercube, they obtain a minimal temporally connected graph with $\Omega(n \log n)$ edges. They also show that any allocation of distinct labels to K_n results in a temporal graph that is not minimally connected. However, they do not give any lower bound on the size of temporal connectivity certificates for K_n. Our Theorem 1 improves on the lower bound of [1] from $\Omega(n \log n)$ to $\Omega(n^2)$. [1] also shows that computing the maximum number of edges that are redundant for temporal connectivity is APX-hard.

Huang et al. [18] consider the Single-Source (but not the All-Pairs) version of Minimum Temporal Connectivity in simple scheduled networks [3]. They show that the problem is APX-hard. Using a transformation to Directed Steiner Tree, they show that the approximation guarantees of [7] carry over to Single-Source Temporal Connectivity for scheduled networks. Although the approximation guarantees are the same, the reduction of [18] is slightly different and less general than ours in Theorem 3 (which we discovered independently). In addition to the approximability result, we present strong inapproximability bounds for r-MTC and show that it is polynomially solvable for graphs with bounded treewidth.

Erlebach et al. [13] study the problem of computing a shortest exploration schedule of a temporal graph, i.e., a shortest strict temporal walk that visits all vertices. They prove that it is NP-hard to approximate the shortest exploration schedule within a factor of $O(n^{1-\varepsilon})$, for any $\varepsilon > 0$, and construct temporal graphs whose exploration requires $\Theta(n^2)$ steps. Since the notion of exploration schedules is much stronger than (r-)connectivity, their results do not have any immediate implications for r-MTC and MTC (e.g., the $\Theta(n^2)$-explorable graphs of [13, Lemma 4] admit a temporally connected subgraph with $O(n)$ edges).

2 The Model and Preliminaries

Throughout, we let $[k] \equiv \{1, \ldots, k\}$, for any integer $k \geq 1$. An (edge weighted) *temporal graph* $\mathcal{G}(V, E, L)$ with vertex set V, edge set E and lifetime L is a sequence of (undirected edge-weighted) graphs $(G_t(V, E_t, w_t))_{t\in[L]}$, where $E_t \subseteq E$ is the set of edges available at time t and $w_t(e)$ (or $w(e, t)$) is the nonnegative weight of each edge $e \in E_t$. We often write $\mathcal{G}$ or $\mathcal{G}(V, E)$, for brevity. A temporal graph $\mathcal{G}$ is *unweighted* if $w(e, t) = 1$ for all $e \in E_t$ and all $t \in [L]$. For each edge $e \in E_t$, we say that (e, t) is a *temporal edge* of $\mathcal{G}$. For each edge $e \in E$, $L_e = \{t \in [L] : e \in E_t\}$ denotes the set of time units (or *time labels*) when e is available. A temporal graph is *simple* if $|L_e| = 1$ for all edges $e \in E$.

We let n be the number of vertices and $M = \sum_e |L_e|$ be the number of temporal edges of $\mathcal{G}$. For temporal connectivity problems, we can assume that at least one temporal edge is available in each time unit, and thus, $L \leq M$. The (static) graph $G(V, E)$ is the *underlying graph* of $\mathcal{G}$. We say that $\mathcal{G}$ has some (non-temporal) graph theoretic property (e.g., is a tree, a cycle, a clique, has bounded treewidth) if the underlying graph G has this property.

For a vertex set S, $G[S]$ (resp. $\mathcal{G}[S]$) is the underlying (resp. temporal) graph induced by S. A spanning subgraph $\mathcal{G}'$ of a temporal graph $\mathcal{G} = (G_t(V, E_t, w_t))_{t\in[L]}$ is a sequence of graphs $(G'_t(V, E'_t, w_t))_{t\in[L]}$ such that $E'_t \subseteq E_t$. The total weight of $\mathcal{G}'$ is $\sum_{t\in[L]} \sum_{e\in E'_t} w(e, t)$.

A *temporal* (or *time-respecting*) path is an alternating sequence of vertices and temporal edges $(v_1, (e_1, t_1), v_2, (e_2, t_2), \ldots, v_k, (e_k, t_k), v_{k+1})$, such that $e_i = \{v_i, v_{i+1}\} \in E_{t_i}$, for all $i \in [k]$, and $1 \leq t_1 \leq t_2 \leq \cdots \leq t_k$. A temporal path is *strict* if $t_1 < t_2 < \cdots < t_k$. Such a temporal path is from v_1 to v_{k+1} (or a temporal $v_1 - v_{k+1}$ path).

A temporal graph $\mathcal{G}$ is (temporally) *r-connected*, for a given source $r \in V$, if there is a temporal path from r to any vertex $u \in V$. A temporal graph $\mathcal{G}$ is (temporally) *connected*, if there is a temporal path from u to v for any ordered pair $(u, v) \in V \times V$. If all temporal paths are strict, $\mathcal{G}$ is strictly connected (or strictly r-connected). An *(r-)connectivity certificate* of $\mathcal{G}$ is any spanning subgraph of $\mathcal{G}$ that is also (r-)connected.

Given a temporal graph $\mathcal{G}$ and a source vertex r, the problem of (Minimum) *Single-Source Temporal Connectivity* (r-MTC) is to compute a temporally r-connected spanning subgraph of $\mathcal{G}$ with minimum total weight. The optimal solution to r-MTC is a simple temporal graph whose underlying graph is a tree (see e.g., [19, Section 6]). Given a temporal graph $\mathcal{G}$, the problem of (Minimum) *All-Pairs Temporal Connectivity* (MTC) is to compute a temporally connected spanning subgraph of $\mathcal{G}$ with minimum total weight.

An algorithm A has *approximation ratio* $\rho \geq 1$ for a minimization problem, such as Single-Source and All-Pairs Temporal Connectivity, if for any instance I, the cost of A on I is at most ρ times I's optimal cost.

Directed Steiner Tree and Forest. To understand the approximability of r-MTC and MTC, we use reductions from and to Directed Steiner Tree and the Directed Steiner Forest.

Given a directed edge-weighted graph $G(V, E)$ with n vertices, a source $r \in V$ and a set of k terminals $S \subseteq V$, the Directed Steiner Tree (DST) problem asks for a subgraph of G that includes a directed path from r to any vertex in S and has minimum total weight. The best known algorithm for DST is due to Charikar et al. [7] and achieves an approximation ratio of $O(k^\varepsilon)$, for any constant $\varepsilon > 0$, in polynomial time, and of $O(\log^3 k)$ in quasipolynomial time. On the negative side, [16, Theorem 1.2] shows that DST cannot be approximated within a factor $O(\log^{2-\varepsilon} n)$, for any constant $\varepsilon > 0$, unless NP $\subseteq$ ZTIME$(n^{\text{poly}\log n})$.

Given a directed edge-weighted graph $G(V, E)$ with n vertices and m edges, and a collection $D \subseteq V \times V$ of k ordered vertex pairs, the Directed Steiner Forest (DSF) problem asks for a subgraph of G that contains an $s - t$ path for each $(s, t) \in D$ and has minimum total weight. [14] presents a polynomial-time $O(n^\varepsilon \min\{n^{4/5}, m^{2/3}\})$-approximation for DSF, for any constant $\varepsilon > 0$.

3 A Lower Bound on the Size of Temporal Connectivity Certificates

In this section, we construct an infinite family of simple temporal graphs with $\Theta(n)$ vertices and lifetime $\Theta(n)$ such that any temporal connectivity certificate has $\Omega(n^2)$ edges. Our construction is essentially best possible, since any temporal graph with n vertices and lifetime L admits a connectivity certificate with $O(\min\{n^2, nL\})$ edges.

▶ **Theorem 1.** *For any even $n \geq 2$, there is a simple connected temporal graph with $3n$ vertices, $n(n+9)/2-3$ edges and lifetime at most $7n/2$, so that the removal of any subset of $5n$ edges results in a disconnected temporal graph.*

Proof sketch. For any even n, we construct a simple connected temporal graph $\mathcal{G}$ with $\Theta(n)$ vertices and $\Theta(n^2)$ edges so that virtually any edge is essential for temporal connectivity.

We start with describing the construction. For any even n, $\mathcal{G}$ consists of $3n$ vertices partitioned into three sets $A = \{a_1, \ldots, a_n\}$, $H = \{h_1, \ldots, h_n\}$ and $C = \{c_1, \ldots, c_n\}$, with n vertices each. The underlying graph $G[A]$ is the complete graph K_n and comprises the *dense* part of the construction with $\Theta(n^2)$ edges. The edges of $G[A]$ are partitioned into $n/2$ edge-disjoint paths $p_1, \ldots, p_{n/2}$. Each path p_i has length $n-1$ and spans all vertices in A (see Figure 1.a). All edges of each path p_i have time label i.

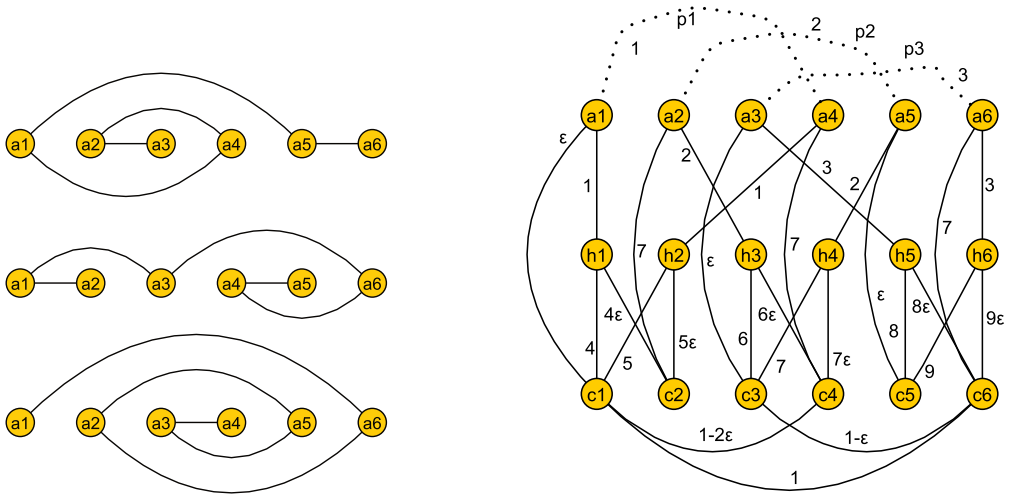
The vertices of H comprise the *intermediate* part of the construction. There are no edges with both endpoints in H. For every $i \in [n/2]$, one endpoint of the path p_i is connected to h_{2i-1} and the other endpoint is connected to h_{2i}. Both edges have time label i.

The vertices of C form the *interconnecting* part of the construction. For each $i \in [n/2]$, we refer to c_{2i-1} (resp. c_{2i}) as the *entry vertex* (resp. the *exit vertex*) for the vertices h_{2i-1} and h_{2i}. There are two edges connecting c_{2i-1} to h_{2i-1} and h_{2i} with labels $n/2+2i-1$ and $n/2+2i$, respectively, and two edges connecting c_{2i} to h_{2i-1} and h_{2i} with labels $(n/2+2i-1)\epsilon$ and $(n/2+2i)\epsilon$, respectively, for some fixed $\epsilon \in (0, 1/(4n))$. We also connect the vertices of C to each other. For every $i \in [n/2-2]$, there are edges connecting c_{2i-1} to c_{2i+2} and to c_n, and a single edge connecting c_{n-3} to c_n. To allocate time labels to these edges, we order them in decreasing order of their endpoint with higher index, breaking ties by ordering them in increasing order of their endpoint with lower index, i.e., the order is $\{c_1, c_n\}$, $\{c_3, c_n\}, \ldots, \{c_{n-3}, c_n\}$, $\{c_{n-5}, c_{n-2}\}$, $\{c_{n-7}, c_{n-4}\}, \ldots, \{c_1, c_4\}$. The time label of the k-th edge in this order is $1-(k-1)\epsilon$. Finally, for every $i \in [n/2]$, there are an edge with time label ϵ connecting the vertex c_{2i-1} to the vertex a_{2i-1} in A and an edge with time label $n+1$ connecting the vertex c_{2i} to the vertex a_{2i} in A (see also Figure 1.b).

The total number of edges is $n(n+9)/2-3$, the number of different time labels is at most $7n/2$, and each edge has a single label.

Next, we present the intuition and discuss the main technical claims. The construction is based on the collection $p_1, \ldots, p_{n/2}$ of $n/2$ edge-disjoint paths, where all edges in each path p_i have label i. Extending each path p_i to vertices h_{2i-1} and h_{2i}, we get a path that connects h_{2i} to h_{2i-1} (and vice versa) and to all vertices in A at time i. Moreover, different time labels make these paths essentially independent of each other, in the sense that if a temporal walk begins and ends at time i, it can use only edges with label i (i.e., only edges of this path) to connect h_{2i} to h_{2i-1}. Formalizing this intuition, we can show that the unique temporal path from h_{2i} to h_{2i-1} is through path p_i. Therefore, all edges of $G[A]$ must be present in any temporally connected spanning subgraph of $\mathcal{G}$. To achieve a dense underlying graph $G[A]$, we observe that the collection of $n/2$ edge-disjoint paths can be defined so that they go through the same n vertices, in a different order each (see Figure 1.a). This describes the main intuition behind our construction and explains how the dense and the intermediate parts work. The only problem now is that H-vertices with high indices, e.g., h_n, cannot reach H-vertices with low indices, e.g., h_1. The vertices in the interconnecting part C serve to carefully connect each h_j to each h_i, with $j > i+1$, without destroying the property that the only temporal path from h_{2i} to h_{2i-1} is through path p_i.

For every vertex pair $h_{2i-1}, h_{2i} \in H$, we introduce a vertex pair $c_{2i-1}, c_{2i} \in C$. As an entry vertex, c_{2i-1} is connected to h_{2i-1} and h_{2i} with "large" labels (larger than $n/2$). Hence, starting from the rest of $\mathcal{G}$, we can reach h_{2i-1} and h_{2i} through c_{2i-1}, but we cannot continue



(a) Partition into 3 Hamiltonian paths. (b) Putting the 3 parts together.

Figure 1 The temporal graph constructed in the proof of Theorem 1 for $n = 6$.

to the edges of p_i (with label $i \leq n/2$). As an exit vertex, c_{2i} is connected to h_{2i-1} and h_{2i} with "very small" labels (at most $1/4$). Thus, starting from c_{2i}, we can reach first h_{2i-1} and h_{2i}, and then all vertices in A and any vertex h_j with index $j > 2i$. Moreover, to avoid creating a temporal path from h_{2i} to h_{2i-1}, the label of the edge $\{h_{2i}, c_{2i-1}\}$ (resp. $\{h_{2i}, c_{2i}\}$) is larger than the label of the edge $\{h_{2i-1}, c_{2i-1}\}$ (resp. $\{h_{2i-1}, c_{2i}\}$).

It remains now to connect the C-vertices to each other, without creating any alternative temporal paths from h_{2i} to h_{2i-1}, for any $i \in [n/2]$. For each $i \in [n/2]$, the edges between C-vertices should create temporal paths from c_{2i-1} and c_{2i} to any vertex c_j with index $j < 2i - 1$. On the other hand, they should not create any temporal $c_{2i} - c_{2i-1}$ paths, since then we would have a new temporal $h_{2i} - h_{2i-1}$ path. We introduce roughly n edges between C-vertices and carefully select their "small" labels in $[3/4, 1]$. Furthermore, to achieve temporal connectivity between all vertex pairs, we introduce an edge $\{c_{2i-1}, a_{2i-1}\}$ with the minimum time label ϵ and an edge $\{c_{2i}, a_{2i}\}$ with label $n + 1$, for each $i \in [n/2]$.

To complete the proof, we need to consider all possible types of ordered vertex pairs and to show that the temporal graph $\mathcal{G}$ is indeed connected. Moreover, since any subset of at least $5n$ edges includes some edges of $G[A]$, we can show that the removal of any edge from $G[A]$ with label i destroys the unique temporal path from h_{2i} to h_{2i-1}. ◀

We should highlight that increasing the label of edge $\{a_1, c_1\}$ from ϵ to 1, in the graph of Theorem 1, results in a temporal graph that admits a connectivity certificate of size $\Theta(n)$. Moreover, it is not hard to modify the construction of Theorem 1 so that all time labels of the edges are distinct, the temporal graph $\mathcal{G}$ is connected by strict temporal paths, and the removal of any subset of $5n$ edges results in a disconnected temporal graph. Therefore, the quadratic lower bound of Theorem 1 also applies to connectivity by strict temporal paths and improves on the lower bound of $\Omega(n \log n)$ in [1, Theorem 3].

4 The Approximability of Single-Source Temporal Connectivity

We proceed to study the approximability of Minimum Single-Source Temporal Connectivity. We show that the polynomial-time approximability of r-MTC is closely related to the

approximability of the classical Directed Steiner Tree (DST) problem and that r-MTC can be solved in polynomial-time for graphs of bounded treewidth.

4.1 A Lower Bound on the Approximability of r-MTC

We start with an approximation-preserving transformation from DST to r-MTC. The intuition is that we can use strict temporal paths to "simulate" the directed edges of DST.

▶ **Theorem 2.** *Any polynomial-time $\rho(n)$-approximation algorithm for r-*MTC *on simple temporal graphs implies a polynomial-time $\rho(n^2)$-approximation algorithm for* DST*.*

Proof sketch. We present an approximation-preserving transformation from the DST to r-MTC. Given an instance $I = (G(V, E, w), S, r)$ of DST with $|V| = n$, we construct a temporal graph $\mathcal{G}'$ with n^2 vertices so that (i) any Steiner tree connecting r to S in G can be mapped to an r-connected subgraph of $\mathcal{G}'$ with no larger cost; and (ii) given any r-connected subgraph of $\mathcal{G}'$, we can efficiently compute a feasible Steiner tree for I with no larger cost.

Each vertex $u \in V$ corresponds to a vertex u in the temporal graph $\mathcal{G}'$. For every directed edge $e = (u, v)$ of G, we create $n - 1$ strict temporal $u - v$ paths of length 2. Specifically, for every $u \in V$, $\mathcal{G}'$ contains auxiliary vertices z_i^u, for all $i \in [n-1]$, and temporal edges $\{u, z_i^u\}$ with time label i and weight 0. For every edge $e = (u, v) \in E$, $\mathcal{G}'$ contains temporal edges $\{z_i^u, v\}$ with time label $i + 1$ and weight $w(e)$, for all $i \in [n-1]$. Let $Z = \{z_i^u\}_{u \in V, i \in [n-1]}$ be the set of all auxiliary vertices. For every vertex $x \in Z \cup (V \setminus S)$, $x \neq r$, $\mathcal{G}'$ contains a temporal edge $\{r, x\}$ with time label $n + 1$ and weight 0. These edges ensure that r is connected to all non-terminal and auxiliary vertices at no additional cost. ◀

Directed Steiner Tree cannot be approximated within a ratio of $O(\log^{2-\varepsilon} n)$, for any constant $\varepsilon > 0$, unless NP $\subseteq$ ZTIME$(n^{\text{poly}\log n})$ [16, Theorem 1.2]. Theorem 2 implies that this inapproximability result carries over to r-MTC. Moreover, any polynomial-time $o(n^{\varepsilon})$-approximation algorithm for r-MTC would immediately improve the best known approximation ratio of the notoriously difficult DST problem.

4.2 An Approximation Algorithm for r-MTC

The following shows an approximation-preserving reduction from r-MTC to DST (see also the more general proof of Theorem 6). Then, we can use the algorithm of [7] and approximate r-MTC within a ratio of $O(n^{\varepsilon})$, for any constant $\varepsilon > 0$, in polynomial time, and within a ratio of $O(\log^3 n)$ in quasipolynomial time.

▶ **Theorem 3.** *Any polynomial-time $\rho(k)$-approximation algorithm for* DST *implies a polynomial-time $\rho(n)$-approximation algorithm for r-*MTC *on general temporal graphs.*

4.3 A Polynomial-Time Algorithm for Graphs with Bounded Treewidth

The following shows that r-MTC can be solved in polynomial time, by dynamic programming, if the underlying graph has bounded treewidth (see e.g., [11] about nice tree decompositions and dynamic programming algorithms for graphs of bounded treewidth).

▶ **Theorem 4.** *Let $\mathcal{G}$ be a temporal graph on n vertices with lifetime L, source vertex r and treewidth at most k. Then, there is a dynamic programming algorithm which given a nice tree decomposition of G, computes an optimal solution to r-*MTC *in time $O(nk^2 3^k (L + k)^{k+1})$.*

5 The Approximability of All-Pairs Minimum Temporal Connectivity

In this section, we study the approximability of the all-pairs version of Minimum Temporal Connectivity in general temporal graphs. Reducing MTC to r-MTC and to Directed Steiner Forest, we obtain polynomial-time approximation algorithms for MTC, albeit with not so strong guarantees (Corollary 5 and Theorem 6). To justify the poor approximation ratios, we reduce Symmetric Label Cover (SLC) to MTC and show that any $\rho(n)$-approximation for MTC implies a $\rho(n^2)$-approximation for SLC (Theorem 7). Moreover, using an approximation-preserving reduction from the Steiner Tree problem, we show that the unweighted version of MTC is APX-hard (Theorem 8).

5.1 Approximation Algorithms for MTC

Using every vertex of the temporal graph as a source vertex and taking the union of the solutions obtained by the algorithm of Theorem 3 for r-MTC, we obtain the following.

▶ **Corollary 5.** *For any constant $\varepsilon > 0$, there is a polynomial-time $O(n^{1+\varepsilon})$-approximation algorithm for* MTC *on temporal graphs with n vertices.*

Next, we present a reduction from MTC to Directed Steiner Forest (DSF) that leads to a different algorithm. Although the approximation ratio may be worse than $O(n^{1+\varepsilon})$ in general, this algorithm gives significantly better guarantees if the total number of temporal edges is quasilinear (and if the maximum degree of the underlying graph is polylogarithmic).

▶ **Theorem 6.** *Let $\mathcal{G}$ be a temporal graph with n vertices and M temporal edges such that the underlying graph has maximum degree Δ. Then, for any constant $\varepsilon > 0$, there is a polynomial-time $O(M^{\varepsilon}\min\{M^{4/5}, (\Delta M)^{2/3}\})$-approximation algorithm for* MTC *on $\mathcal{G}$. If $M = O(n \operatorname{poly}\log n)$, we obtain an approximation ratio of $O(n^{4/5+\varepsilon})$. If both $M = O(n \operatorname{poly}\log n)$ and $\Delta = O(\operatorname{poly}\log n)$, we obtain an approximation ratio of $O(n^{2/3+\varepsilon})$.*

Proof. The reduction from DSF to MTC is a generalized version of the reduction used in the proof Theorem 3. Let I be an instance of MTC consisting of an underlying graph $G(V, E)$, a finite set of time labels L_e for each edge e, and a weight $w(e, t)$ for any temporal edge (e, t). We show how to transform I into an instance I' of DSF so that (i) any feasible solution of I can be mapped to a feasible solution of I' with no larger total weight; and (ii) given a feasible solution of I', we can compute a feasible solution of I with no larger total weight.

For convenience, we denote H the edge-weighted directed graph of the DSF instance I'. For every temporal edge (e, t) of $\mathcal{G}$, H contains two vertices $h^1_{(e,t)}$ and $h^2_{(e,t)}$. Intuitively, $h^1_{(e,t)}$ indicates that we may use (e, t) and $h^2_{(e,t)}$ indicates that we actually use (e, t). For each edge $e \in E$, let $l_1(e) < l_2(e) < ... < l_k(e)$ be the time labels in L_e. For every $i \in [k-1]$, H contains a directed edge $(h^1_{(e,l_i(e))}, h^1_{(e,l_{i+1}(e))})$ with weight 0. Intuitively, these edges indicate that we can wait and use e at some later time up to $l_k(e)$. Moreover, for every $i \in [k]$, H contains a directed edge $(h^1_{(e,l_i(e))}, h^2_{(e,l_i(e))})$ with weight $w(e, l_i(e))$. This edge indicates that we actually use the temporal edge $(e, l_i(e))$ and incur the corresponding cost.

For every ordered pair of temporal edges (e_1, t_1), (e_2, t_2) of $\mathcal{G}$, such that $e_1 \neq e_2$, t_2 is the smallest time label in L_{e_2} such that $t_2 \geq t_1$ ($t_2 > t_1$, for strict connectivity), and e_1 and e_2 share a common endpoint, H contains a directed edge $(h^2_{(e_1,t_1)}, h^1_{(e_2,t_2)})$ with weight 0.

For every vertex $v_i \in V$, $i \in [n]$, H contains a pair of terminal vertices s_i and t_i. For every temporal edge (e, t) incident to v_i, H contains a directed edge $(s_i, h^1_{(e,t)})$ with weight 0 and a directed edge $(h^2_{(e,t)}, t_i)$ with weight 0. The set of connection requirements of the DSF instance I' consists of all pairs (s_i, t_j) for all $i, j \in [n]$ with $i \neq j$.

By construction, any temporal $v_i - v_j$ path, which consists of a temporal edge sequence $((e_1, t_1), (e_2, t_2), \ldots, (e_k, t_k))$, corresponds to a directed $s_i - t_j$ path in H of the form

$$s_i, h^1_{(e_1,t_1)}, h^2_{(e_1,t_1)}, h^1_{(e_2,t''_2)}, h^1_{(e_2,t'_2)}, h^1_{(e_2,t_2)}, h^2_{(e_2,t_2)}, \ldots, h^1_{(e_k,t_k)}, h^2_{(e_k,t_k)}, t_j$$

with the same weight and vice versa. Using this observation, we can now establish claims (i) and (ii). Specifically, to show (i), we construct a feasible solution to I' that includes all directed edges of weight 0 and the directed edges $(h^1_{(e,t)}, h^2_{(e,t)})$ corresponding to the temporal edges (e, t) used in the feasible solution to I. Clearly, the two solutions have the same total weight and any temporal $v_i - v_j$ path in the solution to I corresponds to an $s_i - t_j$ path in the solution to I'. To show (ii), we first observe that any directed path from some s_i to some t_j should include some directed edges of the form $(h^1_{(e,t)}, h^2_{(e,t)})$ with weight $w(e, t)$. So, we construct a feasible solution to I that includes the temporal edges (e, t) corresponding to the positive-weight directed edges $(h^1_{(e,t)}, h^2_{(e,t)})$ included in the feasible solution to I'.

In the resulting DSF instance I', the total number of vertices is $O(n + M) = O(M)$ and the number of connection requirements is $O(n^2)$. If the maximum degree of the underlying graph is Δ, the total number of edges is dominated by the edges of the form $(h^2_{(e_1,t_1)}, h^1_{(e_2,t_2)})$, which are $O(\Delta M)$. Applying the approximation algorithm of [14, Theorem 1.1] to the DSF instance I', we obtain a polynomial-time $O(M^\varepsilon \min\{M^{4/5}, (\Delta M)^{2/3}\})$-approximation algorithm, for any constant $\varepsilon > 0$. In the special case where the number of temporal edges is $M = O(n\text{poly}\log n)$, we obtain an $O(n^{4/5+\varepsilon})$-approximation, for any constant $\varepsilon > 0$. If both $M = O(n\text{poly}\log n)$ and the maximum degree of the underlying graph $\Delta = O(\text{poly}\log n)$, we obtain a polynomial-time $O(n^{2/3+\varepsilon})$-approximation algorithm for any constant $\varepsilon > 0$. ◀

5.2 A Lower Bound on the Approximability of MTC

In this section, we present an approximation-preserving reduction from Symmetric Label Cover to MTC. Our reduction along with standard inapproximability results for Symmetric Label Cover indicate that MTC in general temporal networks is hard to approximate.

▶ **Theorem 7.** MTC *on temporal graphs with n vertices cannot be approximated within a factor of $O(2^{\log^{1-\varepsilon} n})$, for any constant $\varepsilon > 0$, unless* NP $\subseteq$ DTIME$(n^{\text{poly}\log n})$.

Proof. We present a polynomial-time approximation-preserving reduction from the Symmetric Label Cover (SLC) problem to MTC. In SLC (see e.g., [10, Definition 4.1]), we are given a complete bipartite graph $H(U, W)$, with $|U| = |W|$, a finite set of colors C and a binary relation $R(u, w) \subseteq C \times C$ for every vertex pair $(u, w) \in U \times W$. We seek to assign a color subset $\sigma(u) \subseteq C$ to each vertex $u \in U \cup W$ so that for every vertex pair $(u, w) \in U \times U$, there are colors $a \in \sigma(u)$ and $b \in \sigma(w)$ with $(a, b) \in R(u, w)$ and $\sum_{u \in U \cup W} |\sigma(u)|$, i.e., the total number of colors used, is minimized.

Given an instance of SLC, we create a temporal graph $\mathcal{G}$ whose vertex set V is partitioned into six sets V_U, $V_{C(U)}$, V_W, $V_{C(W)}$, V_X and $\{p, q\}$. There is a correspondence between the vertices of the bipartite graph H and the vertices of $\mathcal{G}$ in the sets V_U and V_W. The vertex sets $V_{C(U)} = V_U \times C$ and $V_{C(W)} = V_W \times C$ serve to encode the color assignment to the vertices of U and W in the SLC instance. Moreover, V_X contains a vertex (u, w, a, b) for every vertex pair $(u, w) \in U \times W$ and every allowable color pair $(a, b) \in R(u, w)$. Intuitively, the vertices of V_X serve to ensure that the color assignment is consistent. Finally, the vertices p and q ensure that the temporal graph $\mathcal{G}$ is connected.

For every $u \in V_U$ and $(u, a) \in V_{C(U)}$, $\mathcal{G}$ contains a temporal edge $\{u, (u, a)\}$ with label 1 and weight 1. Similarly, for every $w \in V_W$ and $(w, b) \in V_{C(W)}$, $\mathcal{G}$ contains a temporal

edge $\{w,(w,b)\}$ with label 4 and weight 1. For every vertex $(u,w,a,b) \in V_X$, $\mathcal{G}$ contains the temporal edges $\{(u,a),(u,w,a,b)\}$ with label 2 and weight 0 and $\{(u,w,a,b),(w,b)\}$ with label 3 and weight 0. $\mathcal{G}$ contains temporal edges with label 5 and weight 0 between p and every vertex in $V_U \cup V_{C(U)} \cup V_{C(W)} \cup V_X$ and between q and every vertex in V_U. Moreover, $\mathcal{G}$ contains temporal edges with label 0 and weight 0 between p and every vertex in V_W and between q and every vertex in $V_W \cup V_{C(U)} \cup V_{C(W)} \cup V_X$. We note that $\mathcal{G}$ is temporally connected and has $O(k^2c^2)$ vertices, where $k = |U| = |W|$ and $c = |C|$ (in fact, the number of vertices of $\mathcal{G}$ is of the same order as the total size of all binary relations $R(u,w)$).

We next show that this reduction is approximation-preserving. We first show that any feasible solution to the SLC instance can be mapped to a temporally connected subgraph $\mathcal{G}'$ of $\mathcal{G}$ with at most the same weight. Let us fix any assignment σ of a color set to each vertex of H that is feasible for the SLC instance. We first include in $\mathcal{G}'$ all temporal edges of weight 0. For every vertex $u \in U$ with assigned colors $\sigma(u)$, we include in $\mathcal{G}'$ the temporal edges $\{u,(u,a)\}$, for all $a \in \sigma(u)$. The total weight of these edges is $|\sigma(u)|$. Similarly, for every vertex $w \in W$, we include in $\mathcal{G}'$ the temporal edges $\{w,(w,b)\}$, for all $b \in \sigma(w)$. The total weight of these edges is $|\sigma(w)|$. Therefore, the total weight of the temporal subgraph $\mathcal{G}'$ is equal to the cost of the solution σ for the SLC problem.

It remains to show that $\mathcal{G}'$ is temporally connected. All vertices in $V_U \cup V_{C(U)} \cup V_{C(W)} \cup V_X \cup \{p\}$ are connected with each other (through p) by temporal edges with time label 5. There are also temporal $p-q$ and $q-p$ paths consisting of edges with time label 5 through the vertices of V_U. Similarly, all vertices in $V_W \cup V_{C(U)} \cup V_{C(W)} \cup V_X \cup \{q\}$ are connected with each other (through q) by temporal edges with time label 0. Moreover, there is a temporal path (using edges with time labels 0 and 5) from every vertex in $V_W \cup V_{C(U)} \cup V_{C(W)} \cup V_X \cup \{q\}$ to every vertex in V_U. Also, p is connected to every vertex in V_W with temporal edges of time label 0 and vice versa. All these vertex pairs are connected through temporal paths entirely consisting of 0-weight edges. The really interesting case concerns vertex pairs $(u,w) \in V_U \times V_W$. By the feasibility of the solution σ, for every vertex pair $(u,w) \in U \times W$, there are colors $a \in \sigma(u)$ and $b \in \sigma(w)$ such that $(a,b) \in R(u,w)$. Therefore, the temporal $u-w$ path $(u,(u,a),(u,w,a,b),(w,b),b)$ is included in $\mathcal{G}'$. Hence, $\mathcal{G}'$ is temporally connected.

We also need to show that given a temporally connected subgraph $\mathcal{G}'$ of $\mathcal{G}$, we can efficiently compute an assignment σ of a color set to each vertex in $U \cup W$ that is feasible for the SLC instance and has total cost no larger than the total weight of $\mathcal{G}'$. For every $u \in V_U$ and every temporal edge of the form $(\{u,(u,a)\},1)$ included in $\mathcal{G}'$, we include the color a in $\sigma(u)$. Similarly, for every $w \in V_W$ and every temporal edge of the form $(\{w,(w,b)\},4)$ included in $\mathcal{G}'$, we include the color b in $\sigma(w)$. Since these are the only edges of $\mathcal{G}$ (and $\mathcal{G}'$) with positive weight, the total cost of σ is equal to the total weight of $\mathcal{G}'$.

It remains to show that σ is a feasible solution to the SLC instance. Let $(u,w) \in U \times W$ in the SLC instance. The crucial observation is that the only way to connect $u \in V_U$ to $w \in V_W$ in $\mathcal{G}'$ is through some temporal path $(\{u,(u,a)\},1)$, $(\{(u,a),(u,w,a,b)\},2)$, $(\{(w,b),(u,w,a,b)\},3)$, $(\{w,(w,b)\},4)$, for $(a,b) \in R(u,w)$. This claim immediately implies the feasibility of the assignment σ. To prove this claim, we observe that a temporal $u-w$ path cannot use any temporal edge incident to p or q, since all edges between V_U and $\{p,q\}$ have time label 5 and all edges between V_W and $\{p,q\}$ have time label 0. So, any temporal $u-w$ path in $\mathcal{G}'$ has to move from u to some vertex $(u,a) \in V_{C(U)}$. Such a vertex $(u,a) \in V_{C(U)}$ does not have any neighbors in V_U other than u. Hence, the next vertex of any temporal $u-w$ path in $\mathcal{G}'$ must be to visit some $(u,w,a,b) \in V_X$, where $w \in W$ and $(a,b) \in R(u,w)$. Similarly, since such a vertex $(u,w,a,b) \in V_X$ does not have any neighbors in $V_{C(U)}$ other than (u,a) and any neighbors in $V_{C(W)}$ other than (w,b), we conclude that the next step

of any temporal $u - w$ path in $\mathcal{G}'$ must be to the vertex $(w, b) \in V_{C(W)}$. But now, the last temporal edge used has time label 3, which implies that the $u - w$ path cannot use any edges with time labels 1 and 2 anymore. Thus, the path cannot return to $V_U \cup V_{C(U)}$. The only choice now is that the path moves to w through the temporal edge $(\{w, (w, b)\}, 4)$, which establishes the claim about the structure of any temporal $u - v$ path in $\mathcal{G}'$.

The discussion above establishes the correctness of the reduction from SLC to MTC. Using the fact that the number of vertices of $\mathcal{G}$ is quadratic in the number of vertices of H and standard inapproximability results for SLC (e.g., [10]), we conclude the proof. ◀

Adjusting the proof of Theorem 7, we can get a reduction from the MinRep problem, which is considered in [8], to MTC. Thus, any polynomial-time $\rho(n)$-approximation for MTC on simple temporal graphs implies a polynomial-time $\rho(n^2)$-approximation for MinRep. Since the best known approximation ratio for MinRep is $O(n^{1/3} \log^{2/3} n)$ [8, Section 2], any $O(n^{1/6})$-approximation to MTC would imply an improved approximation ratio for MinRep.

5.3 Inapproximability of Unweighted MTC

The following shows an approximation-preserving reduction from the Steiner Tree problem on undirected graphs with edge weights either 1 or 2 to MTC on unweighted temporal graphs, where all temporal edges have weight equal to 1. Since this version of the Steiner Tree problem is known to be APX-hard [4], we obtain the following.

▶ **Theorem 8.** MTC *on unweighted temporal graphs is* APX*-hard, and thus it does not admit a PTAS, unless* P = NP.

6 All-Pairs Temporal Connectivity on Trees and Cycles

We can do better if the underlying graph is either a tree or a cycle. We can show that if the underlying graph is a tree, there is an optimal solution to the MTC problem that uses each edge with at most two time labels. Using this structural property, we can show that MTC can be solved efficiently by dynamic programming if the underlying graph is a tree.

▶ **Theorem 9.** *Let $\mathcal{G}$ be a temporal tree on n vertices with lifetime L. There is a dynamic programming algorithm that computes an optimal solution to* MTC *on $\mathcal{G}$ in time $O(nL^4)$.*

We also observe that if the underlying graph is a cycle $C_n = (v_0, v_1, \ldots, v_{n-1}, v_0)$, any temporally connected subgraph $\mathcal{G}'$ can be partitioned into *sectors*. A sector is a connected part $(v_i, v_{i+1}, \ldots, v_k)$ of the cycle for which there is a vertex $v_j \notin \{v_i, \ldots, v_{k-1}\}$ such that the temporal paths $p_{\text{incr}} = (v_i, v_{i+1}, \ldots, v_j)$ and $p_{\text{decr}} = (v_k, v_{k-1}, \ldots, v_{j+1})$ are present in $\mathcal{G}'$ (the vertex indices along C_n are taken modulo n). Intuitively, any vertex in the sector $(v_i, v_{i+1}, \ldots, v_k)$ can reach every vertex in C_n through the paths p_{incr} and p_{decr}. Then, we can show that there is an optimal solution to the MTC problem on C_n where each edge is shared by at most two different sectors. Then, ignoring edges shared by different sectors and using dynamic programming to determine a near optimal partitioning of C_n into sectors, we obtain the following.

▶ **Theorem 10.** *There is a polynomial-time* 2*-approximation algorithm for the* MTC *problem on any temporal cycle C_n.*

Abstract

The cryptogenography problem, introduced by Brody, Jakobsen, Scheder, and Winkler (ITCS 2014), is to collaboratively leak a piece of information known to only one member of a group (i) without revealing who was the origin of this information and (ii) without any private communication, neither during the process nor before. Despite several deep structural results, even the smallest case of leaking one bit of information present at one of two players is not well understood. Brody et al. gave a 2-round protocol enabling the two players to succeed with probability 1/3 and showed the hardness result that no protocol can give a success probability of more than 3/8.

In this work, we show that neither bound is tight. Our new hardness result, obtained by a different application of the concavity method used also in the previous work, states that a success probability of better than 0.3672 is not possible. Using both theoretical and numerical approaches, we improve the lower bound to 0.3384, that is, give a protocol leading to this success probability. To ease the design of new protocols, we prove an equivalent formulation of the cryptogenography problem as solitaire vector splitting game. Via an automated game tree search, we find good strategies for this game. We then translate the splits that occurred in this strategy into inequalities relating position values and use an LP solver to find an optimal solution for these inequalities. This gives slightly better game values, but more importantly, also a more compact representation of the protocol and a way to easily verify the claimed quality of the protocol.

Unfortunately, already the smallest protocol we found that beats the previous 1/3 success probability takes up 16 rounds of communication. The protocol leading to the bound of 0.3384 even in a compact representation consists of 18248 game states. These numbers suggest that the task of finding good protocols for the cryptogenography problem as well as understanding their structure is harder than what the simple problem formulation suggests.

1 Introduction

Motivated by a number of recent influential cases of whistle-blowing, Brody, Jakobsen, Scheder, and Winkler [2] proposed the following *cryptogenography problem* as model for anonymous information disclosure in public networks. We have k players (potential information leakers).

A random one of them holds a secret, namely a random bit. All other players only know that they are not the secret holder. Now without any non-public communication, the players aim at both making the secret public and hiding the identity of the secret holder. More precisely, we are looking for a (fully public) communication protocol in which the players as only form of communication broadcast bits, which may depend on public information (including all previous communication), private knowledge (with respect to the secret), and a private source of randomness. After this phase of communication, the protocol outputs a single bit depending solely on all data sent in the communication phase. The complete protocol (regulating the communication and the output function) and all communication is public, and is monitored by an eavesdropper who aims at identifying the secret owner. We say that a run of the protocol is a success for the players, if the protocol output is the secret bit and the eavesdropper fails to identify the secret owner; otherwise it is a success for the eavesdropper. Since everything is public, optimal strategies for the eavesdropper are easy to find (see below). We shall therefore always assume that the eavesdropper plays an optimal strategy. The players' success probability (for a given protocol) then is the probability (taken over the random decisions of the players and the random initial secret distribution) that simultaneously (i) the protocol outputs the true secret and (ii) an optimal eavesdropper does not blame the secret holder.

It is immediately clear that some positive (players') success probability is easy to obtain. A protocol without any communication and outputting a random bit achieves a success probability of $\frac{1}{2} - \frac{1}{2k}$ (the eavesdropper has no strictly better alternative than guessing a random player). Surprisingly, Brody et al. could show that the players, despite the complete absence of private communication, can do better. For two players, they present a protocol having a success probability of $\frac{1}{3}$ (instead of the trivial $\frac{1}{4}$). For k sufficiently large, they present a protocol with success probability 0.5644. They also show two hardness results, namely that a success probability of more than $\frac{3}{4}$ cannot be obtained, regardless of the number of players, and that $\frac{3}{8}$ is an upper bound for the two-player case. While all these results are easy to state, they build on deep analyses of the cryptogenography problem, in particular, on clever reformulations of the problem in terms of certain convex combinations of secret distributions (protocol design) and functions that are concave on a certain infinite set of two-dimensional subspaces ("allowed planes") of the set of secret distributions (hardness results).

The starting point for our work is the incomplete understanding of the two-player case. While the gap between upper and lower bound of $\frac{3}{8} - \frac{1}{3} \approx 0.04167$ is small, our impression is that the current-best protocol achieving the $\frac{1}{3}$ success probability in two rounds together with the abstract hardness result do not give us much understanding of the structure of the cryptogenography problem. We therefore imagine that a better understanding of this smallest-possible problem of leaking one bit from two players, ideally by determining an optimal protocol (that is, matching a hardness result), could greatly improve the situation.

Our Results. We shall be partially successful in achieving these goals. On the positive side, we find protocols with strictly larger success probability than $\frac{1}{3}$ (namely 0.3384) and we prove a stricter hardness result of 0.3672. Our new protocols look very different from the 2-round protocol given by Brody et al., in particular, they use infinite protocol trees (but have an expected finite number of communication rounds). These findings motivate and give new starting points for further research on the cryptogenography problem.

On the not so positive side, our work on better protocols indicates that good cryptogenographic protocols can be very complicated. The simplest protocol we found that beats the $\frac{1}{3}$

barrier already has a protocol tree of depth 16, that is, the two players need to communicate for 16 rounds in the worst case. While we still manage to give a human-readable description and performance proof for this protocol, it is not surprising that previous works not incorporating a computer-assisted search did not find such a protocol. Our best protocol, giving a success probability of 0.3384, already uses 18248 non-equivalent states.

Technical contributions. To find the improved protocols, we use a number of theoretical and experimental tools. We first reformulate the cryptogenography problem as a solitaire vector splitting game over vectors in $\mathbb{R}^{2\times k}_{\geq 0}$. Both for human researchers and for automated protocol searches, this reformulation seems to be easier to work with than the previous reformulation via convex combinations of distributions lying in a common allowed plane [2]. It also proved to be beneficial for improving upon the hardness result.

Restrictions of the vector splitting game to a finite subset of $\mathbb{R}^{2\times k}_{\geq 0}$, e.g., $\{0,\dots,T\}^{2\times k}$, can easily be solved via dynamic programming, giving (due to the restriction possibly sub-optimal) cryptogenographic protocols. Unfortunately, for $k = 2$ even discretizations as fine as $T = 40$ are not sufficient to find protocols beating the $1/3$ barrier and memory usage quickly becomes a bottleneck issue. However, exploiting the simple fact that the game values are homogeneous (that is, multiplying a game position by a non-negative scalar changes the game value by this factor), we can (partially) simulate a much finer discretization in a coarse one. This *extended dynamic programming approach* easily gives cryptogenographic success probabilities larger than $1/3$. Reading off the corresponding protocols, due to the reuse of the same position in different contexts, needs more care, but in the end gives without greater difficulties also the improved protocols.

When a cryptogenographic protocol reuses a state a second time (with a non-trivial split in between), then there is no reason to re-iterate this part of the protocol whenever this position occurs. Such a protocol allows infinite paths, while still needing only an expected finite number of rounds. Since the extended dynamic programming approach in finite time cannot find such protocols, we use a linear programming based post-processing stage. We translate each splitting operation used in the extended dynamic programming search into an inequality relating game values. By exporting these into an LP-solver, we do not only obtain better game values (possibly corresponding to cryptogenographic protocols with infinite paths, for which we would get a compact representation by making the cycles explicit), but also a way to easily certify these values using an optimality check for a linear program instead of having to trust the ad-hoc dynamic programming implementation.

Related work. Despite a visible interest of the research community in the cryptogenography problem, the only relevant follow-up work is Jakobsen's paper [5], which analyses the cryptogenography problem for the case that several of the players know the secret. This allows to leak a much larger amount of information as made precise in [5]. Due to the asymptotic nature of these results, unfortunately, they do not give new insight in the 2-player case. Other work on anonymous broadcasting typically assumes bounded computational power of the adversary (see, e.g., [6]); we refer to [3] for a survey on anonymous communication in communication networks.

In [2], the cryptogenography problem was reformulated to the problem of finding the point-wise minimal function f on the set of secret distributions that is point-wise not smaller than some given function g and that is concave on an infinite set of 2-dimensional planes. Such restricted notions of concavity (or, equivalently, convexity) seem to be less understood. We found work by Matoušek [9] for a similar convexity problem, however, with only a finite

number of one-dimensional directions in which convexity is required. We do not see how to extend these results to our needs.

2 Finding Better Cryptogenography Protocols

This section is devoted to the design of stronger cryptogenographic protocols. In particular, we demonstrate that a success probability of more than 1/3 can be achieved. We start by making the cryptogenography problem precise (Section 2.1) and introduce an equivalent formulation as solitaire vector splitting game (Section 2.2). We illustrate both formulations using the best known protocol for the 2-player case (Section 2.3). In Section 2.4, we state basic properties that simplify the analysis of protocols and aid our automated search for better protocols, which is detailed in Section 2.6. In Section 2.5, we give a simple, human-readable proof that 1/3 is not the optimal success probability by analyzing a protocol with success probability $\frac{449}{1334} \approx 0.3341$. We describe how to post-optimize and certify the results obtained by the automated search using linear programming in Section 2.7 and summarize our findings (in particular, the best lower bound we have found) in Section 2.8. Proofs and details that had to be omitted due to space constraints can be found in an extended version of this article [4].

2.1 The Cryptogenography Problem

Let us fix an arbitrary number k of players called $1, \dots, k$ for simplicity. We write $[k] := \{1, \dots, k\}$ for the set of players. We assume that a random one of the them, the "secret owner" $J \in [k]$, initially has a secret, namely a random bit $X \in \{0, 1\}$. The task of the players is, using public communication only, to make this random bit public without revealing the identity of the secret owner. More precisely, we assume that the players, before looking at the secret distribution, (publicly) decide on a communication protocol π. This is again public, that is, all bits sent are broadcast to all players, and they may depend only on previous communication, the private knowledge of the sender (whether he is the secret owner or not, and if so, the secret), and private random numbers of the sender. At the end of the communication phase, the protocol specifies an output bit Y (depending on all communication).

The aspect of not disclosing the identity of the secret owner is modeled by an adversary, who knows the protocol (because it was discussed in public) and who gets to see all communication (and consequently also knows the protocol output Y). The adversary, based on all this data, blames one player K. The players win this game if the protocol outputs the true secret (that is, $Y = X$) and the adversary does not blame the secret owner (that is, $K \neq J$), otherwise the adversary wins. It is easy to see what the best strategy for the adversary is (given the protocol and the communication), so the interesting part of the cryptogenography problem is finding strategies that maximize the probability that the players win assuming that the adversary plays optimally. We call this the (players') success probability of the protocol.

While the game starts with a uniform secret distribution, it will be useful to regard arbitrary secret distributions. In general, a *secret distribution* is a distribution D over $\{0, 1\} \times [k]$, where D_{ij} is the probability that player $j \in [k]$ is the secret owner and the secret is $i \in \{0, 1\}$. Modulo a trivial isomorphism, D is just a vector in $\mathbb{R}^{2\times k}_{\geq 0}$ with $\|D\|_1 = 1$. We denote by $\Delta = \Delta_k$ the set of all these distributions (this was denoted by $\Delta(\{0, 1\} \times [k])$ in [2]).

Brody et al. [2] observe that any cryptogenographic protocol can be viewed as successive rounds of one-bit communication, where in each step some (a priori) secret distribution probabilistically leads to one of two follow-up (a posteriori) distributions (depending on the bit transmitted) such that the a priori distribution is a convex combination of these and a certain proportionality condition is fulfilled (all three distributions lie in the same "allowed plane"). Conversely, whenever the initial distribution can be written as such a convex combination of certain distributions, then there is a round of a cryptogenographic protocol leading to these two distributions (with certain probabilities). Consequently, the problem of finding a good cryptogenographic protocol is equivalent to iteratively rewriting the initial equidistribution as certain convex combinations of other secret distributions in such a way that the success probability, which can be expressed in terms of this rewriting tree, is large.

2.2 The Solitaire Vector Splitting Game

Instead of directly using the "convex combination" formulation of Brody et al., we propose a slightly different reformulation as *solitaire vector splitting game*. This formulation seems to ease finding good cryptogenographic protocols (lower bounds for the success probability), both for human researchers and via automated search (Section 2.5). The main advantage of our formulation is that it takes as positions all $2k$-dimensional vectors with non-negative entries, whereas the cryptogenographic protocols are only defined on distributions over $\{0,1\} \times [k]$. In this way, we avoid arguing about probabilities and convex combinations and instead simply split a vector (resembling a secret distribution) into a sum of two other vectors. Furthermore, a simple monotonicity property (Proposition 2.5) eases the analyses. Still, there is an easy translation between the two formulations, so that we can re-use whatever results were found in [2].

For reasons of space, we do not repeat in detail the "convex combination" formulation and its equivalence to cryptogenographic protocols (the latter alone takes around two pages in [2]). We focus instead on the formal introduction of the vector splitting game (and argue that its equivalent to the "convex combination" formulation in Lemma 2.6) and refer to [2, 4] for a more detailed exposition.

▶ **Definition 2.1.** Let $D \in \mathbb{R}^{2\times k}_{\geq 0}$. We say that (D_0, D_1) is a *j-allowed split of D* if $D = D_0 + D_1$ and D_0 (and thus also D_1) is proportional to D on $\{0,1\} \times ([k] \setminus \{j\})$, that is, there is a $\lambda \in [0,1]$ such that $(D_0)_{|\{0,1\}\times([k]\setminus\{j\})} = \lambda D_{|\{0,1\}\times([k]\setminus\{j\})}$. We call (D_0, D_1) an *allowed split* of D if it is a j-allowed split of D for some $j \in [k]$.

The objective of the vector splitting game is to recursively apply allowed splits to a given vector $D \in \mathbb{R}^{2\times k}_{\geq 0}$ with the target of maximizing the sum of the

$$p(D') := \max_{x\in\{0,1\}} \left(\sum_{j\in[k]} D'_{x,j} - \max_{j\in[k]} D'_{x,j} \right)$$

values of the resulting vectors (note that when D' is a distribution, then $p(D')$ is the 0-bit success probability of D'; for more details, the reader is referred to [2, 4]). More precisely, an n-round play of the vector splitting game is described by a binary tree of height at most n, where the nodes are labeled with *game positions* in $\mathbb{R}^{2\times k}_{\geq 0}$. The root is labeled with the initial position D. For each non-leaf v, the labels of the two children form an allowed split of the label of v. The payoff of such a play is $\sum_{D'} p(D')$, where D' runs over all leaves of the game tree. The aim is to maximize the payoff. Right from this definition, it is clear that

the maximum payoff achievable in an n-round game started in position D, the *value* of this game, is $\textsc{succ}_n(D)$ as defined below.

▶ **Definition 2.2.** For all $n \in \mathbb{N}$ and for all $D \in \mathbb{R}^{2\times k}_{\geq 0}$, we recursively define

(i) $\textsc{succ}_0(D) := \max\limits_{x\in\{0,1\}} \left(\sum\limits_{j\in[k]} D_{x,j} - \max\limits_{j\in[k]} D_{x,j} \right)$;

(ii) $\textsc{succ}_n(D) := \max\limits_{(D_0,D_1)} \left(\textsc{succ}_{n-1}(D_0) + \textsc{succ}_{n-1}(D_1) \right)$, if $n \geq 1$. Here the maximum is taken over all allowed splits (D_0, D_1) of D.

For an example of an admissible game, we refer to Figure 1 in Section 2.3.

It is easy to see that the game values are non-decreasing in the number of rounds, but bounded. The limiting value is thus well-defined.

▶ **Lemma 2.3.** *Let $D \in \mathbb{R}^{2\times k}_{\geq 0}$ and $n \in \mathbb{N}$. Then $\textsc{succ}_n(D) \leq \|D\|_1$ and $\textsc{succ}_{n+1}(D) \geq \textsc{succ}_n(D)$. Consequently, $\textsc{succ}(D) := \lim_{n\to\infty} \textsc{succ}_n(D)$ is well-defined and is equal to $\sup_{n\in\mathbb{N}} \textsc{succ}_n(D)$.*

▶ **Proposition 2.4** (scalability)**.** *Let $D \in \mathbb{R}^{2\times k}_{\geq 0}$ and $\lambda \geq 0$. Then $\textsc{succ}_n(\lambda D) = \lambda\, \textsc{succ}_n(D)$ for all $n \in \mathbb{N}$. Consequently, $\textsc{succ}(\lambda D) = \lambda\, \textsc{succ}(D)$.*

▶ **Proposition 2.5** (monotonicity)**.** *Let $D, E \in \mathbb{R}^{2\times k}_{\geq 0}$ with $E \geq D$ (component-wise). Then $\textsc{succ}_n(E) \geq \textsc{succ}_n(D)$ for all $n \in \mathbb{N}$. Consequently, $\textsc{succ}(E) \geq \textsc{succ}(D)$.*

From the previous definitions and observations, we derive that the game values for games starting with a distribution D, that is, $\|D\|_1 = 1$, and the success probabilities of the optimal cryptogenographic protocols for D, are equal.

▶ **Lemma 2.6.** *Let $D \in \mathbb{R}^{2\times k}_{\geq 0}$ with $\|D\|_1 = 1$. Then for all $n \in \mathbb{N}$, our definitions of $\textsc{succ}_n$ coincide with the ones of Brody et al., which are the success probabilities of the best n-round cryptogenographic protocols for the distribution D. Consequently, also the definition of $\textsc{succ}(D)$ coincides.*

2.3 Example: The Best-so-far 2-Player Protocol

We now turn to the case of two players. We use this subsection to describe the best known protocol for two players in the different languages. We also use this mini-example to sketch the approaches used in the following subsections to design superior protocols.

For two players, we usually write a game position $D = (D_{01}, D_{11}, D_{02}, D_{12}) \in \mathbb{R}^{2\times 2}_{\geq 0}$ as $D = (a, b, c, d)$. The 0-round game value (equaling the success probability of the 0-bit protocol) then is

$$\textsc{succ}_0(D) = \max\{\min\{a, c\}, \min\{b, d\}\}.$$

As a warmup, let us describe the best known 2-player protocol TwoBit in the two languages. In the language of Brody et al., the first player can send a (randomized) bit that transforms the initial distribution $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ with probability $\frac{1}{2}$ each into the distributions $(\frac{1}{3}, \frac{1}{3}, \frac{1}{6}, \frac{1}{6})$ and $(\frac{1}{6}, \frac{1}{6}, \frac{1}{3}, \frac{1}{3})$. In the first case, the second player can send a bit leading to each of the distributions $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3}, 0)$ and $(\frac{1}{3}, \frac{1}{3}, 0, \frac{1}{3})$ with probability $\frac{1}{2}$, both having a 0-bit success probability of $\frac{1}{3}$. In the second possible result of the first move, the first player can lead to an analogous situation. Consequently, after two rounds of the protocol we end up with four equally likely distributions all having a 0-bit success probability of $\frac{1}{3}$. Hence the protocol TwoBit has a success probability of $\frac{1}{3}$.

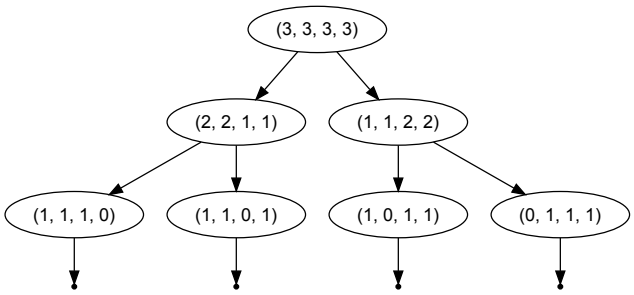

Figure 1 Game tree corresponding to TwoBit.

In the language of the splitting games, we can forget about the probabilities and simply split up the initial distribution. Using the scaling invariance, to ease reading we scaled up all numbers by a factor of 12. Figure 1 shows the game tree corresponding to the TwoBit protocol. It shows that $\text{SUCC}_2(3,3,3,3) \geq 4$, proving again the existence of a cryptogenographic protocol for the distribution $(\frac{1}{4},\frac{1}{4},\frac{1}{4},\frac{1}{4}) = \frac{1}{12}(3,3,3,3)$ with success probability $\frac{4}{12} = \frac{1}{3}$.

Note that each allowed split (D^0, D^1) of D implies the inequality $\text{SUCC}(D) \geq \text{SUCC}(D^0) + \text{SUCC}(D^1)$, which follows from clause (ii) of Definition 2.2 and taking the limit $n \to \infty$. Hence the game tree giving the $\frac{1}{3}$ lower bound for the success probability equivalently gives the following proof via inequalities.

$$\begin{aligned} \text{SUCC}(3,3,3,3) &\geq \text{SUCC}(2,2,1,1) + \text{SUCC}(1,1,2,2), \\ \text{SUCC}(2,2,1,1) = \text{SUCC}(1,1,2,2) &\geq \text{SUCC}(1,0,1,1) + \text{SUCC}(0,1,1,1), \\ \text{SUCC}(1,0,1,1) = \text{SUCC}(0,1,1,1) &\geq \text{SUCC}_0(0,1,1,1) = 1. \end{aligned}$$

The splitting game and the inequality view will in the following be used to design stronger protocols (better lower bounds for the optimal success probability). We shall compute good game trees by computing lower bounds for the game values of a discrete set of positions via repeatedly trying allowed splits. For example, the above game tree for the starting position $(3,3,3,3)$ could have easily be found by recursively computing the game values for all positions in $\{0,1,2,3\}^4$.

It turns out that such an automated search leads to better results when we also allow scaling moves (referring to Proposition 2.4). For example, in the above mini-example of computing optimal game values for all positions $\{0,1,2,3\}^4$, we could try to exploit the fact that $\text{SUCC}(1,1,1,1) = \frac{1}{3}\text{SUCC}(3,3,3,3)$. Such scaling moves are a cheap way of working in $\{0,1,2,3\}^4$ while trying to gain the power of working in $\{0,1,\dots,9\}^4$, which would be computationally more costly, especially with regard to memory usage. Scaling moves may lead to repeated visits of the same position, resulting in cyclic structures. Here translating the allowed splits used in the tree into the inequality formulation and then using an LP-solver is an interesting approach (detailed in Section 2.7). It allows to post-optimize the game trees found, in particular, by solving cyclic dependencies. This leads to slightly better game values and compacter representations of game trees.

2.4 Useful Facts

For some positions of the vector splitting game, the true value is easy to determine. We do this here to later ease the presentation of the protocols.

▶ **Proposition 2.7.** *We have* $\textsc{succ}(a,b,c,d) \le \min\{a,c\} + \min\{b,d\}$.

▶ **Proposition 2.8.** *Let* $D = (a,b,c,0)$. *Then* $\textsc{succ}(D) = \textsc{succ}_0(D) = \min\{a,c\}$.

▶ **Proposition 2.9.** *If* $D = (a,b,c,d)$ *is such that* $a + b \le \min\{c,d\}$, *then* $\textsc{succ}(D) = a + b$.

2.5 Small Protocols Beating the 1/3 Barrier

We now present a sequence of protocols showing that there are cryptogenographic protocols having a success probability strictly larger than $\frac{1}{3}$. These protocols are still relatively simple, so we also obtain a human-readable proof of the following result.

▶ **Theorem 2.10.** $\textsc{succ}(\frac{1}{4},\frac{1}{4},\frac{1}{4},\frac{1}{4}) \ge \frac{449}{1334} \approx 0.3341$.

Proof. To be able to give a readable mathematical proof, we argue via inequalities for game values $\textsc{succ}(\cdot)$. We later discuss how the corresponding protocols (game trees) look like.

We first observe the following inequalities, always stemming from allowed splits (the underlined entries are proportional). Whenever Proposition 2.8 or 2.9 determine a value, we exploit this without further notice.

$$\begin{aligned}\textsc{succ}(\underline{12,12},12,12) &\ge \textsc{succ}(\underline{7,7},6,4) + \textsc{succ}(\underline{5,5},6,8),\\ \textsc{succ}(\underline{5,5},6,8) &\ge \textsc{succ}(\underline{2,2},0,2) + \textsc{succ}(\underline{3,3},6,6) = 2+6=8.\end{aligned}$$

This proves $\textsc{succ}(12,12,12,12) \ge 8 + \textsc{succ}(7,7,6,4)$. To analyze $\textsc{succ}(7,7,6,4)$, we use the allowed split

$$\textsc{succ}(7,7,\underline{6,4}) \ge \textsc{succ}(4,5,\underline{3,2}) + \textsc{succ}(3,2,\underline{3,2}) \tag{1}$$

and regard the two positions $(4,5,3,2)$ and $(3,2,3,2)$ separately in some detail.

Claim 1: The value of $(4,5,3,2)$ satisfies $\textsc{succ}(4,5,3,2) \ge \frac{55}{12}$. By scaling, we have $\textsc{succ}(4,5,3,2) = \frac{1}{2}\textsc{succ}(8,10,6,4)$. We present the allowed splits

$$\begin{aligned}\textsc{succ}(\underline{8,10},6,4) &\ge \textsc{succ}(\underline{4,5},2,4) + \textsc{succ}(\underline{4,5},4,0) = \textsc{succ}(4,5,2,4) + 4,\\ \textsc{succ}(4,5,\underline{2,4}) &\ge \textsc{succ}(1,2,\underline{1,2}) + \textsc{succ}(3,3,\underline{1,2}) = \textsc{succ}(1,2,1,2) + 3,\end{aligned}$$

hence $\textsc{succ}(8,10,6,4) \ge \textsc{succ}(1,2,1,2) + 7$. To bound the latter term, we use the scaling $\textsc{succ}(1,2,1,2) = \frac{1}{6}\textsc{succ}(6,12,6,12)$ and consider the allowed splits

$$\begin{aligned}\textsc{succ}(\underline{6,12},6,12) &\ge \textsc{succ}(\underline{5,10},3,9) + \textsc{succ}(\underline{1,2},3,3) = \textsc{succ}(5,10,3,9) + 3,\\ \textsc{succ}(5,10,\underline{3,9}) &\ge \textsc{succ}(0,6,\underline{2,6}) + \textsc{succ}(5,4,\underline{1,3}) = 6+4=10.\end{aligned}$$

Thus $\textsc{succ}(6,12,6,12) \ge 13$ and $\textsc{succ}(1,2,1,2) \ge \frac{13}{6}$. This shows $\textsc{succ}(4,5,3,2) \ge \frac{1}{2}(\textsc{succ}(1,2,1,2)+7) \ge \frac{55}{12}$.

Claim 2: We have $\textsc{succ}(3,2,3,2) \ge \frac{5}{3} + \frac{2}{9}\textsc{succ}(7,7,6,4)$. By scaling, we obtain $\textsc{succ}(3,2,3,2) = \frac{1}{3}\textsc{succ}(9,6,9,6)$ and compute

$$\begin{aligned}\textsc{succ}(9,6,\underline{9,6}) &\ge \textsc{succ}(6,3,\underline{6,4}) + \textsc{succ}(3,3,\underline{3,2}),\\ \textsc{succ}(6,3,\underline{6,4}) &\ge \textsc{succ}(3,0,\underline{3,2}) + \textsc{succ}(3,3,\underline{3,2}) = 3 + \textsc{succ}(3,3,3,2),\end{aligned}$$

and hence $\textsc{succ}(9,6,9,6) \ge 3 + 2\,\textsc{succ}(3,3,3,2)$. To bound the latter term, we scale $\textsc{succ}(3,3,3,2) = \frac{1}{3}\textsc{succ}(9,9,9,6)$ and present the allowed splits

$$\begin{aligned}\textsc{succ}(\underline{9,9},9,6) &\ge \textsc{succ}(\underline{7,7},6,4) + \textsc{succ}(\underline{2,2},3,2),\\ \textsc{succ}(\underline{2,2},3,2) &\ge \textsc{succ}(\underline{1,1},1,0) + \textsc{succ}(\underline{1,1},2,2) = 1+2=3.\end{aligned}$$

Thus $\textsc{succ}(3,3,3,2) \ge 1 + \frac{1}{3}\textsc{succ}(7,7,6,4)$, implying $\textsc{succ}(3,2,3,2) \ge \frac{5}{3} + \frac{2}{9}\textsc{succ}(7,7,6,4)$.

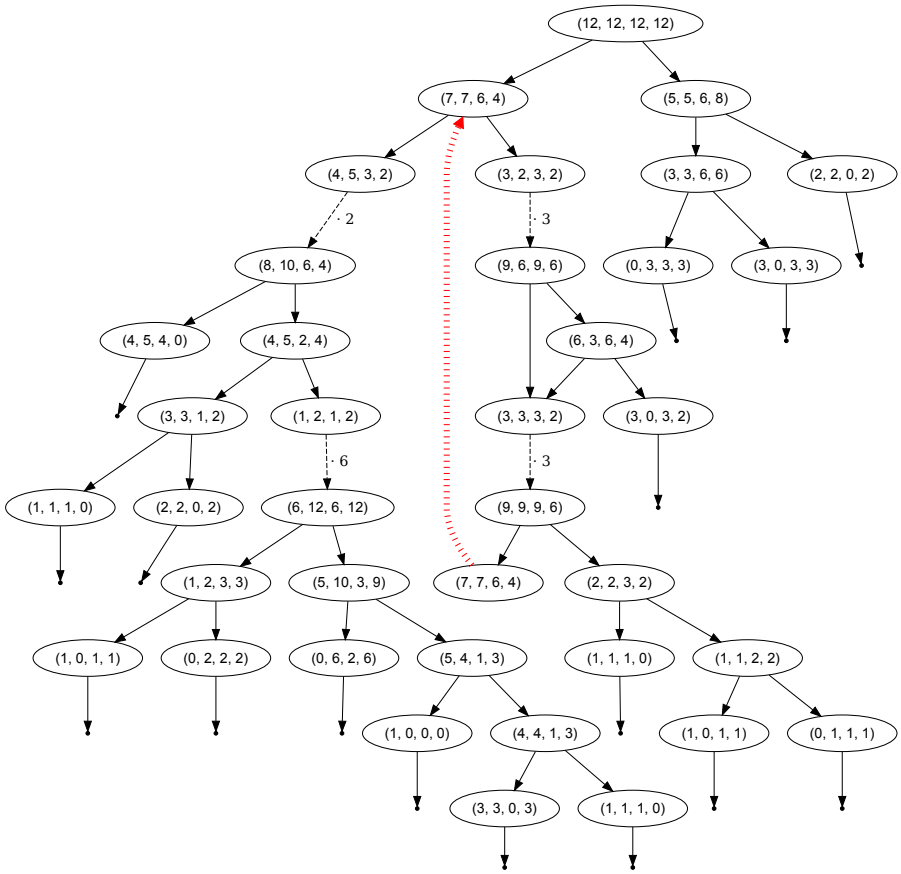

Figure 2 Game tree representation of the protocols of Theorem 2.10.

Putting things together. Claims 1 and 2 together with (1) give

$$\textsc{succ}(7,7,6,4) \geq \tfrac{75}{12} + \tfrac{2}{9}\,\textsc{succ}(7,7,6,4).$$

By solving this elementary equation, we obtain $\textsc{succ}(7,7,6,4) \geq \frac{225}{28}$, and it follows that $\textsc{succ}(12,12,12,12) \geq \frac{225}{28} + 8 = \frac{449}{28} = 16 + \frac{1}{28}$. Scaling leads to the claim of the theorem $\textsc{succ}(\frac{1}{4},\frac{1}{4},\frac{1}{4},\frac{1}{4}) \geq \frac{1}{3} + \frac{1}{1344} = \frac{449}{1344} = 0.33407738\ldots$. ◀

When translating the inequalities into a game tree (see Figure 2 for the result), we first observe that in Claim 2 we obtained two different nodes labeled with the position $(3,3,3,2)$. Since there is no reason to treat them differently, we can identify these two nodes and thus obtain a more compact representation of the game tree. This is the reason why the node labeled $(3,3,3,2)$ in Figure 2 has two incoming edges.

Interestingly, such identifications can lead to cycles. If we translate the equations for position $(7,7,6,4)$ and its children into a graph, then we observe that the node for $(7,7,6,4)$ has a descendant also labeled $(7,7,6,4)$ (this is what led to the inequality $\textsc{succ}(7,7,6,4) \geq \frac{75}{12} + \frac{2}{9}\,\textsc{succ}(7,7,6,4)$). By transforming this inequality to $\textsc{succ}(7,7,6,4) \geq \frac{225}{28}$, we obtain a statement that is true, but that does not anymore refer to an actual (finite) game tree. However, there is a sequence of game trees with values converging to the value we determined. These trees are obtained from recursively applying the above splitting procedure for $(7,7,6,4)$ a certain number ℓ of times and then using the 0-round tree for the lowest node

Table 1 Lower bounds $s(T,\dots,T)/(4T)$ on $\textsc{succ}(\frac{1}{4},\frac{1}{4},\frac{1}{4},\frac{1}{4})$ stemming from the automated search (line 1). Given are also the number of iterations until the automated search procedure converged, i.e., stopped finding improvements using allowed splits or scalings, and the number of game positions and constraints that had an influence on the value of $s(T,\dots,T)$.

T	15	20	25	30
Automated search	0.3369432925	0.3376146092	0.3379027186	0.3381689066
Iterations	119	129	141	146
Constraints	535	1756	4217	13958
Game Positions	394	1326	2956	9646

labeled $(7,7,6,4)$. The value of this game tree is $8+\sum_{i=0}^{\ell-1}(\frac{2}{9})^i\frac{75}{12}+(\frac{2}{9})^\ell\,\textsc{succ}_0(7,7,6,4)=8+\frac{75}{12}\frac{1-(\frac{2}{9})^\ell}{1-\frac{2}{9}}+6\cdot(\frac{2}{9})^\ell=\frac{449}{28}-\frac{57}{28}\,(\frac{2}{9})^\ell$. Hence for $\ell\geq 3$, this is more than 16 (which represents a success probability of $\frac{1}{3}$), corresponding to a game tree of height[1] $4+4\ell\geq 16$.

2.6 Automated Search

The vector splitting game formulation allows to search for good cryptogenographic protocols as follows. We try to determine the game values of all positions from a discrete set $\mathcal{D}:=\{0,\dots,T\}^{2\times k}$ by repeatedly applying allowed splits. More precisely, we store a function $s:\mathcal{D}\to\mathbb{R}$ that gives a lower bound on the game value $\textsc{succ}(D)$ of each position $D\in\mathcal{D}$. We initialize this function with $s\equiv\textsc{succ}_0$ and then in order of ascending $\|D\|_1$ try all allowed splits $D=D_0+D_1$ and update $s(D)\leftarrow s(D_0)+s(D_1)$ in case we find that $s(D)$ was smaller.

Recall that for any secret distribution D, the game value $\textsc{succ}(D)$ is the supremum success probability of cryptogenographic protocols for D. Hence, e.g., the value $s(T,\dots,T)/(2Tk)\leq\textsc{succ}(1/(2k),\dots,1/(2k))$ is a lower bound for this success probability. As we will discuss later, by keeping track of the update operations performed, we can not only compute such a lower bound, but also concrete protocols.

Since even for $k=2$, the size of the position space $\mathcal{D}$ and the number of allowed splits increase quickly with T, only moderate choices of T are computationally feasible, limiting the power of this approach drastically. However, using the scaling invariance $\lambda\textsc{succ}(D)=\textsc{succ}(\lambda D)$, we can introduce a scaling step: we iteratively optimize using allowed splits[2], then backpropagate the computed values (updating, e.g., $s(1,1,1,1)\leftarrow(1/T)\cdot s(T,T,T,T)$) to repeat the process. Surprisingly, this simple modification is sufficient to find protocols that are better than the previous best protocol TwoBit. For a more precise description of the algorithm, see the extended version of this article [4].

The success probabilities of the protocols computed following the above approach, using different values for T, are given in the first line of Table 1. Further results exploiting the post-optimization are given in Table 2 in Section 2.8.

2.7 Post-Optimization via Linear Programming

When letting the automated search also keep track of at what time which update operation was performed, this data can be used to extract strategies for the splitting game (and

[1] Note that the height refers to the number of transmitted bits and thus does not include the number of (virtual) scaling moves.

[2] In fact, we use *relaxed* splits, in which some coordinate in the resulting distributions may additionally be rounded down – this slightly increases the set of admissible splits. For details, see [4].

Table 2 Lower bounds $s(T,\dots,T)/(4T)$ on $\textsc{succ}(\frac{1}{4},\frac{1}{4},\frac{1}{4},\frac{1}{4})$ stemming from the automated search only (line 1) and from the LP solution of the linear system extracted from the automated search data (line 2), when the number of iterations is restricted to 20.

T	30	35	40	45	50
Autom. search	0.3381086510	0.3381937725	0.3383218072	0.3383946540	0.3384414508
LP solution	0.3381527322	0.3382301900	0.3383547901	0.3384303130	0.3384736461
Iterations	20	20	20	20	20
Constraints	5373	8882	12410	18659	24483
Game states	4126	6789	9396	13992	18248

cryptogenographic protocols). Some care has to be taken to only extract those intermediate positions that had an influence on the final game value for the position we are interested in.

While this approach does deliver good cryptogenographic protocols, manually verifying the correctness of the updates or analyzing the structure of the underlying protocol quickly becomes a difficult task, as the size of the protocol grows rapidly. Fortunately, it is possible to output a compact, machine-verifiable certificate for the lower bound obtained by the automated search that might even prove a better lower bound than computed: Each update step in the automated search corresponds to a valid inequality of the form $\textsc{succ}(D) \geq \textsc{succ}(D_0) + \textsc{succ}(D_1)$, $\textsc{succ}(D) \geq \textsc{succ}_0(D)$ or $\lambda \cdot \textsc{succ}(D) = \textsc{succ}(\lambda \cdot D)$. We can extract the (sparse) set $\text{ineq}(T,T,T,T)$ of those inequalities that lead to the computed lower bound on $\textsc{succ}(T,T,T,T)$.

Consider replacing each occurrence of $\textsc{succ}(D')$ in the set of inequalities $\text{ineq}(T,T,T,T)$ found by the automated search by a variable $s_{D'}$. We obtain a system of linear inequalities S that has the feasible solution $s_{D'} = \textsc{succ}(D')$ (for every occurring vector D'). Hence in particular, the optimal solution of the linear program of *minimizing* s_D *subject to* S is a lower bound on $\textsc{succ}(D)$. It is easy to see that this solution is at least as good as the solution stemming from the automated search alone. It can, however, even be better, in particular when a game strategy yields cyclic visits to certain positions. Table 2 contains, for different values of T, the success probabilities found by automated search (run with a bounded iteration number of 20) and by this above linear programming approach. The table also contains the number of linear inequalities (and game positions) that were extracted from the automated search run. We observe that consistently the LP-based solution is minimally better. We also observe that the number of constraints is still moderate, posing no difficulties for ordinary LP solvers (which stands in stark contrast to feeding all allowed splits and scalings over the complete discretization to the LP solver, which quickly becomes infeasible).

Hence the advantage of our approach of extracting the constraints from the automated search stage is that it generates a much sparser sets of constraints that still are sufficiently meaningful. After solving the LP, we can further sparsify this set of inequalities by deleting all inequalities that are not tight in the optimal solution of the LP, since these cannot correspond to the best splits found for the corresponding vector D, yielding a smaller set of relevant inequalities, which might help to analyze the structure of strong protocols.

2.8 Our Best Protocol

We report the best protocol we found using the approach outlined in the previous sections.

▶ **Theorem 2.11.** *In the 2-player cryptogenography problem,* $\textsc{succ}(\frac{1}{4},\frac{1}{4},\frac{1}{4},\frac{1}{4}) \geq 0.3384736$.

Proof. On `http://people.mpi-inf.mpg.de/~marvin/verify.html`, we provide a linear program based on feasible inequalities on the discretization $\mathcal{D}$ with $T = 50$. To verify the

result, one only has to (1) check validity of each inequality, i.e., checking whether each constraints encodes a feasible scaling, allowed split or zero-bit success probability and (2) solve the linear program. Since we represent the distributions $D = (a, b, c, d)$ using a normal form $a \geq b, c, d$ (to break symmetries), checking validity of each splitting constraint is not completely trivial, but easy. We provide a simple checker program to verify validity of the constraints. The LP is output in a format compatible with the LP solver `lp_solve`[3]. ◀

3 A Stronger Hardness Result

In this section, we prove that any 2-player cryptogenographic protocol has a success probability of at most 0.3672. This improves over the previous 0.375 bound of [2].

▶ **Theorem 3.1.** *We have* $\text{SUCC}(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}) \leq \frac{47}{128} = 0.367188$.

To prove the result, we apply the concavity method used by Brody et al. [2] which consists in finding a function s that (i) is lower bounded by SUCC_0 for all distributions and (ii) satisfies a certain concavity condition. Similar concavity arguments have been applied before in information complexity and information theory (see, e.g., [1, 7, 8]). We first relax the lower bound requirement to hold only for six particular simple distributions (namely $(1, 0, 0, 0), \ldots, (0, 0, 0, 1), (\frac{1}{2}, 0, \frac{1}{2}, 0)$ and $(0, \frac{1}{2}, 0, \frac{1}{2})$) instead of all distributions. This simplifies the search for a suitable stronger candidate function satisfying (i) - it remains to verify condition (ii) for the thus found candidate function.

More specifically, we adapt the upper bound function of Brody et al. [2] to

$$\begin{aligned} s(a, b, c, d) &:= \frac{1 - f(a, b, c, d)}{4}, \\ f(a, b, c, d) &:= a^2 + b^2 + c^2 + d^2 - 6(ac + bd) + 8abcd. \end{aligned}$$

In fact, we have changed their upper bound function by introducing an additional term of $8abcd$, which attains a value of zero on the distributions $(\frac{1}{2}, 0, \frac{1}{2}, 0)$, $(1, 0, 0, 0)$, etc., thus not affecting the zero-bit success probability condition of the concavity method. Due to space constraints, we defer the quite technical verification of the concavity condition to [4].

Since this function attains the value of $s(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}) = \frac{47}{128}$ at the uniform distribution, we obtain the stronger upper bound of $\text{SUCC}(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}) \leq \frac{47}{128}$ of Theorem 3.1.

4 Conclusion

Despite the fundamental understanding of the cryptogenography problem obtained by Brody et al. [2], determining the success probability even of the 2-player case remains an intriguing open problem. The previous best protocol with success probability 1/3, while surprising and unexpected at first, is natural and very symmetric (in particular when viewed in the vector splitting game formulation). We disprove the hope that it is an optimal protocol by exhibiting less intuitive and less symmetric protocols having success probabilities up to 0.3384. Concerning hardness results, our upper bound of 0.3671875 shows that also the previous upper bound of 3/8 was not the final answer. These findings add to the impression that the cryptography problem offers a more complex nature than its simple description might suggest and that understanding the structure of good protocols is highly non-trivial.

[3] `http://lpsolve.sourceforge.net`

We are optimistic that our methods support a further development of improved protocols and bounds. (1) Trivially, investing more computational power or optimizing the automated search might lead to finding better protocols. (2) Our improved protocols might motivate to (manually) find infinite protocol families exploiting implicit properties and structure of these protocols. (3) Our reformulations, e.g., as vector splitting game, might ease further searches for better protocols and for better candidate functions for a hardness proof.
