Note for every $y \in B = Y_{\omega^*}$, the $A = X_{\omega^*} = X_y^+(\Gamma_y^*)$ is a set of positive queries on database y, thus $A \times B$ is a monochromatic 1-rectangle in f. This finishes the proof of Lemma 3.

4 Rectangles in conjunction problems

Many natural data structure problems can be expressed as a conjunction of point-wise relations between the query point and database points. Consider data structure problem $f : X \times Y \to \{0,1\}$. Let $Y = \mathcal{Y}^n$, so that each database $y \in Y$ is a tuple $y = (y_1, y_2, \ldots, y_n)$ of n points from $\mathcal{Y}$. A **point-wise function** $g : X \times \mathcal{Y} \to \{0,1\}$ is given. The data structure problem f is defined as the conjunction of these subproblems:

$$\forall x \in X, \forall y = (y_1, y_2, \ldots, y_n) \in Y, \quad f(x,y) = \bigwedge_{i=1}^{n} g(x, y_i)\,.$$

Many natural data structure problems can be defined in this way, for example:

- Membership query: $X = \mathcal{Y}$ is a finite domain. The point-wise function $g(\cdot,\cdot)$ is $\neq$ that indicates whether the two points are unequal.
- (γ,λ)-approximate near-neighbor (γ,λ)-ANN_X^n: $X = \mathcal{Y}$ is a metric space with distance $\mathrm{dist}(\cdot,\cdot)$. The point-wise function g is defined as: for $x, z \in X$, $g(x,z) = 1$ if $\mathrm{dist}(x,z) > \gamma\lambda$, or $g(x,z) = 0$ if $\mathrm{dist}(x,z) \leq \lambda$. The function value can arbitrary for all other cases.
- Partial match $\mathsf{PM}_\Sigma^{d,n}$: Σ is an alphabet, $\mathcal{Y} = \Sigma^d$ and $X = (\Sigma \cup \{\star\})^d$. The point-wise function g is defined as: for $x \in X$ and $z \in \mathcal{Y}$, $g(x,z) = 1$ if there is an $i \in [d]$ such that $x_i \notin \{\star, z_i\}$, or $g(x,z) = 0$ if otherwise.

We show that refuting the large rectangles in the point-wise function g can give us lower bounds for the conjunction problem f.

Let μ, ν be distributions over X and $\mathcal{Y}$ respectively, and let ν^n be the product distribution on $Y = \mathcal{Y}^n$. Let $g : X \times \mathcal{Y} \to \{0,1\}$ be a point-wise function and $f : X \times Y \to \{0,1\}$ a data structure problem defined by the conjunction of g as above.

▶ **Lemma 8.** *For f, g, μ, ν defined as above, assume that there is a deterministic or randomized Las Vegas cell-probing scheme solving f on a table of s cells, each cell containing w bits, with expected t cell-probes under input distribution $\mu \times \nu^n$. If the followings are true:*

- *the density of 0's in g is at most $\frac{\beta}{n}$ under distribution $\mu \times \nu$ for some constant $\beta < 1$;*
- *g does not contain monochromatic 1-rectangle of measure at least $\frac{1}{\Phi} \times \frac{1}{\Psi}$ under distribution $\mu \times \nu$;*

then

$$\left(\frac{sw}{n \log \Psi}\right)^{O(t)} \geq \Phi \quad \text{or} \quad t = \Omega\left(\frac{n \log \Psi}{w + \log s}\right).$$

Proof. By union bound, the density of 0's in f under distribution $\mu \times \nu^n$ is:

$$\Pr_{\substack{x \sim \mu \\ y=(y_1,\ldots,y_n)\sim\nu^n}}\left[\bigwedge_{i=1}^{n} g(x, y_i) = 0\right] \leq n \cdot \Pr_{\substack{x\sim\mu \\ z\sim\nu}}[g(x, z) = 0] \leq n \cdot \frac{\beta}{n} = \beta.$$

By Lemma 3, the $\Omega(1)$-density of 1's in f and the assumption of existing a cell-probing scheme with parameters s, w and t, altogether imply that for any $4t \leq \Delta \leq s$, f has a monochromatic 1-rectangle $A \times B$ such that

$$\mu(A) \geq \left(\frac{\Delta}{s}\right)^{c_1 t} \quad \text{and} \quad \nu^n(B) \geq 2^{-c_2 \Delta(\ln \frac{s}{\Delta} + w)}, \tag{1}$$

for some constants $c_1, c_2 > 0$ depending only on β.

Let $C \subset \mathcal{Y}$ be the largest set of columns in g to form a 1-rectangle with A. Formally,

$$C = \{z \in \mathcal{Y} \mid \forall x \in A, g(x, z) = 1\}.$$

Clearly, for any monochromatic 1-rectangle $A \times D$ in g, we must have $D \subseteq C$. By definition of f as a conjunction of g, it must hold that for all $y = (y_1, y_2, \ldots, y_n) \in B$, none of $y_i \in y$ has $g(x, y_i) = 0$ for any $x \in A$, which means $B \subseteq C^n$, and hence

$$\nu^n(B) \leq \nu^n(C^n) = \nu(C)^n.$$

Recall that $A \times C$ is monochromatic 1-rectangle in g. Due to the assumption of the lemma, either $\mu(A) < \frac{1}{\Phi}$ or $\nu(C) < \frac{1}{\Psi}$. Therefore, either $\mu(A) < \frac{1}{\Phi}$ or $\nu^n(B) < \frac{1}{\Psi^n}$.

We can always choose a Δ such that $\Delta = O\left(\frac{n \log \Psi}{w}\right)$ and $\Delta = \Omega\left(\frac{n \log \Psi}{w + \log s}\right)$ to satisfy

$$2^{-c_2 \Delta(\ln \frac{s}{\Delta} + w)} > \frac{1}{\Psi^n}.$$

If such Δ is less than $32t/(1-\beta)^2$, then we immediately have a lower bound

$$t = \Omega\left(\frac{n \log \Psi}{w + \log s}\right).$$

Otherwise, due to (1), $A \times B$ is monochromatic 1-rectangle in f with $\nu^n(B) > \frac{1}{\Psi^n}$, therefore it must hold that $\mu(A) < \frac{1}{\Phi}$, which by (1) gives us

$$\frac{1}{\Phi} > \mu(A) \geq \left(\frac{\Delta}{s}\right)^{O(t)} = \left(\frac{n \log \Psi}{sw}\right)^{O(t)},$$

which gives the lower bound

$$\left(\frac{sw}{n \log \Psi}\right)^{O(t)} \geq \Phi.$$

◀

5 Isoperimetry and ANN lower bounds

Given a metric space X with distance $\mathrm{dist}(\cdot,\cdot)$ and $\lambda \geq 0$, we say that two points $x, x' \in X$ are λ-close if $\mathrm{dist}(x,x') \leq \lambda$, and λ-far if otherwise. The λ-neighborhood of a point $x \in X$, denoted by $N_\lambda(x)$, is the set of all points from X which are λ-close to x. Given a point set $A \subseteq X$, we define $N_\lambda(A) = \bigcup_{x\in A} N_\lambda(x)$ to be the set of all points which are λ-close to some point in A.

In [17], a natural notion of metric expansion was introduced.

▶ **Definition 9** (metric expansion [17])**.** Let X be a metric space and μ a probability distribution over X. Fix any radius $\lambda > 0$. Define

$$\Phi(\delta) \triangleq \min_{A\subset X, \mu(A)\leq\delta} \frac{\mu(N_\lambda(A))}{\mu(A)}.$$

The expansion Φ of the λ-neighborhoods in X under distribution μ is defined as the largest k such that for all $\delta \leq \frac{1}{2k}$, $\Phi(\delta) \geq k$.

We now introduce a more refined definition of metric expansion using two parameters Φ and Ψ.

▶ **Definition 10** ((Φ,Ψ)-expanding)**.** Let X be a metric space and μ a probability distribution over X. The λ-neighborhoods in X are **(Φ,Ψ)-expanding** under distributions μ if we have $\mu(N_\lambda(A)) \geq 1 - 1/\Psi$ for any $A \subseteq X$ that $\mu(A) \geq 1/\Phi$.

The metric expansion defined in [17] is actually a special case of (Φ,Ψ)-expanding: The expansion of λ-neighborhoods in a metric space X is Φ means the λ-neighborhoods are $(\Phi,2)$-expanding. The notion of (Φ,Ψ)-expanding allows us to describe a more extremal expanding situation in metric space: The expanding of λ-neighborhoods does not stop at measure $1/2$, rather, it can go all the way to be very close to measure 1. This generality may support higher lower bounds for approximate near-neighbor.

Given a radius $\lambda > 0$ and an approximation ratio $\gamma > 1$, recall that the (γ,λ)-approximate near neighbor problem (γ,λ)-ANN^n_X can be defined as a conjunction $f(x,y) = \bigwedge_i g(x,y_i)$ of point-wise function $g : X \times X \to \{0,1\}$ where $g(x,z) = 0$ if x is λ-close to z; $g(x,z) = 1$ if x is $\gamma\lambda$-far from z; and $g(x,z)$ is arbitrary for all other cases. Observe that g is actually (γ,λ)-ANN^1_X, the point-to-point version of the (γ,λ)-approximate near neighbor.

The following proposition gives an intrinsic connection between the expansion of metric space and size of monochromatic rectangle in the point-wise near-neighbor relation.

▶ **Proposition 11.** *If the λ-neighborhoods in X are (Φ,Ψ)-expanding under distribution μ, then the function g defined as above does not contain a monochromatic 1-rectangle of measure $\geq \frac{1}{\Phi} \times \frac{1.01}{\Psi}$ under distribution $\mu \times \mu$.*

Proof. Since the λ-neighborhoods in X are (Φ,Ψ)-expanding, for any $A \subseteq X$ with $\mu(A) \geq \frac{1}{\Phi}$, we have $\mu(N_\lambda(A)) \geq 1 - \frac{1}{\Psi}$. And by definition of g, for any monochromatic $A \times B$, it must hold that $B \cap N_\lambda(A) = \emptyset$, i.e. $B \subseteq X \setminus N_\lambda(A)$. Therefore, either $\mu(A) < \frac{1}{\Phi}$, or $\mu(B) = 1 - \mu(N_\lambda(A)) \leq \frac{1}{\Psi} < \frac{1.01}{\Psi}$. ◀

The above proposition together with Lemma 8 immediately gives us the following corollary which reduces lower bounds for near-neighbor problems to the isoperimetric inequalities.

▶ **Corollary 12.** *Let μ be a distribution over a metric space X. Let $\lambda > 0$ and $\gamma \geq 1$. Assume that there is a deterministic or randomized Las Vegas cell-probing scheme solving (γ,λ)-ANN^n_X on a table of s cells, each cell containing w bits, with expected t cell-probes under input distribution $\mu \times \mu^n$. If the followings are true:*

- $\mathbb{E}_{x\sim\mu}[\mu(N_{\gamma\lambda}(x))] \le \frac{\beta}{n}$ *for a constant* $\beta < 1$*;*
- *the* λ*-neighborhoods in* X *are* (Φ, Ψ)*-expanding under distribution* μ*;*

then

$$\left(\frac{sw}{n\log\Psi}\right)^{O(t)} \ge \Phi \quad \text{or} \quad t = \Omega\left(\frac{n\log\Psi}{w+\log s}\right).$$

▶ Remark. In [17], a lower bound for (γ,λ)-ANN^n_X was proved with the following form:

$$\left(\frac{swt}{n}\right)^t \ge \Phi.$$

In our Corollary 12, unless the cell-size w is unrealistically large to be comparable to n, the corollary always gives the first lower bound

$$\left(\frac{sw}{n\log\Psi}\right)^{O(t)} \ge \Phi.$$

This strictly improves the lower bound in [17]. For example, when the metric space is $\left(2^{\Theta(d)}, 2^{\Theta(d)}\right)$-expanding, this would give us a lower bound $t = \Omega\left(\frac{d}{\log\frac{sw}{nd}}\right)$, which in particular, when the space is linear ($sw = O(nd)$), becomes $t = \Omega(d)$.

5.1 Lower bound for ANN in Hamming space

Let $X = \{0,1\}^d$ be the Hamming space with Hamming distance $\mathrm{dist}(\cdot,\cdot)$. Recall that $N_\lambda(x)$ represents the λ-neighborhood around x, in this case, the Hamming ball of radius λ centered at x; and for a set $A \subset X$, the $N_\lambda(A)$ is the set of all points within distance λ to any point in A. For any $0 \le r \le d$ $B(r) = |N_r(\bar{0})|$ denote the volume of Hamming ball of radius r, where $\bar{0} \in \{0,1\}^d$ is the zero vector. Obviously $B(r) = \sum_{k\le r}\binom{d}{k}$.

The following isoperimetric inequality of Harper is well known.

▶ **Lemma 13** (Harper's theorem [9]). *Let* $X = \{0,1\}^d$ *be the* d*-dimensional Hamming space. For* $A \subset X$*, let* r *be such that* $|A| \ge B(r)$*. Then for every* $\lambda > 0$*,* $|N_\lambda(A)| \ge B(r+\lambda)$*.*

In words, Hamming balls have the worst vertex expansion.

For $0 < r < \frac{d}{2}$, the following upper bound for the volume of Hamming ball is well known:

$$2^{(1-o(1))dH(r/d)} \le \binom{d}{r} \le B(r) \le 2^{dH(r/d)},$$

where $H(x) = -x\log_2 x - (1-x)\log_2(1-x)$ is the Boolean entropy function.

Consider the Hamming (γ,λ)-approximate near-neighbor problem (γ,λ)-ANN^n_X. The hard distribution for this problem is just the uniform and independent distribution: For the database $y = (y_1, y_2, \ldots, y_n) \in X^n$, each database point y_i is sampled uniformly and independently from $X = \{0,1\}^n$; and the query point x is sampled uniformly and independently from X.

▶ **Theorem 14.** *Let* $d \ge 32\log n$*. For any* $\gamma \ge 1$*, there is a* $\lambda > 0$ *such that if* (γ,λ)-ANN^n_X *can be solved by a deterministic or Las Vegas randomized cell-probing scheme on a table of* s *cells, each cell containing* w *bits, with expected* t *cell-probes for uniform and independent database and query, then* $t = \Omega\left(\frac{d}{\gamma^2\log\frac{sw\gamma^2}{nd}}\right)$ *or* $t = \Omega\left(\frac{nd}{\gamma^2(w+\log s)}\right)$.

Proof. Choose λ to satisfy $\gamma\lambda = \frac{d}{2} - \sqrt{2d\ln(2n)}$. Let μ be uniform distribution over X. We are going to show:

- $\mathbb{E}_{x\sim\mu}[\mu(N_{\gamma\lambda}(x))] \le \frac{1}{2n}$;
- the λ-neighborhoods in X are (Φ, Ψ)-expanding under distribution μ for some $\Phi = 2^{\Omega(d/\gamma^2)}$ and $\Psi = 2^{\Omega(d/\gamma^2)}$.

Then the cell-probe lower bounds follows directly from Corollary 12.

First, by the Chernoff bound, $\mu(N_{\gamma\lambda}(x)) \le \frac{1}{2n}$ for any point $x \in X$. Thus trivially $\mathbb{E}_{x\sim\mu}[\mu(N_{\gamma\lambda}(x))] \le \frac{1}{2n}$.

On the other hand, for $d \ge 32\log n$ and n being sufficiently large, it holds that $\lambda \ge \frac{d}{4\gamma}$. Let $r = \frac{d}{2} - \frac{d}{8\gamma}$. And consider any $A \subseteq X$ with $\mu(A) \ge 2^{-(1-H(r/d))d}$. We have $|A| \ge 2^{dH(r/d)} \ge B(r)$. Then by Harper's theorem,

$$|N_\lambda(A)| \ge B\left(r+\lambda\right) \ge B\left(\tfrac{d}{2} + \tfrac{d}{8\gamma}\right) \ge 2^d - B\left(\tfrac{d}{2} - \tfrac{d}{8\gamma}\right) = 2^d - B(r) \ge 2^d - 2^{dH(r/d)},$$

which means $\mu(N_\lambda(A)) \ge 1 - 2^{-(1-H(r/d))d}$. In other words, the λ-neighborhoods in X are (Φ, Ψ)-expanding under distribution μ for $\Phi = \Psi = 2^{(1-H(r/d))d}$, where $r/d = \frac{1}{2} - \frac{1}{8\gamma}$. Apparently $1 - H(\frac{1}{2} - x) = \Theta(x^2)$ for small enough $x > 0$. Hence, $\Phi = \Psi = 2^{\Theta(d/\gamma^2)}$. ◀

5.2 Lower bound for ANN under L-infinity norm

Let $\Sigma = \{0, 1, \ldots, m\}$ and the metric space is $X = \Sigma^d$ with ℓ_∞ distance $\mathrm{dist}(x, y) = \|x - y\|_\infty$ for any $x, y \in X$.

Let μ be the distribution over X as defined in [2]: First define a distribution π over Σ as $p(i) = 2^{-(2\rho)^i}$ for all $i > 0$ and $\pi(0) = 1 - \sum_{i>0}\pi(i)$; and then μ is defined as $\mu(x_1, x_2, \ldots, x_d) = \pi(x_1)\pi(x_2)\ldots\pi(x_d)$.

The following isoperimetric inequality is proved in [2].

▶ **Lemma 15** (Lemma 9 of [2]). *For any $A \subseteq X$, it holds that $\mu(N_1(A)) \ge (\mu(A))^{1/\rho}$.*

Consider the (γ, λ)-approximate near-neighbor problem (γ, λ)-$\mathsf{ANN}^n_{\ell_\infty}$ defined in the metric space X under ℓ_∞ distance. The hard distribution for this problem is $\mu \times \mu^n$: For the database $y = (y_1, y_2, \ldots, y_n) \in X^n$, each database point y_i is sampled independently according to μ; and the query point x is sampled independently from X according to μ. The following lower bound has been proved in [2] and [12].

Fix any $\epsilon > 0$ and $0 < \delta < \frac{1}{2}$. Assume $\Omega\left(\log^{1+\epsilon} n\right) \le d \le o(n)$. For $3 < c \le O(\log\log d)$, define $\rho = \frac{1}{2}(\frac{\epsilon}{4}\log d)^{1/c} > 10$. Now we choose $\gamma = \log_\rho \log d$ and $\lambda = 1$.

▶ **Theorem 16.** *With d, γ, λ, ρ and the metric space X defined as above, if (γ, λ)-$\mathsf{ANN}^n_{\ell_\infty}$ can be solved by a deterministic or Las Vegas randomized cell-probing scheme on a table of s cells, each cell containing $w \le n^{1-2\delta}$ bits, with expected $t \le \rho$ cell-probes under input distribution $\mu \times \mu^n$, then $sw = n^{\Omega(\rho/t)}$.*

Proof. The followings are true

- $\mu(N_{\gamma\lambda}(x)) = \frac{e^{-\log^{1+\epsilon/3} n}}{n} \le \frac{1}{2n}$ for any $x \in X$ (Claim 6 in [2]);
- the λ-neighborhoods in X are $(n^{\delta\rho}, \frac{n^\delta}{n^\delta - 1})$-expanding under distribution μ for $\Phi = n^{\delta\rho}$ and $\Psi = 2^{\Omega(d/\gamma^2)}$.

To see the expansion is true, let $\Phi = n^{\delta\rho}$ and $\Psi = \frac{n^\delta}{n^\delta - 1}$. By Lemma 15, for any set $A \subset X$ with $\mu(A) \ge \Phi$, we have $\mu(N_\lambda(A)) \ge n^{-\delta} \ge 1 - \frac{1}{\Psi}$. This means λ-neighborhoods of $\mathcal{M}$ are $(n^{\delta\rho}, \frac{n^\delta}{n^\delta - 1})$-expanding.

Due to Corollary 12, either $\left(\frac{sw}{n^{1-\delta}}\right)^{O(t)} \ge n^{\delta\rho}$ or $= \Omega\left(\frac{n^{1-\delta}}{w + \log s}\right)$. The second bound is always higher with our ranges for w and t. The first bound gives $sw = n^{\Omega(\rho/t)}$. ◀

Abstract

We study generalizations of classical metric embedding results to the case of *quasimetric* spaces; that is, spaces that do not necessarily satisfy symmetry. Quasimetric spaces arise naturally from the shortest-path distances on directed graphs. Perhaps surprisingly, very little is known about low-distortion embeddings for quasimetric spaces.

Random embeddings into *ultrametric* spaces are arguably one of the most successful geometric tools in the context of algorithm design. We extend this to the quasimetric case as follows. We show that any n-point quasimetric space supported on a graph of treewidth t admits a random embedding into *quasiultrametric* spaces with distortion $O(t \log^2 n)$, where quasiultrametrics are a natural generalization of ultrametrics. This result allows us to obtain $t \log^{O(1)} n$-approximation algorithms for the Directed Non-Bipartite Sparsest-Cut and the Directed Multicut problems on n-vertex graphs of treewidth t, with running time polynomial in both n and t.

The above results are obtained by considering a generalization of random partitions to the quasimetric case, which we refer to as *random quasipartitions*. Using this definition and a construction of [Chuzhoy and Khanna 2009] we derive a polynomial lower bound on the distortion of random embeddings of general quasimetric spaces into quasiultrametric spaces. Finally, we establish a lower bound for embedding the shortest-path quasimetric of a graph G into graphs that exclude G as a minor. This lower bound is used to show that several embedding results from the metric case do not have natural analogues in the quasimetric setting.

1 Introduction

Low-distortion embeddings of metric spaces have become an indispensable tool in the design of algorithms [22, 3, 5, 13]. We consider generalizations of some fundamental metric embedding

problems to the case of *quasimetric spaces*. Formally, a quasimetric space is a pair (X, d) where X is the set of points and $d : X \times X \to \mathbb{R}_+ \cup \{+\infty\}$, satisfying the following conditions:
(C1) For all $x, y \in X$, $d(x, y) = 0$ iff $x = y$.
(C2) For all $x, y, z \in X$, $d(x, y) \leq d(x, z) + d(z, y)$.

In other words, a quasimetric space satisfies all the conditions of a metric space, except for the following symmetry condition:
(C3) For all $x, y \in X$, $d(x, y) = d(y, x)$.

Finite quasimetric spaces are precisely the shortest-path distances of finite directed graphs. Perhaps surprisingly, many basic questions regarding low-distortion embeddings of quasimetric spaces are poorly understood. As we explain below, these problems are of importance in algorithm design, and are intricately tied to the approximability of various cut problems on directed edge-capacitated graphs.

1.1 Our contributions

We now outline our main results, and contrast with what was previously known for the case of metric spaces. We consider quasimetric spaces that arise from the shortest-path distances of directed graphs. For a family $\mathcal{F}$ of undirected graphs, we consider the directed graphs arising from the graphs in $\mathcal{F}$ by replacing every undirected edge $\{u, v\}$ by two edges (u, v) and (v, u) with opposite directions, and by assigning arbitrary positive edge lengths to them. When $\mathcal{F}$ is the family of all trees (resp. graphs of treewidth-t), we refer to the resulting family of quasimetric spaces as *tree quasimetric spaces* (resp. *treewidth-t quasimetric spaces*).

Random embeddings

A very successful metric embedding tool in the context of algorithm design is random embeddings. The high-level idea is that given some "complicated" space, we can find a random embedding into some "simpler" space, preserving all distances in expectation.

Formally, let $M = (X, d)$ be a quasimetric space. A *random embedding* of M is a distribution $\mathcal{F}$ over pairs (f, M') where $M' = (X', d')$ is a quasimetric space and $f : X \to X'$, such that for any $x, y \in X$

$$\Pr[d'(f(x), f(y)) \geq d(x, y)] = 1.$$

Let $\alpha \geq 1$. We say that the random embedding $\mathcal{F}$ has *distortion* α if for all $x, y \in X$

$$\mathbb{E}\,[d'(f(x), f(y))] \leq \alpha\, d(x, y).$$

This definition is of algorithmic interest because for several optimization problems it allows us to reduce instances on general graphs to instances on simpler graphs (see [4, 23] for a more detailed exposition). It has been shown that any n-point metric space admits a random embedding into *ultrametric* spaces with distortion $O(\log n)$ [10] (see also [4, 5, 1]). Here, an ultrametric space is a metric space that satisfies the following stronger version of the triangle inequality:
(C2*) For all $x, y, z \in X$, $d(x, y) \leq \max\{d(x, z), d(z, y)\}$.

It is easy to construct examples of quasimetric spaces that do not admit random embeddings into ultrametric spaces with bounded distortion. This motivates the study of random embeddings of quasimetric spaces into *quasiultrametric* spaces; these are precisely the quasimetric spaces that satisfy conditions (C1) & (C2*). We show that any n-point

treewidth-t quasimetric space admits a random embedding into quasiultrametric spaces with distortion $O(t \log^2 n)$. In a similar fashion, we show that any treewidth-t quasiultrametric admits an embedding into a convex combination of 0-1 quasimetric spaces with distortion $O(t \log^2 n)$; here, a 0-1 quasimetric space requires that all distances are either 0 or 1. As we explain below, this result allows us to obtain new approximation algorithms for directed cut problems on treewidth-t graphs.

Random quasipartitions

A fundamental primitive underlying many metric embedding results is *random partitions* [4]. This primitive has been successfully used in many diverse prolems [16, 18, 15, 19, 7, 20, 21]. It is easy to construct examples of quasimetric spaces that do not admit good random partitions. We overcome this technical obstacle by defining a *quasipartition* to be a transitive reflexive relation. This is a generalization of a partition for the following reason: For a partition P of some set X we can define the relation R on X where for all $x, y \in X$, we set $(x, y) \in R$ iff x and y are in the same cluster in P. It is easy to check that R is indeed transitive and reflexive; however, there are transitive and reflexive relations that do not arise in this fashion.

Let $r \geq 0$. We say that a quasipartition P of M is *r-bounded* if for any $x, y \in X$, if $(x, y) \in P$, then $d(x, y) \leq r$. Let $\mathcal{D}$ be a distribution over r-bounded quasipartitions of M. We say that $\mathcal{D}$ is r-bounded. We also say that $\mathcal{D}$ is *β-Lipschitz*, for some $\beta > 0$, if for any $x, y \in X$, we have that

$$\Pr_{P \sim \mathcal{D}}[(x, y) \notin P] \leq \beta \frac{d(x, y)}{r}.$$

Given a distribution $\mathcal{D}$ over quasipartitions we ocasionally refer to any quasipartition P sampled from $\mathcal{D}$ as a random quasipartition (with distribution $\mathcal{D}$).

We show that for all $r > 0$, any tree quasimetric space admits a $O(1)$-Lipschitz, r-bounded random quasipartition. We remark that no such result is possible using random partitions. We further show that for all $r > 0$, any treewidth-t quasimetric space admits a $O(t \log n)$-Lipschitz, r-bounded random quasipartition. This random quasipartition is at the heart of the random embedding result outlined above.

Using a result of Chuzhoy and Khanna [9] we show that the polynomial dependence on the treewidth is necessary. More precisely, there exist n-point quasimetric spaces that do not admit $o(n^{1/7}/\log^{4/7} n)$-Lipschitz quasipartitions. Using this lower bound we further show that there exist n-point quasimetrics that do not admit random embeddings into quasiultrametric spaces with distortion $o(n^{1/7}/\log^{4/7})$.

Applications to cut problems on directed graphs

Using the above result for embedding treewidth-t quasimetric spaces into a convex combination of 0-1 quasimetric spaces, we show that the integrality gap of the Directed Non-Bipartite Sparsest-Cut LP on graphs of treewidth t it $O(t \log^2 n)$. This implies a $O(t\sqrt{\log t} \log^2 n)$-approximation algorithm for the Directed Sparsest-Cut problem with running time polynomial in both n and t. We remark that dynamic-programming based techniques for graphs of bounded treewidth can only yield algorithms with running time exponential in t, and are thus practical only for very small values of t. Our result provides an interesting trade-off between running time and approximation guarantee for graphs of moderately large treewidth. For example, our result implies a polynomial time $\log^{O(1)}$-approximation for Directed Non-Bipartite Sparsest-Cut on graphs of treewidth $\log^{O(1)} n$.

Similarly, we obtain a $O(t\sqrt{\log t}\log^3 n)$-approximation algorithm for the Directed Multicut problem on graphs of treewidth t, with running time polynomial in both n and t.

Lower bound for random topological simplification

It has been show that for various classes of topologically restricted graphs, there exist constant-distortion random embeddings into topologically simpler graphs. For example, graphs of bounded genus admit constant-distortion random embeddings into planar graphs [14, 6, 23], and similar results are known for more general classes of minor-free graphs [20].

We show that no such result is possible for the case of directed graphs. More precisely, we show that for any directed acyclic graph G, there exists a subdivision G' of G, such that for any embedding of the shortest-path quasimetric of G' into the shortest-path quasimetric of some graph H with bounded distortion, we have that G is a minor of H. For example, this implies that there is no bounded-distortion random embedding of toroidal (i.e. genus-1) quasimetric spaces into planar quasimetric spaces.

2 Quasipartitions of tree quasimetrics

In this section we describe a method to construct an $O(1)$-Lipschitz distribution over r-bounded quasipartitions of tree quasimetric spaces. More precisely, we prove the following result.

▶ **Theorem 1.** *Let M be a shortest path quasimetric space supported on some directed tree T in which every edge has non-negative weights in both directions. For any $r > 0$, there exists an $O(1)$-Lipschitz distribution over r-bounded quasipartitions of M.*

First we describe an algorithm to construct a distribution over r-bounded quasipartitions of M. We will then show that the distribution produced by the algorithm is $O(1)$-Lipschitz.

Algorithm 1 Random quasipartition of a tree quasimetric space

Input: A tree quasimetric space $M = (V(T), d_M)$ and $r > 0$.
Output: An r-bounded probabilistic quasipartition R.

Step 1. Set $R = \emptyset$. Add (u, v) to R for all $(u, v) \in E(M)$.
Step 2. Pick a root vertex t in M arbitrarily.
Step 3. Pick $z \in [0, r/2]$ uniformly at random.
Step 4. For all $(u, v) \in E(M)$ remove (u, v) from R if at least one of the following holds:
  (a) $d_M(u, t) > z + i\frac{r}{2}$ and $d_M(v, t) \leq z + i\frac{r}{2}$ for any integer $i > 0$.
  (b) $d_M(t, v) > z + i\frac{r}{2}$ and $d_M(t, u) \leq z + i\frac{r}{2}$ for any integer $i > 0$.
Step 5. Enforce transitivity on R: For all $u, v, w \in V(M)$, if $(u, v) \in R$ and $(v, w) \in R$, then add (u, w) to R.

We shall now prove some properties of the random quasipartition R in the following Lemmas. We will use these to prove Theorem 1.

▶ **Lemma 2.** *Let $u, v \in V(T)$. Let D be the path from u to v in T. Then either u is in the path from t to v, or v is in the path from u to t, or there exists a vertex w on D such that w lies on the path from u to t and w lies on the path from t to v.*

Proof. Let w be the nearest common ancestor of u and v in T. If $w = u$, then u is in the path from t to v; if $w = v$, then v is in the path from t to u; if $w \neq u$ and $w \neq v$, then w is in the path from t to u and in the path from t to v. ◀

▶ **Lemma 3.** *For any $u, v \in V(T)$ where u is in the path from t to v, let $P = \{a_1 = u, a_2, \ldots, a_m = v\}$ be the path from u to v. If $(a_i, a_{i+1}) \in R$ for all $i \in \{1, \ldots, m-1\}$ after Step 4 then $d_M(u, v) \leq \frac{r}{2}$.*

Proof. Let j be the largest integer such that $d_M(t, a_1) > z + j\frac{r}{2}$. By the choice of j it must be that $z + j\frac{r}{2} < d_M(t, a_1) \leq z + (j+1)\frac{r}{2}$. Since (a_i, a_{i+1}) is not removed from R in Step 4 of the algorithm it must be that $z + j\frac{r}{2} < d_M(t, a_i) \leq z + (j+1)\frac{r}{2}$ for all $i \in \{1, \ldots, m\}$. This implies that $d_M(t, v) \leq z + (j+1)\frac{r}{2} \leq d_M(t, u) + \frac{r}{2}$. Since $d_M(t, v) = d_M(t, u) + d_M(u, v)$, we have that $d_M(u, v) \leq \frac{r}{2}$, which concludes the proof. ◀

▶ **Lemma 4.** *For any $u, v \in V(M)$ where v is in the path from u to t, let $P = \{a_1 = u, a_2, \ldots, a_m = v\}$ be the path from u to v. If $(a_i, a_{i+1}) \in R$ for all $i \in \{1, \ldots, m-1\}$ after Step 4 then $d_M(u, v) \leq r/2$.*

Proof. The proof is similar to the proof of Lemma 3. ◀

▶ **Lemma 5.** *If $(u, v) \in R$ then $d_M(u, v) \leq r$.*

Proof. The fact that $(u, v) \in R$ implies that at the beginning of Step 4 there must have been a path $P = \{a_1 = u, a_2, \ldots, a_m = v\}$ from u to v such that $(a_i, a_{i+1}) \in R$ for all $i \in \{1, \ldots, m-1\}$. Since M is a tree quasimetric space, the shortest path is the single unique path from u to v for any $u, v \in V(T)$. From Lemma 2 we have that one of the following three cases is true:

Case 1: u is in the shortest path from t to v. We have $d_M(u, v) \leq r/2$ from Lemma 3.

Case 2: v is in the shortest path from u to t. We have $d_M(u, v) \leq r/2$ from Lemma 4.

Case 3: There exists a_j that lies on the shortest path from u to t and on the shortest path from t to v. From Lemmas 3 and 4 we have that $d_M(u, a_j) \leq r/2$ and $d_M(a_j, v) \leq r/2$. By the triangle inequality we get $d_M(u, v) \leq r$. ◀

▶ **Lemma 6.** *Any $(u, v) \in E(T)$ is removed with probability at most $2d_M(u, v)/r$ in Step 4 of the algorithm.*

Proof. Since M is a tree quasimetric space there are exactly two cases:

Case 1: The edge (u, v) is in the direction away from t which implies that $d_M(t, u) \leq d_M(t, v)$. Let i be the largest integer such that $i \cdot r/2 \leq d_M(t, u)$. The edge (u, v) is removed from R if z is chosen between $d_M(t, u) - i \cdot r/2$ and $d_M(t, v) - i \cdot r/2$. The probability of that event is bounded by $\int_{d_M(t,u)-i\frac{r}{2}}^{d_M(t,v)-i\frac{r}{2}} p(z)dz = \frac{2}{r}(d_M(t, v) - d_M(t, u)) \leq 2d_M(u, v)/r$ by the triangle inequality.

Case 2: The edge (u, v) is in the direction toward t which implies that $d_M(v, t) \leq d_M(u, t)$. Let i be the largest integer such that $i \cdot r/2 \leq d_M(v, t)$. (u, v) is removed from R if z is chosen between $d_M(v, t) - i \cdot r/2$ and $d_M(u, t) - i \cdot r/2$. The probability of that event is bounded by $\int_{d_M(v,t)-i\cdot r/2}^{d_M(u,t)-i\cdot r/2} p(z)dz = \frac{2}{r}(d_M(u, t) - d_M(v, t)) \leq 2d_M(u, v)/r$ by the triangle inequality. ◀

▶ **Lemma 7.** $\Pr[(u, v) \notin R] \leq 2d_M(u, v)/r$ *for all $u, v \in V(T)$.*

Proof. Let the unique path from u to v in M be $p = \{x_1 = u, x_2, \ldots, x_h = v\}$. Let X_p be the event that path p contains at least one edge (x_i, x_{i+1}) such that $(x_i, x_{i+1}) \notin R$ at the beginning of Step 5. Let $Y_{(a,b)}$ be the event that $(a, b) \notin R$ for $(a, b) \in E(G)$. We have $\Pr[X_p] = \Pr[Y_{(x_1,x_2)} \vee \ldots \vee Y_{(x_{h-1},x_h)}]$. From Lemma 6 and the union bound we have that $\Pr[Y_{(x_1,x_2)} \vee \ldots \vee Y_{(x_{h-1},x_h)}] \leq \Pr[Y_{(x_1,x_2)}] + \ldots + \Pr[Y_{(x_{h-1},x_h)}] \leq 2d_M(x_1, x_2)/r + \ldots + 2d_M(x_{h-1}, x_h)/r = 2d_M(u, v)/r$, concluding the proof. ◀

We are now ready to prove the main result of this Section.

Proof of Theorem 1. It follows by Lemmas 5 and 7 that the algorithm outputs an $O(1)$-Lipschitz distribution over r-bounded quasipartitions of M. ◀

3 Quasipartitions for graphs of small treewidth

In this section we prove the existence of a $O(t \log n)$-Lipschitz distribution over r-bounded quasipartitions for any quasimetric supported on a directed graph of treewidth t. The main result is summarized in the following.

▶ **Theorem 8.** *Let G be a n-vertex directed graph of treewidth t. Let M be the shortest-path quasimetric space induced by G. Then for any $r > 0$, there exists an $O(t \log n)$-Lipschitz distribution over r-bounded quasipartitions of M.*

In the proof of the above theorem we use the following proposition which is immediate from the definition of treewidth.

▶ **Proposition 9.** *Any graph G of treewidth t has a set of vertices $K \subseteq V(G)$ where $|K| \leq t$ such that removing K gives connected components each of which contains at most $\frac{|V(G)|}{2}$ vertices.*

First we introduce an algorithm to construct the required distribution over r-bounded quasipartitions of M. Steps 2 to 4 of the algorithm are recursive. At each recursive call the algorithm works on an associated sub-graph G^* and a global set R which is common to all recursive calls.

Algorithm 2 Random quasipartition of a bounded treewidth graph

Input: A digraph G of treewidth t, and $r > 0$.
Output: A random r-bounded quasipartition R.

Initialization: Set $G^* = G$ and $R = E(G)$. Perform the following recursive algorithm on G^*.

Step 1. Pick $z \in [0, r/2]$ uniformly at random.

Step 2. If $|V(G^*)| \leq 1$, terminate the current recursive call. Otherwise pick a set of vertices $K \subseteq V(G^*)$ such that $|K| \leq t$ and removing K from G^* gives connected components $C_1, \ldots, C_m$, each containing at most $\frac{|V(G^*)|}{2}$ vertices. This is possible by Proposition 9.

Step 3. For all $(u, v) \in E(G^*)$ remove (u, v) from R if one of the following holds:

(a) $d_G(u, x) > z$ and $d_G(v, x) \leq z$ for some vertex $x \in K$.
(b) $d_G(x, v) > z$ and $d_G(x, u) \leq z$ for some vertex $x \in K$.

Step 4. Recursively call Steps 2-4 on the vertex-induced subgraphs $G^*[C_1], \ldots, G^*[C_m]$.

Step 5. Once all branches of the recursion terminate enforce transitivity on R: For all $u, v, w \in V(G)$ if $(u, v) \in R$ and $(v, w) \in R$ add (u, w) to R.

Next we state some properties of the resulting random quasipartition R. We will use these to prove the main theorem. The proofs of all these Lemmas are given in the full version of the paper.

▶ **Lemma 10.** *If $(u, v) \in R$ then $d_G(u, v) \leq r$.*

▶ **Lemma 11.** *The depth of the recursion is $O(\log n)$.*

▶ **Lemma 12.** *Any $(u,v) \in E(G)$ is removed with probability at most $4t\frac{d(u,v)}{r}$ in Step 4 of the algorithm.*

▶ **Lemma 13.** $\Pr[(u,v) \notin R] \leq 4t \log n \frac{d_G(u,v)}{r}$ *for all $u, v \in V(G)$.*

With these Lemmas we can now prove the main result of this section.

Proof of Theorem 8. It follows by Lemmas 10 and 13 that the Algorithm outputs an $O(t \log n)$-Lipschitz distribution over r-bounded quasipartitions of M. ◀

The above algorithm can be implemented in polynomial time with an additional $O(\sqrt{\log t})$ loss on the quality of the partition. This is summarized in the following Theorem.

▶ **Theorem 14.** *Let M be the shortest-path quasimetric space induced by a n-vertex directed graph G of treewidth t. Then, there exists an algorithm with running time polynomial in n and t that computes the set of all quasipartitions in the support of an $O(t\sqrt{\log t} \log n)$-Lipschitz distribution over r-bounded quasipartitions of M, for any $r > 0$.*

Proof. The randomized algorithm described in Theorem 8 can be derandomized to yield a polynomial time algorithm. First we note that it is possible to find in polynomial time a set K, with $|K| = O(t\sqrt{\log t})$ such that removing K from G gives connected components containing at most $\frac{2|V(G)|}{3}$ vertices [11]. We can use this in Step 2 of the algorithm. The only random decision in the algorithm is in Step 1 when z is chosen. Given $r > 0$, we can instead select z exhaustively from all values in the set $S = \{d(u,v) : u, v \in V(G) \text{ and } d(u,v) \leq \frac{r}{2}\}$. It can be observed from Step 3 of the algorithm that picking any other value of z does not produce a new non-trivial r-bounded quasipartition. Since there are less than n^2 elements in S this derandomized version of the algorithm runs in polynomial time in n and the set of quasipartitions returned has less than n^2 elements. ◀

4 Embeddings into quasiultrametrics and into convex combinations of 0-1 quasimetrics

In this Section we present our results on random embeddings into quasiultrametric spaces, and deterministic embeddings into convex combinations of 0-1 quasimetric spaces (quasimetrics where all distances are either 0 or 1).

4.1 Upper bounds

We begin by establishing a relationship between quasipartitions and embeddings of quasimetric spaces into quasiultrametric spaces and 0-1 quasimetric spaces. We say that a distribution over quasipartitions $\mathcal{D}$ is ϵ-*forcing* if whenever $u, v \in X$ are such that $d(u,v) \leq \epsilon r$ then $\Pr_{P \sim \mathcal{D}}[(u,v) \notin P] = 0$. First we state a result, inspired by [4], that we use in subsequent proofs. Its proof can be found in the full version of the paper.

▶ **Lemma 15.** *Let G be a directed graph on n vertices. Let M_W denote the shortest-path quasimetric space induced by G where edge weights are specified by a function $W : E(G) \to \mathbb{R}^+$. Suppose that for all $r > 0$ there exists a β-Lipschitz distribution over r-bounded quasipartitions of M_W. Then for all $r > 0$ there exists a 2β-Lipschitz $\frac{1}{2n}$-forcing distribution over r-bounded quasipartitions of M_W.*

Now we present methods to use quasipartitions for constructing embeddings of quasimetric spaces into quasiultrametric spaces and 0-1 quasimetric spaces. The proof resembles the argument used in [4] for computing random embeddings of a metric space into a tree.

▶ **Theorem 16.** *Let $M = (X, d)$ be an n-point quasimetric space and let $\beta > 0$. Suppose that for any $r > 0$, there exists a β-Lipschitz distribution over r-bounded quasipartitions of M. Then M admits a random embedding into quasiultrametrics with distortion $O(\beta \log n)$.*

Proof. We may assume w.l.o.g. that the minimum distance in M is 1 and the diameter is Δ. By Lemma 15 it follows that for any $r > 0$ there exists a 2β-Lipschitz $\frac{1}{2n}$-forcing distribution $\mathcal{D}_r$ over r-bounded quasipartitions of M. To get the required embedding we combine a series of quasipartitions. Let $S = \{P_0, P_1, \ldots, P_{\lfloor \log \Delta \rfloor}\}$ where $P_i \in \mathcal{D}_{2^i}$ is a randomly chosen 2^i-bounded quasipartition from $\mathcal{D}_{2^i}$.

We combine the quasipartitions as follows to get a quasiultrametric M^*:

Step 1: Set $d_{M^*}(u, v) = 2^{\lfloor \log \Delta \rfloor + 1}$ for all $u, v \in V(M)$. Set $i = \lfloor \log \Delta \rfloor$.

Step 2: Set $d_{M^*}(u, v) = 2^i$ for all $(u, v) \in P_i$ if $d_{M^*}(u, v) = 2^{i+1}$. Decrease i by 1. Repeat step 2 if $i \geq 0$.

We first argue that M^* is a quasiultrametric. To that end, consider any $u, v \in X$. Let j be the maximum value of i such that $(u, v) \notin P_i$. This implies that $d^*_M(u, v) = 2^{i+1}$. Consider any $w \in X$. It must be that either $(u, w) \notin P_j$ or $(w, v) \notin P_j$ because $(u, v) \notin P_j$. This implies that either $d^*_M(u, w) = 2^{i+1}$ or $d^*_M(w, v) = 2^{i+1}$. So, for any $u, v, w \in X$ it must be that $d^*_M(u, v) \leq \max\{d^*_M(u, w), d^*_M(w, v)\}$. This establishes that M^* is a quasiultrametric.

Next we argue that M^* is non-contracting. Let us suppose that the claim is false and that M^* is contracting. This means that for some $u, v \in X$ we have $d_{M^*}(u, v) < d_M(u, v)$. This means that in some iteration of Step 2 we set $d_{M^*}(u, v) = 2^i$ for some $i < \log d_M(u, v)$. This implies that $(u, v) \in P_i$ even though $d_M(u, v) > 2^i$, which is a contradiction.

It remains to show that M^* has expansion $O(\beta \log n)$. Let $u, v \in X$. We have

$$\begin{aligned}
\mathbb{E}\left[\frac{d_{M^*}(u,v)}{d_M(u,v)}\right] &\leq \sum_{i=0}^{\lfloor \log \Delta \rfloor} \Pr[(u,v) \notin P_i] \frac{2^{i+1}}{d_M(u,v)} \\
&\leq \sum_{i=0}^{\lfloor \log d_M(u,v) \rfloor} \frac{2^{i+1}}{d_M(u,v)} + \sum_{i=\lfloor \log d_M(u,v) \rfloor + 1}^{\lfloor \log (2n d_M(u,v)) \rfloor} 2\beta \frac{d_M(u,v)}{2^i} \frac{2^{i+1}}{d_M(u,v)} \\
&\quad + \sum_{i=\lfloor \log (2n d_M(u,v)) \rfloor + 1}^{\lfloor \log \Delta \rfloor]} 0 \cdot \frac{2^{i+1}}{d_M(u,v)} \\
&\leq \frac{4 d_M(u,v)}{d_M(u,v)} + 4\beta \log n = O(\beta \log n),
\end{aligned}$$

concluding the proof. ◀

▶ **Theorem 17.** *Let $M = (X, d)$ be an n-point quasimetric space and let $\beta > 0$. Suppose that for any $r > 0$, there exists a β-Lipschitz distribution over r-bounded quasipartitions of M. Then M admits an embedding into a convex combination of 0-1 quasimetric spaces with distortion $O(\beta \log n)$.*

Proof. We may assume w.l.o.g. that the minimum distance in M is 1 and the diameter is Δ. By Lemma 15 it follows that for any $r > 0$ there exists $\mathcal{D}_r$ a β-Lipschitz $\frac{1}{2n}$-forcing distribution over r-bounded quasipartitions of M. Let $S = \{\mathcal{D}_0, \mathcal{D}_1, \ldots, \mathcal{D}_{\lfloor \log \Delta \rfloor}\}$. Let $c = \sum_{i \in [0, \lfloor \log \Delta \rfloor]} 2^{i+1}$. Let H be a discrete distribution over S where the probability density function F is given by $F(\mathcal{D}_i) = \frac{2^{i+1}}{c}$.

Let us define Y to be the event that a random quasipartition is selected from the distribution $\mathcal{D}_i$ where $\mathcal{D}_i$ is randomly chosen from the distribution H. This gives a distribution over a set of quasipartitions. We can replace every quasipartition P in this set by a 0-1

quasimetric space $Q = (X, d_P)$ where for all $(u, v) \in P$ we have that $d_P(u, v) = 0$ and for all $(u, v) \notin P$ we have that $d_P(u, v) = 1$. This gives a distribution over a set of 0-1 quasimetric spaces which can be interpreted as a convex combination of 0-1 quasimetric spaces. Let the quasimetric space given by this convex combination of 0-1 quasimetric spaces be $\phi = (X, d_\phi)$. We will now show that the distortion is bounded for this embedding. First we claim that for all $u, v \in X$, $d_\phi(u, v) \geq \frac{d(u,v)}{c}$. This can be shown as follows. We have that

$$d_\phi(u,v) = \sum_{i=0}^{\lfloor \log \Delta \rfloor} \frac{2^{i+1}}{c} \Pr_{P \sim \mathcal{D}_i}[(u,v) \notin P] \geq \sum_{i=0}^{\lfloor \log d(u,v) \rfloor} \frac{2^{i+1}}{c} \geq \frac{d(u,v)}{c},$$

which proves the claim. Next we show that for all $x, y \in X$, $d_\phi(x, y) \leq O(\beta \log n)\frac{d(x,y)}{c}$. We have

$$\begin{aligned} d_\phi(u,v) &= \sum_{i=0}^{\lfloor \log \Delta \rfloor} \frac{2^{i+1}}{c} \Pr_{P \sim \mathcal{D}_i}[(u,v) \notin P] \\ &\leq \sum_{i=0}^{\lfloor \log d(u,v) \rfloor} \frac{2^{i+1}}{c} + \sum_{i=\lfloor \log d(u,v) \rfloor + 1}^{\lfloor \log (2nd(u,v)) \rfloor} \beta \frac{d(u,v)}{2^i} \frac{2^{i+1}}{c} + \sum_{i=\lfloor \log (2nd(u,v)) \rfloor + 1}^{\lfloor \log \Delta \rfloor} 0 \cdot \frac{2^{i+1}}{c} \\ &\leq 4\frac{d(x,y)}{c} + 2\beta \log n \frac{d(x,y)}{c} \leq O(\beta \log n)\frac{d(x,y)}{c}. \end{aligned}$$

From the above lower and upper bounds we get that ϕ is an embedding of M with distortion $O(\beta \log n)$. This concludes the proof of the theorem. ◀

We get the following Corollaries by combining the above Theorems with the main result of Section 3.

▶ **Corollary 18.** *Let $M = (X, d)$ be the shortest path quasimetric space induced by a directed graph on n vertices having treewidth t. Then M admits a random embedding into a quasiultrametric space with distortion $O(t \log^2 n)$. Moreover there exists an algorithm with running time polynomial in n and t, that samples a random embedding into a quasiultrametric space with distortion $O(t\sqrt{\log t} \log^2 n)$.*

Proof. The existential part follows from Lemma 15 and Theorems 8 and 16. The computational part uses Theorem 14. ◀

▶ **Corollary 19.** *Let $M = (X, d)$ be the shortest path quasimetric space induced by a directed graph on n vertices having treewidth t. Then M admits an embedding into a convex combination of 0-1 quasimetric spaces with distortion $O(t \log^2(n))$. Moreover, there exists an algorithm with running time polynomial in n and t, that computes an embedding into a convex combination of 0-1 quasimetric spaces with distortion $O(t\sqrt{\log t} \log^2 n)$.*

Proof. This follows from Lemma 15 and Theorem 8 and 17. The computational part uses Theorem 14. ◀

4.2 Lower bounds

We now obtain a lower bound on the distortion of random embeddings of general quasimetric spaces into quasiultrametric spaces. To this end we show that if a quasimetric space admits a random embedding into quasiultrametric spaces, then it is possible to construct a Lipschitz distribution over r-bounded quasipartitions of the quasimetric space for any $r > 0$.

We also show that subdivided directed acyclic graphs cannot embed into a graph with bounded distortion unless there is a minor of the original graph present in the embedding.

▶ **Theorem 20.** *Let $M = (X, d)$ be a quasimetric space and let $\beta > 0$. Suppose that M admits a random embedding into quasiultrametric spaces $\mathcal{D}^*$ with distortion β. Then for any $r > 0$, there exists an β-Lipschitz distribution over r-bounded quasipartitions of M.*

Proof. We get a β-Lipschitz distribution $\mathcal{D}$ over r-bounded quasipartitions of M by modifying $\mathcal{D}^*$. For every quasiultrametric $M^* \in \mathcal{D}^*$ we add the r-bounded quasipartition $R(M^*)$ to $\mathcal{D}$ where $(u, v) \in R(M^*)$ iff $d_{M^*}(u, v) \leq r$. The probability of selecting any $R(M^*) \in \mathcal{D}$ is set to be equal to that of selecting the corresponding $M^* \in \mathcal{D}^*$.

First we claim that $R(M^*)$ is an r-bounded quasipartition of M. Consider any $u, v, w \in V(M)$. Suppose we have that $(u, v) \in R(M^*)$ and $(v, w) \in R(M^*)$ then it must be that $d_{M^*}(u, v) \leq r$ and $d_{M^*}(v, w) \leq r$. Since M^* is a quasiultrametric this implies that $d_{M^*}(u, w) \leq \max\{d_{M^*}(u, v), d_{M^*}(v, w)\} \leq r$. This means that $(u, w) \in R(M^*)$ which implies that $R(M^*)$ is transitive and is hence a quasipartition of M. Since we have $(u, v) \in R(M^*)$ iff $d_{M^*}(u, v) \leq r$ and $d_{M^*}(u, v) \geq d_M(u, v)$ it follows that $R(M^*)$ is an r-bounded quasipartitions of M.

Next we prove that $\mathcal{D}$ is β-Lipschitz. We have

$$\beta = \mathbb{E}\left[\frac{d_{M^*}(u,v)}{d_M(u,v)}\right] \geq \int_{d_M(u,v)}^{\infty} \left(\frac{z}{d_M(u,v)}\right) \Pr[d_{M^*}(u,v) = z]dz$$
$$\geq \left(\frac{r}{d_M(u,v)}\right) \Pr[d_{M^*}(u,v) > r].$$

This implies that $\Pr[d_{M^*}(u, v) > r] \leq \beta \cdot \frac{d_M(u,v)}{r}$. Since $\Pr[d_{M^*}(u, v) > r] = \Pr[(u, v) \notin R(M^*)]$, we have that $\mathcal{D}$ is β-Lipschitz and this concludes the proof of the theorem. ◀

The following Theorem follows directly from the work of Chuzhoy and Khanna [9] and a result (Theorem 4.2) of Charikar, Makarychev and Makarychev [8].

▶ **Theorem 21.** *There exists a quasimetric space M such that any embedding of M into a convex combination of 0-1 quasimetric spaces has distortion $\Omega\left(\frac{n^{1/7}}{\log^{4/7} n}\right)$.*

A lower bound on the flow-cut gap of Directed Sparsest-Cut does not directly give the same lower bound on the quality of Lipschitz quasipartitions of quasimetric spaces. The following Theorem follows from the work of Chuzhoy and Khanna [9]. We present its proof in the full version of the paper.

▶ **Theorem 22.** *There exists a quasimetric space M and a positive r such that any distribution over r-bounded quasipartitions of M is $\Omega\left(\frac{n^{1/7}}{\log^{4/7} n}\right)$-Lipschitz.*

Combining Theorems 20 and 22 gives the following Corollary.

▶ **Corollary 23.** *There exists an n-point quasimetric space $M = (X, d)$ such that any random embedding of M into quasiultrametric spaces has distortion $\Omega\left(\frac{n^{1/7}}{\log n^{4/7}}\right)$.*

The proof of the following theorem is given in the full version of the paper.

▶ **Theorem 24.** *Let $G = (E, V)$ be a directed acyclic graph. Let $G' = (E', V')$ be the graph obtained by subdividing each directed edge of G into three edges in the same direction, i.e., for any directed edge $(u, v) \in E$, E' contains the directed edges $(u, x_{uv}), (x_{uv}, y_{uv}), (y_{uv}, v)$ obtained by subdividing (u, v). Suppose that there exists an embedding of G' into some graph H with bounded distortion. Then H must contain G as a minor.*

5 Applications to directed cut problems

In this section we will use the results from the previous section, for embedding quasimetric spaces into convex combinations of 0-1 quasimetric spaces, to get approximation algorithms for some cut problems on directed graphs.

Directed Non-Bipartite Sparsest-Cut

Let G be a directed graph with non-negative capacities $c(e)$ for all $e \in E(G)$. Let T be a set of terminal vertex pairs $\{(s_1,t_1),(s_2,t_2),\ldots,(s_k,t_k)\}$. Let $\mathsf{dem}(i)$ be a non-negative demand for the terminal pair (s_i,t_i). A *cut* of G is a set of edges $S \subset E(G)$. We define the *capacity* of the cut S to be $c(S) = \sum_{e\in S} c(e)$. Let I_S be the set of all integers $i \in \{1,\ldots,k\}$ such that all paths from s_i to t_i have at least one edge in S. We define the demand separated by the cut S to be $\mathsf{dem}(S) = \sum_{i\in I_S} \mathsf{dem}(i)$. The *sparsity* of a cut S is defined to be $c(S)/\mathsf{dem}(S)$. The goal of the Directed Non-Bipartite Sparsest-Cut problem is to find the cut with minimum sparsity.

For non-uniform demands, there exists a $O(\sqrt{n})$-approximation by [12], which has been improved to $\tilde{O}(n^{11/23})$-approximation [2]. There is also a $2^{\Omega(\log^{1-\epsilon} n)}$-hardness due to Chuzhoy and Khanna [9].

Consider the following standard LP relaxation of the Directed Non-Bipartite Sparsest-Cut Problem on G.

$$\begin{aligned}
\min \quad & \sum_{e\in E(G)} c(e)x(e) \\
& \sum_{(s_i,t_i)\in T} \mathsf{dem}(i)d(s_i,t_i) \geq 1 \\
& x(e) \geq 0 \qquad \forall e \in E(G) \\
& d(u,v) \geq 0 \qquad \forall u,v \in V(G)
\end{aligned}$$

In the LP, the $x(e)$ values can be treated as distance assignments for the edges. The $d(u,v)$ values are the shortest path distances from u to v in G for edge weights defined by the distance assignments. Since d is the shortest path distance, it follows that for all $(u,v) \in E$ we have that $d(u,v) \leq x(e)$ where $e = (u,v)$. Since replacing $x(e)$ with $d(u,v)$ only reduces the objective function while preserving feasibility, we have that the optimal edge distance assignment of the LP is given by a shortest path quasimetric space on G.

Charikar, Makarychev and Makarychev [8] showed that the integrality gap of this LP is closely related to the minimum distortion achievable for embedding a quasimetric space into a convex combination of 0-1 quasimetric spaces. Theorem A.1 from their paper implies that the integrality gap of the LP for a graph G with edge capacities $c(e)$ is equal to the minimum distortion for embedding a shortest path quasimetric space supported on G into a convex combination of 0-1 quasimetric spaces (referred to as 0-1 semimetrics in their paper). We now describe how the minimum distortion embedding of a quasimetric space into a convex combination of 0-1 quasimetric spaces can be used to upper bound the integrality gap of the LP. First we observe that a 0-1 quasimetric space on $V(G)$ corresponds to a cut of G. This is because a 0-1 quasimetric space $M = (V(G), d^*)$ can be used to describe a cut $S \subset E(G)$ where $(u,v) \in S$ iff $d^*(u,v) = 1$ for all $(u,v) \in E(G)$. Let the optimal Sparsest-Cut value for the LP be LP_{OPT}. Let the shortest path quasimetric space on G that gives the optimal

solution for the LP be $M_{\mathsf{OPT}} = (V(G), d_{\mathsf{OPT}})$. We have that,

$$\frac{\sum_{e=(u,v)\in E(G)} c(e) d_{\mathsf{OPT}}(u,v)}{\sum_{i\in[0,k]} \mathsf{dem}(i) d_{\mathsf{OPT}}(s_i,t_i)} = LP_{\mathsf{OPT}}.$$

Let $\phi = \sum_{j\in[0,m]} \alpha_j M_j$ be an $O(\log^2(n))$ embedding of M_{OPT} into a convex combination of 0-1 quasimetric spaces, where $M_j = (V(G), d_j)$ is a 0-1 quasimetric space and α_j is a non-negative real number for any $j \in [0,m]$. We have that,

$$\begin{aligned} O(\log^2(n)) LP_{\mathsf{OPT}} &\geq \frac{\sum_{e=(u,v)\in E(G)} c(e) \sum_{j\in[0,m]} \alpha_j d_j(u,v)}{\sum_{i\in[0,k]} \mathsf{dem}(i) \sum_{j\in[0,m]} \alpha_j d_j(s_i,t_i)} \\ &\geq \frac{\sum_{j\in[0,m]} \alpha_j \sum_{e=(u,v)\in E(G)} c(e) d_j(u,v)}{\sum_{j\in[0,m]} \alpha_j \sum_{i\in[0,k]} \mathsf{dem}(i) d_j(s_i,t_i)} \\ &\geq \min_{j\in[0,m]} \frac{\sum_{e=(u,v)\in E(G)} c(e) d_j(u,v)}{\sum_{i\in[0,k]} \mathsf{dem}(i) d_j(s_i,t_i)}. \end{aligned}$$

Therefore the cut corresponding to the 0-1 quasimetric space in ϕ having minimum sparsity gives an integral solution to the LP that is at most a $O(\log^2(n))$ factor larger than LP_{OPT}. Combined with Corollary 19 and Theorem 14 this implies the following corollary.

▶ **Corollary 25.** *The integrality gap (which is also the flow-cut gap) of the Directed Non-Bipartite Sparsest-Cut LP relaxation on graphs of n vertices and treewidth t is $O(t \log^2 n)$. Moreover there exists a polynomial-time $O(t\sqrt{\log t} \log^2 n)$-approximation algorithm for the Directed Non-Bipartite Sparsest-Cut problem on such graphs with running time linear in t and polynomial in n. If a tree decomposition of width t is given as part of the input, then there exists a polynomial-time $O(t \log^2 n)$-approximation algorithm.*

Directed Multicut

Let G be a directed graph with non-negative capacities $c(e)$ for all $e \in E(G)$. Let T be a set of terminal vertex pairs $\{(s_1,t_1),(s_2,t_2),\ldots,(s_k,t_k)\}$. The goal of the Directed Multicut problem is to find the minimum capacity cut that separates all terminal vertex pairs.

There is a $\tilde{O}(n^{2/3}/\mathsf{OPT}^{1/3})$-approximation by Kortsarts, Kortsarz and Nutov [17], and a $\tilde{O}(n^{11/23})$-approximation by Agarwal, Alon and Charikar [2]. Finally, there is a $2^{\Omega(\log^{1-\epsilon} n)}$-hardness due to Chuzhoy and Khanna [9]. It is known that for all $\beta > 0$, if there exists a polynomial time β-approximation algorithm for Directed Non-Bipartite Sparsest-Cut then there also exists a polynomial time $O(\beta \log n)$-approximation for Directed Multicut. The details are given in the full version of the paper.

▶ **Corollary 26.** *There exist a $O(t\sqrt{\log t} \log^3 n)$-approximation algorithm for the Directed Multicut problem on n-vertex graphs of treewidth t, with running time polynomial in both n and t. If a tree decomposition of width t is given as part of the input, then there exists a polynomial-time $O(t \log^3 n)$-approximation algorithm.*

Abstract

We prove several results which, together with prior work, provide a nearly-complete picture of the relationships among classical communication complexity classes between P and PSPACE, short of proving lower bounds against classes for which no explicit lower bounds were already known. Our article also serves as an up-to-date survey on the state of structural communication complexity.

Among our new results we show that $\mathsf{MA} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}$, that is, Merlin–Arthur proof systems cannot be simulated by zero-sided error randomized protocols with one NP query. Here the class $\mathsf{ZPP}^{\mathsf{NP}[1]}$ has the property that generalizing it in the slightest ways would make it contain $\mathsf{AM} \cap \mathsf{coAM}$, for which it is notoriously open to prove any explicit lower bounds. We also prove that $\mathsf{US} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}$, where US is the class whose canonically complete problem is the variant of set-disjointness where yes-instances are uniquely intersecting. We also prove that $\mathsf{US} \not\subseteq \mathsf{coDP}$, where DP is the class of differences of two NP sets. Finally, we explore an intriguing open issue: are rank-1 matrices inherently more powerful than rectangles in communication complexity? We prove a new separation concerning PP that sheds light on this issue and strengthens some previously known separations.

1 Introduction

Complexity classes form the infrastructure of classical complexity theory. They are used to express the power of models of computation, characterize the complexities of important computational problems, and catalyze proofs of other results. A central project is to ascertain the full, intricate landscape of relationships among complexity classes.

Beginning with [3], there has been a lot of research on the analogues of classical (Turing machine) complexity classes in two-party communication complexity. The analogue of P (the class of decision problems solvable in polynomial time) is the class of functions $F\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ for which Alice and Bob, given x and y respectively, can evaluate $F(x,y)$ with a protocol that uses polylogarithmically many bits of communication. For other classical complexity classes representing other models of computation, one can generally define,

in a canonical way, associated communication complexity classes representing associated models of communication. There are many motivations for studying the relationships (inclusions and non-inclusions) between these communication complexity classes.

- A holy grail of classical complexity is to prove separations of classes between P and PSPACE. Separations relative to oracles can often be viewed as class separations in the restricted setting of *query complexity*; see [52] for an excellent survey. Communication complexity can be viewed as a restricted (but generally less restricted than query complexity) setting for which lower bounds are more difficult to obtain. Such separations in restricted settings are sometimes construed as evidence for the classical separations, or at least as barriers to refuting the classical separations. A stronger form of relativization barriers is known as *algebrization* [2], which directly employs communication complexity class separations.
- Proving lower bounds against strong communication complexity classes has applications to other areas of theoretical computer science. One of the most notorious open problems in communication complexity is to prove lower bounds against the analogue of the polynomial hierarchy (PH) for any explicit two-party function. Proving PH lower bounds is a necessary step for obtaining strong rank rigidity lower bounds [44, 36, 37, 53] (as well as margin complexity rigidity lower bounds [35]), which in turn are related to circuit complexity [50]. Lower bounds against PH are also related to graph complexity [42, 25]. It even remains open to prove communication lower bounds against the subclass of PH known as AM (Arthur–Merlin games) for any explicit function (which would be relevant to streaming delegation [8, 31, 19, 7, 9, 32]).
- Communication complexity has a menagerie of techniques for proving lower bounds (among the oldest being discrepancy and corruption). These techniques often provide lower bounds against powerful communication complexity classes, and in some cases turn out to be *equivalent* to the communication measures corresponding to those classes (e.g., discrepancy is equivalent to PP communication [29], and corruption is equivalent to SBP communication [18]). See [17] for more background on this. Thus, by studying complexity classes, as a byproduct we study the relative strength of lower bound techniques.
- The various models of communication corresponding to complexity classes are mathematically interesting because protocols in these models can be viewed as succinct representations of boolean matrices. The study of classes exposes natural questions about the combinatorial power of such succinct representations.

We contribute to the exploration of the communication complexity landscape by filling in many of the remaining gaps in the known relationships among classes, and discovering new techniques and insights along the way. In Section 2 we state our results more precisely and provide some intuition for the proofs. In the full version, we summarize the state of affairs (including our new results) by showing a map of known inclusions and non-inclusions between pairs of traditional communication classes, and we provide a comprehensive survey of these results. This updates previous surveys by Babai, Frankl, and Simon [3] and Halstenberg and Reischuk [21].

We refer to [33, 26] for background on communication complexity. In the full version we provide a catalog of communication complexity class definitions; throughout the text, we provide definitions on a "need-to-know" basis. If $\mathcal{C}$ is the name of a model (e.g., P for deterministic or NP for nondeterministic), we follow the convention of using $\mathcal{C}$ to denote both a complexity class and the corresponding complexity measure: $\mathcal{C}(F)$ denotes the minimum cost of a correct protocol for the (possibly partial) two-party function F in model $\mathcal{C}$, and $\mathcal{C}$ denotes the class of all (families of) partial functions F with $\mathcal{C}(F) \leq \mathrm{poly}(\log n)$.

2 Our Contributions

Several of our results concern two-party composed functions, so we introduce some general notation for this. A *composed function* is of the form $f \circ g^m$ where $f\colon \{0,1\}^m \to \{0,1\}$ is a (possibly partial) *outer function* and $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$ is an *inner function* also called a *gadget*. We write $F := f \circ g^m\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ where $n := m \cdot b$. We view the inputs to Alice and Bob as $x, y \in (\{0,1\}^b)^m$, which are partitioned into *blocks* $x_i, y_i \in \{0,1\}^b$ for $i \in [m]$. The goal is to compute $F(x,y) := f(g(x_1,y_1),\ldots,g(x_m,y_m))$.

2.1 MA $\not\subseteq$ ZPP$^{\mathsf{NP}[1]}$

A Merlin–Arthur (MA) communication protocol is a proof system in which a nondeterministic party called Merlin sends a proof string (depending on the input) to Alice and Bob (collectively constituting Arthur), who then execute a randomized protocol to verify the proof. Merlin–Arthur communication protocols have been studied many times [28, 43, 2, 16, 30, 19, 20], starting with the work of Klauck [28], who gave a $\Omega(\sqrt{n})$ lower bound on the MA communication complexity of set-disjointness. In contrast, for the related (and stronger) model of Arthur–Merlin (AM) communication protocols, in which Merlin's proof string may depend on Alice's and Bob's randomness, no nontrivial lower bound is known for any explicit function, and such lower bounds have become very sought-after in the recent literature [35, 40, 32, 9].

Our first result concerns the relationship between MA and another class, ZPP$^{\mathsf{NP}[1]}$, which is a slightly obscure but intriguing character with many curious properties. A ZPP-type protocol is randomized and may output the correct answer or $\perp$ (representing "don't know"), and must output the correct answer with high probability on every input; granting the protocol access to one query to an NP oracle yields ZPP$^{\mathsf{NP}[1]}$. It is not a priori clear that the model is robust with respect to the choice of threshold for the success probability, since standard amplification by repetition would increase the number of NP oracle queries. However, it was shown in [11] that ZPP$^{\mathsf{NP}[1]}$ does indeed admit efficient amplification as long as the success probability is $> 1/2$ (the proof for time-bounded complexity also works for communication complexity); hence we define the model with success probability some constant $> 1/2$, say $3/4$.

If we allowed ZPP$^{\mathsf{NP}[1]}$ to have success probability $< 1/2$, the class would change drastically: it would contain AM $\cap$ coAM (see the full version), and hence proving explicit lower bounds for the communication version would yield breakthrough AM communication lower bounds. Granting the model access to two nonadaptive NP queries (and requiring success probability $> 1/2$) would also encompass AM $\cap$ coAM. Thus, in a sense, ZPP$^{\mathsf{NP}[1]}$ represents a boundary beyond which AM lower bounds would be the next step. The class ZPP$^{\mathsf{NP}[1]}$ is also sandwiched between BPP and $\mathsf{S}_2\mathsf{P}$ [6]; $\mathsf{S}_2\mathsf{P}$ is a subclass of the polynomial hierarchy that has not been studied before in communication complexity (the definition appears in the full version), and no nontrivial lower bounds against it are known for any explicit function. This is another sense in which ZPP$^{\mathsf{NP}[1]}$ constitutes a new frontier toward the elusive goal of proving explicit PH communication lower bounds. We also mention that ZPP$^{\mathsf{NP}[1]}$ shows up frequently in the literature on the "two queries problem" (e.g., if $\mathsf{P}_{\|}^{\mathsf{NP}[2]} \subseteq$ ZPP$^{\mathsf{NP}[1]}$ then PH $= \mathsf{S}_2\mathsf{P}$ [49]).

We prove that MA $\not\subseteq$ ZPP$^{\mathsf{NP}[1]}$ in the setting of communication complexity. This can be interpreted as saying that one-round non-interactive[1] proof systems cannot be made to have

[1] Here, the term non-interactive means that Alice and Bob cannot interact with Merlin other than receiving the proof string.

zero-sided error, even if the proof is generalized to an NP oracle query that depends on the randomness.

Before officially stating the theorem, we give the relevant formal definitions. An MA communication protocol computing $F\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ consists of a randomized two-party protocol which takes as input, in addition to the usual inputs x and y, a proof string (witness) $w \in \{0,1\}^k$ that is visible to both Alice and Bob. The completeness criterion is that for every $(x,y) \in F^{-1}(1)$ there exists a w such that the protocol accepts with probability at least $3/4$, and the soundness criterion is that for every $(x,y) \in F^{-1}(0)$ and every w, the protocol rejects with probability at least $3/4$. The cost is the witness length k plus the length of the subsequent transcript between Alice and Bob.

A $\mathsf{ZPP}^{\mathsf{NP}[1]}$ protocol Π computing F is a distribution over $\mathsf{P}^{\mathsf{NP}[1]}$-type protocols, each of which is of the following form: There is a deterministic protocol where for each leaf v having associated rectangle R_v, there is also an associated collection of "witness rectangles" $\left\{S_{v,w} \subseteq R_v \ : \ w \in \{0,1\}^k\right\}$ and an associated "output function" $o_v\colon \{0,1\} \to \{0,1,\perp\}$. The output of the $\mathsf{P}^{\mathsf{NP}[1]}$-type protocol on input (x,y) is obtained by running the deterministic part to reach a leaf v, then applying o_v to the indicator of whether $(x,y) \in \bigcup_w S_{v,w}$. The correctness criterion is that for every $(x,y) \in F^{-1}$, $\mathbb{P}\big[\Pi(x,y) \in \{F(x,y),\perp\}\big] = 1$ and $\mathbb{P}\big[\Pi(x,y) = F(x,y)\big] \geq 3/4$. The cost is the witness length k plus the maximum communication cost of the deterministic part of any of the constituent $\mathsf{P}^{\mathsf{NP}[1]}$-type protocols. The result of [11] shows that changing the success probability from $3/4$ to any other constant strictly between $1/2$ and 1 would only change the measure $\mathsf{ZPP}^{\mathsf{NP}[1]}(F)$ by a constant factor.

We prove a lower bound for the block-equality function Block-Eq, defined as follows:[2] Given $\sqrt{n}$ instances of the equality function Eq of length $\sqrt{n}$, is at least one of them a yes-instance? More formally, we have Block-Eq $\coloneqq$ Or $\circ$ Eq^m where the input to Or is $m \coloneqq \sqrt{n}$ bits, and each input to Eq is $b \coloneqq \sqrt{n}$ bits. In other words, writing $x \coloneqq x_1 \cdots x_{\sqrt{n}} \in (\{0,1\}^{\sqrt{n}})^{\sqrt{n}}$ and $y \coloneqq y_1 \cdots y_{\sqrt{n}} \in (\{0,1\}^{\sqrt{n}})^{\sqrt{n}}$, we have Block-Eq$(x,y) = 1$ iff $x_i = y_i$ for some i. Note that Block-Eq $\in \mathsf{MA}$ since i can be nondeterministically guessed by Merlin, and then $x_i = y_i$ can be verified using a randomized protocol for Eq. (It was first noticed in [34] that Block-Eq $\in \Sigma_2\mathsf{P} \cap \Pi_2\mathsf{P}$, which is a superset of MA.)

▶ **Theorem 1.** $\mathsf{ZPP}^{\mathsf{NP}[1]}(\text{Block-Eq}) = \Theta(\sqrt{n})$, *and hence* $\mathsf{MA} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}$.

To prove Theorem 1 (Section 3), we apply a new lower bound technique that combines the corruption bound with the 1-monochromatic rectangle size bound and asserts that they hold *simultaneously* (under the same distribution over inputs). We prove that, perhaps surprisingly, this combined technique gives a lower bound for $\mathsf{ZPP}^{\mathsf{NP}[1]}$ (though neither of the individual bounds suffices).

To apply our technique to Block-Eq, we first note that it is straightforward to achieve the two bounds separately: the 1-monochromatic rectangle size bound follows by simple counting, and the corruption bound follows by using Razborov's corruption lemma for the set-intersection function Inter [45] together with a simple reduction from Inter to Block-Eq. However, the latter does *not* result in a distribution satisfying the 1-monochromatic rectangle size bound for Block-Eq. To fix this problem, we argue that if we average Razborov's distribution over all ways of implementing the reduction (of which there are many), then the corruption bound is still satisfied, and now the 1-monochromatic rectangle size bound is also satisfied.

[2] The complement of block-equality is often known as list-non-equality.

2.2 US $\not\subseteq$ ZPP$^{\mathsf{NP}[1]}$

For the set-intersection function Inter, Alice and Bob are each given a subset of $[n]$ (and we identify the subset with its characteristic vector, a length-n bit string), and the goal is to output 1 when the sets are intersecting and 0 when they are disjoint.[3] Phrased as a composed function, Inter $:=$ Or $\circ$ And^n (for single-bit And). This is the canonical NP-complete problem in communication complexity, holding a comparable status to satisfiability, the canonical NP-complete problem in time-bounded complexity.

In the literature, "unique-set-intersection" commonly refers to the partial function version of Inter where the intersection is promised to have size 0 or 1. We propose a change in terminology, in order to be consistent with the following corresponding terminology from time-bounded complexity (see, e.g., [4, 51, 10]): Unique-satisfiability is the problem of determining whether the number of satisfying assignments of a formula is exactly 1, and is complete for the complexity class called US. Unambiguous-satisfiability is the problem of determining whether the number of satisfying assignments of a formula is 0 or 1 under the promise that one of these cases holds, and is complete for the complexity class called UP.

Therefore, we make the following declarations: Unique-set-intersection is the total function Unique-Inter: $\{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ that maps (x,y) to 1 iff $|x \cap y| = 1$, i.e., Unique-Inter $:=$ Unique-Or $\circ$ And^n where Unique-Or$(z) = 1$ iff the Hamming weight of z is 1. Unambiguous-set-intersection is the partial function Unambig-Inter: $\{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ that maps (x,y) to $|x \cap y|$ if the latter is in $\{0,1\}$, i.e., Unambig-Inter $:=$ Unambig-Or $\circ$ And^n where Unambig-Or(z) equals the Hamming weight of z if the latter is in $\{0,1\}$.

Note that Unique-Inter is US-complete, where a cost-k US communication protocol is defined as a collection of rectangles $\left\{R_w \subseteq \{0,1\}^n \times \{0,1\}^n \ : \ w \in \{0,1\}^k\right\}$, where on input (x,y) the output of the protocol is 1 iff (x,y) is in R_w for exactly one w.

▶ **Theorem 2.** ZPP$^{\mathsf{NP}[1]}$(Unique-Inter) $= \Theta(n)$, *and hence* US $\not\subseteq$ ZPP$^{\mathsf{NP}[1]}$.

We give two proofs of Theorem 2. Both proofs show that Theorem 2 holds even under the promise that the input sets intersect in at most two coordinates. Also, in both proofs, handling ZPP$^{\mathsf{NP}[1]}$ instead of P$^{\mathsf{NP}[1]}$ incurs almost no extra complication.

The first proof (Section 3) employs the same lower bound technique as in Theorem 1, but where we use Razborov's corruption lemma [45] directly (and we must do a little analysis to verify the 1-monochromatic rectangle size bound). The optional second proof (relegated to the full version) uses information complexity tools (including an adaptation of the "partial information cost" approach from [24]) and, although longer to write, has some minor advantages over the first proof: It is more self-contained, as it does not rely on the corruption lemma (only on some basic facts that are standard in information complexity). Also, it directly handles success probability $1/2 + \epsilon$ (for any constant $\epsilon > 0$) without relying on the amplification result of [11] (whereas the first proof assumes success probability 0.999).

2.3 US $\not\subseteq$ coDP

The class DP was introduced in [39] to capture the complexity of certain exact versions of optimization problems. A set (of all 1-inputs of a function) is in DP iff it is the difference between two NP sets. The classes P, NP, and DP are the 0^{th}, 1^{st}, and 2^{nd} (respectively) levels of the so-called boolean hierarchy.

[3] We let "set-disjointness" refer to the complementary function where 1-inputs are disjoint.

We have $\mathsf{US} \subseteq \mathsf{DP}$ since to check that there is exactly one witness, we can use an NP computation to check that there is at least one witness, and another to check that there are at least two witnesses, and require that the first computation returns 1 and the second returns 0. However, it is unlikely that $\mathsf{US} \subseteq \mathsf{coDP}$: [10] showed that this inclusion cannot hold in the classical time-bounded setting unless the polynomial hierarchy collapses. This result does not yield a communication separation, since it is unknown whether the polynomial hierarchy collapses in the communication setting. Nevertheless, we show that indeed $\mathsf{US} \not\subseteq \mathsf{coDP}$ in communication complexity.

Formally, a cost-k coDP communication protocol is defined as a pair of collections of rectangles, $\{S_w \subseteq \{0,1\}^n \times \{0,1\}^n \ : \ w \in \{0,1\}^k\}$ and $\{T_w \subseteq \{0,1\}^n \times \{0,1\}^n \ : \ w \in \{0,1\}^k\}$, where on input (x,y) the output is 0 iff $(x,y) \in \bigcup_w S_w \setminus \bigcup_w T_w$.

▶ **Theorem 3.** $\mathsf{coDP}(\textsc{Unique-Inter}) = \Theta(n)$*, and hence* $\mathsf{US} \not\subseteq \mathsf{coDP}$*.*

To prove Theorem 3 (Section 3), we show that the same lower bound technique we introduced for $\mathsf{ZPP}^{\mathsf{NP}[1]}$ (the combination of the corruption bound and the 1-monochromatic rectangle size bound) *also* lower bounds coDP complexity. Thus we can simply reuse the application of the technique to Unique-Inter from Theorem 2. (Reusing the application to Block-Eq from Theorem 1 would show that Block-Eq $\notin \mathsf{coDP}$, but in fact Block-Eq $\notin \mathsf{P}^{\mathsf{NP}} \supseteq \mathsf{coDP}$ was already known [23].)

2.4 $\mathsf{ZPP}^{\mathsf{NP}[1]} \subseteq \mathsf{PostBPP}$

Consider bounded-error randomized computations (like in BPP) but with *postselection*: the output may come from $\{0,1,\perp\}$ and must be correct with high probability *conditioned* on not outputting $\perp$ (and the probability of this conditioning event must be positive). The complexity class corresponding to this model was originally called $\mathsf{BPP}_{\mathsf{path}}$ [22], but the name $\mathsf{PostBPP}$ (inspired by [1]) has gained popularity in the recent literature ([17] is one example) and seems more appropriate, so we use it instead.

According to modern conventions, the standard way to define the cost of a $\mathsf{PostBPP}$ communication protocol for F would be as the communication cost plus $\log(1/\alpha)$, where α is the minimum over all $(x,y) \in F^{-1}$ of the probability of not outputting $\perp$. (Allowing public randomness and not charging for α would enable $\mathsf{PostBPP}$ protocols to compute every function with constant cost.) Similarly, the cost of a PP (i.e., unbounded-error randomized) protocol would be the communication cost plus $\log(1/\epsilon)$ where $1/2+\epsilon$ is the minimum over all $(x,y) \in F^{-1}$ of the probability of outputting the correct answer.

However, for reasons that will become clear in Section 2.5, we choose to revert to the original convention of [3] and define $\mathsf{PostBPP}$ and PP in a slightly different but equivalent way: we do not charge for α or ϵ but we require the public randomness to be uniformly distributed over $\{0,1\}^k$ and we charge for k. For both $\mathsf{PostBPP}$ and PP, this cost measure is equivalent to the above "modern" definition within a constant factor and additive $O(\log n)$ term, by standard sparsification of the public randomness [38].

Formally, we define a $\mathsf{PostBPP}$ communication protocol Π for F in the following succinct way: For each outcome of the public randomness (which is uniformly distributed over $\{0,1\}^k$) there is a deterministic protocol outputting values in $\{0,1,\perp\}$. For each $(x,y) \in F^{-1}$ we must have $\mathbb{P}\big[\Pi(x,y) = F(x,y)\big] > 2 \cdot \mathbb{P}\big[\Pi(x,y) = 1 - F(x,y)\big]$. The cost is the randomness length k plus the maximum communication cost of any of the constituent deterministic protocols.

A priori it is not clear that any explicit lower bounds for $\mathsf{ZPP}^{\mathsf{NP}[1]}$ follow from prior work. The following result shows that in fact they do, since many explicit lower bounds for $\mathsf{PostBPP}$ were known.

▶ **Theorem 4.** $\mathsf{PostBPP}(F) \leq O\big(\mathsf{ZPP}^{\mathsf{NP}[1]}(F) + \log n\big)$ *for all* F*, and hence* $\mathsf{ZPP}^{\mathsf{NP}[1]} \subseteq \mathsf{PostBPP}$*.*

It turns out that Theorem 4 can be derived from the lower bound technique we develop for $\mathsf{ZPP}^{\mathsf{NP}[1]}$ in Section 3; however, that approach is more complicated than necessary and, more importantly, is specific to communication complexity. We give a proof of Theorem 4 (in the full version) using a black-box simulation that also works for time-bounded complexity, without exploiting any special properties of communication.

Intuitively, the worst case for simulating a $\mathsf{ZPP}^{\mathsf{NP}[1]}$ protocol is the following situation: Whenever the NP oracle responds "0" the protocol outputs the right answer, and whenever the NP oracle responds "1" the protocol outputs $\perp$ but would have output the wrong answer if the response were "0". In this situation, pretending the oracle always responds "0" would yield a BPP protocol (this is where we crucially need the success probability to be $> 1/2$). To handle more general situations, we must also randomly guess and verify a witness for the NP query, outputting $\perp$ if the witness is invalid.

2.5 Open issue: Rank-1 vs. rectangles

The classes $\mathsf{PostBPP}$ and PP can be further generalized by allowing the use of private randomness, which does not count toward the cost. This gives rise to the so-called "unrestricted probabilities" classes $\mathsf{UPostBPP}$ (which was defined, but not extensively studied, in [17]) and UPP (which is well-studied [41, 13, 48, 46]). In $\mathsf{UPostBPP}$ and UPP we can dispense with public randomness altogether as the public coins could be tossed privately by Alice and then sent to Bob.

Combinatorially, $\mathsf{PostBPP}$ and PP protocols of cost c induce a distribution over 2^c labeled rectangles (rank-1 matrices with 0-1 entries) each occurring with a "restricted" probability of at least 2^{-c} (see the full version). In the case of $\mathsf{UPostBPP}$ and UPP there is a similar characterization with rectangles replaced by nonnegative rank-1 matrices (see the full version). A natural question arises:

> **Informal question:** *Are rank-1 matrices inherently more powerful than rectangles in communication complexity?*

While it has been shown that, e.g., $\mathsf{PP} \neq \mathsf{UPP}$ [5, 47], the known examples of functions $F \in \mathsf{UPP} \setminus \mathsf{PP}$ can actually be computed without exploiting the full power of private randomness (their rank-1 property): we can use a UPP protocol whose associated rank-1 matrices are still rectangles, but occurring with *unrestricted*, possibly tiny, probability. We conclude that "PP vs. UPP" is not the right way to formalize our informal question (and the existing proofs for $\mathsf{PP} \neq \mathsf{UPP}$ do not incidentally answer our question), since UPP protocols can be more powerful than PP protocols for reasons unrelated to their rank-1 property.[4]

A better formalization is as follows. We define new communication classes, $\mathsf{UPostBPP}_{\square} \subseteq \mathsf{UPostBPP}$ and $\mathsf{UPP}_{\square} \subseteq \mathsf{UPP}$, in the same way as $\mathsf{PostBPP}$ and PP, except allowing the public randomness to be arbitrarily distributed over $\{0,1\}^k$ (still charging for k and not for α or ϵ). Combinatorially, we have a distribution over 2^k labeled rectangles, but with no restrictions on their probabilities. Our informal question can now be formalized as follows:

[4] The Log Rank Conjecture (and its variants) also do not adequately formalize our question, since the definition of a protocol imposes constraints on how its rectangles interrelate, whereas there are no analogous constraints on the rank-1 matrices making up a low-rank decomposition. A fairer formalization along these lines would be to compare the power (in representing boolean matrices) of sums of rank-1 matrices vs. linear combinations of rectangles; nothing seems to be known about this question.

Formal question: *Do we have* $\mathsf{UPostBPP} = \mathsf{UPostBPP}_\square$*? How about* $\mathsf{UPP} = \mathsf{UPP}_\square$*?*

The seemingly minor syntactic generalization introduced in the definitions of the $\square$-classes makes a huge difference: We observe (in the full version) that $\mathsf{P}^{\mathsf{NP}} \subseteq \mathsf{UPostBPP}_\square$,[5] whereas it is known that $\mathsf{PostBPP}$ and P^{NP} are incomparable. Hence $\mathsf{UPostBPP}_\square$ is a strict superset of both $\mathsf{PostBPP}$ and P^{NP}. This leaves us with no known examples of functions to witness a separation for our "rank-1 vs. rectangle" question; currently the best gap is $\mathsf{UPostBPP}(F) \leq O(1)$ vs. $\mathsf{UPostBPP}_\square(F) \geq \Omega(\log n)$ where F is the usual Greater-Than function defined by $F(x, y) = 1$ iff $x > y$ when $x, y \in [2^n]$ are viewed as numbers. There is also no clear analogue of the "rank-1 vs. rectangle" distinction in query complexity, so a separation of the two notions in communication complexity might require interesting techniques. In fact, in the context of SBP (subclass of $\mathsf{PostBPP}$), it can be shown that rank-1 matrices do not add any power over mere rectangles [17].

2.6 $\mathsf{PP} \not\subseteq \mathsf{UPostBPP}_\square$

Our final result is to develop and apply a useful lower bound method for the class $\mathsf{UPostBPP}_\square$ introduced above. $\mathsf{PostBPP}$ already has a tight rectangle-based lower bound technique, which was dubbed "extended discrepancy" in [15] but was used earlier in [28] to show that $\mathsf{PP} \not\subseteq \mathsf{PostBPP}$. We strengthen the latter result to show that $\mathsf{PP} \not\subseteq \mathsf{UPostBPP}_\square$. (Showing $\mathsf{PP} \not\subseteq \mathsf{UPostBPP}$ remains open.) In our proof, we make use of the main theorem from [17], which applies to composed functions where the gadget is as follows.

▶ **Definition 5.** The *confounding* gadget g is defined by $g(x_i, y_i) \coloneqq \langle x_i, y_i \rangle \bmod 2$, where $x_i, y_i \in \{0,1\}^b$ and the block length b is $b(m) \coloneqq 100 \log m$.

We introduce the confounded-majority function, defined as Conf-Maj $\coloneqq f \circ g^m$ where f is the majority function and g is the confounding gadget. Note that Conf-Maj has input length $n \coloneqq m \cdot b = m \cdot 100 \log m$ and is in PP since Alice and Bob can pick $i \in [m]$ uniformly at random and then exchange $b + 1 \leq O(\log n)$ bits to evaluate $g(x_i, y_i)$.

▶ **Theorem 6.** $\mathsf{UPostBPP}_\square(\text{Conf-Maj}) = \Theta(n)$*, and hence* $\mathsf{PP} \not\subseteq \mathsf{UPostBPP}_\square$*.*

To prove Theorem 6 (in the full version) we introduce a lower bound technique for $\mathsf{UPostBPP}_\square$ that strengthens the extended discrepancy bound (for $\mathsf{PostBPP}$) by requiring it to hold under a product distribution over inputs (analogously to how [40] showed that the "monochromatic rectangle size bound under product distributions" gives a lower bound for P^{NP}). However, only a $\Omega(\sqrt{n \log n})$ lower bound for Conf-Maj follows using this technique, so to get the $\Omega(n)$ lower bound in Theorem 6, we generalize the technique further by allowing a rectangle's *size* to be measured with respect to some product distribution while its *error* is measured with respect to some other (arbitrary) distribution. (This is very analogous to the idea of relative discrepancy [14, 12].) To apply our general lower bound technique to Conf-Maj, we employ the communication-to-query machinery from [17] in a new, somewhat indirect way.

Finally, we mention another intriguing property of $\mathsf{UPostBPP}_\square$: By our lower bound technique and the results of [15] it follows immediately that to prove the Log Rank Conjecture,

[5] This inclusion also holds for time-bounded complexity. In defining the time-bounded version of $\mathsf{UPostBPP}_\square$, we would allow the distribution of the random string to depend nonuniformly on the input length n, though for the inclusion of P^{NP}, the distribution is computable in exponential time given the string 1^n.

i.e., that $\mathsf{P}(F) \leq \mathrm{poly}(\log \mathrm{rank}(F))$ for all total boolean matrices F, it suffices to prove the same with $\mathsf{UPostBPP}_{\square}$ instead of P. See the full version for more details.

3 Lower Bounds for Block-Equality and Unique-Set-Intersection

We now describe a technique for lower bounding both $\mathsf{ZPP}^{\mathsf{NP}[1]}$ and coDP communication.

▶ **Lemma 7.** *Suppose μ_0 is a distribution over $F^{-1}(0)$, μ_1 is a distribution over $F^{-1}(1)$, and C is a constant such that for every rectangle $R \subseteq \{0,1\}^n \times \{0,1\}^n$, $\mu_0(R) \leq C \cdot \mu_1(R) + \delta$, and if R is 1-monochromatic (i.e., contains no 0-inputs) then $\mu_1(R) \leq \delta$. Then*

(i) $\mathsf{ZPP}^{\mathsf{NP}[1]}(F) \geq \Omega(\log(1/\delta))$,

(ii) $\mathsf{coDP}(F) \geq \Omega(\log(1/\delta))$.

The first half of the technique ($\mu_0(R) \leq C \cdot \mu_1(R) + \delta$) is the corruption bound (which is a tight lower bound technique for so-called coSBP [18]), and the other half is the 1-monochromatic rectangle size bound (which is a tight lower bound technique for NP [33, §2.4]). The combined technique gives a lower bound for both $\mathsf{ZPP}^{\mathsf{NP}[1]}$ and coDP, even though neither of these classes appears to be a "combination" of coSBP and NP.

We prove parts (i) and (ii) of Lemma 7 in Section 3.1 and Section 3.2. Then we apply the technique to Block-Eq in Section 3.3 (thus proving Theorem 1), and finally we apply the technique to Unique-Inter in Section 3.4 (thus proving Theorem 2 and Theorem 3).

3.1 Proof of Lemma 7(i)

Suppose for contradiction there is a cost-$o(\log(1/\delta))$ $\mathsf{ZPP}^{\mathsf{NP}[1]}$ protocol Π computing F. Then in particular we have $\delta \leq o(1)$. By the amplification result of [11], we may assume $\mathbb{P}\big[\Pi(x,y) = \perp\big] \leq 1/10C$ for all $(x,y) \in F^{-1}$. By Markov's inequality and a union bound, we may fix a $\mathsf{P}^{\mathsf{NP}[1]}$-type protocol Π^* in the support of Π such that $\mathbb{P}_{(x,y)\sim\mu_0}\big[\Pi^*(x,y) = \perp\big] \leq 1/5C$ and $\mathbb{P}_{(x,y)\sim\mu_1}\big[\Pi^*(x,y) = \perp\big] \leq 1/5C$. Let the notation $k, R_v, S_{v,w}, o_v$ be with respect to Π^* (see the definition of $\mathsf{ZPP}^{\mathsf{NP}[1]}$ in Section 2.1), and note that without loss of generality, each o_v is non-constant (otherwise we could redefine $S_{v,w} = \emptyset$ for all w and redefine $o_v(1)$ arbitrarily).

For $b \in \{0,1,\perp\}$, define $W_b := \bigcup_{v,w\,:\,o_v(1)=b} S_{v,w}$ as the set of "witnessed" inputs (the NP oracle responds "1") on which Π^* outputs b, and define $N_b := \bigcup_{v\,:\,o_v(0)=b} \big(R_v \setminus \bigcup_w S_{v,w}\big)$ as the set of "non-witnessed" inputs (the NP oracle responds "0") on which Π^* outputs b. Note that $\{W_0, N_0, W_1, N_1, W_\perp, N_\perp\}$ partitions $\{0,1\}^n \times \{0,1\}^n$. By assumption, $\mu_0(W_\perp \cup N_\perp) \leq 1/5C$ and $\mu_1(W_\perp \cup N_\perp) \leq 1/5C$. By the correctness of Π, for $b \in \{0,1\}$ we have $(W_b \cup N_b) \cap F^{-1}(1-b) = \emptyset$.

▶ **Claim 8.** $\mu_0(W_0) \leq 1/4$.

▶ **Claim 9.** $\mu_0(N_0) \leq 1/4$.

This provides the contradiction since then $\mu_0\big(\{0,1\}^n \times \{0,1\}^n\big) = \mu_0(W_0) + \mu_0(N_0) + \mu_0(W_1 \cup N_1) + \mu_0(W_\perp \cup N_\perp) \leq 1/4 + 1/4 + 0 + 1/5C < 1$.

Proof of Claim 8. For each v, w such that $o_v(1) = 0$, we have $\mu_1(S_{v,w}) = 0$ and hence $\mu_0(S_{v,w}) \leq \delta$. Thus by a union bound, $\mu_0(W_0) \leq \sum_{v,w\,:\,o_v(1)=0} \mu_0(S_{v,w}) \leq 2^{o(\log(1/\delta))} \cdot \delta \leq \delta^{1-o(1)} \leq 1/4$. ◀

Proof of Claim 9. If v is such that $o_v(0) = 0$, then we have

$$\mu_0\big(R_v \setminus \bigcup_w S_{v,w}\big) \;\le\; \mu_0(R_v) \;\le\; C \cdot \mu_1(R_v) + \delta \;=\; C \cdot \mu_1\big(\bigcup_w S_{v,w}\big) + \delta$$

by the fact that $\big(R_v \setminus \bigcup_w S_{v,w}\big) \cap F^{-1}(1) = \emptyset$. Also, since each o_v is non-constant, we have

$$\begin{aligned}
\textstyle\sum_{v\,:\,o_v(0)=0} \mu_1\big(\bigcup_w S_{v,w}\big) \;&=\; \textstyle\sum_{v\,:\,o_v(0)=0,\,o_v(1)=\perp} \mu_1\big(\bigcup_w S_{v,w}\big) \\
&\quad + \textstyle\sum_{v\,:\,o_v(0)=0,\,o_v(1)=1} \mu_1\big(\bigcup_w S_{v,w}\big) \\
&\le\; \mu_1(W_\perp) + \textstyle\sum_{v,w\,:\,o_v(1)=1} \mu_1(S_{v,w}) \\
&\le\; \mu_1(W_\perp \cup N_\perp) + 2^{o(\log(1/\delta))} \cdot \delta \\
&\le\; 1/5C + \delta^{1-o(1)}
\end{aligned}$$

where the third line follows since $S_{v,w}$ is 1-monochromatic if $o_v(1) = 1$. Combining these, we have

$$\begin{aligned}
\mu_0(N_0) \;&=\; \textstyle\sum_{v\,:\,o_v(0)=0} \mu_0\big(R_v \setminus \bigcup_w S_{v,w}\big) \\
&\le\; \textstyle\sum_{v\,:\,o_v(0)=0} \Big(C \cdot \mu_1\big(\bigcup_w S_{v,w}\big) + \delta\Big) \\
&\le\; C \cdot \Big(\textstyle\sum_{v\,:\,o_v(0)=0} \mu_1\big(\bigcup_w S_{v,w}\big)\Big) + 2^{o(\log(1/\delta))} \cdot \delta \\
&\le\; C \cdot \big(1/5C + \delta^{1-o(1)}\big) + \delta^{1-o(1)} \\
&\le\; 1/4.
\end{aligned}$$

◀

3.2 Proof of Lemma 7(ii)

Suppose for contradiction there is a cost-k coDP protocol Π computing F where $k \le o(\log(1/\delta))$. Then in particular we have $\delta \le o(1)$. We have a pair of collections of rectangles, $\{S_w \;:\; w \in \{0,1\}^k\}$ and $\{T_w \;:\; w \in \{0,1\}^k\}$, such that if $F(x,y) = 0$ then $(x,y) \in \bigcup_w S_w$ and $(x,y) \notin \bigcup_w T_w$, and if $F(x,y) = 1$ then $(x,y) \notin \bigcup_w S_w$ or $(x,y) \in \bigcup_w T_w$. Since $\mu_0\big(\bigcup_w S_w\big) = 1$, there exists a w^* such that $\mu_0(S_{w^*}) \ge 2^{-k} \ge \delta^{1/3}$ and hence $\mu_1(S_{w^*}) \ge \frac{1}{C} \cdot (\delta^{1/3} - \delta) \ge \delta^{1/2}$. Since $S_{w^*} \cap F^{-1}(1) \subseteq \bigcup_w T_w$, there exists a w' such that $\mu_1(T_{w'}) \ge \mu_1\big(S_{w^*} \cap F^{-1}(1)\big) \cdot 2^{-k} > \delta^{1/2} \cdot \delta^{1/2} = \delta$. But $T_{w'}$ is 1-monochromatic since $F^{-1}(0) \cap \bigcup_w T_w = \emptyset$, so this is a contradiction.

3.3 Proof of Theorem 1

Let μ_0 be the uniform distribution over $\textsc{Block-Eq}^{-1}(0)$, and let μ_1 be the uniform distribution over the subset of $\textsc{Block-Eq}^{-1}(1)$ consisting of all (x,y) for which $x_i = y_i$ for a unique i.

▶ **Lemma 10.** *$\mu_0(R) \le 45 \cdot \mu_1(R) + 2^{-\Omega(\sqrt{n})}$ holds for every rectangle $R \subseteq \{0,1\}^n \times \{0,1\}^n$.*

▶ **Lemma 11.** *$\mu_1(R) \le 2^{-\Omega(\sqrt{n})}$ holds for every 1-monochromatic rectangle R of* $\textsc{Block-Eq}$.

Together, Lemma 10 and Lemma 11 show that the hypothesis of Lemma 7 holds with $F \coloneqq \textsc{Block-Eq}$, $C \coloneqq 45$, and $\delta \coloneqq 2^{-\Omega(\sqrt{n})}$. The lower bound in Theorem 1 follows. For the upper bound, in fact $\mathsf{ZPP}(\textsc{Block-Eq}) \le O(\sqrt{n})$ holds [33, §4.1.1] (though it is slightly quicker to see that $\mathsf{NP}(\textsc{Block-Eq}) \le O(\sqrt{n})$ holds by guessing i and deterministically verifying that $x_i = y_i$).

For the proofs of the lemmas, we define $m \coloneqq \sqrt{n}$ and $b \coloneqq \sqrt{n}$ (as in the notation for the decomposition $\textsc{Block-Eq} \coloneqq \textsc{Or} \circ \textsc{Eq}^m$ where Eq takes b-bit inputs).

Proof of Lemma 10. For $x^0, x^1, y^0, y^1 \in \{0,1\}^b$, we say the tuple (x^0, x^1, y^0, y^1) is *valid* iff $x^0 \neq y^0$, $x^0 \neq y^1$, $x^1 \neq y^0$, and $x^1 = y^1$. We say $\Xi := \big((x_1^0, x_1^1, y_1^0, y_1^1), \ldots, (x_m^0, x_m^1, y_m^0, y_m^1)\big)$ is valid iff it is a tuple of valid tuples. If Ξ is valid then the injection $\Phi_\Xi \colon \{0,1\}^m \times \{0,1\}^m \to \{0,1\}^n \times \{0,1\}^n$ defined by $\Phi_\Xi(u,v) := \big(x_1^{u_1} \cdots x_m^{u_m}, y_1^{v_1} \cdots y_m^{v_m}\big)$ is a reduction from $\textsc{Inter} := \textsc{Or} \circ \textsc{And}^m$ (for single-bit And) to Block-Eq:

$$\textsc{Inter}(u,v) \;=\; \textsc{Block-Eq}\big(\Phi_\Xi(u,v)\big).$$

(In other words, the image of Φ_Ξ, as a submatrix of the Block-Eq matrix, is a copy of the Inter matrix.)

Define $\textsc{Unambig-Inter} := \textsc{Unambig-Or} \circ \textsc{And}^m$ where the partial function Unambig-Or is Or restricted to the domain of strings of Hamming weight 0 or 1; i.e., $\textsc{Unambig-Inter}^{-1}(0)$ consists of all pairs of disjoint sets, and $\textsc{Unambig-Inter}^{-1}(1)$ consists of all pairs of uniquely intersecting sets.

▶ **Lemma 12** ([45]). *There exists a distribution ν_0 over $\textsc{Unambig-Inter}^{-1}(0)$ and a distribution ν_1 over $\textsc{Unambig-Inter}^{-1}(1)$ such that $\nu_0(R) \leq 45 \cdot \nu_1(R) + 2^{-\Omega(m)}$ holds for every rectangle $R \subseteq \{0,1\}^m \times \{0,1\}^m$. Moreover, the uniquely intersecting coordinate in ν_1 is uniformly distributed.*

We claim that for $a \in \{0,1\}$ we have $\mu_a = \mathbb{E}_\Xi\, \Phi_\Xi(\nu_a)$ where a valid Ξ is chosen uniformly at random independently of ν_a. In other words, μ_a equals the distribution obtained by choosing Ξ, then independently taking a sample from ν_a, then applying Φ_Ξ to the sample (i.e., the uniform mixture of the distributions $\Phi_\Xi(\nu_a)$). We only argue that $\mu_1 = \mathbb{E}_\Xi\, \Phi_\Xi(\nu_1)$ (the argument for $\mu_0 = \mathbb{E}_\Xi\, \Phi_\Xi(\nu_0)$ is essentially the same). In fact, we make the stronger claim that for every $(u,v) \in \textsc{Unambig-Inter}^{-1}(1)$, say with $u_i = v_i = 1$, the distribution $\mathbb{E}_\Xi\, \Phi_\Xi(u,v)$ is uniform over the subset of $\textsc{Block-Eq}^{-1}(1)$ consisting of all (x,y) for which $x_i = y_i$ and $x_j \neq y_j$ for all $j \neq i$. The original claim follows from this since the uniquely intersecting coordinate i is uniformly distributed. The stronger claim follows immediately from the facts that the coordinates of Ξ are independent, that (x_i^1, y_i^1) is uniformly distributed over $\textsc{Eq}^{-1}(1)$, and that for $j \neq i$, (x_j^0, y_j^0), (x_j^0, y_j^1), and (x_j^1, y_j^0) are all marginally uniformly distributed over $\textsc{Eq}^{-1}(0)$. The claim is established.

Now for every rectangle $R \subseteq \{0,1\}^n \times \{0,1\}^n$, if we let $\Phi_\Xi^{-1}(R)$ denote the rectangle of all points in $\{0,1\}^m \times \{0,1\}^m$ that map into R under Φ_Ξ, then we have

$$\begin{aligned}
\mu_0(R) &= \mathbb{E}_\Xi \big(\Phi_\Xi(\nu_0)(R)\big) \\
&= \mathbb{E}_\Xi\, \nu_0\big(\Phi_\Xi^{-1}(R)\big) \\
&\leq \mathbb{E}_\Xi \Big(45 \cdot \nu_1\big(\Phi_\Xi^{-1}(R)\big) + 2^{-\Omega(m)}\Big) \\
&= 45 \cdot \mathbb{E}_\Xi\, \nu_1\big(\Phi_\Xi^{-1}(R)\big) + 2^{-\Omega(m)} \\
&= 45 \cdot \mathbb{E}_\Xi \big(\Phi_\Xi(\nu_1)(R)\big) + 2^{-\Omega(m)} \\
&= 45 \cdot \mu_1(R) + 2^{-\Omega(\sqrt{n})}.
\end{aligned}$$

◀

Proof of Lemma 11. Note that μ_1 is uniform over a set of size

$$m \cdot 2^b \cdot (2^{2b} - 2^b)^{m-1} \;=\; m \cdot 2^b \cdot 2^{2b(m-1)} \cdot (1 - 2^{-b})^{m-1} \;\geq\; \Omega(m \cdot 2^b \cdot 2^{2b(m-1)}).$$

If $R := A \times B$ is 1-monochromatic then $|A| \leq m \cdot 2^{b(m-1)}$ (since for any $y \in B$ there are at most $m \cdot (2^b)^{m-1}$ many x's for which $\textsc{Block-Eq}(x,y) = 1$), and similarly $|B| \leq m \cdot 2^{b(m-1)}$, and hence $|R| \leq m^2 \cdot 2^{2b(m-1)}$. It follows that

$$\mu_1(R) \;\leq\; \frac{m^2 \cdot 2^{2b(m-1)}}{\Omega(m \cdot 2^b \cdot 2^{2b(m-1)})} \;\leq\; O(m \cdot 2^{-b}) \;\leq\; 2^{-\Omega(\sqrt{n})}.$$

◀

3.4 Proof of Theorem 2 and Theorem 3

We again use the corruption lemma from [45], but now we need to take a closer look at the distribution over 1-inputs. Let $n = 4\ell - 1$. Let μ_0 be the distribution over $\textsc{Unique-Inter}^{-1}(0)$ that samples uniformly random disjoint sets of size ℓ, and let μ_1 be the distribution over $\textsc{Unique-Inter}^{-1}(1)$ that samples uniformly random uniquely intersecting sets of size ℓ.

▶ **Lemma 13** ([45]). *$\mu_0(R) \leq 45 \cdot \mu_1(R) + 2^{-\Omega(n)}$ holds for every rectangle $R \subseteq \{0,1\}^n \times \{0,1\}^n$.*

▶ **Lemma 14.** *$\mu_1(R) \leq 2^{-\Omega(n)}$ holds for every 1-monochromatic rectangle R of* Unique-Inter.

Together, Lemma 13 and Lemma 14 show that the hypothesis of Lemma 7 holds with $F \coloneqq \textsc{Unique-Inter}$, $C \coloneqq 45$, and $\delta \coloneqq 2^{-\Omega(n)}$. Theorem 2 and Theorem 3 follow.

Proof of Lemma 14. For each $i \in [n]$ let us define the rectangle $R_i \coloneqq \big\{(x,y) \in R \,:\, x_i = y_i = 1\big\}$, and note that the R_i's partition R. For each i we have $|R_i| \leq 2^{n-1}$ since every $(x,y) \in R_i$ is disjoint on the coordinates $[n] \setminus \{i\}$.[6] Hence $|R| \leq n2^{n-1} \leq 2^{(1+o(1))n}$.

Note that μ_1 can be sampled by the following process.

1. Pick a uniformly random $i \in [n]$.
2. Pick a uniformly random $H \subseteq [n] \setminus \{i\}$ of size $2\ell - 2$. There are $\binom{n-1}{2\ell-2} = \Theta(2^n/\sqrt{n})$ choices.
3. Pick a uniformly random partition $H = H_1 \cup H_2$ into sets of size $\ell - 1$. There are $\binom{2\ell-2}{\ell-1} = \Theta(2^{0.5n}/\sqrt{n})$ choices.
4. Let $x \coloneqq \{i\} \cup H_1$ and $y \coloneqq \{i\} \cup H_2$.

Hence μ_1 is uniform over its support of size $n \cdot \Theta(2^n/\sqrt{n}) \cdot \Theta(2^{0.5n}/\sqrt{n}) = \Theta(2^{1.5n}) \geq 2^{(1.5-o(1))n}$. It follows that $\mu_1(R) \leq 2^{(1+o(1))n}/2^{(1.5-o(1))n} \leq 2^{-\Omega(n)}$. ◀

Abstract

The information complexity of a function f is the minimum amount of information Alice and Bob need to exchange to compute the function f. In this paper we provide an algorithm for approximating the information complexity of an arbitrary function f to within any additive error $\epsilon > 0$, thus resolving an open question as to whether information complexity is computable.

In the process, we give the first explicit upper bound on the rate of convergence of the information complexity of f when restricted to b-bit protocols to the (unrestricted) information complexity of f.

1 Introduction

In 1948, Shannon introduced the field of information theory as a set of tools for understanding the limits of one-way communication [15]. One of these tools, the information entropy function $H(X)$, measures the amount of information contained in a random source X.

The analogue of information entropy in communication complexity is *information complexity*. The information complexity of a function f is the least amount of information Alice and Bob need to exchange about their inputs to compute a function f. Just as the information entropy of a random source X provides a lower bound on the amount of communication required to transmit X, the information complexity of a function f provides a lower bound on the communication complexity of f [3]. Moreover, just as Shannon's source coding theorem establishes $H(X)$ as the asymptotic communication-per-message required to send multiple independent copies of X, the information complexity of f is the asymptotic communication-per-copy required to compute multiple copies of f in parallel on independently distributed inputs [7, 5].

These properties make information complexity a valuable tool for proving results in communication complexity. Communication complexity lower bounds themselves have a wide variety of applications to other areas of computer science; for example, results in circuit complexity such as Karchmer-Wigderson games and ACC lower bounds rely on communication complexity lower bounds [12, 4]. In addition, techniques from information complexity have been applied to prove various direct sum results in communication complexity

* A full version of this paper is available at http://arxiv.org/abs/1502.02971.

[8, 2, 11], including the only known direct sum results for general randomized communication complexity [3]. Information complexity has also been applied to prove a tight asymptotic bound on the communication complexity of the set disjointness function [6].

Despite this, many fundamental properties of information complexity remain unknown [6]. It is unknown how the information complexity of a function changes asymptotically as we allow the protocol to fail with probability ϵ. It is unknown how the information complexity of a function grows if we restrict our attention to protocols of bounded depth. Perhaps most surprisingly, it is even unknown if, given the truth table of a function f, whether it is possible to even compute (to within some additive factor of ϵ) the information complexity of f, $IC_\mu(f)$. (Contrast this with the case of the information entropy $H(X)$, which is easily computed given the distribution of X).

In this paper, we resolve the last of these questions; we prove that the information complexity of f is indeed computable. Our main technical result is an explicit bound on the convergence rate of b-bit information complexity (information complexity when restricted to protocols that have total communication at most b bits) to unrestricted information complexity. More specifically, we show how to convert an arbitrary protocol π into a protocol π' that leaks at most ϵ more information than π, but has communication cost at most $(N\epsilon^{-1})^{O(N)}$ bits, where N is the size of the truth table of f (Theorem 12). Equivalently, we show that the b-bit information complexity of f is at most $b^{-O(N^{-1})}$ larger than the information complexity of f. By then enumerating over all protocols with this communication cost, we obtain an algorithm that computes the information complexity of f to within an additive factor of ϵ in time $2^{\exp\left((N\epsilon^{-1})^{O(N)}\right)}$ (here N is the size of the truth table of f).

1.1 Prior Work

In [13, 14], Ma and Ishwar present a method to compute tight bounds on the information complexity of functions for protocols restricted to r rounds of computation. By examining the limit as r tends to infinity, this method allows them to numerically compute the information complexity of several functions (such as the 2-bit AND function). To make these computations provably correct, one would need effective (computable) estimates on the rate of convergence of r-round information complexity to the true information complexity. Such estimates were unknown prior to the present paper.

Plenty of unsolved problems of this flavor – where the computability of some limiting value is unknown despite it being straightforward to compute individual terms of this limit – occur in information theoretic contexts. One famous problem is the problem of computing the Shannon capacity of a graph, the amortized independence number of the kth power of a graph (this limiting quantity also has an interpretation as the zero-error channel capacity of a certain channel defined by this graph). While computing the independence number of any given graph is possible (albeit NP-hard), the rate at which this limit converges is unknown. Indeed, Alon and Lubetzky have shown that the limiting behavior of this quantity can be quite complex; no fixed number of terms of this limit is guaranteed to give a subpolynomial approximation to the Shannon capacity [1]. Another example, from the realm of quantum information theory, occurs in computing the quantum value of games [9]. Here it is straightforward to compute the quantum value of a game when limited to n bits of entanglement, but no explicit bounds are known for how many bits of entanglement are required to achieve within ϵ of optimal performance.

1.2 Outline of Proof

The main result of our paper is that zero-error information complexity is computable. Formally, we prove the following theorem.

▶ **Theorem 1.** *There exists an algorithm which, given a function $f : \mathcal{A} \times \mathcal{B} \to \{0,1\}$, initial distribution $\mu \in \Delta(\mathcal{A} \times \mathcal{B})$, and a real number $\epsilon > 0$, returns a value C between $IC_\mu(f) - \epsilon$ and $IC_\mu(f) + \epsilon$. This can be performed in time $2^{\exp\left((N\epsilon^{-1})^{O(N)}\right)}$, where $N = |\mathcal{A} \times \mathcal{B}|$.*

Throughout this paper, we will take the perspective of an outside observer watching in as Alice and Bob execute some protocol. This observer starts with some probabilistic *belief* about the inputs of Alice and Bob (initially this is just μ, the distribution of inputs to Alice and Bob). As Alice and Bob execute the protocol, they send each other *signals* – Bernoulli random variables that contain information about their inputs – which cause the observer to update his belief. The total amount of information leaked by the protocol to the participants can then be represented directly in terms of the final belief and initial belief. These notions are defined in more detail in Section 2.

The strategy of the proof is as follows. We start with a general protocol π for solving f, and whose information cost is very close to the information complexity of f. Unfortunately, we do not know anything about π besides the fact that it's a finite, discrete protocol that computes f without error. Note that if we could restrict π to a finite family of protocols (e.g. protocols that sent at most b bits, for an explicit bound $b = b(\epsilon, N)$), then we could just brute force over all such π's and compute the approximate information complexity of f. The proof shows that, indeed, there is always a protocol π' that can be derived from π, and which belongs to such an explicit family. The proof proceeds in several steps. In each step, more structure is added to π (structure that is then exploited by the following steps). The difficulty is, of course, ensuring at each step that π can be replaced with a more structured protocol π' while increasing its information cost by only, say, $\epsilon/10$. Ultimately, we manage to turn π into a protocol with r back-and-forth rounds, where r is an explicit function of N and ϵ. Finally, it is shown that an r-rounds of interaction protocol can be replaced with a b-bit protocol where $b = b(\epsilon, N, r) = b(\epsilon, N)$ is an explicit function, while only increasing its information cost by a controlled amount, completing the proof.

The full proof of Theorem 1 is roughly structured into three parts. In the first part, we begin by showing that we can 'discretize' any protocol π; that is, we can simulate any protocol π with a protocol π' that only uses a bounded number of different types of signals, but that only reveals a marginal amount of additional information. We accomplish this by building a 'mesh' of signals and rounding each signal in π to one of the signals in this mesh. This is described in Section 3.1.

In the second part, we show in Section 3.2 that we can transform any suitably discrete protocol π (i.e. one that uses an explicitly bounded number of distinct signals) into a protocol that uses few rounds. We achieve this via a bundling scheme; the main idea is that, where Alice would ordinarily send Bob one instance of a signal, she instead sends Bob several instances of this signal. Then, the next several times Alice would send that signal to Bob, Bob simply refers to the next unused copy sent by Alice, thus decreasing the number of rounds in the protocol.

In the third part, we show in Section 3.3 that it is never advantageous to send more than $\log N$ bits in any round of a protocol, thus providing an explicit bound on the communication complexity of the protocol. We accomplish this by showing that if it is ever the case that Alice sends one of $M > N$ different messages in a round, Alice can use public randomness

to sample a subset of N of these M messages and use $\log N$ bits to send one of these N messages instead.

Combining the above steps allows us to prove the following bound on the convergence rate of b-bit information complexity.

▶ **Theorem 12** (restated). *Let π be a communication protocol with information cost C that successfully computes function f over inputs drawn from distribution μ over $\mathcal{A} \times \mathcal{B}$. Then there exists a protocol π' with information cost at most $C + \epsilon$ that also successfully computes f over inputs drawn from μ, but has communication cost at most $b(f, \epsilon)$ where*

$$b(f, \epsilon) = (N\epsilon^{-1})^{O(N)} \tag{1}$$

and $N = |\mathcal{A} \times \mathcal{B}|$.

Finally, by reapplying the discretization procedure of Section 3.1, we show that it suffices to consider protocols whose signals all belong to an explicit finite set. By enumerating over all protocols of this depth that use signals from this set and computing the minimum information cost of any such protocol, we can therefore approximate $IC_\mu(f)$ to within ϵ, thus completing the proof.

The proof we provide below shows that zero-error internal and external information complexity are computable. We believe similar techniques can be used to show that ϵ-error information complexity is computable, but do not include such a proof in this paper.

1.3 Open Problems

Naturally, the most immediate open problem arising from our work is understanding whether (and how much) the rate of convergence in Theorem 12 can be improved:

▶ **Open Problem 2.** *What is the (worst case) rate of convergence of the b-bit (or r-round) information complexity of f to $IC_\mu(f)$? In other words, for a given $\epsilon > 0$ and truth table size $N = |\mathcal{A} \times \mathcal{B}|$, how large does $b(N, \epsilon)$ need to be to ensure that the b-bit information complexity $IC_{b,\mu}(f)$ satisfies*

$$IC_{b,\mu}(f) > IC_\mu(f) - \epsilon?$$

In this paper we prove that $b(N, \epsilon) \leq (N\epsilon^{-1})^{O(N)}$. On the other hand, [6] shows that when f is the two-bit AND (and thus $N = 4$ is a constant), the tight estimate for b is $b = \Theta(\epsilon^{-1/2})$. Therefore, the polynomial dependence on ϵ, even when N is a constant, is necessary. On the other hand, we do not have any interesting lower bounds on b in terms of N. In particular, it is not known whether the exponential dependence on N is necessary here.

The second open problem is in a similar vein, asking whether Theorem 1 can be improved.

▶ **Open Problem 3.** *What is the computational complexity of computing the (zero-error internal) information complexity of a function f within error ϵ given its truth table? By how much can the bound of $2^{\exp\left((N\epsilon^{-1})^{O(N)}\right)}$ be improved?*

By the analysis in Section 3.4, any progress on Problem 2 will translate into progress on Problem 3. For comparison, it is not hard to see that the trivial algorithm for computing the *average-case communication complexity* of a function $f : [n] \times [n] \to \{0, 1\}$ (so that $N = n^2$) within an additive error ϵ runs in time $2^{n \cdot N^{N/\epsilon}} = 2^{\exp((N\epsilon^{-1})^{O(1)})}$ (it suffices to look at all protocols of depth at most $\frac{N \log N}{\epsilon}$, of which there are at most $2^{n \cdot N^{N/\epsilon}}$). In other words, there is an exponential gap between the trivial communication complexity upper bound and the bound we obtain in Theorem 1.

2 Preliminaries

2.1 Information Theory

For an introduction to the information theoretic notions used throughout this paper, we refer the reader to [10] (A brief introduction can also be found in the full version of this paper).

2.2 Protocols and Information Complexity

In the two-party communication setting, Alice is given an element a from a finite set $\mathcal{A}$, while Bob is given an element b from a finite set $\mathcal{B}$, where (a, b) is drawn from some distribution μ over $\mathcal{A} \times \mathcal{B}$. Their goal is to compute $f(a, b)$, where $f : \mathcal{A} \times \mathcal{B} \to \{0, 1\}$ is a function known to both parties. They would like to accomplish this while revealing as little information as possible; either to each other (in the case of information cost) or to an outside observer (in the case of external information cost). To do this, they execute a *communication protocol*, which we view as being built out of *signals*.

▶ **Definition 4.** A *signal* σ over a set S is an assignment of a probability $\sigma_s \in [0, 1]$ to each element s in S. For a given element s of S, we define $\sigma(s)$ to be the Bernoulli random variable that equals 1 with probability σ_s.

▶ **Definition 5.** A *communication protocol* π is a finite rooted binary tree, where each non-leaf node is labeled by either a signal over $\mathcal{A}$ (corresponding to Alice's move) or a signal over $\mathcal{B}$ (corresponding to Bob's move), and each edge is labeled either 0 or 1. Alice and Bob can execute this protocol by starting at the root and repeatedly performing the following procedure; if the signal σ at the current node is a signal over $\mathcal{A}$, Alice sends Bob an instance of $\sigma(a)$, and they both move down the corresponding edge; likewise, if the signal is a signal over $\mathcal{B}$, Bob performs the analogous procedure.

Each leaf node is labeled with a value 0 or 1. We say the communication protocol *successfully computes* f with zero error if the value of the leaf node Alice and Bob finish the protocol on is always equal to $f(a, b)$ for all $(a, b) \in \mathcal{A} \times \mathcal{B}$ (in particular, even (a, b) where $\mu(a, b) = 0$). The communication cost $CC(\pi)$ of protocol π is equal to the depth of the deepest leaf in π.

This agrees with the usual definition of a private coins protocol (indeed, any bit Alice can ever send in any protocol must be a signal over $\mathcal{A}$, and likewise for Bob). A public coins protocol is simply a distribution over private coins protocols. For our purposes, it suffices to solely examine private coins protocols, since the information cost of a public coins protocol is simply the expected information cost of the corresponding private coins protocols.

As is standard, we will let A and B be random variables representing Alice's input and Bob's input respectively, and let Π be the random variable representing the protocol's transcript. We can then define the *information cost* of a protocol and the *information complexity* of a function as follows.

▶ **Definition 6.** The *information cost* of a protocol π is given by

$$IC_\mu(\pi) = I(A; \Pi | B) + I(B; \Pi | A)\,.$$

The *external information cost* of a protocol π is given by

$$IC^{ext}_\mu(\pi) = I(AB; \Pi)\,.$$

▶ **Definition 7.** The *information complexity* of a function f is given by

$$IC_\mu(f) = \inf_\pi IC_\mu(\pi)$$

where the infimum is over all protocols π that successfully compute f. Likewise, the *external information complexity* of a function f is given by

$$IC^{ext}_\mu(f) = \inf_\pi IC^{ext}_\mu(\pi)\,.$$

where again, the infimum is over all protocols π that successfully compute f.

Throughout the remainder of this paper, it will be useful to think of signals as operating on the space $\Delta(\mathcal{A}\times\mathcal{B})$ of probability distributions over $\mathcal{A}\times\mathcal{B}$, which we term *beliefs*. At the beginning of a protocol, an outside observer's belief is simply given by μ, the distribution (a,b) was drawn from. As this observer observes new signals, his belief evolves according to Bayes' rule; for example, if he observes the signal $\sigma(a)$ sent by Alice, his belief changes from the prior belief p to the posterior belief

$$p_0(a,b) = \frac{(1-\sigma_a)p(a,b)}{\sum_{i,j}(1-\sigma_i)p(i,j)} \tag{2}$$

if $\sigma(a) = 0$ (which occurs with probability $P_0 = \sum_{i,j}(1-\sigma_i)p(i,j)$) and to the posterior belief

$$p_1(a,b) = \frac{\sigma_a p(a,b)}{\sum_{i,j}\sigma_i p(i,j)} \tag{3}$$

if $\sigma(a) = 1$ (which occurs with probability $P_1 = \sum_{i,j}\sigma_i p(i,j)$). As shorthand, we will say that σ *shifts* belief p to (p_0,p_1). Note that the probabilities P_0 and P_1 are uniquely recoverable given p_0 and p_1 (in particular, treating beliefs as vectors in $\mathbb{R}^{|\mathcal{A}\times\mathcal{B}|}$, it must be the case that $P_0p_0 + P_1p_1 = p$ and that $P_0 + P_1 = 1$).

Throughout the remainder of the paper, we will let $N = |\mathcal{A}\times\mathcal{B}| = |\mathcal{A}|\cdot|\mathcal{B}|$. Note that N is the size of the truth table of f and is thus (in some sense) the size of the input to the problem of computing the information complexity of f. All logarithms are to base 2 unless otherwise specified.

3 Computability of Information Complexity

3.1 Discretizing signals

In the first part of the proof, we show that we can convert any protocol for f into a protocol that uses a bounded number of types of signals. In particular, we prove the following theorem.

▶ **Theorem 8.** *Let π be a communication protocol with information cost C. Then, for any $\epsilon > 0$, there exists a communication protocol π' that computes the same function as π with information cost at most $C+\epsilon$ but that only uses $Q = (N\epsilon^{-1})^{O(N)}$ different types of signals.*

Proof Sketch. Recall that signals are simply vectors in $\mathbb{R}^N$. Our general approach will therefore be to build a 'mesh' of signals in $\mathbb{R}^N$ and round each signal in our protocol to one of the nearby signals in the mesh. We can show this rounding procedure preserves the correctness of the protocol but possibly leaks some additional information.

Via the concavity of mutual information, it happens that if we take the width of this mesh to be $poly(\epsilon/N)$, then this rounding procedure leaks at most ϵ additional information. Such a mesh in N dimensions contains at most $(1/poly(\epsilon/N))^N = (N\epsilon^{-1})^{O(N)}$ different signals, as desired. ◀

The above sketch suppresses a number of technical difficulties in proving the above theorem. In particular, in the full paper, we demonstrate how to deal with:

1. Initial distributions μ that lack full support (Section 3.1 in full paper).
2. Signals sent near the boundary of $\Delta(\mathcal{A} \times \mathcal{B})$ (Section 3.2 in full paper).
3. Signals with widely differing magnitudes (Section 3.3 in full paper).

3.2 Bounding the number of alternations

We next show that we can convert a protocol for f that uses a bounded number of distinct signals (yet arbitrarily many of them) into a protocol for f that, while leaking at most ϵ extra information, uses a bounded number of alternations (steps in the protocol where Alice stops talking and Bob starts talking, or vice versa).

We achieve this by 'bundling' signals of the same type together; that is, at a point in the protocol where Alice would send Bob a certain signal, she may instead send him a bundle of t signals. Then, the next $t-1$ times Alice would send Bob this signal, Bob instead refers to the next unused signal in the bundle. If there are unused signals in a bundle, this may increase the information cost of the protocol; however, by choosing the size of the bundle cleverly, we can bound the size of this increase.

▶ **Definition 9.** Let π be a communication protocol and let $v_1, v_2, \ldots, v_k$ be one possible computation path for π. An *alternation* in this computation path is an index i where the signals at v_i and v_{i+1} are sent by different players. The number of alternations in π is the maximum number of alternations over all computation paths of π.

▶ **Theorem 10.** *Let π be a communication protocol with information cost C that only uses Q distinct signals. Then, for any $\epsilon > 0$, there exists a communication protocol π' that computes the same function as π with information cost at most $C + 2\epsilon$ but that uses at most*

$$W = \left(\frac{2Q \log N}{\epsilon} + Q\right) \frac{\log N}{\epsilon}$$

alternations.

Proof Sketch. Label our Q different signals $\sigma^{(1)}$ through $\sigma^{(Q)}$. We will reduce the number of alternations in π by bundling signals of the same type in large groups. That is, if Alice (at a specific point in the protocol) would send Bob signal $\sigma^{(i)}$, she instead sends Bob t copies of signal i (for an appropriately chosen t). Then, the next $t-1$ times in the protocol that Alice would send Bob signal $\sigma^{(i)}$, Bob instead refers to one of the unused t copies Alice originally sent. Once these t copies are depleted and protocol calls for a $(t+1)$st copy, the process repeats and Alice sends a new bundle to Bob (possibly with a different value for t).

We choose t as follows. Without loss of generality, assume Alice is sending a bundle of signals σ to Bob. Let Π_{pre} be the transcript of the protocol thus far. Let $X^t = (X_1, X_2, \ldots, X_t)$ be a random variable corresponding to t independently generated outputs of σ. We consider three cases:

Case 1: It is the case that $I(A; X^1 | \Pi_{pre} B) \geq \frac{\epsilon}{Q}$. In this case we set $t = 1$ (note that this is equivalent to simply following the original protocol).

Case 2: There exists a positive t_0 such that $\frac{\epsilon}{2Q} \leq I(A; X^{t_0} | \Pi_{pre} B) \leq \frac{\epsilon}{Q}$. In this case, we set $t = t_0$.

Case 3: For all positive t, $I(A; X^t | \Pi_{pre} B) \leq \frac{\epsilon}{2Q}$. In this case, we set t to be the maximum number of times signal σ is ever sent in protocol π.

The remainder of this proof is divided into three parts. In the first part, we argue that the three cases above are comprehensive. In the second part, we argue that the information cost of this new protocol is at most $C + \epsilon$. Finally, in the third part we argue that this bundling process decreases the total number of alternations to at most W. We briefly sketch these arguments here (see the full paper for detailed proofs).

Cases are comprehensive

It is not immediately clear that one of the three above cases must occur; it could be the case that $I(A; X^t|\Pi_{pre}B)$ 'jumps' from below $\epsilon/2Q$ to above ϵ/Q as t increases by one step. To show this cannot happen, we prove a 'diminishing returns' theorem for information revealed by additional copies of X (in particular, we show $I(A; X^{t+1}|\Pi_{pre}B) - I(A; X^t|\Pi_{pre}B)$ is decreasing in t).

Information leakage is small

When not all the signals in a bundle are used, this new protocol leaks some additional information over our original protocol. However, by the selection of t, each bundle is either a Case 1 bundle (which is immediately used up) or leaks at most ϵ/Q information. Since there are at most Q unused bundles (one for each signal type), we leak at most ϵ additional information.

Number of alternations is small

The number of alternations is at most the number of bundles sent. With the exception of Case 3 bundles (of which we send at most one of each type, for a total of Q), each bundle increases the expected information revealed by at least $\epsilon/2Q$. Since the amount of information revealed by the protocol is bounded above by $\log N$, in expectation we send at most $Q + \frac{2Q \log N}{\epsilon}$ bundles. To translate this to a worst case result, we simply terminate the protocol after sending at most W bundles; it then follows from Markov's inequality that we leak at most ϵ additional information by doing this. ◀

3.3 Bounding the number of bits

We finally show that each alternation in any protocol can be executed in a way that requires the exchange of at most $\log N$ bits without any loss in information cost; it follows that a protocol with at most W alternations can be converted into an equivalent protocol with communication complexity at most $W \log N$.

▶ **Theorem 11.** *Let π be a communication protocol with information cost C that has W alternations. Then there exists a communication protocol π' with information cost C that computes the same function as π but that sends a total of at most $W \log N$ bits.*

Proof. We will show how to execute each alternation of a protocol in at most $\log N$ bits. For simplicity, we will assume Alice and Bob have access to public randomness; this can later be converted into a protocol with only private randomness via the observation that some fixed choice of public randomness minimizes the information cost of the protocol.

Assume that Alice is speaking during some alternation of π, and let there be M possible strings she may send to Bob. If p is the belief at the beginning of the alternation, then at the end of the alternation we will have shifted to one of M possible beliefs, $p_1, p_2, \ldots, p_M$. Let α_i equal the probability we end up at belief p_i. We can therefore write $p = \sum_{i=1}^{M} \alpha_i p_i$.

In particular, note that p is contained in the convex hull of the p_i. Since the beliefs p_i lie in a space of dimension $N-1$, by Caratheodory's theorem, it follows that there exists some set $T \subset [M]$ such that $|T| \leq N$ and p is a convex combination of $\{p_i | i \in T\}$. Fix such a T. We can then write $p = \sum_{i \in T} \beta_i p_i$.

Let $\gamma = \min_{i \in T} \frac{\alpha_i}{\beta_i}$. Alice and Bob now use public randomness to flip a weighted coin that comes up heads with probability γ. If this coin comes up heads, then Alice samples an element of T according to the distribution induced by the β_i and sends this element to Bob using at most $\log |T| \leq \log N$ bits (by say, specifying its location in T).

If this coin comes up tails, they construct a new probability distribution α' over $[M]$ given by setting $\alpha'_i = \alpha_i - \gamma\beta_i$ for all $i \in [M]$ (where $\beta_i = 0$ if $i \notin T$) and renormalizing. Note that by our choice of γ, it will be the case that $\alpha'_i \geq 0$ for all i; moreover, for at least one i, $\alpha'_i = 0$. They now repeat this process for this new distribution α'.

Note that throughout this modified round, Alice sends in total at most $\log N$ bits to Bob. Moreover, each time they use public randomness, the round either terminates (Alice sends a message to Bob) or the size of the support of α shrinks by one, guaranteeing that the round eventually terminates. Finally, at the end of this process, the probability Bob receives message $i \in [M]$ from Alice is equal to α_i, hence making this modified round information-theoretically equivalent to the original round.

Applying this to every alternation in a protocol π with W rounds results in a protocol π' with communication complexity of at most $W \log N$, as desired. ◀

3.4 Computing Information Complexity

Combining the results of Theorems 8, 10 and 11, we obtain the following result.

▶ **Theorem 12.** *Let π be a communication protocol with information cost C that successfully computes function f over inputs drawn from distribution μ over $\mathcal{A} \times \mathcal{B}$. Then there exists a protocol π' with information cost at most $C + \epsilon$ that also successfully computes f over inputs drawn from μ, but has communication cost at most $b(f, \epsilon)$ where*

$$b(f, \epsilon) = (N\epsilon^{-1})^{O(N)}$$

and $N = |\mathcal{A} \times \mathcal{B}|$.

By a similar rounding technique to that in Section 3.1, we can further ensure each signal in π belongs to a set $\mathbf{S}$ of size $(N\epsilon^{-1})^{O(N^2)}$ (see Section 3.7 of the full paper for details). We can now proceed to prove our main theorem.

Proof of Theorem 1. Fix an $\epsilon > 0$; we will show how to approximate the information complexity of f to within an additive factor of ϵ.

By Theorem 12, there exists some protocol with information cost at most $IC_\mu(f) + \epsilon$ with communication complexity at most $B(f, \epsilon)$ and that only uses signals in the set $\mathbf{S}$. The number of such protocols is finite; in particular each such protocol has at most $2^{B(f,\epsilon)}$ nodes, each of which is labelled by one of $|\mathbf{S}|$ signals. Since $|\mathbf{S}| = (N\epsilon^{-1})^{O(N^2)}$, it follows that the total number of protocols is at most

$$\begin{aligned} |\mathbf{S}|^{2^{B(f,\epsilon)}} &= (N\epsilon^{-1})^{O(N^2)2^{(N\epsilon^{-1})^{O(N)}}} \\ &= 2^{\exp\left((N\epsilon^{-1})^{O(N)}\right)} \end{aligned}$$

The information cost of a protocol with depth B (and thus at most 2^B nodes) can be computed in time $2^{O(B)}$. It follows that computing the minimum information cost of the

above protocols can be done in time $2^{\exp\left((N\epsilon^{-1})^{O(N)}\right)}$, and hence one can approximate $IC_\mu(f)$ to within an additive factor ϵ in time $2^{\exp\left((N\epsilon^{-1})^{O(N)}\right)}$, as desired. ◀

Acknowledgments. We would like to thank Ankit Garg and Noga Ron-Zewi for providing helpful comments on an earlier draft of this paper.

Rényi Information Complexity and an Information Theoretic Characterization of the Partition Bound*

Abstract

In this work we introduce a new information-theoretic complexity measure for 2-party functions, called Rényi information complexity. It is a lower-bound on communication complexity, and has the two leading lower-bounds on communication complexity as its natural relaxations: (external) information complexity and logarithm of partition complexity. These two lower-bounds had so far appeared conceptually quite different from each other, but we show that they are both obtained from Rényi information complexity using two different, but natural relaxations:

1. The relaxation of Rényi information complexity that yields information complexity is to change the order of Rényi mutual information used in its definition from infinity to 1.
2. The relaxation that connects Rényi information complexity with partition complexity is to replace protocol transcripts used in the definition of Rényi information complexity with what we term "pseudotranscripts," which omits the interactive nature of a protocol, but only requires that the probability of any transcript given inputs x and y to the two parties, factorizes into two terms which depend on x and y separately. While this relaxation yields an apparently different definition than (log of) partition function, we show that the two are in fact identical. This gives us a surprising characterization of the partition bound in terms of an information-theoretic quantity.

We also show that if both the above relaxations are simultaneously applied to Rényi information complexity, we obtain a complexity measure that is lower-bounded by the (log of) relaxed partition complexity, a complexity measure introduced by Kerenidis et al. (FOCS 2012). We obtain a sharper connection between (external) information complexity and relaxed partition complexity than Kerenidis et al., using an arguably more direct proof.

Further understanding Rényi information complexity (of various orders) might have consequences for important direct-sum problems in communication complexity, as it lies between communication complexity and information complexity.

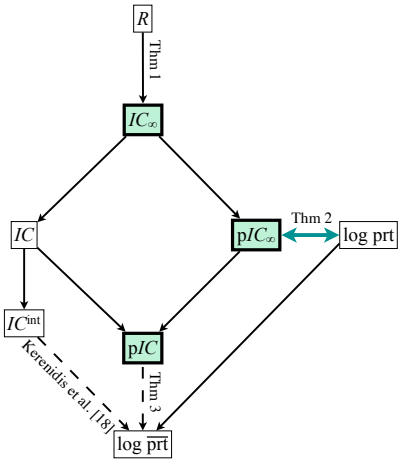

Figure 1 New complexity measures (shaded) and their relation to existing ones. Existing ones shown include the (public-coin) worst-case communication complexity (R), external and internal information complexity (IC and IC^{int}), partition complexity (prt) and relaxed partition complexity ($\overline{\text{prt}}$). An arrow from one measure to another shows that the latter is a lower-bound for the former. (The dashed lines indicate that the lower bound holds up to constant factors and shifts in error bounds.) $\text{p}IC_\infty$ is exactly equal to $\log \text{prt}$.

1 Introduction

Communication complexity, since the seminal work of Yao [26], has been a central question in theoretical computer science. Many of the recent advances in this area have centered around the notion of information complexity, which measures the *amount of information* about the inputs – rather than the *number of bits* – that should be present in a protocol's transcript, if it should compute a function (somewhat) correctly. The more traditional approach for lower bounding communication complexity relied on *combinatorial complexity measures* of functions. The goal of this work is to relate these two lines of studying communication complexity with each other.

Currently, the two leading lower bounds for communication complexity in the literature come from these two lines: (external) information complexity IC [8, 2] and partition complexity prt [14]. Either of these two lower bounds upper-bounds (and hence gives an equally good or better lower bound than) all the other bounds used in the literature. An intriguing problem in this area has been to understand if one of these two bounds is a better lower-bound than the other. An important motivation behind this problem is the possibility of separating IC from communication complexity via an intermediate combinatorial lower bound, which will have consequences for direct-sum results in communication complexity (since IC is known to be equal to amortized communication complexity [5, 4]).

Kerenidis et al. [18] showed that information complexity "subsumes" (the logarithm of) a relaxed variant of partition complexity, $\overline{\text{prt}}$, in the sense that any lower bound on $\log \overline{\text{prt}}$ in fact yields a lower bound on information complexity. Thus bounding $\log \overline{\text{prt}}$ cannot yield stronger lower bounds than bounding information complexity. In turn, all the combinatorial bounds in the literature – other than $\log \text{prt}$ – are subsumed by $\log \overline{\text{prt}}$. On the other hand, in recent breakthrough results, Ganor, Kol and Raz [10, 11] showed that for a certain range of parameters, combinatorial lower bounds can be significantly stronger than information

complexity lower bounds.[1] It remains open if such separations are possible for a less restrictive range of parameters (e.g., with communication complexity that is say, super-logarithmic in the input size). In the absence of a result analogous to that of [18] for prt itself, prt remains a candidate for showing such separations.

In this work, we do not pursue the question of whether $\log \mathrm{prt}$ could be larger than IC or vice versa. Instead, we develop a new information-theoretic complexity measure, IC_∞ which is as large or larger than both IC and $\log \mathrm{prt}$ (see Figure 1), and has *natural* relaxations that yield IC_∞ and $\log \mathrm{prt}$ respectively. *IC_∞ is thus a candidate for separating IC and communication complexity for a larger range of parameters than currently known to be possible.* Further, the relaxation of IC_∞ to $\log \mathrm{prt}$ reveals a surprising information-theoretic definition for prt. Since this new definition of (log of) prt has a markedly different form, we give it a different name, $\mathrm{p}IC_\infty$.

We also consider applying *both the relaxations* mentioned above simultaneously to IC_∞. This yields a new complexity measure $\mathrm{p}IC$. We then show that $\mathrm{p}IC$ is essentially lower bounded by $\log \overline{\mathrm{prt}}$, the relaxed partition complexity. *This recovers a result similar to that of [18], but with sharper parameters and an arguably more direct proof.*[2]

The relation between the new and old complexity measures are shown in Figure 1. (Also see Figure 3 for further extensions.) The new complexity measures are informally described below.

Rényi Information Complexity. (External) Information complexity of a function is defined as the mutual information between the transcript and the inputs, and is a lower bound on the communication complexity of the function. The notion of mutual information in this definition is due to Shannon. Rényi mutual information $I_\alpha(A;B)$, parametrized by $\alpha \geq 0$, is a generalization of Shannon's mutual information (see [25] for a recent treatment), with the latter corresponding to $\alpha \to 1$. We observe that information complexity continues to be a lower bound on communication complexity for all values of α. In particular, we may consider I_∞ instead of I_1 to define information complexity. The resulting notion of information complexity will be called IC_∞.

Pseudotranscript Complexity. Communication complexity, as well as information complexity, is defined in terms of a protocol. In contrast, the more traditional combinatorial lower bounds on communication complexity are defined in terms of simpler combinatorial properties of the function's truth table. We propose complexity measures based on one such property (which has been widely used in the analysis of protocols, but to the best of our knowledge, has never been isolated to define a complexity measure of functions).

Consider a function (generalized later to relations) $f : \mathcal{X} \times \mathcal{Y} \to \mathcal{Z}$. We define a random variable Q over a space $\mathcal{Q}$ to be a *pseudotranscript* for f if there exist two functions $\alpha : \mathcal{Q} \times \mathcal{X} \to \mathbb{R}^+$ and $\beta : \mathcal{Q} \times \mathcal{Y} \to \mathbb{R}^+$, such that $\Pr[Q = q | X = x, Y = y] = \alpha(q,x)\beta(q,y)$, for all $q \in \mathcal{Q}, x \in \mathcal{X}, y \in \mathcal{Y}$. This definition is motivated by the fact that the transcripts in a protocol do satisfy it (see Footnote 7). However, a pseudotranscript need not correspond to a protocol (indeed, any "tiling" of a function's table yields a pseudotranscript, but it need

[1] These results use combinatorial lower bounds to establish that communication complexity could be exponentially larger than information complexity. The communication complexity in these examples is (sub-)logarithmic in the size of the input itself.

[2] Our result does not subsume the result of Kerenidis et al. [18], as they deal with internal information complexity, while it is more natural for us to work with external information complexity. Conversely, the result of [18] does not yield our result for external information complexity (due to the parameters), nor the relation with the intermediate complexity measure $\mathrm{p}IC$.

not correspond to a valid protocol). We also associate a value z_q with a pseudotranscript q; the error $\mathrm{err}_{f,Q}$ is defined in terms of the probability of this value matching the function's output. We do not include any other properties of a protocol in defining a pseudotranscript.

We can define complexity measures $\mathrm{p}IC$ and $\mathrm{p}IC_\infty$ as relaxations of IC and IC_∞, simply by replacing protocols in their definitions with pseudotranscripts.

Relations Among the Complexities. The main results in this work, apart from introducing the new complexity measures, are connections between $\mathrm{p}IC_\infty$ and prt and between $\mathrm{p}IC$ and $\overline{\mathrm{prt}}$.

- Firstly, we show that $\mathrm{p}IC_\infty = \log \mathrm{prt}$. $\mathrm{p}IC_\infty$ and prt are defined very differently. prt is concerned with *tiling* the function table with weighted tiles: a tile t is a rectangle in the input domain along with an output value z_t. prt is the minimum total weight of tiles needed such that for each input (x, y), the weight of the tiles covering it adds up to 1, and the weight of the tiles with $z_t \neq f(x, y)$ is below the error threshold $\mathcal{E}(x, y)$.[3] On the other hand, $\mathrm{p}IC_\infty$ relates to pseudotranscripts q, which are similar to tiles in that they define a value z_q and a rectangle of all (x, y) such that $p(q|x, y) > 0$, but are more general in that there is no single "weight" on such a rectangle. Given our definitions, it is not hard to see that $\log \mathrm{prt}$ is as large or larger than $\mathrm{p}IC_\infty$, as any tiling can be naturally interpreted as a pseudotranscript Q with the same error, and in that case, the log of the value of the tiling indeed equals $I_\infty(X, Y; Q)$. What is more surprising is that any pseudotranscript Q can be converted to a tiling of the appropriate value (and same error). This conversion "slices" an uneven weight function $p(q|x, y)$ over a rectangle into weights $\omega_{q,t}$ over tiles t inside the rectangle; the weight of a tile t is the sum of the contributions to its weight from all the different values of q: $w(t) = \sum_q \omega_{q,t}$. Then it turns out that the value of the tiling so obtained will be equal to $I_\infty(X, Y; Q)$.
  This equivalence gives a new perspective on the partition complexity. Firstly, it shows that partition complexity exploits *exactly* the properties of a pseudotranscript, which is not apparent from its original definition. Secondly, it gives an information theoretic interpretation of a complexity measure defined in a traditional combinatorial manner. This is the first instance of the two lines of lower-bounding techniques for communication complexity – information theoretic and combinatorial – converging.
- Our second main result is that lower bounds on $\log \overline{\mathrm{prt}}$ are in fact lower bounds on $\mathrm{p}IC$. More precisely, we show that $\mathrm{p}IC(f, \varepsilon) \geq \delta \log \overline{\mathrm{prt}}(f, \varepsilon + \delta) - (\delta \log \log |\mathcal{X}||\mathcal{Y}| + 3)$. This is along the same lines as the result of [18], with improved parameters (in [18], the multiplicative overhead in the leading term is δ^2 instead of δ).
  The proof of this result is technically more involved, but is closely based on the simple slicing construction from the above result. The high-level idea is to first slice $p(q|x, y)$ into weights $\omega_{q,t}$ for each tile t, and then discard the contributions to $w(t)$ from those $\omega_{q,t}$ which are too large. One needs to ensure that the weight of the tiles discarded in this fashion is small (as it contributes to the error), while the weight of the remaining tiles is also small (as it contributes to the value of the tiling). For the first part, we show how (Shannon's) mutual information $I(X, Y; Q)$ can be approximated by a convex combination of non-negative values, and then apply Markov's inequality. For the second part, we rely on a geometric argument to derive a bound on the weight of the remaining tiles.

[3] For prt, as well as $\mathrm{p}IC_\infty$ and IC_∞, we use a very general notion of error, in which the error is specified as a function $\mathcal{E} : \mathcal{X} \times \mathcal{Y} \to [0, 1]$.

1.1 Related Work

Many of the recent advances in the field of communication complexity [26] have followed from using various notions of information complexity. Earlier notions of information complexity appeared implicitly in several works [1, 20, 23], and was first explicitly defined in [8] and further developed in [2]. Information complexity has been extensively used or studied in the recent communication complexity literature (e.g., [5, 4, 6, 7, 18, 3, 10, 9, 11]). The notion was also adapted to specialized models or tasks [17, 15, 16, 12].

The partition bound was developed in [14], and has subsumed a long line of combinatorial bounds [19] (see e.g., [14, 9]). The relaxed partition bound put forth in [18], similarly subsumes several combinatorial bounds, with the exception of the partition bound itself.

In 1960, generalizing Shannon's entropy, Rényi proposed new measures of entropy and divergence [22], now known after him. Subsequently, several authors developed different notions of mutual information based on these measures. One such definition attributed to Sibson [24] has recently come to be regarded as the most standard choice [25], and this is the basis for our definition of $I_\infty(A:B)$. Properties of I_α for various parameters α have been studied in [13, 25]. In information theory literature, the use of generalized notions of mutual information to obtain strong lower bounds for "one-shot" versions of communication problems (rather than amortized/direct-sum versions where Shannon's mutual information is often appropriate) has a long history starting with the work of Ziv and Zakai [28, 27]. In the communication complexity literature, Rényi divergence was used as a technical tool in deriving one of the results in [2].

Recently, the authors of this work proposed a distributional complexity measure, *Wyner tension* (or more generally, tension gap) which is a lower bound for information complexity [21]. We leave it for future work to explore the exact connections between these bounds and the ones in the current work. We mention that for the case when the inputs are independent, Wyner tension is identical to $\mathrm{p}IC^{\mathrm{int}}$ (defined in Section 6), and a result in [21] is subsumed by the results in this work.

2 Preliminaries

Let $f : \mathcal{X} \times \mathcal{Y} \to 2^{\mathcal{Z}}$ be a relation. Alice who has input $x \in \mathcal{X}$ and Bob who has input $y \in \mathcal{Y}$ want to output any $z \in f(x,y)$. We consider public-coin protocols, in which Alice and Bob have access to a common random string independent of the inputs; they may also use private local randomness. For such a protocol π, we say that the probability of error, which we view as a **function** of $(x,y) \in \mathcal{X} \times \mathcal{Y}$, is

$$\mathrm{err}_{f,\pi}(x,y) = \Pr[\pi(x,y) \notin f(x,y)],$$

where $\pi(x,y)$ is the *output* of the protocol and the probability is over the randomness in the protocol execution.[4] An error function $\mathcal{E}$ that is of particular interest is the constant (or worst-case) error function: $\mathcal{E}(x,y) = \varepsilon$ for some constant ε, for all $(x,y) \in \mathcal{X} \times \mathcal{Y}$.

For a protocol π, let $\#\mathrm{bits}(\pi,x,y)$ denote the maximum number of bits exchanged in an execution of π with inputs (x,y), in the worst case (i.e., over all choices of randomness). Note that this measure excludes the number of bits in the public randomness. The (worst

[4] For a protocol to be considered valid, we will insist that the two parties output the same value with probability 1; hence the output of a protocol is well-defined.

case) *communication complexity* $R(f,\mathcal{E})$ of f, for an error function $\mathcal{E}$, is defined as

$$R(f,\mathcal{E}) = \inf_{\substack{\text{protocol } \pi: \\ \text{err}_{f,\pi} \leq \mathcal{E}}} \max_{x,y} \quad \#\text{bits}(\pi, x, y).$$

To define information complexities, we will need to consider the distribution $\mathbf{p}_{X,Y}$ on the inputs X, Y. Let Π be the random variable that denotes the communication transcript *and* the public-coins of the protocol π. Then, the external information cost of the protocol π under the input distribution $\mathbf{p}_{X,Y}$ is $I(X,Y;\Pi)$, i.e., the amount of information about the inputs X, Y contained in Π. The (non-distributional) *external information complexity* $IC(f,\mathcal{E})$ is defined as

$$IC(f,\mathcal{E}) = \inf_{\substack{\text{protocol } \pi: \\ \text{err}_{f,\pi} \leq \mathcal{E}}} \max_{\mathbf{p}_{X,Y}} \quad I(X,Y;\Pi).$$

Similarly, internal information complexity is defined as

$$IC^{\text{int}}(f,\mathcal{E}) = \inf_{\substack{\text{protocol } \pi: \\ \text{err}_{f,\pi} \leq \mathcal{E}}} \max_{\mathbf{p}_{X,Y}} \quad I(X;\Pi|Y) + I(Y;\Pi|X).$$

Here the internal information cost, $I(X;\Pi|Y) + I(Y;\Pi|X)$, of the protocol π under input distribution $\mathbf{p}_{X,Y}$ is the sum of the information learned by the parties about each other's input from Π. The following relationship between these quantities is well-known.

$$IC^{\text{int}}(f,\mathcal{E}) \leq IC(f,\mathcal{E}) \leq R(f,\mathcal{E}).$$

A *tile* for $(\mathcal{X},\mathcal{Y},\mathcal{Z})$ is a pair $(r_X \times r_Y, z)$, where $r_X \subseteq \mathcal{X}$, $r_Y \subseteq \mathcal{Y}$ and $z \in \mathcal{Z}$. If $t = (r_X \times r_Y, z)$, then we let $\mathcal{X}_t, \mathcal{Y}_t$, and z_t denote r_X, r_Y and z respectively. We say $(x,y) \in t$ if and only if $x \in \mathcal{X}_t$ and $y \in \mathcal{Y}_t$. The set of all tiles for $(\mathcal{X},\mathcal{Y},\mathcal{Z})$ is denoted by $\mathcal{T}(\mathcal{X},\mathcal{Y},\mathcal{Z})$ or simply $\mathcal{T}$ (if $\mathcal{X},\mathcal{Y},\mathcal{Z}$ are clear from the context).

For a relation $f : \mathcal{X} \times \mathcal{Y} \to 2^{\mathcal{Z}}$ and probability of error $\mathcal{E} : \mathcal{X} \times \mathcal{Y} \to [0,1]$, the partition complexity [14] is defined as follows:[5]

$$\text{prt}(f,\mathcal{E}) = \min_{w:\mathcal{T}\to[0,1]} \sum_{t\in\mathcal{T}} w(t) \qquad \text{subject to}$$

$$\sum_{t\in\mathcal{T}:(x,y)\in t} w(t) = 1, \qquad \forall (x,y) \in \mathcal{X}\times\mathcal{Y} \tag{1}$$

$$\sum_{\substack{t\in\mathcal{T}:(x,y)\in t, \\ z_t \in f(x,y)}} w(t) \geq 1 - \mathcal{E}(x,y), \qquad \forall (x,y) \in \mathcal{X}\times\mathcal{Y}. \tag{2}$$

For a weight function w as above, we define the error function as

$$\text{err}_{f,w}(x,y) = \sum_{\substack{t\in\mathcal{T}:(x,y)\in t, \\ z_t \notin f(x,y)}} w(t);$$

then the condition (2) can be written as a condition on this error function: $\text{err}_{f,w} \leq \mathcal{E}$.

[5] The definition presented in [14] is slightly more restrictive in the kind of relations and error functions considered.

The relaxed partition complexity [18] relaxes the equality constraint in (1) to an inequality. Further, the error function is restricted to be a constant function given by $\mathcal{E}(x,y) = \varepsilon$. Specifically, for a relation f and a constant $0 \le \varepsilon \le 1$,

$$\overline{\mathrm{prt}}(f,\varepsilon) = \min_{w:\mathcal{T}\to[0,1]} \sum_{t\in\mathcal{T}} w(t) \quad \text{subject to}$$

$$\sum_{t\in\mathcal{T}:(x,y)\in t} w(t) \le 1, \qquad \forall (x,y)\in\mathcal{X}\times\mathcal{Y} \tag{3}$$

$$\sum_{\substack{t\in\mathcal{T}:(x,y)\in t,\\ z_t\in f(x,y)}} w(t) \ge 1-\varepsilon, \qquad \forall (x,y)\in\mathcal{X}\times\mathcal{Y}. \tag{4}$$

The distributional form of relaxed partition complexity is defined for a distribution μ and $\varepsilon \in [0,1]$ as follows:

$$\overline{\mathrm{prt}}^{\mu}(f,\varepsilon) = \min_{w:\mathcal{T}\to[0,1]} \sum_{t\in\mathcal{T}} w(t) \quad \text{subject to} \quad \begin{array}{l} \forall (x,y)\in\mathcal{X}\times\mathcal{Y} \sum\limits_{t\in\mathcal{T}:(x,y)\in t} w(t) \le 1, \\ \sum\limits_{x,y}\mu(x,y) \sum\limits_{\substack{t\in\mathcal{T}:(x,y)\in t,\\ z_t\in f(x,y)}} w(t) \ge 1-\varepsilon. \end{array}$$

For a weight function w as above and a distribution μ over $\mathcal{X}\times\mathcal{Y}$, we write $\overline{\mathrm{err}}^{\mu}_{f,w}$ for $1 - \sum_{x,y}\mu(x,y)\sum_{\substack{t\in\mathcal{T}:(x,y)\in t,\\ z_t\in f(x,y)}} w(t)$; so the second condition can be written as $\overline{\mathrm{err}}^{\mu}_{f,w} \le \varepsilon$. As shown in [18], $\overline{\mathrm{prt}}(f,\varepsilon) = \max_{\mu}\overline{\mathrm{prt}}^{\mu}(f,\varepsilon)$.

3 Rényi Information Complexity and Pseudotranscripts

In this section we define our new complexity measures.

Rényi information complexity. For a pair of random variables (A,B) over $\mathcal{A}\times\mathcal{B}$, Rényi mutual information of order ∞ is defined as (see, e.g., [25])

$$I_\infty(A;B) = \log\left(\sum_{b\in\mathcal{B}} \max_{a\in\mathcal{A}:\mathbf{p}_A(a)>0} \mathbf{p}_{B|A}(b|a)\right).$$

For a protocol π and an input distribution $\mathbf{p}_{X,Y}$, we will call $I_\infty(X,Y;\Pi)$ the Rényi information cost. *Rényi information complexity* $IC_\infty(f,\mathcal{E})$ is defined as the smallest worst-case (over input distributions) Rényi information cost of any protocol which has a probability of error at most $\mathcal{E}(x,y), x\in\mathcal{X}, y\in\mathcal{Y}$.

$$IC_\infty(f,\mathcal{E}) = \inf_{\substack{\text{protocol } \pi:\\ \mathrm{err}_{f,\pi}\le\mathcal{E}}} \max_{\mathbf{p}_{X,Y}} I_\infty(X,Y;\Pi).$$

Note the above definition is identical to the definition of $IC(f,\mathcal{E})$ except that I_∞ is used in place of mutual information I. It is easy to see that the inner maximization above is obtained by any input distribution $\mathbf{p}_{X,Y}$ with full support. Hence, we may equivalently write

$$IC_\infty(f,\mathcal{E}) = \inf_{\substack{\text{protocol } \pi:\\ \mathrm{err}_{f,\pi}\le\mathcal{E}}} I_\infty(X,Y:\Pi),$$

where we define $I_\infty(A:B)$ which is a function only of $\mathbf{p}_{B|A}$ as

$$I_\infty(A:B) = \log\left(\sum_{b\in\mathcal{B}} \max_{a\in\mathcal{A}} \mathbf{p}_{B|A}(b|a)\right).$$

▶ **Theorem 1.** *$IC(f,\mathcal{E}) \le IC_\infty(f,\mathcal{E}) \le R(f,\mathcal{E})$.*

Proof. The inequality $IC(f,\mathcal{E}) \le IC_\infty(f,\mathcal{E})$ follows from $I(X,Y;\Pi) \le I_\infty(X,Y;\Pi)$, which in turn follows from the monotonicity of α-mutual information [13, Theorem 4(b)] (see the full version for a self-contained proof).

The proof of $IC_\infty(f,\mathcal{E}) \le R(f,\mathcal{E})$ is simple. Consider any public-coin protocol π. Let $\Pi = (\Phi,\Psi)$ where Φ represents the public-coins and Ψ the transcript of π. W.l.o.g., Ψ can be considered to be a deterministic function of Φ and the inputs X,Y.[6] We write $\Psi(x,y;\phi)$ to denote the transcript of π on inputs (x,y) and public coins ϕ. Note that $\#\text{bits}(\pi,x,y) = \max_\phi |\Psi(x,y;\phi)|$ (where $|\cdot|$ denotes the length of a bit string). We shall show that $I_\infty(X,Y:\Pi) \le \max_{x,y,\phi} |\Psi(x,y;\phi)|$. This suffices since

$$IC_\infty(f,\mathcal{E}) = \inf_{\substack{\text{protocol } \pi:\\ \text{err}_{f,\pi}\le\mathcal{E}}} I_\infty(X,Y:\Pi). \qquad R(f,\mathcal{E}) = \inf_{\substack{\text{protocol } \pi:\\ \text{err}_{f,\pi}\le\mathcal{E}}} \max_{x,y,\phi} |\Psi(x,y;\phi)|.$$

Note that $\mathbf{p}_{\Phi\Psi|XY}(\phi,\psi|x,y) = \mathbf{p}_\Phi(\phi)\mathbf{p}_{\Psi|\Phi XY}(\psi|\phi,x,y)$. Then,

$$\begin{aligned} I_\infty(X,Y:\Phi,\Psi) &= \log \sum_\phi \mathbf{p}_\Phi(\phi) \sum_\psi \max_{x,y} \mathbf{p}_{\Psi|\Phi XY}(\psi|\phi,x,y) \\ &\le \log \max_\phi \sum_\psi \max_{x,y} \mathbf{p}_{\Psi|\Phi XY}(\psi|\phi,x,y) \\ &= \max_\phi \log|\{\psi : \exists(x,y) \text{ s.t. } \psi = \Psi(x,y;\phi)\}| \le \max_{x,y,\phi} |\Psi(x,y;\phi)|. \end{aligned}$$ ◀

Pseudotranscript and pseudo-information complexities. A random variable Q defined on an alphabet $\mathcal{Q}$ and jointly distributed with the inputs X,Y is said to be a *pseudotranscript* if $\mathbf{p}_{Q|X,Y}$ satisfies the following *factorization condition:*

$$\mathbf{p}_{Q|X,Y}(q|x,y) = \alpha(q,x)\beta(q,y), \quad \forall q\in\mathcal{Q}, x\in\mathcal{X}, y\in\mathcal{Y},$$

for some pair of functions $\alpha : \mathcal{Q}\times\mathcal{X} \to \mathbb{R}^+$ and $\beta : \mathcal{Q}\times\mathcal{Y} \to \mathbb{R}^+$. In addition, we will require that Q defines an output, i.e., for each q there is an associated $z_q \in \mathcal{Z}$.

For any protocol π, clearly, Π, which is composed of the public-coins and the transcript, is a pseudotranscript.[7] For a pseudotranscript Q, the probability of error is defined analogously to that for a protocol as

$$\text{err}_{f,Q}(x,y) = \Pr[z_Q \notin f(x,y) | (X,Y) = (x,y)].$$

---

[6] Any protocol using private randomness can be transformed to one with only public randomness, by including the private coins as part of the public-coins, without changing the number of bits communicated. Further, this can only increase the quantity $I_\infty(X,Y;\Pi)$. Hence, it is enough to prove the inequality after carrying out this transformation.

[7] $Q = \Pi$ satisfies the factorization condition, as in that case, for $q = (\phi, m_1, \cdots, m_t)$, $\Pr[q|x,y] = \alpha(q,x)\cdot\beta(q,y)$, where say, $\alpha(q,x) = \Pr[\phi]\cdot\Pi_{\text{odd}\,i}\Pr[m_i \mid \phi, m_1, \cdots, m_{i-1}, x]$, and $\beta(q,y) = \Pi_{\text{even}\,i}\Pr[m_i \mid \phi, m_1, \cdots, m_{i-1}, y]$. Also, we can associate the output of the protocol, which we insisted must be the same for both parties for a valid protocol, as the corresponding output z_Q. Though the output of the parties could in principle depend on the local input and local randomness, the factorization condition and the requirement that the outputs agree together imply that the output can be unambiguously determined from the transcript together with the public-coins.

We define the following "pseudo-quantities" corresponding to IC_∞ and IC where Π is replaced by pseudotranscripts:

$$\mathrm{p}IC_\infty(f,\mathcal{E}) = \inf_{\substack{\text{pseudotranscript } Q:\\ \mathrm{err}_{f,Q}\le\mathcal{E}}} \max_{\mathbf{p}_{X,Y}} I_\infty(X,Y;Q) = \inf_{\substack{\text{pseudotranscript } Q:\\ \mathrm{err}_{f,Q}\le\mathcal{E}}} I_\infty(X,Y:Q)$$

$$\mathrm{p}IC(f,\mathcal{E}) = \inf_{\substack{\text{pseudotranscript } Q:\\ \mathrm{err}_{f,Q}\le\mathcal{E}}} \max_{\mathbf{p}_{X,Y}} I(X,Y;Q).$$

▶ **Observation 2.** *Since, for any protocol, its transcript is a pseudotranscript as well, we have* $\mathrm{p}IC_\infty(f,\mathcal{E}) \le IC_\infty(f,\mathcal{E})$ *and* $\mathrm{p}IC(f,\mathcal{E}) \le IC(f,\mathcal{E})$. *Furthermore, since* $I(A;B) \le I_\infty(A;B)$, *we also have* $\mathrm{p}IC(f,\mathcal{E}) \le \mathrm{p}IC_\infty(f,\mathcal{E})$.

4 $\mathrm{p}IC_\infty$ Equals the Partition Bound

▶ **Theorem 3.** *For any relation* $f : \mathcal{X}\times\mathcal{Y} \to 2^{\mathcal{Z}}$ *and error function* $\mathcal{E}$, $\mathrm{p}IC_\infty(f,\mathcal{E}) = \log \mathrm{prt}(f,\mathcal{E})$.

We prove $\mathrm{p}IC_\infty(f,\mathcal{E}) \le \log\mathrm{prt}(f,\mathcal{E})$ and $\mathrm{p}IC_\infty(f,\mathcal{E}) \ge \log\mathrm{prt}(f,\mathcal{E})$ separately. The first direction is easy and, as shown in the full version, follows by considering the tiles in a given partition as the pseudo transcripts. Below, we turn to the other direction.

▶ **Lemma 4.** $\mathrm{p}IC_\infty(f,\mathcal{E}) \ge \log\mathrm{prt}(f,\mathcal{E})$.

Proof sketch. A detailed proof appears in the full version. Below we sketch the analysis, including details which will be useful as a starting point in proving the result in Section 5.

Suppose $\mathbf{p}_{Q|X,Y}$ satisfies the factorization and output consistency conditions, $\mathrm{err}_{f,Q} \le \mathcal{E}$ and $\mathrm{p}IC_\infty(f,\mathcal{E}) = I_\infty(X,Y:Q)$. Let $\mathcal{T}$ be the set of all tiles. To define the partition $w : \mathcal{T} \to [0,1]$, we shall (in (8)) define quantities $\omega_{q,t}$ (for $(q,t) \in \mathcal{Q}\times\mathcal{T}$) and probability distribution $\mathbf{p}_{T|Q,X,Y}$, where T is a random variable over $\mathcal{T}$, such that the following conditions hold.

$$\omega_{q,t} = 0 \qquad \forall (q,t) \in \mathcal{Q}\times\mathcal{T} \text{ s.t. } z_t \ne z_q \tag{5}$$

$$p(q,t|x,y) = \begin{cases} \omega_{q,t} & \text{if } (x,y)\in t \\ 0 & \text{otherwise} \end{cases} \qquad \forall (q,t)\in\mathcal{Q}\times\mathcal{T}, (x,y)\in\mathcal{X}\times\mathcal{Y} \tag{6}$$

$$\log \sum_{q\in\mathcal{Q},t\in\mathcal{T}} \omega_{q,t} = I_\infty(X,Y:Q) \tag{7}$$

Now, if we let $w : \mathcal{T} \to [0,1]$ be defined by $w(t) = \sum_{q\in\mathcal{Q}} \omega_{q,t}$, then it is easy to verify that (1) and (2) hold, and further $\log\mathrm{prt}(f,\mathcal{E}) \le \log\sum_{t\in\mathcal{T}} w(t) = I_\infty(X,Y:Q) = \mathrm{p}IC_\infty(f,\mathcal{E})$.

Thus, to complete the proof, it suffices to define $\mathbf{p}_{T|Q,X,Y}$ and $\omega_{q,t}$ so that the above conditions (5)-(7) are satisfied. Recall that, since Q is a pseudotranscript, $\mathbf{p}_{Q|X,Y}$ satisfies the factorization condition; i.e., we can write

$$\mathbf{p}_{Q|X,Y}(q|x,y) = \alpha(q,x)\beta(q,y), \quad \forall q\in\mathcal{Q}, x\in\mathcal{X}, y\in\mathcal{Y},$$

for some pair of functions $\alpha : \mathcal{Q}\times\mathcal{X} \to \mathbb{R}^+$ and $\beta : \mathcal{Q}\times\mathcal{Y} \to \mathbb{R}^+$. For $q\in\mathcal{Q}$ and $t\in\mathcal{T}$, let

$$\sigma_{q,t} = \min_{x\in\mathcal{X}_t} \alpha(q,x) - \max_{x'\notin\mathcal{X}_t} \alpha(q,x') \quad \text{and} \quad \tau_{q,t} = \min_{y\in\mathcal{Y}_t} \beta(q,y) - \max_{y'\notin\mathcal{Y}_t} \beta(q,y').$$

Above, in defining $\max_{x' \notin \mathcal{X}_t}$, if no such x' exists – i.e., $\mathcal{X}_t = \mathcal{X}$ – we take the maximum to be 0 (and similarly for $\max_{y' \notin \mathcal{Y}_t}$). Now, let

$$\begin{aligned} \mathcal{T}_q &= \{t \in \mathcal{T} \mid \sigma_{q,t} > 0, \tau_{q,t} > 0, \text{ and } z_q = z_t\} \\ \omega_{q,t} &= \begin{cases} \sigma_{q,t} \cdot \tau_{q,t} & \text{if } t \in \mathcal{T}_q \\ 0 & \text{if } t \notin \mathcal{T}_q. \end{cases} \\ p(t|x,y,q) &= \begin{cases} \sigma_{q,t} \cdot \tau_{q,t} \cdot \frac{1}{p(q|x,y)} & \text{if } (x,y) \in t, t \in \mathcal{T}_q \\ 0 & \text{otherwise.} \end{cases} \end{aligned} \tag{8}$$

The fact that $\mathbf{p}_{T|X,Y,Q}$ is a valid probability distribution and that conditions (5)-(7) are satisfied are proven in the full version, using Claim 5 below. This completes the proof of Lemma 4. ◀

▶ **Claim 5.** *For any $q \in \mathcal{Q}$ and $(x,y) \in \mathcal{X} \times \mathcal{Y}$, $\sum_{t \in \mathcal{T}_q : (x,y) \in t} \sigma_{q,t} \cdot \tau_{q,t} = p(q|x,y)$.*

Proof. Fix $q \in \mathcal{Q}$. Let $\mathcal{X} = \{x_1, \cdots, x_M\}$, such that $\alpha(q, x_i) \geq \alpha(q, x_{i-1})$ for all $i \in [1, M]$; for notational convenience, we also define a dummy x_0 with $\alpha(q, x_0) = 0$. Define $y_0, y_1, \cdots, y_N$ similarly for β, where $N = |\mathcal{Y}|$. Let $t_{ij} = (\mathcal{X}_i \times \mathcal{Y}_j, z_q)$ for $(i,j) \in [M] \times [N]$, where $\mathcal{X}_i = \{x_i, \cdots, x_M\}$, $\mathcal{Y}_j = \{y_j, \cdots, y_N\}$. Then,

$$\mathcal{T}_q = \{t_{ij} \mid (i,j) \in [M] \times [N], \alpha(q, x_i) > \alpha(q, x_{i-1}), \beta(q, y_j) > \beta(q, y_{j-1})\}.$$

Consider an arbitrary $(x,y) \in \mathcal{X} \times \mathcal{Y}$. Let (i^*, j^*) be indices such that $(x,y) = (x_{i^*}, y_{j^*})$ in the above ordering. Note that $(x_{i^*}, y_{j^*}) \in t_{ij}$ if and only if $1 \leq i \leq i^*$ and $1 \leq j \leq j^*$. Also notice that for all $(i,j) \in [M] \times [N]$, if $t_{ij} \notin \mathcal{T}_q$, then $\sigma_{q,t_{ij}}, \tau_{q,t_{ij}} = 0$.

$$\begin{aligned} \sum_{t \in \mathcal{T}_q : (x_{i^*}, y_{i^*}) \in t} \sigma_{q,t} \cdot \tau_{q,t} &= \sum_{i=1}^{i^*} \sum_{j=1}^{j^*} \sigma_{q,t_{ij}} \cdot \tau_{q,t_{ij}} \\ &= \sum_{i=1}^{i^*} (\alpha(q, x_i) - \alpha(q, x_{i-1})) \cdot \sum_{j=1}^{j^*} (\beta(q, y_j) - \beta(q, y_{j-1})) \\ &= \alpha(q, x_{i^*}) \cdot \beta(q, y_{j^*}) = p(q|x_{i^*}, y_{j^*}) \end{aligned}$$

as was required to prove. ◀

5 pIC Subsumes Relaxed Partition Bound

▶ **Theorem 6.** *For any relation $f : \mathcal{X} \times \mathcal{Y} \to 2^{\mathcal{Z}}$ and constants $\varepsilon, \delta \in [0,1]$,*

$$\mathrm{p}IC(f, \varepsilon) \geq \delta \log \overline{\mathrm{prt}}(f, \varepsilon + \delta) - (\delta \log \log(|\mathcal{X}||\mathcal{Y}|) + 3).$$

We prove this theorem in the full version. Below we summarize the main ideas.

Proof sketch. It is enough to show that, given a distribution $\mathbf{p}_{XY} = \mu$ over $\mathcal{X} \times \mathcal{Y}$, and pseudotranscript Q such that $\mathrm{err}_{f,Q} \leq \varepsilon$, there is a partition which demonstrates that $\log \overline{\mathrm{prt}}^{\mu}(f, \varepsilon + \delta) \lesssim I(X,Y;Q)/\delta$.

The proof uses the construction from the proof of Lemma 4, and modifies it carefully. Specifically, we define $\mathbf{p}_{T|Q,X,Y}$ and $\omega_{q,t}$ as in Equation 8. Recall that we originally defined w as $w(t) = \sum_{q \in \mathcal{Q}} \omega_{q,t}$. Our plan now is to remove some of the weight on the tiles so that the log of the sum can be bounded by (roughly) $I(X,Y;Q)/\delta$ as opposed to $I_\infty(X,Y:Q)$.

Towards this, we shall define a set $\mathcal{B}$ of "bad" pairs $(q,t) \in \mathcal{Q} \times \mathcal{T}$ whose weights $\omega_{q,t}$ will not be counted towards our new weight function $w'(t)$:

$$w'(t) = \sum_{(q,t)\in(\mathcal{Q}\times\mathcal{T})\setminus\mathcal{B}} \omega_{q,t}, \qquad \forall t \in \mathcal{T}.$$

The crux of the proof is to define the set $\mathcal{B}$ such that the weight removed $\sum_{(q,t)\in\mathcal{B}} p(q,t)$ is below δ (it manifests as the increase in error), while keeping $\sum_{(q,t)\notin\mathcal{B}} \omega_{q,t}$ (approximately) below $I(X,Y;Q)/\delta$. We show that the following choice of $\mathcal{B}$ has both these properties:

$$\mathcal{B} = \{(q,t) \in \mathcal{Q} \times \mathcal{T} \mid \hat{\alpha}(q,t) \cdot \hat{\beta}(q,t) \geq \theta_q, \}$$

where $\hat{\alpha}(q,t) = \min_{(x,y)\in t} \alpha(q,x)$ and $\hat{\beta}(q,t) = \min_{(x,y)\in t} \beta(q,y)$ and θ_q is an appropriately defined threshold for each $q \in \mathcal{Q}$ (specifically, $\theta_q = p(q)2^{\Delta}$, where $\Delta \approx I(XY;Q)/\delta$).

To upper bound the mass removed, we first write $I(XY;Q) = \sum_{q\in\mathcal{Q},t\in\mathcal{T}} p(q,t)\varphi(q,t)$, where $\varphi(q,t)$ is a quantity that is lower bounded by Δ for all $(q,t) \in \mathcal{B}$. This suggests the possibility of using the Markov inequality to upper bound $\sum_{(q,t)\in\mathcal{B}} p(q,t)$. However, $\varphi(q,t)$ could be negative, and we cannot directly use the above expression for $I(X,Y;Q)$ in a Markov inequality. However, we show that removing the negative terms from $\sum_{q,t} p(q,t)\varphi(q,t)$ does not increase the sum significantly, which will let us still apply the Markov inequality.

To upper bound $\sum_{(q,t)\notin\mathcal{B}} \omega_{q,t}$, we use a geometric interpretation of $\omega_{q,t}$ and the set $\mathcal{B}$. Fix a $q \in \mathcal{Q}$. Then, using the notation in the proof of Claim 5, for each $(i,j) \in [M] \times [N]$, the tile t_{ij} will be represented by an axis-parallel rectangle on the real plane, R_{ij}, as follows. R_{ij} is defined by its diagonally opposite vertices $(\alpha(q,x_{i-1}), \beta(q,y_{j-1}))$ and $(\alpha(q,x_i), \beta(q,y_j))$. (See Figure 2.) R_{ij} could have zero area. These rectangles tile a rectangular region, without overlapping with each other. Further the area of the rectangle R_{ij} is the same as $\omega_{q,t_{ij}}$. Thus $\sum_{t:(q,t)\notin\mathcal{B}} \omega_{q,t}$ is given by the sum of the areas of the rectangles R_{ij} for which $(q,t_{ij}) \notin \mathcal{B}$. The rectangles R_{ij} that correspond to $(q,t_{ij}) \notin \mathcal{B}$ are those which have their top-right vertex (i.e., $(\alpha(q,x_i), \beta(q,y_j))$) fall "below" the hyperbola defined by the equation $xy = \theta_q$. Thus if $(q,t_{ij}) \notin \mathcal{B}$, then the entire rectangle R_{ij} is below the hyperbola $xy = \theta_q$. Hence the sum of their areas is upper-bounded by the area within R that is under this hyperbola, where R is the rectangle with diagonally opposite vertices $(0,0)$ and $(\max_{x\in\mathcal{X}} \alpha(q,x), \max_{y\in\mathcal{Y}} \beta(q,y))$. A calculation yields the required bound. ◀

6 Extensions

We may define internal information complexity associated with pseudotranscripts as

$$\mathrm{p}IC^{\mathrm{int}}(f,\mathcal{E}) = \inf_{\substack{\text{pseudotranscript } Q\colon \mathbf{p}_{X,Y} \\ \mathrm{err}_{f,Q}\leq\mathcal{E}}} \max I(X;Q|Y) + I(Y;Q|X).$$

It is easy to show that for the usual notion of information complexity (defined with respect to protocols), $IC^{\mathrm{int}}(f,\mathcal{E}) \leq IC(f,\mathcal{E})$. The proof hinges on the fact that for any protocol π and distribution $\mathbf{p}_{X,Y}$ on the inputs, the resulting Π satisfies the condition $I(X;Y) \geq I(X;Y|\Pi)$. However, it is unclear whether $\mathrm{p}IC^{\mathrm{int}}(f,\mathcal{E})$ is necessarily upper bounded by $\mathrm{p}IC(f,\mathcal{E})$. Below we define a slightly refined notion of pseudotranscripts so that information complexities defined with respect to that maintain the above inequality.

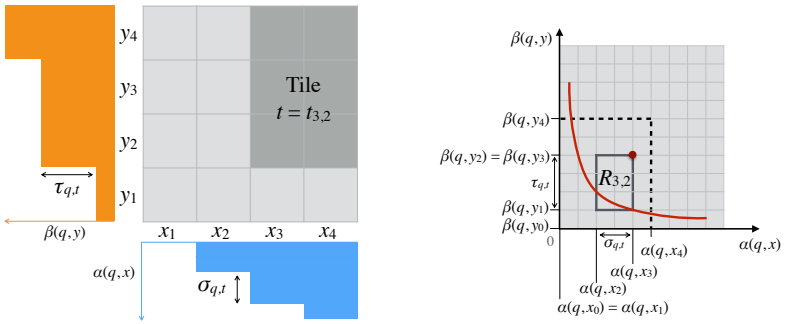

Figure 2 Illustration of the geometric interpretation of $\mathcal{B}$ used in the proof of Theorem 6. The left figure shows the domain $\mathcal{X} \times \mathcal{Y}$ and plots $\alpha(q,x)$ and $\beta(q,y)$ against x and y, which are sorted in the order of increasing $\alpha(q,x)$ and $\beta(q,y)$, respectively (for some fixed q). It also shows a tile $t = t_{3,2}$ in $\mathcal{T}_q$, and indicates the values $\sigma_{q,t}$ and $\tau_{q,t}$. The right figure shows the alternate representation of the tile $t_{3,2}$ using the rectangular region $R_{3,2}$. The area of $R_{3,2}$ equals $\omega_{q,t_{3,2}} = \sigma_{q,t_{3,2}} \cdot \tau_{q,t_{3,2}}$. A hyperbola corresponding to a threshold θ_q is also shown. Since the upper-right vertex of $R_{3,2}$, namely the point $(\alpha(q,x_3), \beta(q,y_2))$ is above the hyperbola, $(q,t_{3,2}) \in \mathcal{B}$. The area within the dotted rectangle that is under the hyperbola gives an upper-bound on the sum of areas of all rectangles under the hyperbola.

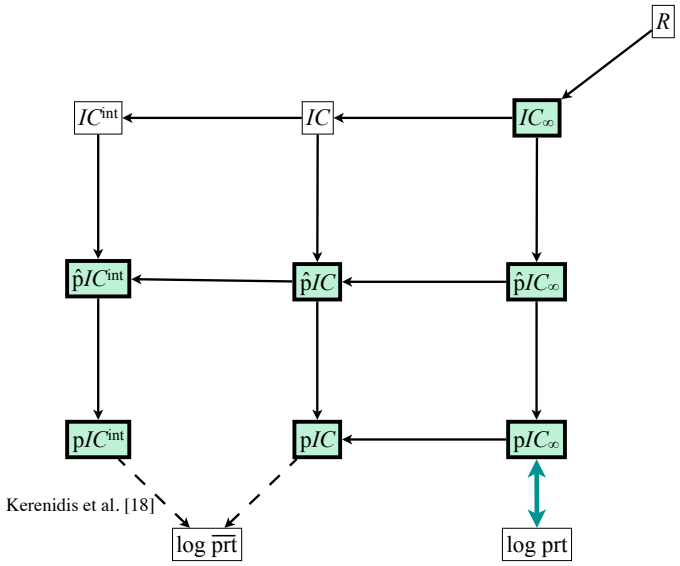

Figure 3 An extended version of the map in Figure 1, including the complexity measures in Section 6.

Refined pseudotranscripts and corresponding information complexities. A pseudotranscript Q given by $\mathbf{p}_{Q|X,Y}$ is called a *refined pseudotranscript* if, for any distribution $\mathbf{p}_{X,Y}$ on the inputs, it holds that $I(X;Y) \geq I(X;Y|Q)$. It is easy to show that for any protocol π and distribution $\mathbf{p}_{X,Y}$ on the inputs, the resulting Π satisfies the above condition and, hence, Π is a refined pseudotranscript.

Analogous to our definition of pseudo-information complexities, we define information complexities with respect to refined pseudotranscripts

$$\hat{\mathrm{p}}IC_\infty(f,\mathcal{E}) = \inf_{\substack{\text{refined pseudotranscript } Q: \\ \mathrm{err}_{f,Q} \leq \mathcal{E}}} I_\infty(X,Y:Q)$$

$$\hat{\mathrm{p}}IC(f,\mathcal{E}) = \inf_{\substack{\text{refined pseudotranscript } Q: \\ \mathrm{err}_{f,Q} \leq \mathcal{E}}} \max_{\mathbf{p}_{X,Y}} I(X,Y;Q)$$

$$\hat{\mathrm{p}}IC^{\mathrm{int}}(f,\mathcal{E}) = \inf_{\substack{\text{refined pseudotranscript } Q: \\ \mathrm{err}_{f,Q} \leq \mathcal{E}}} \max_{\mathbf{p}_{X,Y}} I(X;Q|Y) + I(Y;Q|X).$$

Figure 3 shows the relationship between the different complexities we consider. Since, for any protocol, its transcript is a refined pseudotranscript and refined pseudotranscripts are also pseudotranscripts, we have $\mathrm{p}\mathtt{X}(f,\mathcal{E}) \leq \hat{\mathrm{p}}\mathtt{X}(f,\mathcal{E}) \leq \mathtt{X}(f,\mathcal{E})$, where $\mathtt{X}$ can be IC_∞, IC or IC^{int}. Furthermore, analogous to $IC^{\mathrm{int}}(f,\mathcal{E}) \leq IC(f,\mathcal{E}) \leq IC_\infty(f,\mathcal{E})$, we have $\hat{\mathrm{p}}IC^{\mathrm{int}}(f,\mathcal{E}) \leq \hat{\mathrm{p}}IC(f,\mathcal{E}) \leq \hat{\mathrm{p}}IC_\infty(f,\mathcal{E})$. Finally, in deriving a lower bound for $IC^{\mathrm{int}}(f,\varepsilon)$ in terms of $\overline{\mathrm{prt}}(f,\varepsilon)$ [18] only relies on the fact that the transcript (along with the public-coins) Π satisfies the factorization condition. Hence, the lower bound of [18] holds with IC^{int} replaced by $\mathrm{p}IC^{\mathrm{int}}$.

Abstract

The isoperimetric profile of a graph is a function that measures, for an integer k, the size of the smallest edge boundary over all sets of vertices of size k. We observe a connection between isoperimetric profiles and computational complexity. We illustrate this connection by an example from communication complexity, but our main result is in algebraic complexity.

We prove a sharp super-polynomial separation between monotone arithmetic circuits and monotone arithmetic branching programs. This shows that the classical simulation of arithmetic circuits by arithmetic branching programs by Valiant, Skyum, Berkowitz, and Rackoff (1983) cannot be improved, as long as it preserves monotonicity.

A key ingredient in the proof is an accurate analysis of the isoperimetric profile of finite full binary trees. We show that the isoperimetric profile of a full binary tree constantly fluctuates between one and almost the depth of the tree.

1 Introduction

Computational complexity theory is about understanding the amount of resources required to compute a given function. One general framework for analyzing the limitations of a given computational device is to partition it to two or more parts and study the interactions between them (see [12, 2] and references trerein). This framework is directly related to communication complexity [24, 15], and appears in the study of branching programs (e.g. [4]), in algebraic complexity theory (e.g. [17, 10]), and more.

In this work, we observe the following phenomenon: the *exact* sizes of the parts in the partition matter. Some functions are "easy" to compute when the sizes can be chosen flexibly, but are "difficult" to compute when the sizes are chosen adversarially. The simplest illustration of this phenomenon comes from communication complexity, and is discussed below. Our most convincing application, however, comes from arithmetic circuit complexity, and forms the bulk of this paper.

1.1 Isoperimetric profile of graphs

The aforementioned phenomenon is related to expansion properties of graphs. For a graph $G = (V(G), E(G))$ and $A \subseteq V(G)$, the size of the edge boundary of A is

$$e_G(A) = \big|\{\{a, b\} \in E(G) : a \in A, b \in B\}\big|,$$

where $B = V(G) \setminus A$. The edge isoperimetric profile of G is the function

$$\mathrm{eip}_G(k) = \min\{e_G(A) : A \subseteq V(G), |A| = k\}.$$

For example, G is connected if and only if $\mathrm{eip}(k) \geq 1$ for every non trivial k. Analyzing the isoperimetric profile of a graph is not a simple task. In fact, even understanding simple properties of the isoperimetric profile in manifolds is difficult (see [16] and references therein).

The high-level connection is as follows. Consider functions defined over some graph G. The vertices are labelled by variables, and the edges represent interactions between them. A partitioning of the variables into two parts yields a partition of the vertices of G. Intuitively, the size of the edge boundary represents the amount of interaction between the parts, and so a large boundary implies high complexity.

1.2 Communication complexity

Communication complexity studies the amount of communication two or more parties need to exchange in order to achieve a common goal. It was initiated by Yao in [24] in the context of distributed computing. For simplicity of the presentation, here we focus on the best-case deterministic two player model that was introduced by Papadimitriou and Sipser [18], and applied to study of very-large-scale integration (for more background and details, see the textbook [15]).

The deterministic communication complexity $D(f)$ of a boolean function $f : \{0,1\}^A \times \{0,1\}^B \to \{0,1\}$ is the minimum number of bits two players need to exchange in order to determine the value of $f(x, y)$, where one player sees $x \in \{0,1\}^A$ and the other sees $y \in \{0,1\}^B$. Let $F : \{0,1\}^V \to \{0,1\}$. Given a partition of V to two sets A, B, we can define a function $F_{A,B} : \{0,1\}^A \times \{0,1\}^B \to \{0,1\}$ by $F_{A,B}(x, y) = F(z)$ where $z|_A = x$ and $z|_B = y$. The best-case deterministic communication complexity with partition-size k of F, denoted $D_k^{\mathrm{best}}(F)$, is the minimum of $D(F_{A,B})$ over all partitions of V to two sets A, B with $|A| = k$.

We observe the following connection between the best-case communication complexity and the edge isoperimetric profile for certain functions. Let $G = (V, E)$ be an undirected graph with n vertices and maximum degree Δ. Consider, e.g., the function $F : \{0,1\}^V \to \{0,1\}$ defined via G as[1]

$$F(z) = \bigoplus_{\{u,v\} \in E} z_u \wedge z_v,$$

where $\oplus$ is addition modulo two. Then, for every $1 \leq k \leq n$, it holds that[2]

$$\Omega(\mathrm{eip}_G(k)/\Delta^2) \leq D_k^{\mathrm{best}}(F) \leq O(\mathrm{eip}_G(k)).$$

[1] The definition of F is inspired by a private communication with Avi Wigderson following [19].
[2] In this text, big O and Ω notation means "up to a constant multiplicative factor".

The upper bound is obtained by partitioning the variables according to the minimizer of the edge boundary, noting that the players need only to exchange inputs that appear on edges of the boundary. The lower bound holds for the following reason. For every partition A, B of the inputs with $|A| = k$, the edge boundary of A contains an induced matching of size $m \geq \Omega(\mathrm{eip}_G(k)/\Delta^2)$. Setting the variables not participating in the matching to zero, the lower bound follows from standard lower bounds on the inner product function, $\bigoplus_{i\in[m]} x_i \wedge y_i$.

In other words, the best-case communication complexity of F is determined by the isoperimetric profile of G, as long as G has constant degree. So, if the isoperimetric profile of G changes dramatically with k, then so does $D^{\mathrm{best}}_k(F)$. For example, there are functions F so that $D^{\mathrm{best}}_{n/2}(F) = O(1)$ whereas $D^{\mathrm{best}}_{n/3}(F) = \Omega(n)$.

1.3 Algebraic complexity

Algebraic complexity theory studies the complexity of computing polynomials over a field. For more background and details, see [7, 5, 21] and references within. We start by outlining definitions of the models we consider.

The most general model of computation in this area is that of *arithmetic circuit*. An arithmetic circuit is a directed acyclic graph with fan-in either zero or two. Vertices of fan-in zero are labelled by a field element or a variable. Vertices of fan-in two are labelled by either $+$ or $\times$. Every vertex in an arithmetic circuit computes a polynomial in the obvious way. A weaker model is an *arithmetic formula*: it is a circuit whose underlying graph is a tree. Another model is the *algebraic branching program*, ABP. An ABP is a directed acyclic graph with two special vertices $v_{\mathrm{start}}, v_{\mathrm{end}}$. Each edge e in it is labelled by $L(e)$ which is a variable times a field element. The program computes f, which is the following sum over all directed paths γ from v_{start} to v_{end}:

$$f = \sum_{\gamma : v_{\mathrm{start}} \to v_{\mathrm{end}}} \prod_{e\in\gamma} L(e).$$

The computation performed by ABPs corresponds to the iterated multiplication of matrices. The size parameter in each of the three models is the number of edges in the underlying graph.

We now discuss reductions between these models. Formulas can be losslessly simulated by an ABP, which in turn can be losslessly simulated by a circuit. In the opposite direction, Hyafil [11] showed that every circuit of size s computing a polynomial of degree r can be simulated by a formula of size $2^{O(\log(s)\log(r))}$. Valiant, Skyum, Berkowitz and Rackoff [23] significantly strengthened this result. In their seminal work, they showed that an arithmetic circuit of size s computing a polynomial of degree r can be simulated by a circuit of size $\mathrm{poly}(r, s)$ and depth $O(\log(r)\log(s))$. This result was later used in a sequence of works – Agrawal and Vinay [1], Koiran [13], and Tavenas [22] – to prove non-trivial simulations of circuits by circuits of depth four (and unbounded fan-in). This depth reductions sprung a long sequence of works on lower bounds for constant depth circuits (see [9, 14, 6] are references within).

An intriguing question is whether the simulations discussed above are sharp. It is possible they can be significantly improved. However, since we do not have strong enough methods for proving lower bounds for these models of computation, proving that the reductions are sharp is currently beyond us.

We therefore address this question in the restricted setting of monotone computations. A monotone arithmetic computation is a computation over the real numbers that uses only

non-negative numbers. The aforementioned reductions of Hyafil and Valiant et al. transform a monotone device to a monotone device. We call such reductions monotone.

Since we know how to prove lower bounds for monotone computation, we can in fact show that in the category of monotone reductions the reductions above are indeed sharp. Indeed, the reduction between ABPs and formulas is sharp since Shamir and Snir [20] proved that in order to multiply d matrices of size $n \times n$, we need a monotone formula of size $n^{\Omega(\log d)}$, but on the other hand this can be done via a monotone ABP of size $\mathrm{poly}(n, d)$. The reduction from circuits to ABPs was not previously studied. In this paper, we prove:

▶ **Theorem 1.** *There is a multilinear n-variate polynomial f with zero-one coefficients so that the following hold:*

1. *The polynomial f can be computed by a monotone arithmetic circuit of size $\mathrm{poly}(n)$.*
2. *Every monotone ABP computing f has size at least $2^{\Omega(\log^2(n))}$.*

The simulation of [23] shows that the lower bound in the theorem is tight, up to a constant in the exponent. Stated differently, the theorem shows that any monotone reduction from circuits to ABPs must incur a super-polynomial blowup. To the best of our knowledge, this is the first separation between algebraic branching programs and circuits. Prior to this work, it was conceivable that the monotone construction of [23] or other monotone variants of it can simulate a circuit by an ABP with only a polynomial increase in size.

It is worth mentioning that Gupta, Kamath, Kayal and Saptharishi [8] showed how to simulate a circuit of size s and degree r over n variables by a depth three circuit of size $\exp(O(\sqrt{d \log(d) \log(n) \log(s)}))$, over fields of characteristic 0. Their simulation uses the reductions to depth four from [1, 13, 22] mentioned above, together with two other reductions. Most relevant to our work is that their simulation is not monotone. In fact, as they mention, a simulation to depth three achieving the same parameters can not be monotone.

We now briefly discuss the proof. All lower bounds we know of for monotone algebraic computation are based on combinatorial problems that are related to counting monomials. The lower bounds for circuits use the following structure, which is standard by now (see e.g. [20, 21, 10]). We denote by $\deg(f)$ the total degree of f.

▶ **Lemma 2.** *If f is a homogeneous polynomial of degree r that can be computed by a monotone circuit of size s, then for every integer $2 \leq k \leq r$, we can write*

$$f = \sum_{i=1}^{s} h_i g_i \tag{1}$$

where for each i, both h_i, g_i are homogeneous, monotone, and of degrees $k/3 \leq \deg(h_i) < 2k/3$ and $\deg(g_i) = r - \deg(h_i)$.

A typical monotone lower bound proceeds by showing that the number of monomials in each $h_i g_i$ is small and so s must be large. To separate monotone circuits from ABPs, we must find a polynomial that has a small circuit and use some other property of ABPs. We use the following.

▶ **Lemma 3.** *If f is a homogeneous polynomial of degree r that can be computed by a monotone ABP of size s, then for every integer $0 \leq k \leq r$, we can write*

$$f = \sum_{i=1}^{s} h_i g_i \tag{2}$$

where for each i, both h_i, g_i are homogeneous, monotone, and of degrees $\deg(h_i) = k$ and $\deg(g_i) = r - k$.

Notice the similarities between the two lemmas. The only difference between circuits and ABPs is that circuits are slightly more flexible about the degrees of h_i, g_i in (1), whereas ABPs are not. We exploit this weakness to prove the separation. Motivated by Section 1.2, the polynomial f in Theorem 1 will be defined over an underlying graph G. The setting will be such that for each k, large $\mathrm{eip}_G(k)$ implies a super-polynomial lower bound on s in (2), and hence gives a lower bound on the ABP-size. On the other hand, the graph must be chosen so that f is easy to compute via a monotone circuit. If G is too complex, such as an expander graph, then we do not expect to prove meaningful upper bounds. In fact, in order to circumvent the lower bound implied by (1), the value of $\mathrm{eip}_G(k)$ must be small for many integers k. It turns out that the right graph to choose is the full binary tree, which we discuss next.

1.4 Full binary trees

We analyze the isoperimetric profile of full finite binary trees. The case of the infinite binary tree was previously studied by Bharadwaj, Chandran and Das in [3], where it was shown to be related to meta-Fibonacci sequences and signed almost binary partitions.

For an integer $d \geq 0$, denote by T_d the full binary tree of depth d. It has precisely 2^d leaves and $2^{d+1} - 1$ vertices. It is clear that there are many values $k \leq |V(T_d)|$ for which $\mathrm{eip}_{T_d}(k) = 1$. It is more surprising that for some k, the value of $\mathrm{eip}_{T_d}(k)$ can be fairly large, almost as large as the depth of T_d. This is the content of the first theorem:

▶ **Theorem 4.** *Let $mip(T_d)$ be the maximum of $\mathrm{eip}_{T_d}(k)$ over all $0 \leq k \leq |V(T_d)|$. Then*

$$\frac{d}{2} - O(\log d) \leq mip(T_d) \leq \frac{d}{2} + O(1)\,.$$

In order to analyze the isoperimetric profile of T_d, we relate it to the binary representation of k. For an integer $k \geq 0$, denote the binary representation of k by

$$B(k) = (B_0(k), B_1(k), B_2(k), \ldots) \in \{0,1\}^{\mathbb{N}}.$$

I.e., $k = \sum_{i=0}^{\infty} B_i(k) 2^i$. Denote by $\mathrm{drops}(k)$ the number of drops in $B(k)$:

$$\mathrm{drops}(k) = |\{i \geq 0 : B_i(k) > B_{i+1}(k)\}|.$$

The number of drops is a quantity that is relatively easy to understand, and as the following theorem shows, it captures the isoperimetric profile of binary trees.

▶ **Theorem 5.** *For every $d \geq 0$ and $0 \leq k < |V(T_d)|$,*

$$\frac{\mathrm{drops}(k)}{2} \leq \mathrm{eip}_{T_d}(k) \leq 2\mathrm{drops}(k)\,.$$

Moreover, the lower bound can be improved to $\mathrm{drops}(k) - O(\log(\mathrm{drops}(k)))$.

The theorem provides an almost optimal description of the isoperimetric profile $\mathrm{eip}_{T_d}(k)$ of T_d. It implies that although $\mathrm{eip}_{T_d}(k) = 1$ for many values of k, for most values of k we have $\mathrm{eip}_{T_d}(k) \geq \Omega(d)$.

We get an explicit choice of k for which $\mathrm{eip}(k)$ is large. For even $d \geq 0$, define

$$\sigma_d = 1 + 4 + 16 + \ldots + 2^d \approx \frac{2}{3} 2^{d+1}, \tag{3}$$

and for odd d define $\sigma_d = \sigma_{d-1}$. The number of drops in $B(\sigma_d)$ is at least $d/2$. The number σ_d can be thought of as the truncation of the binary expansion of $2/3$.

▶ **Corollary 6.** *For every $d \geq 0$, we have $\mathrm{eip}_{T_d}(\sigma_d) \geq d/2 - O(\log d) \geq d/4$.*

1.5 Organization

Section 3 contains the proof of the separation between monotone circuits and ABPs. Section 2 contains the proofs concerning the isoperimetric profile of the full binary tree that are needed in Section 3 (due to space limitations, some of the proofs that are not used in Section 3 will appear in the full version of the text).

2 Binary trees

In order to prove the lower bounds in Theorems 4 and Theorem 5, we will introduce the quantity $\mathrm{sbl}(k)$ which, roughly speaking, measures how far k is from powers of 2. We then relate $\mathrm{eip}_{T_d}(k)$ and $\mathrm{sbl}(k)$,

We say that k is a signed power of two if it is of the form $\pm 2^j$ for some integer $j \geq 0$. For $k \in \mathbb{Z}$, the signed binary length of k, denoted $\mathrm{sbl}(k)$, is the minimum b so that there exist b signed powers of two $k_1, \ldots, k_b$ so that $k = \sum_{i=1}^{b} k_i$, where repetitions are a priori allowed. For example, $\mathrm{sbl}(0) = 0$ and if $d \geq 1$ then

$$\mathrm{sbl}(1 + 2 + 4 + \ldots + 2^d) = \mathrm{sbl}(2^{d+1} - 1) = 2.$$

The following lemma gives a lower bound on $\mathrm{eip}_{T_d}(k)$ in terms of $\mathrm{sbl}(k)$.

▶ **Lemma 7.** *For every $d \geq 0$ and $0 < k \leq |V(T_d)|$,*

$$\mathrm{eip}_{T_d}(k) \geq \mathrm{sbl}(k) - O(\log(\mathrm{sbl}(k)))\,.$$

In addition, if $k < |V(T_d)|$ then $\mathrm{eip}_{T_d}(k) \geq \mathrm{sbl}(k)/2$.

Proof. For an integer k, let $\mathrm{st}(k)$ denote the smallest b such that there exist non-negative integers $j_1, \ldots, j_b$ and $\epsilon_1, \ldots, \epsilon_b \in \{-1, 1\}$ with[3]

$$k = \sum_{j=1}^{b} \epsilon_j \cdot (2^j - 1)\,. \tag{4}$$

Recall that if $j > 0$, then $2^j - 1$ is the number of vertices in T_{j-1}. We will prove the following:

▶ **Claim 8.** *For every $U \subseteq V(T_d)$ not containing the root of T_d, we have $\mathrm{st}(|U|) \leq e_{T_d}(U)$.*

Claim 8 implies that for every $U \subseteq V(T_d)$,

$$\mathrm{st}(|U|) \leq e_{T_d}(U) + 1\,. \tag{5}$$

Indeed, if U contains the root of T_d, then apply Claim 8 to the complement $\bar{U} = V(T_d) \setminus U$. Then $\bar{U}$ does not contain the root of T_d and $e_{T_d}(U) = e_{T_d}(\bar{U}) \geq \mathrm{st}(|\bar{U}|)$. But $|U| = |V(T_d)| - |\bar{U}|$ gives $\mathrm{st}(|U|) \leq \mathrm{st}(|\bar{U}|) + 1$.

Proof of Claim 8. The proof is by induction on d. The claim holds for $d = 0$ as $\mathrm{st}(0) = 0$. Assume $d > 0$. Let v_d be the root of T_d and for a node v, let $T(v)$ be the full subtree of T_d with root v. Let $U \subseteq V(T_d)$ be so that $v_d \notin U$. Let M be the subset of maximal vertices in

[3] This quantity previously appeared in [3].

U. That is, a vertex v is in M if $v \in U$ and the shortest path from v to v_d does not contain a vertex from U. For $v \in M$, let $U(v) = U \cap V(T(v))$. Hence,

$$e_{T_d}(U) = |M| + \sum_{v \in M} e_{T(v)}(U(v)).$$

Since $|U| = \sum_{v \in M} |U(v)|$,

$$\mathrm{st}(|U|) \leq \sum_{v \in M} \mathrm{st}(|U(v)|).$$

For every $v \in M$, the inductive assumption and (5) show that

$$\mathrm{st}(|U(v)|) \leq e_{T(v)}(U(v)) + 1.$$

Overall,

$$\mathrm{st}(|U|) \leq \sum_{v \in M} (1 + e_{T(v)}(U(v))) = |M| + \sum_{v \in M} e_{T(v)}(U(v)) = e_{T_d}(U). \quad \blacktriangleleft$$

To prove the lemma, it remains to estimate $\mathrm{sbl}(k)$ in terms of $\mathrm{st}(k)$. If k is written as in (4) with $b = \mathrm{st}(k)$, we have

$$\mathrm{sbl}(k) \leq \mathrm{sbl}(\sum_{j=1}^{b} \epsilon_j 2^j) + \mathrm{sbl}(\sum_{j=1}^{b} \epsilon_j) \leq \mathrm{st}(k) + \log_2(\mathrm{st}(k) + 1).$$

This gives $\mathrm{st}(k) \geq \mathrm{sbl}(k) - O(\log(\mathrm{sbl}(k)))$ and so (5) gives

$$\mathrm{eip}_{T_d}(k) \geq \mathrm{sbl}(k) - O(\log(\mathrm{sbl}(k)))\,,$$

as required.

Finally, assume that $U \neq V(T_d)$. If U does not contain the root, apply Claim 8 and the estimate $\mathrm{sbl}(k) \leq 2\mathrm{st}(k)$, to obtain $e_{T_d}(U) \geq \mathrm{sbl}(|U|)/2$. If U does contain the root, apply Claim 8 to $\bar{U} = V(T_d) \setminus U$ and note that $\mathrm{sbl}(|U|) \leq 2\mathrm{st}(|\bar{U}|)$ whenever $\bar{U} \neq \emptyset$. $\blacktriangleleft$

The next lemma shows that, up to a constant factor, $\mathrm{sbl}(k)$ and $\mathrm{drops}(k)$ are the same.

▶ **Lemma 9.** *For every $k \geq 0$, we have* $\mathrm{drops}(k) \leq \mathrm{sbl}(k) \leq 2\mathrm{drops}(k)$.

Proof. We start by showing that $\mathrm{sbl}(k) \leq 2\mathrm{drops}(k)$. First, note that k can be written as

$$k = \sum_{i=1}^{t} \sum_{r_i \leq j \leq \ell_i} 2^j\,, \tag{6}$$

where $t \leq \mathrm{drops}(k)$ and $r_1 \leq \ell_1 < r_2 \leq \ell_2 < \cdots < r_t \leq \ell_t$ are non-negative integers. Second, note that each sum $\sum_{r_i \leq j \leq \ell_i} 2^j$ can be expressed in terms of at most two signed powers of 2.

In order to prove the other inequality, we first note that for every $k, j \geq 0$

$$|\mathrm{drops}(k + 2^j) - \mathrm{drops}(k)| \leq 1\,. \tag{7}$$

To see (7), assume first that $B_j(k) = 0$. Then adding 2^j can introduce one drop if $B_{j+1}(k) = 0$ and delete one drop if $j > 0$ and $B_{j-1}(k) = 1$. If $B_j(k) = 1$, let ℓ be the smallest integer with $B_\ell(k) = 0$ and $\ell > j$. The binary representations of k and $k + 2^j$ are the same, except that $B_\ell(k + 2^j) = 1$ and $B_i(k + 2^j) = 0$ for every $j \leq i < \ell$. The number of drops in $k + 2^j$

can increase only if $B_{j-1}(k) = 1$ and $j > 0$, and increases at most by one. It can decrease only if $B_{\ell+1}(k) = 1$, and again at most by one.

By induction on $\mathrm{sbl}(k)$, we now prove that for every $k \geq 0$, $\mathrm{drops}(k) \leq \mathrm{sbl}(k)$. If $\mathrm{sbl}(k) = 0$, the statement holds. Otherwise, let $k_1, \ldots, k_b$, with $b = \mathrm{sbl}(k)$, be signed powers of two that sum to k. Choose k_i so that $k - k_i$ is non-negative. Hence, (7) shows that $\mathrm{drops}(k - k_i) \geq \mathrm{drops}(k) - 1$. Furthermore, we have $\mathrm{sbl}(k - k_i) = \mathrm{sbl}(k) - 1$. By the inductive assumption, $\mathrm{sbl}(k - k_i) \geq \mathrm{drops}(k - k_i)$. Altogether, $\mathrm{sbl}(k) = \mathrm{sbl}(k - k_i) + 1 \geq (\mathrm{drops}(k) - 1) + 1 = \mathrm{drops}(k)$, completing the proof. ◀

Proof of Theorems 4 and 5. The lower bounds in both theorems follow from Lemmas 7 and 9, since $\mathrm{drops}(\sigma_d) = d/2$ for σ_d as defined in (3). The proof of the upper bounds is by induction and is not presented due to space considerations. ◀

Remarks

First, none of the bounds in Theorem 5 is tight for all k. For example, the $2\mathrm{drops}(k)$ upper bound exceeds the upper bound from Theorem 4 for $k = \sigma_d$ from (3). Furthermore, we do not know which of the bounds in Theorem 4 is more accurate.

Second, we have $\mathrm{eip}_{T_d}(\sigma_d) \leq d/2 - \Omega(\log d)$. Hence, the lower bound of $\mathrm{drops}(k) - O(\log(\mathrm{drops}(k))$ from Theorem 5 cannot be improved as a function of $\mathrm{drops}(k)$. A similar statement holds for Lemma 7 and $\mathrm{sbl}(k)$.

Third, the quantity $\mathrm{st}(k)$ from Claim 8 characterizes eip almost exactly: $\mathrm{st}(k) - 1 \leq \mathrm{eip}_{T_d}(k) \leq \mathrm{st}(k)$. This can be deduced from Claim 8 and Theorem 2.3 from [3]. It also implies $|\mathrm{eip}_{T_d}(k) - \mathrm{sbl}(k)| \leq O(\log k)$.

Fourth, we do not know of a simple procedure to compute $\mathrm{eip}_{T_d}(k)$, or to find a subset of size k that minimizes the boundary-size. The quantity $\mathrm{sbl}(k)$, however, can be computed exactly and quite easily, in time polynomial in $\log k$, which allows to efficiently approximate $\mathrm{eip}_{T_d}(k)$ more accurately.

3 Algebraic complexity

In this section, we prove the separation between monotone circuits and ABPs stated in Theorem 1, and the structure of ABPs stated in Lemma 3.

3.1 The tree function

We first describe a boolean function $\mathcal{T}_{d,m}$ which is later used to prove our separation. Recall that T_d is the full binary tree of depth d, and let V be the set of its vertices. For an integer $m > 1$, let $\mathbb{Z}_m$ be the additive group of integers modulo m, and let $\mathbb{Z}_m^V$ be the set of functions $\gamma : V \to \mathbb{Z}_m$.

A function $\gamma \in \mathbb{Z}_m^V$ will be called *legal*, if for every vertex v which is not a leaf and its two children v_1, v_2, we have

$$\gamma(v) = \gamma(v_1) + \gamma(v_2)\,.$$

The tree function $\mathcal{T}_{d,m} : \mathbb{Z}_m^V \to \{0,1\}$ takes $\gamma \in \mathbb{Z}_m^V$ and accepts if γ is legal.

For a node $v \in V$, let $T(v)$ be the full subtree of T_d rooted at v and let $\ell(T(v))$ be the set of its leaves. Then γ is legal iff

$$\gamma(v) = \sum_{u \in \ell(T(v))} \gamma(u) \tag{8}$$

holds for every vertex v in T.

The following lemma depicts the key property of $\mathcal{T}_{d,m}$ that we later use. For two functions f, g over the same domain, write $f \leq g$ if $f(x) \leq g(x)$ for all x. Denote by $\sup(f)$ the set of inputs x so that $f(x) = 1$.

▶ **Lemma 10.** *Let V_0, V_1 be a partition of V where $|V_0| = \sigma_d$, as defined in (3). If*

$$h_0 : \mathbb{Z}_m^{V_0} \to \{0,1\}, \quad h_1 : \mathbb{Z}_m^{V_1} \to \{0,1\}, \quad h_0 \wedge h_1 \leq \mathcal{T}_{d,m},$$

then $|\sup(h_0 \wedge h_1)| \leq m^{-d/16} |\sup(\mathcal{T}_{d,m})|$.

Proof. View T_d as directed from leaves to root. A directed path $v_1, \ldots, v_k$ in T_d from $v_1 \in \ell(T(v_k))$ to v_k will be called *pure* if $v_1 \neq v_k$ and there exists $i \in \{0,1\}$ so that $\{v_1, \ldots, v_k\} \cap V_i = \{v_k\}$. A node will be called *pure* if it is the last node of some pure path. Let $P \subset V$ be the set of pure nodes. Let E be the edge boundary of V_0.

To prove the lemma, we use the following two claims.

▶ **Claim 11.** $|P| \geq |E|/4$.

Proof of Claim 11. Let S be the set of nodes $v \in V$ so that the parent of v in T_d is pure. Since $|S| \leq 2|P|$, it is enough to show that $|S| \geq |E|/2$. Let T' be the minor of T_d obtained by contracting all the edges of T_d not in E. The tree T' is a (not necessarily binary) tree with $|E|$ edges. For $x \in V(T')$, let $[x] \subseteq V$ be the set of vertices that have been contracted to x. The root of T' is the vertex x so that the root of T_d is in $[x]$. View T' as directed from leaves to the root. For $x \in V(T')$, let $v(x) \in V$ be the vertex in $[x]$ that is closest to the root of T_d. This is well defined, since the set $[x]$ is connected in T_d. For every leaf $x \in V(T')$, we have $v(x) \in S$. For every $x \in V(T')$ with in-degree one which is not the root of T', the vertex $v(x)$ is also in S. Recall that T' can have at most $|E|/2$ vertices of in-degree at least two. Hence, $|S| \geq (|E|+1) - (|E|/2+1)$, as required. ◀

For every pure node v, fix a leaf $\tilde{v}$ such that the path from $\tilde{v}$ to v is pure. Let $\tilde{P} = \{\tilde{v} : v \in P\}$. The sizes of $\tilde{P}$ and P are the same.

▶ **Claim 12.** *Assume $\sup(h_0) \neq \emptyset$. Then every $\beta \in \sup(h_1)$ is uniquely determined by its values on $(\ell(T_d) \cap V_1) \setminus \tilde{P}$.*

Proof of Claim 12. Fix $\alpha \in \sup(h_0)$. For the sake of contradiction, assume that there are two distinct $\beta_1, \beta_2 \in \sup(h_1)$ which agree on $(\ell(T_d) \cap V_1) \setminus \tilde{P}$. Since $h_0 \wedge h_1 \leq \mathcal{T}_{d,m}$, both $\alpha \cup \beta_1$ and $\alpha \cup \beta_2$ are legal maps satisfying (8). Hence, β_1 and β_2 differ on some leaf in V_1. They agree on leaves outside of $\tilde{P}$ and so there exists a pure node $v \in V_0$ such that $\beta_1(\tilde{v}) \neq \beta_2(\tilde{v})$. We can assume that v is minimal in that for every pure node $u \in T(v) \cap V_0$ with $u \neq v$, we have $\beta_1(\tilde{u}) = \beta_2(\tilde{u})$. Since every pure path that starts in $\ell(T(v)) \cap V_1$ must also end in $T(v)$, we obtain that $\beta_1(u) = \beta_2(u)$ for every leaf in $T(v) \cap V_1$ with the sole exception of $\tilde{v}$. But this is impossible since (8) implies that for every $i \in \{1,2\}$,

$$\alpha(v) - \sum_{u \in \ell(T(v)) \cap V_0} \alpha(u) = \beta_i(\tilde{v}) + \sum_{u \in (\ell(T(v)) \cap V_1) \setminus \{\tilde{v}\}} \beta_i(u)\,,$$

which gives $\beta_1(\tilde{v}) = \beta_2(\tilde{v})$. ◀

To conclude the lemma, assume that $\sup(h_0 \wedge h_1) \neq \emptyset$, otherwise we are done. Claim 12 shows that

$$|\sup(h_0)| \leq m^{|(\ell(T_d) \cap V_0) \setminus \tilde{P}|}\,, \quad |\sup(h_1)| \leq m^{|(\ell(T_d) \cap V_1) \setminus \tilde{P}|}\,.$$

Since $|\sup(\mathcal{T}_{d,m})| = m^{|\ell(T_d)|}$,

$$|\sup(h_0)| \cdot |\sup(h_1)| \leq m^{|\ell(T_d)|-|\tilde{P}|} = m^{-|\tilde{P}|}|\sup(\mathcal{T}_{d,m})|\,.$$

Finally, Claim 11 and Corollary 6 give $|\tilde{P}| = |P| \geq |E|/4 \geq e_{T_d}(V_0)/4 \geq d/16$. ◀

3.2 The tree polynomial

We now describe the polynomial that separates monotone circuits from ABPs. Recall that T_d is the full binary tree of depth d and $\mathcal{T}_{d,m} : \mathbb{Z}_m^V \to \{0,1\}$ is the tree function, where $V = V(T_d)$. For every $v \in T_d$ and $z \in \mathbb{Z}_m$, introduce the variable $x_{v,z}$. For a partial function $\gamma : V \to \mathbb{Z}_m$, define the monomial $x_\gamma = \prod_{v \in \mathrm{dom}(\gamma)} x_{v,\gamma(v)}$. Define the tree polynomial as

$$\mathcal{P}_{d,m} = \sum_{\gamma \in \mathbb{Z}_m^V : \mathcal{T}_{d,m}(\gamma)=1} x_\gamma\,.$$

It is homogeneous of degree $|V| = 2^{d+1} - 1$ and it has $m|V|$ variables.

We now prove a generalization of Theorem 1.

▶ **Proposition 13.** *The polynomial $\mathcal{P}_{d,m}$ can be computed by a monotone arithmetic circuit of size $O(m^2 2^d)$. However, every monotone ABP computing $\mathcal{P}_{d,m}$ has size at least $m^{\Omega(d)}$.*

Theorem 1 follows from Proposition 13 by setting $m = 2^d$.

Proof of Proposition 13. We first prove the lower bound. Assume that $\mathcal{P}_{d,m}$ has a monotone ABP of size s. Let σ_d be as defined in (3). By Lemma 3, we can write

$$\mathcal{P}_{d,m} = \sum_{i=1}^{s} h_i g_i\,,$$

where h_i, g_i are homogeneous and monotone, h_i has degree σ_d and g_i has degree $\deg(\mathcal{P}_{d,m}) - \sigma_d$. We can assume $h_i g_i \neq 0$ for every i. For a polynomial f, let $\mathrm{mon}(f)$ be the set of γ's such that x_γ has a non-zero coefficient in f, and let $f^\star$ be the boolean function with $\sup(f^\star) = \mathrm{mon}(f)$. Monotonicity guarantees that for every $i \in [s]$, there exists $V_i \subseteq V$ with $|V_i| = \sigma_d$ such $\mathrm{mon}(h_i) \subseteq \mathbb{Z}_m^{V_i}$ and $\mathrm{mon}(g_i) \subseteq \mathbb{Z}_m^{V \setminus V_i}$. Therefore,

$$\mathcal{P}^\star_{d,m} = \bigvee_{i=1}^{s} h_i^\star \wedge g_i^\star\,.$$

Since $\mathcal{P}^\star_{d,m} = \mathcal{T}_{d,m}$, Lemma 10 gives $s \geq m^{d/16}$.

For the upper bound, fix m and proceed by induction on d. For $a \in \mathbb{Z}_m$, let $F_{a,d}$ be the polynomial defined as $\mathcal{P}_{d,m}$, except γ range over legal maps with $\gamma(v_d) = a$, where v_d is the root. Hence, $\mathcal{T}_{d,m} = \sum_{a \in \mathbb{Z}_m} F_{a,d}$.

We will show that $F_{d,a}$, for all $a \in \mathbb{Z}_m$, can be simultaneously computed by a circuit of size $s(d) = O(m^3 2^d)$. For $d = 0$, we have $s(d) = O(m)$. Assume that $d > 0$. Let T_ℓ be the left subtree of T_d of depth $d-1$, and let T_r be the right subtree of depth $d-1$. Let C_ℓ, C_r be the two circuits guaranteed by induction on T_ℓ, T_r. For $a \in \mathbb{Z}_m$, denote by $f_{\ell,a}$ the polynomial computed in C_ℓ so that the root of T_ℓ is mapped to a, and similarly define $f_{r,a}$. To define the circuit for $F_{d,a}$, use the following:

$$F_{d,a} = \sum_{a_\ell, a_r \in \mathbb{Z}_m : a = a_\ell + a_r} f_{\ell,a_\ell} f_{r,a_r} x_{v_d,a},$$

Overall, we get the recursion

$$s(d) \leq O(m^2) + 2 \cdot S(d-1),$$

showing that $s(d) = O(m^2 2^d)$. ◀

3.3 The structure of ABPs

We end this section by proving Lemma 3.

Proof of Lemma 3. Let P be an ABP computing a homogeneous polynomial f of degree r. For a vertex v in P, denote by h_v the polynomial

$$h_v = \sum_{\gamma : v_{\text{start}} \to v} \prod_{e \in \gamma} L_P(e)$$

and denote by g_v the polynomial

$$g_v = \sum_{\gamma : v \to v_{\text{end}}} \prod_{e \in \gamma} L_P(e).$$

Since the computation is monotone and f homogeneous, both h_v, g_v are homogeneous and the sum of their degrees is r. Denote by U the set of vertices v in P so that the degree of h_v is k. Every directed path from v_{start} to v_{end} in P passes through U exactly once. It follows that

$$f = \sum_{v \in U} h_v g_v,$$

as needed. ◀

Abstract

We initiate a systematic study of tolerant testers of image properties or, equivalently, algorithms that approximate the distance from a given image to the desired property (that is, the smallest fraction of pixels that need to change in the image to ensure that the image satisfies the desired property). Image processing is a particularly compelling area of applications for sublinear-time algorithms and, specifically, property testing. However, for testing algorithms to reach their full potential in image processing, they have to be tolerant, which allows them to be resilient to noise. Prior to this work, only one tolerant testing algorithm for an image property (image partitioning) has been published.

We design efficient approximation algorithms for the following fundamental questions: What fraction of pixels have to be changed in an image so that it becomes a half-plane? a representation of a convex object? a representation of a connected object? More precisely, our algorithms approximate the distance to three basic properties (being a half-plane, convexity, and connectedness) within a small additive error ϵ, after reading a number of pixels polynomial in $1/\epsilon$ and independent of the size of the image. The running time of the testers for half-plane and convexity is also polynomial in $1/\epsilon$. Tolerant testers for these three properties were not investigated previously. For convexity and connectedness, even the existence of distance approximation algorithms with query complexity independent of the input size is not implied by previous work. (It does not follow from the VC-dimension bounds, since VC dimension of convexity and connectedness, even in two dimensions, depends on the input size. It also does not follow from the existence of non-tolerant testers.)

Our algorithms require very simple access to the input: uniform random samples for the half-plane property and convexity, and samples from uniformly random blocks for connectedness. However, the analysis of the algorithms, especially for convexity, requires many geometric and combinatorial insights. For example, in the analysis of the algorithm for convexity, we define a set of reference polygons P_ϵ such that (1) every convex image has a nearby polygon in P_ϵ and (2) one can use dynamic programming to quickly compute the smallest empirical distance to a polygon in P_ϵ. This construction might be of independent interest.

1 Introduction

Image processing is a particularly compelling area of applications for sublinear-time algorithms and, specifically, property testing. Images are huge objects, and our visual system manages to process them very quickly without examining every part of the image. Moreover, many applications in image analysis have to process a large number of images online, looking for an image that satisfies a certain property among images that are generally very far from satisfying it. Or, alternatively, they look for a subimage satisfying a certain property in a large image (e.g., a face in an image where most regions are part of the background.) There is a growing number of proposed *rejection-based* algorithms that employ a quick test that is likely to reject a large number of unsuitable images (see, e.g., citations in [15]).

Property testing [21, 10] is a formal study of fast algorithms that accept objects with a given property and reject objects that are far. Testing image properties in this framework was first considered in [19]. Ron and Tsur [20] initiated property testing of images with a different input representation, suitable for testing properties of sparse images. Since these models were proposed, several sublinear-time algorithms for visual properties were implemented and used: namely, those by Kleiner et al. and Korman et al. [15, 16, 17].

However, for sublinear-time algorithms to reach their full potential in image processing, they have to be resilient to noise: images are often noisy, and it is undesirable to reject images that differ only on a small fraction of pixels from an image satisfying the desired property. Tolerant testing was introduced by Parnas, Ron and Rubinfeld [18] exactly with this goal in mind—to deal with noisy objects. It builds on the property testing model and calls for algorithms that accept objects that are close to having a desired property and reject objects that are far. Another related task is approximating distance of a given object to a nearest object with the property within additive error ϵ. (Distance approximation algorithms imply tolerant testers in a straightforward way.) The only image problem for which tolerant testers were studied is the image partitioning problem investigated by Kleiner et al. [15].

Our results. We design efficient approximation algorithms for the following fundamental questions: What fraction of pixels have to be changed in an image so that it becomes a half-plane? a representation of a convex object? a representation of a connected object? In other words, we design algorithms that approximate the distance to being a half-plane, convexity and connectedness within a small additive error or, equivalently, tolerant testers for these properties. These problems were not investigated previously in the tolerant testing framework. For all three properties, we give ϵ-additive distance approximation algorithms that run in constant time (i.e., dependent only on ϵ, but not the image size). We remark that even though it was known that these properties can be tested in constant time [19], this fact does not necessarily imply constant-query tolerant testers for these properties. E.g., Fischer and Fortnow [9] exhibit a property (of objects representable with strings of length n) which is testable with a constant number of queries, but for which every tolerant tester requires $n^{\Omega(1)}$ queries. For convexity and connectedness, even the existence of distance approximation algorithms with query (or time) complexity independent of the input size does not follow from previous work. It does not follow from the VC-dimension bounds, since VC dimension of convexity and connectedness, even in two dimensions, depends on the input size[1]. Implications of the VC dimension bound on convexity are further discussed below.

[1] For $n \times n$ images, the VC dimension of convexity is $\Theta(n^{2/3})$ (this is the maximum number of vertices of a convex lattice polygon in an $n \times n$ lattice [1]); for connectedness, it is $\Theta(n)$.

Table 1 Our results on distance approximation. To get complexity of (ϵ_1, ϵ_2)-tolerant testing, substitute $\epsilon = (\epsilon_2 - \epsilon_1)/2$.

Property	Sample Complexity	Run Time	Access to Input
Half-plane	$O\left(\frac{1}{\epsilon^2}\log\frac{1}{\epsilon}\right)$	$O\left(\frac{1}{\epsilon^3}\log\frac{1}{\epsilon}\right)$	uniformly random pixels
Convexity	$O\left(\frac{1}{\epsilon^2}\log\frac{1}{\epsilon}\right)$	$O\left(\frac{1}{\epsilon^8}\right)$	uniformly random pixels
Connectedness	$O\left(\frac{1}{\epsilon^4}\right)$	$\exp\left(O\left(\frac{1}{\epsilon}\right)\right)$	uniformly random blocks of pixels

Our results on distance approximation are summarized in Table 1. Our algorithm for convexity is the most important and technically difficult of our results, requiring a large number of new ideas to get running time polynomial in $1/\epsilon$. To achieve this, we define a set of reference polygons P_ϵ such that (1) every convex image has a nearby polygon in P_ϵ and (2) one can use dynamic programming to quickly compute the smallest empirical distance to a polygon in P_ϵ. It turns out that the empirical error of our algorithm is proportional to the sum of the square roots of the areas of the regions it considers in the dynamic program. To guarantee (2) and keep our empirical error small, our construction ensures that the sum of the square roots of the areas of the considered regions is small. This construction might be of independent interest.

Our algorithms do not need sophisticated access to the input image: uniformly randomly sampled pixels suffice for our algorithms for the half-plane property and convexity. For connectedness, we allow our algorithms to query pixels from a uniformly random block. (See the end of Section 2 for a formal specification of the input access.)

Our algorithms for convexity and half-plane work by first implicitly learning the object[2]. PAC learning was defined by Valiant [23], and agnostic learning, by Kearns et al. [14] and Haussler [12]. As a corollary of our analysis, we obtain fast proper agnostic PAC learners of half-planes and of convex sets in two dimensions that work under the uniform distribution. The sample and time complexity[3] of the PAC learners is as indicated in Table 1 for distance approximation algorithms for corresponding properties.

While the sample complexity of our agnostic half-plane learner (and hence our distance approximation algorithm for half-planes) follows from the VC dimension bounds, its running time does not. Agnostically learning half-spaces under the uniform distribution has been studied by [13], but only for the hypercube $\{-1, 1\}^d$ domains, not the plane. Our PAC learner of convex sets, in contrast to our half-plane learner, dimension lower bounds on sample complexity. (The sample complexity of a PAC learner for a class is at least proportional to the VC dimension of that class [8].) Since VC dimension of convexity of $n \times n$ images is $\Theta(n^{2/3})$, proper PAC learners of convex sets in two dimensions (that work under arbitrary

[2] There is a known implication from learning to testing. As proved in [10], a proper PAC learning algorithm for property $\mathcal{P}$ with sampling complexity $q(\epsilon)$ implies a 2-sided error (uniform) property tester for $\mathcal{P}$ that takes $q(\epsilon/2) + O(1/\epsilon)$ samples. There is an analogous implication from proper agnostic PAC learning to distance approximation with an overhead of $O(1/\epsilon^2)$ instead of $O(1/\epsilon)$. We choose to present our testers first and get learners as corollary because our focus is on testing and because we want additional features for our testers, such as 1-sided error, that do not automatically follow from the generic relationship.

[3] All our results are stated for error probability $\delta = 1/3$. To get results for general δ, by standard arguments, it is enough to multiply the complexity of an algorithm by $\log 1/\delta$.

distributions) must have sample complexity $\Omega(n^{2/3})$. However, one can do much better with respect to the uniform distribution. Schmeltz [22] showed that a non-agnostic learner for that task needs $\Theta(\epsilon^{-3/2})$ samples. Surprisingly, it appears that this question has not been studied at all for agnostic learners. Our agnostic learner for convex sets in 2D under the uniform distribution needs $O\left(\frac{1}{\epsilon^2}\log\frac{1}{\epsilon}\right)$ samples and runs in time $O\left(\frac{1}{\epsilon^8}\right)$.

Finally, we note that for connectedness, we take a different approach. Our algorithms do not try to learn the object first; instead they rely on a combinatorial characterization of distance to connectedness. We show that distance to connectedness can be represented as an average of distances of sub-images to a related property.

Comparison to other related work. Property testing has rich literature on graphs and functions, however, properties of images have been investigated very little. Even though superficially the inputs to various types of testing tasks might look similar, the problems that arise are different. In the line of work on testing dense graphs, started by Goldreich et al. [10], the input is also an $n \times n$ binary matrix, but it represents an adjacency matrix of the dense input graph. So, the problems considered are different than in this work. In the line of work on testing geometric properties, started by Czumaj, Sohler, and Ziegler [7] and Czumaj and Sohler [6], the input is a set of points represented by their coordinates. The allowed queries and the distance measure on the input space are different from ours.

A line of work potentially relevant for understanding connectedness of images is on connectedness of bounded-degree graphs. Goldreich and Ron [11] gave a tester for this property, subsequently improved by Berman et al. [3]. Campagna et al. [5] gave a tolerant tester for this problem. Even though we view our image as a graph in order to define connectedness of images, there is a significant difference in how distances between instances are measured (see [19] for details). We also note, that unlike in [5], our tolerant tester for connectedness is fully tolerant, i.e., it works for all settings of parameters.

The only previously known tolerant tester for image properties was given by Kleiner et al. [15]. They consider the following class of image partitioning problems, each specified by a $k \times k$ binary template matrix T for a small *constant* k. The image satisfies the property corresponding to T if it can be partitioned by $k-1$ horizontal and $k-1$ vertical lines into blocks, where each block has the same color as the corresponding entry of T. Kleiner et al. prove that $O(1/\epsilon^2)$ samples suffice for tolerant testing of image partitioning properties. Note that VC dimension of such a property is $O(1)$, so by Footnote 2, we can get a $O(1/\epsilon^2 \log 1/\epsilon)$ bound. Our algorithms required numerous new ideas to significantly beat VC dimension bounds (for convexity and connectedness) and to get low running time.

For the properties we study, distance approximation algorithms and tolerant testers were not investigated previously. In the standard property testing model, the half-plane property can be tested in $O(\epsilon^{-1})$ time [19], convexity can be tested in $O(\epsilon^{-4/3})$ time [2], and connectedness can be tested in $O(\epsilon^{-2}\log\epsilon^{-1})$ time [19, 3]. As we explained, property testers with running time independent of ϵ do not necessarily imply tolerant testers with that feature. Many new ideas are needed to obtain our tolerant testers. In particular, the standard testers for half-plane and connectedness are adaptive while the testers here need only random samples from the image, so the techniques used for analyzing them are different. The tester for convexity in [2] uses only random samples, but it is not based on dynamic programming.

Open questions. In this paper we give tolerant testers for several important problems on images. It is open whether these testers are optimal. No nontrivial lower bounds are

known for these problems. (For any non-trivial property, an easy lower bound on the query complexity of a distance approximation algorithm is $\Omega(1/\epsilon^2)$. This follows from the fact that $\Omega(1/\epsilon^2)$ coin flips are needed to distinguish between a fair coin and a coin that lands heads with probability $1/2+\epsilon$.) Thus, our testers for half-plane and convexity are nearly optimal in terms of query complexity (up to a logorithmic factor in $1/\epsilon$). But it is open whether their running time can be improved.

Organization. We give formal definitions and notation in Section 2, deferring some standard definitions to the full version of this article. Algorithms for being a half-plane, convexity, and connectedness are given in Sections 3, 4, and 5, respectively. We view our half-plane result as a good preparation for our distance approximation algorithm for convexity, the most technically difficult result in the paper. Corollaries about PAC learners as well as all omitted proofs and numerous figures can be found in the full version of this article.

2 Definitions and Notation

We use $[0..n)$ to denote the set of integers $\{0,1,\ldots,n-1\}$ and $[n]$ to denote $\{1,2,\ldots,n\}$.

Image representation. We focus on black and white images. For simplicity, we only consider square images, but everything in this paper can be easily generalized to rectangular images. We represent an image by an $n\times n$ binary matrix M of pixel values, where 0 denotes white and 1 denotes black. We index the matrix by $[0..n)^2$. The object is a subset of $[0..n)^2$ corresponding to black pixels; namely, $\{(i,j)\mid M[i,j]=1\}$.

The *absolute distance*, $Dist(M_1,M_2)$, between matrices M_1 and M_2 is the number of the entries on which they differ. The *relative distance* between them is $dist(M_1,M_2)=Dist(M_1,M_2)/n^2$. A property $\mathcal{P}$ is a subset of binary matrices.

Access to the input. A *query-based* algorithm accesses its $n\times n$ input matrix M by specifying a query pixel (i,j) and obtaining $M[i,j]$. A *uniform* algorithm accesses its $n\times n$ input matrix by drawing independent samples (i,j) from the uniform distribution over the domain (i.e., $[0..n)^2$) and obtaining $M[i,j]$. A *block-uniform algorithm* accesses its $n\times n$ input matrix by specifying a block length $r\in[n]$. For a block length r of its choice, the algorithm draws $x,y\in[\lceil n/r\rceil]$ uniformly at random and obtains set $\{(i,j)\mid \lfloor i/r\rfloor=x \text{ and } \lfloor j/r\rfloor=y\}$ and $M[i,j]$ for all (i,j) in this set. The sample complexity of a *uniform* or a *block-uniform* algorithm is the number of pixels of the image it examines.

▶ Remark 2.1. Uniform algorithms have access to independent (labeled) samples from the uniform distribution over the domain. *Bernoulli algorithms* only have access to (labeled) Bernoulli samples from the image: namely, each pixel appears in the sample with probability s/n^2, where s is the sample parameter that controls the expected sample complexity. By standard arguments, a Bernoulli algorithm with the sample parameter s can be used to obtain a uniform algorithm that takes $O(s)$ samples and has the same guarantees as the original algorithm (and vice versa).

3 Distance Approximation to the Nearest Half-Plane

An image is a *half-plane* if there exist an angle $\varphi\in[0,2\pi)$ and a real number c such that $M[x,y]=1$ (i.e., pixel (x,y) is black) iff $x\cos\varphi+y\sin\varphi\geq c$. In other words, an image is a half-plane if there is a line, called a *separating line*, that separates black and white pixels of

the image. For all φ and c, let M_c^φ denote the half-plane that satisfies the above inequality with parameters φ and c, and let L_c^φ be the segment of the separating line that belongs to the image. We call φ the *direction* of M_c^φ (and L_c^φ). Note that φ is the oriented angle between the x-axis and a line perpendicular to L_c^φ.

▶ **Theorem 3.1.** *There is a uniform ϵ-additive distance approximation algorithm for the half-plane property with sample complexity $O(\frac{1}{\epsilon^2}\log\frac{1}{\epsilon})$ and time complexity $O(\frac{1}{\epsilon^3}\log\frac{1}{\epsilon})$.*

Proof. At a high level, our algorithm (Algorithm 1) constructs a small set H_ϵ of reference half-planes. It samples pixels uniformly at random and outputs the empirical distance to the closest reference half-plane. The core property of H_ϵ is that the smallest empirical distance to a half-plane in H_ϵ can be computed quickly.

▶ **Definition 3.2** (Reference directions and half-planes)**.** Given $\epsilon \in (0, \frac{1}{4})$, let $a = \epsilon n/\sqrt{2}$. Let D_ϵ be the set of directions of the form $i\epsilon$ for $i \in [0..\lceil 2\pi/\epsilon\rceil)$, called *reference directions*. The set of *reference half-planes*, denoted H_ϵ, consists of half-planes of the form M_c^φ, where $\varphi \in D_\epsilon$, the reference line intersects $[0, n-1]^2$, and c is an integer multiple of a.

In other words, for every reference direction, we space reference half-planes distance a apart. By definition, there are at most $\sqrt{2}n/a = 2/\epsilon$ reference half-planes for each direction in D_ϵ and, consequently, $|H_\epsilon| \le 2\pi/\epsilon \cdot (2/\epsilon) < 13/\epsilon^2$.

Algorithm 1: Distance approximation to being a half-plane.

Input : parameters $n \in \mathbb{N}$, $\epsilon \in (0, 1/4)$; Bernoulli access to an $n \times n$ binary matrix M.

1 Sample a set S of $s = \frac{4}{\epsilon^2}\ln\frac{9}{\epsilon}$ pixels uniformly at random with replacement.
2 Let D_ϵ and H_ϵ be the sets of reference directions and half-planes, respectively (see Definition 3.2) and let $a = \epsilon n/\sqrt{2}$.
`//` Compute $\hat{d} = \min_{M' \in H_\epsilon} \hat{d}(M')$, where $\hat{d}(M') = \frac{1}{s}\cdot|\{p \in S : M[p] \neq M'[p]\}|$:
3 **foreach** $\varphi \in D_\epsilon$ **do**
`//` Lines with direction φ partition the image. Bucket sort samples by position in the partition:
4 Assign each sample $(x, y) \in S$ to bucket $j = \lfloor (x\cos\varphi + y\sin\varphi)/a \rfloor$.
5 For each bucket j, compute w_j and b_j, the number of white and black pixels it has.
6 For each j, where $M_{ja}^\varphi \in H_\epsilon$, compute $\hat{d}(M_{ja}^\varphi) = \frac{1}{s}\sum_{k<j} b_k + \frac{1}{s}\sum_{k\ge j} w_k$.
7 Output $\hat{d}$, the minimum of the values computed in Step 6.

▶ **Lemma 3.3.** *For every half-plane matrix M, there is $M' \in H_\epsilon$ such that $dist(M, M') \le \epsilon/2$.*

Proof. Consider a half-plane M_c^φ. Let φ' be a reference direction closest to φ. Then $|\varphi - \varphi'| \le \epsilon/2$. We consider two cases. See Figures 1 and 2.

Case 1: Suppose that there is a reference half-plane $M_{c'}^{\varphi'}$ such that the separating line segments L_c^φ and $L_{c'}^{\varphi'}$ intersect. Note that the length of every line segment that belongs to the image is at most $\sqrt{2}n$. The symmetric difference of M_c^φ and $M_{c'}^{\varphi'}$ is contained in two regions formed by line segments L_c^φ and $L_{c'}^{\varphi'}$. Each of these regions is either a triangle or (if it contains a corner of the image) a quadrilateral. First, suppose both regions are triangles. The sum of lengths of their bases, that lie on the same line, is at most $\sqrt{2}n$, whereas the

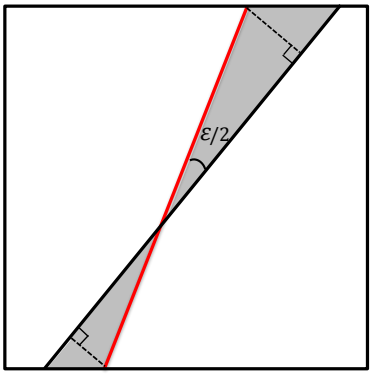

Figure 1 Proof of Lemma 3.3: triangular regions.

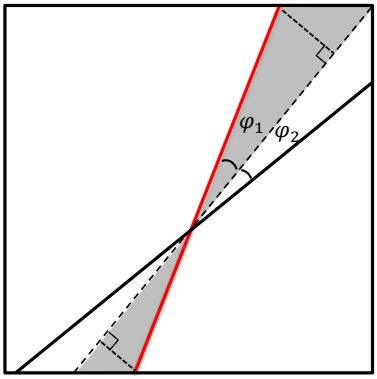

Figure 2 Proof of Lemma 3.3: triangular and quadrilateral regions.

sum of their heights is at most $\sin(\epsilon/2) \times \sqrt{2}n \leq \epsilon n/\sqrt{2}$. Hence, the sum of their areas[4] is at most $\epsilon n^2/2$.

If exactly one of the regions is a quadrilateral, we add a line through the corner of the image contained in the quadrilateral and the intersection point of L_c^{φ} and $L_{c'}^{\varphi'}$. It partitions the symmetric difference of M_c^{φ} and $M_{c'}^{\varphi'}$ into two pairs of triangular regions. Let φ_1 (respectively, φ_2) be the angle between the new line and L_c^{φ} (respectively, $L_{c'}^{\varphi'}$). Then $\varphi_1 + \varphi_2 \leq \epsilon/2$. Applying the same reasoning as before to each pair of regions, we get that the sum of their areas is at most $\varphi_1 n^2 + \varphi_2 n^2 \leq \epsilon n^2/2$. If both regions are quadrilaterals, we add a line as before for each of them and apply the same reasoning as before to the three resulting pairs of regions. Again, the area of the symmetric difference of M_c^{φ} and $M_{c'}^{\varphi'}$ is at most $\epsilon n^2/2$. Thus[4], $M_{c'}^{\varphi'}$ is the required M'.

Case 2: There exist reference half-planes with separating line segments $L = L_{c'}^{\varphi'}$ and $L' = L_{c'+a}^{\varphi'}$ such that the line segment L_c^{φ} is between L and L'. The region between L and L' has length at most $\sqrt{2}n$ and width a. Thus, its area is at most ϵn^2. Partition it into two regions: between L and L_c^{φ} and between L' and L_c^{φ}. One of the two regions has area at most $\epsilon n^2/2$. Thus, $M_{c'}^{\varphi'}$ or $M_{c'+a}^{\varphi'}$ is the required M'. ◀

Analysis of Algorithm 1. Let d_M be the distance of M to being a half-plane. Then there exists a half-plane matrix M^* such that $dist(M, M^*) = d_M$. By a uniform convergence bound (see, e.g., [4]), since $s \geq (2/\epsilon^2)(\ln|H_\epsilon| + \ln 6)$ for all $\epsilon \in (0, 1/4)$, we get that with probability at least 2/3, $|dist(M, M') - \hat{d}(M')| \leq \epsilon/2$ for all $M' \in H_\epsilon$. Suppose this event happened. Then $\hat{d} \geq d_M - \epsilon/2$ because $dist(M, M') \geq d_M$ for all half-planes M'. Moreover, by Lemma 3.3, there is a matrix $\hat{M} \in H_\epsilon$ such that $dist(M, \hat{M}) \leq dist(M, M^*) + dist(M^*, \hat{M}) \leq d_M + \epsilon/2$. For this matrix, $\hat{d}(\hat{M}) \leq dist(M, \hat{M}) + \epsilon/2 \leq d_M + \epsilon$. Thus, $d_M - \epsilon/2 \leq \hat{d} \leq d_M + \epsilon$. That is, $|d_M - \hat{d}| \leq \epsilon$ with probability 2/3, as required.

Sample and time complexity. The number of samples, s, is $O(1/\epsilon^2 \log 1/\epsilon)$. To analyze the running time, recall that $|D_\epsilon| = O(1/\epsilon)$. For each direction in D_ϵ, we bucket sort

[4] For simplicity of presentation, we equate the area of a convex region and the number of pixels in it, thus ignoring additional small-order terms. By Pick's theorem, the number of pixels could be at most the area plus $2n$. It does not affect the asymptotic analysis of our algorithms.

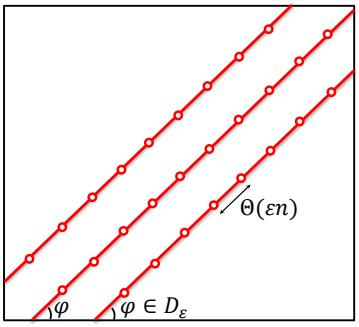

Figure 3 An illustration of reference lines and reference points.

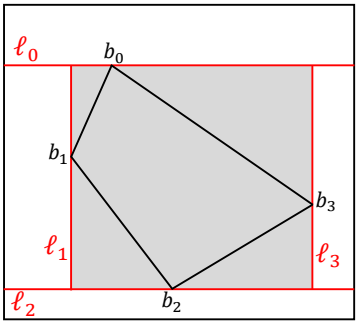

Figure 4 An illustration of a reference box and triangles of $\mathbf{T}_0$.

all samples in expected $O(s)$ time. The remaining steps in the **foreach** loop of Step 3 can be implemented to run in $O(s)$ time. The expected run time of Algorithm 1 is thus $O(1/\epsilon \cdot s) = O(1/\epsilon^3 \log 1/\epsilon)$. Remark 2.1 implies a tester with the same worst case run time. ◀

4 Distance Approximation to the Nearest Convex Image

An image is *convex* if the convex hull of all black pixels contains only black pixels.

▶ **Theorem 4.1.** *There is a uniform ϵ-additive distance approximation algorithm for convexity with sample complexity $O(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon})$ and running time $O(\frac{1}{\epsilon^8})$.*

Proof. The starting point for our algorithm for approximating the distance to convexity (Algorithm 2) is similar to that of Algorithm 1 that approximates the distance to a nearest half-plane. We define a small set P_ϵ of reference polygons. Algorithm 2 implicitly learns a nearby reference polygon and outputs the empirical distance from the image to that polygon. The key features of P_ϵ is that (1) every convex image has a nearby polygon in P_ϵ, and (2) one can use dynamic programming (DP) to quickly compute the smallest empirical distance to a polygon in P_ϵ.

We start by defining reference directions, lines, points, and line-point pairs that are later used to specify our DP instances. Reference directions are almost the same as in Definition 3.2.

▶ **Definition 4.2** (Reference lines, line-point pairs)**.** Fix $\epsilon_0 = \epsilon/144$. The set of *reference directions* is $D_\epsilon = \{\pi/2\} \cup \{i\epsilon_0 : i \in [0, \lceil 2\pi/\epsilon_0 \rceil)\}$. For every $\varphi \in D_\epsilon$, define the set of *reference lines* $L_\varphi = \{\ell : \ell$ passes through the image and satisfies the equation $x \cos\varphi + y \sin\varphi = c$, where c is an integer multiple of $\epsilon_0 n\}$. For each reference line, the set of *reference points on* ℓ contains points w.r.t. ℓ, which are inside $[0, n-1]^2$, spaced exactly $\epsilon_0 n$ apart (it does not matter how the initial point is picked). A *line-point pair* is a pair (ℓ, b), where ℓ is a reference line and b is a reference point w.r.t. ℓ. (Note that there could be reference points on ℓ that were defined w.r.t. some other reference line. This is why we say "a reference point w.r.t. ℓ", and not "a reference point on ℓ".)

Roughly speaking, a reference polygon is a polygon whose vertices are defined by line-point pairs. There are additional restrictions that stem from the fact that we need to be able to efficiently find a nearby reference polygon for an input image. The actual definition specifies

which actions we can take while constructing a reference polygon. Reference polygons are built starting from reference boxes, which are defined next.

▶ **Definition 4.3** (Reference box)**.** A *reference box* is a set of four line-point pairs (ℓ_i, b_i) for $i = 0, 1, 2, 3$, where ℓ_0, ℓ_2 are distinct horizontal lines, such that ℓ_0 is above ℓ_2, and (ℓ_1, ℓ_3) are distinct vertical lines, such that ℓ_1 is to the left of ℓ_3. The reference box defines a vertex set $B_0 = \{b_0, b_1, b_2, b_3\}$ and a triangle set $\mathbf{T}_0$, formed by removing the quadrilateral $b_0b_1b_2b_3$ from the rectangle delineated by the lines $\ell_0, \ell_1, \ell_2, \ell_3$.

Intuitively, by picking a reference box, we decide to keep the area inside the quadrilateral $b_0b_1b_2b_3$ black, the area outside the rectangle formed by $\ell_0, \ell_1, \ell_2, \ell_3$ white, and the triangles in $\mathbf{T}_0$ gray, i.e., undecided for now.

▶ **Definition 4.4.** For points x, y, let $\ell(x, y)$ denote the line that passes through x and y. Let xy denote the line segment between x and y.

Reference polygons are defined next. Intuitively, to obtain a reference polygon, we keep subdividing "gray" triangles in $\mathbf{T}_0$ into smaller triangles and deciding to color the smaller triangles black or white or keep them gray (i.e., undecided for now). We also allow "cutting off" a quadrilateral that is adjacent to black and coloring it black (a.k.a. "the base change operation"). Even though the definition of reference polygons is somewhat technical, the readers can check their understanding of this concept by following Algorithm 2, as it chooses the best reference polygon to approximate the input image.

▶ **Definition 4.5** (Reference polygon)**.** A *reference polygon* is an image of a polygon Hull(B), where the set B can be obtained from a reference box with a vertex set B_0 and a triangle set $\mathbf{T}_0$ by the following recursive process. Initially, $\mathbf{T}_{\text{end}} = \emptyset$ and $B = B_0$. While $\mathbf{T}_0 \neq \emptyset$, move a triangle T from $\mathbf{T}_0$ to $\mathbf{T}_{\text{end}}$ and perform the following steps:

1. (Base Change). Let $T = \triangle b'b''v$, where $b', b'' \in B$. Select reference point b'_0 on $b'v$ w.r.t. line $\ell(b', v)$, and reference point b''_0 on $b''v$ w.r.t. line $\ell(b'', v)$. Add b'_0, b''_0 to B. (This corresponds to coloring the quadrilateral $b'b'_0b''_0b''$ black.) Let h be the height of $\triangle b'_0b''_0v$ w.r.t. the base $b'_0b''_0$.
2. (Subdivision Step) If $h > 6\epsilon_0 n$, choose whether to proceed with this step or go to Step 3 (both choices correspond to a legal reference polygon); otherwise, go to Step 3. Let φ be the angle between $\ell(b'_0, b''_0)$ and the x-axis, and $\hat{\varphi} \in D_\epsilon$ be such that $|\hat{\varphi} - \varphi| \leq \epsilon_0/2$. Select a reference line-point pair (ℓ, b), where the line $\ell \in L_{\hat{\varphi}}$ crosses b'_0v and b''_0v, whereas b is in the triangle $\triangle b'_0b''_0v$. Let v' (resp., v'') be the point of intersection of ℓ and b'_0v (resp., ℓ and b''_0v). Let $T' = \triangle b'_0bv'$, $T'' = \triangle b''_0bv''$. Add b to B and triangles T', T'' to $\mathbf{T}_0$. (This represents coloring $\triangle b'_0b''_0b$ black and keeping T' and T'' gray.)
3. (End of Processing) Do nothing. (This represents coloring $\triangle b'_0b''_0v$ white).

By Remark 2.1, to prove Theorem 4.1, it suffices to design a Bernoulli tester that takes $s = O(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon})$ samples in expectation and runs in time $O(\frac{1}{\epsilon^8})$. Our Bernoulli tester is Algorithm 2. In Algorithm 2, we use the following notation for the (relative) empirical error with respect to an input image M, a set of sampled pixels S, and the size parameter s. For an image M', let $\hat{d}(M') = \frac{1}{s} \cdot |\{u \in S : M[u] \neq M'[u]\}|$. For every region $R \subseteq [0..n)^2$, we let $\hat{d}_+(R) = \frac{1}{s} \cdot |\{u \in S \cap R : M[u] = 0\}|$, and $\hat{d}_-(R) = \frac{1}{s} \cdot |\{u \in S \cap R : M[u] = 1\}|$, i.e., the empirical error if we make R black/white, respectively.

Subroutine Best chooses the option with the smallest empirical relative error among those given in Definition 4.5, items 1-3. Its pseudocode is in the full version of this article.

Our set of reference polygons has two critical features. First, for each convex image there is a nearby reference polygon. It turns out that the empirical error for a region is proportional

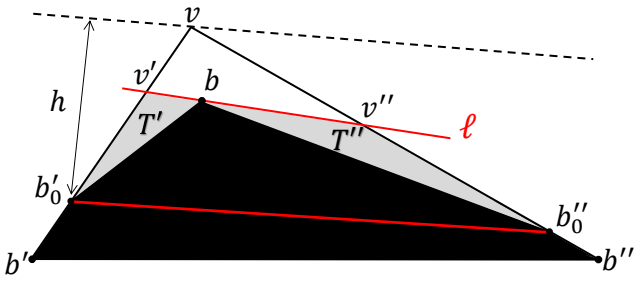

Figure 5 An illustration to Definition 4.5: Triangle $\triangle b'b''v$.

Algorithm 2: Bernoulli approximation algorithm for distance to convexity.

Input : parameters $n \in \mathbb{N}$, $\epsilon \in (0, 1/4)$; Bernoulli access to an $n \times n$ binary matrix M.

1 Set $s = \Theta(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon})$. Include each image pixel in the sample S w.p. $p = s/n^2$.

`// Run the algorithm to find` $\hat{d}$`, the smallest fraction of samples misclassified by a reference polygon in` P_ϵ`. A dynamic programming implementation of the algorithm is given in the full version.`

2 Let W_{ℓ_0} (resp., W_{ℓ_2}) be the set of pixels of the image M that lie either above ℓ_0 or to the left of b_0 on ℓ_0 (resp., either below ℓ_2 or to the left of b_2 on ℓ_2). Let W_{ℓ_1} (resp., W_{ℓ_3}) be the set of pixels of $M - W_{\ell_0} - W_{\ell_2}$ to the left of ℓ_1 (resp., to the right of ℓ_3).

3 Set $\hat{d} = 1$.

4 **forall** *line-point pairs* $(\ell_0, b_0), (\ell_2, b_2)$*, where* ℓ_0, ℓ_2 *are horizontal lines* **do**

5 Set $\hat{d}_{\text{left}} = 1$.

`// The best error for the region to the left of` b_0b_2`, between` ℓ_0 `and` ℓ_2`.`

6 **foreach** *line-point pair* (ℓ_1, b_1)*, where* ℓ_1 *is a vertical line* **do**

7 Let v_0 (resp., v_2) be the point where ℓ_1 intersects ℓ_0 (resp., ℓ_1 intersects ℓ_2).

8 $\hat{d}_{\text{left}} = \min(\hat{d}_{\text{left}}, \hat{d}_-(W_{\ell_1}) + \hat{d}_+(\triangle b_0b_1b_2) + \mathsf{Best}(\triangle b_0b_1v_0) + \mathsf{Best}(\triangle b_1b_2v_2))$

9 Similarly to Steps 5–8, compute $\hat{d}_{\text{right}}$.

`// The best error for the region to the right of` b_0b_2`, between` ℓ_0 `and` ℓ_2`.`

10 Compute $\hat{d} = \min(\hat{d}, \hat{d}_-(W_{\ell_0} \cup W_{\ell_2}) + \hat{d}_{\text{left}} + \hat{d}_{\text{right}})$.

11 **return** $\hat{d}$.

to the square root of its area. The second key feature of our reference polygons is that, for each of them, the set of considered triangles, $\mathbf{T}_{\text{end}}$, has small $\sum_{T \in \mathbf{T}_{\text{end}}} \sqrt{A(T)}$, where $A(T)$ denotes the area of triangle T. The proofs of both features, as well as the analysis of the empirical error, are quite technical and appear in the full version of this article. ◀

Here, we state and partially prove a lemma that puts together different parts of the analysis. It makes it clear why the empirical error of each region is proportional to the square root of its area which is, as explained in Footnote 4, a proxy for the number of pixels in it.

▶ **Lemma 4.6.** *With probability at least* $2/3$ *over the choice of the samples taken by Algorithm 2,* $|\hat{d}(M') - dist(M, M')| \leq 5\epsilon/6$ *for all reference polygons* M'*.*

Proof. Consider a region $R = (R_+, R_-)$, partitioned into two regions R_+ and R_-, such that in some step, the algorithm checks the assumption that R_+ is black and R_- is white, i.e., evaluates $\hat{d}_+(R_+) + \hat{d}_-(R_-)$. Let $\mathbf{R}$ be the set of all such regions R. We show that with probability at least $2/3$, the estimates $\hat{d}_+(R_+) + \hat{d}_-(R_-)$ are accurate on all regions in $\mathbf{R}$.

Fix $R = (R_+, R_-) \in \mathbf{R}$. Let Γ be the set of misclassified pixels in R, i.e., pixels in R_+ which are white in M and pixels in R_- which are black in M. Define $\gamma = |\Gamma|/n^2$. Algorithm 2 approximates γ by $\hat{d}_+(R_+) + \hat{d}_-(R_-) = \frac{1}{s}|\Gamma \cap S|$. Equivalently, it uses the estimate $\frac{1}{p}|\Gamma \cap S|$ for $|\Gamma|$ (recall that $p = s/n^2$). The error of the estimate is $err_S(R) = \frac{1}{p}|\Gamma \cap S| - |\Gamma|$.

▶ **Claim 4.7.** $\Pr[|err_S(R)| > \sqrt{\gamma} \cdot c\epsilon n^2] \leq 2\exp(-\frac{3}{8}c^2\epsilon^2 s)$, *where* $c = 1/21$.

Proof. For each pixel u, define random variables χ_u and X_u, where χ_u is the indicator for the event $u \in S$ (i.e., a Bernoulli variable with the probability parameter p), whereas $X_u = \frac{\chi_u}{p} - 1$. Then our estimate of $|\Gamma|$ is $\frac{1}{p}|\Gamma \cap S| = \frac{1}{p}\sum_{u\in\Gamma}\chi_u$, whereas $err_S(R) = \sum_{u\in\Gamma} X_u$. We use Bernstein inequality to bound $\Pr[\sum_{u\in\Gamma} X_u > \sqrt{\gamma} \cdot c\epsilon n^2]$. The variables X_u are identically distributed. The maximum value of $|X_u|$ is $a = \frac{1-p}{p}$. Note that $\mathbb{E}[X_u^2] = \frac{1}{p^2}\mathbb{E}[(\chi_u - p)^2] = \frac{1}{p^2}\operatorname{Var}[\chi_u] = \frac{1-p}{p} = a$. Assume w.l.o.g. that $z < |\Gamma|$. (If $z \geq |\Gamma|$ then $\sum_{u\in\Gamma} X_u$ cannot exceed z, and the probability we are bounding is 0.) By Bernstein inequality,

$$\begin{aligned}\Pr\left[\sum_{u\in\Gamma} X_u > z\right] &\leq \exp\left(\frac{-z^2/2}{a|\Gamma| + a\cdot z/3}\right) < \exp\left(-\frac{3}{8}\cdot\frac{z^2\cdot p}{|\Gamma|}\right) = \exp\left(-\frac{3}{8}\frac{\gamma c^2\epsilon^2 n^4}{\gamma n^2}\frac{s}{n^2}\right)\\ &= \exp(-\frac{3}{8}c^2\epsilon^2 s).\end{aligned}$$

The second inequality holds because $a < 1/p$ and $z < |\Gamma|$. The equalities are obtained by substituting the expressions for z, $|\Gamma|$, and p, and simplifying. By symmetry, $\Pr[|err_S(R)| \geq z] \leq 2\exp(-\frac{3}{8}c^2\epsilon^2 s)$. ◀

The rest of the proof appears in the full version of this article. ◀

5 Distance Approximation to the Nearest Connected Image

To define *connectedness*, we consider *the image graph* G_M of an image M. The vertices of G_M are $\{(i,j) \mid M[i,j] = 1\}$, and two vertices (i,j) and (i',j') are connected by an edge if $|i - i'| + |j - j'| = 1$. In other words, the image graph consists of black pixels connected by the grid lines. The image is *connected* if its image graph is connected.

▶ **Theorem 5.1.** *There is a block-uniform ϵ-additive distance approximation algorithm for connectedness with sample complexity $O(\frac{1}{\epsilon^4})$ and running time* $\exp\left(O\left(\frac{1}{\epsilon}\right)\right)$.

The first idea in our algorithms for connectedness is that we can modify an image by superimposing a grid on it, and as a result obtain a nearby image whose distance to connectedness is determined by the properties of individual squares into which the grid lines partition the image. The squares and the relevant property of the squares are defined next.

For a set $S \subset [0..n)^2$ and $(i,j) \in [0..n)^2$, we define $S + (i,j) = \{(x+i, y+j) : (x,y) \in S\}$.

▶ **Definition 5.2** (Squares and grid pixels)**.** Fix a side length $n \equiv 1 \pmod r$. For all integers $i, j \in [0..n-r)$, where i and j are divisible by r, the $(r-1)\times(r-1)$ image that consists of all pixels in $[r-1]^2 + (i,j)$ is called an *r-square* of M. The set of all r-squares of M is denoted S_r.

The pixels that do not lie in any squares of S_r, i.e., pixels (i,j) where i or j is divisible by r, are called *grid pixels*. The set of all grid pixels is denoted by GP_r.

▶ **Claim 5.3.** $|GP_r| \leq 2n^2/r$.

Note that a square consists of pixels of an r-block, with the pixels of the first row and column removed. Therefore, a block-uniform algorithm can obtain a uniformly random r-square.

Recall the definition of the border of an image from Section 2.

▶ **Definition 5.4** (Border connectedness)**.** A (sub)image S is *border-connected* if for every black pixel (i,j) of S, the image graph G_S contains a path from (i,j) to a pixel on the border. The property *border connectedness,* denoted $\mathcal{C}'$, is the set of all border-connected images.

The main idea behind Algorithm 3, used to prove Theorem 5.1, is to relate the distance to connectedness to the distance to another property, which we call *grid connectedness*. The latter distance is the average over squares of the distances of these squares to *border connectedness*. The average can be easily estimated by looking at a sample of the squares.

W.l.o.g. assume that $n \equiv 1 \pmod{4/\epsilon}$. (Otherwise, we can pad the image with white pixels without changing whether it is connected and adjust the accuracy parameter.)

Algorithm 3: Distance approximation to connectedness.

Input : $n \in \mathbb{N}$ and $\epsilon \in (0, 1/4)$; block-sample access to an $n \times n$ binary matrix M.

1 Sample $s = 4/\epsilon^2$ squares uniformly and independently from $S_{4/\epsilon}$ (see Definition 5.2).
`// Tho do this draw random blocks from the` $4/\epsilon$`-partition of` $[0..n)^2$`.`

2 For each such square S, compute $dist(S, \mathcal{C}')$, where $\mathcal{C}'$ is border connectedness (see Definition 5.4). Let $\hat{d}_{\text{squares}}$ be the average of computed distances $dist(S, \mathcal{C}')$.

3 **return** $\hat{d} = \left((1 - \frac{\epsilon}{4})(1 - \frac{1}{n})\right)^2 \cdot \hat{d}_{\text{squares}}$.

▶ **Definition 5.5.** Fix $\epsilon \in (0, 1/4)$. Let image M_ϵ be a *gridded image* obtained from image M as follows:

$$M_\epsilon[i,j] = \begin{cases} 1 & \text{if } (i,j) \text{ is a grid pixel from } \mathrm{GP}_{4/\epsilon}; \\ M[i,j] & \text{otherwise.} \end{cases}$$

Let $\mathcal{C}$ be the set of all connected images. For $\epsilon \in (0, 1/4)$, define *grid connectedness* $\mathcal{C}_\epsilon = \{M \mid M \in \mathcal{C}, \text{ and } M[i,j] = 1 \text{ for all } (i,j) \in \mathrm{GP}_{4/\epsilon}\}$.

▶ **Lemma 5.6.** *Let $d_M = dist(M, \mathcal{C})$ and $d_\epsilon = dist(M_\epsilon, \mathcal{C}_\epsilon)$. Then $d_M - \frac{\epsilon}{2} \le d_\epsilon \le d_M$. Moreover,*

$$d_\epsilon = \left(\left(1 - \frac{\epsilon}{4}\right)\left(1 - \frac{1}{n}\right)\right)^2 \cdot \frac{1}{|S_{4/\epsilon}|} \sum_{S \in S_{4/\epsilon}} dist(S, \mathcal{C}').$$

Proof. First, we prove that $d_\epsilon \le d_M$. Let M' be a connected image such that $dist(M, M') = d_M$. Then M'_ϵ, the gridded image obtained from M', satisfies $\mathcal{C}_\epsilon$. Since $dist(M_\epsilon, M'_\epsilon) \le d_M$, it follows that $d_\epsilon \le d_M$. Now we show that $d_M - \frac{\epsilon}{2} \le d_\epsilon$. Let $M''_\epsilon \in \mathcal{C}_\epsilon$ be such that $dist(M_\epsilon, M''_\epsilon) = d_\epsilon$. Then $M''_\epsilon \in \mathcal{C}$ and, by Claim 5.3, $dist(M, M''_\epsilon) \le |\mathrm{GP}_{4/\epsilon}|/n^2 + d_\epsilon \le \epsilon/2 + d_\epsilon$, implying $d_M \le \epsilon/2 + d_\epsilon$, as required.

Finally, observe that to make M_ϵ satisfy $\mathcal{C}_\epsilon$, it is necessary and sufficient to ensure that each square satisfies $\mathcal{C}'$. In other words,

$$d_\epsilon n^2 = \sum_{S \in S_{4/\epsilon}} Dist(S, \mathcal{C}') = (4/\epsilon - 1)^2 \sum_{S \in S_{4/\epsilon}} dist(S, \mathcal{C}').$$

Since $|S_{4/\epsilon}| = (\frac{n-1}{4/\epsilon})^2$, the desired expression for d_ϵ follows. ◀

The rest of the analysis is completed in the full version of this article.

Abstract

Property testers form an important class of sublinear algorithms. In the standard property testing model, an algorithm accesses the input function $f : \mathcal{D} \mapsto \mathcal{R}$ via an oracle. With very few exceptions, all property testers studied in this model rely on the oracle to provide function values at all queried domain points. However, in many realistic situations, the oracle may be unable to reveal the function values at some domain points due to privacy concerns, or when some of the values get erased by mistake or by an adversary. The testers do not learn anything useful about the property by querying those *erased* points. Moreover, the knowledge of a tester may enable an adversary to erase some of the values so as to increase the query complexity of the tester arbitrarily or, in some cases, make the tester entirely useless.

In this work, we initiate a study of property testers that are resilient to the presence of *adversarially erased* function values. An α-erasure-resilient ε-tester is given parameters $\alpha, \varepsilon \in (0, 1)$, along with oracle access to a function f such that at most an α fraction of function values have been erased. The tester does not know whether a value is erased until it queries the corresponding domain point. The tester has to accept with high probability if there is a way to assign values to the erased points such that the resulting function satisfies the desired property $\mathcal{P}$. It has to reject with high probability if, for every assignment of values to the erased points, the resulting function has to be changed in at least an ε-fraction of the non-erased domain points to satisfy $\mathcal{P}$.

We design erasure-resilient property testers for a large class of properties. For some properties, it is possible to obtain erasure-resilient testers by simply using standard testers as a black box. However, there are more challenging properties for which all known testers rely on querying a specific point. If this point is erased, all these testers break. We give efficient erasure-resilient testers for several important classes of such properties of functions including monotonicity, the Lipschitz property, and convexity. Finally, we show a separation between the standard testing and erasure-resilient testing. Specifically, we describe a property that can be ε-tested with $O(\frac{1}{\varepsilon})$ queries in the standard model, whereas testing it in the erasure-resilient model requires number of queries polynomial in the input size.

1 Introduction

In this paper, we revisit the question of how sublinear-time algorithms access their input. With very few exceptions, all algorithms studied in the literature on sublinear-time algorithms have *oracle* access to their input[1]. However, in many applications, this assumption is unrealistic. The oracle may be unable to reveal parts of the data due to privacy concerns, or when some of the values get erased by mistake or by an adversary. Motivated by these scenarios, we propose to study sublinear algorithms that work with partially erased data.

Formally, we view a dataset as a function over some discrete domain $\mathcal{D}$, such as $[n] = \{1, \ldots, n\}$ or $[n]^d$. For example, the classical problem of testing whether a list of n numbers is sorted in nondecreasing order can be viewed as a problem of testing whether a function $f : [n] \to \mathbb{R}$ is monotone (nondecreasing). Given a parameter $\alpha \in (0, 1)$, we say that a function is *α-erased* if at most an α fraction of its domain points are marked as "erased" or protected (that is, an algorithm is denied access to these values). An algorithm that takes an α-erased function as its input does not know which values are erased until it queries the corresponding domain points. For each queried point x, the algorithm either learns $f(x)$ or, if x is an erased point, gets back a special symbol $\perp$. We study algorithms that work in the presence of *adversarial erasures*. In other words, the query complexity of an algorithm is the number of queries it makes in the *worst case* over all α-erased input functions.

In this work, we initiate a systematic study of property testers that are resilient to the presence of adversarial erasures. An α-erasure-resilient ε-tester is given parameters $\alpha, \varepsilon \in (0, 1)$, along with oracle access to an α-erased function f. The tester has to accept with high probability if f can be restored to a function on the whole domain that satisfies the desired property $\mathcal{P}$ and reject with high probability if every restoration of f is ε-far from $\mathcal{P}$ on the nonerased part of the domain.

Generic transformations. Our first goal is to understand which existing algorithms in the standard property testing model [35, 24] can be easily made erasure-resilient. We show (in Section 2) how to obtain erasure-resilient testers for some properties by using standard testers for these properties as black box. Our transformations apply to testers that query uniformly and independently sampled points, with some additional restrictions. More specifically, our transformations work for uniform *proximity oblivious testers* (POTs) [25, 27] and uniform testers for *extendable properties*. As a result, we are able to obtain erasure-resilient testers for being a low-degree polynomial [35], monotonicity over general poset domains [22], convexity of black and white images [7], and having k runs of 0s and 1s.

Erasure-resilient testers for more challenging properties. One challenge in designing erasure-resilient testers by using existing algorithms in the standard model as a starting

[1] Sublinear-time algorithms with various distributional assumptions on the positions of the input the algorithms access have been investigated, for example, in [24, 4, 26]. There is also a line of work, initiated by [6], that studies sublinear algorithms that access distributions, as opposed to fixed datasets. In this work, we focus on fixed datasets.

point is that many existing algorithms are more likely to query certain points in the domain. Therefore, if these points are erased, the algorithms break. Specifically, the optimal algorithms for testing whether a list of numbers is sorted (and there are at least three different algorithms for this problem [17, 8, 13]) have this feature. Moreover, it is known that an algorithm that makes uniformly random queries is far from optimal: it needs $\Theta(\sqrt{n})$ queries instead of $\Theta(\log n)$ for n-element lists [17, 20].

There is a number of well studied properties for which all known optimal algorithms heavily rely on querying specific points. Most prominent examples include monotonicity, the Lipschitz properties and, more generally, bounded-derivative properties of real-valued functions on $[n]$ and $[n]^d$, as well as convexity of real-valued functions on $[n]$. It is especially challenging to deal with real-valued functions in our model, because there are many possibilities for erased values. We give efficient erasure-resilient testers for all aforementioned properties of real-valued functions in Sections 3–5.

Relationships with other models. In the full version of our paper, we provide a separation between our erasure-resilient model and the standard model. Specifically, we prove the existence of a property that can be tested with $O(1/\varepsilon)$ queries in the standard model, but requires polynomially many queries in the length of the input in the erasure-resilient model. This result builds on the ideas of Fischer and Fortnow [21] that separate tolerant testing, defined by Parnas et al. [32], from standard testing.

A tolerant tester for a property $\mathcal{P}$, given two parameters $\varepsilon_1, \varepsilon_2 \in (0,1)$, where $\varepsilon_1 < \varepsilon_2$, is required to, with probability at least $2/3$, accept inputs that are ε_1-close to $\mathcal{P}$ and reject inputs that are ε_2-far from $\mathcal{P}$. Intuitively, the relationship of our erasure-resilient model to tolerant testing is akin to the relationship between error-correcting codes that withstand erasures and error-correcting codes that withstand general errors. In the full version, we prove that the existence of tolerant testers implies the existence of erasure-resilient testers with related parameters. Using this implication and existing tolerant testers for sortedness [36], monotonicity [19], and convexity [18], we get erasure-resilient testers for these properties as corollaries. However, we obtain erasure-resilient testers for these properties with much better parameters in the technical sections of this article. We conjecture that erasure-resilient testing can be separated from tolerant testing in the same strong sense as in our separation of standard testing from erasure-resilient testing.

1.1 The Erasure-Resilient Testing Model

We formalize our erasure-resilient model for the case of property testing. Erasure-resilient versions of other computational models, such as tolerant testing, can be defined analogously.

▶ **Definition 1.1** (α-erased function)**.** Let $\mathcal{D}$ be a domain, $\mathcal{R}$ be a range, and $\alpha \in (0,1)$. A function[2] $f : \mathcal{D} \mapsto \mathcal{R} \cup \{\perp\}$ is *α-erased* if f evaluates to $\perp$ on at most an α fraction of domain points. The points on which f evaluates to $\perp$ are called *erased*. The set of remaining (nonerased) points is denoted by $\mathcal{N}$.

A function f is ε-far from a property (set) $\mathcal{P}$ if it needs to be changed on at least an ε fraction of domain points to obtain a function in $\mathcal{P}$. A function $f' : \mathcal{D} \to \mathcal{R}$ that differs from a function f only on points erased in f is called a *restoration* of f.

[2] Any object can be viewed as a function. E.g., an n-element array of real numbers can be viewed as a function $f : [n] \to \mathbb{R}$, an image—as a map from the plane to the set of colors, and a graph—as a map from the set of vertex pairs to $\{0,1\}$.

▶ **Definition 1.2** (Erasure-resilient tester)**.** An *α-erasure-resilient ε-tester* of property $\mathcal{P}$ gets input parameters $\alpha, \varepsilon \in (0,1)$ and oracle access to an α-erased function $f : \mathcal{D} \to \mathcal{R} \cup \{\perp\}$. It outputs, with probability[3] at least 2/3,

- **accept** if there is a restoration $f' : \mathcal{D} \to \mathcal{R}$ of f that satisfies $\mathcal{P}$;
- **reject** if every restoration $f' : \mathcal{D} \to \mathcal{R}$ of f needs to be changed on at least an ε fraction of $\mathcal{N}$, the nonerased portion of f's domain, to satisfy $\mathcal{P}$ (that is, f' is $\varepsilon \cdot \frac{|\mathcal{N}|}{|\mathcal{D}|}$-far from $\mathcal{P}$).

The tester has *1-sided error* if the first item holds with probability 1.

Let $f_{|\mathcal{N}}$ denote the function f restricted to the set $\mathcal{N}$ of nonerased points. In the full version, we show that if property $\mathcal{P}$ is extendable, we can define a property $\mathcal{P}_{\mathcal{N}}$ such that the erasure-resilient tester is simply required to distinguish the case that $f_{|\mathcal{N}}$ satisfies $\mathcal{P}_{\mathcal{N}}$ from the case that it is ε-far from satisfying it. For example, if $\mathcal{P}$ is monotonicity of functions on a partially-ordered domain $\mathcal{D}$ then $\mathcal{P}_{\mathcal{N}}$ is monotonicity of functions on $\mathcal{N}$. (Most of the properties we consider in this article, including monotonicity, Lipschitz properties and convexity, are extendable properties.) Note that, even for the case of extendable properties, our problem is different from the standard property testing problem because the tester does not know in advance which points are erased.

1.2 Properties We Consider

Next we define properties of real-valued functions considered in this article and summarize previous work on testing them. Most properties of real-valued functions studied in the property testing framework are for functions over the *line* domain $[n]$ and, more generally, the *hypergrid* domain $[n]^d$.

▶ **Definition 1.3** (Hypergrid, line)**.** Given $n, d \in \mathbb{N}$, the hypergrid of size n and dimension d is the set $[n]^d$ associated with an order relation $\preceq$, such that $x \preceq y$ for all $x, y \in [n]^d$ iff $x_i \leq y_i$ for all $i \in [d]$, where x_i (respectively y_i) denotes the i^{th} coordinate of x (respectively, y). The special case $[n]$ is called a *line*.

We consider domains that are subsets of $[n]^d$ to be able to handle arbitrary erasures on $[n]^d$.

Monotonicity. Monotonicity of functions, first studied in the context of property testing in [23], is one of the most widely investigated properties in this model [17, 16, 31, 22, 1, 20, 28, 5, 32, 2, 8, 11, 9, 13, 14, 10, 12]. A function $f : \mathcal{D} \mapsto \mathbb{R}$, defined on a partially ordered domain $\mathcal{D}$ with order $\preceq$, is monotone if $x \preceq y$ implies $f(x) \leq f(y)$ for all $x, y \in \mathcal{D}$. The query complexity of testing monotonicity of functions $f : [n] \mapsto \mathbb{R}$ is $\Theta(\log n/\varepsilon)$ [17, 20]; for functions $f : [n]^d \mapsto \mathbb{R}$, it is $\Theta(d \log n/\varepsilon)$ [13, 14], and for functions over arbitrary partially ordered domains $\mathcal{D}$, it is $O\left(\sqrt{|\mathcal{D}|/\varepsilon}\right)$ [22].

Lipschitz properties. Lipschitz continuity is defined for functions between arbitrary metric spaces, but was specifically studied for real-valued functions on hypergrid domains [29, 3, 13, 15, 10, 12] because of applications to privacy [29, 15]. For $\mathcal{D} \subseteq [n]^d$ and $c \in \mathbb{R}$, a function $f : \mathcal{D} \mapsto \mathbb{R}$ is c-Lipschitz if $|f(x) - f(y)| \leq c \cdot ||x - y||_1$ for all $x, y \in \mathcal{D}$, where $||x - y||_1$ is the L_1 distance between x and y. More generally, f is (α, β)-Lipschitz, where $\alpha < \beta$, if

[3] In general, the error probability can be any $\delta \in (0,1)$. For simplicity, we formulate our model and the results with $\delta = 1/3$. To get results for general δ, by standard arguments, it is enough to multiply the complexity of an algorithm by $\log 1/\delta$.

$\alpha \cdot ||x-y||_1 \leq |f(x)-f(y)| \leq \beta \cdot ||x-y||_1$ for all $x, y \in [n]^d$. All (α, β)-Lipschitz properties can be tested with $O(d \log n/\varepsilon)$ queries [13].

Bounded derivative properties. The class of bounded derivative properties (BDPs), defined by Chakrabarty et al. [12], is a natural generalization of monotonicity and the (α, β)-Lipschitz properties. An ordered set $\mathbf{B}$ of $2d$ functions $l_1, u_1, l_2, u_2, \ldots, l_d, u_d : [n-1] \mapsto \mathbb{R} \cup \{\pm\infty\}$ is a *bounding family* if for all $r \in [d]$ and $y \in [n-1]$, $l_r(y) < u_r(y)$. Let $\mathbf{B}$ be a bounding family of functions and let $\mathbf{e}_r$ be the unit vector along dimension r. The property $\mathcal{P}(\mathbf{B})$ of being $\mathbf{B}$-*derivative bounded* is the set of functions $f : [n]^d \mapsto \mathbb{R}$ such that $l_r(x_r) \leq f(x+\mathbf{e}_r) - f(x) \leq u_r(x_r)$ for all $r \in [d]$ and $x \in [n]^d$ with $x_r \neq n$, where x_r is the r^{th} coordinate of x. Chakrabarty et al. [12] showed that the complexity of testing BDPs of functions $f : [n]^d \mapsto \mathbb{R}$ is $\Theta(d \log n/\varepsilon)$.

Convexity of functions. A function $f : \mathcal{D} \mapsto \mathbb{R}$ is convex if $f(t\mathbf{x} + (1-t)\mathbf{y}) \leq tf(\mathbf{x}) + (1-t)f(\mathbf{y})$ for all $\mathbf{x}, \mathbf{y} \in \mathcal{D}$ and $t \in [0,1]$. If $\mathcal{D} \subseteq [n]$, equivalently, f is convex if $\frac{f(y)-f(x)}{y-x} \leq \frac{f(z)-f(y)}{z-y}$ for all $x < y < z$. Parnas et al. [33] gave a convexity tester for functions $f : [n] \mapsto \mathbb{R}$ with query complexity $O(\log n/\varepsilon)$. Blais et al. [10] gave an $\Omega(\log n)$ bound for nonadaptive testers for this problem.

1.3 Our Results

We give efficient erasure-resilient testers for all properties discussed in Section 1.2. All our testers have optimal complexity for the case with no erasures and have an additional benefit of not relying too heavily on the value of the input function at any specific point.

Monotonicity on the line. We start by giving (in Section 3) an erasure-resilient monotonicity tester on $[n]$.

▶ **Theorem 1.4** (Monotonicity tester on the line). *There exists a one-sided error α-erasure-resilient ε-tester for monotonicity of real-valued functions on the line $[n]$ that works for all $\alpha, \varepsilon \in (0,1)$, with query complexity $O\left(\frac{\log n}{\varepsilon(1-\alpha)}\right)$.*

Without erasure resilience, the complexity of testing monotonicity of functions $f : [n] \mapsto \mathbb{R}$ is $\Theta(\log n/\varepsilon)$ [17, 20]. Thus, the query complexity of our erasure-resilient tester has optimal dependence on the domain size and on ε.

The starting point of our algorithm is the tester for sortedness from [17]. This tester picks a random element of the input array and performs a binary search for that element. It rejects if the binary search does not lead to the right position. The first challenge is that the tester always queries the middle element of the array and is very likely to query other elements that are close to the root in the binary search tree. So, it will break if these elements are erased. To make it resilient to erasures, we randomize the binary tree with respect to which it performs the binary search. The second challenge is that the tester does not know which points are erased. To counteract that, our tester samples points from appropriate intervals until it encounters a nonerased point.

To analyze the tester, we bound the expected number of queries required to traverse a uniformly random search path in an arbitrary binary search tree built over the nonerased points in an α-erased n-element array (Claim 3.2). This expectation depends only on the depth of the tree and α. This is the most interesting part of our analysis and captures the intuition that a randomized binary search for a uniformly random search point is biased towards visiting intervals containing a larger fraction of nonerased points.

BDPs on the hypergrid. In Section 4, we generalize our monotonicity tester in two ways: (1) to work over general hypergrid domains, and (2) to apply to all BDPs. We achieve it by giving (1) a reduction from testing BDPs on the line to testing monotonicity on the line that applies to erasure-resilient testers and (2) an erasure-resilient version of the dimension reduction from [12]. We obtain the following result.

▶ **Theorem 1.5** (BDP tester on the hypergrid)**.** *For every BDP $\mathcal{P}$, there exists a one-sided error α-erasure-resilient ε-tester for $\mathcal{P}$ of real-valued functions on the hypergrid $[n]^d$ that works for all $\alpha, \varepsilon \in (0,1)$, where $\alpha \leq \varepsilon/970d$, with query complexity $O\left(\frac{d \log n}{\varepsilon(1-\alpha)}\right)$.*

Every known tester of a BDP for real-valued functions over general hypergrid domains work by sampling an *axis-parallel line* uniformly at random and checking for violations on the sampled line. Our erasure-resilient testers also follow this paradigm. To check for violations on the sampled line, we use one iteration of our BDP tester for the line. In the full version, we show the existence of α-erased functions $f : \{0,1\}^d \mapsto \mathbb{R}$ that are ε-far from monotone for $\alpha = \Theta(\varepsilon/\sqrt{d})$ but do not have violations to monotonicity along any of the axis parallel lines (which are the edges of the hypercube, in this case). It implies that every tester for monotonicity that follows the paradigm above will fail when $\alpha = \Omega(\varepsilon/\sqrt{d})$. Thus, some restriction on α in terms of d and ε is necessary for such testers.

Convexity on the line. Finally, in Section 5, we develop additional techniques to design a tester for convexity (which is not a BDP) on the line. The query complexity of our tester has the same dependence on n and ε as in the standard convexity tester of Parnas et al. [33]. The dependence on n is known to be optimal for nonadaptive testers [10], and the tester from [33] is conjectured to be optimal in the standard model.

▶ **Theorem 1.6** (Convexity tester on the line)**.** *There exists a one-sided error α-erasure-resilient ε-tester for convexity of real-valued functions on the line $[n]$ that works for all $\alpha, \varepsilon \in (0,1)$, with query complexity $O\left(\frac{\log n}{\varepsilon(1-\alpha)}\right)$.*

Our algorithm for testing convexity combines ideas on testing convexity from [33], testing sortedness from [17], and our idea of randomizing the search. The tester of [33] traverses a uniformly random path in a binary tree on the array $[n]$ by selecting one of the half-intervals of an interval uniformly at random at each step. Instead of doing this, our tester samples a uniformly random nonerased search point and traverses the path to that point in a uniformly random binary search tree just as in our modification of the tester of [17]. This is done to bias our algorithm to traverse paths containing intervals that have a larger fraction of nonerased points. However, instead of checking whether the selected point can be found, as in our monotonicity tester, the convexity tester checks a more complicated "goodness condition" in each visited interval of the binary search tree. It boils down to checking that the slope of the functions between pairs of carefully selected points satisfies the convexity condition. In addition to spending queries on erased points due to sampling, like in the monotonicity tester, our tester also performs "walking queries" to find the nearest nonerased points for the pivots in our random binary search tree. We show that the overhead in the query complexity due to querying erased points is at most a factor of $O(1/(1-\alpha))$.

2 Generic transformations

In this section, we state our transformation theorems that can be applied to some classes of testers that use only uniform samples. We show how to make two classes of testers erasure-resilient: (1) uniform proximity oblivious testers (POTs) defined in [25, 27] (Theorem 2.2),

and (2) uniform testers for extendable properties (Theorem 2.4). All omitted details appear in the full version. We first define POTs.

▶ **Definition 2.1** (POT [25, 27])**.** Let $\mathcal{P}$ be a property of functions of the form $f : \mathcal{D} \mapsto \mathcal{R}$. Let $\rho : (0, 1] \mapsto (0, 1]$ be a monotone function and $c \in (0, 1]$ be a constant. A tester T is a (ρ, c)-*POT* for $\mathcal{P}$ if it decides to accept or reject based only on the answers to the queries that it makes, such that

- for every function $f \in \mathcal{P}$, the probability that T accepts is at least c, and
- for every function $f \notin \mathcal{P}$, the probability that T accepts is at most $c - \rho(\varepsilon_f)$, where ε_f denotes the relative Hamming distance of f from $\mathcal{P}$.

A POT that queries points sampled uniformly and independently at random from $\mathcal{D}$ is called a uniform POT. Next, we state our first generic transformation.

▶ **Theorem 2.2.** *If T is a uniform (ρ,c)-POT for a property $\mathcal{P}$ of functions of the form $f : \mathcal{D} \mapsto \mathcal{R}$ making q queries, then there exists a uniform α-erasure-resilient (ρ',c)-POT T' for $\mathcal{P}$ that makes q queries for all $\alpha < \rho(\varepsilon_f \cdot (1 - \alpha))/q$, where $\rho'(x) = \rho(x \cdot (1 - \alpha)) - \alpha \cdot q$ for $x \in (0, 1]$.*

In the full version, we apply Theorem 2.2 to a tester for the property of being a polynomial of degree at most d due to Rubinfeld and Sudan [35] and get an erasure-resilient tester.

Next, we define extendable properties and state our second transformation. Given $\mathcal{S} \subseteq \mathcal{T}$, the *extension* of a function $f : \mathcal{S} \mapsto \mathcal{R}$ to $\mathcal{T}$ is a function $g : \mathcal{T} \mapsto \mathcal{R}$ that agrees with f on every point in $\mathcal{S}$.

▶ **Definition 2.3** (Extendable properties)**.** For a domain $\mathcal{D}$ and all $\mathcal{S} \subseteq \mathcal{D}$, let $\mathcal{P}_\mathcal{S}$ denote a property of functions $f : \mathcal{S} \mapsto \mathcal{R}$. The class of properties $\{\mathcal{P}_\mathcal{S} : \mathcal{S} \subseteq \mathcal{D}\}$ is extendable if, for all $\mathcal{S}, \mathcal{T} : \mathcal{S} \subseteq \mathcal{T} \subseteq \mathcal{D}$,

- for every function $f : \mathcal{S} \mapsto \mathcal{R}$ satisfying $\mathcal{P}_\mathcal{S}$, there is an extension $f' : \mathcal{T} \mapsto \mathcal{R}$ satisfying $\mathcal{P}_\mathcal{T}$, and
- for every function $f : \mathcal{S} \mapsto \mathcal{R}$ that is ε-far from $\mathcal{P}_\mathcal{S}$, every function $f' : \mathcal{T} \mapsto \mathcal{R}$ satisfying $\mathcal{P}_\mathcal{T}$ differs from f on at least an ε fraction of points in $\mathcal{S}$.

▶ **Theorem 2.4.** *Let $q(\cdot, \cdot)$ be a function that is monotone non-decreasing in the first argument and monotone non-increasing in the second argument. Let $\{\mathcal{P}_\mathcal{S} : \mathcal{S} \subseteq \mathcal{D}\}$ be a class of extendable properties, where $\mathcal{P}_\mathcal{S}$ is a property of functions of the form $f : \mathcal{S} \mapsto \mathcal{R}$. Suppose $T_\mathcal{S}$ is a uniform one-sided error ε-tester of $\mathcal{P}_\mathcal{S}$ that makes $q(|\mathcal{S}|, \varepsilon)$ queries from $\mathcal{S}$, for every $\mathcal{S} \subseteq \mathcal{D}$. Assume also that for each $\mathcal{S} \subseteq \mathcal{D}$, the probability that $T_\mathcal{S}$ tests correctly does not decrease when it makes more queries. Then, there exists a uniform one-sided error α-erasure-resilient ε-tester T' of $\mathcal{P}_\mathcal{D}$ that makes $O\left(q(|\mathcal{D}|, \varepsilon)/(1 - \alpha)\right)$ queries for all $\alpha \in [0, 1)$.*

Using Theorem 2.4, we can make the uniform tester for convexity of black and white images [7] and the uniform tester for monotonicity of real-valued functions over arbitrary partially ordered domains [22] erasure-resilient.

We also develop a uniform tester for the property of being a k-run Boolean function and make it erasure-resilient by applying Theorem 2.4. A function $f : [n] \mapsto \{0, 1\}$ has k *runs* if the list $f(1), f(2), \ldots, f(n)$ has at most $k - 1$ alternations of values. The problem at hand is to test whether a given function $f : [n] \mapsto \{0, 1\}$ has k runs or is ε-far from this property. Kearns and Ron [30] studied a relaxation of this problem. Specifically, they showed that $O(1/\varepsilon^2)$ queries suffice to test whether a Boolean function has k runs or is ε-far from being a k/ε-run function. They also developed a uniform $O(\sqrt{k}/\varepsilon^{2.5})$-query tester for this relaxation

and proved that every uniform ε-tester for the k-run property requires $\Omega(\sqrt{k})$ queries. Balcan et al. [4] obtained a $O(1/\varepsilon^4)$-query tester for this property in the active testing model. They also developed a uniform $O(\sqrt{k}/\varepsilon^5)$-query tester. We prove the following theorem.

▶ **Theorem 2.5.** *There is an ε-tester for the property of having k runs for functions of the form $f : [n] \mapsto \{0, 1\}$ that makes $O\left(\frac{k \log k}{\varepsilon}\right)$ uniform independent queries, where $\varepsilon > k^2/n$.*

3 Erasure-Resilient Monotonicity Tester for the Line

In this section, we prove Theorem 1.4. Recall that, for a function $f : [n] \mapsto \mathbb{R} \cup \{\perp\}$, the set of nonerased points (the ones that map to $\mathbb{R}$) is denoted by $\mathcal{N}$. The function f is monotone if $x < y$ implies $f(x) \leq f(y)$ for all $x, y \in \mathcal{N}$. The tester does not know $\mathcal{N}$ in advance.

We present our tester in Algorithm 1. It has oracle access to f and takes α and ε as inputs. In each iteration, it performs a randomized binary search for a nonerased index sampled uniformly at random (u.a.r.) from $\mathcal{N}$ and rejects if it finds violations to monotonicity. In the description of our tester, we use $I[i, j]$ to denote the set of natural numbers from i until and including j. We alternatively refer to it as the interval from i to j.

Algorithm 1 Erasure-Resilient Monotonicity Tester for the Line

1: **Set** $Q = \left\lceil \frac{60 \log n}{\varepsilon(1-\alpha)} \right\rceil$.
2: **Accept** at any point if the number of queries exceeds Q.
3: **loop** $2/\varepsilon$ times:
4: Sample points u.a.r. from $I[1, n]$ and query them until we get a point $s \in \mathcal{N}$.
5: **Set** $\ell \leftarrow 1$, $r \leftarrow n$.
6: **while** $\ell \leq r$ **do**
7: Sample points u.a.r. from $I[\ell, r]$ and query them until we get a point $m \in \mathcal{N}$.
8: **if** $s < m$ **then set** $r \leftarrow m - 1$ and **Reject** if $f(s) \geq f(m)$.
9: **if** $s > m$ **then set** $\ell \leftarrow m + 1$ and **Reject** if $f(s) \leq f(m)$.
10: **if** $s = m$ **then** Go to Step 3. ▷ Search completed.
11: **Accept**.

Every iteration of Algorithm 1 can be viewed as a traversal of a uniformly random search path in a uniformly random binary search tree defined on the set $\mathcal{N}$ of nonerased points. Given a binary search tree T over $\mathcal{N}$, we associate every node of T with a unique sub-interval I of $I[1, n]$ as follows. The root of T is associated with $I[1, n]$. Suppose the interval associated with a node Γ in T that contains $s \in \mathcal{N}$ is $I[i, j]$. Then the interval associated with the left child of Γ is $I[i, s - 1]$ and the interval associated with the right child of Γ is $I[s + 1, j]$. A search path is a path from the root to some node Γ of T.

If f is ε-far from monotone, we prove that, with high probability, the tester finds a violation. It is easy to prove this, using a generalization of an argument from [17], for the case when Algorithm 1 manages to complete all iterations of Step 3 before it runs out of queries. The challenge is that the algorithm might get stuck pursuing long paths in a random search tree and waste many queries on erased points. To resolve the issue of many possible queries to erased points, we prove an upper bound on the expected number of queries made while traversing a uniformly random search path in a binary search tree on $\mathcal{N}$. We combine this with the fact that the expected depth of a random binary search tree is $O(\log n)$ to obtain the final bound on the probability that the algorithm exceeds its query budget.

3.1 Analysis

We analyze the tester in this section. The query complexity of the tester is clear from its description. The main statement of Theorem 1.4 follows from Lemma 3.1, proved next.

▶ **Lemma 3.1.** *Algorithm 1 accepts if f is monotone, and rejects with probability at least $2/3$ if f is ε-far from monotone.*

Proof. The tester accepts whenever f is monotone. To prove the other part of the lemma, assume that f is ε-far from monotone. Let A be the event that the tester accepts f. Let q denote the total number of queries made. We prove that $\Pr[A] \leq 1/3$. The event A occurs if either $q > Q$ or the tester does not find a violation in any of the $2/\varepsilon$ iterations of Step 3. Thus, $\Pr[A] \leq \Pr[A|q \leq Q] + \Pr[q > Q]$.

First we bound the probability that the tester does not find a violation in one iteration of Step 3, conditioned on the event that $q \leq Q$. Consider an arbitrary binary search tree T defined over points in $\mathcal{N}$. A point $s \in \mathcal{N}$ is called *searchable* with respect to T if Algorithm 1 does not detect a violation to monotonicity while traversing the search path to s in T. Consider two indices $i, j \in \mathcal{N}$, where $i < j$, both searchable with respect to T. Let $a \in \mathcal{N}$ be the pivot corresponding to the lowest common ancestor of the leaves containing i and j. Since i and j are both *searchable*, it must be the case that $f(i) < f(a)$ and $f(a) < f(j)$ and hence, $f(i) < f(j)$. Thus, for every tree T, the function restricted to the domain points that are *searchable* with respect to T is monotone. Therefore, if f is ε-far from monotone, for every binary search tree T, at least an ε-fraction of the points in $\mathcal{N}$ are not *searchable*. Thus, the tester detects a violation with probability ε in each iteration. Consequently, $\Pr[A|q \leq Q] \leq (1-\varepsilon)^{\frac{2}{\varepsilon}} < 1/4$.

In the rest of the proof, we will bound $\Pr[q > Q]$. We will first state and prove a claim that bounds the expected number of queries to traverse a search path, for every binary search tree. Recall that a search path in a search tree T is a path from the root to some node in T. Let I be an interval associated with a node v of T and let α_I denote the fraction of erased points in I. The number of queries to be made to sample a nonerased point from I with uniform sampling is a geometric random variable with expectation $1/(1-\alpha_I)$. We define the *query-weight* of node v to be this expectation. The query-weight of a search path is the sum of query-weights of the nodes on the path (which is the expected number of queries that the algorithm makes while traversing that path).

▶ **Claim 3.2.** *Consider an arbitrary binary search tree T on $\mathcal{N}$ of height h. The expected query-weight of a uniformly random search path in T is at most $h/(1-\alpha)$.*

Proof. There are exactly $|\mathcal{N}|$ search paths in T. Let S denote the sum of query-weights of all the search paths. The expected query-weight is equal to $S/|\mathcal{N}|$.

Consider a node v in T associated with an interval I. There are $|I|(1-\alpha_I)$ nonerased points in I. The search paths from the root of T to all these nonerased points pass through v, and hence, the query-weight of v gets added to the query-weights of all of those paths. Therefore, the total contribution of v towards S is $|I|$, since the query-weight of v is $1/(1-\alpha_I)$. Note that the intervals associated with nodes at the same level of T are disjoint from each other. Therefore, the total contribution to S from all nodes on the same level of T is at most n. Hence the value of S is at most $n \cdot h$. Observe that this quantity is independent of the fraction of erasures α. Therefore, the expected query-weight of a search path is at most $n \cdot h/|\mathcal{N}|$, which is at most $h/(1-\alpha)$, since $|\mathcal{N}| \geq n \cdot (1-\alpha)$. ◀

We will next see a fact on the expected depth of a uniformly random binary search tree and combine it with the above claim to prove the required bound on the expected query-weight of a uniformly random search path in a uniformly random binary search tree.

▶ **Claim 3.3** ([34]). *If H_n is the random variable denoting the height of a random binary search tree on n nodes, then $E[H_n] \leq 5 \log n$.*

▶ **Corollary 3.4.** *The expected number of queries made by Algorithm 1 to traverse a uniformly random search path in a uniformly random binary search tree on $\mathcal{N}$ is at most $5 \log n/(1-\alpha)$.*

By linearity of expectation, the expected number of queries made by the tester over all its iterations is at most $10 \log n/(\varepsilon \cdot (1-\alpha))$. Applying Markov's inequality to q, we can then see that $\Pr[q > Q] \leq 1/6$. Therefore, the probability of the tester not finding a violation is at most $1/3$. This completes the proof of the lemma. ◀

4 Erasure-Resilient Monotonicity Testers for the Hypergrid

In this section, we present our erasure-resilient tester for monotonicity over hypergrid domains and prove the following theorem, which is a special case of Theorem 1.5. We defer the discussion of erasure-resilient testers for all BDPs to the full version.

▶ **Theorem 4.1.** *There exists a one-sided error α-erasure-resilient ε-tester for monotonicity of real-valued functions on the hypergrid $[n]^d$ that works for all $\alpha, \varepsilon \in (0,1)$, where $\alpha \leq \varepsilon/250d$, with query complexity $O(\frac{d \log n}{\varepsilon(1-\alpha)})$.*

Let $\mathcal{L}$ denote the set of all *axis-parallel lines* in the hypergrid. Our monotonicity tester, which is described in Algorithm 2, samples an *axis-parallel line* uniformly at random in each iteration and does a randomized binary search for a uniformly randomly sampled nonerased point on that line. It rejects if and only if a violation to monotonicity is found within its query budget. To analyze the tester, we first state two important properties of a uniformly random axis-parallel line in Lemma 4.2 and Lemma 4.3, which we jointly call the erasure-resilient dimension reduction. The statements and proofs of more general versions of these lemmas, applicable to all BDPs, are given in the full version.

▶ **Lemma 4.2** (Dimension reduction: distance). *Let ε_f be the relative Hamming distance of an α-erased function $f : [n]^d \mapsto \mathbb{R} \cup \{\perp\}$ from monotonicity. Given an axis-parallel line $\ell \in \mathcal{L}$, let $f_\ell : [n] \mapsto \mathbb{R} \cup \{\perp\}$ denote the restriction of f to ℓ and let ε_ℓ denote the relative Hamming distance of f_ℓ from monotonicity. Then $E_{\ell \sim \mathcal{L}}[\varepsilon_\ell] \geq (((1-\alpha) \cdot \varepsilon_f)/4d) - \alpha$.*

▶ **Lemma 4.3** (Dimension reduction: fraction of erasures). *Consider an α-erased function $f : [n]^d \mapsto \mathbb{R} \cup \{\perp\}$. Given $\ell \in \mathcal{L}$, let α_ℓ denote the fraction of erased points in ℓ. Then, for every $\eta \in (0,1)$, we have, $\Pr_{\ell \sim \mathcal{L}}[\alpha_\ell > \alpha/\eta] \leq \eta$.*

The query complexity of the tester is evident from its description. We will now prove its correctness in the following lemma, which will then imply Theorem 4.1.

▶ **Lemma 4.4.** *Algorithm 2 accepts if f is monotone, and rejects with probability at least $2/3$ if f is ε-far from monotone.*

Proof. The tester accepts if f is monotone. So, assume f is ε-far from being monotone. Let A denote the event that no iteration of the tester finds a violation to monotonicity. If q denotes the total number of queries made by the tester, we have, $\Pr[A] \leq \Pr[A | q \leq Q] + \Pr[q > Q]$.

Algorithm 2 Erasure-Resilient Monotonicity Tester for $[n]^d$

Require: parameters $\varepsilon \in (0,1), \alpha \in [0, \varepsilon/250d]$; oracle access to $f : [n]^d \to \mathbb{R}$

1: **Set** $Q = \lceil \frac{1200d \cdot \log n}{\varepsilon(1-\alpha)} \rceil$.
2: **loop** $\frac{12d}{\varepsilon(1-\alpha)-4d\alpha}$ times:
3: Sample a line $\ell \in \mathcal{L}$ uniformly at random.
4: Sample and query points u.a.r. from ℓ and query them until we get a point $s \in \mathcal{N}$.
5: Perform a randomized binary search for s on ℓ as in Algorithm 1.
6: **Reject** if any violation to monotonicity is found.
7: **Accept** at any point if the number of queries exceed Q.

Let t denote the number of iterations of the tester. Let A_i denote the event that the tester does not find a violation in its i-th iteration. For $\ell \in \mathcal{L}$, let f_ℓ denote f restricted to the line ℓ. Let ε_ℓ denote the relative Hamming distance of f_ℓ from monotonicity. We have, $\Pr[A_i | q \leq Q] = \sum_{\ell \in \mathcal{L}} (1 - \varepsilon_\ell) \Pr[\ell] = 1 - \mathrm{E}_{\ell \sim \mathcal{L}}[\varepsilon_\ell]$. By Lemma 4.2 and the fact that $\varepsilon_f \geq \varepsilon$, we have, $\mathrm{E}_{\ell \sim \mathcal{L}}[\varepsilon_\ell] \geq \frac{(1-\alpha)\cdot\varepsilon_f}{4d} - \alpha \geq \frac{(1-\alpha)\cdot\varepsilon}{4d} - \alpha$. Therefore,

$$\Pr[A | q \leq Q] = \prod_{i=1}^{t} \Pr[A_i | q \leq Q] \leq \left(1 - \frac{(1-\alpha)\cdot\varepsilon - 4d\alpha}{4d}\right)^t < \frac{1}{10}.$$

It remains to bound $\Pr[q > Q]$. Let $\eta = 1/10t$. Let α_i be the fraction of erasures in the line sampled during iteration i and let q_i be the number of queries the tester makes in iteration i. Let G be the (good) event that $\alpha_i \leq \alpha/\eta$ for all iterations $i \in [t]$. By Corollary 3.4, $\mathrm{E}[q_i | G] \leq 5\eta \cdot \log n/(\eta - \alpha)$. By the linearity of expectation, $\mathrm{E}[q|G] \leq \log n/(2(\eta - \alpha)) \leq 120d \log n/(\varepsilon(1-\alpha))$, where the last inequality follows from our assumption that $\alpha \leq \varepsilon/250d$. Using Markov's inequality, $\Pr[q > Q | G] \leq 1/10$. Also, by combining Lemma 4.3 with a union bound, we can see that $\Pr[\overline{G}] \leq 1/10$. Therefore, $\Pr[q > Q] \leq \Pr[q > Q|G] + \Pr[\overline{G}] \leq 1/5$. ◀

5 Erasure-Resilient Convexity Tester for the Line

In this section, we prove Theorem 1.6. Given an α-erased function $f : [n] \mapsto \mathbb{R} \cup \{\perp\}$, let ν_i be the i-th nonerased domain point in $[n]$. The derivative of f at a point $\nu_i \in \mathcal{N}$, denoted by $\Delta f(\nu_i)$, is $\frac{f(\nu_{i+1}) - f(\nu_i)}{\nu_{i+1} - \nu_i}$, whenever $\nu_{i+1} \leq n$. The function f is convex iff $\Delta f(\nu_i) \leq \Delta f(\nu_{i+1})$ for all $i \in [|\mathcal{N}| - 2]$. Our tester builds upon the ideas in the convexity tester from [33].

A high level idea of the tester is as follows. Our tester (Algorithm 3) has several iterations. Every iteration of the tester can be thought of as a traversal of a uniformly random *search* path of a uniformly random binary search tree on $\mathcal{N}$, just as Algorithm 1. For each interval on such a path, we check a set of conditions computed based on the values at some nonerased points in the interval, called *anchor points*, and two real numbers, called the left and right slopes. More specifically, we verify that the function restricted to the sampled nonerased points in the interval is convex, by comparing the slopes across consecutive points. The algorithm accepts if all the intervals it sees pass these checks.

The main steps in the analysis of the tester follows that of the analysis of Algorithm 1. To prove that, with high probability, the algorithm does not run out of its budget of queries Q, we classify the queries that the tester makes into two kinds and analyze them separately. The queries where the tester repeatedly samples and queries from an interval until it finds a nonerased domain point are called *sampling queries*. The queries where the tester keeps querying consecutive points, starting from a nonerased point, until it gets the next nonerased

Algorithm 3 Erasure-Resilient Convexity Tester

Require: parameters $\varepsilon, \alpha \in (0,1)$; oracle access to $f : [n] \mapsto \mathbb{R} \cup \{\perp\}$.

Set $Q = \lceil \frac{180 \log n}{\varepsilon(1-\alpha)} \rceil$.
Accept at any point if the number of queries exceeds Q.
loop $2/\varepsilon$ times
    Sample points in $I[1,n]$ u.a.r and query them until we get a point $s \in \mathcal{N}$.
    Test-Interval$(I[1,n], \emptyset, -\infty, +\infty, s)$ and **Reject** if it rejects.
Accept.

point are called *walking queries.* We show that the expected number of walking queries is at most twice the number of the expected number of the sampling queries and use Corollary 3.4 to bound the expected number of sampling queries. We then prove that, conditioned on the tester not running out of its queries, in every iteration, with probability ε, the tester will detect a violation while testing for a function that is ε-far from being convex. This part draws ideas from the proof of correctness of the tester in [33]. The analysis of the tester is deferred to the full version.

Procedure 4 Test-Interval$(I[i,j], \mathcal{A} = \{a_1, a_2, \ldots, a_k\}, m_\ell, m_r, s)$

Require: interval $I[i,j]$; a set of nonerased points $\mathcal{A}$; left slope $m_\ell \in \mathbb{R}$; right slope $m_r \in \mathbb{R}$; search point $s \in \mathcal{N}$.

Sample points u.a.r. from $I[i,j]$ and query them until we get a point $x \in \mathcal{N}$.
Sequentially query points $x+1, x+2 \ldots$ until we get a nonerased point y.
Sequentially query points $x-1, x-2 \ldots$ until we get the nonerased point z.
Let $(a_1, a_2, \ldots, a_k)$ denote the sorted list of points in the set $\mathcal{A} \cup \{x, y, z\}$.
Let $m_i = (f(a_{i+1}) - f(a_i))/(a_{i+1} - a_i)$ for all $i \in [k-1]$.
Reject if $m_\ell \le m_1 \le m_2 \le \cdots \le m_{k-1} \le m_r$ is not true.
Let $\mathcal{A}'_\ell$ and $\mathcal{A}'_r$ be the sets of points in $\mathcal{A}$ that are smaller and larger than x, respectively.
if $s < x$ **then**
    Reject if Test-Interval$(I[i,z], \mathcal{A}'_\ell, m_\ell, \Delta f(z), s)$ rejects.
if $s > x$ **then**
    Reject if Test-Interval$(I[y,j], \mathcal{A}'_r, \Delta f(x), m_r, s)$ rejects.
Accept.

6 Conclusions and Open Problems

In this paper, we initiate a study of property testing in the presence of adversarial erasures. We design efficient erasure-resilient testers for several important properties such as monotonicity, the Lipschitz properties and convexity over different domains. All our testers for properties of functions on the line domain work for an arbitrary fraction of erasures. All our testers have only a small additional overhead of $O(1/(1-\alpha))$ in their query complexity in comparison to the query complexity of the currently best, and, in some cases, optimal, standard testers for the same properties. We also show that not all properties are easy to test in the erasure-resilient testing model by proving the existence of a property that is easy to test in the standard model but hard to test in the erasure-resilient model even for a small fraction of erasures. We now list some open problems.

- We show that tolerant testing is at least as hard as erasure-resilient testing. Determining if tolerant testing is strictly harder than erasure-resilient testing is an interesting direction.

- The fraction of erasures that our monotonicity tester for hypergrid domains ($[n]^d$) can tolerate decreases inversely with d. We also show that an inverse dependence on $\sqrt{d}$ is necessary for testers that work by sampling axis-parallel lines uniformly at random and then test for the property on them. It is an interesting combinatorial question to determine the exact tradeoff between the fraction of erasures and the fraction of axis parallel lines that are far from monotone.

Abstract

In the orthogonal range reporting problem, we are to preprocess a set of n points with integer coordinates on a $U \times U$ grid. The goal is to support reporting all k points inside an axis-aligned query rectangle. This is one of the most fundamental data structure problems in databases and computational geometry. Despite the importance of the problem its complexity remains unresolved in the word-RAM.

On the upper bound side, three best tradeoffs exist, all derived by reducing range reporting to a ball-inheritance problem. Ball-inheritance is a problem that essentially encapsulates all previous attempts at solving range reporting in the word-RAM. In this paper we make progress towards closing the gap between the upper and lower bounds for range reporting by proving cell probe lower bounds for ball-inheritance. Our lower bounds are tight for a large range of parameters, excluding any further progress for range reporting using the ball-inheritance reduction.

1 Introduction

In the orthogonal range reporting problem, we are to preprocess a set of n points with integer coordinates on a $U \times U$ grid. The goal is to support reporting all k points inside an axis-aligned query rectangle. This is one of the most fundamental data structure problems in databases and computational geometry. Given the importance of the problem, it has been extensively studied in all the relevant models of computation including e.g. the word-RAM, pointer machine and external memory model. In the latter two models, we typically work under an assumption of *indivisibility*, meaning that input points have to be stored as they are, i.e. compression techniques such as rank-space reduction and word-packing cannot be used to reduce the space consumption of data structures. The indivisibility assumption greatly alleviates the task of proving lower bounds, which has resulted in a completely tight characterisation of the complexity of orthogonal range reporting in these two models. More specifically, Chazelle [7] presented a pointer machine data structure answering queries in

optimal $O(\lg n + k)$ time using $O(n \lg n / \lg \lg n)$ space and later proved that this space bound is optimal for any query time of the form $O(\lg^c n + k)$, where $c \geq 1$ is an arbitrary constant [8]. In the external memory model, Arge et al. [2] presented a data structure answering queries in optimal $O(\lg_B n + k/B)$ I/Os with $O(n \lg n / \lg \lg_B n)$ space and also proved the space bound to be optimal for any query time of the form $O(\lg_B^c n + k/B)$, where $c \geq 1$ is a constant. Here B is the disk block size. Thus the orthogonal range reporting problem has been completely closed for at least 15 years in both these models of computation. If we instead abandon the indivisibility assumption and consider orthogonal range reporting in the arguably more realistic model of computation, the word-RAM, our understanding of the problem is much more disappointing. Assuming the coordinates are polynomial in n ($U = n^{O(1)}$), the current best word-RAM data structures, by Chan et al. [5], achieve the following tradeoffs:

1. Optimal query time $O(\lg \lg n + k)$ with $O(n \lg^\varepsilon n)$ words of space for any constant $\varepsilon > 0$.
2. Query time $O((1 + k) \lg \lg n)$ with $O(n \lg \lg n)$ words of space.
3. Query time $O((1 + k) \lg^\varepsilon n)$ with optimal $O(n)$ words of space.

Thus we can achieve linear space by paying a $\lg^\varepsilon n$ penalty per point reported. And even if we insist on an optimal $O(\lg \lg n + k)$ query time, it is possible to improve over the optimal space bound in the pointer machine and external memory model by almost a $\lg n$ factor. Naturally the improvements rely heavily on points not being indivisible.

On the lower bounds side, Pătraşcu and Thorup [12, 14] proved that the query time must be $\Omega(\lg \lg n + k)$ for space $n \lg^{O(1)} n$. This lower bound was obtained by reduction from the predecessor search problem. For predecessor search, the query time of $\lg \lg n$ is known to be achievable with linear space. Thus the reduction is incapable of distinguishing the three space regimes of the current best data structures for range reporting. Perhaps it might just be possible to construct a linear space data structure with $O(\lg \lg n + k)$ query time. This would have a huge impact in practice, since the non-linear space solutions are most often abandoned for the kd-trees [3], using linear space and answering queries in $O(\sqrt{n} + k)$ time. This is simply because more than a constant factor above linear space is prohibitive for most applications. Thus ruling out the existence of fast linear space data structures would be a major contribution. The focus of this paper is on understanding this gap and the complexity of orthogonal range reporting in the word-RAM. This boils down to understanding how much compression and word-packing techniques can help us in the regime between linear space and $O(n \lg^\varepsilon n)$ space. Since our results concern definitions made by Chan et al. [5], we first give a more formal definition of the word-RAM and briefly review the technique of rank space reduction and the main ideas in [5].

1.1 Range Reporting in the word-RAM

The word-RAM model was designed to mimic what is possible in modern imperative programming languages such as C. In the word-RAM, the memory is divided into words of $\Theta(\lg n)$ bits. The words have integer addresses and we allow random access to any word in constant time. We also assume all standard word operations from modern programming languages takes constant time. This includes e.g. integer addition, subtraction, multiplication, division, bit-wise AND, OR, XOR, SHIFT etc. Having $\Theta(\lg n)$ bit words is a reasonable assumption since machine words on standard computers have enough bits to address the input and to store pointers into a data structure.

Rank Space Reduction. Most of the previous range reporting data structures for the word-RAM have used rank space reduction (or variants thereof) to save space, see e.g. [1, 11]. Rank space reduction is the following: Given a set P of n points on a $U \times U$ grid, compute

for each point $(x, y) \in P$ the rank $r_x(x)$ of x amongst the x-coordinates of points in P. Similarly compute the rank $r_y(x)$ of y amongst the y-coordinates of points in P. Construct a new point set P^* with each point $(x, y) \in P$ replaced by $(r_x(x), r_y(y))$. The point set P^* is said to be in *rank space*. A point $(x, y) \in P$ lies inside a query range $q = [x_0; x_1] \times [y_0; y_1]$ precisely if $(r_x(x), r_y(y))$ lies inside the range $q^* = [r_x(x_0); r_x(x_1)] \times [r_y(y_0); r_y(y_1)]$. Thus if we store a data structure for mapping q to q^* and a table mapping points in P^* back to points in P, the output of a query q can be computed from the output of the query q^* on P^*. Since the coordinates of a point in P^* can be represented using $\lg n$ bits, this gives a saving in space if $\lg n \ll \lg U$.

In previous range reporting data structures, rank space reductions are often used recursively on smaller and smaller point sets $P_t \subset P_{t-1} \subset \cdots \subset P_1 \subset P$. Applying t rounds of rank space reduction however results in a query time of $O(f(n) + tk)$ since each reported point has to be *decompressed* through t rank space reduction tables.

The Ball-Inheritance Problem. In the following, we present the main ideas of the current best data structures, due to Chan et al. [5]. Their solution is based on an elegant way of combining rank space reductions over all levels of a range tree:

Construct a complete binary tree with the points of P stored in the leaves ordered from left to right by their x-coordinate. Every internal node v is associated with the subset of points P_v stored in the leaves of the subtree rooted at v. For every internal node v, map the points P_v to rank space and denote the resulting set of points P_v^*. Store in v a data structure for answering 3-sided range queries on P_v^*. Here a 3-sided query is either of the form $[x_0; \infty) \times [y_0; y_1]$ or $(-\infty, x_1] \times [y_0; y_1]$. If we require that only the rank space y-coordinate of a point is reported (and not the rank space x-coordinate), these 3-sided data structures can be implemented in $O(n)$ bits and with $O(k)$ query time using succinct data structures for range minimum queries, see e.g. [9]. For each leaf, we simply store the associated point. The total space usage is $O(n \lg n + n \lg U)$ bits, which is $O(n)$ words.

To answer a query $q = [x_0; x_1] \times [y_0; y_1]$, find the lowest common ancestor, w, of the leaves storing the successor of x_0 and the predecessor of x_1 respectively. Let w_ℓ be the left child of w and w_r the right child. The points inside q are precisely the points $P_{w_\ell} \cap [x_0; \infty) \times [y_0; y_1]$ plus $P_{w_r} \cap (-\infty, x_1] \times [y_0; y_1]$. The data structures of Chan et al. now proceeds by mapping these two 3-sided queries to rank space amongst points in $P^*_{w_\ell}$ and $P^*_{w_r}$ respectively and answering the two queries using the 3-sided data structures stored at w_ℓ and w_r. This reports, for every point $(x, y) \in P_{w_\ell} \cap q$ (and $(x, y) \in P_{w_r} \cap q$), the rank of y amongst the y-coordinates of all points in P_{w_ℓ} (P_{w_r}). Assuming one can build an S word auxiliary data structure that supports mapping these rank space y-coordinates back to the original points in t time per point (i.e. through t rank space decompressions), this gives a data structure for orthogonal range reporting that answers queries in $O(\lg \lg n + t(1 + k))$ time using $S + O(n)$ space, see [5] for full details. Chan et al. named this abstract decompression problem *the ball-inheritance problem* and defined it as follows:

▶ **Definition 1** (Chan et al. [5])**.** In the ball-inheritance problem, the input is a complete binary tree with n leaves. In the root node, there is an ordered list of n balls. Each ball is associated with a unique leaf of the tree and we say the ball *reaches* that leaf. Every internal node v also has an associated list of balls, containing those balls reaching a leaf in the subtree rooted at v. The ordering of the balls in v's list is the same as their ordering in the root's list. We think of each ball in v's list as being inherited from v's parent.

A query is specified by a pair (v, i) where v is a node in the tree and i is an index into v's list of balls. The goal is to return the index of the leaf reached by the i'th ball in v's list of balls.

It is not hard to see that a solution to the ball-inheritance problem is precisely what is needed in Chan et al.'s data structures: We have one ball per point. The ball corresponding to a point (x, y) reaches the $r_x(x)$'th leaf, where $r_x(x)$ is the rank of x amongst all x-coordinates. The ordering of the balls inside the lists is just the ordering on the y-coordinates of the corresponding points. Thus answering a ball-inheritance query (v, i) corresponds exactly to determining the leaf storing the point from P_v having a rank space y-coordinate of i. Since Chan et al. stored the points in the leaves, this also recovers the original point.

All three tradeoffs by Chan et al. come from solving the ball-inheritance problem with the following bounds:

▶ **Theorem 2** (Chan et al. [5]). *For any $2 \leq B \leq \lg^{\varepsilon} n$, we can solve the ball-inheritance problem with:* (1) *space $O(nB \lg\lg n)$ and query time $O(\lg_B \lg n)$; or* (2) *space $O(n \lg_B \lg n)$ and query time $O(B \lg\lg n)$.*

While not all previous range reporting data structures directly solve the ball-inheritance problem, they are all based on rank space reductions and decompression of one point at a time, just in less efficient ways. Thus the ball-inheritance problem in some sense captures the essence of all previous approaches to solving range reporting and the bounds obtained for the ball-inheritance problem also sets the current limits for orthogonal range reporting.

We remark that the ball-inheritance problem also has been used to improve the upper bounds for various other problems with a range reporting flavor to them, see e.g. [6, 4]. Thus in light of the lack of progress in proving tight lower bounds for range reporting, it seems like a natural goal to understand the complexity of the ball-inheritance problem.

1.2 Our Results

In this paper, we prove a lower bound for the ball-inheritance problem. Our lower bound is tight for a large range of parameters and is as follows:

▶ **Theorem 3.** *Any word-RAM data structure for the ball-inheritance problem which uses S words of space, must have query time t satisfying:*

$$t = \Omega\left(\frac{\lg\lg n}{\lg(S/n) + \lg\lg\lg n}\right).$$

Comparing to the ball-inheritance upper bounds of Chan et al. (Theorem 2), we see that this essentially matches their first tradeoff and is tight for any $S = \Omega(n \lg^{1+\varepsilon} \lg n)$ where $\varepsilon > 0$ is an arbitrarily small constant. Most importantly, it implies that for constant query time, one needs space $n \lg^{\varepsilon} n$ words. Thus any range reporting data structure based on the ball-inheritance problem cannot improve over the bounds of Chan et al. in the regime of space $S = \Omega(n \lg^{1+\varepsilon} \lg n)$ words. We believe this holds true for any data structure that is based on *decompressing* one point at a time from some subproblem in rank space. Since decompressing from a subproblem in rank space is hard to formalize exactly, we leave it at this.

One can view our lower bound in two ways: Either as a strong indicator that the data structure of Chan et al. is optimal, or as a suggestion for how to find better upper bounds. The lower bound above shows that if we want to develop faster data structures, we have to find a technique that in some sense allows us to decompress $\omega(1)$ points in one batch, faster than decompressing each point in turn. This is not necessarily impossible given the large success of batched evaluations in other problems such as matrix multiplication and multipoint evaluation of polynomials.

We also want to make a remark regarding the gap between the second tradeoff of Chan et al. and our lower bound. We conjecture that the upper bound of Chan et al. is tight, but note that current lower bound techniques (in the cell probe model) are incapable of proving any lower bounds exceeding the one we obtain in Theorem 3: The ball-inheritance problem has only $n \lg n$ queries and the strongest lower bound for any data structure problem with m queries (for any m) is $t = \Omega(\lg(m/n)/\lg(S/n))$ [10], thus apart from our $\lg\lg\lg n$ "dirt factor", our lower bound is as strong as it possibly can be with current techniques. Note that previous papers have stated their lower bounds with a $\lg m$ rather than $\lg(m/n)$ since the data structure problems considered there have m polynomially larger than n. It is however not too difficult to see that previous techniques really are limited to $\lg(m/n)$. For the cell sampling technique [10], one needs to have $n/\operatorname{poly}(\lg n)$ queries surviving the cell sampling, hence queries have to survive the sampling with probability at least $(n/(m \operatorname{poly}(\lg n)))$, thus requiring an m/n term. For the communication game by Pătraşcu and Thorup [13], the player holding queries has $n/\operatorname{poly}(\lg n)$ queries, thus she can specify her set of queries with $\lg \binom{m}{n/\operatorname{poly}(\lg n)}$ bits of communication. This again results in a $\lg(m/n)$ term rather than $\lg m$.

Technical Contributions. As a side remark, we believe our lower bound proof has interest from a purely technical point of view. In the lower bound proof, we carefully exploit that a data structure is *not* non-deterministic. While this might sound odd at first, Wang and Yin [15] recently showed that, with only few exceptions (e.g. the predecessor lower bounds), all previous lower bound techniques yield lower bounds that hold non-deterministically. Thus having a new proof outside this category is an important contribution and may hopefully help in closing fundamental problems where avoiding non-determinism in proofs is crucial. This is e.g. the case for the deterministic dictionaries problem, which is amongst the most fundamental open problems in the field of data structures. This problem is trivially solved with constant update time and query time non-deterministically (just maintain a sorted linked list) and hence lower bound proofs must use ideas similar to those we present in this paper to prove super constant lower bounds for this important problem.

2 Lower Bound Proof

We prove our lower bound in the cell probe model [16], where the complexity of a data structure is the number of cells it reads/probes. More specifically, a data structure with query time t and space S consists of memory of S cells with consecutive integer addresses $0, \ldots, S-1$. Each cell stores w bits and we assume $w = \Omega(\lg n)$. When answering a query, the data structure may probe up to t cells and must announce the answer to the query solely based on the contents of the probed cells. The cell to probe in each step may depend arbitrarily on the query and the contents of previously probed cells. Thus computation is free of charge in the cell probe model and lower bounds proved in this model clearly applies to word-RAM data structures.

2.1 Main Ideas

In the following, we sketch the overall approach in our proof. Assume we have a data structure for the ball-inheritance problem, having space S cells of w bits and with query time t. Assume furthermore that the data structure performs very poorly in the following sense: For every input I to the ball-inheritance problem and every leaf index $b \in [n] = \{0, \ldots, n-1\}$, let $Q(b, I)$ be the set of queries that have b as its answer. Each such query probes at most t

cells of the data structure on input I. Assume these sets of cells are *disjoint*, i.e. information about the leaf b is stored in $|Q(b, I)| = \lg n$ disjoint t-sized locations in the memory.

Now pick a uniform random set C of $\lg(n!)/(4w)$ memory cells. For a query q, we say that q survives if all its t probes lie in C. Then by the disjointness of the probed cells, there will be a surviving query in $Q(b, I)$ with probability roughly $1 - (1 - (|C|/S)^t)^{\lg n}$. If $t = o(\lg \lg n / \lg(S/|C|))$, this is about $1 - \exp(\lg n \cdot (|C|/S)^t) = 1 - \exp(\lg^{1-o(1)} n)$, i.e. each leaf index is almost certainly the answer to a surviving query. Thus C must basically store the entire input. But $|C|$ is too small for this and we get a contradiction, i.e. $t = \Omega(\lg \lg n / \lg(Sw/(n \lg n)))$, which roughly equals the lower bound we claim. There are obviously a few more details to it, but this is the main idea.

Of course any realistic attempt at designing a data structure for the ball-inheritance problem would try to make the queries in $Q(b, I)$ probe the same cells (which is exactly what Chan et al.'s solution does [5]). In our actual proof, we get around this using the following observation: Consider two queries q_1, q_2 to the ball-inheritance problem, where q_2 is asked in a node d levels below the node of q_1. The probability q_1 and q_2 return the same leaf index is exponentially decreasing in d for a uniform random input. In particular this means that for the very first probe, the queries in $Q(b, I)$ will almost certainly read different cells, which is precisely the property we exploited above. If we pick a random sample of cells, there will be many queries in $Q(b, I)$ that have their first probe in the sample. To handle the remaining $t - 1$ probes, we follow [12] and extend the cell probe model with the concepts *published bits* and *accepted queries*. A data structure is allowed to publish bits at preprocessing time that the query algorithm may read free of charge. After inspecting a given query and the published bits, a data structure can choose to reject the query and not return an answer. Otherwise, the query is accepted and the algorithm must output the correct answer. Note that it is only allowed to reject queries before performing any probes.

The crucial idea is now the following: If the data structure has few published bits, then for most leaves $b \in [n]$, the published bits simply contains too little information to make the queries in $Q(b, I)$ probe the same cells. Thus for t rounds, we can pick a random sample of cells and *publish* their contents. For every accepted query, we check if its first probe is amongst the published cells. If so, we continue to accept it and may skip the first probe since we know the contents of the requested cell. Otherwise we simply reject it. If the published cell sets are small enough, there continues to be too little information in the published bits to make the queries in $Q(b, I)$ meet. Since this holds for all t probes, the argument above for the poorly performing data structures carry through and we get our lower bound.

2.2 Deriving the Lower Bound

With the ideas from Section 2.1 in mind, we present our technical lemma that allows us to publish bits for t rounds to eliminate probes while ensuring that most leaves are still the answer to many accepted queries. Before we present the lemma, consider partitioning the ball-inheritance tree into into $\lg n/Y$ disjoint layers of Y consecutive tree levels and group the accepted queries by these layers. Think of Y as looking at the queries at a given zoom level. To measure how much information we have left about the different leaves, we count for each leaf $b \in [n]$ how many layers that have at least one accepted query with b as its answer. If this count is large, then intuitively the answers to all accepted queries carry much information.

Formally, given a data structure for the ball-inheritance problem, define for every $1 \leq Y \leq \lg n$ and index $i \in [\lg n/Y]$ the *query-support set* of a leaf $b \in [n]$ on an input I as the set $Q_i^Y(b, I)$ of accepted queries in the tree levels $\{iY, \ldots, (i+1)Y - 1\}$ that has b as its

answer. Observe that $|Q_i^Y(b,I)| \in \{0,\ldots,Y\}$ since there is precisely one query in each tree level that has b as its answer (it may be less than Y since some queries might be rejected). Define also the *Y-level-support* of an input I, denoted $L^Y(I)$, as the the number of pairs (b,i) such that $Q_i^Y(b,I)$ is non-empty.

With this notation in hand we are ready to state our main Probe Elimination Lemma.

▶ **Lemma 4.** *Let $\mathcal{I}$ be a set of inputs to the ball-inheritance problem where $|\mathcal{I}| \geq n!/2^n$. Assume a ball-inheritance data structure uses S cells of w bits, answers queries in t probes, has $p < n\lg n/\lg^9 \lg n$ published bits and satisfies $L^Y(I) \geq (1-1/Z)n\lg n/Y$ for all $I \in \mathcal{I}$ for some parameters $Z \geq 2$ and $64\lg w \leq Y \leq \lg n/\alpha$, where $\alpha = (Sw\lg^{18}\lg n)/(n\lg n)$. Then there exists a subset of inputs $\mathcal{I}^* \subseteq \mathcal{I}$, with $|\mathcal{I}^*| \geq |\mathcal{I}|/2$, and another ball-inheritance data structure using S cells of w bits, answering queries in $t-1$ probes with $p + O(n\lg n/\lg^{10}\lg n)$ published bits, and satisfying $L^{\alpha Y}(I) \geq (1-1/Z-1/\lg\lg^3 n)n\lg n/(\alpha Y)$ for all $I \in \mathcal{I}^*$.*

In laymans terms, the lemma states that we can decrease the number of probes of a data structure by one, while only increasing the published bits with a lower order term. When we do this, we maintain the essential property that the leaves still have high support, just on a coarser zoom level. The Z factor is basically just a *dirt* factor. The proof of Lemma 4 can be found in the full version of the paper. In the following we use Lemma 4 to prove our main result, Theorem 3.

Assume for contradiction that a ball-inheritance data structure exists satisfying $t = o(\lg\lg_w n/\lg\alpha)$, where $\alpha = (Sw\lg^{18}\lg n)/(n\lg n)$. We proceed by repeatedly applying Lemma 4 to eliminate all t probes of the data structure. In order to guarantee we can apply Lemma 4 t times, we check the conditions for applying it. The conditions involve the number of published bits p, the parameters Z and Y and $|\mathcal{I}|$. The values of these parameters will change for each application, thus we use $p^{(i)}, Z^{(i)}, Y^{(i)}$ and $|\mathcal{I}^{(i)}|$ to denote these parameters just before the i'th invocation of the lemma. For the first round, we have $p^{(1)} = 0$ and $|\mathcal{I}^{(1)}| = n!$. Note also that $L^Y(I) = n\lg n/Y$ for any Y before the first round. Thus we choose $Y^{(1)} = 64\lg w$ to satisfy the conditions $64\lg w \leq Y^{(1)} \leq \lg n/\alpha$. This also means that we are free to choose $Z^{(1)} \geq 2$ as we wish. We simply let $Z^{(1)} = \lg^3\lg n$. Examining the lemma, we conclude that our parameters evolve in the following way (assuming we do not violate any of the conditions):

$$p^{(1+i)} = O(i(n\lg n/\lg^{10}\lg n)), \quad |\mathcal{I}^{(1+i)}| \geq n!/2^i, \quad Y^{(1+i)} = 64\lg w\cdot\alpha^i, \quad Z^{(i)} \geq \lg^3\lg n/i.$$

Since we assumed $t = o(\lg\lg_w n/\lg\alpha)$, this means that

$$p^{(1+t)} = o(n\lg n/\lg^9\lg n), \quad |\mathcal{I}^{(1+t)}| \geq n!/\lg n, \quad Y^{(1+t)} = o(\lg n), \quad Z^{(1+t)} \geq \lg^2\lg n.$$

We conclude that we can apply our lemma for t rounds under the contradictory assumption. Furthermore, the data structure we are left with answers queries in 0 probes on a subset $\mathcal{I}^* = \mathcal{I}^{(1+t)}$ of inputs, where $|\mathcal{I}^*| \geq n!/\lg n$. It has $o(n\lg n/\lg^9\lg n)$ published bits and there is some $Y^* = o(\lg n)$ such that $L^{Y^*}(I) \geq (1-1/\lg^2\lg n)n\lg n/Y^*$ for all $I \in \mathcal{I}^*$. That this is contradictory should not come as a surprise: our 0-probe data structure is capable of answering queries about almost all leaves using only the $o(n\lg n/\lg^9\lg n) \ll \lg|\mathcal{I}^*|$ published bits. The formal argument we use to reach the contradiction is as follows: we show that the 0-probe data structure can be used to uniquely encode every input $I \in \mathcal{I}^*$ into a bit string of length less than $\lg(|\mathcal{I}^*|) = \lg(n!) - \lg\lg n$ bits. This gives the contradiction since there are fewer such bit strings than inputs. We present the encoding and decoding algorithms in the following:

Encoding. Let $I \in \mathcal{I}^*$ be an input to encode. Observe that if we manage to encode the leaf index reached by each ball in the root node's list of balls, then that information completely specifies I. With this in mind, we implement the 0-probe data structure above on I and proceed as follows:

1. First we write down the published bits on input I. This cost $o(n \lg n / \lg^9 \lg n)$ bits.
2. For $i = 1, \ldots, n$ consider the i'th ball in the root node's list of balls. Let b_i denote the index of the leaf reached by that ball. We write down $\lg n/2$ bits for each such ball in turn, specifying the subtree at depth $\lg n/2$ that contains the leaf b_i. This costs $n \lg n/2$ bits.
3. Finally, we go through all leaf nodes from left to right. For a leaf b, we check if there is an accepted query returning b as its answer amongst all queries in all nodes of depth at most $\lg n/2$. If so, we continue to the next leaf. Otherwise we write $\lg n$ bits denoting the rank of the ball reaching b amongst balls the root node's list of balls. If X is the number of leaves with no accepted query reporting it in tree levels $\{0, \ldots, \lg n/2\}$, this step costs $X \lg n$ bits.

Decoding. To recover I from the above encoding, we do as follows.

1. We first go through all nodes v of depth d for $d = 0, \ldots, \lg n/2$. For each such node, let $q_1^v, \ldots, q_{n/2^d}^v$ denote the queries we can ask at node v, i.e. q_i^v asks for the leaf reached by the i'th ball in v's list of balls. We run the query algorithm for each such query in turn using the published bits written in step 1. of the encoding procedure. Since our data structure makes 0 probes, this returns the answer to each such accepted query, i.e. we have collected a set $\mathcal{Q}$ of pairs (q_i^v, b) such that b is the index of the leaf reached by the i'th ball in v's list of balls.
2. We now partition $\mathcal{Q}$ into one set $\mathcal{Q}_b$ for each leaf index b. The set $\mathcal{Q}_b$ contains all pairs $(q_i^v, b') \in \mathcal{Q}$ such that $b' = b$. There are precisely X empty such sets.
3. For each empty set $\mathcal{Q}_b$ in turn (ordered based on b), we use the bits written in step 3. of the encoding procedure to recover the rank of the ball reaching b amongst all balls in the root node's list of balls.
4. For every non-empty set $\mathcal{Q}_b$, pick an arbitrary pair $(q_i^v, b) \in \mathcal{Q}_b$. From this pair alone, we know that the ball reaching b has rank i amongst all balls ending in a leaf of the subtree rooted at v. Now initialize a counter Δ to 0. Using the bits written in step 2. of the encoding procedure, we now go through all balls in the root node's list of balls in turn. For the r'th ball, $r = 1, \ldots, n$, we check the $\lg n/2$ bits written for it and from this we determine if the ball reaches a leaf in v's subtree (possible since v can only be in the first $\lg n/2$ levels by construction). If so, we increment Δ by 1. If this causes Δ to reach i, we conclude that the ball ending in b has rank r in the root node's list of balls.
5. From the above steps, we have for every leaf b determined the rank of the ball reaching it amongst all balls in the root node's list of balls. This information completely specifies I.

Analysis. The encoding above costs

$$o(n \lg n / \lg^9 \lg n) + n \lg n/2 + X \lg n$$

bits. Now observe that if $\mathcal{Q}_b$ is empty for a leaf index b, this means $Q_i^{Y^*}(b, I)$ is empty for every $i \in \{0, \ldots, \lg n/(2Y^*) - 1\}$. This gives $L^{Y^*}(I) \leq n \lg n/Y^* - X(\lg n/(2Y^*))$. But we know $L^{Y^*}(I) \geq (1 - 1/\lg^2 \lg n) n \lg n/Y^*$ and we conclude

$$X \leq 2n/\lg^2 \lg n.$$

The encoding thus costs

$$n \lg n/2 + O(n \lg n/\lg^2 \lg n).$$

Since $\lg(n!) = n \lg n - O(n)$, we conclude that our encoding uses no more than

$$\lg(|\mathcal{I}^*|) - n \lg n/2 + O(n \lg n/\lg^2 \lg n) = \lg(|\mathcal{I}^*|) - \Omega(n \lg n)$$

bits, which completes the proof.

We have thus shown $t = \Omega(\lg \lg_w n/\lg \alpha)$ where $\alpha = (Sw \lg^{18} \lg n)/(n \lg n)$. In the word-RAM, we assume $w = \Theta(\lg n)$ and the lower bound becomes the claimed $t = \Omega(\lg \lg n/(\lg(S/n) + \lg \lg \lg n))$.

2.3 Eliminating Probes

In this section we prove Lemma 4. Recalling the intuition presented in Section 2.1, we want to show that for a data structure with few published bits, the different accepted queries reporting a fixed leaf index $b \in [n]$ have to probe distinct cells in their first probe. If we can establish this, we can pick a small random sample of memory cells and there are many of the accepted queries that make their first probe in the sample.

To formalize the above, we define a memory cell c to be k-popular on input I, if at least k accepted queries make their first probe in c on I. Define for every query-support set $Q_i^Y(b, I)$ the *cell-support set* $C_i^Y(b, I)$ as the set of memory cells that are read in the first probe of a query in $Q_i^Y(b, I)$ on input I. We measure to what extend the queries in $Q_i^Y(b, I)$ probe distinct cells using the following definitions.

▶ **Definition 5.** For an input I and value $Y \in \{1, \ldots, \lg n\}$, we say that a pair (b, i), where $b \in [n]$ and $i \in \{0, \ldots, \lg n/Y - 1\}$, is *$Y$-scattered* on input I if one of the following three holds:

1. $Q_i^Y(b, I)$ contains a query making 0 probes.
2. $C_i^Y(b, I)$ contains a w^3-popular cell.
3. $|C_i^Y(b, I)| \geq \alpha/\lg^6 \lg n$.

We define the *Y-scatter-number* of I, denoted $\Gamma^Y(I)$, as the number of pairs (b, i) that are Y-scattered on I.

If a query makes zero probes, all the information needed to answer it is contained in the already published bits. There are very few w^3-popular cells, so publishing all of them costs few bits. Most interestingly, if the queries in each support $Q_i^Y(b, I)$ set probe many distinct cells in their first probe (case 3.), then a random sample of cells will contain at least one of these cells with good probability.

We need the following lemma that captures the correspondence between large support on zoom level Y, the properties maintained by our Probe Elimination Lemma, and large scattering on a higher zoom level αY.

▶ **Lemma 6.** *Let $\mathcal{I}$ be a set of inputs to the ball-inheritance problem where $|\mathcal{I}| \geq n!/2^n$. Assume a ball-inheritance data structure uses S cells of w bits, has $p < n \lg n/\lg^9 \lg n$ published bits and satisfies $L^Y(I) \geq (1 - 1/Z)n \lg n/Y$ for all $I \in \mathcal{I}$ for some parameters $Z \geq 2$ and $64 \lg w \leq Y \leq \lg n/\alpha$, where $\alpha = (Sw \lg^{18} \lg n)/(n \lg n)$. Then there exists a subset $\mathcal{I}^* \subseteq \mathcal{I}$ of inputs such that $|\mathcal{I}^*| \geq |\mathcal{I}|/2$ and*

$$\Gamma^{\alpha Y}(I) \geq \left(1 - \frac{1}{\lg^3 \lg n}\right) \cdot \left(1 - \frac{1}{Z}\right) \cdot \frac{n \lg n}{\alpha Y}.$$

for all $I \in \mathcal{I}^*$.

We refer to the full version for the proof of Lemma 6, and use it to Prove Lemma 4 instead. Let $\mathcal{I}$ be a set of at least $n!/2^n$ inputs to the ball inheritance problem. Assume furthermore we are given a ball inheritance data structure that uses S cells of w bits, answers queries in t probes, has $p < n \lg n / \lg^9 \lg n$ published bits, and satisfies $L^Y(I) \geq (1 - 1/Z)n \lg n/Y$ for all $I \in \mathcal{I}$ for some parameters $Z \geq 2$ and $64 \lg w \leq Y \leq \lg n/\alpha$ where $\alpha = (Sw \lg^{18} \lg n)/(n \lg n)$ (as in the assumptions of Lemma 4 and Lemma 6). Let $\mathcal{I}^* \subseteq \mathcal{I}$ be the subset of $\mathcal{I}$ promised by Lemma 6. Our goal is to construct a new ball inheritance data structure answering queries in $t - 1$ probes for the inputs $\mathcal{I}^*$ while publishing few bits and keeping $L^{\alpha Y}(I)$ fairly large for all $I \in \mathcal{I}^*$. Given an input $I \in \mathcal{I}^*$, we keep the (old) p published bits and publish some additional bits from our data structure as follows:

1. First we publish all memory cells that are w^3-popular on input I. Since there are no more than $n \lg n$ accepted queries, there are no more than $n \lg n/w^3$ popular cells. The addresses and contents of all such cells can be described using $O(n \lg n/w^2) = O(n/\lg n)$ bits.
2. Next we collect all αY-scattered pairs (b, i) for input I. We remove those pairs for which $Q_i^{\alpha Y}(b, I)$ contains a query making 0 probes, or $C_i^{\alpha Y}(b, I)$ contains a w^3-popular cell. By definition, the remaining αY-scattered pairs (b, i) must satisfy $|C_i^{\alpha Y}(b, I)| \geq \alpha/\lg^6 \lg n$. We now consider all subsets of $n \lg n/(w \lg^{10} \lg n)$ memory cells and publish the subset $P^* \subseteq [S]$ for which most remaining pairs (b, i) satisfies $C_i^{\alpha Y}(b, I) \cap P^* \neq \emptyset$. Specifying the addresses and contents of cells in P^* costs $O(n \lg n/\lg^{10} \lg n)$ bits.

The query algorithm of our modified data structure is simple: We start running the old query algorithm with the p "old" published bits and stop once one of the following happens:

1. If the old query algorithm rejects the query, we also reject it.
2. If the old query algorithm answers the query without any probes, we know the answer to the query and return it.
3. Otherwise the old query algorithm makes at least one memory probe. The (address of the) first cell probed, denoted c, can be determined solely from the old published bits. Before making the actual probe, we check the newly published cells to see if c is amongst them. If so, we have the contents of c in the published bits and therefore skip the probe. We then continue executing the old query algorithm and have successfully reduced the number of probes by one. If c was not published, we simply reject the query.

Clearly our new data structure answers queries in $t-1$ probes and has $p+O(n \lg n/\lg^{10} \lg n)$ published bits. What remains is to argue that $L^{\alpha Y}(I)$ is high for all $I \in \mathcal{I}^*$ for this new data structure. To distinguish the new data structure and the old, we use $\bar{L}, \bar{Q}$ and $\bar{\Gamma}$ in place of L, Q and Γ when referring to the new data structure. L, Q and Γ refers to the old data structure.

So fix an $I \in \mathcal{I}^*$. By our choice of $\mathcal{I}^*$, we have

$$\Gamma^{\alpha Y}(I) \geq \left(1 - \frac{1}{\lg^3 \lg n}\right) \cdot \left(1 - \frac{1}{Z}\right) \cdot \frac{n \lg n}{\alpha Y}.$$

i.e. the old data structure has many pairs (b, i) that are αY-scattered on input I. By definition of $\bar{L}^{\alpha Y}(I)$, we need to lower bound the number of such pairs (b, i) that have $\bar{Q}_i^{\alpha Y}(b, I)$ non-empty, i.e. at least one query reporting b in tree-levels $\{i\alpha Y, \ldots, (i + 1)\alpha Y - 1\}$ is accepted by our new query algorithm. For this, let (b, i) be a pair that was αY-scattered for I in the old data structure. By definition of αY-scattered we know that $Q_i^{\alpha Y}(b, I)$ is non-empty. Now observe that if $Q_i^{\alpha Y}(b, I)$ contains a query that made 0 probes, then that query is also in $\bar{Q}^{\alpha Y}(b, I)$. Similarly if $Q_i^{\alpha Y}(b, I)$ contains a query making its first probe in a w^3-popular

cell, then that query is also in $\bar{Q}_i^{\alpha Y}(b,I)$ since we publish all w^3-popular cells. Hence $\bar{Q}_i^{\alpha Y}(b,I)$ can be empty only if $Q_i^{\alpha Y}(b,I)$ contains no queries making 0 probes and no queries probing a w^3-popular cell. Since (b,i) was αY-scattered, this implies $|C_i^{\alpha Y}(b,I)| \geq \alpha/\lg^6 \lg n$. Furthermore, we get that $\bar{Q}_i^{\alpha Y}(b,I)$ becomes empty only if none of these cells are in P^*.

Letting $\mu = n \lg n/(w \lg^{10} \lg n)$, we get that $C_i^{\alpha Y}(b,I)$ has a non-zero intersection with the following fraction of μ-sized cell sets:

$$1 - \frac{\binom{S-|C_i^{\alpha Y}(b,I)|}{\mu}}{\binom{S}{\mu}} \geq 1 - \frac{(S-\alpha/\lg^6 \lg n)!(S-\mu)!\mu!}{S!(S-\alpha/\lg^6 \lg n-\mu)!\mu!} \geq 1 - \frac{(S-\mu)^{\alpha/\lg^6 \lg n}}{(S-\alpha/\lg^6 \lg n)^{\alpha/\lg^6 \lg n}} =$$
$$1 - \left(\frac{S-\alpha/\lg^6 \lg n+\alpha/\lg^6 \lg n-\mu}{S-\alpha/\lg^6 \lg n}\right)^{\alpha/\lg^6 \lg n} = 1 - \left(1 - \frac{\mu-\alpha/\lg^6 \lg n}{S-\alpha/\lg^6 \lg n}\right)^{\alpha/\lg^6 \lg n}.$$

Since $\alpha = (Sw \lg^{18} \lg n)/(n \lg n) = S \lg^8 \lg n/\mu \ll \mu/2$, this is at least a

$$1 - \left(1 - \frac{\mu}{2S}\right)^{\alpha/\lg^6 \lg n} \geq 1 - \exp\left(-\alpha\mu/(2S \lg^6 \lg n)\right) \geq 1 - 1/\lg n$$

fraction. Since we chose P^* to maximize the number sets $C_i^{\alpha Y}(b,I)$ having a non-empty intersection, we conclude that at least

$$\left(1 - \frac{1}{\lg n}\right) \cdot \left(1 - \frac{1}{\lg^3 \lg n}\right) \cdot \left(1 - \frac{1}{Z}\right) \cdot \frac{n \lg n}{\alpha Y} \geq \left(1 - \frac{1}{Z} - \frac{2}{Z \lg^3 \lg n}\right) \frac{n \lg n}{\alpha Y}$$

sets $\bar{Q}_i^{\alpha Y}(b,I)$ must be non-empty. Since $Z \geq 2$, we finally conclude

$$\bar{L}^{\alpha Y}(I) \geq \left(1 - \frac{1}{Z} - \frac{1}{\lg^3 \lg n}\right) \frac{n \lg n}{\alpha Y}.$$

Abstract

We study data structure problems related to document indexing and pattern matching queries and our main contribution is to show that the pointer machine model of computation can be extremely useful in proving high and unconditional lower bounds that cannot be obtained in any other known model of computation with the current techniques. Often our lower bounds match the known space-query time trade-off curve and in fact for all the problems considered, there is a very good and reasonable match between our lower bounds and the known upper bounds, at least for some choice of input parameters.

The problems that we consider are *set intersection* queries (both the *reporting* variant and the *semi-group counting* variant), indexing a set of documents for *two-pattern* queries, or *forbidden-pattern* queries, or *queries with wild-cards*, and indexing an input set of *gapped-patterns* (or *two-patterns*) to find those matching a document given at the query time.

1 Introduction

In this paper we study a number of data structure problems related to document indexing and prove space and query time lower bounds that in most cases are almost tight. Unlike many of the previous lower bounds, we disallow random accesses by working in the pointer machine model of computation, however, we obtain high and unconditional space and query time lower bounds that almost match the best known data structures for all the problems considered; at the moment, obtaining such unconditional and tight lower bounds in other models of computation is a hopelessly difficult problem. Furthermore, compared to the previous lower bounds in the area, our lower bounds probe deeper and thus are much more informative. Consequently, these results show the usefulness of the pointer machine model.

Document indexing is an important problem in the field of information retrieval. Generally, the input is a collection of documents $\mathcal{D} = \{d_1, d_2, \ldots d_D\}$ with a total length of n characters

Table 1 At every row, the 3rd cell presents our space lower bound for data structures that have a query time bounded by the 2nd cell. PM stands for the pointer machine model. n is the input size and t is the output size.

Problem	Query Bound	Space Lower Bound	Assumptions
2P, FP, SI, 2FP (counting)	$Q(n)$	$\Omega(n^{2-o(1)}/Q^2(n))$	Semi-group
2P, FP, SI, 2FP (reporting)	$Q(n)+\mathcal{O}(t)$	$\Omega(n^{2-o(1)}/Q(n))$	PM
2P, FP, SI, 2FP (reporting)	$\mathcal{O}((nt)^{\frac{1}{2}-\alpha}+t)$	$\Omega\left(n^{\frac{1+6\alpha}{1+2\alpha}-o(1)}\right)$	PM, $\alpha>0$ a parameter
WCI (reporting)	$Q(n,\kappa)+\mathcal{O}(t)$	$\Omega\left(\frac{n}{\kappa}\Theta\left(\frac{\log n}{\kappa\log Q(n,\kappa)}\right)^{\kappa-1}\right)$	PM, κ wild-cards, $\kappa\leq\log_{Q(n,\kappa)} n$
WCI (reporting)	$\mathcal{O}(2^{\kappa/2}+t)$	$\Omega\left(n^{1+\Theta(1/\log k)}\right)$	PM, κ wild-cards, $3\sqrt{\log n}\leq\kappa=o(\frac{\log n}{\log\log n})$
κ-GPI	$o\left(\frac{D\gamma^\kappa}{(2+2\log D)^{\kappa+1}}\right)$	$n^{\Omega(\log^{1/(2\kappa)} n)}$	PM, $\alpha_i=0,\beta_i=\gamma$ $\kappa=o(\frac{\log\log n}{\log\log\log n})$

and usually the goal is to index them such that given a query, all the documents matching the query can be either found efficiently (the *reporting variant*) or counted efficiently (the *searching variant*). When the query is just one text pattern, the problem is classical and well-studied and there are linear space solutions with optimal query time [33]. Not surprisingly, there have been various natural extensions of this problem. We summarize the problems we study and our results below.

1.1 New and Previous Results

1.1.1 Two-pattern and the Related Queries

The *two-pattern query problem* (abbreviated as the 2P problem) was introduced in 2001 by Ferragina et al. [22] and since then it has attracted lots of attention. In the 2P problem, each query is composed of two patterns and a document matches the query if both patterns occur in the document. One can also define the *Forbidden Pattern* (FP) problem [23] where a document matches the query if it contains one pattern but not the other. For symmetry, we also introduce and consider the *Two Forbidden Patterns* (2FP) problem where none of the patterns are allowed to match the document.

Previous Results. Ferragina et al. [22] presented a number of solutions for the 2P problem with space and query times that depend on the "average size" of each document but the worst case query time and space is $\mathcal{O}(P_1+P_2+n^\alpha+t)$ and $\mathcal{O}(n^{2-\alpha}\log^{\mathcal{O}(1)} n)$, for any $0<\alpha<1$, respectively. Here P_1 and P_2 are the sizes of the query patterns and t is the output size (see also [33]). Cohen and Porat [18] offered a solution that uses $\mathcal{O}(n\log n)$ space with $\mathcal{O}(P_1+P_2+\sqrt{nt}\log^{2.5} n)$ query time. The space was improved to $\mathcal{O}(n)$ and the query time to $\mathcal{O}(P_1+P_2+\sqrt{nt}\log^{1.5} n)$ by Hon et al. [24]. The query time was reduced by a $\mathcal{O}(\sqrt{\log n})$ in [29] factor and finally the query time $\mathcal{O}(P_1+P_2+\sqrt{nt})$ was achieved in [10].

The FP problem was introduced by Fischer et al. [23] and they presented a data structure that stores $\mathcal{O}(n^{3/2})$ bits and answers queries in $\mathcal{O}(P_1+P_2+\sqrt{n}+t)$ time. Another solution was given by Hon et al. [25] that uses $\mathcal{O}(n)$ space but has $\mathcal{O}(P_1+P_2+\sqrt{nt}\log^{2.5} n)$ query time. For the searching variant (unweighted) their solution can answer queries in

$\mathcal{O}(P_1 + P_2 + \sqrt{n}\log\log n)$ time. As Larsen et al. [29] remark, the $\log\log n$ factor can be removed by using range emptiness data structures and that the same data structure can be used to count the number of matching documents for the two pattern problem.

The difficulty of obtaining fast data structures using (near) linear space has led many to believe that very efficient solutions are impossible to obtain. Larsen et al. [29] specifically focus on proving such impossibility claims and they show that the 2P and FP problems are at least as hard as Boolean Matrix Multiplication, meaning, with current techniques, $P(n) + nQ(n) = \Omega(n^{\omega/2})$ where $P(n)$ and $Q(n)$ are the preprocessing and the query times of the data structure, respectively and ω is the exponent of the best matrix multiplication algorithm (currently $\omega = 2.3728639$). If one assumes that there is no "combinatorial" matrix multiplication algorithm with better running time than $O(n^{3-o(1)})$, then the lower bound becomes $P(n) + nQ(n) = \Omega(n^{1.5-o(1)})$. Other conditional lower bounds for the 2P and FP problems but from the integer 3SUM conjecture were obtained by Kopelowitz, et al. [27, 28].

The above results are conditional. Furthermore, they tell us nothing about the complexity of the space usage, $S(n)$, versus the query time which is what we are truly interested in for data structure problems. Furthermore, even under the relatively generous assumption[1] that $P(n) = \mathcal{O}(S(n)n^{o(1)})$, the space and query lower bounds obtained from the above results have polynomial gaps compared with the current best data structures.

We need to remark that the only unconditional space lower bound is a pointer machine lower bound that shows with query time of $\mathcal{O}(\text{poly}(\log n) + k)$ the space must be $\Omega(n(\log n/\log\log n)^3)$ [23]. However this bound is very far away from the upper bounds (and also much lower than our lower bounds).

Our Results. We show that all the known data structures for 2P and FP problems are optimal within $n^{o(1)}$ factors, at least in the pointer machine model of computation: Consider a pointer machine data structure that uses $S(n)$ space and can report all the t documents that match a given 2P query (or FP query, or 2FP query) in $Q(n) + \mathcal{O}(P_1 + P_2 + t)$ time. We prove that we must have $S(n)Q(n) = \Omega\left(n^{2-o(1)}\right)$. As a corollary of our lower bound construction, we also obtain that any data structure that can answer 2P query (or FP query, or 2FP query) in $\mathcal{O}((nt)^{1/2-\varepsilon} + t)$ time, for any fixed constant $\varepsilon > 0$ must use super-linear space. As a side result, we show that surprisingly, the counting variant of the problem is in fact easier: in the semi-group model of computation (see [15] or the full version of this paper [5] for a description of the semi-group model), we prove that we must have

$$S(n)Q^2(n) = \Omega(n^2/\log^4 n)\,.$$

1.1.2 Set Intersection Queries

The interest in set intersection problems has grown considerably in recent years and variants of the set intersection problem have appeared in many different contexts. Here, we work with the following variants of the problem. The input is m sets, $S_1, \cdots, S_m$ of total size n, from a universe $\mathcal{U}$ and a query is a pair of indices i and j. The *decision variant* asks whether $S_i \cap S_j = \emptyset$. The *reporting variant* asks for all the elements in $S_i \cap S_j$. In the *counting variant*, the result should be $|S_i \cap S_j|$. In the *searching variant*, the input also includes a weight function $w : \mathcal{U} \to G$ where G is a semi-group. The query asks for $\sum_{x \in S_i \cap S_j} w(x)$.

[1] There are problems, such as jumbled indexing [13], where the preprocessing time is a polynomial factor larger than the space complexity.

Previous Results. The set intersection queries have appeared in many different formulations and variants (e.g., see [19, 37, 36, 1, 27, 18]). The most prominent conjecture is that answering the decision variant with constant query time requires $\Omega(n^{2-o(1)})$ space (see [37] for more details). For the reporting variant, Cohen and Porat [18] presented a data structure that uses linear space and answers queries in $\mathcal{O}(\sqrt{nt})$ time, where t is the output size. They also presented a linear-space data structure for the searching variant that answers queries in $\mathcal{O}(\sqrt{n})$ time. In [26] the authors study set intersection queries because of connections to dynamic graph connectivity problems. They offer very similar bounds to those offered by Cohen and Porat (with a $\sqrt{\log n}$ factor worse space and query times) but they allow updates in $\mathcal{O}(\sqrt{n \log n})$ time. It is commonly believed that all set intersection queries are hard. Explicitly stated conjectures on set intersection problems are used to obtain conditional lower bounds for problems such as distance oracles [37, 36, 19] while other well-known conjectures, such as the 3SUM conjecture, can be used to show conditional lower bounds for variants of set intersection problems [27, 1]. For other variants see [9, 34, 21].

Dietz et al. [21] considered set intersection queries in the semi-group model (a.k.a *the arithmetic model*) and they presented near optimal dynamic and offline lower bounds. They proved that given a sequence of n updates and q queries one must spend $\Omega(q + n\sqrt{q})$ time (ignoring polylog factors); in the offline version a sequence of n insertions and q queries are used but in the dynamic version, the lower bound applies to a dynamic data structure that allows insertion and deletion of points, as well as set intersection queries.

Our Results. Our lower bounds for the 2P problem easily extend to the SI problem. Perhaps the most interesting revelation here is that the searching variant is much easier than the reporting variant ($S(n)Q(n) = \Omega(n^{2-o(1)})$ for reporting versus $S(n)Q(n)^2 = \Omega(n^{2-o(1)})$ for searching)[2]. Based on this, we make another conjecture that even in the RAM model, reporting the elements in $S_i \cap S_j$ for two given query indices i and j, in $\mathcal{O}(n^{1-\varepsilon} + |S_i \cap S_j|)$ time, for any fixed constant $\varepsilon > 0$, requires $\omega(n)$ space. Such a separation between counting and reporting is a rare phenomenon with often counting being the difficult variant.

Observe that conditional lower bounds based on the Boolean Matrix Multiplication or the integer 3SUM conjectures have limitations in distinguishing between the counting and the reporting variants: For example, consider the framework of Larsen et al. [29] and for the best outcome, assume $P(n) = S(n)n^{o(1)}$ and also that boolean matrix multiplication requires $\Omega(n^{3-o(1)})$ time; then their framework yields that $S(n) + nQ(n) = \Omega(n^{3/2-o(1)})$. When $Q(n) = \Theta(n^{2/3})$ this does not rule out the possibility of having $S(n) = \mathcal{O}(n)$ (in fact the counting variant *can* be solved with linear space). However, our lower bound shows that even with $Q(n) = \Theta(n^{2/3})$ the reporting variant requires $\Omega(n^{4/3-o(1)})$ space.

1.1.3 Wild Card Indexing

We study the document indexing problem of matching with "don't cares", also known as *wild card matching* or *indexing* (WCI). The setup is the same as for the 2P problem, except a query is a single pattern but it also contains wild cards denoted by a special character "$*$". A "$*$" matches any *one* character. The task is to report all documents matched by the query. This is a well-studied problem from the upper bound perspective and there are generally two variations: either the maximum number of wild cards is bounded or it supports any number

[2] While we believe our lower bounds are certainly interesting (particularly since they separate counting and reporting variants), they do not make any progress towards resolving the status of the decision version which is considered a major open problem.

of wild cards. We consider the bounded version where patterns contain up to κ wild cards and κ is known in advance by the data structure.

Previous Results. Cole et al. [20] presented a data structure that uses $\mathcal{O}(n\frac{\log^\kappa n}{\kappa!})$ words of space and answers queries in $\mathcal{O}(P + 2^\kappa \log\log n + t)$, where t is the number of occurrences and P is the length of the query pattern. The space has been improved to $\mathcal{O}(n\log^{\kappa+\varepsilon} n)$ bits while keeping the same query time [30]. Another improvement came as a trade-off that increased query time to $\mathcal{O}(P + \beta^j \log\log n + t)$ and reduced space usage $\mathcal{O}(n\log n\log_\beta^{\kappa-1} n)$ for any $2 \le \beta \le \sigma$ where σ is the alphabet size and $j \le \kappa$ is the number of wild cards in the query [8]. In the same paper an alternate solution with $\mathcal{O}(P + t)$ query time and $\mathcal{O}(n\sigma^{\kappa^2}\log^\kappa n\log n)$ space usage was also presented. Other results have focused on reducing space while increasing the query time but their query time now depends on the alphabet size, e.g., in [31] the authors provide a data structure with $\mathcal{O}(n\log^\varepsilon n\log\sigma)$ space but with the query time of $\mathcal{O}(m + \sigma^\kappa\sqrt{\log\log\log n} + t)$.

From these bounds we note three things, first that all solutions have some exponential dependency on κ and second the alternate solution by Bille et al. [8] has an odd σ^{κ^2} factor, which is exponential on a *quadratic* function of κ as opposed to being exponential on a linear function of κ (such as 2^κ, σ^κ, or $\log^\kappa n$). Third, when the query time is forced to be independent of σ, there is a discrepancy between query and space when varying κ: Increasing κ (when it is small) by one increases the space by approximately a $\log n$ factor, while to increase the query time by a $\log n$ factor, κ needs to be increased by $\log\log n$. Based on the third point, it is quite likely that unlike SI or 2P problems, WCI does not have a simple trade-off curve.

Other results that are not directly comparable to ours include the following: One is an $\mathcal{O}(n)$ space index with $\mathcal{O}(P + \alpha)$ query time [38] where α is the number of occurrences of all the subpatterns separated by wild card characters. Note that α could be much larger than t and in fact, this can result in a worst case linear query time, even with small values of t. Nonetheless, it could perform reasonably well in practice. Two, there are lower bounds for the *partial match* problem, which is a related problem (see [35] for more details).

Our Results. For WCI with κ wild cards, we prove two results, both in the pointer machine model. In summary, we show that the exponential dependency of space complexity or query time on κ generally cannot be avoided.

As our first result and for a binary alphabet ($\sigma = 2$), we prove that for $3\sqrt{\log n} \le \kappa = o(\frac{\log n}{\log\log n})$, any data structure that answers queries in $\mathcal{O}(2^{\kappa/2} + P + t)$ time must consume $n^{1+\Theta(1/\log\kappa)}$ space. This result rules out the possibility of lowering the σ^{κ^2} factor in the alternate solution offered by Bille et al. [8], over all values of κ, to $\sigma^{\kappa^{2-\varepsilon}}$ for any constant $\varepsilon > 0$: by setting $\kappa = 3\sqrt{\log n}$ (and $\sigma = 2$), such a bound will be much smaller than our space lower bound (essentially involves comparing $2^{\mathcal{O}(\log^{1-\varepsilon/2} n)}$ factor to a $2^{\Omega(\log n/\log\log n)}$ factor). While this does not rule out improving the space bound for small values of κ, it shows that the exponential dependency on κ^2 is almost tight at least in a particular point in the range of parameters.

As our second result, we prove that answering WCI queries in $Q(n,\kappa) + \mathcal{O}(P + t)$ time requires $\Omega(\frac{n}{\kappa}\Theta\left(\frac{\log_{Q(n,\kappa)} n}{\kappa}\right)^{\kappa-1})$ space, as long as $\kappa < \log_{Q(n,\kappa)} n$. Note that this query time is assumed to be independent of σ. This result also has a number of consequences. One, it shows that any data structure with query time of $\mathcal{O}(\log^{\mathcal{O}(1)} n + P + t)$ requires $\Omega(\frac{n}{\kappa}\left(\frac{\log n}{\kappa\log\log n}\right)^{\kappa-1})$ space. Note that this is rather close to the space complexity of the

data structure of Cole et al. [20] ($2^{\mathcal{O}(\kappa)}(\log\log n)^\kappa$ factor away). In other words, the data structure of Cole et al. cannot be significantly improved both in space complexity and query time; e.g., it is impossible to answer WCI queries in $\mathcal{O}(\log^{\mathcal{O}(1)} n + P + t)$ time using $\mathcal{O}\left(n\left(\frac{\log n}{\kappa}\right)^{\kappa(1-\varepsilon)}\right)$ space, for any constant $\varepsilon > 0$.

Two, $\kappa = 2$ is the smallest value where linear space becomes impossible with polylogarithmic query time. This is very nice since $\kappa = 1$ can be solved with almost linear space [30]. Furthermore this shows that the increase by a $\log n$ factor in the space complexity for every increase of κ is necessary (for small values of κ).

Three, we can combine our second result with our first result when $\kappa = 3\sqrt{\log n}$. As discussed before, our first result rules out fast queries (e.g., when $Q(n) \leq 2^{\kappa/2}$), unless the data structure uses large amounts of space, so consider the case when $Q(n) = \mathcal{O}(2^\kappa)$. In this case, we can rule out lowering the space usage of the data structure of Cole et al. to $\Omega\left(n\left(\frac{\log n}{\kappa}\right)^{\kappa^{1-\varepsilon}}\right)$ for any constant $\varepsilon > 0$: apply our second lower bound with fewer wild cards, specifically, with $\kappa' = \kappa^{1-\delta}$ wild cards, for a small enough constant $\delta > 0$ that depends on ε. Observe that $\kappa' < \log_{Q(n)} n$, so the second result lower bounds the space by $\Omega\left(\frac{n}{\kappa'}\Theta\left(\log^{\frac{\delta}{2}\kappa^{1-\delta}} n\right)\right)$, which for a sufficiently small δ is greater than $\Omega\left(n\left(\frac{\log n}{\kappa}\right)^{\kappa^{1-\varepsilon}}\right)$.

As mentioned in the beginning, our results show that the exponential dependency of space or query time on κ cannot be improved in general. Furthermore, at a particular point in the range of parameters (when $\kappa = 3\sqrt{\log n}$), all the known exponential dependencies on κ are almost tight and cannot be lowered to an exponential dependency on $\kappa^{1-\varepsilon}$ (or on $\kappa^{2-\varepsilon}$ for the alternate solution) for any constant $\varepsilon > 0$. Nonetheless, there are still gaps between our lower bounds and the known data structures. We believe it is quite likely both our lower bounds and the existing data structures can be improved to narrow the gap.

1.1.4 Gapped Pattern Indexing

A κ-gapped pattern is a pattern $p_1\{\alpha_1, \beta_1\}p_2\{\alpha_2, \beta_2\}, \cdots, p_\kappa\{\alpha_\kappa, \beta_\kappa\}p_{\kappa+1}$ where α_i and β_i, $1 \leq i \leq \kappa$ are integers, and each p_i, $1 \leq i \leq \kappa + 1$, is a string over an alphabet of size σ. Such a κ-gapped pattern matches a documents in which one can find one occurrence of every p_i such that there are at least α_i and at most β_i characters between the occurrence of p_i and the occurrence of p_{i+1}, $1 \leq i \leq \kappa$.

Previous Results. The gapped pattern indexing is often considered both in the online and the offline version (e.g., see [7, 40]). However, the result most relevant to us is [6], where they consider the following data structure problem: given a set of 1-gapped patterns of total size n, where all the patterns are in the form of $p_1\{\alpha, \beta\}p_2$, store them in a data structure such that given a document of length D at the query time, one can find all the gapped patterns that match the query document (in general we call this the *κ-gapped pattern indexing (κ-GPI)* problem). In [6], the authors give a number of upper bounds and conditional lower bounds for the problem. Among a number of results, they can build a data structure of linear size that can answer queries in $\tilde{\mathcal{O}}(D(\beta - \alpha) + t)$ where $\tilde{\mathcal{O}}$ notation hides polylogarithmic factors and t is the output size. For the lower bound and among a number of results, they can show that with linear space $\Omega(D(\beta - \alpha)^{1-o(1)} + t)$ query time is needed.

Our Results. We consider the general κ-GPI problem where $\beta_i - \alpha_i = \gamma$ for all $1 \leq i \leq \kappa$, and a prove lower bound that is surprisingly very high: any pointer machine data structure

that can answer queries in $o(D\gamma^\kappa/(2\log D)^{\kappa+1})$ time must use *super polynomial* space of $n^{\Omega(\log^{1/(\kappa+1)} n)}$. By construction, this result also holds if the input is a set of $\kappa+1$ patterns where they all need to match the query document (regardless of their order and size of the gaps). In this case, answering queries in $o(D^{\kappa+1}/(2\log D)^{\kappa+1})$ requires the same super-polynomial space. Note that in this case $\kappa = 1$ is the "dual" of the 2P problem: store a set of two-patterns in data structure such that given a query document, we can output the subset of two-patterns that match the document.

1.2 Technical Preliminaries

The Pointer Machine Model [39]. This models data structures that solely use pointers to access memory locations (e.g., any tree-based data structure)[3]. We focus on a variant that is the popular choice when proving lower bounds [14]. Consider an abstract "reporting" problem where the input includes a universe set $\mathcal{U}$ where each query q reports a subset, $q_\mathcal{U}$, of $\mathcal{U}$. The data structure is modelled as a directed graph G with outdegree two (and a root node $r(G)$) where each vertex represents one memory cell and each memory cell can store one element of $\mathcal{U}$; edges between vertices represent pointers between the memory cells. All other information can be stored and accessed for free by the data structure. The only requirement is that given the query q, the data structure must start at $r(G)$ and explore a connected subgraph of G and find its way to vertices of G that store the elements of $q_\mathcal{U}$. The size of the subgraph explored is a lower bound on the query time and the size of G is a lower bound on the space.

An important remark. The pointer-machine can be used to prove lower bounds for data structures with query time $Q(n) + \mathcal{O}(t)$ where t is the output size and $Q(n)$ is "search overhead". Since we can simulate any RAM algorithm on a pointer-machine with $\log n$ factor slow down, we cannot hope to get high unconditional lower bounds if we assume the query time is $Q(n) + \mathcal{O}(t \log n)$, since that would automatically imply RAM lower bounds for data structures with $Q(n)/\log n + \mathcal{O}(t)$ query time, something that is hopelessly impossible with current techniques. However, when restricted to query time of $Q(n) + \mathcal{O}(t)$, the pointer-machine model is an attractive choice and it has an impressive track record of proving lower bounds that match the best known data structures up to very small factors, even when compared to RAM data structures; we mention two prominent examples here. For the fundamental *simplex range reporting* problem, all known solutions are pointer-machine data structures [32, 11, 17] and the known pointer machine lower bounds match these up to an $n^{o(1)}$ factor [2, 16]. One can argue that it is difficult to use the power of RAM for simplex range reporting problem. However, for the other fundamental *orthogonal range reporting*, where it is easy to do various RAM tricks, the best RAM data structures save at most a $\log n$ factor compared to the best known pointer machine solutions (e.g., see [3, 4, 12]). Also, where cell-probe lower bounds cannot break the $\log n$ query barrier, very high lower bounds are known for the orthogonal range reporting problem in the pointer machine model [3, 4, 14].

Known Frameworks. The fundamental limitation in the pointer machine model is that starting from a memory cell v, one can visit at most 2^ℓ other memory cells using ℓ pointer

[3] Many of the known solutions for various indexing problems use tree structures, such as suffix trees or wavelet trees. While sometimes trees are can be encoded using bit-vectors with rank/select structures on top, these tricks can only save polylogarithmic factors in space and query times.

navigations. There are two known methods that exploit this limitation and build two different frameworks for proving lower bounds.

The first lower bound framework was given by Bernard Chazelle [14, 16]. However, we will need a slightly improved version of his framework that is presented in the following lemma; essentially, we need a slightly tighter analysis on a parameter that was originally intended as a large constant. Due to lack of space, the proof is only available in the full version [5].

▶ **Theorem 1.** *Let $\mathcal{U}$ be a set of n input elements and $\mathcal{Q}$ a set of queries where each query outputs a subset of $\mathcal{U}$. Assume there exists a data structure that uses $S(n)$ space and answers each query in $Q(n) + \alpha k$ time, where k is the output size. Assume (i) the output size of any query $q \in \mathcal{Q}$, denoted by $|\mathcal{U} \cap q|$, is at least t, for a parameter $t \geq Q(n)$ and (ii) for integers ℓ and β, and indices, $i_1, \cdots, i_\ell$, $|\mathcal{U} \cap q_{i_1} \cap \cdots \cap q_{i_\ell}| < \beta$. Then, $S(n) = \Omega\left(\frac{|\mathcal{Q}|t}{\ell \cdot 2^{O(\alpha\beta)}}\right)$.*

The second framework is due to Afshani [2] and it is designed for "geometric stabbing problems": given an input set of n geometric regions, the goal is store them in a data structure such that given a query point q, one can output the subset of regions that contain q. The framework is summarized below.

▶ **Theorem 2** ([2])**.** *Assume one can construct a set of n geometric regions inside the d-dimensional unit cube such that (i) every point of the unit cube is contained in at least t regions [4], and (ii) the volume of the intersection of every β regions is at most v, for some parameters β, t, and v. Then, for any pointer-machine data structure that uses $S(n)$ space and can answer geometric stabbing queries on the above input in time $g(n)+O(k)$, where k is the output size and $g(\cdot)$ is some increasing function, if $g(n) \leq t$ then $S(n) = \Omega(tv^{-1}2^{-O(\beta)})$.*

These two frameworks are not easily comparable. In fact, for many constructions, often only one of them gives a non-trivial lower bound. Furthermore, as remarked by Afshani [2], Theorem 2 does not need to be operated in the d-dimensional unit cube and in fact any measure could be substituted instead of the d-dimensional Lebesgue measure.

Our Techniques. Our first technical contribution is to use Theorem 2 in a non-geometric setting by representing queries as abstract points under a discrete measure and each input object as a range that contains all the matching query points. Our lower bound for the κ-GPI problem and one of our WCI lower bounds are proved in this way. The second technical contribution is actually building and analyzing proper input and query sets to be used in the lower bound frameworks. In general, this is not easy and in fact for some problems it is highly challenging[5]. Also see Section 5 (Conclusions) for a list of open problems.

In the rest of this article, we present the technical details behind our κ-GPI lower bound and most of the details of our first WCI lower bound. Due to lack of space, the rest of the technical details can be found in the full version [5].

We begin with the κ-GPI problem since it turns out for this particular problem we can get away with a simple deterministic construction. For WCI, we need a more complicated randomized construction to get the best result and thus it is presented next.

---

[4] In [2] this is stated as "exactly t ranges" but the proof works with only a lower bound on t.

[5] A good example is the classical halfspace range reporting problem where constructing proper input and query sets has been a longstanding open problem; the current best lower bound uses a highly inefficient reduction from the simple range reporting problem [2].

2 Gapped Pattern Lower Bound

In this section we deal with the data structure version of the gapped pattern problem. The input is a collection of κ-gapped patterns (typically called a dictionary), with total length n (in characters). The goal is to store the input in a data structure such that given a document of size D, one can report all the input gapped patterns that match the query. We focus on special κ-gapped patterns that we call *standard*: a standard κ-gapped pattern in the form of $p_1 \{0,\gamma\} p_2 \{0,\gamma\} \dots \{0,\gamma\} p_{\kappa+1}$ where each p_i is a string (which we call a *subpattern*) and γ is an integer.

▶ **Theorem 3.** *For $\kappa = o(\frac{\log\log n}{\log\log\log n})$ and in the pointer machine model, answering κ-GPI queries in $o\left(\frac{D\gamma^\kappa}{(2+2\log D)^{\kappa+1}}\right) + O(t)$ time requires $n^{\Omega(\log^{1/(2\kappa)} n)}$ space.*

To prove this theorem, we build a particular input set of standard κ-gapped patterns. We pick the alphabet $\Sigma = \{0, 1, \#\}$, and the gapped patterns only use $\{0, 1\}$. Each subpattern in the input is a binary string of length p. The subpatterns in any gapped pattern are in lexicographic order, and a subpattern occurs at most once in a pattern (i.e., no two subpatterns in a pattern are identical). The input set, S, contains all possible gapped patterns obeying these conditions. Thus, $|S| = \binom{2^p}{\kappa+1}$. Each query is a text composed of concatenation of $D/(p+1)$ substrings (for simplicity, we assume $D/(p+1)$ is an integer) and each substring is in the form '$\#\{0,1\}^p$'. We restrict the query substrings to be in lexicographic order and without repetitions (no two substrings in a query are identical). The set of all query texts satisfying these constraints is denoted by Q. Thus, $|Q| = \binom{2^p}{D/(p+1)}$.

▶ **Lemma 4.** *For $D \geq 2\kappa\gamma$, any text $T \in Q$ matches $\Theta\left(\frac{D\gamma^\kappa}{(p+1)^{\kappa+1}}\right)$ gapped patterns in S.*

Proof. Consider a text $T \in Q$. To count the number of gapped patterns that can match it, we count the different ways of selecting $\kappa+1$ positions that correspond to the starting positions of a matching subpattern. Each position starts immediately after '#', with at most γ characters between consecutive positions. Since $D \geq 2\kappa\gamma$, we have $\Theta(D/p)$ choices for picking the first position, i.e., the starting position of a gapped pattern matching T. After fixing the first match, there are at most $\gamma/(p+1)$ choices for the position of the next match between a subpattern and substring. However, if the first match happens in the first half of text T, there are always $\gamma/(p+1)$ choices for the position of each subpattern match (since $D \geq 2\kappa\gamma$). Thus, we have $\Theta\left(D\gamma^k/(p+1)^{\kappa+1}\right)$ choices. As input subpatterns are in lexicographically increasing order, different choices result in distinct gapped patterns that match the query. ◀

To apply Theorem 2, we consider each query text T in Q as a "discrete" point with measure $1/|Q|$. Thus, the total measure of Q (i.e., the query space) is one and Q functions as the "unit cube" within the framework of Theorem 2. We consider an input gapped pattern P in S as a range that contains all the points of Q that match P. Thus, to apply Theorem 2, we need to find a lower bound on the output size of every query (condition (i)) and an upper bound on v, the measure of the intersection of β inputs (condition (ii)). By the above lemma, meeting the first condition is quite easy: we pick $t = \Theta\left(\frac{D\gamma^\kappa}{(p+1)^{\kappa+1}}\right)$ (with the right hidden constant). Later we shall see that $p = 1 + 2\log D$ so this can be written as $t = \Theta\left(\frac{D\gamma^\kappa}{(2+2\log D)^{\kappa+1}}\right)$ Thus, we only need to upper bound v which we do below.

▶ **Lemma 5.** *Consider β patterns $P_1, \cdots, P_\beta \in S$. At most $\binom{2^p - \beta^{1/(\kappa+1)}}{D/(p+1) - \beta^{1/(\kappa+1)}}$ texts in Q can match all patterns $P_1, \cdots, P_\beta$.*

Proof. Collectively, $P_1, \cdots, P_\beta$ must contain at least $r = \beta^{1/(\kappa+1)}$ distinct subpatterns: otherwise, we can form at most $\binom{r}{\kappa+1} < \beta$ different gapped patterns, a contradiction. This in turn implies that any text T matching $P_1, \cdots, P_\beta$ must contain all these at least r distinct subpatterns. Clearly, the number of such texts is at most $\binom{2^p - \beta^{1/(\kappa+1)}}{D/(p+1) - \beta^{1/(\kappa+1)}}$. ◀

As the measure of each query in Q is $1/|Q|$, by the above theorem, we have $v \leq \binom{2^p - \beta^{1/(\kappa+1)}}{D/(p+1) - \beta^{1/(\kappa+1)}}/|Q|$. We now can apply Theorem 2. Each pattern in the input has $\Theta(p\kappa)$ characters and thus the total input size, n, is $\Theta(p\kappa|S|) = \Theta(p\kappa\binom{2^p}{\kappa+1})$. By the framework, and Lemmata 5 and 4, we know that the space usage of the data structure is at least

$$\Omega\left(\frac{D\gamma^\kappa}{(p+1)^{\kappa+1}} \cdot \frac{\binom{2^p}{D/(p+1)}}{\binom{2^p - \beta^{1/(\kappa+1)}}{D/(p+1) - \beta^{1/(\kappa+1)}}} \cdot 2^{-\mathcal{O}(\beta)}\right) = \Omega\left(1 \cdot \left(\frac{(p+1)2^{(p-1)}}{D}\right)^{\beta^{1/(\kappa+1)}} \cdot 2^{-\mathcal{O}(\beta)}\right)$$

where to obtain the rightmost equation we expand the binomials, simplify, and constrain $\beta^{1/(\kappa+1)} < 2^p/2$ to lower bound $2^p - \beta^{1/(\kappa+1)}$ with 2^{p-1}. Now we work out the parameters. We know that $n = \Theta(p\kappa\binom{2^p}{\kappa+1}) = 2^{\Theta(p(\kappa+1))}$; this is satisfied by setting $p = c_p(\log n)/(\kappa+1)$ for some constant c_p. Observe that there is an implicit constraint on D and p: there should be sufficient bits in the subpatterns to fill out a query with distinct subpatterns, i.e. $2^p > D/(p+1)$; we pick $D = n^{c_D 1/(\kappa+1)}$ for some other constant c_D such that $D = 2^{p/2-1}$ and thus $(p+1)2^{p-1}/D = 2^{p/2}$. Using these values, the space lower bound is simplified to

$$\Omega\left(2^{\beta^{1/(\kappa+1)}\frac{c_p}{2}\frac{\log n}{\kappa+1}} \cdot 2^{-c_\beta\beta}\right)$$

where c_β is another constant. We now optimize the lower bound by picking β such that $c_\beta\beta = \frac{1}{2}\beta^{1/(\kappa+1)}\frac{c_p}{2}\frac{\log n}{\kappa+1}$ which solves to $\beta = \Theta((\frac{\log n}{\kappa+1})^{1+1/\kappa})$. Thus, for constant c, the space complexity of the data structure is

$$\Omega\left(2^{c\left(\frac{\log n}{\kappa+1}\right)^{1+\frac{1}{\kappa}}}\right) = \Omega\left(2^{\log n \cdot c \log^{\frac{1}{\kappa}} n\left(\frac{1}{\kappa+1}\right)^{1+\frac{1}{\kappa}}}\right) = n^{\Omega\left(\log^{\frac{1}{\kappa}} n\left(\frac{1}{\kappa+1}\right)^{1+\frac{1}{\kappa}}\right)} = n^{\Omega\left(\log^{\frac{1}{2\kappa}} n\right)}$$

where the last part follows from $\kappa = o(\log\log n/\log\log\log n)$.

3 Wild Card Indexing

In this section we consider the wild card indexing (WCI) problem and prove both space and query lower bounds in the pointer machine model of computation. Note that our query lower bound applies to an alphabet size of two (i.e., binary strings).

3.1 The Query Lower Bound

Assume for any input set of documents of total size n, we can build a data structure such that given a WCI query of length m containing κ wild cards, we can find all the documents that match the query in $Q(n,\kappa) + O(m+t)$ time, where t is the output size. Furthermore, assume κ is a fixed parameter known by the data structure and that the data structure consumes $S(n,\kappa)$ space. Our main result here is the following.

▶ **Theorem 6.** *If* $3\sqrt{\log n} \leq \kappa = o(\log n)$ *and* $Q(n,\kappa) = O(2^{\frac{\kappa}{2}})$, *then* $S(n,\kappa) \geq n^{1+\Theta(\frac{1}{\log\kappa})}$.

To prove the lower bound, we build a *particular* set of documents and patterns and prove that if the data structure can answer the queries fast, then it must consume lots of space, for this particular input, meaning, we get lower bounds for the function $S(\cdot)$. We now present the details. We assume $Q(n,\kappa) \leq 2^{\kappa/2}$, as otherwise the theorem is trivial.

Documents and patterns. We build the set of documents in two stages. Consider the set of all bit strings of length m with exactly $\ell = \kappa/2$ "1"s. In the first stage, we sample each such string independently with probability r^{-1} where $r = 2^{\kappa/3}$. Let $\mathcal{D}$ be the set of sampled strings. In the second stage, for every set of $\ell + \ell'$ indices, $1 \leq i_1 < i_2 < \cdots < i_{\ell+\ell'} \leq m$, where $\ell' = (\log_\ell r)/2 = \Theta(\kappa/\log\kappa)$, we perform the following operation, given another parameter β: if there are more than β strings in $\mathcal{D}$ that have "1"s only among positions $i_1, \cdots, i_{\ell+\ell'}$, then we remove all such strings from $\mathcal{D}$. Consequently, among the remaining strings in $\mathcal{D}$, "1"s in every subset of β strings will be spread over at least $\ell + \ell' + 1$ positions. The set of remaining strings $\mathcal{D}$ will form our input set of documents. Now we consider the set $\mathcal{P}$ of all the patterns of length m that have exactly κ wild cards and $m - \kappa$ "0"s. We remove from $\mathcal{P}$ any pattern that matches fewer than $\binom{\kappa}{\ell}/(2r)$ documents from $\mathcal{D}$. The remaining patterns in $\mathcal{P}$ will form our query set of patterns. In the full version [5], we prove the following.

▶ **Lemma 7.** *With positive probability, we get a set $\mathcal{D}$ of $\Theta(\binom{m}{\ell}/r)$ documents and a set $\mathcal{P}$ of $\Theta(\binom{m}{\kappa})$ patterns such that (i) each pattern matches $\Theta(\binom{\kappa}{\ell}/r)$ documents, and (ii) there are no $\beta = \Theta(\log_\kappa m)$ documents whose "1"s are contained in a set of $\ell + \ell'$ indices.*

To prove the lower bound, we use Theorem 2. We use a discrete measure here: each pattern is modelled as a "discrete" point with measure $\frac{1}{|\mathcal{P}|}$, meaning, the space of all patterns has measure one. Each document forms a range: a document d_i contains all the patterns (discrete points) that match d_i. Thus, the measure of every document $d_i \in \mathcal{D}$ is $t_i/|\mathcal{P}|$, where t_i is the number of patterns that match d_i. We consider the measure of the intersection of β documents (regions) $d_1, \ldots, d_\beta$. By Lemma 7, there are $\ell + \ell'$ indices where one of these documents has a "1"; any pattern that matches all of these documents must have a wild card in all of those positions. This means, there are at most $\binom{m-\ell-\ell'}{\kappa-\ell-\ell'}$ patterns that could match documents $d_1, \ldots, d_\beta$. This means, when we consider documents as ranges, the intersection of every β documents has measure at most $\binom{m-\ell-\ell'}{\kappa-\ell-\ell'}/|\mathcal{P}|$ which is an upper bound for parameter v in Theorem 2. For the two other parameters t and $g(n)$ in the theorem we have, $t = \Theta(\binom{\kappa}{\ell}/r)$ (by Lemma 7) and $g(n) = Q(n,\kappa) + O(m)$. To obtain a space lower bound from Theorem 2, we must check if $g(n) \leq t = \Theta(\binom{\kappa}{\ell}/r)$. Observe that $\binom{\kappa}{\ell} = \binom{\kappa}{\kappa/2} \geq 2^\kappa/\kappa$ since the binomials $\binom{\kappa}{i}$ sum to 2^κ for $0 \leq i \leq \kappa$ and $\binom{\kappa}{\kappa/2}$ is the largest one. As $r = 2^{-\kappa/3}$, we have $t = \Omega(2^\kappa 2^{-\kappa/3}/\kappa) = \omega(2^{\kappa/2}) = \omega(Q(n,k))$. However, $g(n)$ also involves an additive $O(m)$ term. Thus, we must also have $t = \omega(m)$ which will hold for our choice of parameters but we will verify it later.

By guaranteeing that $g(n) \leq t$, Theorem 2 gives a space lower bound of $\Omega(tv^{-1}2^{-O(\beta)})$. However, we would like to create an input of size $\Theta(n)$ which means the number of sampled documents must be $\Theta(n/m)$ and thus we must have $\binom{m}{\ell}/r = \Theta(n/m)$. As $m = \omega(\kappa)$, it follows that $\binom{m}{\ell} = (\Theta(1)m/\ell)^\ell$. Thus, $(\Theta(1)m/\ell)^\ell = \Theta(rn/m)$. Thus, we have that

$$v^{-1} \geq \frac{|P|}{\binom{m-\ell-\ell'}{\kappa-\ell-\ell'}} \geq \frac{\Theta\left(\binom{m}{\kappa}\right)}{\binom{m-\ell-\ell'}{\kappa-\ell-\ell'}} = \Theta(1)\cdot\frac{\frac{m!}{\kappa!(m-\kappa)!}}{\frac{(m-\ell-\ell')!}{(\kappa-\ell-\ell')!(m-\kappa)!}} \geq \Theta(1)\cdot\frac{m^{\ell+\ell'}}{(2\kappa)^{\ell+\ell'}} = \frac{\Theta(1)\cdot n}{m\Theta(1)^\kappa}\cdot\left(\frac{m}{2\kappa}\right)^{\ell'}$$

where the last step follows from $(\Theta(1)m/\ell)^\ell = \Theta(rn/m)$, $r = 2^{\kappa/3}$ and $\ell = \kappa/2$.

Now we bound m in terms of n. From $(m/(2\kappa))^\ell = \frac{n}{mc^\kappa}$ we obtain that $m = \kappa^{\ell/(\ell+1)} \cdot n^{1/(\ell+1)}/\Theta(1)^\kappa = n^{2/(\kappa+2)}/\Theta(1)^\kappa$. Remember that $\ell' = \Theta(\kappa/\log\kappa)$. Based on this, we get that $v^{-1} = n \cdot n^{\Theta(1/\log\kappa)}/\Theta(1)^\kappa$ and since $\kappa = o(\log n/\log\log n)$ the $\Theta(1)^\kappa$ term is dominated and we have $v^{-1} = n \cdot n^{\Theta(1/\log\kappa)}$. It remains to handle the extra $2^{-O(\beta)}$ factor in the space lower bound. From Lemma 7, we know that $\beta = c\log_\kappa m$. Based on the value of m, this means $\beta = \Theta(\log n/(\kappa\log\kappa))$ which means $2^{-O(\beta)}$ is also absorbed in $n^{\Theta(1/\log\kappa)}$

factor. It remains to verify one last thing: previously, we claimed that we would verify that $t = \omega(m)$. Using the bound $t = \omega(2^{\kappa/2})$ this can be written as $2^{\kappa/2} = \omega(m)$ which translates to $\kappa/2 = (2\log n)/(\kappa+2) + \omega(1)$ which clearly holds if $\kappa \geq 3\sqrt{\log n}$.

3.2 The Space Lower Bound

The details of our space lower can be found in the full version [5], where we prove the following.

▶ **Theorem 8.** *labelthm:wcis Any pointer-machine data structure that answers WCI queries with κ wild cards in time $Q(n) + O(m + t)$ over an input of size n must use $\Omega\left(\frac{n}{\kappa}\Theta\left(\frac{\log_{Q(n)} n}{\kappa}\right)^{\kappa-1}\right)$ space, as long as $\kappa < \log_{Q(n)} n$, where t is the output size, and m is the pattern length.*

Refer to the introduction for a discussion of the consequences of these lower bounds.

4 Two Pattern Document Indexing and Related Problems

Due to lack of space we only state the primary results for 2P, FP, 2FP, and SI. The proofs for Theorems 9 and 10 can be found in the full version [5].

▶ **Theorem 9.** *Any data structure on the Pointer Machine for the 2P, FP, 2FP, and SI problems with query time $Q(n)$ and space usage $S(n)$ must obey $S(n)Q(n) = \Omega\left(n^{2-o(1)}\right)$.*

Also, if $Q(n,k) = O((nk)^{1/2-\alpha} + k)$ for a constant $0 < \alpha < 1/2$, then $S(n) = \Omega\left(n^{\frac{1+6\alpha}{1+2\alpha}-o(1)}\right)$.

The above theorem is proved using Theorem 1 which necessitates a randomized construction involving various high probability bounds. Unlike our lower bound for κ-GPI we were unable to find a deterministic construction that uses Theorem 2.

We also prove the following lower bound in the semi-group model which addresses the difficulty of the counting variants of 2P and the related problems.

▶ **Theorem 10.** *Answering 2P, FP, 2FP, and SI queries in the semi-group model requires $S(n)Q^2(n) = \Omega(n^2/\log^4 n)$.*

5 Conclusions

In this paper we proved unconditional and high space and query lower bounds for a number of problems in string indexing. Our main message is that the pointer machine model remains an extremely useful tool for proving lower bounds, that are close to the *true complexity* of many problems. We have successfully demonstrated this fact in the area of string and document indexing. Within the landscape of lower bound techniques, the pointer machine model, fortunately or unfortunately, is the only model where we can achieve *unconditional, versatile, and high* lower bounds and we believe more problems from the area of string and document indexing deserve to be considered in this model. To this end, we outline a number of open problems connected to our results.

1. Is it possible to generalize the lower bound for 2P to the case where the two patterns are required to match within distance γ? This is essentially a "dual" of the 1-GPI problem.
2. Recall that our space lower bound for the WCI problem (Subsection 3.2) assumes that the query time is independent of the alphabet size σ. What if the query is allowed to increase with σ?

3. Our query lower bound for the WCI (Subsection 3.1) is proved for a binary alphabet. Is it possible to prove lower bounds that take σ into account? Intuitively the problem should become more difficult as σ increases, but we were unable to obtain such bounds.
4. We require certain bounds on κ for the WCI problem. Is it possible to remove or at least loosen them? Or perhaps, can the upper bounds be substantially improved?
5. What is the difficulty of the κ-GPI problem when κ is large?

Acknowledgements. We thank Karl Bringmann for simplifying the construction of our documents for the 2P problem. We thank Moshe Lewenstein for bringing the WCI problem to our attention. We also thank the anonymous referees for pointing us to [21].

Proof Complexity Modulo the Polynomial Hierarchy: Understanding Alternation as a Source of Hardness

Abstract

We present and study a framework in which one can present alternation-based lower bounds on proof length in proof systems for quantified Boolean formulas. A key notion in this framework is that of *proof system ensemble*, which is (essentially) a sequence of proof systems where, for each, proof checking can be performed in the polynomial hierarchy. We introduce a proof system ensemble called *relaxing QU-res* which is based on the established proof system *QU-resolution*. Our main results include an exponential separation of the tree-like and general versions of relaxing QU-res, and an exponential lower bound for relaxing QU-res; these are analogs of classical results in propositional proof complexity.

1 Introduction

Background. Traditionally, the area of *propositional proof complexity* studies proof length in propositional proof systems for certifying the unsatisfiability of instances of the *SAT problem*, which instances are quantifier-free propositional formulas [16, 5, 26]. This line of study is supported by multiple motivations; let us highlight a few. First, while satisfiable formulas can be easily certified by a satisfying assignment, it is also natural to desire efficiently verifiable proofs for unsatisfiable formulas (for instance, to check that a SAT algorithm judged unsatisfiability correctly); understanding whether and when proof systems have succinct proofs is a prime concern of this area. Relatedly, *SAT algorithms* for deciding the SAT problem can be typically shown to implicitly generate proofs in a proof system, and thus insight into proof length in the resulting proof system can be used to gain insight into the running-time behavior of SAT algorithms (see for example the discussions in [4, 1]). In addition, the question of whether or not there are proof systems admitting *polynomially bounded proofs* is (when formalized) equivalent to the question of whether or not NP is equal to coNP [16], and one can thus suggest that studying proof length in propositional proof systems sheds light on the relationship between these two complexity classes.

Over recent years, researchers have devoted increasing attention to methods for solving the *QBF problem*, a generalization of the SAT problem and a canonical PSPACE-complete

problem; an instance of this problem is a propositional formula where each variable is either existentially or universally quantified. (*QBF* is short for *quantified Boolean formula*.) It is often suggested that the move to studying this more general problem is based on advances in the efficacy of SAT algorithms (see for example [27]). As reinforces this suggestion, let us point out that one can find QBF solution techniques which use SAT algorithms as black-box, primitive components, and hence which arguably conceive of and treat the SAT problem as feasibly solvable. For instance, sKizzo, a QBF solver dating back to 2005, would convert the QBF being processed to a SAT instance and then call a SAT solver, whenever this was *affordable* [8]. As another example, a different QBF solver which extensively calls a SAT solver during a backtrack-style search was developed and studied [25].

The rise in the study of the QBF problem has resulted in the identification of a number of core algorithmic techniques and corresponding proof systems that aim to capture these (see for example [13, 18, 17, 23, 3, 21, 9, 10] and the references therein). We refer to these proof systems as *QBF proof systems*; they can be used as a basis for certifying a decision for a QBF instance. One can motivate the study of QBF proof systems in much the same way that the study of propositional proof systems has been motivated; hence, these QBF proof systems would seem to suggest a new chapter in the study of proof complexity, and a new domain for the existing lines of inquiry thereof.

However, one is immediately confronted with a dilemma upon inspecting the very basic question of whether or not a typical QBF proof system requires long (exponentially sized) proofs – again, a primary type of question in traditional proof complexity. As an example, let us discuss *Q-resolution* [13], a QBF proof system which is heavily studied and used, in both theory and practice (see for example [2, 19, 18, 22, 23, 3, 9] and the references therein). When applied to SAT instances (viewed as instances of QBF where all variables are existentially quantified), Q-resolution behaves identically to resolution (a heavily studied propositional proof system), and hence the known exponential lower bounds on resolution proof length [20, 7] transfer immediately to Q-resolution. This observation leaves one with a lingering sentiment – which is often expressed by members of the community – that there is something left to be said. After all, Q-resolution is defined on QBF instances, which are substantially more general than SAT instances; the observation does not yield any information about how Q-resolution handles this extra generality, that is, how it copes with alternation of quantifiers. Indeed, there is a sharp disconnect between observing a lower bound for a QBF proof system via a set of SAT instances, and the mentioned treatment of the SAT problem, by QBF algorithms, as a feasibly solvable primitive. These considerations naturally lead to the question of whether or not one can formulate and prove a lower bound which arises from alternation.

Contributions. In this article, we present and study a framework in which it is possible to present such alternation-based lower bounds on proof length in QBF proof systems.

We define a *proof system ensemble* to be an infinite collection of proof systems, where in each proof system, whether or not a given string π constitutes a proof of a given formula Φ can be checked in the polynomial hierarchy (Definition 2). A proof system ensemble is considered to have *polynomially bounded proofs* (for a language) if it contains a proof system which has polynomially bounded proofs in the usual sense (Definition 4). As a result, it is straightforward to define proof system ensembles that have succinct proofs for any set of QBFs with bounded alternation, such as a set of SAT instances (and the proof system ensembles studied herein all have this property); this in turn forces proof length lower bounds, by

nature, to arise from a proof system's inability to cope with quantifier alternation.[1] In terms of complexity classes, the question of whether or not there exists a polynomially bounded proof system ensemble for the QBF problem (or any other PSPACE-complete problem) is equivalent to the question of whether or not PSPACE is contained in PH, the polynomial hierarchy (Proposition 5). Indeed, the relationship that traditional proof complexity bears to the NP equals coNP question is analogous to the relationship between the present framework and the PSPACE equals PH question. (Let us point out that no direct implication is known between these two open questions, and so, in a certain sense, progress in one framework may proceed orthogonally to progress in the other!)

One of our main motivations in pursuing this work was to gain further insight into Q-resolution; here, we focus on a slight extension, *QU-resolution* [18], where from existing clauses one can derive new clauses in two ways: by a rule for eliminating literals on universally quantified variables and by resolving two clauses on any variable (in Q-resolution, one can only resolve on existentially quantified variables). Q-resolution, QU-resolution, and their relatives are typically defined only for clausal QBFs – QBFs that consist of a quantifier prefix followed by a conjunction of clauses. We show how to parameterize and lift QU-resolution to obtain a proof system ensemble which we call *relaxing QU-res* which is in fact defined on arbitrary QBFs (indeed, it is defined on what we call *quantified Boolean circuits*), and not just those in clausal form; relaxing QU-res is the main proof system ensemble that we study. Let us overview how we define it.

- We define an *axiom* of a QBF to be a clause which is, in a certain precise sense, entailed by the QBF (see Section 4.1).
- We then show that, given a QBF Φ and a partial assignment a to some of its variables, one can define a QBF $\Phi[a]$ derived naturally from Φ, where the variables on which a is defined have been instantiated (in a certain precise sense; see Section 4.2). This QBF $\Phi[a]$ has the key property that if it is false, then the clause corresponding to a is an axiom of the QBF Φ (see Proposition 8 for a precise statement). We view the notion of inferring clauses from the falsity of QBFs whose variables are partially instantiated as highly natural; indeed, in the case of SAT, performing such inferences is a basis of modern backtracking SAT solvers that perform *clause learning*.
- Recall that each proof system in our proof system ensemble may use, as an oracle, a level of the PH; in particular, the QBF problem restricted to a constant number of alternations may be used as an oracle. In order to infer clauses from a QBF Φ using the method just described, we need a way of detecting falsity of QBFs having the form $\Phi[a]$. But in general, this is difficult; such a QBF $\Phi[a]$ may have a high number of alternations, and thus might not be immediately decidable using an oracle of the described form. To the end of permitting the falsity detection of QBFs $\Phi[a]$ using such oracles, we define the notion of a *relaxation* of a QBF. A relaxation of a QBF Φ is obtained from Φ by changing the order of the quantifier/variable pairs in the quantifier prefix; roughly speaking, such a pair Qv may be moved to the left if Q is the universal quantifier ($\forall$), and may be moved to the right if Q is the existential quantifier ($\exists$). (See Section 4.2 for the precise definition.) A key property of this notion is that if a relaxation of a QBF Φ is false, then the QBF Φ is false (Proposition 9).

[1] Note that there is, a priori, a difference between allowing proof systems oracle access to the SAT problem – which would be natural for modelling QBF solvers that treat the SAT problem as feasibly solvable – and allowing oracle access to arbitrary levels of the PH. We focus on the latter for various reasons: the proof length lower bounds will arise from alternation; we believe that this results in a more robust model; and, this focus causes the proof length lower bounds, which are here of primary interest, to be stronger.

With this notion of relaxation in hand, we define, for each $k \geqslant 2$, the set $H(\Phi, \Pi_k)$ to contain the axioms that arise from QBFs $\Phi[a]$ having Π_k-relaxations (relaxations with a Π_k prefix) that are false. That is, in this set we collect the axioms obtainable by detecting falsity of QBFs $\Phi[a]$ via the consideration of Π_k-relaxations. (Hence, the detection is sound in that it is always correct, but it is not complete). Note that it holds that

$$H(\Phi, \Pi_2) \subseteq H(\Phi, \Pi_3) \subseteq H(\Phi, \Pi_4) \subseteq \cdots .$$

- This gives us a sequence of versions of QU-resolution: for each k, we obtain a version by defining a proof to be a sequence of clauses derived from the axioms $H(\Phi, \Pi_k)$ and the two aforementioned rules of QU-resolution. This sequence is the proof system ensemble *relaxing QU-res*. Let us remark that each of these versions is sound and complete, in a precise sense (see Definition 2 and Proposition 12).

A couple of remarks are in order. First, note that the empty clause is an axiom in $H(\Phi, \Pi_k)$ whenever Φ is a false QBF whose quantifier prefix is Π_k. Consequently, relaxing QU-res is polynomially bounded on any set of false QBFs having bounded alternation. Let us also note that although here we explicitly lift QU-resolution to a proof system ensemble, the approach that we take here can be applied to analogously lift any proof system which is based on deriving clauses from a set of axiom clauses.

Apart from the formulation of the framework, our main results are as follows. We prove an exponential separation between the tree-like and general versions of relaxing QU-res (Section 6), by exhibiting a set of formulas which have polynomial size QU-resolution proofs, but which require exponential size proofs in tree-like relaxing QU-res; this gives an alternation-based analog of the known separation between tree-like and general resolution [12, 6]. Tree-like QU-resolution proofs can be viewed as the traces of a natural backtrack-style QBF decision procedure (this is evident from the viewpoint in Section 4.3, and is also developed explicitly in [14, Section 4.3]), and so this separation formally differentiates the power of such backtracking and general QU-resolution. The lower bound of this separation is based on a prover-delayer game for tree-like QU-resolution proofs (Section 5), which can be viewed as a generalization of a known prover-delayer game for tree-like resolution [24]; note that independently of our work [15], a game similar to ours was presented for tree-like Q-resolution [11]. We also prove an exponential lower bound for relaxing QU-res (Section 7).

All in all, the ideas and techniques developed in this work draw upon and interface concepts from two-player game interaction, proof complexity, and quantified propositional logic. We believe that further progress could benefit from creative input from each of these areas, and certainly look forward to future research on the presented framework.

2 Preliminaries

For each integer k, we use $[k]$ to denote the set that is equal to $\{1, \ldots, k\}$ when $k \geqslant 1$, and that is equal to the empty set $\varnothing$ when $k < 1$. We use $\mathbb{N}$ to denote the natural numbers $\{0, 1, 2, \ldots\}$.

We use $\mathrm{dom}(f)$ to indicate the domain of a function. A function f is a *restriction* of a function g if $\mathrm{dom}(f) \subseteq \mathrm{dom}(g)$ and, for each $a \in \mathrm{dom}(f)$, it holds that $g(a) = f(a)$; when this holds, we also say that g is an *extension* of f. When f is a function, we use $f[a \to b]$ to denote the function on domain $\mathrm{dom}(f) \cup \{a\}$ that maps a to b, and otherwise behaves like f. We write $f \restriction S$ to denote the restriction of a function f to the set S. We say that two functions f and g *agree* if for each element $a \in \mathrm{dom}(f) \cap \mathrm{dom}(g)$, it holds that $f(a) = g(a)$.

When A and B are sets, we use $[A \to B]$ to denote the set of functions from A to B.

Clauses. In this article, we employ the following terminology to discuss clauses. A *literal* is a propositional variable v or the negation $\overline{v}$ thereof. Two literals are *complementary* if one is a variable v and the other is $\overline{v}$; each is said to be the *complement* of the other. A *clause* is a disjunction of literals that contains, for each variable, at most one literal on the variable. A clause is sometimes viewed as the set of the literals that it contains; two clauses are considered equal if they are equal as sets. A clause is *empty* if it does not contain any literals. The variables of a clause are simply the variables that underlie the clause's literals, and the set of variables of a clause α is denoted by $\mathrm{vars}(\alpha)$. When α is a clause, we use $\mathrm{assign}(\alpha)$ to denote the unique propositional assignment f with $\mathrm{dom}(f) = \mathrm{vars}(\alpha)$ such that α evaluates to false under f. In the other direction, when f is a propositional assignment, we use $\mathrm{clause}(f)$ to denote the unique clause α with $\mathrm{vars}(\alpha) = \mathrm{dom}(f)$ that evaluates to false under f. *We will freely and tacitly interchange between a clause α and its corresponding assignment* $\mathrm{assign}(\alpha)$. A clause γ is a *resolvent* of two propositional clauses α and β on variable v if there exists a literal $L \in \alpha$ such that its complement M is in β, $\gamma = (\alpha \backslash \{L\}) \cup (\beta \backslash \{M\})$, and v is the variable underlying L and M.

Quantified Boolean circuits and formulas. We assume basic familiarity with quantified propositional logic. A *QBC* (short for *quantified Boolean circuit*) consists of a quantifier prefix $\vec{P} = Q_1 v_1 \ldots Q_n v_n$, where each Q_i is a quantifier in $\{\forall, \exists\}$ and each v_i is a propositional variable; and, a Boolean circuit ϕ built from the constants 0 and 1, propositional variables among $\{v_1, \ldots, v_n\}$, and the gates AND ($\wedge$), OR ($\vee$), and NOT ($\neg$). We refer to the computational problem of deciding whether or not a QBC is false as the *QBC problem*. For brevity, we sometimes refer to existentially quantified variables as $\exists$-variables, and universally quantified variables as $\forall$-variables. While it is typical to notate a QBC by simply specifying the prefix $\vec{P}$ immediately followed by the circuit ϕ, we will typically separate these two parts by a colon for the sake of readability, using for example $\vec{P} : \phi$. We assume that each quantifier prefix does not contain repeated variables. When $\Phi = \vec{P} : \phi$ is a QBC, by a *partial assignment of* Φ, we refer to a propositional assignment $f : S \to \{0, 1\}$ defined on a subset S of the variables appearing in $\vec{P}$. A *QBF* is a QBC $\vec{P} : \phi$ where ϕ is a Boolean formula. A *clausal QBF* is a QBF $\vec{P} : \phi$ where ϕ is the conjunction of clauses.

Quantifier prefixes. Let $i \geqslant 1$. A quantifier prefix $\vec{P} = Q_1 v_1 \ldots Q_n v_n$ is Π_i if $Q_1 \ldots Q_n$, viewed as a string over the alphabet $\{\forall, \exists\}$, is contained in the language denoted by the regular expression $\forall^*\exists^*\forall^*\exists^* \ldots$, which contains i starred quantifiers, beginning with $\forall^*$ and alternating; Σ_i is defined similarly, but with respect to the regular expression $\exists^*\forall^*\exists^*\forall^* \ldots$.

The following notation is relative to a quantifier prefix $\vec{P} = Q_1 v_1 \ldots Q_n v_n$; when we use it, the prefix will be clear from context. We write $v_i \preceq v_j$ if $i \leqslant j$ or if $j < i$ and $Q_j = Q_{j+1} = \cdots = Q_i$. We extend this binary relation (and others) to sets in the following natural way: when U and V are sets of variables, we write $U \preceq V$ if for each $u \in U$ and each $v \in V$, it holds that $u \preceq v$. We also write, for example, that $U \preceq v$ for a single variable v when $U \preceq \{v\}$. We write $v_i \equiv v_j$ if $v_i \preceq v_j$ and $v_j \preceq v_i$. It is straightforward to verify that $\equiv$ is an equivalence relation; we refer to each equivalence class of $\equiv$ as a *quantifier block*. We write $v_i \precneqq v_j$ if $v_i \preceq v_j$ and $v_i \not\equiv v_j$. When S is a set of variables, we use $\mathrm{last}(S)$ to denote the variable of S appearing last in the quantifier prefix, that is, the variable v_m, where $m = \max\{i \mid v_i \in S\}$. Typically, when we use the function $\mathrm{last}(S)$, it is in conjunction with the just-defined binary relations, and hence what is most relevant will be the relative location of the quantifier block of $\mathrm{last}(S)$.

Strategies. Let $\Phi = \vec{P} : \phi$ be a QBC; let X denote the $\exists$-variables of Φ, and let Y denote the $\forall$-variables of Φ. When $x \in X$, define $Y_{<x}$ to be the set of variables $\{y \in Y \mid y \precnsim x\}$; dually, when $y \in Y$, define $X_{<y}$ to be the set of variables $\{x \in X \mid x \precnsim y\}$.

An *$\exists$-strategy* is a sequence of mappings $\sigma = (\sigma_x)_{x \in X}$ where each σ_x is a mapping from $[Y_{<x} \to \{0,1\}]$ to $\{0,1\}$. When $\tau : Y \to \{0,1\}$ is an assignment to the universally quantified variables, we use $\langle \sigma, \tau \rangle$ to denote the assignment f defined by $f(y) = \tau(y)$ for each $y \in Y$ and $f(x) = \sigma_x(\tau \restriction Y_{<x})$ for each $x \in X$. We say that $(\sigma_x)_{x \in X}$ is a *winning $\exists$-strategy* if for every assignment $\tau : Y \to \{0,1\}$, it holds that the assignment $\langle \sigma, \tau \rangle$ satisfies ϕ. A *model* of Φ is defined to be a winning $\exists$-strategy of Φ.

Dually, we define a *$\forall$-strategy* to be a sequence of mappings $\tau = (\tau_y)_{y \in Y}$ where each τ_y is a mapping from $[X_{<y} \to \{0,1\}]$ to $\{0,1\}$. When $\sigma : X \to \{0,1\}$ is an assignment to the existentially quantified variables, we use $\langle \tau, \sigma \rangle$ to denote the assignment f defined by $f(x) = \sigma(x)$ for each $x \in X$ and $f(y) = \tau_y(\sigma \restriction X_{<y})$ for each $y \in Y$. We say that $(\sigma_y)_{y \in Y}$ is a *winning $\forall$-strategy* if for every assignment $\sigma : X \to \{0,1\}$, it holds that the assignment $\langle \tau, \sigma \rangle$ falsifies ϕ.

The following are well-known facts that we will treat as basic.

▶ **Proposition 1.** *Let Φ be a QBC.*

- *There exists a winning $\exists$-strategy for Φ (that is, a model of Φ) if and only if Φ is true.*
- *There exists a winning $\forall$-strategy for Φ if and only if Φ is false.*

3 Proof system ensembles

In this section, we formalize the notion of *proof system ensemble* and present some basic associated notions.

For each $m \geqslant 1$, fix $S(m)$ to be the QBC problem restricted to QBCs having a Σ_m prefix, which is a Σ^p_m-complete problem; for $m = 0$, fix $S(m)$ to be a polynomial-time decidable problem.

Let O be a language; when discussing an algorithm A that makes oracle calls, we use A^O to denote the instantiation of A where oracle calls are answered according to O.

▶ **Definition 2.** A *proof system ensemble (A, r) for a language L* consists of an algorithm A which may make oracle calls and receives inputs of the form $(k, (x, \pi))$ where $k \in \mathbb{N}$ and x and π are strings; and, a computable function $r : \mathbb{N} \to \mathbb{N}$ such that:

- For each $k \in \mathbb{N}$, there exists a polynomial p_k such that (for each pair (x, π)) the algorithm $A^{S(r(k))}$ halts on an input $(k, (x, \pi))$ within time $p_k(|(x, \pi)|)$.
- For each $k \in \mathbb{N}$, when L_k is set to $\{(x, \pi) \mid (k, (x, \pi))$ is accepted by $A^{S(r(k))}\}$, it holds that the language $\{x \mid \exists \pi$ such that $(x, \pi) \in L_k\}$ is equal to L.

Let us provide an intuitive explanation of Definition 2. For each fixed value of k, the algorithm A provides a proof system for the language L; on inputs of the form $(k, (x, \pi))$, the algorithm is provided oracle access to $S(r(k))$, and needs to accept or reject within polynomial time (in $|(x, \pi)|$). Acceptance indicates that π is judged to be a proof that $x \in L$. The second condition in the definition states that each such proof system is sound and complete, that is, for each fixed k, an arbitrary string x is in L iff there exists a string π such that $(k, (x, \pi))$ is accepted by A.

We use the following terminology to present lower bounds on proof size in proof system ensembles.

▶ **Definition 3.** Let Z be a set of functions from $\mathbb{N}$ to $\mathbb{N}$. A proof system ensemble (A, r) *requires proofs of size* Z on a sequence $\{\Phi_1, \Phi_2, \ldots\}$ of instances if for each k, there exists $z \in Z$ where (for all $n \geqslant 1$ and all strings π) it holds that $(\Phi_n, \pi) \in L_k$ implies $|\pi| \geqslant z(n)$. Here, $|\pi|$ denotes the size of π. We also apply this terminology to other measures defined on proofs.

We say that a function f mapping strings to strings is a *polynomial-length function* if there exists a polynomial q such that, for each string x, it holds that $|f(x)| \leqslant q(|x|)$.

▶ **Definition 4.** A proof system ensemble (A, r) is *polynomially bounded* on a language L if there exists $k \in \mathbb{N}$ and there exists a polynomial-length function f (mapping strings to strings) such that the following holds: if $x \in L$, then it holds that $(x, f(x)) \in L_k$, where L_k is defined as in Definition 2.

▶ **Proposition 5.** *There exists a polynomially bounded proof system ensemble for a language L if and only if L is in the polynomial hierarchy.*

4 Relaxing QU-resolution

4.1 QU-resolution

Let $\Phi = \vec{P} : \phi$ be a QBC. We define an *axiom set of* Φ to be a set H of clauses on variables of $\vec{P}$ such that, for each $C \in H$, C is an *axiom* of Φ in the following sense: each model of $\vec{P} : \phi$ is a model of $\vec{P} : C$. Let us give examples. First, if the QBC Φ is false, then the empty clause is an axiom of Φ. Second, if C is any clause which is entailed by ϕ, then C is an axiom of Φ. A case of this is when a is an assignment to all variables of Φ that falsifies ϕ; then, clause(a) is entailed by ϕ and is an axiom of Φ.

Relative to a QBC $\Phi = \vec{P} : \phi$, we say that a clause C is obtainable from a second clause D by $\forall$-*elimination* if there exists a literal $L \in D$ such that $C = D \backslash \{L\}$ and the variable y underlying L is a $\forall$-variable and has $\text{vars}(C) \preceq y$.

With these notions, we define QU-resolution for quantified Boolean circuits in the following way.

▶ **Definition 6.** A *QU-resolution proof* of a QBC $\Phi = \vec{P} : \phi$ from an axiom set H (of Φ) is a finite sequence of clauses where each clause is either in H, is obtainable from a previous clause by $\forall$-elimination, or is obtainable from two previous clauses as a resolvent; in the last two cases, we assume that the clause is annotated with the previous clause(s) from which it is derived (this is to provide a clean correspondence between proofs and certain graphs to be defined, see Section 4.3). The *size* of such a proof is defined as the number of clauses. Such a proof is said to be a *falsity proof* if it ends with the empty clause.

It is a folklore and readily verified fact that when one has a clausal QBF $\Phi = \vec{P} : \phi$ with clause set H, and C appears in a QU-resolution proof of Φ from H, then any model of Φ is a model of $\vec{P} : C$. From this fact and the definition of axiom set, we immediately obtain the following proposition.

▶ **Proposition 7.** *Let C be a clause appearing in a QU-resolution proof of a QBC $\Phi = \vec{P} : \phi$ from axiom set H. Each model of $\vec{P} : \phi$ is a model of $\vec{P} : C$. Consequently, if C is the empty clause, then the QBC Φ is false.*

4.2 Relaxing

In order to define a proof system ensemble based on QU-resolution proofs, we now describe how to obtain a sequence of axiom sets for a given QBC. We start by exhibiting a way to infer that a partial assignment is an axiom of a QBC.

Let a be a partial assignment of a QBC $\Phi = \vec{P} : \phi$. Define $\vec{P}[a]$ to be the quantifier prefix which is equal to $\vec{P}$ but where the variables in $\mathrm{dom}(a)$ and their corresponding quantifiers are removed, and where each quantifier of a variable v with $v \preceq \mathrm{last}(a)$ is changed (if necessary) to an existential quantifier. Define $\phi[a]$ to be the circuit obtained from ϕ by replacing each variable $v \in \mathrm{dom}(a)$ with the constant $a(v)$. Define $\Phi[a]$ to be $\vec{P}[a] : \phi[a]$.

▶ **Proposition 8.** *Assume that a is a partial assignment of a QBC $\Phi = \vec{P} : \phi$ such that $\Phi[a]$ is false. Then* $\mathrm{clause}(a)$ *is an axiom of Φ, that is, each model of $\vec{P} : \phi$ is a model of $\vec{P} : \mathrm{clause}(a)$.*

We believe that Proposition 8 provides a natural way to derive axioms from a QBC. Consider the case where Φ is a SAT instance, that is, $\vec{P}$ is purely existential. In this case, if a is a partial assignment such that $\Phi[a]$ is false, then $\mathrm{clause}(a)$ is an axiom of Φ. Indeed, in this case $\Phi[a]$ is simply the QBC instance obtained by instantiating variables according to a, and then removing the instantiated variables from the quantifier prefix. Note that, in the context of backtrack search for SAT, it is typical that, when some variables have been set according to a partial assignment a, a solver attempts to detect falsity of $\Phi[a]$ by heuristics such as unit propagation and generalizations thereof.

In the case of general QBCs, it is natural to ask, when one has a partial assignment a and then instantiates its variables in ϕ to obtain $\phi[a]$, under what conditions $\mathrm{clause}(a)$ can be inferred as an axiom. Proposition 8 provides an answer to this question; let us explain intuitively why the quantifier prefix is adjusted to $\vec{P}[a]$. Consider the case where the first quantifier block of $\vec{P}$ is existential and a is a partial assignment to variables from this first block; then $\vec{P}[a]$ is simply $\vec{P}$ but with the variables of a removed, and so this case of the proposition generalizes the purely existential case just discussed. In the case where a is arbitrary, $\vec{P}[a]$ can be viewed as the prefix where the lowest number of quantifiers have been changed from universal to existential such that the first quantifier block is existential, and all variables of a fall into this first block.

Prima facie, Proposition 8 may appear to be of limited utility; even if one has oracle access to a level of the polynomial hierarchy, it may be that many partial assignments a give rise to a quantifier prefix $\vec{P}[a]$ which has too many alternations to be resolved by the oracle. In order to expand the class of axioms derivable by this proposition (relative to such an oracle), we introduce now the notion of a *relaxation* of a QBC.

A *relaxation* of a quantifier prefix $\vec{P} = Q_1 v_1 \dots Q_n v_n$ is a quantifier prefix which has the form $\vec{P'} = Q_{\pi(1)} v_{\pi(1)} \dots Q_{\pi(n)} v_{\pi(n)}$ where $\pi : [n] \to [n]$ is a permutation and where, for each $\forall$-variable y and for each $\exists$-variable x, it holds that $y \preceq x$ implies $y \preceq' x$; here, $\preceq$ and $\preceq'$ denote the binary relations of $\vec{P}$ and $\vec{P'}$, respectively. As an example, consider the quantifier prefix $\vec{P} = \exists x_1 \exists x_2 \forall y \forall y' \exists x_3$; relaxations thereof include $\forall y \forall y' \exists x_1 \exists x_2 \exists x_3$, $\exists x_1 \forall y' \exists x_2 \forall y \exists x_3$, and $\forall y' \exists x_2 \forall y \exists x_1 \exists x_3$. A *relaxation of a QBC $\vec{P} : \phi$* is a QBC of the form $\vec{P'} : \phi$ where $\vec{P'}$ is a relaxation of $\vec{P}$; such a QBC is said to be a *Π_i-relaxation* if $\vec{P'}$ is Π_i.

The following is straightforward to verify.

▶ **Proposition 9.** *If a relaxation of a QBC Φ is false, then the QBC Φ is false.*

Note that for any quantifier prefix, a relaxation may be obtained by simply placing the universal quantifiers and their variables first, followed by the existential quantifiers and their

variables. Hence, in this sense, each QBC has a canonical Π_2-relaxation, and in the sequel, we focus the discussion on relaxations that are Π_k-relaxations for values of k greater than or equal to 2.

Let Φ be a QBC; for $k \geqslant 2$, we define $H(\Phi, \Pi_k)$ to be the set that contains a clause C if there exists a Π_k-relaxation of $\Phi[\text{assign}(C)]$ that is false. The following fact follows immediately from Propositions 8 and 9.

▶ **Proposition 10.** *When Φ is a QBC and $k \geqslant 2$, it holds that $H(\Phi, \Pi_k)$ is an axiom set of Φ.*

▶ **Definition 11.** *Relaxing QU-res* is defined as the pair (A, r) where r is defined by $r(k) = k + 3$ and A is an algorithm defined to accept an input $(k, (\Phi, \pi))$ if Φ is a QBC and π is a QU-resolution falsity proof of Φ from axioms in $H(\Phi, \Pi_{k+2})$. In particular, the algorithm A examines each clause in π in order; when a clause C is not derived from previous ones by resolution or by $\forall$-elimination, membership of C in $H(\Phi, \Pi_{k+2})$ is checked by the Σ_{k+3} oracle. (Such an oracle can nondeterministically guess a Π_{k+2}-relaxation and then check this relaxation for falsity.)

▶ **Proposition 12.** Relaxing QU-res *is a proof system ensemble for the language of false QBCs.*

Let us now introduce some notions which will be used in our study of *tree-like relaxing QU-res* (defined below). Let f and g be partial assignments of a QBC Φ. We say that g is a *semicompletion* of f if g is an extension of f such that for each universally quantified variable y with $\text{dom}(f) \preceq y$ and $y \notin \text{dom}(f)$, it holds that $\text{dom}(g) \preceq y$ and $y \notin \text{dom}(g)$. A set H of partial assignments of Φ is *semicompletion-closed* if, whenever $f \in H$ and g is a semicompletion of f, it holds that $g \in H$.

4.3 A graph-based view

When $\pi = C_1, \ldots, C_n$ is a QU-resolution proof of a QBC $\vec{P} : \phi$ from axioms H, define $G(\pi)$ to be the directed acyclic graph where there is a vertex for each clause occurrence C_i, which vertex has label $\text{assign}(C_i)$; and, where (for all pairs of clauses C_i, C_j) there is a directed edge from the vertex of C_j to the vertex of C_i if C_j is derived from C_i.

▶ **Proposition 13.** *Let π be a QU-resolution proof of a QBC $\vec{P} : \phi$ from axioms H. The directed acyclic graph $G(\pi)$ has the following properties:*

(α) *If a node with label a has no out-edges, then* $\text{clause}(a)$ *is an element of H.*

(β) *If a node with label a has 1 out-edge to a node with label a', then a' is an extension of a with $\text{dom}(a') = \text{dom}(a) \cup \{y\}$ where y is a universally quantified variable with $\text{dom}(a) \preceq y$.*

(γ) *If a node with label a has 2 out-edges to nodes with labels a_1 and a_2, then there exists a variable v such that a_1 and a_2 are defined on v and $a_1(v) \neq a_2(v)$; $(\text{dom}(a_1) \cup \text{dom}(a_2)) \backslash \{v\} = \text{dom}(a)$; a and a_1 are equal on the variables where they are both defined; and, a and a_2 are equal on the variables where they are both defined.*

Moreover, a labelled graph with these three properties naturally induces a QU-resolution proof: for each node, let a be its label, and associate to it $\text{clause}(a)$. □

▶ **Definition 14.** We say that a QU-resolution proof π is *tree-like* if the graph $G(\pi)$ is a tree. We define *tree-like relaxing QU-res* to be the proof system ensemble (A', r) described as follows. Let (A, r) denote relaxing QU-res. Then, the algorithm A' accepts an input $(k, (x, \pi))$ if A accepts it and π is tree-like.

5 A prover-delayer game for *tree-like relaxing QU-res*

In this section, we present a game that can be used to exhibit lower bounds on the size of tree-like QU-resolution proofs; this game can be viewed as a generalization of a game for studying tree-like resolution, which game was presented by Pudlák and Impagliazzo [24].

We first give an intuitive description of the game. Note, however, that this description is meant only to be suggestive. For a precise description, we urge the reader to consult the formal definition, which follows (Definition 15).

Relative to a QBC Φ and a set H of axioms, the game is played between two players, *Prover* and *Delayer*, which maintain a partial assignment. Prover's goal is to reach a partial assignment in H, while Delayer tries to slow down Prover, scoring points in the process. Prover starts by announcing the empty assignment, and Delayer responds with a semicompletion thereof. After this, the play proceeds in a sequence of rounds. In each round, Prover may perform one of three actions to the current assignment f: select a restriction of f; assign a value to a $\forall$-variable $y \notin \mathrm{dom}(f)$ having $\mathrm{dom}(f) \preceq y$; or, select a variable $v \notin \mathrm{dom}(f)$. In the first two cases, Delayer responds with a semicompletion of the resulting assignment. In the third case, Delayer may give a choice to the Prover. When a choice is given, the Prover sets the value of v, and Delayer may elect to claim a point which is then associated with v. When no choice is given, Delayer sets the value of v. After v is set, Delayer responds (as in the first two cases) with a semicompletion of the resulting assignment. Delayer is said to have a p-point strategy if, he has a strategy where, by the time that Prover achieves her goal, there are p variables on which the final assignment is defined such that Delayer has claimed points on these variables. In what follows, we assume $p \geqslant 1$.

▶ **Definition 15.** Let Φ be a QBC. Relative to a set H of axioms, a *p-point delayer strategy* consists of a set F of partial assignments of Φ and a function $s : F \to \mathbb{N}$ called the *score function* such that the following properties hold:

- *(semicompletion-of-empty)* There exists a semicompletion $g \in F$ of the empty assignment such that $s(g) = 0$.
- *(all-points)* If $f \in F \cap H$, then $s(f) \geqslant p$.
- *(monotonicity)* If $g \in F$, then each restriction of g has a semicompletion $f \in F$ such that $s(f) \leqslant s(g)$.
- *($\forall$-branching)* If $f \in F$ and $y \notin \mathrm{dom}(f)$ is a universally quantified variable with $\mathrm{dom}(f) \preceq y$, then, for each $b \in \{0,1\}$, the assignment $f[y \to b]$ has a semicompletion $g \in F$ with $s(g) = s(f)$.
- *(double-branching)* If $f \in F$ and $v \notin \mathrm{dom}(f)$, there exists a value $b \in \{0,1\}$ such that $f[v \to b]$ has a semicompletion $g \in F$ where (1) $s(g) \leqslant s(f) + 1$ and (2) if $s(g) = s(f) + 1$, the assignment $f[v \to \neg b]$ has a semicompletion $g' \in F$ with $s(g') \leqslant s(f) + 1$.

▶ **Theorem 16.** *Assume that there exists a p-point delayer strategy for a QBC Φ with respect to a semicompletion-closed axiom set H, and that π is a tree-like QU-resolution proof ending with the empty clause, from axioms H. Then, the tree $G(\pi)$ has at least 2^p leaves.*

6 Separation of the tree-like and general versions of *relaxing QU-res*

The family of sentences to be studied in this section is defined as follows. For each $i \in \{0\} \cup [n]$, define X_i to be the variable set $\{x_{i,j,k} \mid j,k \in \{0,1\}\}$, and for each $i \in [n]$, define X'_i analogously to be the variable set $\{x'_{i,j,k} \mid j,k \in \{0,1\}\}$. Define $\vec{P}_n$ to be the prefix $\exists X_0 \exists X'_1 \forall y_1 \exists X_1 \exists X'_2 \forall y_2 \exists X_2 \ldots \exists X'_n \forall y_n \exists X_n$. Note that, for a set of variables X, we use the

notation $\exists X$ to represent the existential quantification of the variables in X, in any order (our discussion will always be independent of any particular order chosen). For $i \in [n]$, we refer to the variables in $X'_i \cup \{y_i\} \cup X_i$ as the *level i variables*.

- Define $B = \{\neg x_{0,j,k} \mid j,k \in \{0,1\}\} \cup \{x_{n,j,0} \vee x_{n,j,1} \mid j \in \{0,1\}\}$.
- For each $i \in [n]$ and each $j \in \{0,1\}$ define $H_{i,j} = \{\neg x'_{i,0,k} \vee \neg x'_{i,1,l} \vee x_{i-1,j,0} \vee x_{i-1,j,1} \mid k,l \in \{0,1\}\}$.
  Observe that the clause $\neg x'_{i,0,k} \vee \neg x'_{i,1,l} \vee x_{i-1,j,0} \vee x_{i-1,j,1}$ is logically equivalent to $(x'_{i,0,k} \wedge x'_{i,1,l}) \to (x_{i-1,j,0} \vee x_{i-1,j,1})$.
- For each $i \in [n]$, define $T_i = \{\neg x_{i,0,k} \vee y_i \vee x'_{i,0,k} \mid k \in \{0,1\}\} \cup \{\neg x_{i,1,k} \vee \neg y_i \vee x'_{i,1,k} \mid k \in \{0,1\}\}$.

Define ϕ_n to be the conjunction of the clauses contained in the just-defined sets. Define Φ_n as $\vec{P}_n : \phi_n$. This definition of this family of sentences was inspired partially by the separating formulas of [12, 6].

Let us explain intuitively what the clauses mandate and why the sentences Φ_n are false. By the clauses in B, all of the variables $x_{0,j,k}$ must be set to 0. By the clauses in the sets $H_{1,j}$, either both variables $x'_{1,0,k}$ or both variables $x'_{1,1,k}$ must be set to 0. Once this occurs, the universal player can set the variable y_1 to 0 or 1 to force either both variables $x_{1,0,k}$ or both variables $x_{1,1,k}$ to 0 (respectively), via the clauses in T_1. This reasoning can then be repeated; for instance, at the next level, either both variables $x'_{2,0,k}$ or both variables $x'_{2,1,k}$ must be set to 0, and then after universal player assigning y_2 appropriately, either both variables $x_{2,0,k}$ or both variables $x_{2,1,k}$ are forced to 0. In the end, the existential player must violate one of the two clauses in B concerning level n.

▶ **Proposition 17.** *The sentences $\{\Phi_n\}_{n \geqslant 1}$ have QU-resolution proofs of size linear in n.*

Let $n \geqslant 1$; we will use the following terminology to discuss Φ_n.

We say that r is a *normal realization* of level $i \in [n]$ if it is an assignment defined on the level i variables such that, when b is set to $r(y_i)$, the following hold:

- $0 = r(x_{i,b,0}) = r(x'_{i,b,0}) = r(x_{i,b,1}) = r(x'_{i,b,1})$
- $r(x_{i,\neg b,0}) = r(x'_{i,\neg b,0}) \neq r(x_{i,\neg b,1}) = r(x'_{i,\neg b,1})$

We say that r is a *funny realization* of level $i \in [n]$ if it is an assignment defined on the level i variables such that, when b is set to $r(y_i)$, the following hold:

- $r(x_{i,b,0}) = r(x'_{i,b,0}) \neq r(x_{i,b,1}) = r(x'_{i,b,1})$
- $0 = r(x'_{i,\neg b,0}) = r(x'_{i,\neg b,1})$
- $r(x_{i,\neg b,0}) \neq r(x_{i,\neg b,1})$

We state two key and straightforwardly verified properties of realizations in the following proposition.

▶ **Proposition 18.** *No assignment defined on the level i variables is both a normal realization and a funny realization. Also, each normal realization and each funny realization (of level i) satisfies all clauses in T_i.*

We define the set of assignments F_n to be the set containing all *normal assignments* and all *funny assignments*, which we now turn to define. Let f be a partial assignment of Φ_n. Let $\ell \geqslant 0$ denote the maximum level ℓ such that f is defined on an $\exists$-variable in level ℓ.

We say that f is a *normal assignment* if the following hold:

- f is defined on the variables in $\{x_{0,j,k} \mid j,k \in \{0,1\}\}$ and equal to 0 on them.

- For each $i \in [\ell - 1]$, the restriction of f to the level i variables is a normal realization of level i.
- If $\ell \geqslant 1$, either the restriction of f to the level ℓ variables is a normal realization of level ℓ; or, f is *half-defined* on level ℓ, by which is meant that f is not defined on any variables in $\{x_{\ell,j,k} \mid j,k \in \{0,1\}\}$, but is defined on all variables in $\{x'_{\ell,j,k} \mid j,k \in \{0,1\}\}$ and has $\sum_{j,k\in\{0,1\}} x'_{\ell,j,k} = 1$.

For each normal assignment f, we define $s_n(f) = \ell$.

We say that f is a *funny assignment* if there exists $m \in [\ell]$ such that the following hold:

- f is defined on the variables in $\{x_{0,j,k} \mid j,k \in \{0,1\}\}$ and equal to 0 on them.
- For each $i \in [m-1]$, the restriction of f to the level i variables is a normal realization of level i.
- The restriction of f to the level m variables is a funny realization of level m.
- For each i with $m < i \leqslant \ell$ and for each $j \in \{0,1\}$, if f is defined on one of the four variables in $\{x_{i,j,k}, x'_{i,j,k} \mid k \in \{0,1\}\}$, then it is defined on all of them and $f(x_{i,j,0}) = f(x'_{i,j,0}) \neq f(x_{i,j,1}) = f(x'_{i,j,1})$.

The following result is obtained by applying the main theorem of the previous section to the strategies (F_n, s_n).

▶ **Theorem 19.** *Tree-like relaxing QU-res requires proofs of size $\Omega(2^n)$ on the sentences $\{\Phi_n\}_{n\geqslant 1}$.*

7 Lower bound for *relaxing QU-res*

We define a family of QBCs, to be studied in this section, as follows. Let $n \geqslant 1$. Define $\vec{P}_n$ to be the quantifier prefix $\exists x_1 \forall y_1 \ldots \exists x_n \forall y_n$. Define $\phi_{n,j}$ to be true if and only if $j + \sum_{i=1}^{n}(x_i + y_i) \not\equiv n \pmod 3$. Define Φ_n to be the sentence $\vec{P}_n : \phi_{n,0}$; these are the sentences that will be used to prove the lower bound. It is straightforward to verify that ϕ_n can be represented as a circuit of size polynomial in n, and we assume that ϕ_n is so represented.

▶ **Proposition 20.** *For each $n \geqslant 1$, the sentence Φ_n is false.*

To obtain the lower bound, we show that for any proof π, the graph $G(\pi)$ must have exponentially many sinks. We begin by showing that any assignment to an initial segment of the $\exists$-variables can be mapped naturally to a sink.

▶ **Lemma 21.** *Let π be a relaxing QU-res proof of Φ_n from an axiom set, and suppose $t \geqslant 1$. Let $f : \{x_1, \ldots, x_{n-\lceil t/2\rceil}\} \to \{0,1\}$ be an assignment. There exists a sink of $G(\pi)$ whose label agrees with f.*

We next show that each sink must be defined on a variable that occurs *towards the end* of the quantifier prefix, made precise as follows.

▶ **Lemma 22.** *Let π be a relaxing QU-res proof of Φ_n from axiom set $H(\Phi, \Pi_t)$, where $t \geqslant 2$ and $n \geqslant \lceil t/2\rceil$. Each sink of $G(\pi)$ has a label a that is defined on one of the following variables:*

$$x_{n-(\lceil t/2\rceil-1)}, y_{n-(\lceil t/2\rceil-1)}, \ldots, x_{n-1}, y_{n-1}, x_n, y_n\,.$$

When f is a partial assignment of Φ_n, we refer to the elements of $\{v \mid v \preceq \mathrm{last}(f)\}\backslash\mathrm{dom}(f)$ as *holes*.

▶ **Lemma 23.** *Let π be a relaxing QU-res proof of Φ_n from an axiom set of the form $H(\Phi_n, \Pi_t)$. Each sink of $G(\pi)$ has a label f having at most one hole.*

▶ **Theorem 24.** *Suppose that $t \geqslant 2$ and that $n \geqslant \lceil t/2 \rceil$. Let π be a QU resolution proof of Φ_n from the axiom set $H(\Phi_n, \Pi_t)$. The graph $G(\pi)$ has at least $2^{n-\lceil t/2 \rceil - 1}$ sinks.*

From the previous theorem, we immediately obtain the following.

▶ **Theorem 25.** *Relaxing QU-res requires proofs of size $\Omega(2^n)$ on the sentences $\{\Phi_n\}_{n \geqslant 1}$.*

Past, Present, and Infinite Future

Abstract

I was supposed to deliver one of the speeches at Wolfgang Thomas's retirement ceremony. Wolfgang had called me on the phone earlier and posed some questions about temporal logic, but I hadn't had good answers at the time. What I decided to do at the ceremony was to take up the conversation again and show how it could have evolved if only I had put more effort into answering his questions. Here is the imaginary conversation with Wolfgang.

The contributions are (1) the first direct translation from counter-free ω-automata into future temporal formulas, (2) a definition of bimachines for ω-words, (3) a translation from arbitrary temporal formulas (including both, future and past operators) into counter-free ω-bimachines, and (4) an automata-based proof of separation: every arbitrary temporal formula is equivalent to a boolean combination of pure future, present, and pure past formulas when interpreted in ω-words.

1 Act I

Wolfgang is sitting at his desk. Thomas is standing in his office, looking over the bay. They are talking to each other on the phone.

Wolfgang. I am teaching a course on applied automata theory this semester, and I would like to explain to my students how one can translate a counter-free ω-automaton into a temporal formula. I took a look at your STACS paper from 1999 [17], but the translation you give there is only for finite words. How does the whole story go for infinite words?

Thomas. I don't know of any published translation which comes close to what I present in the STACS paper. There is Volker and Paul's comprehensive contribution to the volume that celebrated your 60th birthday [4], but the construction presented therein is probably not what you are looking for, given its algebraic nature.

Wolfgang. I know what Volker and Paul did. Indeed, I am looking for something which is more automata-theoretic.

Thomas. I may have a suggestion for you.

Wolfgang. So?

Thomas. First of all, we need to choose the right ω-automaton model. Imagine you wanted to translate a future temporal formula over finite words into a finite-state automaton. Which model of automaton would you use?

Wolfgang. When I use ordinary automata, which read a word from left to right, I end up with a nondeterministic automaton, because the automaton can only guess what will happen in the future. When I use backward automata, which read a word from right to left,

43rd International Colloquium on Automata, Languages, and Programming (ICALP 2016).

Leibniz International Proceedings in Informatics
Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

I end up with a deterministic automaton right away, simply because what happens in the future can easily be determined when coming back from it.

Thomas. That's the point. When translating counter-free ω-automata into temporal formulas, we start out best from backward deterministic ω-automata, the model introduced by Olivier and Max Michel in their 1999 paper [3]. Do you recall how these automata are defined?

Wolfgang. Sure, I do. I think Jean-Éric and Dominique call them "prophetic" automata in their book [11], but backward deterministic ω-automata is also a good term. Anyway, such an automaton is given by a finite state set Q, an initial recurrence condition $\mathcal{I}$, a backward transition function $\rho\colon \Sigma \times Q \to Q$, and a set $F \subseteq Q$ of final states. It is required that for every ω-word over Σ there is exactly one initial run.

Thomas. Which recurrence conditions do you have in mind?

Wolfgang. Nothing in particular. How about you?

Thomas. Generalized transition Büchi conditions will come in handy. With such a condition, $\mathcal{I}$ is a set of sets $T \subseteq \Sigma \times Q$, each of them referred to as a transition recurrence set. A run $q_0q_1q_2\ldots$ on a word $w \in \Sigma^\omega$ needs to satisfy $q_i = \rho(w(i), q_{i+1})$ for every $i < \omega$. For such a run to be initial it is required that for every transition recurrence set $T \in \mathcal{I}$ there are infinitely many i with $\langle w(i), q_{i+1}\rangle \in T$. It is final if $q_0 \in F$, and it is accepting if it is initial and final, just as usual, only that we are going the other direction.

Wolfgang. OK. So we agree on the automaton model to be used.

Thomas. The next thing we need to agree on is what "counter freeness" should mean for such automata.

Wolfgang. To me, there seems to be a straightforward definition. For every finite word $w \in \Sigma^*$ we consider the function ${}^\rho w\colon Q \to Q$ induced by w on the state space. This is defined as usual, that is, ${}^\rho w(q) = {}^*\rho(w, q)$ for every $q \in Q$, where ${}^*\rho$ is the backward transition function extended from Σ to Σ^*. We say the automaton has a counter if there exists some word $w \in \Sigma^+$ and some nonempty subset $Q' \subseteq Q$ such that ${}^\rho w$ operates as a non-trivial permutation on Q'. More precisely, ${}^\rho w|_{Q'}$ is a bijection and ${}^\rho w|_{Q'} \neq \mathrm{id}_{Q'}$. If there is no counter, the automaton is counter-free.

Thomas. You are perfectly right. There is no difference to what we know from finite words, and the definition coincides with Volker and Paul's definition for Büchi automata in general.

Wolfgang. What I don't see right away is that the definition really captures the essence of counter freeness in general. I would like to understand this, but, maybe, it is better to return to this later.

Thomas. Promised. – Let's start to work on a translation from counter-free backward deterministic ω-automata to future temporal formulas. I suggest we work with the usual vocabulary for temporal logic. For every symbol a in the alphabet, we have an atomic formula a, which is true in a word if the word starts with a. We may use the temporal operator "next", which we write as X, and the stutter-free "until", which we write as U. We may also use derived operators such as "eventually" and "always", which we write as F and G, respectively. Finally, boolean constants and operators are allowed as well.

Wolfgang. I recall that your translation from counter-free automata to temporal logic is defined by induction, on the number of states of the given automaton in the first place and the size of the alphabet in the second place. Do we proceed in the same fashion for ω-words?

Thomas. Yes, exactly. Recall that for every ω-word there is exactly one initial run of a given backward deterministic ω-automaton on this word. Let's call the first state of this

run the halting state of the word. The inductive claim is that for every $q \in Q$, there exists a temporal formula defining the set of words with halting state q. – Wolfgang, things are getting more technical now. Let's use a desktop sharing software.

Thomas walks to his laptop. Wolfgang, already sitting in front of his screen, initiates a session between the two of them.

Thomas. I was saying that for every $q \in Q$, we construct a temporal formula $\alpha[q, \rho, \mathcal{I}]$, which defines the set of ω-words with halting state q. For convenience, let's write $L_\omega(q, \rho, \mathcal{I})$ for this language.

Wolfgang. I also recall you proceed by a simple case distinction. The almost trivial case is that all symbols induce the identity, which would mean ${}^\rho a = \mathrm{id}_Q$ for every $a \in \Sigma$.

Thomas. We proceed by the same case distinction here. If all symbols induce the identity function, the translation is simple and does not need the inductive assumption, but it is slightly more complicated than for finite words, because we are using generalized transition Büchi conditions.

Wolfgang. What exactly do you mean?

Thomas. When every symbol induces the identity, then every run is of the form q^ω for some $q \in Q$. Whether or not such a run is initial for a given word depends on the symbols occurring infinitely often in the word.

Wolfgang. That's funny. My first thought was that this case is really trivial.

Thomas. It is almost trivial, because for every set $\Sigma' \subseteq \Sigma$ the formula

$$\bigwedge_{a \in \Sigma'} \mathrm{GF}a \wedge \bigwedge_{a \in \Sigma \setminus \Sigma'} \mathrm{FG}\neg a$$

specifies exactly the ω-words where Σ' is the set of symbols occurring infinitely often.

Wolfgang. That's indeed almost trivial. *(Smiling.)* Let me understand what is going on in the more complicated case, when there is some symbol $c \in \Sigma$ such that ${}^\rho c$ is not the identity, that is, the image of ${}^\rho c$ is a strict subset of Q.

Thomas. Let's say this image is Q', and let's refer to $\Sigma \setminus \{c\}$ by Γ.

Wolfgang. In the proof for finite words, you split up each word in the positions where c occurs. If we do this here as well, there are three cases to distinguish: *i.* words which belong to Γ^ω, *ii.* words which belong to $\Sigma^* c \Gamma^\omega$, and *iii.* words which belong to $(\Gamma^* c)^\omega$.

Thomas. That's exactly right. We can deal with these three cases separately, because if we have a formula for each of these cases, their disjunction is the formula we are looking for. Case i is almost straightforward. We restrict the given backward transition function ρ to the smaller alphabet Γ, say the result is ρ', and the induction hypothesis applies right away. We obtain a formula $\alpha[q, \rho', \mathcal{I}]$ for $L_\omega(q, \rho', \mathcal{I})$, and we can set

$$\alpha[q, \rho, \mathcal{I}] = \mathrm{G}\neg c \wedge \alpha[q, \rho', \mathcal{I}] \ .$$

In other words, we take what we get from the induction hypothesis and rule out the symbol c.

Wolfgang. Why do we need to rule out c?

Thomas. Here is a simple example. Assume our alphabet was $\{a, b, c\}$ and the formula we obtained by induction was the formula a. Then ac^ω would be a model of the formula a, but this word does not belong to Γ^ω.

Wolfgang. Interesting, but I also have another question. Isn't it true that when we restrict ρ to ρ' as above we also need to restrict $\mathcal{I}$ appropriately, because in $\mathcal{I}$ there might be sets T with elements $\langle c, q \rangle$, but c does not belong to the underlying alphabet?

Thomas. Strictly speaking, you are right. That's why we should agree, once and for all, that we implicitly restrict recurrence conditions to the symbols occurring in the respective transition function.

Wolfgang. OK. – I think I know how to proceed in Case *ii*. Every word in $\Sigma^* c \Gamma^\omega$ can be broken up in a unique fashion. It can be written as ucv where $v \in \Gamma^\omega$. For the first part, u, we use what we know from finite words, and for the second part, v, we use the induction hypothesis.

Thomas. That's exactly right, but let's make it more precise. Let's write $L_*(q, \rho, q')$ for the language recognized by the backward deterministic automaton on finite words with initial state q', backward transition function ρ, and final state q. Then the language we are interested in, $L_\omega(q, \rho, \mathcal{I}) \cap \Sigma^* c \Gamma^\omega$, is the finite union of all languages

$$L_*(q, \rho, \rho(c, q'))\, c\, L_\omega(q', \rho', \mathcal{I}) \ , \tag{1}$$

for q' ranging over Q.

Wolfgang. Because of what we know about finite words, we have a temporal formula $\beta[q, \rho, q']$ for each language $L_*(q, \rho, q')$. And because of the induction hypothesis, we have a temporal formulas $\alpha[q', \rho', \mathcal{I}]$ for each language $L_\omega(q', \rho', \mathcal{I})$.

Thomas. Right! – A formula for a language as above, as given in (1), is therefore given by

$$\mathrm{xt}(\beta[q, \rho, \rho(c, q')]) \wedge \mathrm{F}(c \wedge \mathrm{XG}\neg c \wedge \mathrm{X}\alpha[q', \rho', \mathcal{I}]) \ ,$$

where $\mathrm{xt}(\beta)$ extends β to ω-words.

Wolfgang. I think I know what you mean by "extending" β to ω-words. You mean that for each $u \in \Sigma^*$ and $v \in \Gamma^\omega$, the word ucv is a model of $\mathrm{xt}(\beta)$ if, and only if, u is a model of β.

Thomas. You are perfectly right. – It is easy to obtain $\mathrm{xt}(\beta)$ from β by an inductive construction. The only interesting parts are the base case for a symbol and the induction steps involving temporal operators, because then the formula may "look" beyond the last occurrence of c, what is to be avoided:

$$\begin{aligned} \mathrm{xt}(a) &= a \wedge \mathrm{XF}c \ , \\ \mathrm{xt}(\mathrm{X}\psi) &= \mathrm{X}(\mathrm{xt}(\psi) \wedge \mathrm{F}c) \ , \\ \mathrm{xt}(\psi_0 \mathrm{U} \psi_1) &= \mathrm{xt}(\psi_0)\mathrm{U}(\mathrm{xt}(\psi_1) \wedge \mathrm{F}c) \ . \end{aligned}$$

Wolfgang. So the really interesting case is the last one, Case *iii*, when we consider words which belong to $(\Gamma^* c)^\omega$. Do you use an encoding trick like the one you use for finite words?

Thomas. Yes, the construction is very similar to the one in the finite-word setting, but considerably trickier. Let w be any word in $(\Gamma^* c)^\omega$. We can write w as $v_0 c v_1 c v_2 c \ldots$ where $v_i \in \Gamma^*$ for every $i < \omega$. There is exactly one initial run for w, say $q_0 q_1 q_2 \ldots$. Consider the subsequence $q_{i_0} q_{i_1} q_{i_2} \ldots$ which collects the states the automaton assumes just left of any c.

Wolfgang. Because we assume the image of ${}^\rho c$ is Q', these states are special in the sense that each of them belongs to Q'. So in some sense, each of the cv_i's transforms some state from Q' to some state from Q'.

Thomas. That's it! – Basically, we classify each word in $c\Gamma^*$ according to how it operates on Q', more precisely, to every such word w we assign the function $\tilde{w} \colon Q' \to Q'$ defined by $\tilde{w}(q) = {}^*\rho(w, q)$ for every $q \in Q'$.

Wolfgang. I understand that, but what I am concerned about is that we lose information about the recurrence condition!

Thomas. That's why I said "basically". We do a little bit more. We not only assign $\tilde{w}$ to w but also $\dot{w}$, a function $Q' \to 2^{\mathcal{I}}$, which collects the information about the recurrence condition we need.

Wolfgang. I can guess how $\dot{w}$ is defined. For every state $q \in Q'$ we consider the backward run of A – viewed as a backward automaton on finite words – on w starting in q and collect in $\dot{w}(q)$ all transition recurrence sets it passes through.

Thomas. Exactly, that's how we do it. – The code alphabet, let's call it Δ, is large. For each finite word $w \in c\Gamma^*$ it contains the symbol $\langle \tilde{w}, \dot{w} \rangle$.

Wolfgang. How do we construct the backward deterministic ω-automaton, let's call it C, which uses this alphabet?

Thomas. Its state space is Q', which is smaller than the state space of A. Its backward transition function – let's denote it τ – is defined by $\tau(\langle f, g \rangle, q') = f(q')$ for every $q' \in Q'$. For each transition Büchi set $T \in \mathcal{I}$, the transition Büchi set $\mathcal{J}$ of C has a Büchi set T', which is given by $T' = \{\langle \langle f, g \rangle, q' \rangle \mid T \in g(q')\}$. Most importantly, C is a counter-free backward deterministic ω-automaton as defined above.

Wolfgang. I immediately see how C mimics A. Let's define a function $h_0 \colon c\Gamma^* \to \Delta$ by $h_0(w) = \langle \tilde{w}, \dot{w} \rangle$ and use this to define a function $h \colon (c\Gamma^*)^\omega \to \Delta^\omega$ by setting $h(cw_0cw_1 \dots) = h_0(cw_0)h_0(cw_1) \dots$ for any choice of $w_i \in \Gamma^*$. Then, for every word $w \in (c\Gamma^*)^\omega$, the image $h(w)$ has halting state q' in C if, and only if, w has halting state q' in A. Or, formally, $L_\omega(q, \rho, \mathcal{I}) \cap (\Gamma^* c)^\omega$ is the finite union of all languages

$$L_*(q, \rho', q')\, h^{-1}(L_\omega(q', \tau, \mathcal{J})) \ , \tag{2}$$

where q' ranges over all states in Q'.

Thomas. That's right! – Did you observe where the generalized transition Büchi condition came in handy?

Wolfgang. Yes, I did. If we had used some other condition, transferring it from A to C could have easily blown up the state space of C.

Thomas. So you see how we can use the induction hypothesis!?

Wolfgang. Sure. We can apply it to C, because C has a smaller state space than A, and obtain, for every $q' \in Q'$, a temporal formula $\alpha[q', \tau, \mathcal{J}]$ for $L_\omega(q', \tau, \mathcal{J})$, the alphabet being Δ.

Thomas. And do you see where the results from the finite-word setting come into the picture?

Wolfgang. Sure. They are used in two different places. First, for every $q \in Q$ and every $q' \in Q'$ there is a temporal formula $\beta[q, \rho, q']$ that defines $L_*(q, \rho', q')$. Second, for every symbol $\langle f, g \rangle \in \Delta$ there is a temporal formula $\chi_{f,g}$ such that a word $w \in \Gamma^*$ is a model of $\chi_{f,g}$ if, and only if, $h_0(cw) = \langle f, g \rangle$.

Thomas. Precisely! – What is left to be done is to assemble all these formulas in the right fashion.

Wolfgang. I can take over the first programming task. We need to transform every formula φ over Γ into a formula $\mathrm{xt}'(\varphi)$ over Σ such that for all $u \in \Gamma^*$ and $v \in \Sigma^\omega$, the formula φ is a model of u if, and only if, the formula $\mathrm{xt}'(\varphi)$ is a model of ucv. The crucial

definitions are:

$$\begin{aligned} \mathrm{xt}'(a) &= a \ , \\ \mathrm{xt}'(\mathrm{X}\psi) &= \neg c \wedge \mathrm{X}\,\mathrm{xt}'(\psi) \ , \\ \mathrm{xt}'(\psi_0 \mathrm{U} \psi_1) &= (\mathrm{xt}'(\varphi) \wedge \neg c)\mathrm{U}\,\mathrm{xt}'(\psi) \ . \end{aligned}$$

Thomas. Second, we need to transform every formula φ over Δ into a corresponding formula $\mathrm{lft}(\varphi)$, which "lifts" the formula from the alphabet Δ to the alphabet Σ, more precisely, for each $u \in (c\Sigma^*)^\omega$, the word u is a model of $\mathrm{lft}(\varphi)$ if, and only if, $h(u)$ is a model of φ. Here, we can set:

$$\begin{aligned} \mathrm{lft}(\langle f, g \rangle) &= \mathrm{xt}'(\chi_{f,g}) \ , \\ \mathrm{lft}(\mathrm{X}\varphi) &= \mathrm{X}(\neg c \mathrm{U}(c \wedge \mathrm{X}\,\mathrm{lft}(\varphi))) \ , \\ \mathrm{lft}(\varphi \mathrm{U} \psi) &= (c \to \mathrm{X}\,\mathrm{lft}(\varphi))\mathrm{U}(c \wedge \mathrm{X}\,\mathrm{lft}(\psi)) \ . \end{aligned}$$

Wolfgang. We are done. The overall formula for a language as in (2) is

$$\mathrm{GF}c \wedge \mathrm{xt}'(\beta[q, \rho', q']) \wedge \neg c \mathrm{U}(c \wedge \mathrm{lft}(\alpha)[q', \tau, \mathcal{J}]) \ .$$

Thomas, I need to run. There's a meeting I have to attend ...

Wolfgang grabs a pile of documents from a bookshelf and leaves his room in a hurry.

2 Act II

Wolfgang, wearing a headset, and Thomas are sitting at their desks. On Thomas's screen, a notification from the desktop sharing software pops up. Wolfgang is trying to connect. Thomas puts on his headset.

Thomas. Wolfgang?

Wolfgang. Thomas! Can I come back to the discussion on temporal logic and counter-free automata we has the other day?

Thomas. Sure. What is it that you would like to talk about?

Wolfgang. You said that your definition of "counter-free ω-automaton" is a good one; you even said it would be the right one. Can you explain that to me?

Thomas. From finite words we know that there are many equivalent definitions of what it means for a formal language to be star-free: recognizable by a counter-free automaton [13], definable in first-order logic [10], definable in temporal logic (with future and past operators) [8], definable in future temporal logic [7], ... For ω-words, the same equivalences hold, in particular, first-order logic, the two variants of temporal logic, and star-free expressions are equally expressive [9, 15, 8, 7]. Do you recall this? *(Smiling.)* Anyway, any notion of "counter freeness" that is equivalent to one of these formalisms should be ok.

Wolfgang. I agree! – What we already know is that every counter-free automaton according to your definition is equivalent to a future temporal logic formula. So if you can also prove the converse to me, I will be happy.

Thomas. To tell you the truth, parts of this were already proved a long time ago, but went unnoticed. What I mean is that the straightforward translation of a future temporal formula into a generalized Büchi automaton yields a counter-free backward deterministic

ω-automaton. In fact, for all I know, this observation was the motivation for defining backward deterministic ω-automata [1] and you can find the translation, for instance, in a paper by Olivier [2]. – The problem is to show that this translation yields a counter-free automaton.

Wolfgang. *(Indignant, but smiling.)* Thomas! – That we obtain backward deterministic Büchi automata when translating future temporal formulas into automata is something I have known for years, in fact, I explained this to one of the anonymous referees of this paper already 15 years ago. But I didn't look at counter freeness at the time I have to admit. So let's see what happens when we follow a construction like the one Pierre and Moshe suggested [16]?

Thomas. A typical automaton for a temporal formula guesses, for each point in time, which subformulas are true at that point and which are not.

Wolfgang. So we model a state as a function $f\colon \mathrm{sbf}(\varphi) \to \{0,1\}$, where $\mathrm{sbf}(\varphi)$ stands for the set of subformulas of φ. The functions considered are required to satisfy the following straightforward conditions: $f(\top) = 1$; $f(\neg\psi) = 1$ if, and only if, $f(\psi) = 0$; $f(\psi_0 \vee \psi_1) = 1$ if, and only if, $f(\psi_0) = 1$ or $f(\psi_1) = 1$. Here, ψ and $\psi_0 \vee \psi_1$ stand for elements of $\mathrm{sbf}(\varphi)$. The transition relation, let's denote it by Δ, is defined according to the semantics of temporal logic, more precisely, $(f, a, g) \in \Delta$ if, and only if, the following conditions are satisfied:

- $f(a) = 1$,
- $f(b) = 0$ for every symbol $b \in \Sigma$ with $b \neq a$,
- $f(\mathrm{X}\psi) = g(\psi)$,
- $f(\psi_0 \mathrm{U} \psi_1) = 1$ if, and only if, $f(\psi_1) = 1$ or, $f(\psi_0) = 1$ and $g(\psi_0 \mathrm{U} \psi_1) = 1$.

Just as above, $\mathrm{X}\psi$ and $\psi_0 \mathrm{U} \psi_1$ stand for elements of $\mathrm{sbf}(\varphi)$. And, of course, the transition relation Δ is backward deterministic, that is, $\rho(a, g) = f$ for $(f, a, g) \in \Delta$ is well-defined.

Thomas. What about the recurrence condition?

Wolfgang. We need to make sure that when a U-formula is guessed to be true it becomes true eventually. To this end, we use a generalized state Büchi recurrence condition, which can easily be transformed into a generalized transition Büchi condition. For every U-subformula, say $\psi_0 \mathrm{U} \psi_1$, we have the set

$$\{f \mid f(\psi_0 \mathrm{U} \psi_1) = 0 \text{ or } f(\psi_1) = 1\}$$

as an element of the recurrence condition. – So how do we know this automaton is counter-free?

Thomas. This needs a proof indeed. – Suppose $Q' \subseteq Q$ is a nonempty subset of the state space and ${}^{\rho}w$ restricted to Q' is a permutation for some word $w \in \Sigma^+$. We want to show ${}^{\rho}w(f) = f$ for every state $f \in Q'$. One way to do this is to fix an element $f_0 \in Q'$ and consider the orbit of f_0.

Wolfgang. What do you mean by "orbit"?

Thomas. Define f_{i+1} by $f_{i+1} = {}^{\rho}w(f_i)$ for $i < \omega$. Then, because we assume ${}^{\rho}w$ restricted to Q' is a permutation, $f_m = f_0$ for some $m > 0$. The set $\{f_m \mid i < m\}$ is what we call the orbit of f_0.

Wolfgang. I see. If we can prove $f_1 = f_0$, or, equivalently, $f_i = f_{i'}$ for all $i, i' < m$, we are done, because this means ${}^{\rho}w(f_0) = f_0$.

Thomas. Exactly. By induction, we show $f_i(\psi) = f_{i'}(\psi)$ for every $\psi \in \mathrm{sbf}(\varphi)$ and all $i, i' < m$, which is sufficient. In fact, we prove something stronger.

Wolfgang. I have no idea what that could be.

Thomas. We refine the picture in an adequate fashion by introducing more states and making it cyclic. Let $n = |w|$. First, we extend w in both directions by repeating it, that is,

we consider the sequence $(a_i)_{i\in\mathbf{Z}}$ defined by $a_{i+kn} = w(i)$ for all $i < n$ and $k \in \mathbf{Z}$ with $k \neq 0$. Second, we define, for every $i \in \mathbf{Z}$, a state g_i by

$$\begin{aligned} g_0 &= f_0 \ , \\ g_i &= {}^{\rho}a_i(g_{i+1}) && \text{for } i \text{ with } -mn < i < 0 \ , \\ g_{i+kmn} &= g_i && \text{for } i \text{ with } -mn < i \leq 0 \text{ and } k \neq 0 \ . \end{aligned}$$

Then $g_{-ni} = f_i$ for every $i \in \mathbf{N}$ and $g_i = {}^{\rho}a_i(g_{i+1})$ for all $i \in \mathbf{Z}$. Furthermore, $g_i(\psi) = g_{i'}(\psi)$ for all $i, i' \in \mathbf{N}$ with $i \equiv i' \,(mn)$ and $\psi \in \mathrm{sbf}(\varphi)$. I write $i \equiv i' \,(l)$ to denote the fact that i and i' are identical after reduction modulo l. The stronger claim is that $g_i(\psi) = g_{i'}(\psi)$ holds for all $i, i' \in \mathbf{Z}$ with $i \equiv i' \,(n)$ and $\psi \in \mathrm{sbf}(\varphi)$.

Wolfgang. I see, this contains the original claim as a special case. – I am curious to see how the inductive proof goes.

Thomas. For $\psi = \top$, the claim is trivial. For the other base case, assume $a \in \Sigma$ and $\psi = a$. We have $g_i(a) = 1$ if, and only if, $a = a_i$, which proves the claim, because if $i \equiv i' \,(n)$, then $a_i = a_{i'}$, by definition of $(a_i)_{i\in\mathbf{Z}}$.

Wolfgang. Now it's my turn. First, the claim is trivial for the boolean connectives $\neg$ and $\vee$. Assume $\mathrm{X}\psi \in \mathrm{sbf}(\varphi)$. Then $g_i(\mathrm{X}\psi) = g_{i+1}(\psi)$ for every $i \in \mathbf{Z}$, because of the definition of Δ. By induction hypothesis, we have $g_{i+1}(\psi) = g_{i'+1}(\psi)$ for all i and i' with $i \equiv i' \,(n)$, which then implies the claim.

Thomas. Let me conclude the proof by looking at the case where $\psi_0 \mathrm{U} \psi_1 \in \mathrm{sbf}(\varphi)$. It is good to proceed by a case distinction.

Wolfgang. I can imagine what the cases are.

Thomas. The first case is when $g_i(\psi_0) = 1$ holds for all $i \in \mathbf{Z}$. If $g_{i_0}(\psi_0 \mathrm{U} \psi_1) = 1$ for some i_0, then, by definition of Δ, $g_i(\psi_0 \mathrm{U} \psi_1) = 1$ for all $i \leq i_0$. Since $g_{i_0}(\psi_0 \mathrm{U} \psi_1) = 1$ means $g_{i_0+kmn}(\psi_0 \mathrm{U} \psi_1) = 1$ for all $k \in \mathbf{N}$, we even have $g_i(\psi_0 \mathrm{U} \psi_1) = 1$ for all $i \in \mathbf{Z}$.

The second case is when $g_{i_0}(\psi_0) = 0$ holds for some $i_0 \in \mathbf{Z}$. In this case, $g_{i_0+kmn}(\psi_0) = 0$ for all $k \in \mathbf{Z}$. So if $g_i(\psi_0 \mathrm{U} \psi_1) = 1$ for some $i \in \mathbf{Z}$, then, because of the definition of Δ, there exists some $l \in \mathbf{N}$ with $g_{i+l}(\psi_1) = 1$ and $g_{i+k}(\psi_0) = 1$ for all k with $k < l$ – a simple proof by induction shows that. Let i' be such that $i \equiv i' \,(n)$. Then $i + j \equiv i' + j \,(n)$ for every $j \in \mathbf{Z}$. So from the induction hypothesis, we can conclude $g_{i'+l}(\psi_1) = 1$ and $g_{i'+k}(\psi_0) = 1$ for all k with $k < l$. Hence, $g_{i'}(\psi_0 \mathrm{U} \psi_1) = 1$.

Wolfgang. We are done. Perfect!

Thomas. Wolfgang, my theory lecture starts in a few minutes. I hope you don't mind me hanging up now. I am calling back later.

Wolfgang. I am sorry. Please, go ahead.

Thomas grabs his tablet, a copy of Sipser's book [14], and leaves his room; Wolfgang takes a notebook and starts scribbling.

3 Act III

Wolfgang is still sitting at his desk, contemplating. Thomas just entered his office, carrying his tablet and Sipser's book, and went straight to his laptop. He is initiating another session with Wolfgang.

Wolfgang. Thomas, thanks for calling back. I hope your lecture went well. Here is what I thought about in the meantime. Now that we know how to deal with counter-free ω-automata and future temporal logic, can we also say something about temporal logic in general? When future *and* past operators are allowed?

Thomas. Why are you asking? – We somehow know what happens because of the result by Gabbay, Pnueli, Shelah, and Stavi [7].

Wolfgang. I know this result settles the question in the sense that every arbitrary temporal formula is equivalent to a future temporal formula when interpreted in the first position of ω-words. I also know that by a result by Gabbay [6] every arbitrary temporal formula is equivalent to a boolean combination of pure past, present, and pure future formulas. But proofs of these results are technically involved and I am missing automata theory in this picture!

Thomas. Oh, that's an interesting thought.

Thomas thinking ...

Thomas. I think we can say something really nice here. Again, we need to agree on the right automaton model.

Wolfgang. What are you thinking of?

Thomas. Well, arbitrary temporal logic formulas are interpreted in some position in an ω-word. In some sense, the semantics of such a formula is a function $[\![\varphi]\!]$ which maps ω-words over Σ to ω-words over $\{0,1\}$, where the bit at position i of the image of a given word is the truth value of the formula when interpreted at position i in the given word. So what I think we should do is to come up with a slick automaton model for describing such functions.

Wolfgang. There are many ways to define functions from ω-words to ω-words and even more ways to define functions from finite words to finite words. A very general notion is that of a rational function and it has been studied in detail. For instance, there is a result by Elgot and Mezei which states that a rational function of finite words is the composition of a left-sequential and a right-sequential function [5], and I believe I have come across a similar result for ω-words.

Thomas. That is true. Elgot and Mezei's result was generalized to ω-words by Olivier [2]. I am thinking of extending Schützenberger's bimachines [12] to ω-words in a way adequate for dealing with temporal logic.

Wolfgang. I remember Schützenberger's bimachines. How do we extend them to ω-words?

Thomas. Suppose we want to realize a function $\nu\colon \Sigma^\omega \to \Gamma^\omega$. Suppose we are given a word $w \in \Sigma^\omega$. And suppose we want to know the symbol at position i in $\nu(w)$, that is, we want to know $\nu(w)(i)$. What we could do first is to split w at position i, that is, write w as uav where the length of u is i. Then we could run a forward deterministic automaton on u, a backward deterministic ω-automaton on v, and output $\nu(w)(i)$ depending on the two halting states and the symbol a. – Here is a picture. *(Drawing on the screen.)*

Wolfgang. That is very close to what Schützenberger suggested for finite words, only that he allowed an arbitrary word to be output, rather than a single symbol. – Let me try to make your picture formal and define what we may call ω-bimachines. Such a machine, let's call it A, consists of

- a forward deterministic automaton without final condition, say with finite state set Q, initial state q_I, and transition function $\delta\colon Q \times \Sigma \to Q$,
- a backward deterministic ω-automaton without final condition, say with finite state set S, initial recurrence condition $\mathcal{I}$, and a backward transition function $\rho\colon \Sigma \times S \to S$, and
- an output function $o\colon Q \times \Sigma \times S \to \Gamma$.

Thomas. That's it. The semantics is a function $\Sigma^\omega \to \Gamma^\omega$, which we denote by ν. Assume $w \in \Sigma^\omega$ and we want to define $\nu(w)(i)$ for some $i \in \omega$. We take the halting state of the forward automaton for the word $w(0) \dots w(i-1)$, say this is q. We take the halting state of the backward automaton for the word $w(i+1)w(i+2)\dots$, say this is s. Then $\nu(w)(i) = o(q, w(i), s)$.

Wolfgang. That is indeed a very simple and intuitive definition. It also connects nicely with rational functions, because from Olivier's results it should follow that the class of functions computed by ω-bimachines is the same as the class of total letter-to-letter rational functions. – What we want to do is to transform every temporal formula into an equivalent ω-bimachine.

Thomas. We should even strive for a counter-free ω-bimachine, where this simply means that the forward and the backward automaton are counter-free. Because if we manage to achieve that, we also have a proof of the result by Gabbay, saying that every arbitrary temporal formula is equivalent to a boolean combination of pure future, present, and pure past formulas – completely in automata-theoretic terms.

Wolfgang. That sounds like an interesting plan and I would like to give it a shot. In the future-only setting, it was easy to describe the state space in one go – it was a function $\mathrm{sbf}(\varphi) \to \{0,1\}$. I believe it is going to be more complicated here, which is the reason I suggest we try an inductive definition.

Thomas. I will be happy with an inductive definition!

Wolfgang. There are two base cases: $\psi = \top$ and $\psi = a$ for some $a \in \Sigma$. In both cases, we can choose the forward and the backward automaton to be a 1-state automaton. In the first case, we can set $o(q, a, s) = 1$ for every $a \in \Sigma$; in the second case, we can set $o(q, a, s) = 1$ and $o(q, b, s) = 0$ for all $b \in \Sigma \setminus \{a\}$. – Easy!

Thomas. Clearly, these automata are counter-free.

Wolfgang. In the inductive step, we have to take care of boolean operators and temporal operators.

Thomas. Boolean operators can be dealt with easily, only the temporal operators are interesting.

Wolfgang. We have four temporal operators when we admit future as well as past operators and follow standard syntax and semantics: X – next, P – previously, U – until, and S – since. I suggest we consider "previously" and "until", the two other can be dealt with in a similar fashion.

Thomas. What we need for each of the two operators are two things. First, we need a construction. Second, we need a proof that it preserves counter freeness.

Wolfgang. So let's turn to "previously" and assume we are given a counter-free ω-bimachine which computes a function $\mu\colon \Sigma^\omega \to \{0,1\}^\omega$. We want to construct a new counter-free ω-bimachine which computes the function ν defined by $\nu(w)(i+1) = \mu(w)(i)$ and $\nu(w)(0) = 0$ for every $i < \omega$. Apparently, we don't have to change the backward automaton; we only need to adapt the forward automaton and the output function.

Thomas. I agree. This seems to be a simple construction.

Wolfgang. We make the forward automaton lag behind in the sense that it keeps track of its previous state and the symbol just read. In the beginning, we start from a new state. So

the state space is $Q \times \Sigma \cup \{\bot\}$ and the transition function is given by $\delta'(\langle q, a\rangle, b) = \langle \delta(q, a), b\rangle$ and $\delta'(\bot, a) = \langle q_I, a\rangle$. The output function, o', is given by $o'(\langle q, a\rangle, b, s) = o(q, a, \rho(b, s))$ and $o'(\bot, a, s) = 0$.

Thomas. This is quite convincing. In fact, the construction does not only seem to be correct to me. It also preserves counter freeness, as far as I can see.

Wolfgang. So let's turn to "until".

Thomas. We assume we are given two counter-free ω-bimachines computing functions $\mu_0 \colon \Sigma^\omega \to \{0,1\}^\omega$ and $\mu_1 \colon \Sigma^\omega \to \{0,1\}^\omega$, respectively, and we want to construct a counter-free ω-bimachine computing the function $\nu \colon \Sigma^\omega \to \{0,1\}^\omega$ given by $\nu(w)(i) = 1$ if, and only if, there exists some $k \geq i$ such that $\mu_1(w)(k) = 1$ and $\mu_0(w)(j) = 1$ for all j with $i \leq j < k$. – By taking a product of the two forward automata and the two backward automata, we can simplify the situation in the sense that we can think of only one counter-free ω-bimachine but with two output functions, o_0 and o_1, where the first one is for μ_0 and the second one is for μ_1. – Do you see what we need to do?

Wolfgang. Yes, right away. Let's call the given automaton A and the one to be constructed A'. It is important that the backward automaton of A' knows, at any point, those states from the forward automaton of A from which the U-formula can be satisfied. – I am aware of the fact that this is a vague description, but it should become clear when we work out the details.

Thomas. Let me see if I understand what you mean. The state space of the backward automaton of A' is $S \times 2^Q$. Its backward transition function is defined by

$$\rho'(a, \langle s, P\rangle) = \langle \rho(a, s), P'\rangle \ ,$$

where P stands for a subset of Q and P' is defined by

$$P' = \{q \in Q \mid o_1(q, a, s) = 1\} \cup \{q \in Q \mid \delta(q, a) \in P \text{ and } o_0(q, a, s) = 1\} \ .$$

The forward automaton of A' is the same as the one of A. The output function of A', let's denote it o', is given by $o'(q, a, \langle s, P\rangle) = 1$ if, and only if, $o_1(q, a, s) = 1$, or $o_0(q, a, s) = 1$ and $\delta(q, a) \in P$.

Wolfgang. This is what I was thinking of. The transition function ρ' reflects the semantics of the until operator in a particular sense, which I would like to make precise. For every state $q \in Q$, let A_q denote the ω-bimachine which is obtained from A by changing the initial state of the forward automaton to q. Further, let ν_0^q and ν_1^q denote the corresponding functions. Now suppose $w \in \Sigma^\omega$ and $\langle s_0, P_0\rangle\langle s_1, P_1\rangle \dots$ is a run of the backward automaton of A' on w such that $s_0 s_1 \dots$ is an initial run of the backward automaton of A and write P for P_0. Then the following is true for every state $q \in Q$ and can be proved by a straightforward induction:

1. If there is some j such that $\nu_1^q(j) = 1$ and $\nu_0^q(i) = 1$ for every $i < j$, then $q \in P$.
2. If $q \in P$, then either
   a. there is some j such that $\nu_1^q(j) = 1$ and $\nu_0^q(i) = 1$ for every $i < j$, or
   b. $\nu_0^q(i) = 1$ for all $i < \omega$.

The problem I see is that we really want 2.a for each $q \in P$. For a U-formula to be true, it is not enough to have 2.b only.

Thomas. Your concern is completely valid. Without any further measure, the construction may "overapproximate". The problem is similar to the fairness problem we had when we looked at the backward deterministic ω-automaton for a given future temporal formula and introduced a recurrence set for every U-subformula.

Wolfgang. What do you suggest? Are we going to do the same here?

THOMAS. The situation is more complicated. Here is the basic idea. For every q satisfying 2.a there is a smallest j with the specified property. Let's denote this by j_q. We assign a natural number $p(q)$ to every state $q \in P$ such that $p(q)$ reflects the order of the j_q's, that is, $p(q) < p(q')$ if, and only if, $j_q < j_{q'}$. We then make sure by appropriate recurrence conditions that the numbers that are assigned to the successors of q decrease over time until j_q is finally reached.

WOLFGANG. That sounds interesting. Can you make this precise?

THOMAS. Let $m = |Q|$ and set $M = \{0, \ldots, m-1, \infty\}$. A state of the backward automaton of A' is then a pair $\langle s, p \colon Q \to M \rangle$ where P from above is now given by $\{q \in Q \mid p(q) \neq \infty\}$.

WOLFGANG. Given this, I think I can describe how the correct backward deterministic transition function works. In a first step, we set

- $p_0(q) = -1$ for every q with $o_1(q, a, s) = 1$,
- $p_0(q) = p(\delta(q, a))$ for every q with $o_0(q, a, s) = 1$ and $o_1(q, a, s) = 0$, and
- $p_0(q) = \infty$ for all other $q \in Q$.

This is consistent with the definition of P' from above in the sense that $P' = \{q \in Q \mid p(q) \neq \infty\}$, but there are values out of range – we may have -1 as a value. We adjust p_0 to obtain p' by increasing some of its values as follows, where t is defined by $t = \min\{j \in \{-1, \ldots, m-1\} \mid p_0^{-1}(j) = \emptyset\}$.

- $p'(q) = p_0(q) + 1$ for all q with $p(q) < t$.
- $p'(q) = p_0(q)$ for all other $q \in Q$.

In some sense, we are adjusting as little as is necessary.

THOMAS. This is absolutely correct. What we still have to define is an appropriate recurrence condition. This will be the union of two recurrence sets $\mathcal{I}_0$ and $\mathcal{I}_1$, where $\mathcal{I}_0$ simply extends $\mathcal{I}$ to the new state space in a straightforward way. More precisely, $\mathcal{I}_0 = \{S' \times M^Q \mid S' \in \mathcal{I}\}$.

The set $\mathcal{I}_1$ contains a transition recurrence set T_i for every $i \in \{0, \ldots, m-1\}$. This set contains a pair $\langle a, \langle s, p \rangle \rangle$ if, and only if, $t = i$ for the value t as defined above or $p'(q) \in \{0, \ldots, i-1, \infty\}$ for every $q \in Q$ and p' as defined above.

WOLFGANG. Thomas, I understand what you are saying, but I think a rigorous correctness proof is needed here.

THOMAS. I agree. As the construction is inspired by Oliver and Max Michel's work, we can also borrow some of their ideas for the correctness proof.

WOLFGANG. Anyway, we also need to prove that our construction really yields a counter-free automaton.

THOMAS. I agree again. The proof of this is tedious, but doable. One can use what we know from the proof that the backward deterministic ω-automaton for a given future temporal formula is counter-free.

WOLFGANG. OK. There is still some work to be done before I can present the material to the students. I am calling it a day. Thanks a lot, and see you soon, Thomas!

THOMAS. Bye, bye. And, please, say "hello" to Renate.

Wolfgang and Thomas close their desktop sharing applications.

4 Epilogue

A few weeks later, Thomas receives the following email.

Hi, Thomas!

You probably want to know how it went with my lectures. First of all, it didn't take me much time to work out all the details of what we talked about. Then everything went fine, only the students came up with a fair number of questions I couldn't answer right away. Here are the most interesting ones, maybe:

- What is the complexity of the translation from counter-free backward deterministic ω-automata to future temporal formulas?
- What is the complexity of the translation from arbitrary temporal formulas to ω-bimachines? Non-elementary?
- Say "prop" is some interesting class of deterministic automata. What happens when we consider "prop" ω-bimachines instead of counter-free ω-bimachines?

Any ideas?

All the best, Wolfgang

Thin MSO with a Probabilistic Path Quantifier

Mikołaj Bojańczyk

University of Warsaw, Warsaw, Poland

Abstract

This paper is about a variant of MSO on infinite trees where:

- there is a quantifier "zero probability of choosing a path $\pi \in 2^\omega$ which makes $\varphi(\pi)$ true";
- the monadic quantifiers range over sets with countable topological closure.

We introduce an automaton model, and show that it captures the logic.

1 Introduction

The ambient topic of this paper is MSO on infinite binary trees, extended by a quantifier $\mathsf{zero}\pi\ \varphi(\pi)$ which says that there is zero probability of choosing a path π in the tree so that $\varphi(\pi)$ is true. Here we assume that each bit (i.e. turn) in the path is chosen independently at random. This logic was introduced by Michalewski and Mio in [10], where the decidability of satisfiability was left open.

That satisfiability question is not solved here, but we make a small step in its direction. We consider a fragment of the logic, called TMSO+zero, standing for *thin* MSO+zero. In this fragment, the monadic set quantifiers are restricted to sets which are thin in the following sense: a set of nodes is *thin* if there are countably many paths which visit it infinitely often. For example, every path (when seen as a set of nodes) is thin, and every finite set is thin. In the logic TMSO+zero, one has existential and universal quantification over nodes and thin sets of nodes, as well as the probabilistic path quantifier zero. Being thin is definable in MSO, and therefore without the zero quantifier, the logic would be a special case of MSO, and with the zero quantifier it is a special case of the logic from [10].

The contribution of this paper is the definition of an automaton model, called zero automata, and a proof that every formula of TMSO+zero can be effectively translated to an equivalent zero automaton.

Motivation

The first source of motivation for this paper is the study of probabilistic temporal logics [1, 8, 13, 4]. An important example is the logic PCTL. It is an open problem whether this logic has decidable satisfiability. Much of the difficulty stems from the ability of talking about probabilities like 1/2 or 1/3. If one can only compare probabilities to 0 or 1, which is in the spirit of our logic TMSO+zero, then we get *qualitative* PCTL, whose satisfiability was shown decidable by Brázdil, Forejt, Kretínský and Kucera in [4]. Actually, the qualitative fragment of PCTL, as well as stronger qualitative logics like PCTL*, can be straightforwardly formalised in TMSO+zero, and therefore, by the main result of this paper, translated into zero automata. Another example that we discuss later in the paper is the probabilistic version of tree automata by Carayol, Haddad and Serre [6]; these are also a special case of zero automata.

The second source of motivation is trying to find a robust classes of languages of infinite words or trees which remains decidable (e.g. with respect to satisfiability). The point of departure is MSO, with its famous decidability results by Büchi [5] and Rabin [11]. One way of departing from that point is to add unary predicates, e.g. extending MSO over ω-words by a predicate "x is a position of the form $n!$", see [12] for a survey. Another way is to add new quantifiers. Due to the strength of MSO, it is not so easy to come up with a quantifier extending MSO that is not obviously undecidable, and yet not already definable in MSO. For example, a nice quantifier is "there exist uncountably many sets with a given property" – but as shown in [2], this quantifier does not add to the expressive power of MSO. A logic that *does* properly extend MSO is MSO+U, which is an extension of MSO by a quantifier which can say that a given property is true for finite sets of unbounded size. The logic is itself undecidable, but has many decidable fragments, typically variants of weak MSO. See [3] for a survey of MSO+U and related logics, including the cost logics of Colcombet [7]. The logic studied in this paper, TMSO+zero, is another example of a logic that is not contained in MSO (and even contains MSO, if the logic is extended by allowing an outermost layer of non-weak existential set quantifiers, which does not affect decidability of satisfiability).

2 The logic and the automaton

This section describes the two main models used in the paper: the logic TMSO+zero and zero automata. The following sections discuss how the logic is translated into the automaton.

Tree notation

The logics and automata of this paper describe properties of possibly infinite binary labelled trees. We treat a node in a tree as a sequence in 2^*, with 2 denoting the set of directions $\{0, 1\}$. Define a *tree* over an alphabet Σ to be a partial function $t : 2^* \to \Sigma$ whose domain is closed under prefixes. The special case when function is total is called a *complete tree*, but we do allow incomplete trees, e.g. trees with finite domains. We use standard terminology for trees: node, root, left child, right child, leaf, ancestor and descendant. In our definition, a node might have a right child but not a left child. We write $\mathsf{trees}\Sigma$ for the set of trees over Σ.

Probability measure over paths

A *path* is defined to be a sequence in 2^ω, which is viewed as an infinite sequence of left or right turns. An equivalent definition is that a path is an ancestor-closed set of nodes that is totally ordered by the ancestor relation. When saying that a path is contained in a set of nodes, or contains a node, the second definition is used. When talking about the probability of a subset of 2^ω we use the *coin-flipping* measure, i.e. we assume that each bit is chosen independently at random, with 0 and 1 having equal probability. The probability is defined at least for all Borel subsets of 2^ω.

▶ **Definition 1.** We say a set $\Pi \subseteq 2^\omega$ has *zero probability* if it is contained in a Borel set with coin-flipping measure zero.

The sets of paths that will appear in the logic TMSO+zero will always be Borel, so the closure under subsets in the above definition will not play much of a role.

2.1 The logic

Before defining the logic TMSO+zero, we discuss the probability-free fragment TMSO.

Thin MSO without the zero quantifier

A set of nodes $X \subseteq 2^*$ is called *thin* if its *closure* defined by

$$\bar{X} \stackrel{\text{def}}{=} \{\pi \in 2^\omega : \pi \text{ passes through infinitely many nodes from } X\}$$

is countable. For example, every finite set is thin, because it has empty closure, and every path is thin, when viewed as a set of nodes, because its closure has one path. Thin sets are closed under arbitrary intersections and finite unions, but not under countable unions, because the countable set of all nodes has all paths in its closure, and is therefore not thin.

The logic *thin* MSO, denoted by TMSO, is the variant of MSO as in Rabin's theorem, except that set quantifiers range only over thin sets. The syntax of the logic is the same as for MSO from Rabin's theorem: there are two types of variable in the logic: *node variables*, which range over nodes in the domain of the input tree, and *(thin) set variables*, which range over thin subsets of the domain of the input tree. There are binary predicates for the left and right child relations, and there is a unary predicate for every label in the input alphabet. By the Cantor-Bendixson theorem, a set of nodes X is thin if and only if one cannot find a subset $Y \subseteq X$ such that Y, when ordered by the descendant relation, is a complete binary tree. Since this alternative characterisation can be formalised in MSO, it follows that TMSO is a fragment of MSO in terms of expressive power. On the other hand, TMSO is at least as expressive as WMSO with path quantifiers.

As far as the author knows, the logic TMSO was not considered explicitly in the literature so far, and it might be interesting to examine its expressive power, e.g. prove that it is strictly weaker than MSO and maybe, in the long run, find an algorithm which inputs a formula of MSO and decides if the formula is equivalent to some formula in TMSO. This investigation, however, is not the topic of the present paper. The present paper is about extending TMSO with a quantifier for zero probability.

Thin MSO with the zero quantifier

We now define the main topic of this paper, i.e. the logic TMSO+zero. First we explain why our point of departure for adding the zero quantifier is TMSO and not some other fragment of MSO. The reason is that TMSO is the strongest logic we could find such that the set quantifiers commute with the probabilistic quantifier in a way which will be made more precise in Section 6. The key observation reason is this: if the domain of the input tree is thin, then it has countably many paths, and therefore the zero quantifier can be eliminated because it always says "yes".

A parameter in the definition of TMSO+zero is a family zero of subsets of 2^ω. The example we have in mind is that zero is the sets with zero probability according to Definition 1, but the results will also work for other choices of zero. The logic TMSO+zero is the extension of the logic TMSO defined above, by adding a quantifier, called zero, which binds a thin set variable π, and such that

$$\mathsf{zero}\pi\ \varphi(\pi)$$

is true if zero contains the set of paths π which are contained in the domain of the input tree and make $\varphi(\pi)$ true, assuming that a path is treated as a set of nodes. (Formally speaking, the path π is seen as a set of nodes when evaluating $\varphi(\pi)$, and as an element of 2^ω when measuring how many paths π make $\varphi(\pi)$ true.)

▶ **Example 2.** Consider an alphabet $\{a, b\}$. The following formula says that zero contains the set of paths that visit at least one a:

$$\mathsf{zero}\pi\ \exists x\ (x \in \pi \wedge a(x)).$$

If the parameter zero is prefix independent (see Definition 7 for a more precise treatment) and does not contain the set 2^ω of all paths, then the above formula is equivalent to $\forall x\ \neg a(x)$, and therefore the zero quantifier can be avoided.

▶ **Example 3.** Consider an alphabet $\{a, b\}$. The following formula says that zero contains the set of paths which visit b finitely often:

$$\mathsf{zero}\pi\ \exists x\big(x \in \pi \wedge \forall y\ (y \geq x \wedge y \in \pi \Rightarrow b(x))\big)$$

If zero is our guiding example of zero probability, the negation of the above formula says that the Büchi condition is satisfied with probability one. As shown in [6], Theorem 21, the property above is not definable in MSO.

▶ **Example 4.** The reduction from qualitative PCTL* in Theorem 5 from [10] produces formulas where set quantification is only used for paths. Therefore, qualitative PCTL* is a special case of TMSO+zero.

Beyond Thin MSO with the zero quantifier

In the logic TMSO+zero, the set variables are restricted to thin sets. The obvious question is about the more general case, where set variables range over arbitrary sets of nodes, not necessarily thin ones. As mentioned in the introduction, the more general logic was introduced in [10], under the name MSO$+\forall_\pi^{=1}$, and the authors asked about decidability of its satisfiability problem. A long term project for this research is to find out if the satisfiability problem for the more general logic is decidable – or not. In this paper we only begin the project, by studying the thin variant. One scenario is that the thin variant is decidable, but the non-thin variant is undecidable, which would be similar to the situation for MSO+U, where weak variants are decidable, but the full logic is undecidable. However, one should not take the analogy with MSO+U too far: e.g. the thin variant of MSO+U would already be undecidable, because MSO+U is undecidable already for ω-words.

Another natural version of MSO with probability would be to choose a subset of 2^* at random, with each node chosen independently, and then have a quantifier that says there is zero probability of finding a subset with a given property. This logic was proved undecidable in [10], already for ω-words (which can be seen as a special case of TMSO), and the undecidability proof works also for formulas of the form

$$\text{there is zero probability of choosing a set } X \subseteq \mathbb{N} \text{ which makes } \varphi(X) \text{ true,}$$

where $\varphi(X)$ is a formula of first-order logic that defines a set of ω-words over alphabet 2. Therefore, it seems that this kind of probabilistic quantifier is doomed to undecidability.

2.2 The automaton

Having defined the logic TMSO+zero, we define our main automaton model, which is called a zero *automaton*. Like in the logic TMSO+zero, a parameter of the semantics for the automaton is a family zero of subsets of 2^ω. The idea is that the automaton extends a nondeterministic parity automaton with the ability to say that the set of paths satisfying the parity condition belongs, or does not belong, to zero.

▶ **Definition 5.** The syntax of a zero automaton is a tuple

$$\underbrace{Q}_{\text{states}} \qquad \underbrace{\Sigma}_{\text{input alphabet}} \qquad \underbrace{I \subseteq Q}_{\text{initial states}} \qquad \underbrace{\bigcup_{C \subseteq 2} \delta_C \subseteq Q \times \Sigma \times Q^{|C|}}_{\text{transitions}},$$

with all components finite, together with a total order on Q and four subsets

$$Q_{\text{all}}, Q_{\text{zero}}, Q_{\text{nonzero}}, Q_{\text{seed}} \subseteq Q.$$

The idea behind the transitions is that $\delta_{\{0,1\}}$ is used for those nodes which have both children defined, but e.g. $\delta_{\{1\}}$ is used for nodes where only the right child is defined, and $\delta_\emptyset$ is used for leaves.

The semantics are defined as follows. The automaton is run on a tree over the input alphabet, which might not necessarily be complete. A *run* of the automaton is a tree labelled by states with the same domain as the input tree, which is consistent with the transition relation in the following sense: if a node x is in the domain, and we define

$$C \stackrel{\text{def}}{=} \{i \in 2 : xi \text{ is in the domain}\}$$

then there must be a transition in δ_C which relates the state in x, the label of x in the input tree, and the states in the children of x that are in the domain. A tree is accepted if it admits a run which has the initial state in the root and is accepting in the following sense. Define the *maxinf state* on a path in a run to be the maximal state that appears infinitely often on the path. When talking about a maximal state, we refer to the total order on states that is given in the syntax of the automaton. A run ρ is accepting if all of the following conditions hold, assuming that $\mathsf{paths}\,\rho \subseteq 2^\omega$ denotes the set of paths contained in ρ:

1. **all paths acceptance condition:** every path from $\mathsf{paths}\,\rho$ has maxinf in Q_{all}; and
2. **zero acceptance condition:** zero contains the set of paths from $\mathsf{paths}\,\rho$ which have maxinf state in Q_{zero}; and
3. **nonzero acceptance condition:** for every node x in the run with state $q \in Q_{\text{seed}}$:

$$\mathsf{zero} \not\ni \{\pi \in \mathsf{paths}\,\rho : \begin{cases} \pi \text{ passes through } x, \text{ and} \\ \pi \text{ sees only states } < q \text{ after } x, \text{ and} \\ \pi \text{ has maxinf state in } Q_{\text{nonzero}} \end{cases} \}$$

An automaton is called *zeroless* if Q_{zero} is empty (which makes the zero condition vacuously true) and *seedless* if there are no seed states, i.e. Q_{seed} is empty (which makes the nonzero condition vacuously true). In particular, a zeroless and seedless automaton is the same thing as a parity automaton, which proves the zero automata are at least as powerful as MSO.

▶ **Example 6.** Assume that zero is probability zero as in Definition 1. Consider the special case of a zero automaton where Q_{all} is all states and Q_{seed} is empty. A run is accepting if and only if there is zero probability of having maxinf state in Q_{zero}. Equivalently, the probability of having maxinf state outside Q_{zero} is one. Languages recognised by such automata are the *qualitative tree languages* from [6]. The class of *positive tree languages* from [6] is obtained when Q_{all} and Q_{zero} are empty, and the initial state is used only once in the root, is maximal in the total order, and is the unique seed state.

3 Fat Cantor

In this section, we illustrate the logic and automaton with an extended example. Let us fix zero to be probability zero according to Definition 1. Define the *fat Cantor language* to be the set of complete trees over the alphabet $\{a, b\}$ which satisfy the following property:

$$\underbrace{\neg \mathsf{zero}\pi\big(\forall x\ x \in \pi \wedge b(x)\big)}_{\text{nonzero probability of avoiding } a} \quad \wedge \quad \underbrace{\forall x \exists y\ y \geq x \wedge a(y)}_{a\text{'s are dense}}$$

Note that "avoiding a" is a Borel property of paths, and therefore "nonzero probability of avoiding a" means that the sets of paths avoiding a have defined positive probability. This argument will be true in general for our logic – for every fixed input tree, any property of paths definable in the logic will be Borel, and therefore not belonging to zero will mean that it there is defined and positive probability.

The fat Cantor language is nonempty. To construct a tree in the fat Cantor language, choose a fast growing sequence of natural numbers

$$n_1 < n_2 < n_3 < \cdots$$

and then choose a tree (which is unique up to reordering siblings) where a labels are found only at depths from the sequence above, and every node at depth n_i has a unique descendant at depth n_{i+1} with label a. If the sequence (n_i) grows fast enough, then there is nonzero probability of avoiding a. Let us now argue that the fat Cantor language contains no regular tree, i.e. no tree with finitely many nonisomorphic subtrees. Suppose then that t is a regular tree, with n distinct subtrees. If a's are dense in this tree, it follows from regularity that every node has a descendant at distance at most n that has label a. This means there is some constant $\epsilon > 0$ such that for every interval $I \subseteq \mathbb{N}$ of n consecutive positions, the probability of a path visiting a at depth from I is at least ϵ. These events are independent for disjoint intervals, and therefore the probability of seeing a at least once, and even infinitely often, is 1. Summing up: the fat Cantor language is nonempty but contains no regular trees.

Fat Cantor automaton

We now show a zero automaton which recognises the fat Cantor language described above. To simplify notation, we define an automaton which works only on complete trees, i.e. it recognises the intersection of the fat Cantor language with the set of complete trees. In particular, when talking about transitions, we only consider transitions δ_C for $C = \{0, 1\}$.

The input alphabet is $\{a, b\}$. The automaton has four states, totally ordered as follows:

$$\underbrace{q_a}_{\text{already saw } a} < \underbrace{q_1}_{\text{searching for } a} < \underbrace{q_2}_{\text{not searching for } a} < \underbrace{q_0}_{\text{initial state}}$$

The automaton begins in state q_0 in the root, this state will not be visited again during the run. When the automaton is in state q_i with $i \in \{0, 1, 2\}$ and it reads a node with label b, then it sends q_1 to some child and q_2 to the other child, as witnessed by the following transitions:

$$(q_i, b, q_j, q_k) \quad \text{for } i \in \{0, 1, 2\} \text{ and } \{j, k\} = \{1, 2\}.$$

Choosing which child gets q_1 and which child gets q_2 is the only source of nondeterminism in this automaton. When the automaton sees letter a, it sends q_a to both children regardless of

its current state, and q_a is a sink state that cannot be left, as witnessed by the following transitions:

$$(q, a, q_a, q_a) \quad \text{for all } q \in Q \qquad (q_a, a, q_a, q_a) \qquad (q_a, b, q_a, q_a)$$

Since q_0 is used only once in the root, and q_a is a sink state, it follows that on every path either q_a is seen from some point on, or q_a is never seen and the maxinf state is one of q_1, q_2. The acceptance condition is defined by the following sets:

$$Q_{\text{all}} = \{q_a, q_2\} \qquad Q_{\text{zero}} = \emptyset \qquad Q_{\text{nonzero}} = \{q_1, q_2\} \qquad Q_{\text{seed}} = \{q_0\}$$

Because Q_{zero} is empty, every run satisfies the zero acceptance condition. The state q_0 appears only once in the root, and therefore it is never used as a maxinf state. By choice of Q_{all}, the state q_1 is forbidden as a maxinf state, which means that in an accepting run, every path eventually stabilises on either q_a or q_2. Since the only way of leaving q_1 is by seeing an a letter, it follows that a's must be dense. The only seed state is the initial state, which is used only once in the root, and is also the most important state. Therefore, a run satisfies the nonzero acceptance condition if and only if its there is nonzero probability of having maxinf state in $\{q_1, q_2\}$, which means there is nonzero probability of avoiding a.

4 From logic to automata

The main technical result of this paper is that every formula of TMSO+zero can be effectively translated to an equivalent zero automaton. The result works not just for zero probability, but for other choices of zero, as described in the following definition.

▶ **Definition 7.** For a family zero of subsets of 2^ω, consider the following properties:

1. **σ-ideal:** zero is closed under subsets and countable union;
2. **atomless:** zero contains all singletons;
3. **prefix independence:** every set $\Pi \subseteq 2^\omega$ satisfies

$$\Pi \in \mathsf{zero} \Leftrightarrow i\Pi \in \mathsf{zero} \qquad \text{for every } i \in 2$$

4. **recurrent nonzero:** there is a zero automaton which recognises the language

$$\{t \in \mathsf{trees}\{1,2,3\} : \text{for every subtree, the set of paths with maxinf 2 is } \notin \mathsf{zero}\}$$

In the recurrent nonzero condition, it is important that the trees are not necessarily complete. For such a tree, a subtree is obtained by shifting the root to some node in the domain. In particular, if a tree belongs to the language from the recurrent nonzero condition, then it cannot have any leaves.

Here is the main result of this paper.

▶ **Theorem 8.** *Let* zero *be a family of subsets of* 2^ω *satisfying conditions 1-4 in Definition 7. Then for every formula of* TMSO+zero *one can compute an equivalent* zero *automaton.*

The proof has three steps. In Section 5, we show closure properties of languages recognised by zero automata, of which the most interesting is closure under intersection. In Section 6, we show that the logic TMSO+zero has the same expressive power as a certain transducer model. In Section 7, we complete the proof of the theorem, by translating transducers into zero automata. The results in Section 5 and 6 only use properties 1-3 in Definition 7, while Section 7 uses also property 4.

The following corollary shows the main application of Theorem 8.

▶ **Corollary 9.** *Let* zero *be the subsets of* 2^ω *that have zero probability in the sense of Definition 1. Then for every formula of* TMSO+zero *one can compute an equivalent* zero *automaton.*

Other examples of zero which can be shown to satisfy the assumptions of Theorem 8 include "countable sets of paths [2]" and "meagre sets of paths [9]". These other examples are less interesting because they can already be formalised in MSO alone, i.e. parity automata are sufficient. Theorem 8 can be seen as an alternative way of recovering the results from [2, 9]: one only needs to check that the assumptions of Theorem 8 are satisfied for a particular choice of zero, and that zero automata can be captured by MSO. In view of the results from [2, 9], we have only one example of zero that satisfies the assumptions of Theorem 8, and which strictly extends MSO, namely probability zero.

5 Closure properties of zero automata

This section is about closure properties of the class of languages recognised by zero automata. We show that this class is closed under positive Boolean operations – with intersection being by far the more interesting case. We do not know if languages recognised by zero automata are closed under complementation. If they would be, then zero automata would have exactly the same expressive power as full MSO+zero.

Define a *Mealy machine* to be a deterministic finite automaton on words over some input alphabet Σ, where every transition is labelled by a letter from some output alphabet Γ. Such a machine can be run on a finite word, yielding a length preserving function $\Sigma^* \to \Gamma^*$, it can also be run on an ω-word, yielding a function $\Sigma^\omega \to \Gamma^\omega$, or finally it can be run on all paths in a tree, yielding a function $\mathsf{trees}\Sigma \to \mathsf{trees}\Gamma$ which does not change the domain of the tree. The last case will be called a *tree transducer recognised by a Mealy machine.*

▶ **Lemma 10.** *Languages recognised by* zero *automata are closed under union, as well as images and inverse images under tree transducers recognised by Mealy machines.*

Proof sketch. The lemma does not require any closure properties from the set zero. For union, we use disjoint union of automata (and gluing the initial state). For images use nondeterminism, and for both images and inverse images use a Cartesian product construction to simulate the Mealy machine in the state space of the zero automaton. Note that state spaces in zero automata are ordered. Therefore we impose some random total order on a Mealy machine, and in the Cartesian product we use a lexicographic ordering, with the order on the original zero automaton being more important. ◀

We now show another closure property, which is closure under factorisations, as described below. Define a *factor* to be a set of nodes that is connected with respect to the child relation. In particular, a factor has a unique *root*, i.e. a unique node which is least with respect to the descendant ordering. If X is a factor, then define the *restriction to* X of a tree t to be the tree obtained from t by keeping only the nodes from X. We now show that if L is a language recognised by a zero automaton, then there is a zero automaton which inputs a tree together with a decomposition into disjoint factors, and checks that L contains every tree obtained by restricting the input tree to one of the factors in the partition.

We begin by describing how a decomposition into factors is given on the input. If X is a set of nodes, then define an X-factor to be a set of nodes obtained by taking some $x \in X$ and adding all descendants y such that $(x..y]$ is disjoint with X, where $(x..y]$ denotes proper descendants of x that are (not necessarily proper) ancestors of y. By abuse of notation, we

define an X-factor of a tree t to be any tree obtained from t by restricting it to some X-factor. Finally, if X is a set of nodes in a tree $t \in \mathsf{trees}\Sigma$, then define $t \otimes X \in \mathsf{trees}(\Sigma \times 2)$ to be the tree obtained from t by extending the label of each node by a bit indicating membership in X.

▶ **Lemma 11** (Factorisation Lemma). *Assume that* zero *satisfies conditions 1–3 in Definition 7. If $L \subseteq \mathsf{trees}\Sigma$ is recognised by a* zero *automaton, then so is*

$$\{t \otimes X : t \in \mathsf{trees}\Sigma \text{ and } X \text{ is a set of nodes in } t \text{ such that } L \text{ contains every } X\text{-factor of } t\}.$$

The main idea in the proof is that to use the "nested" character of the nonzero acceptance condition; here by nesting we mean that the paths contributing to the nonzero condition are cut off whenever a more important state is seen.

We finish this section by stating the most challenging result, which is closure under intersection, as stated in the following lemma.

▶ **Lemma 12** (Intersection Lemma). *Assume that* zero *satisfies conditions 1-3 in Definition 7. Then languages recognised by* zero *automata are closed under intersection.*

The proof has several steps. One of these steps, namely the first step, is showing that languages recognised by zero automata are closed under intersection with languages recognised by zero automata which do not use the nonzero acceptance condition. The first step uses McNaughton's Latest Appearance Record construction.

6 Transducers

To prove Theorem 8, we use a transducer characterisation of the logic TMSO+zero. The transducer characterisation is an "if and only if" characterisation, unlike the translation in the main Theorem 8.

Transducers

Define a *tree transducer* to be any function $\mathsf{trees}\Sigma \to \mathsf{trees}\Gamma$ which does not change the domain of the input tree. Our goal is to show each language definable MSO+zero can be described by composing transducers of certain basic types. To model a language as a transducer, we use the following definition.

▶ **Definition 13.** For a tree language $L \subseteq \mathsf{trees}\Sigma$, define

$$\mathsf{trans}L : \mathsf{trees}\Sigma \to \mathsf{trees}2,$$

called the *characteristic transducer of* L, to be the transducer which labels each node of the input tree by a bit saying whether or not the subtree rooted in that node belongs to L.

We define the *combination* $t_0 \otimes t_1$ of two trees t_0, t_1 over possibly different alphabets Σ_0, Σ_1 but with equal domains, to be the unique tree over $\Sigma_0 \times \Sigma_1$ which projects to each t_i on the i-th coordinate. In the following theorem, composition of transducers is defined as for functions, while the combination of two transducers f_1, f_2 with the same input alphabet but possibly different output alphabets is the transducer $t \mapsto f_1(t) \otimes f_2(t)$.

▶ **Theorem 14.** *Assume that* zero *has the closure properties 1-3 from Theorem 8. Then a tree language is definable in* TMSO+zero *if and only if its characteristic transducer belongs to the smallest class of transducers which is closed under composition and combination, and which contains the following transducers:*

1. **Zero base.** *The characteristic transducers of all languages of the form:*

$$\mathsf{Z}_n \stackrel{def}{=} \{t \in \mathsf{trees}\{1,\dots,n,\bot\} : \mathsf{zero} \ni \{\pi \in \mathsf{paths}\, t : \begin{cases} \pi \text{ does not visit } \bot, \text{ and} \\ \pi \text{ has even maxinf} \end{cases} \}\}$$

2. **Zeroless base.** *The characteristic transducers of all languages definable in* TMSO.
3. **Child number transducer.** *Transducers of the form* $\mathsf{trees}\Sigma \to \mathsf{trees}2$ *which map each node to its child number, with the convention that the root gets label* 0.
4. **Mealy machine on trees.** *Transducers recognised by Mealy machines.*

The difficult implication is from logic to transducers; here we use the composition method. Intuitively speaking, the above theorem shows that formula of TMSO+zero can be decomposed into parts that do not talk about zero at all, and into the very basic property Z_n.

7 From transducers to zero automata

In this section we complete the proof of Theorem 8, by showing that the transducers from the previous section can be compiled into zero automata. We say that a tree transducer f is *recognised* by a zero automaton if there is a zero automaton recognising the set of trees $t \otimes f(t)$ where t ranges over all input trees for the tree transducer.

▶ **Lemma 15.** *Transducers recognised by* zero *automata are closed under composition, combination and include the child number transducers, transducers induced by Mealy machines, and the characteristic transducers of all languages definable in* TMSO.

Proof sketch. For composition, the automaton guesses the intermediate result, and checks both underlying transducers in parallel, using the Intersection Lemma. Combination also uses intersection. For the child-number transducers, Mealy machines and characteristic transducers of languages definable in TMSO, one observes that their corresponding languages are definable in MSO, and zero automata generalise nondeterministic parity tree automata. ◀

By Theorem 14 and the above lemma, in order to prove Theorem 8 it suffices to show that zero automata recognise the characteristic transducers of the languages of the form Z_n as used in Theorem 14. By unraveling the definitions, we need to show the following lemma.

▶ **Lemma 16.** *For every* $n \in \mathbb{N}$ *there is a* zero *automaton recognising the set of trees*

$$t \otimes s \qquad \text{with } t \in \mathsf{trees}\{1,\dots,n,\bot\},\ s \in \mathsf{trees}2$$

such that for every node x*, its label in* s *is* 1 *iff* Z_n *contains the subtree of* t *rooted in* x*.*

Proof. Let L be the language in the statement of the lemma. For a tree $t \otimes s$, define a $\bot$-factor to be a maximal factor contained in the domain of the tree that does not use label $\bot$ in t. It is not difficult to see that $t \otimes s$ belongs to L if and only if: (a) every node with label $\bot$ in t has label 1 in s; and (b) every $\bot$-factor belongs to L. Condition (a) can be easily checked by a parity automaton, so thanks to the Intersection Lemma it suffices to produce a zero automaton which checks (b). By the Factorisation Lemma, it suffices to find a zero automaton which tests memberhip in L for individual $\bot$-factors.

Summing up, we can assume without loss of generality that t does not use label $\bot$ at all. Therefore, in the rest of the proof, we show a zero automaton which recognises the language L restricted to the case where $t \in \{1,\dots,n\}$.

For $i \in \{1, \ldots, n\}$, consider the function

$$f_i : \mathsf{trees}\{1, \ldots, n\} \to \mathsf{trees}\{1, 2, 3\} \qquad \text{label of } x \text{ in } f_i(t) = \begin{cases} 1 & \text{if label of } x \text{ in } t \text{ is } < i \\ 2 & \text{if label of } x \text{ in } t \text{ is } = i \\ 3 & \text{if label of } x \text{ in } t \text{ is } > i \end{cases}.$$

We will only use this function for even i. For $t \in \mathsf{trees}\{1, \ldots, n\}$, define nonzero$(t)$ to be the set of nodes in t whose subtree does not belong to Z_n. In terms of this definition, a tree $t \otimes s$ belongs to L if and only if nonzero(t) is exactly the nodes that have label 0 in s. Also, condition 4 from Definition 7 says that there is a zero automaton recognising the language

$$\mathsf{N} \stackrel{\text{def}}{=} \{t \in \mathsf{trees}\{1, 2, 3\} : \text{nonzero}(t) \text{ is all nodes of } t\}$$

▶ **Claim 17.** *Let $t \in \mathsf{trees}\{1, \ldots, n\}$ and $s \in \mathsf{trees2}$ be trees with the same domain. Then $t \otimes s \in L$ if and only if one can find an ancestor closed set of nodes $\{X_i\}_i$, with i ranging over even numbers in $\{1, \ldots, n\}$, such that the following conditions hold:*

1. *a node has label 0 in s if and only if it belongs to some X_i;*
2. *for every even $i \in \{1, \ldots, n\}$, restricting $f_i(t)$ to the nodes from X_i yields a tree in N;*
3. $\mathsf{zero} \ni \{\pi \in \mathsf{paths}\, t : \pi$ *has even t-maxinf and sees 0 finitely often in s*$\}$

Before proving the claim, let us observe how it implies the lemma. Since a zero automaton can nondeterministically guess the sets X_i, it suffices to show that there is a zero automaton which checks conditions 1, 2, 3 in the claim. By the Intersection Lemma, it suffices to check each condition individually. Condition 1 is definable in MSO. Condition 2, for any fixed i, follows from the assumption that N is recognised by a zero automaton and the Factorisation Lemma. For condition 3, it is straightforward to construct a zero automaton – it essentially copies the labels from t into its states, except that nodes with label 0 in s trigger a state which is maximal in the total order. It remains to prove the claim.

Proof. We begin with the following observation, which follows from the assumption that zero satisfies conditions 1-3 in Definition 7. For every $t \in \mathsf{trees}\{1, \ldots, n\}$, the set nonzero$(t)$ is closed under ancestors and a node x belongs to nonzero(t) if and only if

$$\mathsf{zero} \not\ni \{\pi \in \mathsf{paths}\, t : \begin{cases} \pi \text{ is contained in nonzero}(t), \text{ and} \\ \pi \text{ passes through } x, \text{ and} \\ \pi \text{ has even } t\text{-maxinf} \end{cases} \} \tag{1}$$

By definition of the tree transducers f_i, a path has even t-maxinf if and only if it has even $f_i(t)$-maxinf for some even i. Therefore, by closure of zero under countable – and therefore also finite – unions, we see that

$$\text{nonzero}(t) = \bigcup_i \text{nonzero}(f_i(t)), \tag{2}$$

where i ranges over even numbers in $\{1, \ldots, n\}$.

Let us now prove the claim.

Let us begin with the bottom-up implication. From condition 2 it follows that every node in X_i belongs to nonzero(t). From condition 1 it follows that all nodes with label 0 are in nonzero(t). From condition 1, it follows that the set of nodes with label 0 in s is closed under ancestors. Therefore, condition 3 implies that for every node with label 1 in s is outside

nonzero(t). Thus nonzero(t) is exactly the nodes which have label 0 in s, which means that $t \otimes s \in L$.

Consider the top-down implication. Our assumption is that nonzero(t) is exactly the nodes which have label 0 in s. Define X_i to be nonzero($f_i(t)$). By (2), we see that condition 1 in the statement of the claim holds. From (1) applied to the trees $f_i(t)$, we get condition 2. To prove condition 3, by definition of nonzero(t) and prefix independence of zero, we know that every node $x \notin$ nonzero(t) satisfies

$$\mathsf{zero} \ni \{\pi \in \mathsf{paths}\, t : \pi \text{ passes through } x \text{ and has even } t\text{-maxinf}\}$$

Since nonzero(t) is ancestor closed, it follows that a path passes through some $x \notin$ nonzero(t) if and only if it sees 0 in s finitely often. Therefore, by closure of zero under countable unions, we get condition 3 in the statement of the claim. ◀
◀

8 Conclusion

We have proved that, under certain conditions on zero, every formula of the logic TMSO+zero is recognised by a zero automaton. Therefore, in order to decide satisfiability of TMSO+zero, it suffices to decide emptiness for zero automata. Unlike the logic, zero automata involve no nesting, which makes the emptiness check easier. A planned followup paper will show that emptiness is indeed decidable for zero automata, assuming that zero is the sets of probability zero.

Apart from the emptiness question for zero automata, the main open problem is decidability for the full logic MSO+zero, and not just the thin variant considered in this paper. It is not at all clear if zero automata are closed under complement, and therefore it is quite possible that zero automata are not the right model for MSO+zero. There is another logic, which sits between TMSO+zero and MSO+zero, and which might still admit a translation to zero automata. In this intermediate logic, the condition on sets $X \subseteq 2^*$ is relaxed: instead of thin sets, we consider sets which satisfy $\bar{X} \in$ zero. We leave open the question whether this intermediate logic admits a translation to zero automata.

Acknowledgment. I would like to thank Henryk Michalewski and Matteo Mio for introducing me into this area, and for their many valuable comments and suggestions.

Abstract

The piecewise testable separability problem asks, given two input languages, whether there exists a piecewise testable language that contains the first input language and is disjoint from the second. We prove a general characterisation of piecewise testable separability on languages in a well-quasi-order, in terms of ideals of the ordering. This subsumes the known characterisations in the case of finite words. In the case of finite ranked trees ordered by homeomorphic embedding, we show using effective representations for tree ideals that it entails the decidability of piecewise testable separability when the input languages are regular. A final byproduct is a new proof of the decidability of whether an input regular language of ranked trees is piecewise testable, which was first shown in the unranked case by Bojańczyk, Segoufin, and Straubing [Log. Meth. in Comput. Sci., 8(3:26), 2012].

1 Introduction

The *separability* problem for a class $\mathcal{C}$ of input languages and a class $\mathcal{S}$ of separators, asks given two input languages L and L' from $\mathcal{C}$ whether there exists a language S from $\mathcal{S}$ such that $L \subseteq S$ and $S \cap L' = \emptyset$. This classical problem has been studied in formal language theory since the 70's [27], but has sparked renewed interest due in particular to its connection with the *definability* problem: given L from $\mathcal{C}$, does L belong to $\mathcal{S}$? When $\mathcal{C}$ is effectively closed under complement, this last question reduces to the separability of L and of its complement. Separability thus generalises definability, and has been instrumental in the recent advances on the definability problem for the alternation hierarchy over finite words [25].

We focus in this paper on the class of *piecewise testable* languages as class $\mathcal{S}$ of separators. Over finite words, this coincides with the languages defined by $\mathcal{B}\Sigma_1(<)$, the Boolean combinations of existential first-order sentences with order, and is one of the oldest and best-known classes of languages with decidable definability: Simon [26] showed that a language is piecewise-testable if and only if its syntactic monoid is $\mathcal{J}$*-trivial*. Lately, this has been extended in two different directions:

- Over finite unranked ordered trees, Bojańczyk, Segoufin, and Straubing [6] generalise Simon's algebraic approach and characterise the syntactic forest algebræ of piecewise

testable tree languages defined by the most common signatures. This yields the decidability of the piecewise testable definability problem for regular unranked tree languages.

- Over finite words, Almeida and Zeitoun [2, 3] first proved the decidability of the PTL separability problem for regular input languages, based on a topological characterisation of separability. This abstract characterisation has been turned into a much more efficient characterisation in terms of patterns found simultaneously in L and L' [24, 11], which culminated in the work of Czerwiński, Martens, van Rooijen, Zeitoun, and Zetzsche [12] with a proof of the decidability of piecewise separability for many classes $\mathcal{C}$ of input languages, which even includes higher-order languages [17, 8, 4]. The crux of this proof is a reduction to the computation of representations for downward-closures [30] ordered by scattered subword embedding.

Separability for Tree Languages. Considering these two lines of research side by side begs the question whether piecewise testable separability might be decidable over richer structures than words, and in particular over trees. In this paper, we answer positively by proving:

▶ **Theorem 1.** *Piecewise testable separability is decidable for regular languages of ranked trees ordered by homeomorphic embedding.*

Since the class of regular tree languages is effectively closed under complement, Theorem 1 entails as a sub-problem the decidability of the corresponding definability problem:

▶ **Corollary 2.** *Piecewise testable definability is decidable for regular languages of ranked trees ordered by homeomorphic embedding.*

Thus, apart from the restriction to ranked trees, Theorem 1 also yields as a byproduct a new proof of decidability for the piecewise testable definability problem studied by Bojańczyk et al. [6], in the most challenging case of homeomorphic embeddings.

Order-Theoretic Framework. We employ vastly different techniques from Bojańczyk et al.'s, and Theorem 1 should be thought of as a proof of concept for our main contribution, which is a very general order-theoretic framework for piecewise testable separability:

- We characterise in Section 3 separability by piecewise testable languages over any combinatorial *well-quasi-order*; this encompasses for instance words ordered by scattered subword embedding and trees ordered by homeomorphic embedding or minor ordering. Our characterisation proceeds similarly to the topological characterisation of Almeida [2] by comparing the closures of L and L', but is stated in purely order-theoretic terms and compares the *ideals* – i.e. the irreducible downwards-closed sets – adherent to L and L'. The advantage of this approach is that it scales to more complex structures than words – we have a toolkit of effective ideal representations at our disposal [13, 15] – and leads to a very simple and general proof, that delegates syntactic manipulations to the ideal representation. Our techniques encompass the word case: e.g. the patterns derived by Czerwiński et al. [12] turn out to be representations for word ideals [19, 1], and we eschew the technical work on patterns that absorbed a large part of Czerwiński et al.'s proof.
- We then show in Section 4 how to turn our characterisation into a generic decision procedure, by reduction to the *adherence membership* problem for the class $\mathcal{C}$. Provided we have effective representations for ideals, this yields directly the decidability for regular tree languages. We also derive the reduction of Czerwiński et al. to the computation of downward-closures in full generality.

- In order to instantiate this framework for tree languages, we provide in Section 5 our last ingredient: an effective representation for ideals of ranked trees ordered by homeomorphic embedding. This is a contribution of independent interest, which fixes an issue with the representation proposed in [13].

We start in Section 2 by defining piecewise testable languages in the general setting of combinatorial quasi-orders, and by recalling their logical characterisation. We assume the reader is already familiar with tree languages; see [9] for a general reference.

2 Piecewise Testable Languages

We work in the first part of this paper with *combinatorial* classes X of elements, where X is a countable set equipped with a *size* function $|.|: X \to \mathbb{N}$ such that $X_{\leq n} \stackrel{\text{def}}{=} \{x \in X \mid |x| \leq n\}$ is finite for every n. As soon as we equip X with a quasi-ordering $\leq$, we can define a notion of piecewise-testable languages (see Section 2.1). The usual setting for piecewise testable languages is however that of classes of finite structures along with the embedding relation, in which case those sets also enjoy a logical characterisation (see Section 2.2).

2.1 Pieces

Two elements x and y are *n-piecewise equivalent*, noted $x \equiv_n y$, if for every $z \in X_{\leq n}$, $z \leq x$ if and only if $z \leq y$. A subset S of X is called *n-piecewise testable* (an n-PTL) over $(X, \leq)$ if S is a union of n-piecewise equivalence classes. A subset S of X is *piecewise testable* (a PTL) if it is an n-PTL for some $n \geq 0$. This is well-known to be equivalent to the following formulation:

▶ **Fact 3.** *S is an n-PTL over $(X, \leq)$ if and only if S is a finite Boolean combination of* principal filters $\uparrow x \stackrel{\text{def}}{=} \{x' \in X \mid x \leq x'\}$ *where $x \in X_{\leq n}$.*

2.2 Logical Characterisation

Although the choice of the particular quasi-order $(X, \leq)$ is irrelevant to Fact 3 and the treatment in Section 3, one normally chooses X to be a class $\mathcal{K}$ of finite structures over some signature σ and $\leq$ to be the *induced substructure* ordering, which we denote by '$\sqsubseteq$'. When $(\mathcal{K}, \sqsubseteq)$ is a *well-quasi-order*, this leads to a well-known logical characterisation in terms of the Boolean closure of existential first-order formulæ– one of the chief motivations for studying piecewise testable languages. Other orderings may lead to different logical characterisations, or have no logical characterisation.

2.2.1 Finite Structures

We consider finite relational structures $\mathfrak{M} = \langle M, (R_i)_{i \in I} \rangle$ over a finite signature $\sigma = (R_i)_{i \in I}$ (we conflate the names of relations in σ with their interpretations in $\mathfrak{M}$). The finite set M is the (potentially empty) domain of $\mathfrak{M}$ and each relation $R_i \subseteq M^{r_i}$ has a prescribed arity $r_i > 0$. The size $|\mathfrak{M}|$ of $\mathfrak{M}$ is the cardinality of its domain. A class $\mathcal{K}$ of structures is a set of such finite structures sharing the same signature σ and closed under isomorphism.

▶ **Example 4** (Finite Words)**.** Let Σ be a finite alphabet; we write Σ^* for the set of finite words over Σ. Such a word w can be seen as a relational structure over $\sigma_s \stackrel{\text{def}}{=} ((P_a)_{a \in \Sigma}, <)$ with its set of positions $\{1, \ldots, |w|\}$ as domain (where $|w|$ denotes the length of w, and thus coincides with its size), and $P_a(x)$ for $x \in \{1, \ldots, |w|\}$ holds if and only if the xth symbol of w is $a \in \Sigma$, while $x < y$ has the obvious interpretation.

▶ **Example 5** (Ranked Trees). Fix a finite ranked alphabet $\mathcal{F}$, where each symbol f is mapped to a single rank $r(f) \geq 0$, and write $\mathcal{F}_r$ for the subset of $\mathcal{F}$ with rank r. A (finite, ranked, ordered) tree is defined inductively as a term $f(t_1, \ldots, t_r)$ where $f \in \mathcal{F}_r$ and $t_1, \ldots, t_r$ are trees (see e.g. [9]). The notions of node, child, parent, descendant, and ancestor relations between nodes of a tree are defined as usual. We denote by $T(\mathcal{F})$ the set of trees over $\mathcal{F}$.

A tree can be seen as a structure with its set of nodes as domain – note that this domain is never empty by definition –; several signatures are then pertinent (see [6] and the full paper). We shall focus on the signature $\sigma_T \stackrel{\text{def}}{=} ((P_f)_{f \in \mathcal{F}}, <, <_{\text{dfs}}, \sqcap)$ where, for all nodes x, y,

- $P_f(x)$ holds whenever x is labelled by f,
- $x < y$ whenever x is an ancestor of y,
- $x <_{\text{dfs}} y$ whenever x is visited before y in a depth-first, left-first traversal of the tree – this is known as the *document order* –, and
- $z = x \sqcap y$ whenever z is the *least* common ancestor of x and y, i.e. z is the unique descendant of all the nodes which are ancestors of both x and y.

Embeddings. Recall that $\mathfrak{A} \sqsubseteq \mathfrak{B}$ holds between two structures $\mathfrak{A}$ and $\mathfrak{B}$ if and only if there exists an *embedding* from $\mathfrak{A}$ to $\mathfrak{B}$, i.e. an injective mapping e from A to B that preserves the relations: for all $i \in I$ and $a_1, \ldots, a_{r_i} \in A$, $(a_1, \ldots, a_{r_i}) \in R_i$ in $\mathfrak{A}$ if and only if $(e(a_1), \ldots, e(a_{r_i})) \in R_i$ in $\mathfrak{B}$. As $\sqsubseteq$ is transitive and reflexive, $(\mathcal{K}, \sqsubseteq)$ is a *quasi-order* (a qo).

Well-Quasi-Orders. Given a qo $(X, \leq)$ and a subset $S \subseteq X$, the *downward-closure* of S is $\downarrow S \stackrel{\text{def}}{=} \{x \in X \mid \exists s \in S \,.\, x \leq s\}$. A subset $D \subseteq X$ is *downwards-closed* if $D = \downarrow D$; when D is a singleton $\{x\}$ we write more succinctly $\downarrow x$. The notions of *upward-closure* and *upwards-closed* subsets are defined similarly.

A qo $(X, \leq)$ is a *well-quasi-order* (wqo) if in every infinite sequence $x_0, x_1, \ldots$ of elements of X, one can find an infinite sequence of indices $i_0 < i_1 < \cdots$ such that $x_{i_0} \leq x_{i_1} \leq \cdots$ [18, 20]. Equivalently, $(X, \leq)$ is well-founded (there are no infinite descending sequences $x_0 > x_1 > \cdots$) and satisfies the *finite antichain condition* (FAC), i.e. all its antichains are finite. Still equivalently, $(X, \leq)$ has the *descending chain condition*: there are no infinite descending sequences $D_0 \supsetneq D_1 \supsetneq \cdots$ of downwards-closed subsets $D_i \subseteq X$. For instance, any finite set ordered by equality is a wqo by the Pigeonhole Principle. As another example, if $(X, \leq_X)$ and $(Y, \leq_Y)$ are two wqos, then by Dickson's Lemma, their Cartesian product $X \times Y$ is well-quasi-ordered by the *product ordering* defined by $(x, y) \leq (x', y')$ if and only if $x \leq_X x'$ and $y \leq_Y y'$.

▶ **Example 6** (Scattered Subword Embedding). The signature σ_s of Example 4 for finite words in Σ^* gives rise to an embedding relation $\sqsubseteq_s$ known as the (scattered) *subword embedding*: $u \sqsubseteq_s v$ if and only if $u = a_1 \cdots a_m$ and $v = v_0 a_1 v_1 \cdots v_{m-1} a_m v_m$ for some $a_1, \ldots, a_m \in \Sigma$ and $v_0, \ldots, v_m \in \Sigma^*$.

By Higman's Lemma [18], the subword embedding relation $\sqsubseteq_s$ well-quasi-orders Σ^*.

▶ **Example 7** (Homeomorphic Tree Embedding). Using the signature σ_T of Example 5 for trees in $T(\mathcal{F})$, the ordering $t \sqsubseteq_T t'$ is better known as the *homeomorphic tree embedding* relation, and holds for $t = f(t_1, \ldots, t_r)$ and $t' = g(t'_1, \ldots, t'_s)$ if and only if

- there exists $1 \leq i \leq s$ such that $t \sqsubseteq_T t'_i$, or
- $f = g$ (and thus $r = s$) and for every $1 \leq i \leq r$, $t_i \sqsubseteq_T t'_i$;

see the full paper for a proof of this folklore result. Note that $(\Sigma^*, \sqsubseteq_s)$ is isomorphic to $(T(\mathcal{F}_\Sigma), \sqsubseteq_T)$ where $\mathcal{F}_\Sigma \stackrel{\text{def}}{=} \Sigma \uplus \{\$\}$ assigns rank 1 to letters in Σ and rank 0 to \$, so our results on ranked trees properly generalise the case of finite words.

As first shown by Higman [18], the homeomorphic tree embedding relation $\sqsubseteq_T$ similarly well-quasi-orders $T(\mathcal{F})$, and Kruskal's Tree Theorem [20] shows that this generalises to unranked trees.

Existential First-Order Logic. Consider first-order logic over the signature σ, and a class of structures $\mathcal{K}$ over σ. Given a sentence φ, the set of structures $\mathfrak{M} \in \mathcal{K}$ such that $\mathfrak{M} \models \varphi$ is called the (first-order) *language* of φ. It is well-known that *existential sentences* in $\Sigma_1(\sigma)$ define *upwards-closed* first-order languages S with respect to embeddings, i.e. such that $S = \uparrow S \stackrel{\text{def}}{=} \{\mathfrak{M}' \in \mathcal{K} \mid \exists \mathfrak{M} \in S . \mathfrak{M} \sqsubseteq \mathfrak{M}'\}$; however the converse does not necessarily hold [28].

We are interested here in the Boolean closure $\mathcal{B}\Sigma_1(\sigma)$ of $\Sigma_1(\sigma)$:

▶ **Fact 8.** *If a set S is an n-PTL over $(\mathcal{K}, \sqsubseteq)$, then it is definable by a sentence in $\mathcal{B}\Sigma_1(\sigma)$ with at most n variables. Conversely, assuming additionally that $(\mathcal{K}, \sqsubseteq)$ is a wqo, if S is definable by a sentence in $\mathcal{B}\Sigma_1(\sigma)$, then it is a PTL over $(\mathcal{K}, \sqsubseteq)$.*

3 Ideal Characterisation of PTL Separability

A set $S \subseteq X$ *separates* $L \subseteq X$ from $L' \subseteq X$ if $L \subseteq S$ and $S \cap L' = \emptyset$. This can be turned into a decision problem when restricting L and L' to a class $\mathcal{C} \subseteq 2^X$ of finitely representable sets:

▶ **Problem** (PTL separability for $\mathcal{C}$ over $(X, \leq)$).
Input: *Representations of L and L' from $\mathcal{C}$*
Question: *Are L and L'* PTL separable*, i.e. does there exist S a PTL over $(X, \leq)$ that separates L from L'?*

Throughout this section, we assume that $(X, \leq)$ is a well-quasi-order. Under this assumption, we establish in Section 3.2 a characterisation of PTL separability in terms of *ideals* of $(X, \leq)$ (whose definition we recall in Section 3.1). This yields a generic framework in which the decidability of PTL separability can be tackled, which we present in Sections 4 and 5 and instantiate for the case of $(T(\mathcal{F}), \sqsubseteq_T)$ the set of ranked trees together with homeomorphic embeddings against the class $\mathcal{C} = \mathrm{Reg}(T(\mathcal{F}))$ of regular tree languages.

3.1 Ideals

An *ideal* of a qo $(X, \leq)$ is a downwards-closed and (up-)*directed* subset $I \subseteq X$, where this last condition ensures that I is non-empty and that, given any $x \in I$ and $y \in I$, there exists $z \in I$ with $x \leq z$ and $y \leq z$. A related notion is the following. A downwards-closed subset D of $(X, \leq)$ is *irreducible* if and only if it is non-empty, and for any two downwards-closed subsets D_1, D_2 such that $D \subseteq D_1 \cup D_2$, D is contained in D_1 or in D_2 already; equivalently, D is non-empty and cannot be written as the union of two proper, downwards-closed subsets.

▶ **Fact 9** (cf. Lemma 1 in [7]). *The following are equivalent for a downwards-closed subset D of a quasi-ordered set: (a) D is an ideal; (b) D is directed; (c) D is irreducible.*

We write $\mathrm{Idl}(X)$ for the set of ideals of X. Ideals are especially useful when $(X, \leq)$ is a wqo: for one thing, when X is countable, $\mathrm{Idl}(X)$ is then also countable [7, Theorem 1], and furthermore any downwards-closed subset has a decomposition as a finite union of ideals:

▶ **Fact 10** (cf. Lemma 2 in [7]). *A qo is FAC if and only if every downwards-closed subset is a finite union of ideals.*

3.2 Characterising Separability

Over any qo $(X, \leq)$, the case where L and L' are not PTL separable has a well-known characterisation in terms of sequences of indistinguishable witnesses, which is a straightforward consequence of the definitions:

▶ **Lemma 11.** *L and L' are* not *PTL separable over a qo $(X, \leq)$ if and only if there exist two sequences of elements $(x_n)_{n\in\mathbb{N}}$ in L and $(x'_n)_{n\in\mathbb{N}}$ in L' such that for every n, $x_n \equiv_n x'_n$.*

Proof Idea. It suffices to observe that L and L' are not n-PTL separable if and only if there exist $x_n \in L$ and $x'_n \in L'$ such that $x_n \equiv_n x'_n$. See the full paper for a detailed proof. ◀

When $(X, \leq)$ is a wqo, we have another characterisation in terms of directed subsets of L and L' defining the same ideal. The fact that $(X, \leq)$ is wqo is needed in order for Lemma 12 to hold: otherwise, the full paper presents a counter-example for the *subtree ordering* over $T(\mathcal{F})$.

▶ **Lemma 12** (Key Lemma)**.** *L and L' are not PTL separable over a wqo $(X, \leq)$ if and only if there exist two directed sets $\Delta \subseteq L$ and $\Delta' \subseteq L'$ such that $\downarrow\Delta = \downarrow\Delta'$.*

Proof of 'if'. Let $\Delta \subseteq L$ and $\Delta' \subseteq L'$ be two directed sets with $\downarrow\Delta = \downarrow\Delta'$. Let us show that for every $n \in \mathbb{N}$, there exist $x_n \in L$ and $x'_n \in L'$ such that $x_n \equiv_n x'_n$, from which Lemma 11 yields the result. Write I for the ideal $\downarrow\Delta = \downarrow\Delta'$. Observe that, for every $n \in \mathbb{N}$, $I \cap X_{\leq n}$ is finite since X is a combinatorial class. Furthermore, for every $z \in I \cap X_{\leq n}$, by definition of I there exist $x_z \in \Delta$ with $z \leq x_z$ and $x'_z \in \Delta'$ with $z \leq x'_z$. Since Δ and Δ' are directed, we can find $x_n \in \Delta$ and $x'_n \in \Delta'$ greater or equal to all those finitely many x_z and x'_z when z ranges over $I \cap X_{\leq n}$ (if $I \cap X_{\leq n} = \emptyset$ then any $x_n \in \Delta$ and $x'_n \in \Delta'$ fit). Then $x_n \equiv_n x'_n$, since for any $z \in X_{\leq n}$, either $z \in I$ and then both $z \leq x_z \leq x_n$ and $z \leq x'_z \leq x'_n$, or $z \notin I$ and then both $z \not\leq x_n$ and $z \not\leq x'_n$ since I is downwards-closed. ◀

Proof of 'only if'. Assume L and L' are not PTL separable, hence by Lemma 11 there exist two infinite sequences $(x_n)_n$ in L and $(x'_n)_n$ in L' with $x_n \equiv_n x'_n$ for every n.

Let us consider the infinite sequence of *pairs* $(x_n, x'_n)_{n\in\mathbb{N}}$. By Dickson's Lemma, $X \times X$ is a wqo for the product ordering, hence there exists an infinite sequence of indices $i_0 < i_1 < \cdots$ such that $x_{i_j} \leq x_{i_{j+1}}$ and $x'_{i_j} \leq x'_{i_{j+1}}$ for every $j \in \mathbb{N}$. Define $\Delta \stackrel{\text{def}}{=} \{x_{i_j} \mid j \in \mathbb{N}\}$ and $\Delta' \stackrel{\text{def}}{=} \{x'_{i_j} \mid j \in \mathbb{N}\}$. These two sets are directed; they are actually infinite chains $x_{i_0} \leq x_{i_1} \leq \cdots$ and $x'_{i_0} \leq x'_{i_1} \leq \cdots$.

It remains to show that $\downarrow\Delta = \downarrow\Delta'$. By symmetry, it suffices to show $\Delta \subseteq \downarrow\Delta'$. Consider some $x_{i_j} \in \Delta$; then there exists some index $i_k > \max(i_j, |x_{i_j}|)$. Hence $x_{i_j} \leq x_{i_k}$, and since $x_{i_k} \equiv_{i_k} x'_{i_k}$, $x_{i_j} \leq x'_{i_k}$ and thus $x_{i_j} \in \downarrow\Delta'$. ◀

Related Work over Finite Words. Let S be a subset of X. We define the *adherence* of S as the set of ideals defined by the directed subsets of S:

$$\mathrm{Adh}(S) \stackrel{\text{def}}{=} \{\downarrow\Delta \in \mathrm{Idl}(X) \mid \Delta \subseteq S \text{ is directed } \}\,. \tag{1}$$

Lemma 12 can be restated as saying that L and L' are PTL separable if and only if their adherences are disjoint, i.e. $\mathrm{Adh}(L) \cap \mathrm{Adh}(L') = \emptyset$. This makes Lemma 12 quite reminiscent of several results on separability for word languages over Σ^*. Almeida [2] showed that two regular languages over Σ are PTL separable over $(\Sigma^*, \sqsubseteq_s)$ if and only if their topological closures inside a specific profinite semigroup do not intersect. This lead to a first decision procedure [3] by explicitly constructing representations for these topological closures and

testing their intersection for emptiness – the counterpart in terms of Lemma 12 would be to compute the adherences of L and L'.

Major improvements were brought by Place et al. [24] and Czerwiński et al. [11] and culminate in Theorem 2.1 of [12], by reducing this non-empty intersection check to identifying a common pattern 'densely' matched by both L and L'. It turns out that these patterns are essentially finite representations for ideals of $(\Sigma^*, \sqsubseteq_s)$, so Lemma 12 subsumes Theorem 2.1 of Czerwiński et al. [12] – and has a considerably simpler proof.

4 Deciding PTL Separability

While Lemma 12 provides a general characterisation for PTL separability, turning it into a decision procedure requires finite representations and effectiveness assumptions on its various ingredients. We define a set of such assumptions in Section 4.1, which is sufficient to derive a generic algorithm. We describe the latter in two steps: we first show in Section 4.2 a reduction to the *adherence membership problem*. The final step in Section 4.3 is to show that this last problem is decidable for the set of regular tree languages over $(T(\mathcal{F}), \sqsubseteq_T)$.

4.1 Effectiveness Assumptions

In order to put Lemma 12 into practice, we need to consider in more details how we are going to represent PTLs over $(X, \leq)$, ideals in $\mathrm{Idl}(X)$, and languages in $\mathcal{C}$.

PTLs. Fact 3 provides a natural representation for PTLs as finite Boolean combinations of principal filters, i.e. more concretely as terms of the free Boolean algebra with elements of X as atoms.

Ideals. Recall that over a countable wqo $(X, \leq)$, $\mathrm{Idl}(X)$ is also countable [7]. In Section 4.2, we only need to have explicit *ideal representations* as a means of enumerating ideals, while Corollary 15 further needs a means of computing representations as regular tree languages. Section 5 fulfils both requirements by providing ideal representations for $(T(\mathcal{F}), \sqsubseteq_T)$ as regular tree expressions.

Languages. Our last effectiveness assumptions regard the class of languages $\mathcal{C}$. We call $\mathcal{C}$ *PTL-effective* over a qo $(X, \leq)$ if $\mathcal{C}$ has *decidable emptiness*: given a representation for $L \in \mathcal{C}$, there is an algorithm that decides whether $L = \emptyset$, and if $\mathcal{C}$ is *effectively closed under intersection with PTLs*: given a representation for $L \in \mathcal{C}$ and one for S a PTL over $(X, \leq)$, there is an algorithm that constructs a representation for $L \cap S$ in $\mathcal{C}$.

For instance, both over $(\Sigma^*, \sqsubseteq_s)$ and over $(T(\mathcal{F}), \sqsubseteq_T)$, a principal filter $\uparrow x$ is a regular language, and since regular languages are closed under Boolean operations by Fact 3 any PTL is regular. Thus, PTL-effective classes of word and tree languages abound, starting with regular languages themselves, but also context-free, etc.

4.2 Reducing to Adherence Membership

We describe our decision procedure in two steps. The first one reduces the PTL separability problem for a PTL-effective class $\mathcal{C}$ to the following problem:

▶ **Problem** (Adherence Membership for $\mathcal{C}$ over $(X, \leq)$).
Input: *A representation for* $L \in \mathcal{C}$ *and one for* $I \in \mathrm{Idl}(X)$.
Question: *Is* $I \in \mathrm{Adh}(L)$*?*

▶ **Proposition 13.** *Let $(X, \leq)$ be a wqo with ideal representations and $\mathcal{C} \subseteq 2^X$ be PTL-effective over $(X, \leq)$. Then there is a Turing reduction from the PTL separability problem to the adherence membership problem.*

Proof. Given an oracle for the adherence membership problem for $\mathcal{C}$ over $(X, \leq)$, our algorithm consists of two semi-decision procedures that take representations for $L \in \mathcal{C}$ and $L' \in \mathcal{C}$ as input. The first attempts to show that L and L' are PTL separable, and enumerates representations of PTLs S until $L \cap (X \setminus S) = \emptyset$ and $L' \cap S = \emptyset$. This is possible because $\mathcal{C}$ is PTL-effective and complementing a PTL representation is trivial. The second relies on Lemma 12 and attempts to show that L and L' are not PTL separable by enumerating representations of ideals I until $I \in \mathrm{Adh}(L)$ and $I \in \mathrm{Adh}(L')$, using the oracle for adherence membership for the tests. ◀

4.3 Deciding Adherence Membership

Regular Languages. In the case of regular tree languages over $T(\mathcal{F})$, the adherence membership problem is decidable thanks to the following lemma:

▶ **Lemma 14.** *Let $(X, \leq)$ be a qo and $L \subseteq X$. Then $I \in \mathrm{Adh}(L)$ if and only if $I \subseteq {\downarrow}(I \cap L)$.*

Proof. The 'only if' part is immediate or the 'if' part we show that $I \cap L$ is directed. Since I is non-empty and included in ${\downarrow}(I \cap L)$, $I \cap L$ is also non-empty. Furthermore, if x, y are in $I \cap L$, then since I is directed there exists $z \in I$ such that $x \leq z$ and $y \leq z$, and since $I \subseteq {\downarrow}(I \cap L)$ there exists $z' \in I \cap L$ such that $z \leq z'$. ◀

Now, if L is a regular tree language, I is also effectively regular using the ideal representations from Section 5, and so are $I \cap L$ and ${\downarrow}(I \cap L)$, hence $I \subseteq {\downarrow}(I \cap L)$ is decidable since inclusion of regular tree languages is decidable, proving Theorem 1:

▶ **Corollary 15.** *Adherence membership is decidable for regular tree languages over $(T(\mathcal{F}), \sqsubseteq_T)$.*

Generic Approach. Let us finally generalise the previous idea. Our issue is that, for instance when $\mathcal{C}$ is the class of context-free languages over Σ^*, while I is a regular language and ${\downarrow}(I \cap L)$ is a computable context-free language, the inclusion test between a regular language and a context-free one is in general undecidable. Thankfully, ${\downarrow}(I \cap L)$ is regular for arbitrary languages L by Fact 10, since it is a finite union of ideals and ideals are regular. However, the issue is then to compute a representation of ${\downarrow}(I \cap L)$ *as a regular language*, or more generally to solve the following problem:

▶ **Problem** (Ideal Decomposition for $\mathcal{C}$ over $(X, \leq)$)**.**
Input: *A representation for $L \in \mathcal{C}$*
Output: ${\downarrow}L$ *as a finite union of representations of ideals in* $\mathrm{Idl}(X)$.

The following result requires effective operations on ideal representations. We refer the reader to [13, 15] for a systematic study of algorithms on finite ideal representations for wqos; here we use the notion of *effective* ideal representations as defined by Goubault-Larrecq et al. [15] to prove (see the full paper):

▶ **Proposition 16.** *Let $(X, \leq)$ be a wqo with effective ideal representations and $\mathcal{C} \subseteq 2^X$ be PTL-effective over $(X, \leq)$. Then the adherence membership problem and the ideal decomposition problem are Turing-equivalent.*

The seemingly innocuous hypothesis that $\mathcal{C}$ is PTL-effective is actually crucial: Theorem V.2 and Theorem VIII.1 in [22] provide an instance of undecidable adherence membership but computable ideal decompositions over a wqo with effective ideal representations; in these results, $\mathcal{C}$ is the set of run structures between two configurations of a vector addition system, and has decidable emptiness but lacks effective closure under intersection with PTLs.

Related Work over Finite Words. Propositions 13 and 16 together show that PTL separability reduces to the computation of ideal decompositions for downward-closures over any wqo with effective ideal representations. This includes as a special case $(\Sigma^*, \sqsubseteq_s)$ using the representations in [19, 1], and since ideal decompositions of downward-closures are computable for many classes of PTL-effective word languages [30] – including context-free languages [29, 10], reachability languages of vector addition systems [16], matrix languages [30], and higher-order languages [17, 8, 4] –, PTL separability is decidable for them.

In fact, propositions 13 and 16 subsume most of Theorem 2.5 of Czerwiński et al. [12], which is stated for *full trios* $\mathcal{C}$ over Σ^*, i.e. classes of languages closed under rational transductions – which are thus effectively closed under intersection with PTLs. There is a small price to pay for our level of generality, which is that their Theorem 2.5 also shows a converse reduction over $(\Sigma^*, \sqsubseteq_s)$ from the ideal decomposition problem back to the PTL separability problem. In our general setting, the best we know is that $L \stackrel{\text{def}}{=} I$ and $L' \stackrel{\text{def}}{=} X \setminus {\downarrow}(I \cap S)$ are PTL-separable if and only if $I \in \mathrm{Adh}(S)$ by Lemma 14, but this either uses the closure of $\mathcal{C}$ under complementation and downward-closure, or already uses computable ideal decompositions. The former however holds for regular languages:

▶ **Proposition 17.** *There is a many-one reduction from the adherence membership problem to the PTL separability problem for regular tree languages over* $(T(\mathcal{F}), \sqsubseteq_T)$.

5 Ideals for Ranked Trees with Homeomorphic Embedding

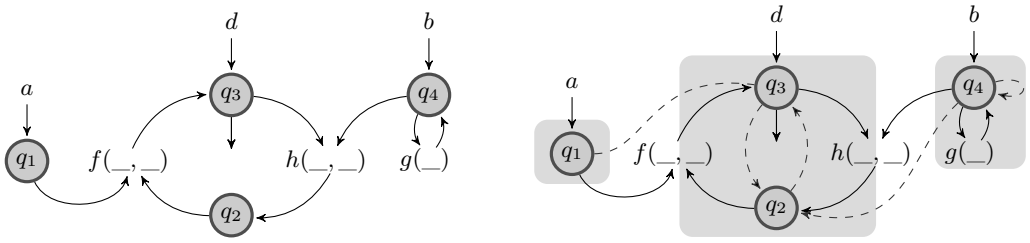
In this section, we provide finite representations for ideals of ranked trees ordered by homeomorphic embedding. These representations are expressed as tree regular expressions [9, Section 2.2]. We show in Section 5.1 that any downwards-closed subset of $T(\mathcal{F})$ can be represented as a *simple tree regular expression* (STRE), which we construct from its tree automaton. In Section 5.2, we then characterise ideals in this syntax as *tree products*, obtained as the summands of the normal form according to a rewrite system. Thanks to this particular proof strategy, the entire construction also solves the ideal decomposition problem: given a regular tree language, first build the STRE for its downward-closure, then normalise this STRE into a union of tree products representing its ideals.

Note that a concrete syntax for ranked tree ideals was proposed in [13]. However, no proof was given, and indeed the proposed tree regular expressions failed to be downwards-closed.

5.1 Simple Tree Regular Expressions

Let $L \subseteq T(\mathcal{F})$ be a downwards-closed language. Its complement is upwards-closed and has finitely many minimal elements, i.e. $T(\mathcal{F}) \setminus L = {\uparrow}\{t_1, \ldots, t_n\} = \bigcup_{1 \leq i \leq n} {\uparrow} t_i$, hence this is a regular tree language and L is also regular. Thus L is recognised by a finite (bottom-up) tree automaton $\mathcal{A}$, or equivalently by a tree regular expression [9, Section 2.2].

We shall see that $\mathcal{A}$ is equivalent to an expression of a specific shape, called a *simple tree regular expression* (STRE). We describe next a general procedure that converts any (ε-free) finite tree automaton $\mathcal{A}$ to an STRE S whose language is the downward-closure ${\downarrow} L(\mathcal{A})$ of the



(a) Initial tree automaton. **(b)** ε-strongly connected components.

Figure 1 Converting tree automata to STREs.

language recognised by $\mathcal{A}$. This procedure is best explained on an example: see Figure 1a, where there is one 0-ary transition a (from no state) to state q_1, one binary transition f from the pair of states q_1, q_2 to q_3, and so on. In textual form, we write these transitions as rewrite rules [9]: $a \to q_1$, $f(q_1, q_2) \to q_3$, $h(q_3, q_3) \to q_2$, $c \to q_3$, $g(q_4) \to q_4$, $b \to q_4$.

We first extend our automaton with ε-transitions. An ε-transition from s to s' will be drawn as a dashed arrow (see Figure 1b), and is just a rewrite rule of the new form $s \to s'$. This implies that every tree recognised at s is also recognised at s'. For each transition, say $f(s_1, s_2, \cdots, s_n) \to s$, of $\mathcal{A}$, we add n ε-transitions $s_1 \to s$, $s_2 \to s$, ..., $s_n \to s$. Call the resulting automaton $\downarrow\mathcal{A}$. It is an easy exercise to show that $L(\downarrow\mathcal{A}) = \downarrow L(\mathcal{A})$.

There is a graph underlying $\downarrow\mathcal{A}$, whose vertices are the states of $\downarrow\mathcal{A}$, and whose edges are the ε-transitions. Consider its strongly connected components, shown against a grey background in Figure 1b. Any two states in the same strongly connected component C recognise exactly the same trees, so it makes sense to talk of the language $L_C(\downarrow\mathcal{A})$ of those trees recognised at any state of C. Let $C \to C'$ if and only if $s \to s'$ for some $s \in C$, $s' \in C'$. The strict ordering $\prec \stackrel{\text{def}}{=} \to^+$ is well-founded, and we shall build an expression S_C whose language is $L_C(\downarrow\mathcal{A})$ by induction along $\prec$.

Trivial Components. If C is a trivial strongly connected component (one state s, no self-edge), then enumerate its incoming non-ε transitions $f_i(s_{i1}, s_{i2}, \cdots, s_{in_i}) \to s$, $1 \leq i \leq m$. Let S_{ij} be an expression whose language is the set of trees recognised at s_{ij}, which is given by induction hypothesis. Then $S_C \stackrel{\text{def}}{=} P_1 + \cdots + P_m$ with $P_i \stackrel{\text{def}}{=} f_i^?(S_{i1}, S_{i2}, \cdots, S_{in_i})$ is our desired expression. For instance, the set of trees recognised at the leftmost state q_1 of Figure 1b is the language of $S_1 \stackrel{\text{def}}{=} a^?$.

Here, a tree t is in the language of an expression $P = f^?(S_1, \ldots, S_n)$ (written '$t \in P$') for $f \in \mathcal{F}_n$ and expressions $S_1, \ldots, S_n$ if and only if either t is of the form $f(t_1, \cdots, t_n)$ with $t_i \in S_i$ for every i, $1 \leq i \leq n$, *or* if $t \in \bigcup_{i=1}^n S_i$; as the notation suggests, for $S = P_1 + \cdots + P_m$, $t \in S$ if and only if $t \in P_j$ for some j, $1 \leq j \leq m$.

Iterators. If C is a non-trivial strongly connected component, then enumerate the non-ε transitions $f_i(s_{i1}, s_{i2}, \cdots, s_{in_i}) \to s_i$, $1 \leq i \leq m$, whose end state s_i is in C. For each pair i, j, if s_{ij} is in C, then $S_{\Box ij} \stackrel{\text{def}}{=} \Box$ is a placeholder; otherwise, let $S_{\Box ij}$ be an expression whose language is the set of trees recognised at s_{ij}, which we obtain by induction hypothesis. Then $S_C \stackrel{\text{def}}{=} (A_1 + \cdots + A_m)^*.0$ for $A_i \stackrel{\text{def}}{=} f_i(S_{\Box i1}, S_{\Box i2}, \cdots, S_{\Box in_i})$ is a suitable expression. For example, the rightmost strongly connected component $\{q_4\}$ of Figure 1b yields the expression $S_4 \stackrel{\text{def}}{=} (b + g(\Box))^*.0$. One might have expected an expression of the more intuitive form $(g(\Box))^*.b^?$, however, as we are going to see, they define exactly the same language.

Here, 0 denotes the empty sum with empty language, and intuitively the language of an *iterator* $C^*.S$ for $C = A_1 + \cdots + A_m$ should consist of all trees obtained by repeatedly applying *contexts* from $A_1, \ldots, A_m$ – i.e. trees over the extended alphabet $\mathcal{F} \cup \{\Box\}$ where $\Box$ has arity 0 –, until one reaches a tree in S. More precisely, the language of an *atom* $A = f(S_{\Box 1}, \cdots, S_{\Box n})$ consists of those contexts in $T(\mathcal{F} \cup \{\Box\})$ of the form $f(c_1, \cdots, c_n)$ where $c_i \in S_{\Box i}$ for every i. In turn, $c \in S_\Box$ if and only if either $S_\Box = \Box$ and c is the trivial context $\Box$, or $S_\Box$ is an expression S, c is a tree t in $T(\mathcal{F})$, and $t \in S$. The language of $C = A_1 + \cdots + A_m$ is the union of the languages of A_j, $1 \leq j \leq m$. For example, $(f(\Box))^*.a^?$ will recognise all trees of the form $f^n(a)$, $n \in \mathbb{N}$. There are however two catches:

1. The first one has to do with atoms A where the placeholder $\Box$ occurs more than once: as usual with tree regular expressions, when replacing $\Box$ by a tree from S, several occurrences of $\Box$ can be replaced by *different* trees from S. Hence $(f(\Box, \Box))^*.(a^? + b^?)$ consists of all binary-branching trees with inner nodes labelled f and leaves labelled a or b, including $f(f(a, a), a)$ and $f(f(b, b), b)$ but also $f(f(a, b), a))$ or $f(f(b, b), a)$ among others. For a context c, and a set of trees S, we shall write $c[S]$ for the set of trees obtained from c by replacing each occurrence of $\Box$ by a (possibly different) tree in S.
2. The second catch has to do with downward-closure. It is tempting to define the trees of $C^*.S$ as those in $c_1[\cdots[c_k[S]]\cdots]$, for some $k \in \mathbb{N}$ and some $c_1, \cdots, c_k \in C$. However, there are cases where that language would fail to be downwards-closed, e.g., $(f(a^?, \Box))^*.b^?$ would contain $f(a, b)$ but not a, according to that semantics.
   We repair that as follows. For $A = f(S_{\Box 1}, \cdots, S_{\Box n})$, define $\operatorname{supp} A$ as follows: if those $S_{\Box i}$, $1 \leq i \leq n$, that are different from $\Box$ define non-empty languages, then $\operatorname{supp} A$ is the union of those languages; if some $S_{\Box i} \neq \Box$ has an empty language, then $\operatorname{supp} A = \emptyset$. Hence, for example, $\operatorname{supp} f(\Box, \Box) = \emptyset$, $\operatorname{supp} f(a^?, \Box) = a^? = \{a\}$, and $\operatorname{supp} f'(a^?, \Box, 0) = \emptyset$. For $C = A_1 + \cdots + A_m$, let $\operatorname{supp} C = \bigcup_{j=1}^m \operatorname{supp} A_j$.

We are now ready to define the language of $C^*.S$, as the language of trees in $c_1[\cdots[c_k[S \cup \operatorname{supp} C]]\cdots]$, for some $k \in \mathbb{N}$ and some $c_1, \cdots, c_k \in C$.

Finally, $\downarrow L(\mathcal{A})$ is the union of the languages of the strongly connected components containing a final state of $\mathcal{A}$; in our example the strongly connected component in the middle yields the final expression $(d + f(S_1, \Box) + h(\Box, S_4))^*.0$.

General Syntax. Summing up, we define *simple tree regular expressions* (STREs) by the following abstract syntax:

$$S ::= P_1 + \cdots + P_m \qquad P ::= f^?(S, \cdots, S) \mid C^*.S$$
$$C ::= A + \cdots + A \qquad A ::= f(S_\Box, \cdots, S_\Box) \qquad S_\Box ::= S \mid \Box$$

where $f \in \mathcal{F}_r$ in $f^?(S_1, \cdots, S_r)$ and in $f(S_{\Box 1}, \cdots, S_{\Box r})$, the sum operation $+$ is associative and commutative (we shall sometimes write $\sum_{i=1}^m P_i$ for $P_1 + \cdots + P_m$) with 0 denoting the empty sum, and $\Box \notin \mathcal{F}$ is a placeholder. Note that $\Box$ is not meant to denote a family of placeholders, rather a single one. The STREs of the form P are called *tree pre-products*. Among them, the *tree products* will be our notations for ideals, see Section 5.2.

▶ **Proposition 18.** *Every STRE defines a downwards-closed language of $(T(\mathcal{F}), \sqsubseteq_T)$. Every downwards-closed language of $(T(\mathcal{F}), \sqsubseteq_T)$ is the language of some STRE.*

Proof. The first part can be shown by structural induction on STREs; see the full paper for details. The second part was sketched above. ◀

$$
\begin{array}{rcll}
P + P' & \to_1 & P' & \text{if } P \subseteq P' \\
0 + P & \to_1 & P & \\
0^*.S & \to_1 & S & \\
f^?(\vec{S}_1, 0, \vec{S}_2) & \to_1 & 0 & \\
f(\vec{S}_{\Box 1}, 0, \vec{S}_2) & \to_1 & 0 & \\
C^*.0 & \to_1 & 0 & \\

\end{array}
$$

Figure 2 The rewrite relation $\to_1$.

5.2 Tree Products

We now characterise the STREs that define ideals of $(T(\mathcal{F}), \sqsubseteq_T)$. We define a rewrite relation $\to_1$ on STREs that moves all $+$ signs to the outside: for a $\to_1$-normal STRE $S = P_1 + \cdots + P_m$, each P_i will be irreducible, hence S will be an ideal if and only if $m = 1$ by Fact 9.

The rewrite relation $\to_1$ is defined in Figure 2. Recall that $+$ is understood modulo associativity and commutativity. Letters matter, too: S, S', S_1, …, S_n are STREs, while P, P' are those special STREs of the form $f^?(S_1, \cdots, S_n)$ or $C^*.S$, etc. In particular, the third rule of the second column applies provided the pattern $f(S_1, \cdots, S_n)$ does not contain $\Box$ at all. In the first rules, note that inclusion of STREs is decidable. For the two bottom rules, we need some auxiliary definitions. Say that a pattern $A = f(S_{\Box 1}, \cdots, S_{\Box n})$ is $\Box$-*linear* if and only if at most one $S_{\Box i}$ is the placeholder $\Box$. Writing C as $A_1 + \cdots + A_m$, we say that C is $\Box$-linear if and only if every non-empty A_i is $\Box$-linear. The $\Box$-linearity restriction imposed on the last two rules is needed for the following to hold.

▶ **Fact 19.** *If $S \to_1^* S'$ then S and S' define the same language.*

▶ **Lemma 20.** *Every STRE S has a normal form with respect to $\to_1$.*

Proof. Using Bachmair and Plaisted's associative path ordering $>_{apo}$ [5] on a precedence where $+$ is minimal, $f > f^?$ for each symbol f, and the $(\_)^*.\_$ operator has lexicographic status, we see that $\to_1$ is even a terminating relation. ◀

▶ **Definition 21.** A *tree product* is any $\to_1$-normal tree pre-product P.

▶ **Lemma 22.** *Every ideal of $T(\mathcal{F})$ is the language of some tree product.*

Proof. By Proposition 18, an ideal I is the language of some STRE S, which has a $\to_1$-normal form by Lemma 20; write it $P_1 + \cdots + P_m$. Since I is non-empty, $m \geq 1$, and since I is irreducible (Fact 9), it is included in, hence equal to, the language of some P_i. ◀

Conversely, the language of any tree product is directed (see the full paper for a proof), thus:

▶ **Theorem 23.** *The ideals of $T(\mathcal{F})$ are exactly the languages of tree products.*

6 Concluding Remarks

We have presented a general order-theoretic characterisation of PTL separability, and shown that it could be applied to decide PTL separability of languages beyond finite words, namely of ranked regular tree languages ordered by homeomorphic embedding. Our work further adds

to the growing body of algorithmic applications of downwards-closed sets and ideals of well-quasi-orders in logic and verification, e.g. in forward analysis [13, 14], backward analysis [21], inference of inductive invariants [23], and reachability in vector addition systems [22].

We are confident our techniques apply to unranked trees, by defining suitable ideal representations. In the same vein, it would be interesting to develop ideal representations for the tree minor ordering, and to try to decide PTL separability for context-free tree languages.

An open-ended question is how to finely relate our order-theoretic characterisation with the algebraic and topological characterisations typically employed for the definability and separability problems. For instance, can one derive the characteristic equations of Bojańczyk et al. [6] for piecewise-testable tree languages from Lemma 12?

Computation Tree Logic for Synchronization Properties*†

Krishnendu Chatterjee[1] and Laurent Doyen[2]

1 **IST Austria, Wien, Austria**
2 **LSV, ENS Cachan & CNRS, Paris, France**

Abstract

We present a logic that extends CTL (Computation Tree Logic) with operators that express synchronization properties. A property is synchronized in a system if it holds in all paths of a certain length. The new logic is obtained by using the same path quantifiers and temporal operators as in CTL, but allowing a different order of the quantifiers. This small syntactic variation induces a logic that can express non-regular properties for which known extensions of MSO with equality of path length are undecidable. We show that our variant of CTL is decidable and that the model-checking problem is in $\Delta_3^{\mathrm{P}} = \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$, and is hard for the class of problems solvable in polynomial time using a parallel access to an NP oracle. We analogously consider quantifier exchange in extensions of CTL, and we present operators defined using basic operators of CTL* that express the occurrence of infinitely many synchronization points. We show that the model-checking problem remains in Δ_3^{P}. The distinguishing power of CTL and of our new logic coincide if the Next operator is allowed in the logics, thus the classical bisimulation quotient can be used for state-space reduction before model checking.

1 Introduction

In computer science, it is natural to view computations as a tree, where each branch represents an execution trace, and all possible execution traces are arranged in a tree. To reason about computations, the logical frameworks that express properties of trees have been widely studied [10, 20, 24], such as CTL, CTL*, μ-calculus, MSO, etc. These logics can express ω-regular properties about trees.

A key advantage of logics is to provide concise and formal semantics, and a rigorous language to express properties of a system. For example, the logic CTL is widely used in verification tools such as NuSMV [9], and hyperproperties, i.e. tree-based properties that cannot be defined over individual traces, are relevant in security [11, 12].

One key property that has been studied in different contexts is the property of synchronization, which intuitively requires that no matter how the system behaves it synchronizes to a common good point. Note that the synchronization property is inherently a tree-based property, and is not relevant for traces. Synchronization has been studied for automata [25, 8],

probabilistic models such as Markov decision processes [15, 16], as well as partial-information, weighted, and timed models [19, 17, 14], and has a rich collection of results as well as open problems, e.g., Černý's conjecture about the length of synchronizing words in automata is one of the long-standing and well-studied problems in automata theory [5, 25]. A natural question is how can synchronization be expressed in a logical framework.

First, we show that synchronization is a property that is not ω-regular. Hence it cannot be expressed in existing tree-based logics, such as MSO, CTL*, etc. A natural candidate to express synchronization in a logical framework is to consider MSO with quantification over path length. Unfortunately the quantification over path length in MSO leads to a logic for which the model-checking problem is undecidable [23, Theorem 11.6]. Thus an interesting question is how to express synchronization in a logical framework where the model-checking problem is decidable.

Contributions. In this work we introduce an elegant logic, obtained by a natural variation of CTL. The logic allows to exchange the temporal and path quantifiers in classical CTL formulas. For example, consider the CTL formula $\forall Fq$ expressing the property that in all paths there exists a position where q holds (quantification pattern $\forall\text{paths} \cdot \exists\text{position}$). In our logic, the formula $F\forall q$ with quantifiers exchanged expresses that there exists a position k such that for all paths, q holds at position k (quantification pattern $\exists\text{position} \cdot \forall\text{paths}$), see Figure 1a. Thus q eventually holds in all paths at the same position, expressing that the paths are eventually synchronized.

We show that the model-checking problem is decidable for our logic, which we show is in $\Delta_3^{\mathrm{P}} = \mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ (in the third level of the polynomial hierarchy) and is hard for the class $\mathrm{P}_{\parallel}^{\mathrm{NP}}$ of problems solvable in polynomial time using a parallel access to an NP oracle (Theorem 1). The problems in $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ can be solved by a polynomial-time algorithm that uses an oracle for a problem in $\mathrm{NP}^{\mathrm{NP}}$, and the problems in $\mathrm{NP}^{\mathrm{NP}}$ can be solved by a non-deterministic polynomial-time algorithm that uses an oracle for an NP-complete problem; the problems in $\mathrm{P}_{\parallel}^{\mathrm{NP}}$ can be solved by a polynomial-time algorithm that works in two phases, where in the first phase a list of queries is constructed, and in the second phase the queries are answered by an NP oracle (giving a list of yes/no answers) and the algorithm proceeds without further calling the oracle [26, 21].

We present an extension of our logic that can express the occurrence of infinitely many synchronization points (instead of one as in eventually sychronizing), and the absence of synchronization from some point on, with the same complexity status (Section 3). These properties are the analogue of the classical liveness and co-liveness properties in the setting of synchronization. We show that such properties cannot be expressed in the basic logic (Section 4). In Section 6, we consider the possibility to further extend our logic with synchronization to CTL*, and show that the exchange of quantifiers in CTL* formulas would lead to either a counter-intuitive semantics, or an artificial logic that would be inelegant.

We study the distinguishing power of the logics in Section 5, that is the ability of the logics, given two models, to provide a formula that holds in one model, and not in the other. The distinguishing power is different from the expressive power of a logic, as two logics with the same expressive power have the same distinguishing power but not vice versa. The distinguishing power can be used for state-space reduction before running a model-checking algorithm, in order to obtain a smaller equivalent model, that the logic cannot distinguish from the original model, and thus for which the answer of the model-checking algorithm is the same. We show that if the Next operator is allowed in the logic, then the distinguishing power coincides with that of CTL (two models are indistinguishable if and only if they

are bisimilar), and if the Next operator is not allowed, then the distinguishing power lies between bisimulation and stuttering bisimulation, and is NP-hard to decide. In particular, it follows that with or without the Next operator the state-space reduction with respect to bisimulation, which is computable in polynomial time, is sound for model-checking. Detailed proofs are available in [6].

2 CTL + Synchronization

We introduce the logic CTL+Sync after presenting basic definitions related to Kripke structures. A *Kripke structure* is a tuple $K = \langle T, \Pi, \pi, R\rangle$ where T is a finite set of states, Π is a finite set of atomic propositions, $\pi : T \to 2^{\Pi}$ is a labeling function that maps each state t to the set $\pi(t)$ of propositions that are true at t, and $R \subseteq T \times T$ is a transition relation. We denote by $R(t) = \{t' \mid (t, t') \in R\}$ the set of successors of a state t according to R, and given a set $s \subseteq T$ of states, let $R(s) = \bigcup_{t\in s} R(t)$. A Kripke structure is *deterministic* if $R(t)$ is a singleton for all states $t \in T$. A *path* in K is an infinite sequence $\rho = t_0 t_1 \dots$ such that $(t_i, t_{i+1}) \in R$ for all $i \geq 0$. For $n \in \mathbb{N}$, we denote by $\rho + n$ the suffix $t_n t_{n+1} \dots$.

2.1 Syntax and semantics

In the CTL operators, a path quantifier always precedes the temporal quantifiers (e.g., $\exists\mathcal{U}$ or $\forall\mathcal{U}$). We obtain the logic CTL+Sync from traditional CTL by allowing to switch the order of the temporal and path quantifiers. For example, the CTL formula $p\,\forall\mathcal{U}\,q$ holds in a state t if for all paths ($\forall$) from t, there is a position where q holds, and such that p holds in all positions before ($\mathcal{U}$). In the CTL+Sync formula $p\mathcal{U}\forall\, q$, the quantifiers are exchanged, and the formula holds in t if there exists a position k, such that for all positions $j < k$ before ($\mathcal{U}$), in all paths ($\forall$) from t, we have that q holds at position k and p holds at position j (see Figure 1d). Thus the formula $p\mathcal{U}\forall\, q$ requires that q holds synchronously after the same number of steps in all paths, while the formula $p\,\forall\mathcal{U}\,q$ does not require such synchronicity across several paths.

The syntax of the formulas in CTL+Sync is as follows:

$$\varphi ::= p \mid \neg\varphi_1 \mid \varphi_1 \vee \varphi_2 \mid Q\mathcal{X}\,\varphi_1 \mid \varphi_1\, Q\mathcal{U}\,\varphi_2 \mid \varphi_1\,\mathcal{U}Q\,\varphi_2$$

where $p \in \Pi$ and $Q \in \{\exists, \forall\}$. We define true and additional Boolean connectives as usual, and let

- $\exists F\varphi \equiv \mathsf{true}\,\exists\mathcal{U}\,\varphi$, and $F\exists\varphi \equiv \mathsf{true}\mathcal{U}\exists\,\varphi$, etc.
- $\exists G\varphi \equiv \neg\forall F\neg\varphi$, etc.

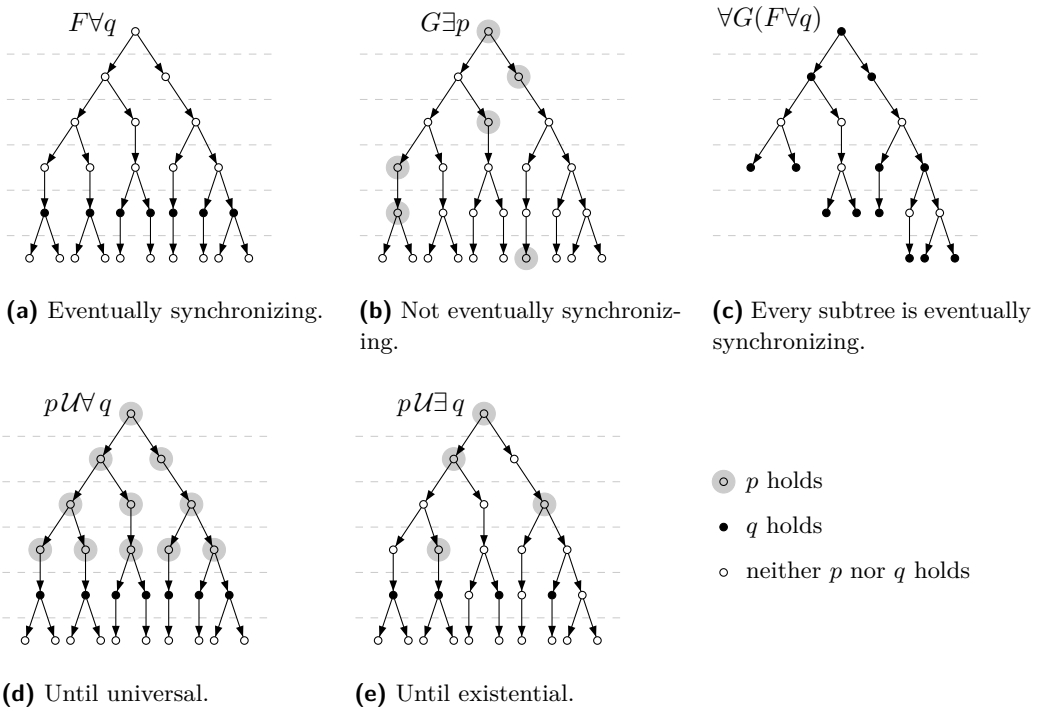
Note that the Next operators $Q\mathcal{X}$ has only one quantifier, and thus there is no point in switching quantifiers or defining an operator $\mathcal{X}Q$.

Given a Kripke structure $K = \langle T, \Pi, \pi, R\rangle$, and a state $t \in T$, we define the satisfaction relation $\models$ as follows. The first cases are standard and exist already in CTL:

- $K, t \models p$ if $p \in \pi(t)$.
- $K, t \models \neg\varphi_1$ if $K, t \not\models \varphi_1$.
- $K, t \models \varphi_1 \vee \varphi_2$ if $K, t \models \varphi_1$ or $K, t \models \varphi_2$.
- $K, t \models \exists\mathcal{X}\,\varphi_1$ if $K, t' \models \varphi_1$ for some $t' \in R(t)$.
- $K, t \models \forall\mathcal{X}\,\varphi_1$ if $K, t' \models \varphi_1$ for all $t' \in R(t)$.

The interesting new cases are built using the until operator of CTL:

- $K, t \models \varphi_1\,\exists\mathcal{U}\,\varphi_2$ if there exists a path $t_0 t_1 \dots$ in K with $t_0 = t$ and there exists $k \geq 0$ such that: $K, t_k \models \varphi_2$, and $K, t_j \models \varphi_1$ for all $0 \leq j < k$.



(a) Eventually synchronizing.

(b) Not eventually synchronizing.

(c) Every subtree is eventually synchronizing.

(d) Until universal.

(e) Until existential.

Figure 1 Formulas of CTL+Sync.

- $K, t \models \varphi_1 \mathcal{U}\exists\, \varphi_2$ if there exists $k \geq 0$ such that for all $0 \leq j < k$, there exists a path $t_0 t_1 \dots$ in K with $t_0 = t$ such that $K, t_j \models \varphi_1$ and $K, t_k \models \varphi_2$.
- $K, t \models \varphi_1 \forall\mathcal{U}\, \varphi_2$ if for all paths $t_0 t_1 \dots$ in K with $t_0 = t$, there exists $k \geq 0$ such that: $K, t_k \models \varphi_2$, and $K, t_j \models \varphi_1$ for all $0 \leq j < k$.
- $K, t \models \varphi_1 \mathcal{U}\forall\, \varphi_2$ if there exists $k \geq 0$ such that for all $0 \leq j < k$ and for all paths $t_0 t_1 \dots$ in K with $t_0 = t$, we have $K, t_j \models \varphi_1$ and $K, t_k \models \varphi_2$.

We often write $t \models \varphi$ when the Kripke structure K is clear from the context.

Examples of formulas are given in Figure 1. The examples show the first steps of the unravelling of Kripke structures defined over atomic propositions $\{p, q\}$. The formula $F\forall q$ expresses that q eventually holds synchronously on all paths, after the same number of steps (Figure 1a). This is different from the CTL formula $\forall F q$, which expresses that all paths eventually visit a state where q holds, but not necessarily after the same number of steps in all paths. The dual formula $G\exists p$ requires that at every depth (i.e., for all positions k), there exists a path where p holds at depth k (Figure 1b). On the other hand note that $F\exists q \equiv \exists F q$ and dually $G\forall p \equiv \forall G p$. Another example is the formula $\forall G(F\forall q)$ expressing that every subtree is eventually synchronizing (Figure 1c). The until universal formula $p\mathcal{U}\forall\, q$ holds if q holds at a certain position in every path (like for the formula $F\forall q$), and p holds in all positions before (Figure 1d). The until existential formula $p\mathcal{U}\exists\, q$ says that it is possible to find path(s) where q holds at the same position, and such that for all smaller positions there is one of those paths where p holds at that position (Figure 1e).

▶ Remark. The definition of CTL+Sync, although very similar to the definition of CTL, interestingly allows to define non-regular properties, thus not expressible in CTL (or even in MSO over trees). It is easy to show using a pumping argument that the property

$F\forall q$ of eventually sychronizing is not regular (Figure 1a). This property of eventually sychronizing can be expressed in MSO extended with a length predicate, by a formula such as $\exists \rho \in T^* \cdot \forall \rho' \in T^* : |\rho| = |\rho'| \implies q(\rho')$ where $T = \{0,1\}$ and $q(\cdot)$ is a monadic predicate for the proposition q over the binary tree T^*, where $q(\rho)$ means that q holds in the last state of ρ. However, model-checking for the logic MSO extended with the "equal-length" predicate p defined by $p(\rho, \rho') \equiv |\rho| = |\rho'|$ is undecidable [23, Theorem 11.6]. In contrast, we show in Theorem 1 that the logic CTL+Sync is decidable.

2.2 Model-checking

Given a CTL+Sync formula φ, a Kripke structure K, and a state t, the *model-checking problem for CTL+Sync* is to decide whether $K, t \models \varphi$ holds.

Model-checking of CTL+Sync can be decided by considering a powerset construction for the Kripke structure, and evaluating a CTL formula on it. For example, to evaluate a formula $\varphi_1 \mathcal{U} \forall \varphi_2$ from state t_I in a Kripke structure K, it suffices to consider the sequence $s_1 s_2 \dots$ defined by $s_1 = \{t_I\}$ and $s_{i+1} = R(s_i)$ for all $i \geq 1$, where a set s is labeled by φ_1 if $K, t \models \varphi_1$ for all $t \in s$ (and analogously for φ_2). The formula $\varphi_1 \mathcal{U} \forall \varphi_2$ holds in t_I if and only if the formula $\varphi_1 \mathcal{U} \varphi_2$ holds in the sequence $s_1 s_2 \dots$ (note that on a single sequence the operators $\forall\mathcal{U}$ and $\exists\mathcal{U}$ are equivalent, thus we simply write $\mathcal{U}$).

For the formula $\varphi_1 \mathcal{U} \exists \varphi_2$, intuitively it holds in t_I if there exists a set P of finite paths $\rho_1, \rho_2, \dots, \rho_n$ from t_I in K, all of the same length k, such that φ_2 holds in the last state of ρ_i for all $1 \leq i \leq n$, and for every $1 \leq j < k$ there is a path ρ_{i_j} such that φ_1 holds in the jth state of ρ_{i_j}. To evaluate $\varphi_1 \mathcal{U} \exists \varphi_2$ from t_I, we construct the Kripke structure $2^K = \langle 2^T, \{\varphi_1, \varphi_2\}, \pi, \hat{R} \rangle$ where $(s, s') \in \hat{R}$ if for all $t \in s$ there exists $t' \in s'$ such that $(t, t') \in R$, thus we have to choose (nondeterministically) at least one successor from each state in s, that is for every set P of paths $\rho_1, \rho_2, \dots, \rho_n$ as above, there is a path $s_1, s_2, \dots, s_k$ (with $s_1 = \{t_I\}$) in 2^K where the sets s_i are obtained by following simultaneously the finite paths $\rho_1, \dots, \rho_n$, thus such that s_i is the set of states at position i of the paths in P. The path $s_1, s_2, \dots, s_k$ in 2^K corresponds to a set P of finite paths in K that show that $\varphi_1 \mathcal{U} \exists \varphi_2$ holds if (1) φ_2 holds in all states of s_k, and (2) φ_1 holds in some state of s_i $(i = 1, \dots, k-1)$. Hence we define the labeling function π in 2^K as follows: for all $s \in 2^T$ let $\varphi_2 \in \pi(s)$ if $K, t \models \varphi_2$ for all $t \in s$, and let $\varphi_1 \in \pi(s)$ if $K, t \models \varphi_1$ for some $t \in s$. Finally it suffices to check whether the CTL formula $\varphi_1 \exists \mathcal{U} \varphi_2$ holds in 2^K from $\{t_I\}$.

This approach gives an exponential algorithm, and even a PSPACE algorithm by exploring the powerset construction on the fly. However, we show that the complexity of the model-checking problem is much below PSPACE. For example our model-checking algorithm for the formula $F\forall q$ relies on guessing a position $k \in \mathbb{N}$ (in binary) and checking that q holds on all paths at position k. To compute the states reachable after exactly k steps, we compute the kth power of the transition matrix $M \in \{0,1\}^{T \times T}$ where $M(t, t') = 1$ if there is a transition from state t to state t'. The power M^k can be computed in polynomial time by successive squaring of M. For this formula, we obtain an NP algorithm. For the whole logic, combining the guessing and squaring technique with a dynamic programming algorithm that evaluates all subformlas, we obtain an algorithm in $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ for the model-checking problem [6]. We present a hardness result for the class $\mathrm{P}_{\parallel}^{\mathrm{NP}}$ of problems solvable in polynomial time using a parallel access to an NP oracle [26, 21].

▶ **Theorem 1.** *The model-checking problem for CTL+Sync lies in $P^{NP^{NP}}$ and is $P_{\parallel}^{NP}$-hard.*

The complexity lower bounds for the model-checking problem in Theorem 1 are based on Lemma 2 where we establish complexity bounds for fixed formulas.

▶ **Lemma 2.** *Let $p, q \in \Pi$ be two atomic propositions. The model-checking problem is:*
- *NP-complete for the formulas $p\mathcal{U}\forall\, q$ and $F\forall q$,*
- *DP-hard for the formula $p\mathcal{U}\exists\, q$, and*
- *coNP-complete for the formula $G\exists q$.*

Proof. We prove the hardness results (complexity lower bounds), since the complexity upper bounds follow from the proof of Theorem 1.

The proof technique is analogous to the NP-hardness proof of [22, Theorem 6.1], and based on the following. Given a Boolean propositional formula ψ over variables $x_1, \ldots, x_n$, consider the first n prime numbers $p_1, \ldots, p_n$. For a number $z \in \mathbb{N}$, if $z \mod p_i \in \{0, 1\}$ for all $1 \leq i \leq n$, then the binary vector $(z \mod p_1, \ldots, z \mod p_n)$ defines an assignment to the variables of the formula. Note that conversely, every such binary vector can be defined by some number $z \in \mathbb{N}$ (by the Chinese remainder theorem).

NP-hardness of $F\forall q$ (and thus of $p\mathcal{U}\forall\, q$). The proof is by a reduction from the Boolean satisfiability problem 3SAT which is NP-complete [13]. Given a Boolean propositional formula ψ in CNF, with set C of (disjunctive) clauses over variables $x_1, \ldots, x_n$ (where each clause contains three variables), we construct a Kripke structure K_ψ as follows: for each clause $c \in C$, we construct a cycle $t_0, t_1, \ldots, t_{r-1}$ of length $r = p_u \cdot p_v \cdot p_w$ where the three variables in the clause are x_u, x_v, and x_w. We call t_0 the origin of the cycle, and we assign to every state t_i the label q if the number i defines an assignment that satisfies the clause c. The Kripke structure K_ψ is the disjoint union of the cycles corresponding to each clause, and an initial state t_I with transitions from t_I to the origin of each cycle. Note that the Kripke structure K_ψ can be constructed in polynomial time, as the sum of the first n prime numbers is bounded by a polynomial in n: $\sum_{i=1}^{n} p_i \in O(n^2 \log n)$ [2].

It follows that a number z defines an assignment that satisfies the formula ψ (i.e., satisfies all clauses of ψ) if and only if every path of length $z+1$ from t_I reaches a state labelled by q. Therefore the formula ψ is satisfiable if and only if $K_\psi, t_I \models F\forall q$, and it follows that the model-checking problem is NP-hard for the formulas $F\forall q$ and for $p\mathcal{U}\forall\, q$ (let p hold in every state of K_ψ).

NP-hardness of $p\mathcal{U}\exists\, q$. The proof is by a reduction from 3SAT [13]. The reduction is illustrated in Figure 2. Given a Boolean propositional formula ψ in CNF, with set C of (disjunctive) clauses over variables $x_1, \ldots, x_n$ (where each clause contains three variables), we construct a Kripke structure K as follows: let $m = |C|$ be the number of clauses in ψ, and construct m disjoint simple paths π_i from t_I of length $m+1$ (of the form $t_I, t_1, \ldots, t_m$), where the last state of each path π_i has a transition to the origin of a cycle corresponding to the ith clause (the cycles and their labeling are as defined in the NP-hardness proof of $F\forall q$). The state t_I and all states of the cycles are also labelled by p, and in the ith path from t_I, the ith state after t_I is labelled by p. The construction can be obtained in polynomial time.

We show that ψ is satisfiable if and only if the formula $p\mathcal{U}\exists\, q$ holds from t_I in K. Recall that $p\mathcal{U}\exists\, q$ holds if there exists $k \geq 0$ such that for all $0 \leq j < k$, there exists a path $t_0 t_1 \ldots$ in K with $t_0 = t_I$ and $K, t_j \models p$ and $K, t_k \models q$.

For the first direction of the proof, if ψ is satisfiable, then let $z \in \mathbb{N}$ define a satisfying assignment, and let $k = m + 2 + z$. Then all paths of length k from t_I in K end up in a state labelled by q. Now we consider an arbitrary $j < k$ and show that there exists a path of length k from t_I that ends up in a state labelled by q, and with the jth state labelled by p. For $j = 0$ and for $j > m$, the conditions are satisfied by all paths, and for $j \leq m$, the conditions are satisfied by the jth path from t_I.

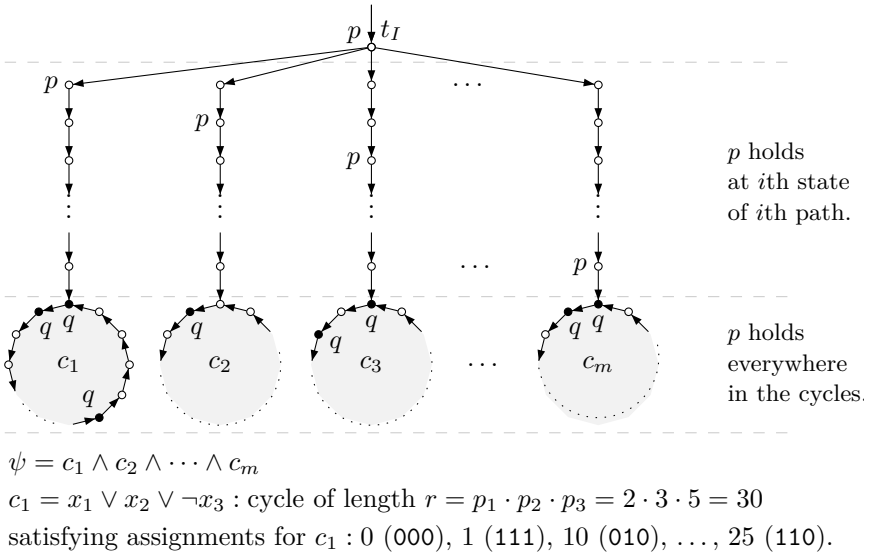


Figure 2 Reduction to show NP-hardness of $p\mathcal{U}\exists\, q$ in Lemma 2.

For the second direction of the proof, let k be a position such that for all $0 \leq j < k$, there exists a path $t_0 t_1 \dots$ in K with $t_0 = t_I$ and $K, t_j \models p$ and $K, t_k \models q$. Then $k \geq m+2$ since only the states in the cycles are labelled by q. Consider the set P containing, for each $j = 1, 2, \dots, m$, a path $t_I t_1 \dots$ in K with $K, t_j \models p$ and $K, t_k \models q$. It is easy to see by the construction of K that P contains all the paths of length k in K. Therefore, all paths of length $z = k - (m+2)$ from the origin of each cycle end up in a state labelled by q. It follows that z defines an assignment that satisfies all clauses in ψ, thus ψ is satisfiable.

DP-hardness of $p\mathcal{U}\exists\, q$. The DP-hardness proof of $p\mathcal{U}\exists\, q$ uses a reduction of the same flavor as in the NP-hardness of $F\forall q$ [6].

coNP-hardness of $G\exists q$. The result follows from the NP-hardness of $F\forall q$ since $G\exists q$ is equivalent to $\neg F\forall \neg q$. ◀

The complexity result of Theorem 1 is not tight, with a $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}}$ upper bound and hardness for $\mathrm{P}_{\|}^{\mathrm{NP}}$. Even for the fixed formula $p\mathcal{U}\exists\, q$, the gap between the $\mathrm{NP}^{\mathrm{NP}}$ upper bound and the DP-hardness result provides an interesting open question for future work.

3 Extension of CTL+Sync with Always and Eventually

We consider an extension of CTL+Sync with formulas of the form $\mathcal{T}Q\varphi$ where $\mathcal{T} \in \{F, G\}^+$ is a sequence of unary temporal operators Eventually (F) and Always (G). For example, the formula $FG\forall p$ expresses strong synchronization, namely that from some point on, all positions on every path satisfy p; the formula $GF\forall p$ expresses weak synchronization, namely that there are infinitely many positions such that, on every path at those positions p holds. In fact only the combination of operators FG and GF need to be considered, as the other combinations of operators reduce to either FG or GF using the LTL identities $FGF\varphi \equiv GF\varphi$ and $GFG\varphi \equiv FG\varphi$. Formally, define:

- $K, t \models GF\forall\varphi_1$ if for all $k \geq 0$, there exists $j \geq k$ such that for all paths $t_0 t_1 \dots$ in K with $t_0 = t$, we have $K, t_j \models \varphi_1$.
- $K, t \models GF\exists\varphi_1$ if for all $k \geq 0$, there exists $j \geq k$ and there exists a path $t_0 t_1 \dots$ in K with $t_0 = t$ such that $K, t_j \models \varphi_1$.
- $K, t \models FG\forall\varphi_1$ if $K, t \not\models GF\exists\neg\varphi_1$.
- $K, t \models FG\exists\varphi_1$ if $K, t \not\models GF\forall\neg\varphi_1$.

The model-checking problem for the formula $GF\forall\varphi_1$ is NP-complete: guess positions $n, k \leq 2^{|T|}$ (represented in binary) and check in polynomial time that the states reachable by all paths of length n satisfy φ_1, and that set of the states reachable after $n + k$ steps is the same as the set of states reachable after n steps, where $k > 0$. This corresponds to finding a lasso in the subset construction for the Kripke structure K. A matching NP lower bound follows from the reduction in the NP-hardness proof of $F\forall q$ (Lemma 2).

The model-checking problem for the formula $GF\exists\varphi_1$ can be solved in polynomial time, as this formula is equivalent to saying that there exists a state labeled by φ_1 that is reachable from a reachable non-trivial strongly connected component (SCC) — an SCC is trivial if it consists of a single state without self-loop. To prove this, note that if a state t^* labeled by φ_1 is reachable from a reachable non-trivial SCC, then t^* can be reached by an arbitrarily long path, thus the formula $GF\exists\varphi_1$ holds. For the other direction, if no state labeled by φ_1 is reachable from a reachable non-trivial SCC, then every path to a state labeled by φ_1 is acyclic (otherwise, the path would contain a cycle, belonging to an SCC). Since acyclic paths have length at most $|T|$, it follows that the formula $GF\exists\varphi_1$ does not hold, which concludes the proof.

From the above arguments, it follows that the complexity status of the model-checking problem for this extension of CTL+Sync is the same as the complexity of CTL+Sync model-checking in Theorem 1.

▶ **Theorem 3.** *The model-checking problem for CTL+Sync extended with sequences of unary temporal operators lies in $P^{NP^{NP}}$ and is $P_{\|}^{NP}$-hard.*

4 Expressive Power

The expressive power of CTL+Sync (even extended with Always and Eventually) is incomparable with the expressive power of MSO. By the remark at the end of Section 2.1, CTL+Sync can express non-regular properties, and thus is not subsumed by MSO, and standard argument based on counting properties [27] showing that CTL is less expressive than MSO apply straightforwardly to show that formulas of MSO are not expressible in CTL+Sync [10].

We show that the formulas $GF\forall p$ and $FG\forall p$ for weak and strong synchronization cannot be expressed in the logic CTL+Sync, thus CTL+Sync extended with sequences of unary temporal operators is strictly more expressive than CTL+Sync. The result holds if the Next operator is not allowed, and also if the Next operator is allowed.

▶ **Theorem 4.** *The logic CTL+Sync (even without the Next operator) extended with sequences of unary temporal operators is strictly more expressive than CTL+Sync (even using the Next operator).*

Proof. We show that the formula $GF\forall p$ cannot be expressed in CTL+Sync, even using the Next operator. To prove this, given an arbitrary CTL+Sync formula φ, we construct two

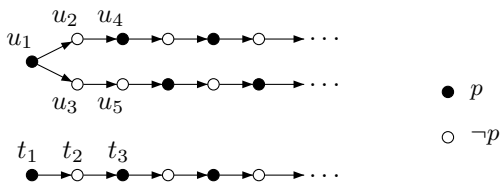

Figure 3 States t_1 and u_1 are indistinguishable by formulas of CTL+Sync.

Kripke structures such that φ holds in both Kripke structures, but the formula $GF\forall p$ holds in one and not in the other. It follows that φ is not equivalent to $GF\forall p$.

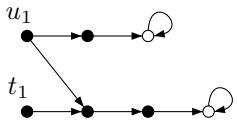
Given the formula φ, we construct the two Kripke structures as follows. Consider two Kripke structures whose unravelling is shown in Figure 3 where the states reachable from t_1 are satisfying alternately p and $\neg p$, and the states reachable from u_2 and u_5 are satisfying alternately $\neg p$ and p. Call black states the states where p holds, and white states the states where $\neg p$ holds. If n is the maximum number of nested Next operators in φ, then we construct the n-stuttering of the two Kripke structures in Figure 3, where the n-stuttering of a Kripke structure $K = \langle T, \Pi, \pi, R\rangle$ is the Kripke structure $K^n = \langle T \times \{1, \ldots, n\}, \Pi, \pi^n, R^n\rangle$ where $\pi^n(t, i) = \pi^n(t)$ for all $1 \leq i \leq n$, and the transition relation R^n contains all pairs $((t, i), (t, i + 1))$ for all $t \in T$ and $1 \leq i < n$, and all pairs $((t, n), (t', 1))$ for all $(t, t') \in R$.

We claim that the formula φ holds either in both $(t_1, 1)$ and $(u_1, 1)$, or in none of $(t_1, 1)$ and $(u_1, 1)$, while the formula $GF\forall p$ holds in $(t_1, 1)$ and not in $(u_1, 1)$. We show by induction on the nesting depth of CTL+Sync formulas φ (that have at most n nested Next operators) that (t_1, i) and (u_1, i) are equivalent for φ (for all $1 \leq i \leq n$), and that for all black states t, u, the copies $(t, 1)$ and $(u, 1)$ are equivalent for φ, and analogously for all pairs of white states.

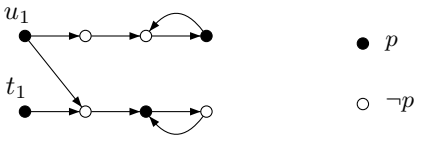
The result holds trivially for formulas of nesting depth 0, that is atomic propositions. For the induction step, assume the claim holds for formulas of nesting depth k, and consider a formula φ of nesting depth $k + 1$. If the outermost operator of φ is a Boolean operator, or a CTL operator ($Q\mathcal{X}$ or $Q\mathcal{U}$), then the result follows from the induction hypothesis and the result of [18, Theorem 2] showing two paths that differ only in the number of consecutive repetitions of a state, as long as the number of repetitions is at least n, are equivalent for the formulas with at most n nested Next operators. If the outermost operator of φ is either $\mathcal{U}\exists$ or $\mathcal{U}\forall$, that is $\varphi \equiv \varphi_1 \mathcal{U}\exists \varphi_2$ or $\varphi \equiv \varphi_1 \mathcal{U}\forall \varphi_2$, then consider a state where φ holds: either φ_2 holds in that state, and by the induction hypothesis, φ_2 also holds in the corresponding state (that we claimed to be equivalent), or φ_2 holds in the states of the other color than the current state, and φ_1 holds on the path(s) at all positions before. By the induction hypothesis, at the same distance from the claimed equivalent states, we can find a state where φ_2 holds in all paths, and φ_1 holds on all positions before, which concludes the proof for the induction step. ◀

5 Distinguishing Power

Two states of a Kripke structure can be distinguished by a logic if there exists a formula in the logic that holds in one state but not in the other. Each logic induces an indistinguishability relation (which is an equivalence) on Kripke structures that characterizes the distinguishing power of the logic. Two states t and t' of a Kripke structure K are indistinguishable by a logic $\mathcal{L}$ if they satisfy the same formulas of $\mathcal{L}$, that is $\{\varphi \in \mathcal{L} \mid K, t \models \varphi\} = \{\varphi \in \mathcal{L} \mid K, t' \models \varphi\}$.



(a) The states t_1 and u_1 are stuttering bisimilar (they satisfy the same CTL formulas without the Next operator), but they can be distinguished by the CTL+Sync formula $p\mathcal{U}\forall\,\neg p$ which holds in t_1 but not in u_1.



(b) The states t_1 and u_1 are indistinguishable by CTL+Sync formulas, but they are not bisimilar, i.e. they can be distinguished by CTL formulas with the Next operator, for example $\forall\mathcal{X}\,\forall\mathcal{X}\,p$ which holds in t_1 but not in u_1.

Figure 4 The distinguishing power of CTL+Sync lies strictly between bisimulation and stuttering bisimulation.

For CTL (with the Next operator), the distinguishing power is standard bisimulation, and for CTL without the Next operator, the distinguishing power is stuttering bisimulation [4]. Stuttering bisimulation is a variant of bisimulation where intuitively several transitions can be used to simulate a single transition, as long as the intermediate states of the transitions are all equivalent (for stuttering bisimulation). We omit the definition of bisimulation and stuttering bisimulation [4], and in this paper we consider that they are defined as the distinguishing power of respectively CTL and CTL without the Next operator.

It is easy to show by induction on the nesting depth of formulas that the distinguishing power of CTL+Sync is the same as for CTL, since (i) CTL+Sync contains CTL, and (ii) if two states t and t' are bisimilar, there is a correspondence between the paths starting from t and the paths starting from t' (for every path from t, there is a path from t' such that their states at position i are bisimilar, for all $i \in \mathbb{N}$, and analogously for every path of t' [4, Lemma 3.1]), which implies the satisfaction of the same formulas in CTL+Sync. The same argument holds for CTL+Sync extended with unary temporal operators (Section 3).

▶ **Theorem 5.** *Two states t and t' of a Kripke structure K are indistinguishable by CTL+Sync formulas (even extended with unary temporal operators) if and only if t and t' are bisimilar.*

Without the Next operator, the logic CTL+Sync has a distinguishing power that lies strictly between bisimulation and stuttering bisimulation, as shown by the examples in Figure 4a and Figure 4b. Indistinguishability by CTL+Sync formulas without the Next operator implies indistinguishability by standard CTL without the Next operator, and thus stuttering bisimilarity. We obtain the following result.

▶ **Theorem 6.** *The following implications hold for all states t, t' of a Kripke structure K:*

- *if t and t' are bisimilar, then t and t' are indistinguishable by CTL+Sync formulas without the Next operator (even extended with unary temporal operators);*
- *if t and t' are indistinguishable by CTL+Sync formulas without the Next operator (even extended with unary temporal operators), then t and t' are stuttering bisimilar.*

It follows from the first part of Theorem 6 that the state-space reduction techniques based on computing a bisimulation quotient before evaluating a CTL formula will work for CTL+Sync. Although the exact indistinguishability relation for CTL+Sync is coarser than bisimulation, we show that deciding this relation is NP-hard, and thus it may not be relevant to compute it for quotienting before model-checking, but rather use the polynomial-time computable bisimulation.

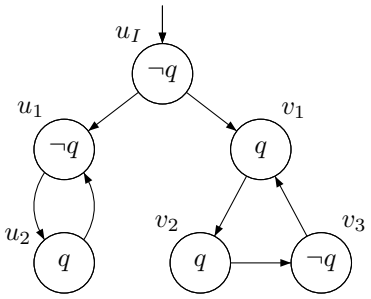


Figure 5 The Kripke structure K in the proof of Theorem 7.

▶ **Theorem 7.** *Deciding whether two states of a Kripke structure are indistinguishable by CTL+Sync formulas without the Next operator is NP-hard.*

Proof. The proof is by a reduction from the Boolean satisfiability problem 3SAT which is NP-complete [13]. Given a Boolean propositional formula ψ in CNF, we construct two Kripke structures K and K_ψ that are indistinguishable (from their initial state) if and only if ψ is satisfiable, where:

- K is the Kripke structure shown in Figure 5, and
- K_ψ is the Kripke structure constructed in the NP-hardness proof of $F\forall q$ (Lemma 2).

We know from the proof of Lemma 2 that $K_\psi, t_I \models F\forall q$ if and only if ψ is satisfiable. Hence, it suffices to show that K and K_ψ are indistinguishable if and only if the formula $F\forall q$ holds in t_I. Since the formula $F\forall q$ holds in u_I, we only need to show that if $F\forall q$ holds in t_I, then K and K_ψ are indistinguishable. To do this, we assume that $F\forall q$ holds in t_I, and we show that for all CTL+Sync formulas φ without the Next operator, $t_I \models \varphi$ if and only if $u_I \models \varphi$. The proof proceeds by induction on the nesting depth of φ and simple combinatorial arguments [6]. ◀

6 CTL* + Synchronization

CTL* is a branching-time extension of LTL (and of CTL) where several nested temporal operators and Boolean connectives can be used under the scope of a single path quantifier. For example the CTL* formula $\exists(G\varphi \to G\psi)$ says that there exists a path in which either φ does not hold in every position, or ψ holds at every position. Note that φ and ψ may also contain path quantifiers.

Extending CTL+Sync with formula quantification analogous to CTL* presents some difficulties. Even considering only Boolean connectives and $\{F, G\}$ operators leads to a logic that is hard to define. For example, one may consider a formula like $(Fp \vee Fq)\forall$ which could be naturally interpreted as there exist two positions $m, n \geq 0$ such that on all paths ρ, either p holds at position m in ρ, or q holds at position n in ρ. In this definition the $\vee$ operator would not be idempotent, that is $\psi_1 = (Fp \vee Fp)\forall$ is not equivalent to $\psi_2 = (Fp)\forall$, where ψ_1 means that the set of all paths can be partitioned into two sets of paths where p holds synchronously at some position, but not necessarily the same position in both sets, while ψ_2 expresses the property that p holds synchronously at some position in all paths.

Another difficulty with binary operators is the semantics induced by the order of the operands. For instance, the formula $(Fp \vee Gq)\forall$ can be interpreted as (i) there exists a position $m \geq 0$ such that for all positions $n \geq 0$, on all paths ρ, either $\rho + m \models p$ or $\rho + n \models q$;

or it can be interpreted as (ii) for all $n \geq 0$, there exists $m \geq 0$ such that on all paths ρ, either $\rho + m \models p$ or $\rho + n \models q$. These two interpretations differ on the Kripke structure that produces exactly two paths ρ_1 and ρ_2 such that p and q hold at the following positions (p holds nowhere except at position 1 in ρ_1 and position 3 in ρ_2, and q holds everywhere except position 2 in ρ_1 and position 4 in ρ_2):

in ρ_1:	$\{\bar{p}, q\}$	$\{p, q\}$	$\{\bar{p}, \bar{q}\}$	$\{\bar{p}, q\}$	$\{\bar{p}, q\}$	$\{\bar{p}, q\}$	$\ldots$
in ρ_2:	$\{\bar{p}, q\}$	$\{\bar{p}, q\}$	$\{\bar{p}, q\}$	$\{p, q\}$	$\{\bar{p}, \bar{q}\}$	$\{\bar{p}, q\}$	$\ldots$
	0	1	2	3	4	5	

Note that the two paths agree on their initial position, and we can construct a Kripke structure that produces exactly those two paths. It is easy to see that the formula $(Fp \vee Gq)\forall$ does not hold according to the first interpretation (indeed, for $m = 1$ we can take $n = 4$ and consider the path ρ_2 where p does not hold at position 1 and q does not hold at position 4, and for all other values of m, take $n = 2$ and consider the path ρ_1 where p does not hold at position m and q does not hold at position 2), but it does hold according to the second interpretation (for $n = 2$ take $m = 1$, for $n = 4$ take $m = 3$, and for all other values of n take arbitrary value of m, for example $m = n$). The trouble is that the order of the existential quantifier (associated to the left operand Fp) and the universal quantifier (associated to the right operand Gq) actually matters in the semantics of the formula, leading to an annoying situation that $(Fp \vee Gq)\forall$ is not equivalent to $(Gq \vee Fp)\forall$ in any of the interpretations. One way could be to use the branching Henkin quantifiers, like $\binom{\exists m}{\forall n}$ where the existential choice of m does not depend on the universal choice of m. This interpretation suffers from lack of symmetry, as the negation of such a branching Henkin quantifier is in general not expressible as a branching Henkin quantifier [3].

7 Conclusion

The logic CTL+Sync and its extensions presented in this paper provide an elegant framework to express non-regular properties of synchronization. It is intriguing that the exact optimal complexity of the model-checking problem remains open, specially even for the fixed formula $p\mathcal{U}\exists\, q$ (which we show is in $\mathrm{NP}^{\mathrm{NP}}$, and DP-hard). Extending CTL+Sync to an elegant logic *à la* CTL* seems challenging. One may want to express natural properties with the flavor of synchronization, such as the existence of a fixed number of synchronization points, or the property that all paths synchronize in either of a finite set of positions, etc. (see also Section 6). Another direction is to consider alternating-time temporal logics (ATL [1]) with synchronization. ATL is a game-based extension of CTL for which the model-checking problem remains in polynomial time. For instance, ATL can express the existence of a winning strategy in a two-player reachability game. For the synchronized version of reachability games (where the objective for a player is to reach a target state after a number of steps that can be fixed by this player, independently of the strategy of the other player), it is known that deciding the winner is PSPACE-complete [15]. Studying general game-based logics such as ATL or strategy logic [7] combined with quantifier exchange is an interesting direction for future work.

Abstract

We study the topological complexity of languages of Büchi automata on infinite binary trees. We show that such a language is either Borel and WMSO-definable, or Σ^1_1-complete and not WMSO-definable; moreover it can be algorithmically decided which of the two cases holds. The proof relies on a direct reduction to deciding the winner in a finite game with a regular winning condition.

1 Introduction

The class of regular languages of infinite trees is one of the most important classes of properties of infinite computations. Similarly to the arithmetic hierarchy, the class is structured into the so called Mostowski–Rabin index hierarchy. This hierarchy reflects the complexity of a language in terms of an alternation of fix-points needed to express it, or equivalently, in terms of the minimal complexity of the acceptance condition of an automaton accepting the language. While we know for about two decades that the hierarchy is infinite [5], we are still very far from understanding it. One important objective in this area is to effectively characterise every level of the hierarchy: for a given regular language of infinite trees calculate its level in the hierarchy.

The difficulty in understanding the Mostowski–Rabin index hierarchy of tree languages is linked to the lack of deterministic acceptors for such languages. Thus, on a smaller scale, we face here the same problem as in the complexity theory, namely the problem of understanding the structure of non-deterministic computations. When restricted to deterministic acceptors, the Mostowski–Rabin hierarchy is by now well-understood. For every level we know a pattern such that the pattern appears in a deterministic tree automaton if and only if the language recognised by this automaton is hard for this level [21, 18, 19]. The pattern method has been extended to the so called game automata [12], but there is no hope to use it for non-deterministic automata.

Apart from decidability questions, a promising way to understand the Mostowski–Rabin hierarchy is to relate it to the topological hierarchy. (For an introduction to the classes

of topological complexity see for instance [15].) Topological properties of sets defined by automata are discussed in [24]. It is well-known that all regular languages of infinite trees are contained in the $\mathbf{\Delta}^1_2$ level of the projective hierarchy. The languages of Büchi automata, or equivalently those definable in existential MSO logic, are contained in the $\mathbf{\Sigma}^1_1$ level. The languages of weak-alternating automata, or equivalently definable in weak MSO (WMSO), are Borel; moreover for every finite level of the Borel hierarchy there is a complete weakly definable language [23]. In [23], Skurczyński asks if every regular language that is Borel is necessarily weakly definable. In this paper we answer this question for languages recognised by Büchi automata, as expressed by the main theorem.

▶ **Theorem 1.** *If $\mathcal{B}$ is a non-deterministic Büchi tree automaton then one of the following possibilities holds and it is possible to effectively decide which one it is:*
1. $\mathrm{L}(\mathcal{B})$ *is Borel and* WMSO*-definable,*
2. $\mathrm{L}(\mathcal{B})$ *is $\mathbf{\Sigma}^1_1$-complete and not* WMSO*-definable.*

The theorem is proved through a game construction. Given a Büchi automaton $\mathcal{B}$ we construct a finite game $\mathcal{F}(\infty)$ such that if $\exists$ wins in this game then the language of $\mathcal{B}$ is $\mathbf{\Sigma}^1_1$-complete; but if $\forall$ wins then the language of $\mathcal{B}$ can be accepted by a weak alternating automaton constructed from $\mathcal{B}$. A similar technique of relying on the finite memory determinacy of regular games was used in [1].

Related work. Colcombet, Kuperberg, Löding, and Vanden Boom [16, 8] have proved the algorithmic part of the above theorem; using some decidability result in the theory of cost functions and a reduction of Colcombet and Löding [9] they have shown how to decide if the language of a Büchi automaton is weakly definable. The topological counterpart of Theorem 1 seems not to follow from their construction. Our proof relies only on standard facts from automata theory, and may be simpler, at least for those who are not familiar with the theory of cost functions.

Finding effective characterisations of various classes of infinite tree languages is an important topic of language theory. As we noted above, for languages of deterministic tree automata the situation is quite well-understood; but for the case of all regular tree languages for some time it was only known how to decide if a given regular language can be accepted by an automaton with a trivial acceptance condition [17, 25]. The theory of cost functions allows to decide if a given language can be accepted by a non-deterministic co-Büchi automaton [8]. Bojańczyk and Idziaszek [2] have recently shown decidability of definability in a temporal logic EF. Bojańczyk and Place [4] show how to decide if a given language is a Boolean combination of open sets.

The study of topological properties of regular languages of trees has seen important advances too [10, 13, 6, 18, 19, 3, 11]. Over a decade ago an interesting gap property has been observed [20] for languages of deterministic tree automata: a language is either $\mathbf{\Pi}^1_1$-complete, or contained in the $\mathbf{\Pi}^0_3$ level of the Borel hierarchy. A similar gap property has been recently shown for languages of thin trees [14]: a regular language of thin trees, treated as a subset of all trees, is either definable in weak MSO logic or $\mathbf{\Pi}^1_1$-complete. Our theorem shows a gap property for languages of non-deterministic Büchi automata.

2 Preliminaries and an outline of the construction

We write ω for the natural numbers, and $\overline{\omega}$ for the extension of ω with a greatest element ∞. So $n < \infty$ for all $n \in \omega$, and $\infty - 1 = \infty$. We assume standard definitions of non-deterministic

and alternating automata on infinite binary trees. All trees we consider are binary, the two directions are $\mathtt{L}$ and $\mathtt{R}$. The root of a tree is ϵ. By $\preceq$ we denote the prefix order on the nodes of a tree. In this paper we will use perfect information two player games of infinite duration. The players are denoted $\exists$ (Eve) and $\forall$ (Adam).

A non-deterministic Büchi automaton is a tuple $\mathcal{B} = \langle Q, A, q_{\mathrm{I}} \in Q, \delta \subseteq Q \times A \times Q \times Q, F \subseteq Q \rangle$. We will use the standard notion of a run ρ over a tree t. A run of $\mathcal{B}$ is accepting if on every branch some state from F appears infinitely often. A weak alternating automaton is very similar but for a total quasi-order on states, and the transition relation that now sends a non-empty set of states in every direction $\delta \subseteq Q \times A \times \mathsf{P}^+(Q) \times \mathsf{P}^+(Q)$ (by $\mathsf{P}^+(X)$ we denote the set of non-empty subsets of X). The transition relation should respect the order on the states in a sense that if $(q, a, S_{\mathtt{L}}, S_{\mathtt{R}}) \in \delta$ then all the states in $S_{\mathtt{L}} \cup S_{\mathtt{R}}$ should not be bigger than q, and if $q \in F$ is accepting then all not accepting states in $S_{\mathtt{L}} \cup S_{\mathtt{R}}$ should be strictly smaller than q in this order. A weak alternating automaton $\mathcal{A}$ induces a game on every tree t: the positions of this game are (u, q) with $u \in \{\mathtt{L}, \mathtt{R}\}^*$ and $q \in Q$; the initial position is $(\epsilon, q_{\mathrm{I}})$; from a position (u, q) first $\exists$ chooses a transition $(q, t(u), S_{\mathtt{L}}, S_{\mathtt{R}})$, then $\forall$ chooses a direction d and a state $q' \in S_d$, the successive position is (ud, q'). A play is won by $\exists$ if it contains infinitely many accepting states. Without loss of generality we assume that all the considered automata are complete: for every state $q \in Q$ and every letter $a \in A$ there is at least one transition from q over a. For an automaton $\mathcal{A}$, by $\mathrm{L}(\mathcal{A})$ we denote the set of trees accepted by $\mathcal{A}$.

Our proof of Theorem 1 will use two games, or rather game families constructed from $\mathcal{B}$. The first game, $\mathcal{G}(t)$, will be played on a tree t. The game will encode in a compact way not only the acceptance of t by $\mathcal{B}$, but also possible approximations of $\mathcal{B}$ by weak automata. It is motivated by the technical core of the construction in [22]. More precisely, for every $K \in \overline{\omega}$ we will have a variant $\mathcal{G}(t, K)$ of the game. Each game defines a language of trees

$$\mathrm{L}(\mathcal{G}, K) = \{t \mid \exists \text{ wins } \mathcal{G}(t, K)\}. \tag{1}$$

The game $\mathcal{G}(t, \infty)$ will encode the acceptance of t by $\mathcal{B}$, i.e., $\mathrm{L}(\mathcal{G}, \infty) = \mathrm{L}(\mathcal{B})$. For every $K \in \omega$, the game $\mathcal{G}(t, K)$ will encode the acceptance of t by some specific weak alternating automaton obtained from $\mathcal{B}$; in particular $\mathrm{L}(\mathcal{G}, K)$ will be WMSO-definable. The parameter K will control the quality of the approximation of $\mathcal{B}$, in a sense that

$$\mathrm{L}(\mathcal{G}, 0) \supseteq \mathrm{L}(\mathcal{G}, 1) \supseteq \cdots \supseteq \mathrm{L}(\mathcal{B}) \,.$$

We will show that $\mathrm{L}(\mathcal{B})$ is WMSO-definable if and only if $\mathrm{L}(\mathcal{B}) = \mathrm{L}(\mathcal{G}, K)$ for some finite bound $K \in \omega$. Moreover, we will show that a candidate K_0 for this bound can be computed from $\mathcal{B}$. These results will be obtained from the analysis of another game that we call $\mathcal{F}$.

The game $\mathcal{F}$, and its variants $\mathcal{F}(K)$ for all $K \in \overline{\omega}$, will be central for our arguments. For every $K \in \overline{\omega}$, the game $\mathcal{F}(K)$ will be finite in a sense that there will be a finite number of positions reachable from the initial position. The game $\mathcal{F}(K)$ will in some sense simulate $\mathcal{G}(t, K)$ for an unknown t. We will show that when $K \in \omega$ is too small for $\mathcal{B}$, i.e. when $\mathrm{L}(\mathcal{G}, K) \supsetneq \mathrm{L}(\mathcal{B})$, then $\exists$ has a winning strategy in $\mathcal{F}(K)$. Next, we examine $\mathcal{F}(\infty)$ and show that the winner in this game determines if $\mathrm{L}(\mathcal{B})$ is WMSO-definable. If $\exists$ does not win in $\mathcal{F}(\infty)$ then she does not win in $\mathcal{F}(K_0)$ for some K_0 computable from $\mathcal{B}$ (Proposition 10). Thus $\mathrm{L}(\mathcal{B}) = \mathrm{L}(\mathcal{G}, K_0)$ is WMSO-definable. The most difficult part of the proof is to show that if $\exists$ wins in $\mathcal{F}(\infty)$ then $\mathrm{L}(\mathcal{B})$ is $\mathbf{\Sigma}^1_1$-complete and thus not WMSO-definable (Proposition 11).

The way in which the game $\mathcal{F}$ is obtained from $\mathcal{G}$ is motivated by the concept of *history determinism* and in particular by the combinatorial structure of *domination games*, see [7].

3 The game $\mathcal{G}(t)$

Let us start with the game $\mathcal{G}(t)$. The positions of $\mathcal{G}(t)$ are of the form (q, u, K, z) where $q \in Q^{\mathcal{B}}$ is a state, $u \in \{\mathtt{L}, \mathtt{R}\}^*$ is a node of t, $K \in \overline{\omega}$ is a counter value, and z is one of the three special symbols: *choice*, *safe*, or *reach*. The z component determines the possible choices from a position (q, u, K, z):

- $z = \textbf{\textit{choice}}$: In this case $\forall$ chooses $z' \in \{safe, reach\}$. If he chooses $z' = safe$ then $K' = K$, if he chooses $z' = reach$ then $K' = K - 1$; in particular if $K = 0$ then $\forall$ has to choose $z' = safe$. The game proceeds to the position (q, u, K', z').
- $z = \textbf{\textit{safe}}$: First $\exists$ proposes a transition of $\mathcal{B}$ of the form $(q, t(u), q_{\mathtt{L}}, q_{\mathtt{R}})$ and then $\forall$ chooses a direction $d \in \{\mathtt{L}, \mathtt{R}\}$. The game proceeds to the position $(q_d, ud, K, choice)$.
- $z = \textbf{\textit{reach}}$: First $\exists$ proposes a transition of $\mathcal{B}$ of the form $(q, t(u), q_{\mathtt{L}}, q_{\mathtt{R}})$ and then $\forall$ chooses a direction $d \in \{\mathtt{L}, \mathtt{R}\}$. If q_d is an accepting state then the game proceeds to the position $(q_d, ud, K, choice)$, otherwise it proceeds to the position $(q_d, ud, K, reach)$.

Every play of $\mathcal{G}(t)$ is infinite. Such a play is won by $\forall$ if $z = reach$ from some point on. In the opposite case (i.e. if $z = choice$ infinitely many times) $\exists$ wins.

As we can see from the definition, the game proceeds in phases. It is $\forall$ who chooses if the game should be in a *safe* phase or in a *reach* phase. In the *safe* phase players just construct a path from a run of $\mathcal{B}$ ignoring the acceptance condition. In the *reach* phase $\exists$ needs to provide a finite part of a run until the next accepting states. The counter K gives a bound on the number of *reach* phases: each time $\forall$ chooses *reach*, K is decreased. Notice that if K is ∞ then it stays ∞ during the whole play, so there can be infinitely many *reach* phases.

For $K \in \overline{\omega}$ we denote by $\mathcal{G}(t, K)$ the game $\mathcal{G}(t)$ with the initial position $(q_{\mathrm{I}}^{\mathcal{B}}, \epsilon, K, choice)$.

▶ **Example 2.** For our running example we consider trees over the alphabet $\{a, b\}$ and a Büchi automaton $\mathcal{B}$ accepting the trees with a branch having infinitely many occurrences of a. This automaton has three states $q_a, q_b, \top$, with both q_a, and $\top$ accepting. For a state q_x the transition relation $\delta^{\mathcal{B}}$ on a letter y contains the transitions $(q_x, y, q_y, \top)$ and $(q_x, y, \top, q_y)$; for $x, y \in \{a, b\}$. From $\top$ the automaton stays in $\top$ on every letter and in every direction.

Using the notation from (1) we can see that for $K = 0$ the language $L(\mathcal{G}, K)$ is simply the language of all trees. For $K > 0$, it is the language of trees having a path such that every node on this path has a descendant whose label is a and the subtree rooted in this descendant is in $\mathrm{L}(\mathcal{G}, K - 1)$.

The next three lemmas give connections between the game $\mathcal{G}(t)$ and the automaton $\mathcal{B}$. They refer to the languages $\mathrm{L}(\mathcal{G}, K)$ of the game as defined in (1).

▶ **Lemma 3.** $\mathrm{L}(\mathcal{B}) = \mathrm{L}(\mathcal{G}, \infty)$.

▶ **Lemma 4.** *If $\exists$ wins $\mathcal{G}(t)$ from a position (q, u, K, z) and $K' \leq K \in \overline{\omega}$ then $\exists$ wins $\mathcal{G}(t)$ from the position (q, u, K', z). In other words $\mathrm{L}(\mathcal{G}, K') \supseteq \mathrm{L}(\mathcal{G}, K) \supseteq \mathrm{L}(\mathcal{G}, \infty)$.*

▶ **Lemma 5.** *For every $K \in \omega$ the set of trees $\mathrm{L}(\mathcal{G}, K)$ can be recognised by a weak alternating automaton (or equivalently, it is wmso-definable).*

4 The game $\mathcal{F}$

We proceed to a definition of the game $\mathcal{F}$, and its variants $\mathcal{F}(K)$, for $K \in \overline{\omega}$. For all $K \in \overline{\omega}$, the game $\mathcal{F}(K)$ will simulate $\mathcal{G}(t, K)$ with an unknown t generated *on-the-fly*.

Let us fix a non-deterministic parity tree automaton $\mathcal{A}$ recognising the complement of $\mathrm{L}(\mathcal{B})$ ($\mathcal{A}$ may not be equivalent to a Büchi automaton). We will construct $\mathcal{F}$ from $\mathcal{A}$ and $\mathcal{B}$. Intuitively, in $\mathcal{F}$ we ask the players to proceed as follows:

- $\exists$ should successively construct a tree t and a run $\rho^{\mathcal{A}}$ of $\mathcal{A}$ on t;
- at the same time $\forall$ should select directions in this tree constructing an infinite branch α of t, aiming to show that the run $\rho^{\mathcal{A}}$ proposed by $\exists$ is not accepting;
- moreover $\exists$ would aim at showing that the tree t she constructs is difficult in a sense that she can win $\mathcal{G}(t, K)$ for all finite K. $\forall$ will aim to refute this claim, by showing that he can win with some finite K. It is crucial for our argument that $\forall$ can do this in a *history-deterministic* way in the sense of [7].

4.1 Positions and multi-transitions

The positions of $\mathcal{F}$ are of the form (S, p, κ, r) where:

- $S \in \mathsf{P}(Q^{\mathcal{B}} \times \{\mathit{safe}, \mathit{reach}\})$ is a set of *active states*,
- $p \in Q^{\mathcal{A}}$ is a state of the automaton $\mathcal{A}$,
- $\kappa \colon S \to \overline{\omega}$ assigns to the active states their *counter values*,
- $r \in \{0, 1, 2\}$ is a *sub-round number*.

Using the first and the third component $\exists$ will try to prove that she wins in all the games $\mathcal{G}(t, K)$. In the second component she will construct a run of $\mathcal{A}$. The fourth component makes the definition of the game more modular.

Similarly as before, for $K \in \overline{\omega}$ by $\mathcal{F}(K)$ we denote the game $\mathcal{F}$ with the initial position $(\{(q_{\mathrm{I}}^{\mathcal{B}}, \mathit{safe})\}, q_{\mathrm{I}}^{\mathcal{A}}, \kappa, 0)$ where $\kappa(q_{\mathrm{I}}^{\mathcal{B}}, \mathit{safe}) = K$.

We say that an active state (q, z) is *in the safe phase* if $z = \mathit{safe}$; and *in the reach phase* if $z = \mathit{reach}$. A pair (s, s') *changes phases* if s and s' are in different phases. So (s, s') can *change phases from safe to reach*, or *change phases from reach to safe*.

The edges of $\mathcal{F}$ will have an additional structure (i.e. an edge will be more than just a pair of positions of the game). This richer structure will be used to define the winning condition of $\mathcal{F}$ that will refer to a sequence of edges. From our definition it will be easy to see how to transform such a game into a standard two player game. To underline that edges have additional structure we refer to them as *multi-transitions*.

A *multi-transition* μ from a position (S, p, κ, r) to a position (S', p', κ', r') contains:

- the *pre-state* (S, p, κ, r),
- the *post-state* (S', p', κ', r') with $r' = r + 1 \mod 3$,
- a set $e \subseteq S \times S'$ of *edges* from the active states in S to the active states in S',
- a set $\bar{e} \subseteq e$ of *boldfaced edges*, with exactly one boldfaced edge leading to every $s' \in S'$:

$$\forall_{s' \in S'} \ \big|\{s : (s, s') \in \bar{e}\}\big| = 1 \tag{2}$$

We additionally require the following condition on κ, called *boldface-decreasing*. Assume that $(s, s') \in \bar{e}$. If (s, s') changes phases from *safe* to *reach* then[1] $\kappa'(s') = \max(\kappa(s) - 1, 0)$. Otherwise $\kappa'(s') = \kappa(s)$.

An example multi-transition is depicted in Figure 1. The role of e is to trace the origins of each active state in a similar way as for determinisation of Büchi automata. With the boldfaced edges $\forall$ will indicate which of the possible origins of an active state he finds the most promising for him. The *boldface-decreasing* condition says that on boldfaced traces the counter should behave in the same way as in a game $\mathcal{G}(t, K)$ for the tree t being constructed. The exact rules how the multi-transitions are selected by the players are given in Section 4.2.

[1] By the rules of the game, we shall never have $\kappa(s) < 1$ in this case.

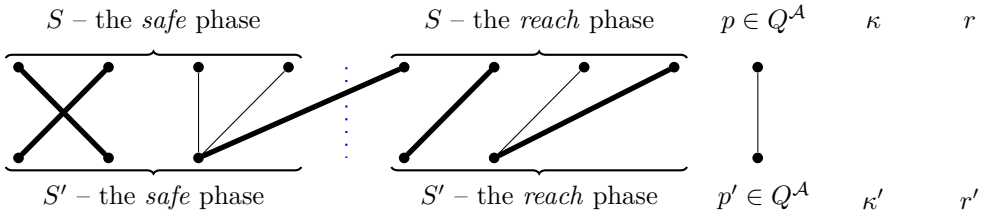

Figure 1 An example multi-transition μ. The big dots correspond to the active states and the state of $\mathcal{A}$. The convention is that all the active states from the *safe* phase are drawn on the left, all the active states from the *reach* phase are drawn in the middle, then comes the state of $\mathcal{A}$, and finally the counter values κ and the sub-round number r are drawn on the right. For the purpose of the layout, we additionally draw an edge between the states p and p' of $\mathcal{A}$ (this edge does not belong to e). The dotted line separates the *safe* phase from the *reach* phase. Boldfaced edges are boldfaced. Every active state in S' has one incoming boldfaced edge as required by (2).

Notice that for a fixed $K \in \overline{\omega}$ the game $\mathcal{F}(K)$ has only finitely many reachable positions and finitely many multi-transitions – if $K = \infty$ then all the counter values κ are equal ∞, otherwise the counter values in the reachable positions are at most K.

4.2 Rules of the game $\mathcal{F}$

In this section we describe the rules of the game $\mathcal{F}$. From a position (S, p, κ, r) the players interact constructing a new position (S', p', κ', r') and a multi-transition between the two positions. For this they select a set of edges $e \subseteq S \times (Q^{\mathcal{B}} \times \{safe, reach\})$ and a state $p' \in Q^{\mathcal{A}}$ according to the rules given below. Then $\forall$ chooses an arbitrary multi-transition μ that *respects* (S, p, κ, r), e, *and* p' in the following sense:

- the pre-state of μ is (S, p, κ, r),
- the post-state of μ is (S', p', κ', r'); where $S' = \{s' : (s, s') \in e\}$ consists of the targets of the edges e, κ' is determined by the boldface-decreasing condition, and $r' = r + 1 \mod 3$,
- the edges of μ are e,
- the boldfaced edges $\bar{e}$ of μ can be chosen arbitrarily by $\forall$ subject to condition (2).

Observe that a multi-transition μ that respects (S, p, κ, r), e, and p' is unique but for the choice of the boldfaced edges $\bar{e}$.

Assume that the current position in $\mathcal{F}$ is (S, p, κ, r) and consider the following cases depending on the number of the sub-round r. In all the cases the players construct a multi-transition μ that leads to a post-state (S', p', κ', r'):

(R0) $r = 0$**:** There are two cases. If the *reach* phase is not empty i.e. $S \cap (Q^{\mathcal{B}} \times \{reach\}) \neq \emptyset$, then e contains all the pairs (s, s) for $s \in S$. The second case is when there are no states in the *reach* phase. We call this situation a *flush*. In that case $\forall$ can choose[2] any set $C \subseteq Q^{\mathcal{B}}$ of states q such that

$$(q, safe) \in S \quad \text{and} \quad \kappa(q, safe) > 0 \ . \tag{3}$$

The chosen active states get copied to the *reach* phase thanks to the edge relation defined as: $e = \{(s, s) \mid s \in S\} \cup \big\{\big((q, safe), (q, reach)\big) \mid q \in C\big\}$. In both cases the state $p' = p$ of $\mathcal{A}$ is not changed and $\forall$ chooses μ that respects (S, p, κ, r), e, and p'.

[2] Even if $\forall$ declares $C = \emptyset$, the fact that the *reach* phase was empty implies that we have a *flush*.

(R1) $r = 1$**:** $\exists$ declares: (i) a letter $a \in A$; (ii) a transition $\delta_s = (q, a, q^s_{\mathtt{L}}, q^s_{\mathtt{R}})$ of $\mathcal{B}$, for every $s = (q, z) \in S$; (iii) a transition $\delta = (p, a, p'_{\mathtt{L}}, p'_{\mathtt{R}})$ of $\mathcal{A}$. Then $\forall$ responds by selecting a direction $d \in \{\mathtt{L}, \mathtt{R}\}$. We put $p' = p'_d$, and e contains all the pairs of the form $((q, z), (q^s_d, z))$ for $s = (q, z) \in S$. $\forall$ chooses μ that respects (S, p, κ, r), e, and p'.

(R2) $r = 2$**:** Deterministically, every active state (q, reach) in the *reach* phase with q accepting (i.e. $q \in F$) is moved to the *safe* phase. Formally, for each $(q, z) \in S$, the relation e contains pairs $((q, z), (q, z'))$ such that either: (i) $z = z' = \mathit{safe}$; or (ii) $z = z' = \mathit{reach}$ and $q \notin F$; or (iii) $z = \mathit{reach}$, $z' = \mathit{safe}$, and $q \in F$. The state $p' = p$ of $\mathcal{A}$ is not changed. $\forall$ chooses μ that respects (S, p, κ, r), e, and p'.

If $(s, s') \in e$ we say that s' is a *μ-successor* of s. By the definition of the sub-rounds of the game, we obtain the following fact.

▶ **Fact 6.** *Every active state has between one and two μ-successors. The only case when an active state (q, z) can have two μ-successors is when $r = 0$, $z = \mathit{safe}$, and we have a* flush*.*

4.3 The winning condition of $\mathcal{F}$

Now we will define the winning condition for $\exists$ in $\mathcal{F}$. It will depend on the sequence of multi-transitions $\pi = \mu_0\mu_1 \dots$ that were played in $\mathcal{F}$. We will refer to the pre-state of μ_n as $(S_n, p_n, \kappa_n, r_n)$. Analogously, we will use $(S'_n, p'_n, \kappa'_n, r'_n)$ for the post-state, e_n for the edges, and $\bar{e}_n$ for the boldfaced edges of μ_n, respectively. Since π is a play, $(S'_n, p'_n, \kappa'_n, r'_n) = (S_{n+1}, p_{n+1}, \kappa_{n+1}, r_{n+1})$ and $r_n \equiv n \mod 3$.

A *trace in π* is a sequence $\alpha = s_0, s_1, \dots$ such that $(s_i, s_{i+1}) \in e_i$ of all i. A trace is *boldfaced* if $(s_i, s_{i+1}) \in \bar{e}_i$ for all i. For every $s \in S'_n$ there is a boldfaced trace ending in s, and it is unique due to condition (2); we call it the *boldfaced history of s in π*.

The winning condition will be a boolean combination of three properties of plays. We list them separately as they will be of independent interest in the proof.

W1. Infinitely many times there is a *flush* in the sub-round (R0).
W2. Some boldfaced trace changes phases infinitely many times.
W3. The sequence of states $p_0, p_1, \dots$ of the automaton $\mathcal{A}$ is accepting.
Now we declare a play to be winning for $\exists$ if it satisfies

$$\mathrm{W1} \ \wedge \ (\mathrm{W2} \vee \mathrm{W3}). \tag{4}$$

Note that Condition W2 implies Condition W1 – if some trace in a play changes phases infinitely often then the play must have infinitely many times a *flush*.

Intuitively, Condition W1 expresses that $\exists$ has not stayed forever in the *reach* phase – she has reached an accepting state of $\mathcal{B}$ whenever $\forall$ asked for it.

Condition W2 says that $\forall$ has not succeeded to bound the number of changes of phases; so he has failed to prove that on the constructed tree t he can win in $\mathcal{G}(t, K)$ for some finite K. Condition W3 takes care of the situation when the constructed tree is not in $\mathrm{L}(\mathcal{B})$. One can think of it as an escape option for $\exists$. She uses it when $\forall$ plays very cautiously and gives $\exists$ no chance to construct a trace satisfying Condition W2; an extreme example is when $\forall$ never chooses to move some active states to the *reach* phase.

▶ **Example 7.** Let $\mathcal{B}$ be the Büchi automaton from the example on page 4. Consider an automaton $\mathcal{A}$ accepting the complement of $\mathrm{L}(\mathcal{B})$, namely the set of trees with only finitely many a's on every branch. This automaton is a deterministic co-Büchi automaton having two states: p_a and p_b, with p_a being a rejecting state. So a run of $\mathcal{A}$ will be accepting if on every branch the state p_a appears only finitely often. For a state p_x the transition relation $\delta^{\mathcal{A}}$ on a letter $y \in \{a, b\}$ contains the transition (p_x, y, p_y, p_y).

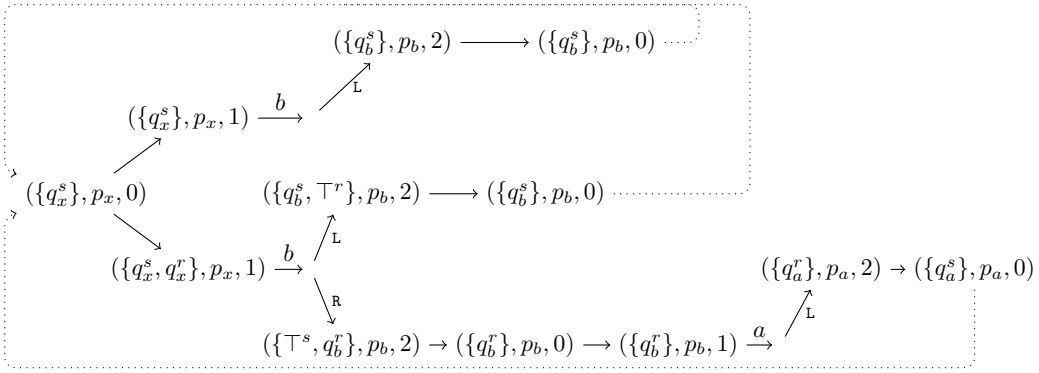

Figure 2 A symbolic representation of a strategy $\sigma_\exists$ of $\exists$. The subscript x in q_x^s or q_x^r stands for a or b. The superscript indicates if a state is in the *safe* phase or in the *reach* phase. Only branches not evidently losing for the player $\forall$ are presented.

We claim that $\exists$ has a winning strategy in $\mathcal{F}(\infty)$ constructed from $\mathcal{B}$ and $\mathcal{A}$. This strategy is schematically presented in Figure 2. For compactness of the notation we omit the third component of the position that is always ∞ and omit active states of the form $(\top, z)$ – it is trivial for $\exists$ to play from them.

The root position is a *flush*, so $\forall$ can choose whether to copy the unique active state to the *reach* phase. If he does not (i.e. he goes up in the picture) then $\exists$ chooses b and plays the transition $(q_x, b, q_b, \top)$. Then it is clear that it is better for $\forall$ to move to the left. The game gets to a similar position as in the root. If $\forall$ constantly chooses to play like this then he will lose as the play will have infinitely many times a *flush* and only states p_b, thus it will satisfy Conditions W1 and W3.

If $\forall$ decides to copy the active state during a *flush* then $\exists$ still chooses b but plays different transitions for the two copies: for the active state in the *safe* phase she chooses $(q_x, b, q_b, \top)$, for the active state in the *reach* phase she chooses $(q_x, b, \top, q_b)$. If $\forall$ chooses the left direction then the play gets to a similar position as in the root. Since there is a *flush*, and $\forall$ does not manage to see a new p_a state, the result is the same as in the case when $\forall$ has not copied the active state. If $\forall$ chooses the right direction then the play reaches a position where the only interesting active state is in the *reach* phase. Then $\exists$ chooses the letter a and the transition $(q_b, a, q_a, \top)$. It is then more interesting for $\forall$ to move to the left. The play reaches a position of the same form as the one in the root. The interesting thing that happens on this path is that the unique boldfaced trace changes phases. So, if $\forall$ chooses infinitely often to copy an active state and then go to the right then the play will satisfy Conditions W1 and W2. Otherwise there will be only finitely many occurrences of the state p_a and $\forall$ will lose since there still will be infinitely many times a *flush*.

We have already noticed that for every $K \in \overline{\omega}$, the game $\mathcal{F}(K)$ is finite. By the definition of Conditions W1, W2, and W3, the winning condition of $\mathcal{F}(K)$ is a regular property of sequences of multi-transitions. By adding multi-transitions of $\mathcal{F}(K)$ to the positions, one can obtain an equivalent game with the winning condition on sequences of positions. So up to presentation, $\mathcal{F}(K)$ is essentially a finite game with a regular winning condition, and we can solve it effectively.

▶ **Fact 8.** *For a fixed $K \in \overline{\omega}$, the winner of $\mathcal{F}(K)$ can be effectively found and he/she can win using a finite memory winning strategy. Let $m_\forall$ be the bound on the size of the memory of $\forall$ needed to win the game $\mathcal{F}(\infty)$.*

5 Characterisation

We show that $\mathcal{F}(\infty)$ characterises when $\mathrm{L}(\mathcal{B})$ is WMSO-definable. This is formulated in the following two propositions that complete the proof of Theorem 1. They rely on the following standard fact, see for instance [24].

▶ **Fact 9.** *If L is a language of a Büchi tree automaton then $L \in \mathbf{\Sigma}^1_1$. If L is a* WMSO*-definable tree language then L is Borel.*

▶ **Proposition 10.** *If $\forall$ wins $\mathcal{F}(\infty)$ then $\mathrm{L}(\mathcal{B})$ is* WMSO*-definable.*

▶ **Proposition 11.** *If $\exists$ wins $\mathcal{F}(\infty)$ then $\mathrm{L}(\mathcal{B})$ is $\mathbf{\Sigma}^1_1$-complete and not* WMSO*-definable.*

In the rest of the section we will outline the proof of Proposition 11. Suppose that $\exists$ wins in $\mathcal{F}(\infty)$. Let us fix a winning strategy $\sigma_\exists$ for $\exists$ in $\mathcal{F}(\infty)$.

We need to prove that $\mathrm{L}(\mathcal{B})$ is $\mathbf{\Sigma}^1_1$-hard, so we will construct an appropriate continuous reduction. Let $\omega\mathrm{Tr}$ denote the space of partial ω-branching trees. Such a tree τ is a non-empty, prefix-closed subset of ω^*. We say that an ω-branching tree τ is *ill-founded* if it contains an infinite branch, i.e. there exists $\alpha \in \omega^\omega$ such that for every $x \prec \alpha$ we have $x \in \tau$. We use IF to denote the set of all ill-founded ω-branching trees. If an ω-branching tree is not ill-founded then it is *well-founded*.

▶ **Fact 12.** IF *is $\mathbf{\Sigma}^1_1$-complete.*

Therefore, it is enough to construct a continuous reduction from IF to $\mathrm{L}(\mathcal{B})$. Our aim is to construct a tree $t(\tau)$ such that $t(\tau) \in \mathrm{L}(\mathcal{B})$ if and only if τ is ill-founded. The tree $t(\tau)$ will be obtained by evaluating the strategy $\sigma_\exists$ against a certain family of strategies of $\forall$, called *τ-genuine strategies*.

Let us explain this point in more detail. A strategy for $\exists$ in $\mathcal{F}(\infty)$ can be seen as a strategy tree where branching represents the choices of $\forall$ (see Figure 2). Recall from the definition of the game that $\forall$ not only chooses directions (in the sub-round (R1)), but also copies active states to the *reach* phase (during a *flush* in the sub-round (R0)), and selects boldfaced edges (in all the sub-rounds). We want to extract from the strategy tree $\sigma_\exists$ a tree where we leave only branching corresponding to the choice of directions. To this end we define τ-genuine strategies of $\forall$, where his choices to copy and to select boldfaced edges are determined by the history of the play so far. This means that a strategy tree for $\exists$ against all τ-genuine strategies of $\forall$ will be a tree with branching corresponding only to the choices of directions by $\forall$. Then we show that we have not restricted the power of $\forall$ too much, namely from this strategy tree for $\exists$ we can read out the required tree $t(\tau)$.

To properly define τ-genuine strategies of $\forall$ we will use the Kleene-Brouwer ordering, see [15, Section 2.G]. For $x, y \in \omega^*$, we say that $x \leq_{\mathrm{KB}} y$ if either: (i) $x \succeq y$, or (ii) for some $n < m < \omega$ and $v, x', y' \in \omega^*$ we have $x = vnx'$ and $y = vmy'$. Intuitively, $x \leq_{\mathrm{KB}} y$ if x is below or to the left of y. ϵ is the $\leq_{\mathrm{KB}}$-maximal element of ω^*. There is no $\leq_{\mathrm{KB}}$-minimal element in ω^*, e.g. for every $x \in \omega^*$ and its 0-successor $x \cdot 0$ we have $x \cdot 0 <_{\mathrm{KB}} x$.

▶ **Fact 13** (See [15, Proposition 2.12])**.** *An ω-branching tree τ is well-founded if and only if $\leq_{\mathrm{KB}}$ is a well-order on the vertices of τ.*

For certain technical reasons it will be useful to have the following construction.

▶ **Definition 14.** First, assume that $\mathrm{list}\colon \omega \to \omega^*$ has the property that for each $x \in \omega^*$, the pre-image $\mathrm{list}^{-1}(\{x\})$ is infinite (i.e. every vertex appears infinitely many times in this enumeration). Now, given $x \in \omega^*$ let $\mathrm{down}(x, n)$ be either $\mathrm{list}(n)$ if $\mathrm{list}(n) <_{\mathrm{KB}} x$ or $x \cdot 0$ otherwise.

▶ **Fact 15.** *The following conditions are satisfied for every $x \in \omega^*$:*

- $\forall_{n\in\omega}\ \mathrm{down}(x,n) <_{\mathrm{KB}} x$,
- *for every $y <_{\mathrm{KB}} x$ there are infinitely many n such that* $\mathrm{down}(x,n) = y$.

Now we can proceed with the definition of τ-genuine strategies. Our aim is to make sure that for every sequence of successive directions $d_0, d_1, \ldots$ played in the sub-rounds (R1), there is a unique τ-genuine strategy of $\forall$. A τ-genuine strategy will depend on certain additional information accumulated during a play, and this information will be related to the ω-branching tree τ. Therefore, $\forall$ will keep track of an *extended position* – a position (S, p, κ, r) of $\mathcal{F}$ together with a mapping $\nu\colon S \to \tau$ and a counter $c \in \omega$. The function ν will measure the progress of every active state with respect to the $\leq_{\mathrm{KB}}$ order over τ. The counter c will count the number of times when a *flush* happened in the play.

The initial extended position of the game is the initial position of $\mathcal{F}(\infty)$ together with ν assigning to $(q_{\mathrm{I}}^{\mathcal{B}}, \mathit{safe})$ the root ϵ of τ; and the counter $c = 0$.

A strategy $\sigma_\forall$ of $\forall$ is called *τ-genuine* if it satisfies the three conditions defined below: *genuine-copying*, *flush-counting*, and *KB-tracking*.

A strategy $\sigma_\forall$ satisfies *genuine-copying* if during a *flush* in the sub-round (R0) it copies an active state s from the *safe* phase to the *reach* phase if and only if $\mathrm{down}(\nu(s), c) \in \tau$.

The condition of *flush-counting* says that $\forall$ increments c by 1 exactly when there is a *flush* in the sub-round (R0); otherwise he keeps the value c unchanged.

The last condition *KB-tracking* determines how the set of boldfaced edges $\bar{e}$ should be chosen and how to update ν. We say that a multi-transition μ from $(S, p, \kappa, r, \nu, c)$ to $(S', p', \kappa', r', \nu', c')$ with edges e and boldfaced edges $\bar{e}$ satisfies the *KB-tracking* condition when:

- If μ is not a *flush* then for every $s' \in S'$:

  $$\nu'(s') = \max_{\leq_{\mathrm{KB}}} \{\nu(s) : (s, s') \in e\}\ .$$

  Moreover, the unique boldfaced edge to s' should come from s_0 realising the maximum above, i.e., $\nu'(s') = \nu(s_0)$ (if there is more than one such s_0 then we choose the smallest one according to some fixed ordering on active states).
- If μ is a *flush* then for every $s' \in S'$ from the *safe* phase, the vertex $\nu'(s')$ of τ and the boldfaced edges are determined as above. For every $s' \in S'$ in the *reach* phase there is a unique $s \in S$ with $(s, s') \in e$. This edge needs to be boldfaced and we set

  $$\nu'(s') = \mathrm{down}(\nu(s), c)\ .$$

Notice that in this last case the node $\mathrm{down}(\nu(s), c)$ is in τ thanks to the *genuine-copying* condition.

▶ **Fact 16.** *Using the above notions, the following inequalities hold:*

- *if $(s, s') \in \bar{e}$ then $\nu(s) \geq_{\mathrm{KB}} \nu'(s')$,*
- *if $(s, s') \in e$ and (s, s') changes phases from safe to reach then $\nu(s) >_{\mathrm{KB}} \nu'(s')$,*
- *if $(s, s') \in e$ and (s, s') does not change phases from safe to reach then $\nu(s) \leq_{\mathrm{KB}} \nu'(s')$.*

▶ **Corollary 17.** *Suppose τ is well-founded. If π is an infinite play of $\mathcal{F}(\infty)$ consistent with a τ-genuine strategy of $\forall$ then π does not satisfy W2 (no boldfaced trace changes phases infinitely many times).*

▶ Remark. Observe that all the choices of $\forall$ except the directions d are uniquely determined in a τ-genuine strategy. Therefore, to define a τ-genuine strategy it is enough to say what will be the directions proposed by $\forall$ in the sub-rounds (R1). For the next definition it is also useful to note that all the maximal plays in $\mathcal{F}(\infty)$ are infinite.

▶ **Definition 18.** For every $\alpha \in \{\mathtt{L},\mathtt{R}\}^\omega$ by $\sigma_{\forall}(\tau,\alpha)$ we denote the unique τ-genuine strategy of $\forall$ that for every $n \in \omega$ plays $d = \alpha(n)$ in the n-th sub-round (R1). Let $\pi(\tau,\alpha)$ be the infinite play of $\mathcal{F}(\infty)$ obtained when $\exists$ is playing $\sigma_{\exists}$ and $\forall$ is playing $\sigma_{\forall}(\tau,\alpha)$.

For every finite prefix $u \prec \alpha$ we denote by $\pi(\tau,u)$ the corresponding prefix of $\pi(\tau,\alpha)$. This play is defined until $\forall$ is asked to determine the $(n{+}1)$-th direction in the sub-round (R1). Let $(S_u, p_u, \kappa_u, r_u, \nu_u, c_u)$ be the extended position of this play at the beginning of the last round (i.e. when $r_u = 0$).

We can finally define the tree $t(\tau)$.

▶ **Definition 19.** We define the tree $t(\tau)$ together with a run $\rho^{\mathcal{A}}(\tau)$ of $\mathcal{A}$. For a vertex $u \in \{\mathtt{L},\mathtt{R}\}^*$, let $t(\tau)(u)$ and $\rho^{\mathcal{A}}(\tau)(u)$ be the letter a and the state p of $\mathcal{A}$ played by $\exists$ in the sub-round (R1) of the last round of the play $\pi(\tau,u)$.

Observe that by the construction, $\rho^{\mathcal{A}}(\tau)$ is a run of $\mathcal{A}$ over $t(\tau)$. Notice also that since the strategy $\sigma_{\forall}(\tau,u)$ queries whether $v \in \tau$ for finitely many v at a time, the function mapping τ to $t(\tau)$ is continuous. We show that indeed the mapping is the required reduction from IF as expressed by the following two lemmas.

▶ **Lemma 20.** *If τ is well-founded then $\rho^{\mathcal{A}}(\tau)$ is accepting and thus $t(\tau) \notin \mathrm{L}(\mathcal{B})$.*

▶ **Lemma 21.** *If τ is ill-founded then $t(\tau) \in \mathrm{L}(\mathcal{B})$.*

Lemma 20 follows from Corollary 17. Consider any infinite branch α of $t(\tau)$ and the corresponding play $\pi(\tau,\alpha)$ of $\sigma_{\exists}$ against $\sigma_{\forall}(\tau,\alpha)$. Since $\sigma_{\exists}$ is winning we know that it satisfies the disjunction W2 $\vee$ W3. By Corollary 17 we know that no play consistent with $\sigma_{\forall}(\tau,\alpha)$ can satisfy Condition W2. Therefore, Condition W3 needs to be satisfied and therefore, the run $\rho^{\mathcal{A}}(\tau)$ is accepting on α.

To prove Lemma 21 we fix an ω-branching ill-founded tree $\tau \in \mathrm{IF}$. We then extract an accepting run $\rho^{\mathcal{B}}$ of $\mathcal{B}$ on $t(\tau)$ from the strategy $\sigma_{\exists}$ in $\mathcal{F}(\infty)$. The crucial point is to make sure that $\forall$ will copy infinitely often the active states of the constructed run to the *reach* phase. For this we need to rely on the condition of *genuine-copying*. Let us now describe how this construction works on our running example.

▶ **Example 22.** Recall the example from page 4 and the winning strategy for $\exists$ from the example on page 7 (see Figure 2). In this strategy $\forall$ has a choice of whether to copy or not the active state q^s_x; this corresponds to going down or up from the root, respectively. Next, $\forall$ chooses a direction. In a τ-genuine strategy a state q^s_x is assigned a node $\nu(q^s_x)$ of τ and c counts the number of flushes. The condition of *genuine-copying* requires $\forall$ to copy the state q^s_x to the *reach* phase if $\mathrm{down}(\nu(q^s_x), c) \in \tau$. Since all loops of $\sigma_{\exists}$ contain a *flush*, the value c counts the number of times either of the loops has been taken.

According to the definition of a τ-genuine strategy, the only moment when the value $\nu(q^s_x)$ may change is when $\forall$ copies (i.e. takes the down successor of the root at Figure 2) and in that case the value $\nu(q^r_x)$ becomes $\mathrm{down}(\nu(q^s_x), c)$ according to the *KB-tracking* condition. This becomes the new value of $\nu(q^s_x)$ if and only if the play then follows the direction $\mathtt{R}$.

If τ is well-founded then there is no infinite $\leq_{\mathrm{KB}}$-descending chain in τ and therefore, for every branch $\alpha \in \{\mathtt{L},\mathtt{R}\}^\omega$, the play $\pi(\tau,\alpha)$ follows only finitely many times the down path of $\sigma_{\exists}$. Therefore, the produced tree $t(\tau)$ contains only finitely many letters a on every branch and $t(\tau) \notin \mathrm{L}(\mathcal{B})$.

Now assume that τ is ill-founded and $v_0 >_{\mathrm{KB}} v_1 >_{\mathrm{KB}} \dots$ is an infinite $\leq_{\mathrm{KB}}$-descending chain of nodes of τ. We will use this sequence to find a branch of $t(\tau)$ that contains infinitely many a's. We start in the root of $t(\tau)$ and keep track of the current vertex $\nu(q^s_x)$ of τ. We will

preserve an invariant that when being in a node $u \in \{\mathtt{L}, \mathtt{R}\}^*$ with n the number of occurrences of a on u in $t(\tau)$ then $\nu(q_x^s) = v_n$ – the vertex of τ pointed to by ν is the n-th vertex in our $\leq_{\mathrm{KB}}$-descending chain. Consider the following two cases:

1. If $\mathrm{down}(\nu(q_x^s), c) = v_{n+1}$ then $\forall$ chooses to copy, i.e., go down from the root. We follow the $\mathtt{R}$-successor in $t(\tau)$. Then $t(\tau)(u\mathtt{R}) = a$ and the game gets to the node $u\mathtt{RL}$. The number of times we have seen an a is incremented (i.e. $n' = n + 1$), and the invariant is preserved since after this loop we have $\nu(q_x^s) = v_{n+1}$.
2. Otherwise either (i) $\mathrm{down}(\nu(q_x^s), c) \notin \tau$ so $\forall$ does not copy, or (ii) $\mathrm{down}(\nu(q_x^s), c) \in \tau$ so $\forall$ copies, but we choose the direction $\mathtt{L}$. In both cases we end up in the left successor of our current node (i.e. in $u\mathtt{L}$). The new value $\nu(q_x^s)$ does not change, neither does n.

Therefore, in both cases the invariant $\nu(q_x^s) = v_n$ is preserved. Since the value of c tends to infinity, Fact 15 tells us that $\mathrm{down}(\nu(q_x^s), c) = v_{n+1}$ will eventually hold, and we will see an a. In the limit, the branch of $t(\tau)$ we follow will have infinitely many letters a.

6 Conclusions

While regular languages of infinite trees are widely used nowadays, their structure is still very poorly understood. The main reason for this is probably the lack of deterministic acceptors for such languages. This paper exhibits a gap property for languages of non-deterministic Büchi tree automata: such a language is either weakly definable, or $\mathbf{\Sigma}^1_1$-complete. Our proof uses a reduction to a finite game. Given a Büchi automaton $\mathcal{B}$, we construct a game $\mathcal{F}(\infty)$ of exponential size w.r.t. $\mathcal{B}$, and with a parity condition of size proportional to the size of $\mathcal{B}$. Thus our reduction gives an EXPTIME decision algorithm. This matches a known lower bound [25].

Abstract

The Continuous Skolem Problem asks whether a real-valued function satisfying a linear differential equation has a zero in a given interval of real numbers. This is a fundamental reachability problem for continuous linear dynamical systems, such as linear hybrid automata and continuous-time Markov chains. Decidability of the problem is currently open – indeed decidability is open even for the sub-problem in which a zero is sought in a bounded interval. In this paper we show decidability of the bounded problem subject to Schanuel's Conjecture, a unifying conjecture in transcendental number theory. We furthermore analyse the unbounded problem in terms of the frequencies of the differential equation, that is, the imaginary parts of the characteristic roots. We show that the unbounded problem can be reduced to the bounded problem if there is at most one rationally linearly independent frequency, or if there are two rationally linearly independent frequencies and all characteristic roots are simple. We complete the picture by showing that decidability of the unbounded problem in the case of two (or more) rationally linearly independent frequencies would entail a major new effectiveness result in Diophantine approximation, namely computability of the Diophantine-approximation types of all real algebraic numbers.

1 Introduction

The Continuous Skolem Problem is a fundamental decision problem concerning reachability in continuous-time linear dynamical systems. The problem asks whether a real-valued function satisfying an ordinary linear differential equation has a zero in a given interval of real numbers. More precisely, an instance of the problem comprises an interval $I \subseteq \mathbb{R}_{\geq 0}$ with rational endpoints, an ordinary differential equation

$$f^{(n)} + a_{n-1}f^{(n-1)} + \ldots + a_0 f = 0 \tag{1}$$

whose coefficients are real algebraic, together with initial conditions $f(0), \ldots, f^{(n-1)}(0)$ that are also real algebraic numbers. Writing $f : \mathbb{R}_{\geq 0} \to \mathbb{R}$ for the unique solution of the

differential equation subject to the initial conditions, the question is whether there exists $t \in I$ such that $f(t) = 0$. Decidability of this problem is currently open. Decidability of the sub-problem in which the interval I is bounded, called the Bounded Continuous Skolem Problem, is also open [4, Open Problem 17].

The nomenclature *Continuous Skolem Problem* is based on an analogy with the Skolem Problem for linear recurrence sequences, which asks whether a given linear recurrence sequence has a zero term [12]. Whether the latter problem is decidable is an outstanding question in number theory and theoretical computer science; see, e.g., the exposition of Tao [20, Section 3.9].

The continuous dynamics of linear hybrid automata and the evolution of continuous-time Markov chains, amongst many other examples, are determined by linear differential equations of the form $\boldsymbol{x}'(t) = A\boldsymbol{x}(t)$, where $\boldsymbol{x}(t) \in \mathbb{R}^n$ and A is an $n \times n$ matrix of real numbers [1]. A basic reachability question in this context is whether, starting from an initial state $\boldsymbol{x}(0)$, the system reaches a given hyperplane $\{\boldsymbol{y} \in \mathbb{R}^n : \boldsymbol{u}^T\boldsymbol{y} = 0\}$ with normal vector $\boldsymbol{u} \in \mathbb{R}^n$. For example, one can ask whether the continuous flow of a hybrid automaton leads to a particular transition guard being satisfied or an invariant being violated. Now the function $f(t) = \boldsymbol{u}^T\boldsymbol{x}(t)$ satisfies a linear differential equation of the form (1), and it turns out that the hyperplane reachability problem is inter-reducible with the Continuous Skolem Problem (see [4, Theorem 6] for further details). Moreover, under this reduction the Bounded Continuous Skolem Problem corresponds to a time-bounded version of the hyperplane reachability problem.

The *characteristic polynomial* of the differential equation (1) is

$$\chi(x) := x^n + a_{n-1}x^{n-1} + \ldots + a_0\,.$$

Let $\lambda_1, \ldots, \lambda_m$ be the distinct roots of χ. Any solution of (1) has the form $f(t) = \sum_{j=1}^{m} P_j(t)e^{\lambda_j t}$, where the P_j are polynomials with algebraic coefficients that are determined by the initial conditions of the differential equation. We call a function f in this form an *exponential polynomial*. If the roots of χ are all simple then f can be written as an exponential polynomial in which the polynomials P_j are all constant.

The Continuous Skolem Problem can equivalently be formulated in terms of whether an exponential polynomial has a zero in a given interval of reals. If the characteristic roots have the form $\lambda_j = r_j + i\omega_j$, where $r_j, \omega_j \in \mathbb{R}$, then we can also write $f(t)$ in the form $f(t) = \sum_{j=1}^{m} e^{r_j t}(Q_{1,j}(t)\sin(\omega_j t) + Q_{2,j}(t)\cos(\omega_j t))$, where the polynomials $Q_{1,j}, Q_{2,j}$ have real algebraic coefficients. We call $\omega_1, \ldots, \omega_m$ the *frequencies* of f.

Our first result is to show decidability of the Bounded Continuous Skolem Problem subject to Schanuel's Conjecture, a unifying conjecture in transcendental number theory that plays a key role in the study of the exponential function over both the real and complex numbers [21, 22]. Intuitively, decidability of the Bounded Continuous Skolem Problem is non-trivial because an exponential polynomial can approach 0 tangentially. Assuming Schanuel's Conjecture, we show that any exponential polynomial admits a factorisation such that the zeros of each factor can be detected using finite-precision numerical computations. Our method, however, does not bound the precision required to find zeros, so we do not obtain a complexity bound for the procedure.

A celebrated paper of Macintyre and Wilkie [18] obtains decidability of the first-order theory of $\mathbb{R}_{\exp} = (\mathbb{R}, 0, 1, <, \cdot, +, \exp)$ assuming Schanuel's Conjecture over $\mathbb{R}$. The proof of [17, Theorem 3.1] mentions an unpublished result of Macintyre and Wilkie that generalises [18] to obtain decidability when $\mathbb{R}_{\exp}$ is augmented with the restricted functions $\sin\restriction_{[0,2\pi]}$ and $\cos\restriction_{[0,2\pi]}$, this time assuming Schanuel's Conjecture over $\mathbb{C}$. This result immediately implies

(conditional) decidability of the Bounded Continuous Skolem Problem. However, decidability of the latter problem is simpler and, as we show below, can be established more directly.

In the unbounded case, we analyse exponential polynomials in terms of the number of rationally linearly independent frequencies. We show that the unbounded problem can be reduced to the bounded problem if there is at most one rationally linearly independent frequency, or if there are two rationally linearly independent frequencies and all characteristic roots are simple. These two reductions are unconditional and rely on the cell decomposition theorem for semi-algebraic sets [3] and Baker's Theorem on linear forms in logarithms of algebraic numbers [2].

In the full version on this paper [7] we complete the picture by showing that decidability of the unbounded problem in the case of two (or more) rationally linearly independent frequencies would entail a major new effectiveness result in Diophantine approximation – namely computability of the Diophantine-approximation types of all real algebraic numbers. As we discuss in [7], currently essentially nothing is known about Diophantine-approximation types of algebraic numbers of degree three or higher, and they are the subject of several longstanding open problems.

The question of deciding whether an exponential polynomial f has infinitely many zeros is investigated in [8]. There the problem is shown to be decidable if f satisfies a differential equation of order at most 7. This result does not rely on Schanuel's Conjecture. It is also shown in [8] that, as with the Continuous Skolem Problem, decidability of the Infinite Zeros Problem in the general case would entail significant new effectiveness results in Diophantine approximation.

2 Mathematical Background

2.1 Zero Finding

Let $f : [a, b] \to \mathbb{R}$ be a function defined on a closed interval of reals with endpoints $a, b \in \mathbb{Q}$. Suppose the following two conditions hold: (i) there exists $M > 0$ such that f is M-Lipschitz, i.e., $|f(s) - f(t)| \leq M|s - t|$ for all $s, t \in [a, b]$; (ii) given $t \in [a, b] \cap \mathbb{Q}$ and positive error bound $\varepsilon \in \mathbb{Q}$, we can compute $q \in \mathbb{Q}$ such that $|f(t) - q| < \varepsilon$. Then given a positive rational number δ we can compute piecewise linear functions $f_\delta^+, f_\delta^- : [a, b] \to \mathbb{R}$ such that $f_\delta^-(t) \leq f(t) \leq f_\delta^+(t)$ and $f_\delta^+(t) - f_\delta^-(t) \leq \delta$ for all $t \in [a, b]$. We do this as follows:

1. Pick $N \in \mathbb{N}$ such that $\frac{1}{N} < \frac{\delta}{4(b-a)M}$ and consider sample points $s_j := a + \frac{(b-a)j}{N}$, $j = 0, \ldots, N$, dividing the interval $[a, b]$ into N sub-intervals, each of length at most $\frac{\delta}{4M}$.
2. For each sample point s_j compute $q_j \in \mathbb{Q}$ such that $|q_j - f(s_j)| < \frac{\delta}{4}$, define $f_\delta^-(s_j) = q_j - \frac{\delta}{2}$, $f_\delta^+(s_j) = q_j + \frac{\delta}{2}$, and extend f_δ^- and f_δ^+ linearly between sample points.

Note that the Lipschitz condition on f ensures that $f_\delta^- \leq f \leq f_\delta^+$.

Now suppose that f satisfies the following additional conditions: (iii) $f(a) \neq 0, f(b) \neq 0$; (iv) for any $t \in (a, b)$ such that $f(t) = 0$, $f'(t)$ exists and is non-zero, i.e., f has no tangential zeros. Then we can decide the existence of a zero of f by computing upper and lower approximations f_δ^+ and f_δ^- for successively smaller values of δ. If $f_\delta^+(t) < 0$ for all t or $f_\delta^-(t) > 0$ for all t then we conclude that f has no zero on $[a, b]$; if $f_\delta^+(s) < 0$ and $f_\delta^-(t) > 0$ for some s, t then we conclude that f has a zero; otherwise we proceed to a smaller value of δ. This procedure terminates since by (iii) and (iv) either f has a zero in $[a, b]$ or it is bounded away from zero.

2.2 Number-Theoretic Algorithms

For the purposes of establishing decidability, we can assume that an instance of the Continuous Skolem Problem is a real-valued exponential polynomial $f(t) = \sum_{j=1}^{m} P_j(t)e^{\lambda_j t}$, where $\lambda_1, \ldots, \lambda_m$ and the coefficients of the polynomials $P_1, \ldots, P_m$ are algebraic, see [4, Theorem 6].

For computational purposes we represent an algebraic number α by a polynomial P with rational coefficients such that $P(\alpha) = 0$, together with a numerical approximation $p + qi$, where $p, q \in \mathbb{Q}$, of sufficient accuracy to distinguish α from the other roots of P [9, Section 4.2.1]. Given this representation we can obtain numerical approximations of α with arbitrary precision [19]

Let K be the extension field of $\mathbb{Q}$ generated by $\lambda_1, \ldots, \lambda_m$ and the coefficients of the polynomials $P_1, \ldots, P_m$. Note that K is closed under complex conjugation. We can compute a primitive element of K, that is, an algebraic number θ such that $K = \mathbb{Q}(\theta)$, together with a representation of each characteristic root λ_j as a polynomial in θ with rational coefficients (see [9, Section 4.5]). From the representation of $\lambda_1, \ldots, \lambda_m$ as elements of $\mathbb{Q}(\theta)$, it is straightforward to determine maximal $\mathbb{Q}$-linearly independent subsets of $\{\mathrm{Re}(\lambda_j) : 1 \leq j \leq m\}$ and $\{\mathrm{Im}(\lambda_j) : 1 \leq j \leq m\}$ (see [14, Section 1]).

Let log denote the branch of the complex logarithm defined by $\log(re^{i\theta}) = \log(r) + i\theta$ for a positive real number r and $0 \leq \theta < 2\pi$. Recall that one can compute $\log z$ and e^z to within arbitrarily small additive error given a sufficiently precise approximation of z [6].

2.3 Laurent Polynomials

Let K be a sub-field of $\mathbb{C}$ that has finite dimension over $\mathbb{Q}$ and is closed under complex conjugation. Fix non-negative integers r and s, and consider a single variable x and tuples of variables $\boldsymbol{y} = \langle y_1, \ldots, y_r \rangle$ and $\boldsymbol{z} = \langle z_1, \ldots, z_s \rangle$. Consider the ring of Laurent polynomials

$$\mathcal{R} := K[x, y_1, y_1^{-1}, \ldots, y_r, y_r^{-1}, z_1, z_1^{-1}, \ldots, z_s, z_s^{-1}]\,,$$

which can be seen as a localisation[1] of the polynomial ring $\mathcal{A} := K[x, y_1, \ldots, y_r, z_1, \ldots, z_s]$ in the multiplicative set generated by the set of variables $\{y_1, \ldots, y_r\} \cup \{z_1, \ldots, z_s\}$. The multiplicative units of $\mathcal{R}$ are the non-zero monomials in variables $y_1, \ldots, y_r$ and $z_1, \ldots, z_s$. As the localisation of a unique factorisation domain, $\mathcal{R}$ is itself a unique factorisation domain [10, Theorem 10.3.7]. From the proof of this fact it moreover easily follows that $\mathcal{R}$ inherits from $\mathcal{A}$ computability of factorisation into irreducibles (e.g., using the algorithm of [16]).

We extend the operation of complex conjugation to a ring automorphism of $\mathcal{R}$ as follows. Given a polynomial

$$P = \sum_{j=1}^{n} a_j x^{u_j} {y_1}^{v_{j1}} \ldots {y_r}^{v_{jr}} {z_1}^{w_{j1}} \ldots {z_s}^{w_{js}}\,,$$

where $a_1, \ldots, a_n \in K$, define its conjugate to be

$$\overline{P} := \sum_{j=1}^{n} \overline{a_j} x^{u_j} {y_1}^{v_{j1}} \ldots {y_r}^{v_{jr}} {z_1}^{-w_{j1}} \ldots {z_s}^{-w_{js}}\,.$$

[1] Recall that the *localisation* of a commutative ring $\mathcal{U}$ in a multiplicatively closed subset S such that $0_{\mathcal{U}} \notin S$ is the ring of formal fractions $\mathcal{U}_S = \{a/s : a \in \mathcal{U}, s \in S\}$, with addition and multiplication defined as usual.

This definition is motivated by thinking of the variables x and $y_1, \ldots, y_r$ as real-valued and the variables $z_1, \ldots, z_s$ as taking values in the unit circle in the complex plane.

We will need the following proposition characterising those polynomials in $P \in \mathcal{R}$ such that P and $\overline{P}$ are associates, i.e., such that $\overline{P}$ is equal to the product of P by a monomial. Here we use pointwise notation for exponentiation: given a tuple of integers $\boldsymbol{u} = \langle u_1, \ldots, u_s \rangle$, we write $\boldsymbol{z}^{\boldsymbol{u}}$ for the monomial $z_1^{u_1} \ldots z_s^{u_s}$. The proof of the proposition can be found in the full version [7].

▶ **Proposition 1.** *Let $P \in \mathcal{R}$ be such that $P = \boldsymbol{z}^{\boldsymbol{u}}\overline{P}$ for $\boldsymbol{u} \in \mathbb{Z}^s$. Then either (i) P has the form $P = \boldsymbol{z}^{\boldsymbol{u}}Q$ for some $Q \in \mathcal{R}$ with $Q = \overline{Q}$, or (ii) there exists $Q \in \mathcal{R}$ such that $P = Q + \boldsymbol{z}^{\boldsymbol{u}}\overline{Q}$ and P does not divide Q in $\mathcal{R}$.*

2.4 Transcendence Theory

We will use transcendence theory in our analysis of both the bounded and unbounded variants of the Continuous Skolem Problem. In the unbounded case we will use the following classical result.

▶ **Theorem 2** (Gelfond-Schneider). *Let a, b be algebraic numbers not equal to 0 or 1. Then for any branch of the logarithm function, $\frac{\log(b)}{\log(a)}$ is either rational or transcendental.*

In fact we will make use of the following corollary, which is obtained by applying Theorem 2 to the algebraic numbers $a = e^{i(\alpha_2 - \alpha_1)}$ and $b = e^{i(\beta_2 - \beta_1)}$.

▶ **Corollary 3.** *Let $\alpha_1 \neq \beta_1$, $\alpha_2 \neq \beta_2$ all lie in $[0, \pi]$ and suppose that $\cos(\alpha_1), \cos(\alpha_2), \cos(\beta_1)$ and $\cos(\beta_2)$ are algebraic. Then $\frac{\beta_2 - \alpha_2}{\beta_1 - \alpha_1}$ is either rational or transcendental.*

Our results in the bounded case depend on Schanuel's conjecture, a unifying conjecture in transcendental number theory [15], which, if true, greatly generalises many of the central results in the field (including the Gelfond-Schneider Theorem, above). Recall that a *transcendence basis* of a field extension L/K is a subset $S \subseteq L$ such that S is algebraically independent over K and L is algebraic over $K(S)$. All transcendence bases of L/K have the same cardinality, which is called the *transcendence degree* of the extension.

▶ **Conjecture 4** (Schanuel's Conjecture [15]). *Let $a_1, \ldots, a_n$ be complex numbers that are linearly independent over $\mathbb{Q}$. Then the field $\mathbb{Q}(a_1, \ldots, a_n, e^{a_1}, \ldots, e^{a_n})$ has transcendence degree at least n over $\mathbb{Q}$.*

A special case of Schanuel's conjecture, that is known to hold unconditionally, is the Lindemann-Weierstrass Theorem [15]: if $a_1, \ldots, a_n$ are algebraic numbers that are linearly independent over $\mathbb{Q}$, then $e^{a_1}, \ldots, e^{a_n}$ are algebraically independent.

We apply Schanuel's conjecture via the following proposition.

▶ **Proposition 5.** *Given non-negative integers r and s, let $\{a_1, \ldots, a_r\}$ and $\{b_1, \ldots, b_s\}$ be $\mathbb{Q}$-linearly independent sets of real algebraic numbers. Furthermore, let $P, Q \in \mathcal{R}$ be two polynomials that have algebraic coefficients and are coprime in $\mathcal{R}$. Then the equations*

$$P(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t}) = 0 \tag{2}$$

$$Q(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t}) = 0 \tag{3}$$

have no non-zero common solution $t \in \mathbb{R}$.

Proof. Consider a solution $t \neq 0$ of Equations (2) and (3). By passing to suitable associates, we may assume without loss of generality that P and Q lie in $\mathcal{A}$, i.e., that all variables in P and Q appear with non-negative exponent. Moreover, since P and Q are coprime in $\mathcal{R}$, their greatest common divisor R in $\mathcal{A}$ is a monomial. In particular,

$$R(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t}) \neq 0\,.$$

Thus, dividing P and Q by R, we may assume that P and Q are coprime in $\mathcal{A}$ and that Equations (2) and (3) still hold.

Since coprime univariate polynomials cannot have a common root, we may assume without loss of generality that $r + s \geq 1$. By Schanuel's conjecture, the extension

$$\mathbb{Q}(a_1 t, \ldots, a_r t, ib_1 t, \ldots, ib_s t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t})/\mathbb{Q}$$

has transcendence degree at least $r + s$. Since $a_1, \ldots, a_r$ and $b_1, \ldots, b_s$ are algebraic over $\mathbb{Q}$, writing

$$S := \langle t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t} \rangle\,,$$

it follows that the extension $\mathbb{Q}(S)/\mathbb{Q}$ also has transcendence degree at least $r + s$.

From Equations (2) and (3) we can regard S as specifying a common root of P and Q. Pick some variable $\sigma \in \{x, y_j, z_j : 1 \leq i \leq r, 1 \leq j \leq s\}$ that has positive degree in P. Then the component of S corresponding to σ is algebraic over the remaining components of S. We claim that the remaining components of S are algebraically dependent and thus S comprises at most $r + s - 1$ algebraically independent elements, contradicting Schanuel's conjecture. The claim clearly holds if σ does not appear in Q. On the other hand, if σ has positive degree in Q then, since P and Q are coprime in $\mathcal{A}$, the multivariate resultant $\mathrm{Res}_\sigma(P, Q)$ is a non-zero polynomial in the set of variables $\{x, y_j, z_j : 1 \leq i \leq r, 1 \leq j \leq s\} \setminus \{\sigma\}$ which has a root at S (see, e.g., [11, Page 163]). Thus the claim also holds in this case. In either case we obtain a contradiction to Schanuel's conjecture and we conclude that Equations (2) and (3) have no non-zero solution $t \in \mathbb{R}$. ◀

3 Decidability of the Bounded Continuous Skolem Problem

Given non-negative integers r and s, suppose that $\{a_1, \ldots, a_r\}$ and $\{ib_1, \ldots, ib_s\}$ are $\mathbb{Q}$-linearly independent sets of real and imaginary numbers respectively. Let the ring of Laurent polynomials $\mathcal{R}$ be as in Section 2.3 and consider the exponential polynomial

$$f(t) = P(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t})\,, \tag{4}$$

where $P \in \mathcal{R}$ is irreducible. We say that f is a *type-1* exponential polynomial if P and $\overline{P}$ are not associates in $\mathcal{R}$, we say that f is *type-2* if $P = \alpha\overline{P}$ for some $\alpha \in K$, and we say that f is *type-3* if $P = U\overline{P}$ for some non-constant unit $U \in \mathcal{R}$.

▶ **Example 6.** The simplest example of a type-3 exponential polynomial is $g(t) = 1 + e^{it}$. Here $g(t) = P(e^{it})$, where $P(z) = 1 + z$ is an irreducible polynomial that is associated with its conjugate $\overline{P}(z) = 1 + z^{-1}$. Note that the exponential polynomial $f(t) = 2 + 2\cos(t)$, which has infinitely many tangential zeros, factors as the product of two type-3 exponential polynomials $f(t) = g(t)\overline{g(t)}$.

In the case of a type-2 exponential polynomial $P = \alpha\overline{P}$ it is clear that we must have $|\alpha| = 1$. Moreover, by replacing P by βP, where $\beta^2 = \overline{\alpha}$, we may assume without loss of

generality that $P = \overline{P}$. Similarly, in the case of a type-3 exponential polynomial, we can assume without loss of generality that $P = \boldsymbol{z}^{\boldsymbol{u}}\overline{P}$ for some non-zero vector $\boldsymbol{u} \in \mathbb{Z}^s$.

Now consider an arbitrary exponential polynomial $f(t) := \sum_{j=1}^{m} P_j(t)e^{\lambda_j t}$. Assume that the coefficient field K of $\mathcal{R}$ contains the coefficients of $P_1, \ldots, P_m$. Let $\{a_1, \ldots, a_r\}$ be a basis of the $\mathbb{Q}$-vector space spanned by $\{\mathrm{Re}(\lambda_j) : 1 \leq j \leq m\}$ and let $\{b_1, \ldots, b_s\}$ be a basis of the the $\mathbb{Q}$-vector space spanned by $\{\mathrm{Im}(\lambda_j) : 1 \leq j \leq m\}$. Without loss of generality we may assume that each characteristic root λ is an integer linear combination of $a_1, \ldots, a_r$ and $ib_1, \ldots, ib_s$. Then $e^{\lambda t}$ is a product of positive and negative powers of $e^{a_1 t}, \ldots, e^{a_r t}$ and $e^{ib_1 t}, \ldots, e^{ib_s t}$, and hence there is a Laurent polynomial $P \in \mathcal{R}$ such that

$$f(t) = P(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t})\,. \tag{5}$$

Since P can be written as a product of irreducible factors in $\mathcal{R}$, it follows that f can be written as product of type-1, type-2, and type-3 exponential polynomials, and moreover this factorisation can be computed from f. Thus it suffices to show how to decide the existence of zeros of these three special forms of exponential polynomial. We will handle all three cases using Schanuel's conjecture.

Writing the exponential polynomial $f(t)$ in (5) in the form $f(t) = \sum_{j=1}^{m} Q_j(t)e^{\lambda_j t}$, it follows from the irreducibility of P that the polynomials $Q_1, \ldots, Q_m$ have no common root. But then by the Lindemann-Weierstrass Theorem any zero of f must be transcendental (see [4, Theorem 8]).

▶ **Theorem 7.** *The Bounded Continuous Skolem Problem is decidable subject to Schanuel's conjecture.*

Proof. Consider an exponential polynomial

$$f(t) = P(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t})\,, \tag{6}$$

where $P \in \mathcal{R}$ is irreducible. Suppose that $\{a_1, \ldots, a_r\}$ and $\{ib_1, \ldots, ib_s\}$ are $\mathbb{Q}$-linearly independent sets of, respectively, real and imaginary numbers lying in the coefficient field K of $\mathcal{R}$. We show how to decide whether f has a zero in a bounded interval $I \subseteq \mathbb{R}_{\geq 0}$, considering separately the case of type-1, type-2, and type-3 exponential polynomials.

Case (i): f is a type-1 exponential polynomial

Note that P and $\overline{P}$ are coprime in $\mathcal{R}$ since, by assumption, they are both irreducible and are not associates. We claim that in this case the equation $f(t) = 0$ has no solution $t \in \mathbb{R}$. Indeed $f(t) = 0$ implies

$$\begin{aligned} P(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t}) &= 0 \\ \overline{P}(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t}) &= 0\,, \end{aligned}$$

and the non-existence of a zero of f follows immediately from Proposition 5.

Case (ii): f is a type-2 exponential polynomial

In this case we have $P = \overline{P}$ and so f is real-valued. Our aim is to use the procedure of Section 2.1 to determine whether or not f has a zero in $[c, d]$, where $c, d \in \mathbb{Q}$. To this end, notice first that $f(c), f(d) \neq 0$ since any root of f must be transcendental. Moreover, since f' is bounded on $[c, d]$, f is Lipschitz on $[c, d]$. It remains to verify that the equations $f(t) = 0, f'(t) = 0$ have no common solution $t \in [c, d]$.

We can write $f'(t)$ in the form

$$f'(t) = Q(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t}),$$

where Q is the polynomial

$$Q = \frac{\partial P}{\partial x} + \sum_{j=1}^{r} a_j y_j \frac{\partial P}{\partial y_j} + \sum_{j=1}^{s} i b_j z_j \frac{\partial P}{\partial z_j}.$$

We claim that P and Q are coprime in $\mathcal{R}$. Indeed, since P is irreducible, P and Q can only fail to be coprime if P divides Q.

If P has strictly positive degree k in x then Q has degree $k-1$ in x and thus P cannot divide Q. (Recall that all polynomials in $\mathcal{R}$ have non-negative degree in the variable x.) On the other hand, if P has degree 0 in x then Q is obtained from P by multiplying each monomial $\boldsymbol{y}^{\boldsymbol{u}}\boldsymbol{z}^{\boldsymbol{v}}$ appearing in P by the complex-number constant $\sum_{j=1}^{r} a_j u_j + i \sum_{j=1}^{s} b_j v_j$. Moreover, by the assumption of linear independence of $\{a_1, \ldots, a_r\}$ and $\{b_1, \ldots, b_s\}$, each monomial in P is multiplied by a different constant. Since P is not a unit, it has at least two different monomials and so P is not a constant multiple of Q. Furthermore, for each variable $\sigma \in \{y_j, y_j^{-1} : 1 \leq j \leq r\} \cup \{z_j, z_j^{-1} : 1 \leq j \leq s\}$, its degree in P is equal to its degree in Q. Thus P cannot be a multiple of Q by a non-constant polynomial either.

We conclude that P does not divide Q and hence P and Q are coprime. It now follows from Proposition 5 that the equations $f(t) = f'(t) = 0$ have no solution $t \in \mathbb{R}$.

Case (iii): f is a type-3 exponential polynomial

Suppose that f is a type-3 exponential polynomial. Then in (6) we have that $P = \boldsymbol{z}^{\boldsymbol{u}}\overline{P}$ for some non-zero vector $\boldsymbol{u} \in \mathbb{Z}^s$. By Proposition 1 we can write $P = Q + \boldsymbol{z}^{\boldsymbol{u}}\overline{Q}$ for some polynomial $Q \in \mathcal{R}$ that is coprime with P.

Now define

$$g_1(t) := Q(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t})$$

and $g_2(t) := e^{ib_1 u_1} \cdots e^{ib_s u_s}\overline{g_1(t)}$, so that $f(t) = g_1(t) + g_2(t)$ for all t.

We show that $g_2(t) \neq 0$ for all $t \in \mathbb{R}$. Indeed if $g_2(t) = 0$ for some t then we also have $g_1(t) = 0$ and hence $f(t) = 0$. For such a t it follows that

$$\begin{aligned} P(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t}) &= 0 \\ Q(t, e^{a_1 t}, \ldots, e^{a_r t}, e^{ib_1 t}, \ldots, e^{ib_s t}) &= 0. \end{aligned}$$

But P and Q are coprime and so these two equations cannot both hold by Proposition 5. Not only do we have $g_2(t) \neq 0$ for all $t \in \mathbb{R}$, but, applying the sampling procedure in Section 2.1 we can compute a strictly positive lower bound on $|g_2(t)|$ over the interval $[c, d]$.

Since $g_2(t) \neq 0$ for all $t \in \mathbb{R}$ we may define the function $h : [c, d] \to \mathbb{R}$ by

$$h(t) := \pi + i \log\left(\frac{g_1(t)}{g_2(t)}\right).$$

Notice that $h(t) = 0$ if and only if $f(t) = 0$. Our aim is to use the procedure of Section 2.1 to decide the existence of a zero of h in the interval $[c, d]$, and thus decide whether f has a zero in $[c, d]$.

Let $t \in (c,d)$ be such that $h(t) = 0$. Then $g_1(t) = -g_2(t)$ and so $\frac{g_1(t)}{g_2(t)} = -1$ does not lie on the branch cut of the logarithm function. It follows that h is differentiable at t and

$$\begin{aligned} h'(t) = 0 \quad &\text{iff} \quad \frac{g_2(t)}{g_1(t)} \frac{g_1'(t)g_2(t) - g_2'(t)g_1(t)}{g_2(t)^2} = 0 \\ &\text{iff} \quad g_1'(t)g_2(t) - g_2'(t)g_1(t) = 0 \quad (\text{since } |g_1(t)| = |g_2(t)| \neq 0) \\ &\text{iff} \quad g_1'(t)g_2(t) + g_2'(t)g_2(t) = 0 \quad (\text{since } g_1(t) = -g_2(t)) \\ &\text{iff} \quad g_1'(t) + g_2'(t) = 0 \\ &\text{iff} \quad f'(t) = 0\,. \end{aligned}$$

Thus $h(t) = h'(t) = 0$ implies $f(t) = f'(t) = 0$. But the proof in Case (ii) shows that $f(t) = f'(t) = 0$ is impossible. (Nothing in that argument hinges on f being real-valued.) Thus h has no tangential zeros in (c,d).

We cannot directly use the procedure in Section 2.1 to decide whether h has a zero in $[c,d]$ since h is not necessarily continuous: its value can jump from $-\pi$ to π (or *vice versa*) due to the branch cut of the logarithm along the positive real axis. However, due to the strictly positive lower bound on $|g_2(t)|$, the function $|h|$ *is* Lipschitz on $[c,d]$. Thus, applying the sampling procedure in Section 2.1 for computing lower and upper bounds of Lipschitz functions we can compute a set $E \subseteq [c,d]$ such that E is a finite union of intervals with rational endpoints, $|f(t)| \leq \frac{2\pi}{3}$ for $t \in E$, and $|f(t)| \geq \frac{\pi}{3}$ for $t \notin E$. In particular, E contains all zeros of f in $[c,d]$ and f is Lipschitz on E. Thus we can apply the zero-finding procedure from Section 2.1 to the restriction $h \restriction E$ and thereby decide whether h has a zero on $[c,d]$. ◀

4 The Unbounded Case

In this section we consider the unbounded case of the Continuous Skolem Problem. For our analysis it is convenient to present exponential polynomials in the form

$$f(t) = \sum_{j=1}^{n} e^{r_j t} \left(P_{1,j}(t)\cos(\omega_j t) + P_{2,j}(t)\sin(\omega_j t)\right)\,, \tag{7}$$

where r_j, ω_j are real algebraic numbers and $P_{1,j}, P_{2,j}$ are polynomials with real algebraic coefficients for $j = 1, \ldots, n$. Our aim is to classify the difficulty of the problem in terms of the number of rationally linear independent frequencies $\omega_1, \ldots, \omega_n$.

Recall that in Section 3 we have shown the bounded problem to be decidable subject to Schanuel's Conjecture. In the full version of this paper [7] we give a reduction of the unbounded problem to the bounded problem in case the set of frequencies spans a one-dimensional vector space over $\mathbb{Q}$. In the present section we give a reduction of the unbounded problem to the bounded problem in case the set of frequencies spans a two-dimensional vector space over $\mathbb{Q}$ and the polynomials $P_{1,j}$ and $P_{2,j}$ are all constant. (This last condition is equivalent to the assumption that $f(t)$ is simple.) The argument in the two-dimensional case is a more sophisticated version of that in the one-dimensional case, although the result is not more general due the assumption of simplicity.

In the full version [7] we present a family of instances showing that obtaining decidability of the unbounded problem in the two-dimensional case without the assumption of simplicity would require much finer Diophantine-approximation bounds than are currently known.

4.1 Background on Semi-Algebraic Sets

A subset of $\mathbb{R}^n$ is *semi-algebraic* if it is defined by a Boolean combination of constraints of the form $P(x_1, \ldots, x_n) > 0$, where P is a polynomial with real algebraic coefficients. A partial function $f : \mathbb{R}^n \to \mathbb{R}$ is semi-algebraic if its graph is a semi-algebraic subset of $\mathbb{R}^{n+1}$. The Tarski-Seidenberg Theorem [5, Section 1] states that the semi-algebraic sets are closed under projection and are therefore precisely the first-order definable sets over the structure $(\mathbb{R}, <, +, \cdot, 0, 1)$.

Let $(i_1, \ldots, i_n)$ be a sequence of zeros and ones of length $n \geq 1$. An $(i_1, \ldots, i_n)$-*cell* is a subset of $\mathbb{R}^n$, defined by induction on n as follows:

(i) A (0)-cell is a singleton subset of $\mathbb{R}$ and a (1)-cell is an open interval $(a, b) \subseteq \mathbb{R}$.

(ii) Let $X \subseteq \mathbb{R}^n$ be a $(i_1, \ldots, i_n)$-cell and $f : X \to \mathbb{R}$ a continuous semi-algebraic function. Then $\{(\boldsymbol{x}, f(\boldsymbol{x})) \in \mathbb{R}^{n+1} : \boldsymbol{x} \in X\}$ is a $(i_1, \ldots, i_n, 0)$-cell, while $\{(\boldsymbol{x}, y) \in \mathbb{R}^{n+1} : \boldsymbol{x} \in X \wedge y < f(\boldsymbol{x})\}$ and $\{(\boldsymbol{x}, y) \in \mathbb{R}^{n+1} : \boldsymbol{x} \in X \wedge y > f(\boldsymbol{x})\}$ are both $(i_1, \ldots, i_n, 1)$-cells.

(iii) Let $X \subseteq \mathbb{R}^n$ be a $(i_1, \ldots, i_n)$-cell and $f, g : X \to \mathbb{R}$ continuous semi-algebraic functions such that $f(\boldsymbol{x}) < g(\boldsymbol{x})$ for all $\boldsymbol{x} \in X$. Then $\{(\boldsymbol{x}, y) \in \mathbb{R}^{n+1} : f(\boldsymbol{x}) < y < g(\boldsymbol{x})\}$ is a $(i_1, \ldots, i_n, 1)$-cell.

A cell in $\mathbb{R}^n$ is a $(i_1, \ldots, i_n)$-cell for some (necessarily unique) sequence $(i_1, \ldots, i_n)$.

A fundamental result about semi-algebraic sets, that we will use below, is the Cell-Decomposition Theorem [3]: given a semi-algebraic set $E \subseteq \mathbb{R}^n$ one can compute a partition of E as a disjoint union of cells $E = C_1 \cup \ldots \cup C_m$.

We will also need the following result, proved in [7].

▶ **Lemma 8.** *Let $D \subseteq \mathbb{R}^n$ be a semi-algebraic set, $g : D \to \mathbb{R}$ a bounded semi-algebraic function, and $r_1, \ldots, r_n$ real algebraic numbers. Define $S = \{t \in \mathbb{R}_{\geq 0} : (e^{r_1 t}, \ldots, e^{r_n t}) \in D\}$. Then*

1. *It is decidable whether or not S is bounded. If S is bounded then we can compute $T_0 \in \mathbb{N}$ such that $S \subseteq [0, T_0]$ and if S is unbounded then we can compute $T_0 \in \mathbb{N}$ such that $(T_0, \infty) \subseteq S$.*
2. *If S is unbounded then the limit $g^* = \lim_{t \to \infty} g(e^{r_1 t}, \ldots, e^{r_n t})$ exists, is an algebraic number, and there are effective constants $T_1, \varepsilon > 0$ such that $|g(e^{r_1 t}, \ldots, e^{r_n t}) - g^*| < e^{-\varepsilon t}$ for all $t > T_1$.*

4.2 Two Linearly Independent Frequencies

The following lemma, which is a reformulation of [4, Lemma 13], plays an instrumental role in this section. The lemma itself relies on a powerful quantitative result in transcendence theory – Baker's Theorem on linear forms in logarithms of algebraic numbers [2].

▶ **Lemma 9.** *Let b_1, b_2 be real algebraic numbers, linearly independent over $\mathbb{Q}$. Furthermore, let φ_1, φ_2 be real numbers such that $e^{i\varphi_1}$ and $e^{i\varphi_2}$ are algebraic. Then there exist effectively computable constants $N, T > 0$ such that for all $t \geq T$ and all $k_1, k_2 \in \mathbb{Z}$, at least one of $|b_1 t - \varphi_1 - 2k_1\pi| > 1/t^N$ and $|b_2 t - \varphi_2 - 2k_2\pi| > 1/t^N$ holds.*

The main result of the section is the following.

▶ **Theorem 10.** *Let $f(t) = \sum_{j=1}^{n} e^{r_j t} \left(a_{1,j} \cos(\omega_j t) + a_{2,j} \sin(\omega_j t)\right)$ be an exponential polynomial where $r_j, a_{1,j}, a_{2,j}, \omega_j$ are real algebraic numbers and the $\mathbb{Q}$-span of $\{\omega_1, \ldots, \omega_n\}$ has dimension two as a $\mathbb{Q}$-vector space. Then we can decide whether or not $\{t \in \mathbb{R}_{\geq 0} : f(t) = 0\}$ is bounded and, if bounded, we can compute an integer T such that $\{t \in \mathbb{R}_{\geq 0} : f(t) = 0\} \subseteq [0, T]$.*

Proof. Let b_1, b_2 be real algebraic numbers, linearly independent over $\mathbb{Q}$, such that ω_j is an integer linear combination of b_1 and b_2 for $j = 1, \dots, n$. For each $n \in \mathbb{Z}$, $\sin(nb_1t)$ and $\cos(nb_1t)$ can be written as polynomials in $\sin(b_1t)$ and $\cos(b_1t)$ with integer coefficients, and similarly for b_2. It follows that we can write f in the form

$$f(t) = Q(e^{r_1 t}, \dots, e^{r_n t}, \cos(b_1 t), \sin(b_1 t), \cos(b_2 t), \sin(b_2 t))$$

for some polynomial Q with real algebraic coefficients that is computable from f.

Write $R_{++} = \{t \geq 0 : \sin(b_1t) \geq 0 \wedge \sin(b_2t) \geq 0\}$, $R_{+-} = \{t \geq 0 : \sin(b_1t) \geq 0 \wedge \sin(b_2t) \leq 0\}$, and likewise define R_{-+}, R_{--} for the two remaining sign conditions on $\sin(b_1t)$ and $\sin(b_2t)$. We show how to decide boundedness of $\{t \in R_{++} : f(t) = 0\}$. (The cases for R_{+-}, R_{-+}, and R_{--} follow *mutatis mutandis*.) The idea is to compute a partition of $\{t \in R_{++} : f(t) = 0\}$ into components $Z_1, \dots, Z_m$ and to separately decide boundedness of each component Z_j.

Define a semi-algebraic set

$$E = \left\{(\boldsymbol{u}, x_1, x_2) \in \mathbb{R}^{n+2} : \exists y_1, y_2 \geq 0 \left(x_1^2 + y_1^2 = x_2^2 + y_2^2 = 1 \wedge Q(\boldsymbol{u}, x_1, y_1, x_2, y_2) = 0\right)\right\}.$$

Then for $t \in R_{++}$ we have $f(t) = 0$ if and only if $(e^{\boldsymbol{r}t}, \cos(b_1t), \cos(b_2t)) \in E$, where $\boldsymbol{r} = (r_1, \dots, r_n)$. Now consider a cell decomposition $E = C_1 \cup \dots \cup C_m$ for cells $C_1, \dots, C_m \subseteq \mathbb{R}^{n+2}$, and define

$$Z_j = \{t \in R_{++} : (e^{\boldsymbol{r}t}, \cos(b_1t), \cos(b_2t)) \in C_j\}, \qquad j = 1, \dots, m, \tag{8}$$

Then $\{t \in R_{++} : f(t) = 0\} = Z_1 \cup \dots \cup Z_m$.

Now fix $j \in \{1, \dots, m\}$. We show how to decide boundedness of Z_j. To this end, write $D_j \subseteq \mathbb{R}^n$ for the projection of the corresponding cell $C_j \subseteq \mathbb{R}^{n+2}$ on the first n coordinates.

First suppose that $\{t \in \mathbb{R} : e^{\boldsymbol{r}t} \in D_j\}$ is bounded. Then by Lemma 8 we can compute an upper bound T of this set. But $Z_j \subseteq \{t \in \mathbb{R}_{\geq 0} : e^{\boldsymbol{r}t} \in D_j\}$ and so $Z_j \subseteq [0, T]$.

On the other hand, suppose that $\{t \in \mathbb{R} : e^{\boldsymbol{r}t} \in D_j\}$ is unbounded. Then, by Lemma 8, this set contains an unbounded interval (T, ∞) for some $T \in \mathbb{N}$. Write $I = [-1, 1]$ and define functions $g_1, g_2, h_1, h_2 : D_j \to \mathbb{R}$ by

$$g_1(\boldsymbol{u}) = \inf\{x \in I : \exists y\, (\boldsymbol{u}, x, y) \in C_j\} \qquad g_2(\boldsymbol{u}) = \inf\{y \in I : \exists x\, (\boldsymbol{u}, x, y) \in C_j\} \tag{9}$$

$$h_1(\boldsymbol{u}) = \sup\{x \in I : \exists y\, (\boldsymbol{u}, x, y) \in C_j\} \qquad h_2(\boldsymbol{u}) = \sup\{y \in I : \exists x\, (\boldsymbol{u}, x, y) \in C_j\} \tag{10}$$

These functions are all semi-algebraic by quantifier elimination. Hence by Lemma 8 the limits $g_i^* = \lim_{t\to\infty} g_i(e^{\boldsymbol{r}t})$ and $h_i^* = \lim_{t\to\infty} h_i(e^{\boldsymbol{r}t})$ exist for $i = 1, 2$ and are algebraic numbers. Clearly we have $g_1^* \leq h_1^*$ and $g_2^* \leq h_2^*$. We now consider three cases according to the strictness of these inequalities.

Case I: $g_1^* = h_1^*$ and $g_2^* = h_2^*$

We show that Z_j is bounded and that we can compute T_2 such that $Z_j \subseteq [0, T_2]$.

By Lemma 8 there exist $T_1, \varepsilon > 0$ such that for all $t > T_1$ and $i = 1, 2$,

$$|g_i(e^{\boldsymbol{r}t}) - g_i^*| < e^{-\varepsilon t} \text{ and } |h_i(e^{\boldsymbol{r}t}) - h_i^*| < e^{-\varepsilon t}. \tag{11}$$

Then for $t \in R_{++}$ such that $t > T_1$ we have

$$\begin{aligned} t \in Z_j &\iff \left(e^{\boldsymbol{r}t}, \cos(b_1t), \cos(b_2t)\right) \in C_j \quad \text{(by (8))} \\ &\implies g_1(e^{\boldsymbol{r}t}) \leq \cos(b_1t) \leq h_1(e^{\boldsymbol{r}t}) \text{ and } g_2(e^{\boldsymbol{r}t}) \leq \cos(b_2t) \leq h_2(e^{\boldsymbol{r}t}) \quad \text{(by (9)(10))} \\ &\implies |\cos(b_1t) - g_1^*| < e^{-\varepsilon t} \text{ and } |\cos(b_2t) - g_2^*| < e^{-\varepsilon t} \quad \text{(by (11))} \end{aligned} \tag{12}$$

Write $g_1^* = \cos(\varphi_1)$ and $g_2^* = \cos(\varphi_2)$ for some $\varphi_1, \varphi_2 \in [0, \pi]$. Since $|\cos(\varphi_1 + x) - \cos(\varphi_1)| \geq x^3/3$ for all x sufficiently small (by a Taylor expansion), the inequality (12) implies that for some $k_1, k_2 \in \mathbb{Z}$,

$$|b_1 t - \varphi_1 - 2k_1\pi| < 3e^{-\varepsilon t/3} \text{ and } |b_2 t - \varphi_2 - 2k_2\pi| < 3e^{-\varepsilon t/3}\,. \tag{13}$$

Combining the upper bounds in (13) with the polynomial lower bounds $|b_1 t - \varphi_1 - 2k_1\pi| > 1/t^N$ and $|b_2 t - \varphi_2 - 2k_2\pi| > 1/t^N$ from Lemma 9 we obtain an effective bound T_2 for which $t \in Z_j$ implies $t < T_2$.

Case II: $g_1^* < h_1^*$

In this case we show that Z_j is unbounded. The geometric intuition is as follows. We imagine a particle in the plane whose position at time t is $(\cos(b_1 t), \cos(b_2 t))$, together with a "moving target" whose extent at time t is $\Gamma_t = \{(x, y) : (e^{\boldsymbol{r}t}, x, y) \in C_j\}$. Below we essentially argue that such a particle is bound to hit Γ_t at some time t since its orbit is dense in $[-1, +1]^2$ and Γ_t has positive dimension in the limit.

Proceeding formally, first notice that C_j cannot be a $(\ldots, 0, 1)$-cell or a $(\ldots, 0, 0)$-cell, for then we would have $g_1(\boldsymbol{u}) = h_1(\boldsymbol{u})$ for all $\boldsymbol{u} \in D_j$ and hence $g_1^* = h_1^*$. Thus C_j must either be a $(\ldots, 1, 0)$-cell or a $(\ldots, 1, 1)$-cell. In either case, C_j includes a cell of the form $\{(\boldsymbol{u}, x, \xi(\boldsymbol{u}, x)) : \boldsymbol{u} \in D, g_1(\boldsymbol{u}) < x < h_1(\boldsymbol{u})\}$ for some semi-algebraic function ξ.

Let c, d be real algebraic numbers such that $g_1^* < c < d < h_1^*$. Write $c = \cos(\psi')$ and $d = \cos(\psi)$ for $0 \leq \psi < \psi' \leq \pi$. By Lemma 8 the limits $\lim_{t\to\infty} \xi(e^{\boldsymbol{r}t}, c)$ and $\lim_{t\to\infty} \xi(e^{\boldsymbol{r}t}, d)$ exist and are algebraic numbers in the interval $[-1, 1]$. Let $\theta, \theta' \in [0, \pi]$ be such that $\cos(\theta) = \lim_{t\to\infty} \xi(e^{\boldsymbol{r}t}, d)$ and $\cos(\theta') = \lim_{t\to\infty} \xi(e^{\boldsymbol{r}t}, c)$.

By Corollary 3 we know that $\frac{\theta'-\theta}{\psi'-\psi}$ is either rational or transcendental. In particular we know that it is not equal to $\frac{b_2}{b_1}$, which is algebraic and irrational. Let us suppose that $\frac{\theta'-\theta}{\psi'-\psi} > \frac{b_2}{b_1}$ (the converse case is almost identical). Then there exists θ'' with $\theta < \theta'' < \theta'$, such that

$$\theta < \theta'' + \frac{b_2}{b_1}(\psi' - \psi) < \theta'\,. \tag{14}$$

Since $2\pi, b_1, b_2$ are linearly independent over $\mathbb{Q}$ it follows from Kronecker's approximation theorem that $\{(b_1 t, b_2 t) \bmod 2\pi : t \in \mathbb{R}_{\geq 0}\}$ is dense in $[0, 2\pi)^2$ (see [13, Chapter 23]). Thus there is an increasing sequence $t_1 < t_2 < \ldots$, with $b_1 t_n \equiv \psi \bmod 2\pi$ for all n, such that $b_2 t_n \bmod 2\pi$ converges to θ''. Then, defining $s_1 < s_2 < \ldots$ by $s_n = t_n + \frac{\psi'-\psi}{b_1}$, we have $b_1 s_n \equiv \psi' \bmod 2\pi$ for all n and, by (14),

$$\lim_{n\to\infty} b_2 s_n = \lim_{n\to\infty} b_2 t_n + \frac{b_2}{b_1}(\psi' - \psi) = \theta'' + \frac{b_2}{b_1}(\psi' - \psi) < \theta' \pmod{2\pi}\,.$$

Let $\eta(t) = \xi(e^{\boldsymbol{r}t}, \cos(b_1 t)) - \cos(b_2 t)$. Then for $t \in R_{++}$ such that $g(e^{\boldsymbol{r}t}) < \cos(b_1 t) < h(e^{\boldsymbol{r}t})$,

$$\begin{aligned} \eta(t) = 0 &\implies \cos(b_2 t) = \xi(e^{\boldsymbol{r}t}, \cos(b_1 t)) \\ &\implies (e^{\boldsymbol{r}t}, \cos(b_1 t), \cos(b_2 t)) \in C_j \\ &\implies t \in Z_j \text{ (by (8))}\,. \end{aligned}$$

Now $\lim_{n\to\infty} \eta(t_n) = \cos(\theta) - \cos(\theta'') > 0$ and $\lim_{n\to\infty} \eta(s_n) < \cos(\theta') - \cos(\theta') = 0$. Moreover for n sufficiently large we have $[t_n, s_n] \subseteq R_{++}$. It follows that $\eta(t)$ has a zero in every interval $[t_n, s_n]$ for n large enough. We conclude that Z_j is unbounded.

Case III: $g_2^* < h_2^*$

This case is symmetric to Case II and we omit details. ◀

Abstract

In 2007, Abdulla *et al.* introduced the elegant concept of decisive Markov chain. Intuitively, decisiveness allows one to lift the good properties of finite Markov chains to infinite Markov chains. For instance, the approximate quantitative reachability problem can be solved for decisive Markov chains (enjoying reasonable effectiveness assumptions) including probabilistic lossy channel systems and probabilistic vector addition systems with states. In this paper, we extend the concept of decisiveness to more general stochastic processes. This extension is non trivial as we consider stochastic processes with a potentially continuous set of states and uncountable branching (common features of real-time stochastic processes). This allows us to obtain decidability results for both qualitative and quantitative verification problems on some classes of real-time stochastic processes, including generalized semi-Markov processes and stochastic timed automata.

1 Introduction

Given its success for finite-state systems, the model checking approach to verification has been extended to various models based on automata, and including features such as time, probability and infinite data structures. Such models allow one to represent software systems more faithfully, and at the same time, they offer the possibility to consider *quantitative* verification questions. Such problems become particularly hard to solve for infinite-state systems, often requiring the development of dedicated techniques for each class of systems.

A decade ago, Abdulla *et al.* introduced the concept of decisiveness for denumerable Markov chains [2]. A Markov chain is decisive w.r.t. a set of states F if runs almost-surely reach F or a state from which F can no longer be reached. The concept of decisiveness rules out some weird behaviours in denumerable Markov chains, and lifts most good properties of finite Markov chains to infinite Markov chains. In particular, it enables the quantitative model checking of (repeated) reachability properties, by providing an approximation scheme, which is guaranteed to terminate for decisive Markov chains. Decisiveness also elegantly subsumes other concepts such as the existence of finite attractors, or coarseness [2].

Dense time required for representing real-time systems, is a potential source of infinity. However, stochastic real-time systems cannot be handled by the theory of decisive Markov chains, as both the state space and the branching are in general non-denumerable. The general philosophy for models with dense time is to design an abstraction that preserves some properties of the original model, and is amenable to efficient model checking techniques. A prominent example of such abstractions is the region graph for timed automata [4]. However, abstractions often do not preserve quantitative properties, and they may be too coarse already for the evaluation of the probability of properties as simple as reachability properties.

In this paper, we generalize the concept of decisiveness to arbitrary stochastic systems, thus including the ones generated by real-time stochastic systems. While stochastic systems are often viewed operational in the model checking community (that is, one considers executions of a system), we take here a more abstract point-of-view, and consider the general mathematical model of stochastic processes.

Our first contribution is to define a notion of decisiveness for stochastic processes, generalizing the concept introduced by Abdulla *et al.* for denumerable Markov chains. This generalization is non trivial as we consider stochastic processes with a potentially continuous state space and uncountable branching, both being common features for modelling real-time stochastic processes. Moreover, in order to discriminate which verification techniques are sound, we refine the notion of decisiveness in three variants.

Our second contribution concerns the qualitative model checking of reachability and repeated reachability properties. We show that, under some decisiveness assumption, the almost-sure model checking of (repeated) reachability properties reduces to a simpler problem, namely to a reachability problem with probability 0. We advocate that this reduction simplifies the problem: in countable models, the 0-reachability amounts to the non existence of a path, in the underlying non-probabilistic system; beyond countable models, checking that a reachability property is satisfied with 0 probability amounts to exhibiting a somehow regular set of executions with positive measure.

A third contribution concerns quantitative model checking, here again for (repeated) reachability properties. Under some further decisiveness assumption, we prove that an approximation scheme, inspired from the path enumeration algorithm [17], is guaranteed to terminate. One can thus approximate, up to a desired precision, the probability of (repeated) reachability properties.

We then realize that non-Zeno real-time stochastic processes have good decisiveness properties when focusing on time-bounded reachability properties, which enables the evaluation of such properties within arbitrary precision.

Last, but not least, we introduce a generic notion of abstraction and explain how to derive decisiveness of the concrete model, using similar properties on the abstraction. We instantiate our framework with generalized semi-Markov processes (GSMP) and stochastic timed automata (STA), two models combining dense-time and probabilities. While the decidability of the qualitative model-checking was already known for STA [9], the current approach yields general approximation results for the quantitative model-checking, which were not known before.

2 Preliminaries

2.1 Stochastic processes

Let $(\Omega, \Sigma, \mathbb{P})$ be a probabilistic space, that is, Ω is a set called the *universe*, Σ is a σ-algebra, and $\mathbb{P}$ is a probability measure over (Ω, Σ). Let (S, Σ') be a measurable space. A *stochastic*

process over $(\Omega, \Sigma, \mathbb{P})$ and (S, Σ') is a sequence $X = (X_i)_{i\geq 0}$ of random variables, where $X_i \colon \Omega \to S$ is a measurable function. Note that we do not assume stochastic processes are homogeneous or discrete.

Let $X = (X_i)_{i\geq 0}$ be a stochastic process. Given B a measurable set of S (that is, $B \in \Sigma'$), we will abuse notation and write B for the *uniform* sequence $(B_i)_{i\in\mathbb{N}}$ such that $B_i = B$ for every $i \geq 0$. Given B a measurable set of S, we will sometimes write $X_i \in B$ for the event $X_i^{-1}(B)$, and when B is a singleton $\{q\}$, we might even write $X_i = q$.

We fix for the rest of the paper a universe $(\Omega, \Sigma, \mathbb{P})$, and a measurable space (S, Σ').

▶ **Example 1.** Let us give an example of a discrete stochastic process representing a random walk over the state space $S = \{q_n \mid n \in \{-1\} \cup \mathbb{N}\}$. The stochastic process X is defined by

- $\mathbb{P}(X_0^{-1}(q_0)) = 1; \quad \forall i \geq 0\ \mathbb{P}(X_{i+1}^{-1}(q_{-1}) \mid X_i^{-1}(q_{-1})) = 1;$
- $\forall i \geq 0,\ \forall n \in \mathbb{N}\ \mathbb{P}(X_{i+1}^{-1}(q_{n+1}) \mid X_i^{-1}(q_n))) = \frac{3}{4}$ and $\mathbb{P}(X_{i+1}^{-1}(q_{n-1}) \mid X_i^{-1}(q_n))) = \frac{1}{4}$.

It should be noted that we do not mention the universe Ω. It is always possible to construct a universe that has such a probability measure $\mathbb{P}$, so that it is irrelevant to introduce it (see [14]). This remark holds true in each example of the paper.

▶ **Example 2.** Another example, is the following non-Markovian stochastic process X over the state space $S = \{q_0, q_0', q_1, q_1'\}$:

- $\mathbb{P}(X_0 = q_0) = \mathbb{P}(X_0 = q_0') = \frac{1}{2}; \quad \forall i \geq 1,\ \mathbb{P}(X_i = q_1' \mid X_0 = q_0') = 1;$
- $\mathbb{P}(X_1 = q_1 \mid X_0 = q_0) = \lambda_1$ and $\mathbb{P}(X_1 = q_1' \mid X_0 = q_0) = 1 - \lambda_1;$
- $\forall i \geq 1,\ \mathbb{P}(X_{i+1} = q_1 \mid X_i = q_1, X_0 = q_0) = \mathbb{P}(X_{i+1} = q_1 \mid X_i = q_1', X_0 = q_0) = \lambda_i;$
- $\forall i \geq 1,\ \mathbb{P}(X_{i+1} = q_1' \mid X_i = q_1, X_0 = q_0) = \mathbb{P}(X_{i+1} = q_1' \mid X_i = q_1', X_0 = q_0) = 1 - \lambda_i;$

where $(\lambda_i)_{i\in\mathbb{N}}$ is a sequence of reals in $[0, 1]$. Note that X could be made Markovian by changing the state space, with one bit of memory to remember the initial state.

Real-time stochastic processes. A particular class of stochastic processes will be of interest to us, namely real-time stochastic processes, in which the time evolution is important. We define (S_t, Σ_t) as the measurable space defined by $S_t = S \times \mathbb{R}_+$, and where Σ_t is the σ-algebra generated by Σ' and the Borel sets of $\mathbb{R}_+$ (denoted $\mathcal{B}(\mathbb{R}_+)$). A *real-time stochastic process* over (S, Σ) is a stochastic process $Z = (Z_i)_{i\geq 0}$ over (S_t, Σ_t) such that:

- for every $i \geq 0$, $Z_i = (X_i, \tau_i)$, where $X_i \colon \Omega \to S$ and $\tau_i \colon \Omega \to \mathbb{R}_+$ are random variables;
- for each $i \geq 0$, $\mathbb{P}\big(\{\omega \in \Omega \mid \tau_i(\omega) < \tau_{i+1}(\omega)\}\big) = 1$.

The process $X = (X_i)_{i\geq 0}$ somehow represents the spatial behaviour of the system, while the process $\tau = (\tau_i)_{i\geq 0}$ gives the time evolution of the system. The second condition ensures that time almost-surely progresses. We will say that Z is *almost-surely non-Zeno* whenever

$$\mathbb{P}\big(\{\omega \in \Omega \mid (\tau_i(\omega))_{i\geq 0} \text{ is bounded}\}\big) = 0.$$

In Section 5.3, we will see two classes of models that naturally fit into the framework of real-time stochastic processes. We can already mention here continuous-time Markov chains (we can find many examples of applications in [15]), or queuing systems (see below).

▶ **Example 3.** We consider a G/G/1-queue (of infinite capacity). A state of such a queue consists in the number of tasks waiting in the queue, the time delay since the last arrival in the queue (t_a) and the time delay since the last execution (t_e). Task arrivals follow a probability measure F_a, and task services are performed according to probability measure F_e. If at some point, the process is in state (n, t_a, t_e), the next arrival time in the queue is chosen according to $F_{a|t_a}$ and the next execution time is chosen according to $F_{e|t_e}$ where $F_{a|t_a}$ (resp. $F_{e|t_e}$) corresponds to the probability F_a (resp. F_e) given that at least t_a (resp.

t_e) has elapsed. This induces a stochastic process $X = (X_i)_{i\in\mathbb{N}}$ where X_i is the state of the queue after i steps. To turn it into a real-time stochastic process, one simply adds global time τ giving at step i the amount of time spent since the beginning.

▶ Remark. Real-time stochastic processes as defined above are *discrete-time* stochastic processes (if we follow standard vocabulary), since the random variables are indexed by $\mathbb{N}$. However they abstract real-time continuous behaviours by giving relevant snapshots of the system (at all times given by the τ_i's). Such abstractions are used for instance in [18, Theorem 1] for abstracting continuous-space pure jump Markov processes while keeping relevant information on the process. We will see in Section 5.3 that these processes capture behaviours of intrinsically time continuous systems.

Events. A stochastic process X over $(\Omega, \Sigma, \mathbb{P})$ and (S, Σ') allows one to define various events expressed using LTL-like notations. Let $\mathcal{L}_{S,\Sigma'}$ be the set of formulas defined by the grammar: $\varphi ::= B\,\mathbf{U}_{\bowtie n}\,B' \mid \mathbf{G}\,\mathbf{F}\,B \mid \varphi_1 \vee \varphi_2 \mid \varphi_1 \wedge \varphi_2 \mid \neg\varphi$, where $B = (B_i)_{i\geq 0}$ and $B' = (B'_i)_{i\geq 0}$ are sequences of measurable subsets of S, $\bowtie \in \{\geq, \leq, =\}$ is a comparison operator and $n \in \mathbb{N}$ is an integer. The semantics of formulas in $\mathcal{L}_{S,\Sigma'}$ in terms of events is defined inductively:

$$\mathsf{Ev}_X(B\,\mathbf{U}_{\bowtie n}B') = \bigcup_{i\bowtie n}\big(X_i^{-1}(B'_i) \cap \bigcap_{0\leq j<i} X_j^{-1}(B_j)\big)\ ;\ \mathsf{Ev}_X(\mathbf{G}\,\mathbf{F}\,B) = \bigcap_{i\geq 0}\bigcup_{j\geq i} X_j^{-1}(B_j)\ ;$$
$$\mathsf{Ev}_X(\varphi_1 \vee \varphi_2) = \mathsf{Ev}_X(\varphi_1) \cup \mathsf{Ev}_X(\varphi_2)\ ;\ \mathsf{Ev}_X(\varphi_1 \wedge \varphi_2) = \mathsf{Ev}_X(\varphi_1) \cap \mathsf{Ev}_X(\varphi_2)\ ;$$
$$\mathsf{Ev}_X(\neg\varphi) = \Omega \setminus \mathsf{Ev}_X(\varphi).$$

Note that all these events are measurable in Ω. Following the intuition behind the LTL notations, event $\mathsf{Ev}_X(B\,\mathbf{U}_{\bowtie n}B')$ means that the stochastic process X will eventually satisfy B' (within step constraint $\bowtie n$), and only visit B beforehand. Also, the intuition of $\mathbf{G}\,\mathbf{F}\,B$ is that B should be visited infinitely often. We use classical shorthands: $\top = (S)_{i\geq 0}$; $\bot = (\emptyset)_{i\geq 0}$; $B\,\mathbf{U}\,B' = B\,\mathbf{U}_{\geq 0}B'$; $\mathbf{F}\,B = \top\,\mathbf{U}\,B$; $\mathbf{F}_{\bowtie n}B = \top\,\mathbf{U}_{\bowtie n}B$; $\mathbf{G}\,B = \neg\mathbf{F}\,(\neg B)$, where $\neg B = (S \setminus B_i)_{i\geq 0}$.

2.2 Decisiveness

Abdulla *et al.* originally defined a denumerable Markov chain to be decisive w.r.t. a set of states F if its runs almost-surely reach F or a state from which F can no longer be reached [2]. In order to extend the concept of *decisiveness* to general stochastic processes, we first provide an analogue to the set of states from which F is not reachable.

▶ **Definition 4.** Let B, B' be sequences of measurable sets of S. B' is a *B-avoidance sequence* for the stochastic process X if it satisfies

$$\forall n \geq 0,\ \mathbb{P}\big(\mathsf{Ev}_X(\mathbf{F}_{=n}\,B' \wedge \mathbf{F}_{\geq n}\,B)\big) = 0. \tag{1}$$

Intuitively, B' corresponds to 'states' from which B is almost-surely avoided (due to non-homogeneity of X, it needs to be defined as a sequence by slices).

▶ Remark. For every sequence B, $(\emptyset)_{i\geq 0}$ is a B-avoidance sequence for X. One can also check that B-avoidance sequences are closed under denumerable unions and intersections.

▶ **Example 5.** Let us illustrate the notion of avoidance sequences on the stochastic processes from Examples 1 and 2. In Example 1, we consider the uniform sequence $B = \{q_5\}$. It can be shown that the set of B-avoidance sequences corresponds to all sequences B' with $B'_i \subseteq \{q_{-1}\}$. In Example 2, the following sequence defines a B-avoidance set for $B = \{q_1\}$: $B'_0 = \{q'_0\}$ and for every $n \geq 1$, $B'_n = \emptyset$.

For the rest of the section, we fix a stochastic process $X = (X_i)_{i\geq 0}$ with $X_i \colon \Omega \to S$. Several notions of decisiveness were proposed for discrete-time and implicitly denumerable Markov chains [2]. In this paper, we define three notions of decisiveness, adapting and refining the ones of [2] to general stochastic processes.

▶ **Definition 6.** Let B be a sequence of measurable sets in S and let B' be a B-avoidance sequence for X. We say that the stochastic process X is

- *initially decisive* (ID) w.r.t. B with *witness* B' if $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B \vee \mathbf{F}\, B')) = 1$
- *initially strongly decisive* (ISD) w.r.t. B with *witness* B' if $\mathbb{P}(\mathsf{Ev}_X(\mathbf{G}\,\mathbf{F}\, B \vee \mathbf{F}\, B')) = 1$
- *persistently decisive* (PD) w.r.t. B with *witness* B' if $\forall n \geq 0, \mathbb{P}\big(\mathsf{Ev}_X(\mathbf{F}_{\geq n}\, B \vee \mathbf{F}_{\geq n}\, B')\big) = 1$.

We will then say that X is ID (resp. ISD, PD) w.r.t. B whenever there is some B-avoidance sequence B' such that X is ID (resp. ISD, PD) w.r.t. B with witness B'.

▶ Remark. Note that X might be ID (resp. ISD, PD) w.r.t. B for some witness B', but not for some other B-avoidance sequence B''. However if $B' \subseteq B''$ and X is ID (resp. ISD, PD) w.r.t. B with witness B', then it is also decisive w.r.t. B with witness B'': the larger (for the inclusion) is the B-avoidance sequence, the better it is for decisiveness properties.

We can establish a relationship between the three decisiveness notions.

▶ **Lemma 7.** *Let B be a sequence of measurable sets in S and let B' be a B-avoidance sequence for X. X is* PD *w.r.t. B with witness B' implies that X is* ISD *w.r.t. B with witness B', which, in turns, implies that X is* ID *w.r.t. B with witness B'. Moreover, the converse implications do not hold.*

Example 1 shows that initial decisiveness and initial strong decisiveness are not equivalent (take $B = \{q_5\}$), and Example 2 shows the non-equivalence of initial strong decisiveness and persistent decisiveness (take $\lambda_i = \frac{1}{2}$ for every $i \in \mathbb{N}$, and $B = \{q_1\}$).

In the sequel, we will write B' for an arbitrary B-avoidance sequence for X. However, whenever X is ID (resp. ISD, PD) w.r.t. B with some witness B', we will choose an arbitrary witness and write it $\mathsf{Av}_{\mathsf{dec}}(B)$ (resp. $\mathsf{Av}_{\mathsf{str}}(B)$, $\mathsf{Av}(B)$). When they exist, it is then possible to recursively define B'- (resp. $\mathsf{Av}_{\mathsf{dec}}(B)$-, $\mathsf{Av}_{\mathsf{str}}(B)$- and $\mathsf{Av}(B)$-)avoidance sequences for X: those are then order-two avoidance sequences for B, which record states from which one avoids states, from which states in B are avoided! The previous notations extend in the same way for these order-two avoidance sequences.

▶ **Example 8.** Back to Example 2, for $B = \{q_1\}$, we saw that B' defined by $B'_0 = \{q'_0\}$ and $B'_i = \emptyset$ for each $i \geq 1$, is a B-avoidance sequence for X. Then, we can define a B'-avoidance sequence for X as follows: $B''_0 = \{q_0, q_1, q'_1\}$ and for each $i \geq 1$, $B''_i = \{q_0, q_1, q'_0, q'_1\}$. In fact, we can show that all B'-avoidance sequences are the sequences included in B''.

3 Analysis of decisive stochastic processes

In this section we show how decisiveness properties can help analysing stochastic processes. In the first part, we focus on qualitative (that is, probability 0 or 1) reachability and repeated reachability properties, and we reduce all the corresponding model-checking questions to checking that some reachability property has probability 0. While this could be reduced to graph properties in [2], this is not the case here, since our models might have infinite non-denumerable branching. When we will apply these results in Subsection 5.3, models will have good properties allowing to solve the 0-probability properties of reachability properties. In the two next parts, we will use decisiveness properties to draw general procedures for

computing (arbitrary) approximations of the probability of a (repeated) reachability property. Effectiveness of these procedures will of course rely on good effectiveness properties of the models that we want to analyze.

3.1 Qualitative reachability and repeated reachability

We aim at describing a procedure for checking the almost-sure satisfiability of a reachability (resp. a repeated reachability) property, that is, an event of the form $\mathbf{F}\, B$ (resp. $\mathbf{G}\,\mathbf{F}\, B$), where B is a sequence of measurable sets. We fix B' a B-avoidance sequence, and we recall the notations $\mathsf{Av}_{\mathsf{dec}}(B)$, $\mathsf{Av}_{\mathsf{str}}(B)$ and $\mathsf{Av}(B)$ for such sequences when X is ID, resp. ISD, resp. PD w.r.t. B.

▶ **Proposition 9.**
- *If* $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B)) = 1$, *then* $\mathbb{P}(\mathsf{Ev}_X(\neg B\,\mathbf{U}\, B')) = 0$.
- *If* X *is* ID *w.r.t.* B *and* $\mathbb{P}(\mathsf{Ev}_X(\neg B\,\mathbf{U}\,\mathsf{Av}_{\mathsf{dec}}(B))) = 0$, *then* $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B)) = 1$.

Under an initial decisiveness assumption, this reduces the almost-sure model-checking of reachability properties to checking that some kind of (constrained) reachability property is satisfied with probability 0. Note that, contrary to the case of discrete-time denumerable Markov chains, we cannot reduce to graph properties, yet we advocate that for reachability properties, checking whether the probability is 0, is simpler than checking whether it is 1. We will see in Subsection 5.3 how this can be exploited on specific examples.

Turning to almost-sure repeated reachability, one can show the following proposition:

▶ **Proposition 10.**
- *If* $\mathbb{P}(\mathsf{Ev}_X(\mathbf{G}\,\mathbf{F}\, B)) = 1$, *then* $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B')) = 0$;
- *If* X *is* ISD *w.r.t.* B *and* $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\,\mathsf{Av}_{\mathsf{str}}(B))) = 0$, *then* $\mathbb{P}(\mathsf{Ev}_X(\mathbf{G}\,\mathbf{F}\, B)) = 1$.

Under an initial strong decisiveness assumption, this reduces the almost-sure model-checking of a repeated reachability property to the 0-model-checking of some reachability property.

Concerning the positive model-checking of repeated reachability properties, one can show:

▶ **Proposition 11.**
- *If* X *is* PD *w.r.t.* B *and* ID *w.r.t.* $\mathsf{Av}(B)$, *and if* $\mathbb{P}\big(\mathsf{Ev}_X(\mathbf{G}\,\mathbf{F}\, B)\big) > 0$, *then* $\mathbb{P}\big(\mathsf{Ev}_X(\mathbf{F}\,\mathsf{Av}_{\mathsf{dec}}(\mathsf{Av}(B)))\big) > 0$;
- *If* X *is* PD *w.r.t* B *and* $\mathbb{P}\big(\mathsf{Ev}_X(\mathbf{F}\,\mathsf{Av}(B)')\big) > 0$, *then* $\mathbb{P}\big(\mathsf{Ev}_X(\mathbf{G}\,\mathbf{F}\, B)\big) > 0$.

Note that the existence of a witness B' such that X is PD w.r.t. B does not imply the existence of a witness such that X is ID w.r.t. B'.

3.2 Quantitative reachability

We assume B is a sequence of measurable sets of S and B' is a B-avoidance sequence. We define the two following sequences ($n \in \mathbb{N}$):

$$\begin{cases} p_n^{\mathsf{Yes}} & = \mathbb{P}\big(\mathsf{Ev}_X(\mathbf{F}_{\leq n}\, B)\big) \\ p_n^{\mathsf{No}} & = \mathbb{P}\big(\mathsf{Ev}_X(\neg B\,\mathbf{U}_{\leq n}\, B')\big) \end{cases}$$

The next proposition gives straightforward properties of these two sequences.

▶ **Proposition 12.** *The sequences* $(p_n^{\mathsf{Yes}})_{n\geq 0}$ *and* $(p_n^{\mathsf{No}})_{n\geq 0}$ *are non-decreasing and converge respectively to* $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B))$ *and* $\mathbb{P}(\mathsf{Ev}_X(\neg B\,\mathbf{U}\, B'))$.

▶ **Corollary 13.** *If X is* ID *w.r.t. B and $B' = \mathsf{Av}_{\mathsf{dec}}(B)$, then* $\lim_{n\to\infty} p_n^{\mathsf{Yes}} + p_n^{\mathsf{No}} = 1$.

Corollary 13 can be used to derive an approximation scheme to evaluate the probability of reachability properties in ID stochastic processes. Indeed, given a fixed error bound $\varepsilon > 0$, in order to compute $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B))$ up to ε, one only needs to iteratively compute the values p_n^{Yes} and p_n^{No} until $1 - p_n^{\mathsf{Yes}} - p_n^{\mathsf{No}} \leq \varepsilon$ to deduce that $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B)) - p_n^{\mathsf{Yes}} \leq \varepsilon$. In case p_n^{Yes} and p_n^{No} cannot be computed exactly, but can only be approximated up to any desired error bound, this scheme can be refined to obtain a 2ε-approximation for $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B))$.

▶ Remark. Note that the quality of the above approximation scheme depends on the choice of the sequence $\mathsf{Av}_{\mathsf{dec}}(B)$: the larger $\mathsf{Av}_{\mathsf{dec}}(B)$, the faster convergence. Intuitively, $\mathsf{Av}_{\mathsf{dec}}(B)$ permits to stop the exploration when the reachability goal can no longer be satisfied, hence the sooner the better.

3.3 Quantitative repeated reachability

We assume B is a sequence of measurable sets of S, B' is a B-avoidance sequence, and B'' is a B'-avoidance sequence. We define the two following sequences ($n \in \mathbb{N}$):

$$\begin{cases} q_n^{\mathsf{Yes}} = \mathbb{P}\big(\mathsf{Ev}_X(\neg B'\, \mathbf{U}_{\leq n}\, B'')\big) \\ q_n^{\mathsf{No}} = \mathbb{P}\big(\mathsf{Ev}_X(\neg B''\, \mathbf{U}_{\leq n}\, B')\big) \end{cases}$$

▶ **Proposition 14.** *The sequences $(q_n^{\mathsf{Yes}})_{n\geq 0}$ and $(q_n^{\mathsf{No}})_{n\geq 0}$ are non-decreasing and converge respectively to $\mathbb{P}\big(\mathsf{Ev}_X(\neg B'\, \mathbf{U}\, B'')\big)$ and $\mathbb{P}\big(\mathsf{Ev}_X(\neg B''\, \mathbf{U}\, B')\big)$.*

▶ **Proposition 15.** *If X is* PD *w.r.t. B (with witness $B' = \mathsf{Av}(B)$) and* ID *w.r.t. $\mathsf{Av}(B)$ (with witness $B'' = \mathsf{Av}_{\mathsf{dec}}(\mathsf{Av}(B))$), then the two sequences $(q_n^{\mathsf{Yes}})_{n\geq 0}$ and $(1 - q_n^{\mathsf{No}})_{n\geq 0}$ are adjacent and converge to $\mathbb{P}(\mathsf{Ev}_X(\mathbf{G}\, \mathbf{F}\, B))$.*

Here again, the convergence of the two adjacent sequences can be used to derive an approximation scheme for $\mathbb{P}(\mathsf{Ev}_X(\mathbf{G}\, \mathbf{F}\, B))$ in PD stochastic processes.

Note that the persistent decisiveness property is required for the approximation scheme to be correct: consider again Example 2 and assume the sequence $(\lambda_i)_{i\in\mathbb{N}}$ satisfies $\prod_{i\in\mathbb{N}}(1-\lambda_i) > 0$. Under that hypothesis, one can show that $\mathbb{P}(\mathsf{Ev}_X(\mathbf{G}\, \mathbf{F}\, B)) < \frac{1}{2}$. On the other hand, whatever the choice of the avoidance sequences, we never get that the two sequences $(q_n^{\mathsf{Yes}})_{n\geq 0}$ and $(1 - q_n^{\mathsf{No}})_{n\geq 0}$ converge to that value.

4 Time-bounded reachability in real-time stochastic processes

In this section, we explain how to use decisiveness towards the quantitative analysis of time-bounded reachability (or safety) properties for real-time stochastic processes.

We fix (S_t, Σ_t) the measurable space for real-time stochastic processes we will consider. For $\Delta \in \mathbb{R}_+$ a time bound and B a sequence of measurable sets of S_t, we define the sequence $B \cap (t \leq \Delta)$ by: $(B \cap (t \leq \Delta))_i = \{(s, \tau) \in B_i \mid \tau \leq \Delta\}$. $B \cap (t \leq \Delta)$ is thus the restriction of B in which the time component is bounded by Δ.

First, decisiveness w.r.t. a sequence B propagates to its time-bounded restriction:

▶ **Proposition 16.** *Let $Z = (X_i, \tau_i)_{i\geq 0}$ be a real-time stochastic process, B be a sequence of measurable sets of S_t, and Δ be a time bound. If Z is* ID*, resp.* ISD*, resp.* PD *w.r.t. B, then Z is* ID*, resp.* ISD*, resp.* PD *w.r.t. $B \cap (t \leq \Delta)$.*

More importantly, non-Zeno real-time stochastic processes are PD w.r.t. time-bounded sequences:

▶ **Theorem 17.** *Let $Z = (X_i, \tau_i)_{i\geq 0}$ be a real-time stochastic process, let B be a sequence of measurable sets, and let $\Delta \in \mathbb{R}_+$ be a time bound. If Z is almost-surely non-Zeno, then Z is* PD *w.r.t. any time-bounded sequence $B \cap (t \leq \Delta)$.*

The main argument to establish this theorem is that, assuming almost-sure non-Zenoness, the sequence defined by $t > \Delta$ is a $(B \cap (t \leq \Delta))$-avoidance sequence for every B.

The almost-sure non-Zenoness hypothesis is standard and a desirable property of a system, and it expresses that the system should not have infinitely many discrete changes in a bounded amount of time. This assumption is satisfied by continuous-time Markov chains [6], and is easily enforced in many other models, such as continuous-time Markov processes with bounded transition rates [12], or continuous-space pure jump Markov processes (cPJMPs) assuming a non-explosive property [18].

This result then implies that for all these systems, if B is simple enough (like a uniform sequence of sets), provided one can compute (or approximate) the probability in n steps to reach some set of states, one can approximate the probability of satisfying a time-bounded reachability or safety property. This allows us to partly recover the result for cPJMPs [18, Theorem 3] which was established in a more analytical way.

In its generality, our approximation scheme does not provide any convergence rate, but for stochastic processes for which we can have an upper bound on the probability of completing at least n discrete changes within Δ time units, we will be able to compute a convergence rate for the various schemes. For instance for continuous-time (denumerable) Markov chains whose transition rates are upper-bounded by Λ, that probability can be bounded using a Poisson process of rate Λ.

5 Effectivity through abstraction

Proving decisiveness of general stochastic processes can be a hard task, in particular when their state-space is continuous. Decidability results in this context are often obtained through discrete abstractions. Therefore, in order to analyze the decisiveness of such stochastic processes, we propose to rely on an abstraction. More precisely, we give in this section sufficient conditions on an abstraction to ensure decisiveness of the original stochastic process. The qualitative verification algorithms and quantitative approximation schemes can then be applied to the concrete model. Note that, in general, the abstractions we propose only preserve qualitative properties, so that approximation schemes should be applied to the concrete model, not to the abstraction.

We then explain how this methodology can be applied to two classes of real-time stochastic processes, namely the ones generated by generalized semi-Markov processes and by stochastic timed automata. These models can be abstracted into discrete-time Markov chains while preserving the almost-sure satisfaction of reachability properties; this allows us to derive good decisiveness properties of the original models, and thus to infer approximation schemes.

5.1 Decisiveness for homogeneous denumerable Markov chains

Let us recall some basics of Markov chains. A denumerable Markov chain (MC, for short) is a stochastic process $Y = (Y_i)_{i\geq 0}$ with a denumerable state space T and which has the Markov property: for every $n \geq 0$, for all $t, t_0, t_1, \ldots, t_n \in T$, as soon as $\mathbb{P}(\bigwedge_{i=0}^{n} Y_i = t_i) > 0$, then $\mathbb{P}(Y_{n+1} = t \mid \bigwedge_{i=0}^{n} Y_i = t_i) = \mathbb{P}(Y_{n+1} = t \mid Y_n = t_n)$. The MC is *homogeneous* if for every n and for all $t, t' \in T$, $\mathbb{P}(Y_{n+1} = t' \mid Y_n = t) = \mathbb{P}(Y_n = t' \mid Y_{n-1} = t)$. In that case, the Markov chain is generated by a transition matrix $p_Y \colon T \times T \to [0, 1]$ such that

for every $t \in T$, $\sum_{t' \in T} p_Y(t,t') = 1$ and for every $n \geq 0$, $p_Y(t,t') = \mathbb{P}(Y_{n+1} = t' \mid Y_n = t)$. Under the condition that Y is homogeneous, one can simply define runs generated by Y. Precisely, a sequence $t_0, t_1, \cdots, t_n$ is a run, denoted $t_0 \to t_1 \cdots \to t_n$ if $p_Y(t_i, t_{i+1}) > 0$ for every $0 \leq i < n$; n is then the *length* of the run, and we write $t \to^* S$ as soon as there exists a state $t' \in S \subseteq T$ and a run $t = t_0 \to t_1 \cdots \to t_k = t'$.

Let us first explain how to characterize our various notions of decisiveness in the case of homogeneous MCs, and how they compare to the decisiveness of [2]. For every subset of states $C \subseteq T$, borrowing notations from [2], we let $\widetilde{C} = \{t \in T \mid t \not\to^* C\}$. State $t_0 \in T$ is an initial state of Y if $\mathbb{P}_Y(Y_0 = t_0) > 0$, and Y is said initialized at t_0 whenever t_0 is the unique initial state, that is $\mathbb{P}_Y(Y_0 = t_0) = 1$. If Y is a homogeneous MC, we write $Y[t]$ for the MC initialized at t, with transition matrix p_Y.

▶ **Lemma 18.** *Let Y be a homogeneous MC. For every C, $\widetilde{C}$ is a C-avoidance uniform sequence for Y. Moreover, it is maximal for the inclusion.*

The maximality property stated above allows to check decisiveness properties only with the witness $\widetilde{C}$: if Y is decisive with witness B', since $B' \subseteq \widetilde{C}$, it will also be decisive with witness $\widetilde{C}$. Recovering partly the original definitions of [2], we obtain the following characterization of our three notions of decisiveness:

▶ **Corollary 19.** *Let Y be a homogeneous MC, and C a set of states. Then:*

1. *Y is* ID *w.r.t. C iff $\mathbb{P}_Y\big(\mathsf{Ev}_Y(\mathbf{F}\, C \vee \mathbf{F}\, \widetilde{C})\big) = 1$;*
2. *Y is* ISD *w.r.t. C iff $\mathbb{P}_Y\big(\mathsf{Ev}_Y(\mathbf{G}\,\mathbf{F}\, C \vee \mathbf{F}\, \widetilde{C})\big) = 1$;*
3. *Y is* PD *w.r.t. C iff for every $p \geq 0$, $\mathbb{P}_Y\big(\mathsf{Ev}_Y(\mathbf{F}_{\geq p}\, C \vee \mathbf{F}_{\geq p}\, \widetilde{C})\big) = 1$ iff for every state t reachable from an initial state, $Y[t]$ is* ID *w.r.t. C.*

The third characterization implies that the decisiveness notion of [2] corresponds to our persistent decisiveness notion, in the case of homogeneous MCs.

Contrary to the case of general stochastic processes, initial strong decisiveness and persistent decisiveness coincide for homogeneous MCs (we recover here [2, Lemma 3.2]).

▶ **Lemma 20.** *Let Y be a homogeneous MC, and C a set of states. Then, Y* ISD *w.r.t. C iff Y is* PD *w.r.t. C.*

Note though that, even in this restricted context, initial decisiveness is not equivalent to initial strong decisiveness (recall Example 5). Finally, as already noticed in [2]:

▶ **Lemma 21.** *Let Y be a finite homogeneous MC, and C a set of states. Then, Y is* PD *w.r.t. C.*

5.2 Sound abstraction for decisiveness

Let us define a suitable notion of abstraction relating an arbitrary stochastic process X and a homogeneous MC Y such that decisiveness of Y implies decisiveness for X.

▶ **Definition 22.** Let $X = (X_i)_{i \geq 0}$ be a stochastic process, $Y = (Y_i)_{i \geq 0}$ be a homogeneous MC with denumerable state-space T equipped with the discrete σ-algebra $\Theta = 2^T$, and $\alpha : (S, \Sigma') \to (T, \Theta)$ be a mapping such that α and α^{-1} are measurable. The MC Y is an *α-abstraction* of X if for every sequence $A = (A_n)_{n \geq 0}$ of sets in Θ and for every $n \geq 0$

$$\mathbb{P}_Y\big(Y_n^{-1}(A_n) \mid \bigcap_{i<n} Y_i^{-1}(A_i)\big) > 0 \iff \mathbb{P}\big(X_n^{-1}(\alpha^{-1}(A_n)) \mid \bigcap_{i<n} X_i^{-1}(\alpha^{-1}(A_i))\big) > 0 \ .$$

Intuitively, Y is an α-abstraction of X if through the mapping α it preserves the events that may happen with positive probability.

In order to lift avoidance sequence from the abstraction to the concrete stochastic process, we rely on α-closed sets. A set $B \in \Sigma'$ is *α-closed* if $b \in B$ and $\alpha(b) = \alpha(b')$ implies $b' \in B$. Given $B \in \Sigma'$, by Lemma 18, $\widetilde{\alpha(B)}$ is an $\alpha(B)$-avoidance sequence for Y. Assuming B is α-closed, we obtain a B-avoidance sequence for X.

▶ **Lemma 23.** *Let Y be an α-abstraction of X and $B \in \Sigma'$ be an α-closed set. Then $(\alpha^{-1}(\widetilde{\alpha(B)}))$ is a B-avoidance sequence for X.*

However, α-abstractions do not necessarily preserve decisiveness properties, yet these can be ensured thanks to the following soundness notions.

▶ **Definition 24.** Let Y be an α-abstraction of X.

- Y is *sound* if for every α-closed set B, $\mathbb{P}_Y(\mathsf{Ev}_Y(\mathbf{F}\, \alpha(B))) = 1$ implies $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}\, B)) = 1$.
- Y is *persistently sound* if for every α-closed set B and every $p \geq 0$, $\mathbb{P}_Y(\mathsf{Ev}_Y(\mathbf{F}_{\geq p}\, \alpha(B))) = 1$ implies $\mathbb{P}(\mathsf{Ev}_X(\mathbf{F}_{\geq p}\, B)) = 1$.

Roughly said, sound abstractions preserve almost-sure satisfaction of reachability properties. Moreover, they allow to transfer decisiveness properties to the original stochastic process.

▶ **Proposition 25.** *Let Y be an α-abstraction of X and B an α-closed set.*

- *If Y is sound and* ID *w.r.t. $\alpha(B)$, then X is* ID *w.r.t. B with witness $(\alpha^{-1}(\widetilde{\alpha(B)}))$.*
- *If Y is persistently sound and* PD *w.r.t. $\alpha(B)$, then X is* PD *w.r.t. B with witness $(\alpha^{-1}(\widetilde{\alpha(B)}))$.*

▶ **Example 26.** Back to the queue of Example 3, we assume it is M/M/1, that is, F_a and F_e are exponential distributions of parameters λ and μ, respectively. Assuming $\lambda < \mu$, we can exhibit a persistently sound abstraction. Indeed, consider the random walk over $\mathbb{N}$ defined by $p(0,1) = 1$, and if $i \geq 1$, $p(i, i+1) = \frac{\lambda}{\lambda+\mu}$ and $p(i, i-1) = \frac{\mu}{\lambda+\mu}$. Since $\lambda < \mu$, this MC is PD w.r.t. each set of states and thus, the queue is PD w.r.t. each set of states that is closed under the abstraction.

5.3 Applications

We apply the previous study to two classes of systems.

5.3.1 Generalized semi-Markov processes

A generalized semi-Markov process [10, 13] is a stochastic process built on a finite set of events. Each event is equipped with a random variable representing its duration: either a variable-delay defined by a density function or a fixed-delay modelled by a Dirac distribution. A transition is characterized by a set of events which expire, and schedules a set of new events. This model is known to generalize continuous-time Markov chains.

The semantics of a GSMP $\mathcal{M}$ is given as a general state-space Markov chain (GSSMC), defined by a set of configurations and a transition kernel. Configurations of a GSMP are pairs consisting of a state and a valuation assigning a time value to each *scheduled* event. Such a value represents the time elapsed since the event was scheduled. Transitions between configurations combine a time-elapse and the occurrence of some scheduled events and/or the scheduling of new events. The set of configurations can be equipped with a natural σ-algebra $\mathcal{G}$, and the transition system induced by $\mathcal{M}$ is equipped with a transition kernel: for a configuration γ and a set $A \in \mathcal{G}$, $P_{\mathcal{M}}(\gamma, A)$ is the probability to move in one step from

configuration γ to some configuration in A. This probability expresses a race between all enabled events, taking into account their residual density functions. The set of runs, *i.e.* infinite sequences of configurations, can then be equipped with a probability measure $\mathbb{P}_{\mathcal{M}}$. The GSSMC associated with a GSMP $\mathcal{M}$ can thus naturally be viewed as a (real-time) stochastic process $X^{\mathcal{M}}$.

Decisiveness. In general, GSMPs do not enjoy any decisiveness property. Indeed, [10, Section 3] presents an example that is not ID w.r.t. any region-closed set. Still, Brázdil *et al.* identified a sufficient condition, that ensures some kind of fairness: GSMP should be *single-ticking* (GSMP with some restriction on fixed-delay events, see [10] for the definition of this condition). Under that condition and using results of [10], one can show that the standard region abstraction for GSMPs is a persistently sound abstraction. More precisely, we consider as an abstraction the (finite-state) Markov chain $Y^{\mathcal{M}}$, whose states are regions, and such that there is a transition between region r and region r' as soon as there is a configuration $\gamma \in r$ from which the probability to reach r' in one step in $X^{\mathcal{M}}$ is positive. Probabilities are assumed to be uniform in $Y^{\mathcal{M}}$.

▶ **Theorem 27.** *Let $\mathcal{M}$ be a single-ticking GSMP with stochastic process $X^{\mathcal{M}}$. Then the region Markov chain $Y^{\mathcal{M}}$ is an persistently sound abstraction of $X^{\mathcal{M}}$.*

Proposition 25 then suffices to derive the decisiveness of the original stochastic process $X^{\mathcal{M}}$:

▶ **Corollary 28.** *Let $\mathcal{M}$ be a single-ticking GSMP with stochastic process $X^{\mathcal{M}}$. Then for every region-closed set B, the stochastic process $X^{\mathcal{M}}$ is* PD *w.r.t. B.*

As a consequence, we can apply all results of Section 3 to single-ticking GSMPs. We remark here that checking whether a reachability property has probability 0 can easily be done using the region graph abstraction: it amounts to checking in the (finite) region abstraction that there is no path from the initial state to the target [10]. Hence all qualitative questions related to region-based (repeated) reachability properties can be solved. For what concerns quantitative verification, assuming the distributions equipping the GSMPs can be handled numerically, this allows one to approximate the probability of reachability or repeated reachability properties, as well as all time-bounded reachability properties. We believe our approach gives new hints into the approximate model-checking problem for GSMPs, for which, up to our knowledge, only few results are known. For instance in [3, 7], the authors approximate the probability of until formulas of the form "the system reaches a target before time T within k discrete events, while staying within a set of safe states" (resp. "the system reaches a target while staying within a set of safe states") for GSMPs (resp. a restricted class of GSMPs which can be proved to be PD), and study numerical aspects. Our result permits to do the same with any reachability (resp. time-bounded reachability) property on the whole class of single-ticking GSMPs (resp. which are a.s. non-Zeno). The numerical aspects in our computations can be dealt with as in [3, 7].

5.3.2 Stochastic timed automata

Stochastic timed automata [9] are stochastic processes derived from timed automata [4] by randomizing both the delays and the edge choices. One can naturally associate a (real-time) stochastic process $X^{\mathcal{A}}$ with an STA $\mathcal{A}$.

Decisiveness. Similarly to GSMP, STA are not decisive in general. Adapting an example from [9], one can indeed exhibit an STA which is not ID w.r.t. a given region-closed set. Still, under some fairness property, one can build an abstraction of the STA, that is sound for the almost-sure model checking of LTL properties and the-like [9]. It turns out that this fairness assumption ensures that the same abstraction is also sound for decisiveness. As for GSMPs, we consider the natural region abstraction, and we define a finite-state Markov chain $Y^{\mathcal{A}}$, in which the states are regions, and there is a transition from one region r to another r' as soon as there exists a configuration γ in r from which the probability to reach r' in one step in $X^{\mathcal{A}}$ is positive. As mentioned earlier, as such, the abstraction $Y^{\mathcal{A}}$ is not sound in general. Yet, it preserves almost-sure satisfaction of LTL properties when the stochastic timed automaton is *almost-surely fair* [9]. Here fairness refers as the following property, which depends on $Y^{\mathcal{A}}$: every edge of $Y^{\mathcal{A}}$ which is enabled infinitely often along a run should be taken infinitely often. Denoting fair this property, the assumption $\mathbb{P}(\mathsf{Ev}_{X^{\mathcal{A}}}(\mathsf{fair})) = 1$ suffices to prove that $Y^{\mathcal{A}}$ is a sound abstraction for the almost-sure model checking for LTL properties [9].

▶ **Theorem 29.** *Let $\mathcal{A}$ be an STA with associated stochastic process $X^{\mathcal{A}}$, and let $Y^{\mathcal{A}}$ be its region abstraction. If $\mathbb{P}(\mathsf{Ev}_{X^{\mathcal{A}}}(\mathsf{fair})) = 1$ then $Y^{\mathcal{A}}$ is a persistently sound abstraction for $X^{\mathcal{A}}$.*

As a consequence of Proposition 25 and Theorem 29, we derive the decisiveness of the original stochastic process $X^{\mathcal{A}}$:

▶ **Corollary 30.** *Let $\mathcal{A}$ be an STA with stochastic process $X^{\mathcal{A}}$ and $Y^{\mathcal{A}}$ its region abstraction. If $\mathbb{P}(\mathsf{Ev}_{X^{\mathcal{A}}}(\mathsf{fair})) = 1$ then for every region-closed set B, $X^{\mathcal{A}}$ is PD w.r.t. B.*

As a consequence, we can apply all results of Section 3 to almost-surely fair stochastic timed automata. While the decidability of qualitative model-checking questions that we can infer from Section 3.1 were already known [9] and can be solved on the region abstraction, the approximation schemes that we can derive from Sections 3.2 and 3.3 are new. Obtaining decidability results even for the qualitative model-checking of large classes of STA required quite some effort (now combined in [9]). Here, we show that our earlier approach importantly implied decisiveness properties for STA. Moreover, the approximation schemes of Sections 3.2 and 3.3 can now be effectively applied to STA, as soon as distributions in the model have good numerical properties. Notice that a first decidability result was obtained in [8] for the quantitative model-checking of a restricted class of single-clock STA: while the current approximation schemes apply to all single-clock STA, the closed-form expression obtained in [8], although more precise requires a condition on the cycles of the automaton.

6 Conclusion and future work

In this paper, we introduced and studied decisiveness for general stochastic processes, setting sufficient conditions for the decidability of qualitative model-checking of (repeated) reachability properties, and more importantly for the approximability of the quantitative evaluation of such properties. We then showed that non-Zeno real-time stochastic processes have good decisiveness properties, allowing one to approximate the probability of all time-bounded properties. Finally we described a framework to obtain decisiveness properties through abstractions, and demonstrated its applicability to generalized semi-Markov processes and stochastic timed automata, thus yielding new approximability results for the quantitative model-checking of stochastic timed automata.

As further work, we would like to extend the applicability of our approach to other classes of stochastic timed systems, like probabilistic extensions of timed lossy channel systems [1]

or communicating timed systems [11]. Also, the approximation scheme for reachability properties can be adapted to evaluate an expected accumulated reward, provided the reward evolves linearly in the model, as in Markov reward models [5, 16]. Finally, extending the approximation schemes to Muller conditions would enable the quantitative analysis of properties given as LTL formulas.

Abstract

Conventional approaches for parallel composition of stochastic systems relate probability measures of the individual components in terms of product measures. Such approaches rely on the assumption that components interact stochastically independent, which might be too rigid for modeling real world systems. In this paper, we introduce a parallel-composition operator for stochastic transition systems that is based on couplings of probability measures and does not impose any stochastic assumptions. When composing systems within our framework, the intended dependencies between components can be determined by providing so-called spans and span couplings. We present a congruence result for our operator with respect to a standard notion of bisimilarity and develop a general theory for spans, exploiting deep results from descriptive set theory. As an application of our general approach, we propose a model for stochastic hybrid systems called stochastic hybrid motion automata.

1 Introduction

When modeling complex systems, compositional approaches enjoy many favorable properties compared to their monolithic counterparts. They allow for a systematic system design, facilitate the interchangeability and reusability of components, and thus also ease the maintainability. A major objective in defining compositional frameworks is to separate concerns into components – specifying the operational behavior – and composition operators – addressing the communication and interaction of the components. Within conventional approaches for stochastic systems, the composition operator relates probability distributions of the individual components in terms of product distributions. Therefore, such operators

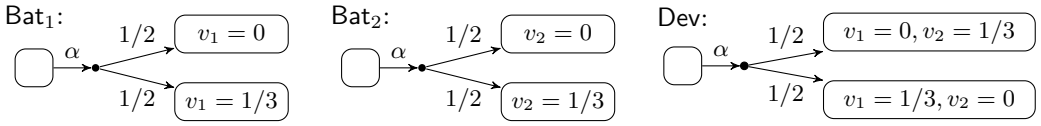
are based on the assumption that the components interact stochastically independent, which is often not adequate. For instance, let us regard a systems composed of a device Dev and two batteries Bat_1 and Bat_2 providing the energy for Dev as detailed below:



In this example, the device provides the environmental context in which Bat_1 and Bat_2 are operating. Hence, Dev may, e.g., be the reason for common cause failures arising in the system. Let the variables v_1 and v_2 capture the amount of energy stored within Bat_1 and Bat_2, respectively. The action label α stands for the occurrence of a failure after which all the components will crash. As a consequence, the level of the stored energy of the batteries instantaneously drops to either 0 or 1/3 with probability 1/2, respectively. When considering the batteries in isolation, Bat_1 and Bat_2 appear stochastically independent in the first place and thus, product distributions in the parallel composition $\mathsf{Bat}_1 \parallel \mathsf{Bat}_2$ seem to be adequate. However, additional dependencies can be imposed by Dev, influencing the interplay between the batteries. The assumption that Bat_1 and Bat_2 are stochastically independent is hence not adequate. Assume, e.g., that Dev uses Bat_1 as the default power supply and Bat_2 as a backup. Then, within a failure situation, Bat_1 is more likely to be affected than Bat_2. The most likely case is that Bat_1 drops to 0 whereas Bat_2 drops to 1/3. Hence, v_1 and v_2 might be not independent in the composite system $(\mathsf{Bat}_1 \parallel \mathsf{Bat}_2) \parallel \mathsf{Dev}$.

Motivated by this example, we consider hybrid systems that combine discrete behaviors and continuous dynamics. In this setting, the most prominent modeling formalism are hybrid automata, which comprise a control graph with discrete jumps between (control) locations and flows that model the evolution of continuous variables over time. When time passes in a hybrid system, a flow starting from the current variable evaluation is selected non-deterministically and then the variables evolve according to the chosen flow. Besides the stochastic independence, additional aspects are relevant for the composition of hybrid systems. Let us assume that α_1 is a (local) action of Bat_1 which cannot be observed by Bat_2 or Dev. Particularly, α_1 does not affect the value of variable v_2. The hybrid automaton $\mathsf{Bat}_1 \parallel \mathsf{Bat}_2$ has states of the form $\langle s^1, s^2 \rangle$. Suppose $\langle s_1^1, s_1^2 \rangle \to^{t_1} \langle s_2^1, s_2^2 \rangle \to^{\alpha_1} \langle s_3^1, s_3^2 \rangle \to^{t_2} \langle s_4^1, s_4^2 \rangle$ is a finite path in $\mathsf{Bat}_1 \parallel \mathsf{Bat}_2$, comprising two timed transitions with time passages t_1 and t_2 and one jump transition involving action α_1. As α_1 cannot be observed by Bat_2, we expect $s_1^2 \to^{t_1+t_2} s_4^2$ in Bat_2. In particular, a faithful model for the composite system would allow for selecting a flow for v_1 within time passage t_1, which is continued within the subsequent time passage. Thus, the adaption of the flow for variable v_2 should only be possible when executing an action involving Bat_2 or Dev. This aspect is also crucial in the context of modeling controller strategies for hybrid systems. Typically, control decisions are made at distinct points and fixed until a next control decision is enabled. For instance, when considering a traffic alert and collision avoidance systems on aircraft, the advise of a corrective maneuver is determined when a critical situation occurs and fixed until sensor values exceed a threshold that indicates changes of the situation. A crucial point is to identify exactly those situations where adaptation of flows is allowed and required, as from a practical point of view it is important to minimize costs of adaptation and to keep the complexity of controllers manageable.

Contribution. We introduce a generic composition operator for stochastic transition systems (STSs) [16] based on spans and span couplings. Our operator does not rely on the assumption that the STSs to be composed are stochastically independent and covers standard composition

operators by dealing with specific spans. Spans provide a formal approach for introducing a universal notion of coupling probability measures. We develop an extensive theory for spans exploiting profound results known from descriptive set theory [34]. Based on a standard notion of bisimulation, we provide a congruence result with respect to our span composition. In the second part of the paper, we instantiate our general approach and introduce stochastic hybrid motion automata (SHMA) in which the progressing flow is recorded within states. We present a compositional framework for SHMA including an STS-semantics, a composition operator that does not rely on the assumption of stochastic independence, and where the adjustment of flows is always accompanied with an action. We show that the congruence result for STSs transfers to our SHMA framework.

Additional material and detailed proofs can be found in the technical report [25].

Related Work. We are not aware of a compositional modeling approach of stochastic systems which does not rely on the assumption that the components to be composed are stochastically independent. Our work thus addresses a fundamental challenge in the context of probabilistic operational models. The recent work [28] gives a comprehensive overview on compositional probabilistic modeling formalisms regarding expressive power and available analysis techniques. The concept of compositionality has its roots in the theory of process calculi [37, 32] and there are many fundamental contributions in the field of stochastic extensions of process calculi and probabilistic automata [39, 1, 2, 18, 13, 19]. Results on discrete systems have been extended to formalisms with continuous state spaces [16, 35]. The theory on non-deterministic labeled Markov processes (NLMPs) provide elegant notions and results on bisimulation and its logical characterization [21, 22, 17, 20, 6, 31]. Unfortunately, NLMPs are a priori not appropriate for our purposes as the class of NLMPs is not closed under the composition of stochastic transition systems [25]: Given two NLMPs, the transition function of their composition does not need to be measurable. When considering real-time systems, an important distinguishing aspect is the notion of residence time, which is the time spend in a state before moving to a successor state. In prominent compositional frameworks, timing behavior is modeled by clocks (timed automata) [4, 9, 38, 11] or one has exponential-distributed holding times (Markov automata and interactive Markov chains) [30, 23]. A general theory on compositionality and behavioral equivalences has been also achieved for probabilistic real-time systems modeled by interactive generalized semi-Markov processes [14, 12]. When adding flows to specify the evolution of continuous variables between jumps, one enters the field of hybrid systems [3, 29, 10]. The spirit of our work concerning hybrid systems is closest to the compositional frameworks developed for hybrid extensions of I/O-automata [36] and reactive modules [5] in the non-stochastic case. [36] studies parallel composition, simulation relations, and the receptiveness property and deals with prefix-, suffix- and concatenation-closed sets of flows on a syntactic level to obtain time-transitivity. Probabilistic hybrid automata [40, 26] extend classical hybrid automata by discrete probabilistic updates for the jumps. In [24, 27, 26], stochastic hybrid automata are considered where variables can be updated according to continuous distributions. Different from these hybrid automata, the change of flows in SHMA is only possible when some action is executed. Stochastic flows, i.e., where stochastic choices can be made continuously over time, are considered in [15, 33]. Our framework does not incorporate this kind of flows so far.

2 Preliminaries

We suppose the reader is familiar with standard concepts from measure and probability theory [8]. We briefly summarize our notations used throughout this paper.

Couplings. Within our work we understand couplings as a "modeling tool". Intuitively, couplings relate given measures in a product space by a measure with corresponding marginals. $\mathsf{Prob}(X)$ denotes the set of all probability measures on the measurable space X. Let X_1 and X_2 be measurable spaces. Given $\mu_1 \in \mathsf{Prob}(X_1)$ and $\mu_2 \in \mathsf{Prob}(X_2)$, $\mu \in \mathsf{Prob}(X_1 \times X_2)$ is called a *coupling of* (μ_1, μ_2) if $\mu(M_1 \times X_2) = \mu_1(M_1)$ and $\mu(X_1 \times M_2) = \mu_2(M_2)$ for all measurable $M_1 \subseteq X_1$ and $M_2 \subseteq X_2$. The *independent coupling of* (μ_1, μ_2) is the *product measure* of μ_1 and μ_2 denoted by $\mu_1 \otimes \mu_2$. If $\mu_1 = \mathsf{Dirac}[x_1]$ for some $x_1 \in X_1$, then there is exactly one coupling of (μ_1, μ_2), namely the independent one. Here, $\mathsf{Dirac}[x_1]$ denotes the probability measure where for all measurable $M_1 \subseteq X_1$, $\mathsf{Dirac}[x_1](M_1) = 1$ iff $x_1 \in M_1$.

Polish spaces. A separable and completely metrizable topological space is called a *Polish space* [34]. If X is a Polish space, then $\mathsf{Prob}(X)$ is well equipped with the topology induced by the weak convergence of probability measures. To obtain a measurable space, Polish spaces are equipped with the Borel sigma algebra, i.e., the coarsest sigma-algebra where all open sets are measurable. We call a measurable space X *standard Borel* if there exists a Polish topology on X where the induced Borel sigma-algebra coincides with the given one. The Polish topology is in general not uniquely determined. We refer to measurable subsets of standard Borel spaces as *Borel sets*. Of course, every Polish space is standard Borel.

Functions for probability measures. Given a measurable function $f\colon X_1 \to X_2$ between measurable spaces X_1 and X_2, the *pushforward of* f is defined by $f_\sharp\colon \mathsf{Prob}(X_1) \to \mathsf{Prob}(X_2)$, $f_\sharp(\mu)(M_2) = \mu(f^{-1}(M_1))$. Assuming Polish spaces X_1 and X_2, a *Markov kernel* is a Borel function $k\colon X_1 \to \mathsf{Prob}(X_2)$. Here, for every $\mu_1 \in \mathsf{Prob}(X_1)$ we define *semi-product measure* $\mu_1 \rtimes k \in \mathsf{Prob}(X_1 \times X_2)$, $\mu_1 \rtimes k(M_1 \times M_2) = \int_{M_1} k(x_1)(M_2)\, d\mu_1(x_1)$.

Relations. Let $R \subseteq X_1 \times X_2$ be a binary relation over some sets X_1 and X_2. We usually write $x_1\, R\, x_2$ instead of $\langle x_1, x_2\rangle \in R$. Then, R is called *lr-total in* $X_1 \times X_2$ if for all $x_1 \in X_1$ there exists $x_2 \in X_2$ such that $x_1\, R\, x_2$ and vice versa, i.e., also for all $x_2 \in X_2$ there exists $x_1 \in X_1$ where $x_1\, R\, x_2$. Assume X_1 and X_2 constitute measurable spaces and let $\mu_1 \in \mathsf{Prob}(X_1)$ and $\mu_2 \in \mathsf{Prob}(X_2)$. A *weight function for* (μ_1, R, μ_2) is a coupling W of (μ_1, μ_2) such that $x_1\, R\, x_2$ for W-almost all $\langle x_1, x_2\rangle \in X_1 \times X_2$. We write $\mu_1\, R^w\, \mu_2$ if there exists a weight function for (μ_1, R, μ_2). Notice, R^w constitutes a relation in $\mathsf{Prob}(X_1) \times \mathsf{Prob}(X_2)$. Notice, weight functions are also well-established in the discrete setting [39].

Variables. Let Var denote a countable set of variables and $V \subseteq \mathsf{Var}$. We denote by $\mathsf{Ev}(V)$ the set of all *variable evaluations for* V, i.e., functions from V to $\mathbb{R}$. As the countable product of Polish spaces equipped with the product topology again yields a Polish space, $\mathsf{Ev}(V)$ constitutes a Polish space. Let $e \in \mathsf{Ev}(\mathsf{Var})$ and $\eta \in \mathsf{Prob}(\mathsf{Ev}(\mathsf{Var}))$. The projection $e_{|V} \in \mathsf{Ev}(V)$ is given by $e_{|V}(v) = e(v)$ for all $v \in V$. As $f\colon \mathsf{Ev}(\mathsf{Var}) \to \mathsf{Ev}(V)$, $f(e) = e_{|V}$ is measurable, we can safely define $\eta_{|V} = f_\sharp(\eta)$. $\mathsf{Cond}(\mathsf{Var})$ denotes the set of all Boolean conditions over Var and we write $e \models c$ if the variable evaluation e satisfies condition c. For instance, $e \models (v \leq 3.14159) \wedge (v \geq 2.71828)$ iff $e(v) \leq 3.14159$ and $e(v) \geq 2.71828$.

Stochastic transition systems. An *STS* is a triple $\mathcal{T} = (S, \Gamma, \to)$ comprising a measurable space S of *states*, a set Γ of *labels*, and a relation $\to \subseteq S \times \Gamma \times \mathsf{Prob}(S)$ of *transitions*. If S is a standard Borel space, then $\mathcal{T}$ is called *standard Borel*. Let $\mathcal{T}_a = (S_a, \Gamma, \to_a)$ and $\mathcal{T}_b = (S_b, \Gamma, \to_b)$ be STSs with the same sets of labels. A relation $R \subseteq S_a \times S_b$ is a *bisimulation for* $(\mathcal{T}_a, \mathcal{T}_b)$ if R is lr-total in $S_a \times S_b$ and for all $s_a\, R\, s_b$ and $\gamma \in \Gamma$ it holds:

Given $\mu_a \in \mathsf{Prob}(S_a)$ where $s_a \to_a^\gamma \mu_a$, then there exists $\mu_b \in \mathsf{Prob}(S_b)$ such that $s_b \to_b^\gamma \mu_b$ and $\mu_a \, R^w \, \mu_b$. Vice versa, given $\mu_b \in \mathsf{Prob}(S_b)$ with $s_b \to_b^\gamma \mu_b$, then there is $\mu_a \in \mathsf{Prob}(S_a)$ where $s_a \to_a^\gamma \mu_a$ and $\mu_a \, R^w \, \mu_b$. We emphasize that a bisimulation is not required to be measurable. In the context of bisimulation an important question is how to lift a relation $R \subseteq S_a \times S_b$ to probability measures. However, there are other approaches using R-stable pairs instead [22], closely related to the weight lifting [41, 39]. Given STSs $\mathcal{T}_1 = (S_1, \Gamma_1, \to_1)$ and $\mathcal{T}_2 = (S_2, \Gamma_2, \to_2)$ and a set of synchronization labels $\mathsf{Sync} \subseteq \Gamma_1 \cap \Gamma_2$, their composition is the STS $\mathcal{T}_1 \parallel_{\mathsf{Sync}}^{\otimes} \mathcal{T}_2 = (S_1 \times S_2, \Gamma_1 \cup \Gamma_2, \to)$ with $\langle s_1, s_2 \rangle \to^\gamma \mu_1 \otimes \mu_2$ iff the following holds [16]: If $\gamma \in \Gamma_1 \setminus \mathsf{Sync}$, then $s_1 \to^\gamma \mu_1$ and $\mu_2 = \mathsf{Dirac}[s_2]$. If $\gamma \in \Gamma_2 \setminus \mathsf{Sync}$, then $\mu_1 = \mathsf{Dirac}[s_1]$ and $s_2 \to^\gamma \mu_2$. If $\gamma \in \mathsf{Sync}$, then $s_1 \to^\gamma \mu_1$ and $s_2 \to^\gamma \mu_2$.

Flows. By $\mathbb{T} = \mathbb{R}_{\geq 0}$ we denote the *time axis*. A *flow* is a function $\vartheta \colon \mathbb{T} \to \mathsf{Ev}(\mathsf{Var})$ that has the càdlàg property, i.e., ϑ is right continuous and has left limits everywhere. $\mathsf{Flow}(\mathsf{Var})$ denotes the set of all flows. Let $\vartheta \oplus T(t) = \vartheta(T+t)$ denote the *shift of* ϑ *at time* $T \in \mathbb{T}$ *by time* $t \in \mathbb{T}$. A subset F of $\mathsf{Flow}(\mathsf{Var})$ is *shift invariant* if $\vartheta \oplus T \in F$ for every $\vartheta \in F$ and $T \in \mathbb{T}$. In the theory of stochastic processes, the càdlàg property is well established as, amongst others, there is a topology on $\mathsf{Flow}(\mathsf{Var})$ such that $\mathsf{Flow}(\mathsf{Var})$ becomes a Polish space [7]. The exact definition of this topology is not relevant for our purposes. If $V \subseteq \mathsf{Var}$ and $\vartheta \in \mathsf{Flow}(\mathsf{Var})$, then $\vartheta_{|V} \in \mathsf{Flow}(V)$ is given by $\vartheta_{|V}(t) = \vartheta(t)_{|V}$ for all $t \in \mathbb{T}$. Given $V_1, V_2 \subseteq \mathsf{Var}$ where $V_1 \cap V_2 = \varnothing$ and $\vartheta_1 \in \mathsf{Flow}(V_1)$ and $\vartheta_2 \in \mathsf{Flow}(\mathsf{Var}_2)$, then $\vartheta_1 \uplus \vartheta_2 \in \mathsf{Flow}(V_1 \cup V_2)$ is the flow obtained by merging ϑ_1 and ϑ_2.

3 Composition of stochastic transition systems

We develop our approach towards the composition of STSs. As a preparation, we introduce spans first and give some insights on our mathematical theory for those. After that, we present the main contribution of the paper, namely our composition operator for STSs. We then give a congruence theorem having a quite challenging proof. Section 4 presents an application of our framework in the context of stochastic hybrid systems.

3.1 Spans

We will formalize dependencies for the composition of STSs using spans and span couplings, which is a generic and flexible formalism our framework benefits from in many occasions. The idea is to allow for arbitrary Polish spaces together with continuous functions that specify the relationships between the components. Various properties of spans then transfer to their probabilistic version, e.g., properness or the existence of inverses. This is an essential point in the context of stochastic models and hence also for STSs. We will then use spans within the definition of our composition in STS and later on also in the context of stochastic hybrid systems as a mathematical tool for our argumentation.

▶ **Definition 1.** A *span* is a tuple $\mathcal{X} = (X, X_1, X_2, \iota_1, \iota_2)$ consisting of Polish spaces X, X_1, and X_2 and continuous functions $\iota_1 \colon X \to X_1$ and $\iota_2 \colon X \to X_2$. We call $\mathcal{X}$ *proper*, if $\iota_1^{-1}(K_1) \cap \iota_2^{-1}(K_2)$ is compact in X for all compact sets $K_1 \subseteq X_1$ and $K_2 \subseteq X_2$.

Intuitively, X denotes the joint state space of X_1 and X_2, where ι_1 and ι_2 are projective functions from X to X_1 and X_2, respectively. Properness connects topological aspects of the involved spaces. The following examples are natural instances of proper spans:

- $\mathcal{X}$ is a *Cartesian span* if $X = X_1 \times X_2$ and ι_1 and ι_2 are the natural projections.

- $\mathcal{X}$ is a *variable span* if $X_1 = \mathsf{Ev}(\mathsf{Var}_1)$, $X_2 = \mathsf{Ev}(\mathsf{Var}_2)$, and $X = \mathsf{Ev}(\mathsf{Var}_1 \cup \mathsf{Var}_2)$ for some sets of variables Var_1 and Var_2, and ι_1 and ι_2 are the natural projections.
- $\mathcal{X}$ is a *identity span* if $X = X_1 = X_2$ and $\iota_1(x) = x$ and $\iota_2(x) = x$ for all $x \in X$.

Span couplings are a crucial notion for our approach towards a composition operator in the next section. Given $\mu_1 \in \mathsf{Prob}(X_1)$ and $\mu_2 \in \mathsf{Prob}(X_2)$, we call $\mu \in \mathsf{Prob}(X)$ a $\mathcal{X}$*-coupling of* (μ_1, μ_2) if $(\iota_1)_\sharp(\mu) = \mu_1$ and $(\iota_2)_\sharp(\mu) = \mu_2$. Recall that $(\iota_1)_\sharp$ and $(\iota_2)_\sharp$ denote the pushforwards of ι_1 and ι_2, respectively. A span coupling places two probability measures in the same probabilistic space specified by the span by exhibiting an adequate witness measure over pairs. Thus, the ordinary notion for couplings is generalized. For all x and μ we use $x_{|1}$, $x_{|2}$, $\mu_{|1}$, and $\mu_{|2}$ as shorthand notations for $\iota_1(x)$, $\iota_2(x)$, $(\iota_1)_\sharp(\mu)$, and $(\iota_2)_\sharp(\mu)$ respectively. Given $x_1 \in X_1$ and $x_2 \in X_2$, we then write $x_1 \,\mathcal{X}\, x_2$ if there exists $x \in X$ where $x_{|1} = x_1$ and $x_{|2} = x_2$. Similarly, we write $\mu_1 \,\mathcal{X}^c\, \mu_2$ if there is a $\mathcal{X}$-coupling of (μ_1, μ_2). We sometimes drop the projection functions from the tuple and refer to (X, X_1, X_2) as a span.

Probabilistic version. There are various operations for spans that yield complex spans out of some given basic spans. The question whether the operation preserves properness is important for practical purposes. For instance, using Tychonoff's theorem, a countable product of proper spans yields a proper span again. Within stochastic models, the following operation is important: For a span $\mathcal{X} = (X, X_1, X_2, \iota_1, \iota_2)$ its *probabilistic version* is given by the tuple $\mathsf{Prob}(\mathcal{X}) = (\mathsf{Prob}(X), \mathsf{Prob}(X_1), \mathsf{Prob}(X_2), (\iota_1)_\sharp, (\iota_2)_\sharp)$. Notice, $\mathsf{Prob}(\mathcal{X})$ involves all $\mathcal{X}$-couplings and $\mu_1 \,\mathcal{X}^c\, \mu_2$ iff $\mu_1 \,\mathsf{Prob}(\mathcal{X})\, \mu_2$ for all $\mu_1 \in \mathsf{Prob}(X_1)$ and $\mu_2 \in \mathsf{Prob}(X_2)$.

▶ **Proposition 2.** *The probabilistic version of a span is a span. Moreover, the probabilistic version of a proper span is proper as well.*

The claim regarding properness follows from Prokhorov's theorem [7], which characterizes relatively compact subsets of $\mathsf{Prob}(X)$: If $P \subseteq \mathsf{Prob}(X)$ is a set of probability measures, then P is relatively compact in $\mathsf{Prob}(X)$ iff P is tight in $\mathsf{Prob}(X)$, i.e., for every $\varepsilon \in \mathbb{R}_{>0}$ there is a compact set $K \subseteq X$ where $\mu(K) > 1 - \varepsilon$ for all $\mu \in P$.

Span inverse. In a compositional setting, the states of the components determine the states of the composed system. Within our approach, a state as an element of X in the composed system is not required to be uniquely determined: Given a span $\mathcal{X} = (X, X_1, X_2)$, $x_1 \in X_1$, and $x_2 \in X_2$, every $x \in X$ where $x_{|1} = x_1$ and $x_{|2} = x_2$ stands for a state in the composed system resulting from the states x_1 and x_2 of the components. However, in applications later it is important to have a mapping with additional properties: Given a span $\mathcal{X} = (X, X_1, X_2)$, a Borel function $f \colon X_1 \times X_2 \to X$ is called an $\mathcal{X}$*-inverse*, if for all $x_1 \in X_1$ and $x_2 \in X_2$, if $x_1 \,\mathcal{X}\, x_2$, then $f(x_1, x_2)_{|1} = x_1$ and $f(x_1, x_2)_{|2} = x_2$.

▶ **Theorem 3.** *Every proper span $\mathcal{X}$ has an $\mathcal{X}$-inverse.*

It follows $\mu_1 \,\mathcal{X}^c\, \mu_2$ iff $\mu_1 \,\mathsf{Rel}(\mathcal{X})^w\, \mu_2$ for all $\mu_1 \in \mathsf{Prob}(X_1)$ and $\mu_2 \in \mathsf{Prob}(X_2)$, where $\mathsf{Rel}(\mathcal{X}) = \{\langle x_{|1}, x_{|2}\rangle \,;\, x \in X\}$. Our proof of Theorem 3 is an application of a *measurable selection theorem* [8]: Take some $\hat{x} \in X$ and define $\Phi \colon X_1 \times X_2 \to 2^X$, $\Phi(x_1, x_2) = \{x \in X \,;\, x_{|1} = x_1 \text{ and } x_{|2} = x_2\}$, if the set on the right-hand side is non-empty, and $\Phi(x_1, x_2) = \{\hat{x}\}$, otherwise. It suffices to argue that Φ admits a measurable selection, i.e., there is a measurable function $f \colon X_1 \times X_2 \to X$ where $f(x_1, x_2) \in \Phi(x_1, x_2)$ for all $x_1 \in X_1$ and $x_2 \in X_2$. To do so, we rely on results from descriptive set theory. Notice, together with Proposition 2, Theorem 3 yields an $\mathsf{Prob}(\mathcal{X})$-inverse if $\mathcal{X}$ is proper, which is an important observation for our discussions later. This is not obvious even for simple spans considering

for instance the probabilistic version of a variable span. We remark that there are spans $\mathcal{X}$ that have no $\mathcal{X}$-inverses and thus, the properness assumption is important [25].

3.2 Composition

A major objective in defining compositional frameworks is to separate the concerns of components specifying the operational behavior and composition operators addressing their interaction or coordination. We start with two STSs $\mathcal{T}_1 = (S_1, \Gamma_1, \to_1)$ and $\mathcal{T}_2 = (S_2, \Gamma_2, \to_2)$, where we assume S_1 and S_2 are Polish spaces. To declare the interactions between $\mathcal{T}_1$ and $\mathcal{T}_2$, we specify a set of synchronization labels $\mathsf{Sync} \subseteq \Gamma_1 \cap \Gamma_2$, a span $\mathcal{S} = (S, S_1, S_2)$ to characterizes the state space of the composition, and an so-called agreement $\mathcal{G} = (LC_1, LC_2)$ between $\mathcal{T}_1$ and $\mathcal{T}_2$. Here, LC_1 and LC_2 are so-called local constraints and for the moment, to present the central definition of this paper, it suffices to require $LC_1, LC_2 \subseteq S \times \mathsf{Prob}(S)$. Intuitively, we use local constraints to specify the behavior of local variables within local transitions (see below).

▶ **Definition 4.** We define the STS $\mathcal{T}_1 \parallel_{\mathcal{S},\mathcal{G},\mathsf{Sync}} \mathcal{T}_2 = (S, \Gamma_1 \cup \Gamma_2, \to)$, where for all $s \in S$, $\gamma \in \Gamma$, and $\mu \in \mathsf{Prob}(S)$ it holds $s \to^\gamma \mu$ iff one of the following three conditions hold:

- $\gamma \in \Gamma_1 \setminus \mathsf{Sync}$ and $s_{|1} \to_1^\gamma \mu_{|1}$ and $s \, LC_2 \, \mu$.
- $\gamma \in \Gamma_2 \setminus \mathsf{Sync}$ and $s \, LC_1 \, \mu$ and $s_{|2} \to_2^\gamma \mu_{|2}$.
- $\gamma \in \mathsf{Sync}$ and $s_{|1} \to_1^\gamma \mu_{|1}$ and $s_{|2} \to_2^\gamma \mu_{|2}$.

To illustrate the crux of our composition operator, we regard the case where $\mathcal{S}$ is a Cartesian span, i.e., $S = S_1 \times S_2$. Former approaches [39, 16] assume that $\mathcal{T}_1$ and $\mathcal{T}_2$ behave stochastically independent in a synchronizing step, i.e., if $s_{|1} \to_1^\gamma \mu_1$ and $s_{|2} \to_2^\gamma \mu_2$, then $s \hookrightarrow^\gamma \mu_1 \otimes \mu_2$ in $\mathcal{T}_1 \parallel_H^\otimes \mathcal{T}_2$. Our operator does not rely on any stochastic assumptions: Instead of considering only the independent coupling we take all the couplings into account, i.e., if $s_{|1} \to_1^\gamma \mu_1$ and $s_{|2} \to_2^\gamma \mu_2$, then $s \to^\gamma \mu$ for all couplings μ of (μ_1, μ_2). During a discussion about the example from the introduction and SHMAs, we will see how additional stochastic information between the components can be incorporated within our general framework.

Local constraints. Our composition operator is indexed by a span, which determines the dependencies between the states of $\mathcal{T}_1$ and $\mathcal{T}_2$. For instance, one can specify shared and local variables using the variable span. When composing STSs, one has to ensure that local transitions and variables of the components behave in a compatible way. Let us illustrate this and regard again the case where $\mathcal{S}$ is a Cartesian span. If $\mathcal{T}_1$ performs a local transition, i.e., a transition that is labeled by some $\gamma \in \Gamma_1 \setminus \mathsf{Sync}$, then the current state of $\mathcal{T}_2$ must not change. The properties of a local constraint should hence guarantee $s \, LC_2 \, \mu$ iff $\mu_{|2} = \mathsf{Dirac}[s_{|2}]$. It then follows that $\langle s_1, s_2 \rangle \to^\gamma \mu_1 \otimes \mathsf{Dirac}[s_2]$ for all $s_2 \in S_2$ and $s_1 \to_1^\gamma \mu_1$ where $\gamma \in \Gamma_1 \setminus \mathsf{Sync}$. Of course, the same discussion applies for $\mathcal{T}_1$ and the local constraint LC_1. This leads to the following requirements for a local constraint $LC_2 \subseteq S \times \mathsf{Prob}(S)$:

- For all $s \in S$ and $\mu \in \mathsf{Prob}(S)$, if $\mu_{|2} = \mathsf{Dirac}[s_{|2}]$, then $s \, LC_2 \, \mu$.
- For all $s \, LC_2 \, \mu$ and $\mu' \in \mathsf{Prob}(S)$, if $\mu_{|1} = \mu'_{|1}$ and $\mu_{|2} = \mu'_{|2}$, then $s \, LC_2 \, \mu'$.
- For all $s \, LC_2 \, \mu$, if $\mu_{|1} \, \mathcal{S}^c \, \mathsf{Dirac}[s_{|2}]$, then μ is a $\mathcal{S}$-coupling of $(\mu_{|1}, \mathsf{Dirac}[s_{|2}])$.

The requirements for LC_1 are similar. Intuitively, the first requirement for LC_2 ensures that the STS $\mathcal{T}_2$ cannot block a local transition of $\mathcal{T}_1$ which is not critical from the view of $\mathcal{T}_2$, i.e., variables of $\mathcal{T}_2$ are not affected within the transition of $\mathcal{T}_1$. Thus, such local transition of $\mathcal{T}_1$ are independent of $\mathcal{T}_2$ and can happen autonomously. Different couplings of given probability measures cannot be distinguished within local constraints imposed by the second property.

The third requirement intuitively demands that whenever $\mathcal{T}_1$ performs a local transition where no local variables of $\mathcal{T}_2$ are modified, the state of $\mathcal{T}_2$ must not change. In case of a Cartesian span the above requirements yield

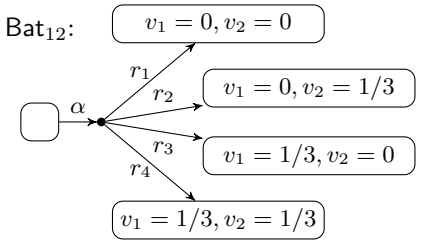
$$LC_2 = \{\langle\langle s_1, s_2\rangle, \mu_1 \otimes \mathsf{Dirac}[s_2]\rangle \,;\, s_1 \in S_1 \text{ and } s_2 \in S_2 \text{ and } \mu_1 \in \mathsf{Prob}(S_1)\} \quad \text{and}$$
$$LC_1 = \{\langle\langle s_1, s_2\rangle, \mathsf{Dirac}[s_1] \otimes \mu_2\rangle \,;\, s_1 \in S_1 \text{ and } s_2 \in S_2 \text{ and } \mu_2 \in \mathsf{Prob}(S_2)\}.$$

Hence, the agreement $\mathcal{G}$ is uniquely determined by STSs $\mathcal{T}_1$ and $\mathcal{T}_2$. We thus simply write $\mathcal{T}_1 \parallel_{\times,\mathsf{Sync}} \mathcal{T}_2$ instead of $\mathcal{T}_1 \parallel_{\mathcal{S},\mathcal{G},\mathsf{Sync}} \mathcal{T}_2$. Observe that $\mathcal{T}_1 \parallel_{\times,\mathsf{Sync}} \mathcal{T}_2$ and $\mathcal{T}_1 \parallel^{\otimes}_{\mathsf{Sync}} \mathcal{T}_2$ are not bisimilar in general. This is due to the fact that our composition operator does not incorporate any stochastic assumptions concerning the interaction of $\mathcal{T}_1$ and $\mathcal{T}_2$. In case where $\mathcal{S}$ is a variable span, i.e., $S_1 = \mathsf{Ev}(\mathsf{Var}_1)$, $S_2 = \mathsf{Ev}(\mathsf{Var}_2)$, and $S = \mathsf{Ev}(\mathsf{Var}_1 \cup \mathsf{Var}_2)$ for some sets of variables Var_1 and Var_2, there are more possible local constraints:

$$LC_2' = \{\langle e, \eta\rangle \in S \times \mathsf{Prob}(S) \,;\, \eta_{|\mathsf{Var}_1} = \mathsf{Dirac}[e_{|\mathsf{Var}_1}] \text{ implies } \eta = \mathsf{Dirac}[e]\},$$
$$LC_2'' = \{\langle e, \eta\rangle \in S \times \mathsf{Prob}(S) \,;\, \eta_{|\mathsf{Var}_2 \setminus \mathsf{Var}_1} = \mathsf{Dirac}[e_{|\mathsf{Var}_2 \setminus \mathsf{Var}_1}]\}, \quad \text{and}$$
$$LC_2''' = \{\langle e, \eta\rangle \in S \times \mathsf{Prob}(S) \,;\, \eta_{|\mathsf{Var}_2} = \mathsf{Dirac}[e_{|\mathsf{Var}_2}]\}$$

all enjoy the requirements for a local constraint where $LC_2' \supseteq LC_2'' \supseteq LC_2'''$. Considering for instance LC_2'', all the variables in $\mathsf{Var}_2 \setminus \mathsf{Var}_1$ cannot be modified within a local transition of $\mathcal{T}_1$. Constraint LC_2''' is more restrictive: Here, all the variables in Var_2 are controlled by $\mathcal{T}_2$ and cannot be modified in a local transition of $\mathcal{T}_1$, i.e., variables in $\mathsf{Var}_1 \cap \mathsf{Var}_2$ can be observed by $\mathcal{T}_1$ only. It turns out $LC_2' \supseteq LC_2$ for every local constraint LC_2. Every local constraint hence enjoys the property that variables in $\mathsf{Var}_2 \setminus \mathsf{Var}_1$ must not be adapted within a local transition of $\mathcal{T}_1$ if the evaluations of the variables in Var_1 remain the same.

Example from the introduction. We return to the introductory stochastic systems illustrated in Section 1. Of course, Bat_1, Bat_2, and Dev can be seen as STSs with sets of states $\mathsf{Ev}(\{v_1\})$, $\mathsf{Ev}(\{v_2\})$, and $\mathsf{Ev}(\{v_1, v_2\})$, respectively. When composing them, we need not to worry about local constraints as there is only one synchronization action α. In what follows, we rely on the obvious variable spans. The composition of Bat_1 and Bat_2 yields the STS Bat_{12} depicted below.



There are infinitely many transitions: Every solution of the linear equation system $r_1 + r_2 = r_1 + r_3 = r_2 + r_4 = r_3 + r_4 = 1/2$ where $r_1, r_2, r_3, r_4 \in [0, 1]$ represents a coupling of the involved measures. When composing Bat_{12} and Dev, the set of all couplings is refined. We are moreover able to handle more complex stochastic information that depend on the operational behavior of the components. To illustrate this, assume systems which result from Bat_1 and Bat_2 such that α can be executed repeatedly (e.g., add some local transitions back to the blank state). An additional component might encode that, if the system has crashed repeatedly in the past, the event that the stored energy drops to 0 in both batteries

at the same time becomes more likely within an execution of α. We emphasize that the ordinary composition of STSs can be expressed within our framework using an additional component [25].

3.3 Congruence

In the context of process calculi, an important issue of bisimulation is the compatibility with syntactic operators in the process calculus, such as parallel composition. We show that bisimulation is a congruence for our composition operator under reasonable side-constraints, i.e., our composition operator enjoys the substitution property with respect to bisimulation. Suppose STSs $\mathcal{T}_{a1} = (S_{a1}, \Gamma_1, \to_{a1})$, $\mathcal{T}_{a2} = (S_{a2}, \Gamma_2, \to_{a2})$, $\mathcal{T}_{b1} = (S_{b1}, \Gamma_1, \to_{b1})$, and $\mathcal{T}_{b2} = (S_{b2}, \Gamma_2, \to_{b2})$ such that $\mathcal{T}_{a1} \sim \mathcal{T}_{b1}$ and $\mathcal{T}_{a2} \sim \mathcal{T}_{b2}$. Define

$$\mathcal{T}_a = \mathcal{T}_{a1} \parallel_{\mathcal{S}_a, \mathcal{G}_a, \mathsf{Sync}} \mathcal{T}_{a2} \quad \text{and} \quad \mathcal{T}_b = \mathcal{T}_{b1} \parallel_{\mathcal{S}_b, \mathcal{G}_b, \mathsf{Sync}} \mathcal{T}_{b2},$$

where $\mathsf{Sync} \subseteq \Gamma_1 \cap \Gamma_2$, $\mathcal{S}_a = (S_a, S_{a1}, S_{a2})$ and $\mathcal{S}_b = (S_b, S_{b1}, S_{b2})$ are proper spans, and $\mathcal{G}_a = (LC_{a1}, LC_{a2})$ and $\mathcal{G}_b = (LC_{b1}, LC_{b2})$ are agreements. Assume R_1 is a bisimulation for $(\mathcal{T}_{a1}, \mathcal{T}_{b1})$ and R_2 is a bisimulation for $(\mathcal{T}_{a2}, \mathcal{T}_{b2})$ and define

$$R_1 \wedge R_2 = \{\langle s_a, s_b \rangle \in S_a \times S_b \,;\, s_{a|1}\, R_1\, s_{b|1} \text{ and } s_{a|2}\, R_2\, s_{b|2}\}.$$

We aim to show that $R_1 \wedge R_2$ is a bisimulation for $(\mathcal{T}_a, \mathcal{T}_b)$ and hence $\mathcal{T}_a \sim \mathcal{T}_b$. However, we cannot expect this result without any compatibility requirements for the involved spans and agreements, since important relationships concerning the communication of the components are determined within our composition operator. This motivates the following notions: We refer to the tuple $\mathcal{C} = (\mathcal{S}_a, \mathcal{S}_b, R_1, R_2)$ as *span connection* and call $\mathcal{C}$ *adequate* if for all $\mu_{a1}\, R_1^w\, \mu_{b1}$ and $\mu_{a2}\, R_2^w\, \mu_{b2}$ it holds $\mu_{a1}\, \mathcal{S}_a^c\, \mu_{a2}$ iff $\mu_{b1}\, \mathcal{S}_b^c\, \mu_{b2}$. Intuitively, adequacy requires that the existence of span couplings is preserved by the relations R_1 and R_2. Observe, if $\mathcal{S}_a$ and $\mathcal{S}_b$ are Cartesian spans, then $\mathcal{C}$ is always adequate. The local constraints LC_{a2} and LC_{b2} are called *$\mathcal{C}$-bisimilar* if for all $s_a\, (R_1 \wedge R_2)\, s_b$ holds:

- For all $\mu_a \in \mathsf{Prob}(S_a)$ and $\mu_{b1} \in \mathsf{Prob}(S_{b1})$, if $s_a\, LC_{a2}\, \mu_a$ and $\mu_{a|1}\, R_1^w\, \mu_{b1}$, then there is $\mu_b \in \mathsf{Prob}(S_b)$ where $s_b\, LC_{b2}\, \mu_b$, $\mu_{b|1} = \mu_{b1}$, and $\mu_{a|2}\, R_2^w\, \mu_{b|2}$.
- For all $\mu_b \in \mathsf{Prob}(S_b)$ and $\mu_{a1} \in \mathsf{Prob}(S_{a1})$, if $s_b\, LC_{b2}\, \mu_b$ and $\mu_{a1}\, R_1^w\, \mu_{b|1}$, then there is $\mu_a \in \mathsf{Prob}(S_a)$ where $s_a\, LC_{a2}\, \mu_a$, $\mu_{a|1} = \mu_{a1}$, and $\mu_{a|2}\, R_2^w\, \mu_{b|2}$.

LC_{a1} and LC_{b1} are called *$\mathcal{C}$-bisimilar* if analogous properties are fulfilled. Observe that the stated requirement is motivated by the definition of bisimulation in the sense that each element of a local constraint LC_{a2} can be mimicked by LC_{b2} regarding the relations R_1 and R_2. If LC_{a2} and LC_{b2} as well as LC_{a1} and LC_{b1} are $\mathcal{C}$-bisimilar, respectively, then we refer to $\mathcal{G}_a$ and $\mathcal{G}_b$ as *$\mathcal{C}$-bisimilar*.

▶ **Theorem 5.** *If the span connection $\mathcal{C}$ is adequate and the agreements $\mathcal{G}_a$ and $\mathcal{G}_b$ are $\mathcal{C}$-bisimilar, then $R_1 \wedge R_2$ is a bisimulation for $(\mathcal{T}_a, \mathcal{T}_b)$.*

The challenging part of the proof can be summarized by the following claim [25]: Let $\mu_a \in \mathsf{Prob}(S_a)$, $\mu_{b1} \in \mathsf{Prob}(S_{b1})$, and $\mu_{b2} \in \mathsf{Prob}(S_{b2})$ where $\mu_{a|1}\, R_1^w\, \mu_{b1}$ and $\mu_{a|2}\, R_2^w\, \mu_{b2}$. Then there is an $\mathcal{S}_b$-coupling μ_b of (μ_{b1}, μ_{b2}) such that $\mu_a\, (R_1 \wedge R_2)^w\, \mu_b$. Our proof of this claim proceeds as follows. Assume W_1 is a weight function for $(\mu_{a|1}, R_1, \mu_{b1})$ and W_2 is a weight function for $(\mu_{a|2}, R_2, \mu_{b2})$. Using disintegration of measures [34], there are Markov kernels $k_1 \colon S_{a1} \to \mathsf{Prob}(S_{a2})$ and $k_2 \colon S_{b1} \to \mathsf{Prob}(S_{b2})$ such that $W_1 = \mu_{a|1} \rtimes k_1$ and $W_2 = \mu_{a|2} \rtimes k_2$. The crucial point is now to argue that there is a Markov kernel $k \colon S_a \to \mathsf{Prob}(S_b)$ where $k(s_a)$

is an $\mathcal{S}_b$-coupling of $(k_1(s_{a|1}), k_2(s_{a|2}))$ for μ_a-almost all $s_a \in S_a$. Here, we make use of an $\mathcal{S}_b$-inverse (cf. Theorem 3). With this Markov kernel at hand, we define $W \in \mathsf{Prob}(S_a \times S_b)$ by $W = \mu \rtimes k$ and $\mu_b \in \mathsf{Prob}(S_b)$ by $\mu_b(M_b) = W(S_a \times M_b)$. It turns out that μ_b is an appropriate $\mathcal{S}_b$-coupling. To summarize, we defined a potential weight function W out of the weight functions W_1 and W_2 and then introduced the measure μ_b via W.

Path measures. When resolving the non-determinism in STSs using schedulers, one obtains a probability measure – the path measure – on the set of all infinite paths of the STS [16]. Besides our congruence result, we expect compatibility of path measures induced by schedulers in our compositional framework. To provide an intuition, assume STSs $\mathcal{T}_1$ and $\mathcal{T}_2$ and let $\mathcal{T}$ be an STSs obtained by a composition involving $\mathcal{T}_1$ and $\mathcal{T}_2$. Assume that $\mathfrak{S}_1$ and $\mathfrak{S}_2$ are schedulers for $\mathcal{T}_1$ and $\mathcal{T}_2$, respectively, and $\mathfrak{S}$ is a scheduler for $\mathcal{T}$. If $\mathfrak{S}$ satisfies certain compatibility requirements regarding $\mathfrak{S}_1$ and $\mathfrak{S}_2$, one can show that the induced path measure for $\mathcal{T}$ is a coupling of the corresponding path measures for $\mathcal{T}_1$ and $\mathcal{T}_2$. Here, we consider a natural span that connects the sets of all infinite paths of $\mathcal{T}_1$, $\mathcal{T}_2$, and $\mathcal{T}$.

4 Stochastic hybrid motion automata

We apply our general results of the preceding sections and develop a compositional modeling framework for stochastic hybrid systems. The formal definition of our model relies on a standard schema of hybrid automata [3, 29, 26], i.e., there are a discrete control structure consisting of locations and jumps in-between, and continuous variables whose values evolve according to a flow formalized by a motion function. Within a jump, the variables can be updated instantaneously. The novelty of our approach is that every jump is indexed by a set of those variables that are not affected in the corresponding discrete step. As a consequence, the adjustment of flows is always accompanied by a specific command.

Syntax. Every jump in our hybrid-automaton model is labeled by a command: Given a set Var of variables and a set Act of actions, a *command on* $(\mathsf{Var}, \mathsf{Act})$ is a tuple $\langle c, \alpha, V, \mathsf{upd}\rangle$ consisting of a *guard* $c \in \mathsf{Cond}(\mathsf{Var})$, an *action* $\alpha \in \mathsf{Act}$, a set of *disabled* variables $V \subseteq \mathsf{Var}$, and an *(non-deterministic) update* $\mathsf{upd}\colon \mathsf{Ev}(\mathsf{Var}) \to 2^{\mathsf{Prob}(\mathsf{Ev}(\mathsf{Var}))}$ where $\eta_{|V} = \mathsf{Dirac}[e_{|V}]$ for all $\eta \in \mathsf{upd}(e)$ and $e \in \mathsf{Ev}(\mathsf{Var})$. $\mathsf{Cmd}(\mathsf{Var}, \mathsf{Act})$ denotes the set of all commands on $(\mathsf{Var}, \mathsf{Act})$. Intuitively, a jump is enabled if the current variable evaluation satisfies the guard. The action name indicates whether the jump is an internal location switch or subject to an interaction with another component. The set of disabled variables specifies those variables which are not affected within the jump. This also clarifies the additional requirement for updates.

▶ **Definition 6.** An *SHMA* is a tuple $(\mathsf{Loc}, \mathsf{Var}, \mathsf{Act}, \mathsf{Inv}, \mathsf{Mot}, \twoheadrightarrow)$ where Loc is a finite set of *locations*, Var is a set of variables, Act is a set of actions, $\mathsf{Inv}\colon \mathsf{Loc} \to \mathsf{Cond}(\mathsf{Var})$ is an *invariant function*, $\mathsf{Mot}\colon \mathsf{Loc} \to 2^{\mathsf{Flow}(\mathsf{Var})}$ is a *motion function* which assigns a shift-invariant set of flows to every location, and $\twoheadrightarrow \subseteq \mathsf{Loc} \times \mathsf{Cmd}(\mathsf{Var}, \mathsf{Act}) \times \mathsf{Prob}(\mathsf{Loc})$ is a *jump relation*.

We write $l \mathrel{-\!\![} \mathit{cmd} \mathrel{]\!\!\rightarrow\!\!\!\!\!\rightarrow} \lambda$ instead of $\langle l, \mathit{cmd}, \lambda\rangle \in \twoheadrightarrow$. The behavior in a location l depends on the current variable evaluation e. In a discrete step, a jump $l \mathrel{-\!\![} c, \alpha, V, \mathsf{upd} \mathrel{]\!\!\rightarrow\!\!\!\!\!\rightarrow} \lambda$ where $e \models c$ is chosen non-deterministically. Then, action α is executed and a successor location is sampled according to λ. The evaluation of the variables changes according to a non-deterministically chosen probability measure contained in $\mathsf{upd}(e)$. Entering a location l', a flow in $\mathsf{Mot}(l')$ is also chosen non-deterministically and the variables then evolve according to this flow.

Semantics. Every SHMA $\mathcal{H} = (\mathsf{Loc}, \mathsf{Var}, \mathsf{Act}, \mathsf{Inv}, \mathsf{Mot}, \twoheadrightarrow)$ can be interpreted as an STS resulting from unfolding. In what follows, $S = \mathsf{Loc} \times \mathsf{Flow}(\mathsf{Var})$ denotes the set of states. Notice, S constitutes a Polish space as $\mathsf{Flow}(\mathsf{Var})$ is known to be a Polish space [7]. Intuitively, a state $\langle l, \vartheta \rangle$ represents the actual location l and the current active flow ϑ, i.e., ϑ corresponds to the flow chosen in the preceding jump. Moreover, $\vartheta(0)$ stands for the present variable evaluation. We call $\langle l, \vartheta \rangle$ *well-formed* if $\vartheta \in \mathsf{Mot}(l)$ and $\vartheta(0) \models \mathsf{Inv}(l)$.

There are two kinds of transitions within our STS for $\mathcal{H}$, namely transitions where time passes and transitions corresponding to a jump. Time can pass in a location l as long as the flow does not violate the invariant $\mathsf{Inv}(l)$. Transitions for jumps are more intricate. Assume $l \multimap[\, c, \alpha, V, \mathsf{upd} \,]\twoheadrightarrow \lambda$ is enabled in state $\langle l, \vartheta \rangle$, i.e., $e \models c$ where $e = \vartheta(0)$. Basically, jumps in SHMAs proceed in two phases: First, a successor location and a variable evaluation are sampled according to λ and some $\eta \in \mathsf{upd}(e)$, respectively. In the second phase, a flow is chosen non-deterministically for those variables which are not disabled, i.e., the variables in $\mathsf{Var} \setminus V$. This is formalized as follows: A *flow adapter for* (ϑ, V) is a Borel function $\chi \colon \mathsf{Loc} \times \mathsf{Ev}(\mathsf{Var}) \to \mathsf{Flow}(\mathsf{Var})$ such that for all $l' \in \mathsf{Loc}$ and $e', \tilde{e}' \in \mathsf{Ev}(\mathsf{Var})$:

$$\chi(l', e')_{|V} = \vartheta_{|V} \quad \text{and} \quad e'_{|\mathsf{Var}\setminus V} = \tilde{e}'_{|\mathsf{Var}\setminus V} \text{ implies } \chi(l', e')_{|\mathsf{Var}\setminus V} = \chi(l', \tilde{e}')_{|\mathsf{Var}\setminus V}.$$

Intuitively, if state $\langle l', e' \rangle$ is sampled within the first phase of a jump, then $\chi(l', e')$ represents the new flow, i.e., the flow which determines the evolution of variables in a subsequent time passage. The first condition for a flow adapter requires that the flow for disabled variables is not allowed to change. The required implication ensures that a flow is chosen independently of the disabled variables. This is important for our compositional approach, as we want to make sure that the choice of a new flow in an SHMA obtained by composition does not depend on the local variables of the respective communication partners. If χ is a flow adapter, then we define the auxiliary function $\hat{\chi} \colon \mathsf{Loc} \times \mathsf{Ev}(\mathsf{Var}) \to S$, $\hat{\chi}(l, e) = \langle l, \chi(l, e) \rangle$.

▶ **Definition 7.** The *semantics of* $\mathcal{H}$ is given by the STS $[\![\mathcal{H}]\!] = (S, \mathbb{T} \cup \mathsf{Act}, \to)$, where $\to$ is the smallest relation satisfying the following requirements for all well-formed states $s = \langle l, \vartheta \rangle$:

- For all $T \in \mathbb{T}$, if $\vartheta(t) \models \mathsf{Inv}(l)$ for every $t \in [0, T]$, then $s \to^t \mathsf{Dirac}[\langle l, \vartheta \oplus T \rangle]$.
- For all $l \multimap[\, c, \alpha, V, \mathsf{upd} \,]\twoheadrightarrow \lambda$, $\eta \in \mathsf{upd}(e)$, couplings ν of (λ, η), and flow adapter χ for (ϑ, V), if $e \models c$ and for ν-almost all $\langle l', e' \rangle \in \mathsf{Loc} \times \mathsf{Ev}(\mathsf{Var})$ the state $\hat{\chi}(l', e')$ is well-formed, then $s \to^\alpha \hat{\chi}_\sharp(\nu)$. Here, we abbreviate $e = \vartheta(0)$.

An SHMA almost surely enters a well-formed state, i.e., if $s \to^\gamma \mu$ where $\gamma \in \mathbb{T} \cup \mathsf{Act}$, then s' is well-formed for μ-almost all $s' \in S$. We emphasize that for our approach concerning the adaption of flows it is crucial that the current flow is part of a state. Otherwise, it would be not possible to ensure that the flow for disabled variables is not allowed to change.

Composition. We now introduce a composition operator for SHMAs. For $i \in \{1, 2\}$ let $\mathcal{H}_i = (\mathsf{Loc}_i, \mathsf{Var}_i, \mathsf{Act}_i, \mathsf{Inv}_i, \mathsf{Mot}_i, \twoheadrightarrow_i)$ be SHMAs. When running $\mathcal{H}_1$ and $\mathcal{H}_2$ in parallel, $\mathcal{H}_1$ and $\mathcal{H}_2$ synchronize on all actions contained in $\mathsf{Act}_1 \cap \mathsf{Act}_2$ and the variables in $\mathsf{Var}_1 \cap \mathsf{Var}_2$ are shared, i.e., $\mathsf{Var}_1 \setminus \mathsf{Var}_2$ and $\mathsf{Var}_2 \setminus \mathsf{Var}_1$ represent the sets of the respective local variables. Abbreviate $\mathsf{Loc} = \mathsf{Loc}_1 \times \mathsf{Loc}_2$, $\mathsf{Var} = \mathsf{Var}_1 \cup \mathsf{Var}_2$, and $\mathsf{Act} = \mathsf{Act}_1 \cup \mathsf{Act}_2$. Let upd_1 and upd_2 be updates for Var_1 and Var_2, respectively. The Var-*lifting of* $(\mathsf{upd}_1, \mathsf{upd}_2)$ is the update upd for Var such that for all $e \in \mathsf{Ev}(\mathsf{Var})$, $\mathsf{upd}(e)$ consists of all $\eta \in \mathsf{Prob}(\mathsf{Ev}(\mathsf{Var}))$ where $\eta_{|\mathsf{Var}_1} = \eta_1$ and $\eta_{|\mathsf{Var}_2} = \eta_2$ for some $\eta_1 \in \mathsf{upd}(e_{|\mathsf{Var}_1})$ and $\eta_2 \in \mathsf{upd}(e_{|\mathsf{Var}_2})$. We define Var-liftings with respect to an update accordingly, i.e., upd is a Var-lifting of upd_1 if for all $e \in \mathsf{Ev}(\mathsf{Var})$, $\mathsf{upd}(e)$ consists of all $\eta \in \mathsf{Prob}(\mathsf{Ev}(\mathsf{Var}))$ where $\eta_{|\mathsf{Var}_1} = \eta_1$ for some $\eta_1 \in \mathsf{upd}(e_{|\mathsf{Var}_1})$ and $\eta_{|\mathsf{Var}\setminus\mathsf{Var}_1} = \mathsf{Dirac}[e_{|\mathsf{Var}\setminus\mathsf{Var}_1}]$. Notice, the definition of Var-liftings involves couplings concerning a variable span, which provides a connection to the preceding sections.

▶ **Definition 8.** $\mathcal{H}_1 \parallel \mathcal{H}_2 = (\mathsf{Loc}, \mathsf{Var}, \mathsf{Act}, \mathsf{Inv}, \mathsf{Mot}, \twoheadrightarrow)$ is the SHMA with $\mathsf{Inv}(l_1, l_2) = \mathsf{Inv}(l_1) \wedge \mathsf{Inv}(l_2)$ and $\mathsf{Mot}(l_1, l_2) = \{\vartheta \in \mathsf{Flow}(\mathsf{Var}) \,;\, \vartheta_{|\mathsf{Var}_1} \in \mathsf{Mot}_1(l_1) \text{ and } \vartheta_{|\mathsf{Var}_2} \in \mathsf{Mot}_2(l_2)\}$ for all $\langle l_1, l_2\rangle \in \mathsf{Loc}$ and $\twoheadrightarrow$ is the smallest relation such that $\langle l_1, l_2\rangle \dashv[\, c, \alpha, V, \mathsf{upd} \,]\!\!\rightarrow\!\!\!\!\twoheadrightarrow \lambda$, if λ is a coupling of $\lambda_1 \in \mathsf{Prob}(\mathsf{Loc}_1)$ and $\lambda_2 \in \mathsf{Prob}(\mathsf{Loc}_2)$ and one of the following holds:

- $\alpha \in \mathsf{Act}_1 \setminus \mathsf{Act}_2$, $\lambda_2 = \mathsf{Dirac}[l_2]$, and there is $l_1 \dashv[\, c_1, \alpha, V_1, \mathsf{upd}_1 \,]\!\!\rightarrow\!\!\!\!\twoheadrightarrow_1 \lambda_1$ such that $c = c_1$, $V = V_1 \cup (\mathsf{Var}_2 \setminus \mathsf{Var}_1)$, and upd is the Var-lifting of upd_1.
- $\alpha \in \mathsf{Act}_2 \setminus \mathsf{Act}_1$, $\lambda_1 = \mathsf{Dirac}[l_1]$, and there is $l_2 \dashv[\, c_2, \alpha, V_2, \mathsf{upd}_2 \,]\!\!\rightarrow\!\!\!\!\twoheadrightarrow_2 \lambda_2$ such that $c = c_2$, $V = V_2 \cup (\mathsf{Var}_1 \setminus \mathsf{Var}_2)$, and upd is the Var-lifting of upd_2.
- $\alpha \in \mathsf{Act}_1 \cap \mathsf{Act}_2$ and there are $l_1 \dashv[\, c_1, \alpha, V_1, \mathsf{upd}_1 \,]\!\!\rightarrow\!\!\!\!\twoheadrightarrow_1 \lambda_1$ and $l_2 \dashv[\, c_2, \alpha, V_2, \mathsf{upd}_2 \,]\!\!\rightarrow\!\!\!\!\twoheadrightarrow_2 \lambda_2$ where $c = c_1 \wedge c_2$, $V = V_1 \cup V_2$, and upd is the Var-lifting of $(\mathsf{upd}_1, \mathsf{upd}_2)$.

When composing SHMAs, local variables of participating SHMAs become disabled for corresponding internal jumps. Within our semantics, flow adapters thus ensure that the adaption of flows in internal jumps in $\mathcal{H}_1 \parallel \mathcal{H}_2$ are independent of the local variables of the respective communication partners. Moreover, flows for local variables of $\mathcal{H}_2$ cannot be adapted within an internal jump of $\mathcal{H}_1$ and vice versa. It is easy to see that the composition operator for SHMAs is commutative and associative.

Congruence. We aim for a congruence theorem for SHMAs relying on Theorem 5. For this, we relate the composition of SHMAs with our general approach towards a composition of STSs, i.e., we represent the STS $[\![\mathcal{H}_1 \parallel \mathcal{H}_1]\!]$ as a composition involving the components $[\![\mathcal{H}_1]\!]$ and $[\![\mathcal{H}_2]\!]$. Notice that sampling a successor location in $\mathcal{H}_1 \parallel \mathcal{H}_2$ happens according to a coupling measure. This observation also applies when combining measures for locations and variable evaluations within our semantics of SHMAs. To this end, it is easy to define the corresponding span $\mathcal{S}$ and agreement $\mathcal{G}$ such that

$$[\![\mathcal{H}_1 \parallel \mathcal{H}_2]\!] = [\![\mathcal{H}_1]\!] \parallel_{\mathcal{S},\mathcal{G},\mathsf{Act}_1 \cap \mathsf{Act}_2} [\![\mathcal{H}_2]\!].$$

More precisely, $\mathcal{S}$ is a span arising from a Cartesian span for the locations and a span for the sets of flows. For the agreement $\mathcal{G}$, we regard local constraints where the shared variables can be modified by both involved systems $\mathcal{H}_1$ and $\mathcal{H}_2$. The obtained representation of $[\![\mathcal{H}_1 \parallel \mathcal{H}_2]\!]$ underpins again the flexibility of our composition operator for STS.

We rephrase Theorem 5 in the context SHMAs. Two SHMAs are bisimilar if their semantics in terms of STSs are bisimilar. Let $\mathcal{H}_{a1}$ and $\mathcal{H}_{b1}$ be SHMAs with the same sets of variables Var_1 and actions Act_1 and similar, let $\mathcal{H}_{a2}$ and $\mathcal{H}_{b2}$ be SHMAs with variables Var_2 and actions Act_2. Abbreviate $\mathsf{LVar}_1 = \mathsf{Var}_1 \setminus \mathsf{Var}_2$, $\mathsf{LVar}_2 = \mathsf{Var}_2 \setminus \mathsf{Var}_1$, and $\mathsf{SVar} = \mathsf{Var}_1 \cap \mathsf{Var}_2$.

▶ **Theorem 9.** *Let R_1 and R_2 be bisimulations for $(\mathcal{H}_{a1}, \mathcal{H}_{b1})$ and $(\mathcal{H}_{a2}, \mathcal{H}_{b2})$, respectively. $\mathcal{H}_{a1} \parallel \mathcal{H}_{a2}$ and $\mathcal{H}_{b1} \parallel \mathcal{H}_{b2}$ are bisimilar if R_1 and R_2 do not involve shared variables, i.e.,*

$$\begin{aligned} R_1 = \{\langle\langle l_{a1}, \vartheta_{a1|\mathsf{LVar}_1} \uplus \vartheta^S\rangle, \langle l_{b1}, \vartheta_{b1|\mathsf{LVar}_1} \uplus \vartheta^S\rangle\rangle \,;\, \\ \langle l_{a1}, \vartheta_{a1}\rangle \, R_1 \, \langle l_{b1}, \vartheta_{b1}\rangle \text{ and } \vartheta^S \in \mathsf{Flow}(\mathsf{SVar})\}, \\ R_2 = \{\langle\langle l_{a2}, \vartheta_{a2|\mathsf{LVar}_2} \uplus \vartheta^S\rangle, \langle l_{b2}, \vartheta_{b2|\mathsf{LVar}_2} \uplus \vartheta^S\rangle\rangle \,;\, \\ \langle l_{a2}, \vartheta_{a2}\rangle \, R_2 \, \langle l_{b2}, \vartheta_{b2}\rangle \text{ and } \vartheta^S \in \mathsf{Flow}(\mathsf{SVar})\}. \end{aligned}$$

Our requirement that R_1 and R_2 do not distinguish between shared variables yields the compatibility assumption required for Theorem 5. Our proof then simply exploits the representation of $[\![\mathcal{H}_{a1} \parallel \mathcal{H}_{a2}]\!]$ and $[\![\mathcal{H}_{b1} \parallel \mathcal{H}_{b2}]\!]$ in terms of a composition of STSs.

5 Concluding remarks

In this paper, we introduced a generic parallel-composition operator for STSs and SHMAs. The essential new feature that distinguishes the novel composition from previous ones is that it uses the mathematical concepts of spans and couplings to model the effect of composing (potentially dependent) stochastic behaviors. The latter is crucial for systems where the components communicate via shared variables. A further feature of the novel stochastic-hybrid-system model (SHMA) is that the adaption of flows depends on commands rather happening on arbitrary occasions. We proved important algebraic properties in the context of composition, e.g., congruence with respect to bisimulation. This shows that even within our generic operator one does not have to forgo desired properties of compositional systems. There is plenty room for further elaborations. Firstly, we are going to develop a mathematical theory for SHMA that also involves stochastic flows. Furthermore, we will work on a modeling language for couplings and spans in order to obtain a theoretical basis for practical tools. Also other kinds of models, where spans yield a powerful approach for compositional modeling, could be investigated. Moreover, our approach concerning couplings as a modeling formalism enables many new verification questions, e.g., for directly reasoning about the coordination between components.

Abstract

Nonnegative matrix factorization (NMF) is the problem of decomposing a given nonnegative $n \times m$ matrix M into a product of a nonnegative $n \times d$ matrix W and a nonnegative $d \times m$ matrix H. Restricted NMF requires in addition that the column spaces of M and W coincide. Finding the minimal inner dimension d is known to be NP-hard, both for NMF and restricted NMF. We show that restricted NMF is closely related to a question about the nature of minimal probabilistic automata, posed by Paz in his seminal 1971 textbook. We use this connection to answer Paz's question negatively, thus falsifying a positive answer claimed in 1974.

Furthermore, we investigate whether a rational matrix M always has a restricted NMF of minimal inner dimension whose factors W and H are also rational. We show that this holds for matrices M of rank at most 3 and we exhibit a rank-4 matrix for which W and H require irrational entries.

1 Introduction

Nonnegative matrix factorization (NMF) is the task of factoring a matrix of nonnegative real numbers M (henceforth a *nonnegative* matrix) as a product $M = W \cdot H$ such that matrices W and H are also nonnegative. The smallest inner dimension of any such factorization is called the *nonnegative rank* of M, written $\mathrm{rank}_+(M)$.

In machine learning, NMF was popularized by the seminal work of Lee and Seung [14] as a tool for finding features in facial-image databases. Since then, NMF has found a broad range of applications – including document clustering, topic modelling, computer vision, recommender systems, bioinformatics, and acoustic signal processing [5, 4, 7, 19, 21, 22]. In applications, matrix M can typically be seen as a matrix of data points: each column of M corresponds to a data point and each row to a feature. Then, computing a nonnegative factorization $M = W \cdot H$ corresponds to expressing the data points (columns of M) as convex combinations of latent factors (columns of W), i.e., as linear combinations of latent factors with nonnegative coefficients (columns of H).

From a computational perspective, perhaps the most basic problem concerning NMF is whether a given nonnegative matrix of rational numbers M admits an NMF with inner dimension at most a given number k. Formally, the *NMF problem* asks whether $\text{rank}_+(M) \leq k$. In practical applications, various heuristics and local-search algorithms are used to compute an approximate nonnegative factorization, but little is known in terms of their theoretical guarantees. The NMF problem under the *separability* assumption of Donoho and Stodden [9] is tractable: an NMF $M = W \cdot H$ is called *separable* if every column of W is also a column of M. In 2012, Arora et al. [2] showed that it is decidable in polynomial time whether a given matrix admits a separable NMF with a given inner dimension. Further progress was made recently, with several efficient algorithms for computing near-separable NMFs [13, 12].

Vavasis [20] showed that the problem of deciding whether the rank of a nonnegative matrix is equal to its nonnegative rank is NP-hard. This result implies that generalizations of this problem, such as the aforementioned NMF problem, the problem of computing the factors W, H (in both exact and approximate versions), and nonnegative rank determination, are also NP-hard. It is not known whether any of these problems are in NP.

Vavasis [20] notes that the difficulty in proving membership in NP lies in the fact that a certificate for a positive answer to the NMF problem seems to require the sought factors: a pair of nonnegative matrices W, H such that $M = W \cdot H$. Related to this, Cohen and Rothblum [8] posed the question of whether, given a nonnegative matrix of rational numbers M, there always exists an NMF $M = W \cdot H$ of inner dimension equal to $\text{rank}_+(M)$ such that both W and H are also matrices of rational numbers. A natural route to proving membership of the NMF problem in NP would be to give a positive answer to the question of Cohen and Rothblum (as well as a polynomial bound on the bit-length of the factors W and H). However, the question remains open. Currently the best complexity bound for the NMF problem is membership in PSPACE, which is obtained by translation into the existential theory of real-closed fields [2]. Such a translation shows that one can always choose the entries of W and H to be algebraic numbers.

In this work, we focus on the so-called *restricted* NMF (RNMF) problem, introduced by Gillis and Glineur [11]. The RNMF problem is defined as the NMF problem, except that the column spaces of M and W are required to coincide. (Note that for any NMF, the column space of M is a subspace of the column space of W.) This problem has a natural geometric interpretation as the *nested polytope problem (NPP)*: the problem of finding a minimum-vertex polytope nested between two given convex polytopes. In more detail, for a rank-r matrix M, finding an RNMF with inner dimension d is known to correspond exactly to finding a nested polytope with d vertices in an $(r-1)$-dimensional NPP.

Our contributions are as follows.

1. We establish a tight connection between NMF and the coverability relation in labelled Markov chains (LMCs). The latter notion was introduced by Paz [15]. Loosely speaking, an LMC $\mathcal{M}'$ *covers* an LMC $\mathcal{M}$ if for any initial distribution over the states of $\mathcal{M}$ there is

an initial distribution over the states of $\mathcal{M}'$ such that $\mathcal{M}$ and $\mathcal{M}'$ are equivalent. In 1971, Paz [15] asked a question about the nature of minimal covering LMCs. The question was supposedly answered positively in 1974 [3]. However, we show that the correct answer is negative, thus falsifying the claim in [3]. Instrumental to our counterexample is the observation that restricted nonnegative rank and nonnegative rank can be different. (Indeed, the wrong claims in [3] seem to implicitly rely on the opposite assumption, although the notions of NMF and RNMF had not yet been developed.)

2. We show that the RNMF problem for matrices M of rank 3 or less can be solved in polynomial time. In fact, we show that there is always a *rational* NMF of M with inner dimension $\mathrm{rank}_+(M)$, and that it can be computed in polynomial time in the Turing model of computation. This improves a result in [11] where the RNMF problem is shown to be solvable in polynomial time assuming a RAM model with unit-cost arithmetic. Both our algorithm and the one in [11] exploit the connection to the 2-dimensional NPP, allowing us to take advantage of a geometric algorithm by Aggarwal et al. [1]. We need to adapt the algorithm in [1] to ensure that the occurring numbers are rational and can be computed in polynomial time in the Turing model of computation.
3. We exhibit a rank-4 matrix that has an RNMF with inner dimension 5 but *no rational* RNMF with inner dimension 5. We construct this matrix via a particular instance of the 3-dimensional NPP, again taking advantage of the geometric interpretation of RNMF. Our result answers the RNMF variant of Cohen and Rothblum's question in [8] negatively. The original (NMF) variant remains open.

Detailed proofs of all results can be found in the full version of this paper.

2 Nonnegative Matrix Factorization

Let $\mathbb{N}$ and $\mathbb{N}_0$ denote the set of all positive and nonnegative integers, respectively. For every $n \in \mathbb{N}$, we write $[n]$ for the set $\{1, 2, \ldots, n\}$ and write I_n for the identity matrix of order n. For any ordered field $\mathbb{F}$, we denote by $\mathbb{F}_+$ the set of all its nonnegative elements. For any vector v, we write v_i for its i^{th} entry. A vector v is called *stochastic* if its entries are nonnegative real numbers that sum up to one. For every $i \in [n]$, we write e_i for the i^{th} coordinate vector in $\mathbb{R}^n$. We write $\mathbf{1}^{(n)}$ for the n-dimensional column vector with all ones. We omit the superscript if it is understood from the context.

For any matrix M, we write M_i for its i^{th} row, M^j for its j^{th} column, and $M_{i,j}$ for its $(i,j)^{\text{th}}$ entry. The *column space* (resp., *row space*) of M, written $\mathrm{Col}(M)$ (resp., $\mathrm{Row}(M)$), is the vector space spanned by the columns (resp., rows) of M. A matrix is called *nonnegative* (resp., *zero* or *rational*) if so are all its entries. A nonnegative matrix is *column-stochastic* (resp., *row-stochastic*) if the element sum of each of its columns (resp., rows) is one.

2.1 Nonnegative Rank

Let $\mathbb{F}$ be an ordered field, such as the reals $\mathbb{R}$ or the rationals $\mathbb{Q}$. Given a nonnegative matrix $M \in \mathbb{F}_+^{n\times m}$, a *nonnegative matrix factorization (NMF) over* $\mathbb{F}$ of M is any representation of the form $M = W \cdot H$ where $W \in \mathbb{F}_+^{n\times d}$ and $H \in \mathbb{F}_+^{d\times m}$ are nonnegative matrices. Note that $\mathrm{Col}(M) \subseteq \mathrm{Col}(W)$. We refer to d as the *inner dimension* of the NMF, and hence refer to NMF $M = W \cdot H$ as being *d-dimensional*. The *nonnegative rank over* $\mathbb{F}$ of M is the smallest number $d \in \mathbb{N}_0$ such that there exists a d-dimensional NMF over $\mathbb{F}$ of M. An equivalent characterization [8] of the nonnegative rank over $\mathbb{F}$ of M is as the smallest number of rank-1 matrices in $\mathbb{F}_+^{n\times m}$ such that M is equal to their sum. The nonnegative rank over $\mathbb{R}$ will

henceforth simply be called nonnegative rank, and will be denoted by $\text{rank}_+(M)$. For any nonnegative matrix $M \in \mathbb{R}_+^{n\times m}$, it is easy to see that $\text{rank}(M) \leq \text{rank}_+(M) \leq \min\{n, m\}$.

Given a nonzero matrix $M \in \mathbb{F}_+^{n\times m}$, by removing the zero columns of M and dividing each remaining column by the sum of its elements, we obtain a column-stochastic matrix M' with equal nonnegative rank. Similarly, if $M = W \cdot H$ then after removing zero columns in W and multiplying with a suitable diagonal matrix D, we get $M = W \cdot H = WD \cdot D^{-1}H$ where WD is column-stochastic. If M is column-stochastic then $\mathbf{1}^\top = \mathbf{1}^\top M = \mathbf{1}^\top WD \cdot D^{-1}H = \mathbf{1}^\top D^{-1}H$, hence $D^{-1}H$ is column-stochastic as well. Thus, without loss of generality one can consider NMFs of column-stochastic matrices into column-stochastic matrices [8, Theorem 3.2].

NMF problem: Given a matrix $M \in \mathbb{Q}_+^{n\times m}$ and $k \in \mathbb{N}$, is $\text{rank}_+(M) \leq k$?

The NMF problem is NP-hard, even for $k = \text{rank}(M)$ (see [20]). On the other hand, it is reducible to the existential theory of the reals, hence by [6, 16] it is in PSPACE.

For a matrix $M \in \mathbb{Q}_+^{n\times m}$, its nonnegative rank over $\mathbb{Q}$ is clearly at least $\text{rank}_+(M)$. While those ranks are equal if $\text{rank}(M) \leq 2$, a longstanding open question by Cohen and Rothblum asks whether they are always equal [8]. In other words, it is conceivable that there exists a rational matrix $M \in \mathbb{Q}_+^{n\times m}$ with $\text{rank}_+(M) = d$ that has no *rational* NMF with inner dimension d. Recently, Shitov [17] exhibited a nonnegative matrix (with irrational entries) whose nonnegative rank over a subfield of $\mathbb{R}$ is different from its nonnegative rank over $\mathbb{R}$.

2.2 Restricted Nonnegative Rank

For all matrices $M \in \mathbb{F}_+^{n\times m}$, an NMF $M = W \cdot H$ is called *restricted NMF (RNMF)* [11] if $\text{rank}(M) = \text{rank}(W)$. As we know $\text{Col}(M) \subseteq \text{Col}(W)$ holds for all NMF instances, the condition $\text{rank}(M) = \text{rank}(W)$ is then equivalent to $\text{Col}(M) = \text{Col}(W)$. The *restricted nonnegative rank over* $\mathbb{F}$ of M is the smallest number $d \in \mathbb{N}_0$ such that there exists a d-dimensional restricted nonnegative factorization over $\mathbb{F}$ of M. Unless indicated otherwise, henceforth we will assume $\mathbb{F} = \mathbb{R}$ when speaking of the restricted nonnegative rank of M, and denote it by $\text{rrank}_+(M)$.

RNMF problem: Given a matrix $M \in \mathbb{Q}_+^{n\times m}$ and $k \in \mathbb{N}$, is $\text{rrank}_+(M) \leq k$?

We have the following basic properties.

▶ **Lemma 1** ([11]). *Let* $M \in \mathbb{R}_+^{n\times m}$. *Then* $\text{rank}(M) \leq \text{rank}_+(M) \leq \text{rrank}_+(M) \leq m$. *Moreover, if* $\text{rank}(M) = \text{rank}_+(M)$ *then* $\text{rank}(M) = \text{rrank}_+(M)$.

Thus, with the above-mentioned NP-hardness result, it follows that the RNMF problem is also NP-hard and in PSPACE.

For a matrix $M \in \mathbb{Q}_+^{n\times m}$, its restricted nonnegative rank over $\mathbb{Q}$ is clearly at least $\text{rrank}_+(M)$. As with nonnegative rank, in general it is not known whether the restricted nonnegative ranks of M over $\mathbb{R}$ and over $\mathbb{Q}$ are equal. By [8, Theorem 4.1] and Lemma 1, this is true when $\text{rank}(M) \leq 2$.

RNMF has the following geometric interpretation. For a dimension $\ell \in \mathbb{N}$, the *convex combination* of a set $\{v_1, \ldots, v_m\} \subset \mathbb{R}^\ell$ is a point $\lambda_1 v_1 + \cdots + \lambda_m v_m$ where $(\lambda_1, \ldots, \lambda_m)$ is a stochastic vector. The *convex hull* of $\{v_1, \ldots, v_m\}$, written as $\text{conv}\{v_1, \ldots, v_m\}$, is the set of all convex combinations of $\{v_1, \ldots, v_m\}$. We call $\text{conv}\{v_1, \ldots, v_m\}$ a *polytope spanned by* $v_1, \ldots, v_m$. A *polyhedron* is a set $\{\, x \in \mathbb{R}^\ell \mid Ax + b \geq 0 \,\}$ with $A \in \mathbb{R}^{n\times\ell}$ and $b \in \mathbb{R}^n$. A set is a polytope if and only if it is a bounded polyhedron. A polytope is *full-dimensional* (i.e., has volume) if the matrix $(A \;\; b) \in \mathbb{R}^{n\times(\ell+1)}$ has rank $\ell + 1$.

Nested polytope problem (NPP): Given $r, n \in \mathbb{N}$, let $A \in \mathbb{Q}^{n\times(r-1)}$ and $b \in \mathbb{Q}^n$ be such that $P = \{\, x \in \mathbb{R}^{r-1} \mid Ax + b \geq 0 \,\}$ is a full-dimensional polytope. Let $S \subseteq P$ be a full-dimensional polytope described by spanning points. The *nested polytope problem (NPP)* asks, given A, b, S and a number $k \in \mathbb{N}$, whether there exist k points that span a polytope Q with $S \subseteq Q \subseteq P$. Such a polytope Q is called *nested* between P and S.

The following proposition appears as Theorem 1 in [11].

▶ **Proposition 2.** *The RNMF problem and the NPP are interreducible in polynomial time.*

More specifically, the reductions are as follows.

1. Given a nonnegative matrix $M \in \mathbb{Q}_+^{n\times m}$ of rank r, one can compute in polynomial time $A \in \mathbb{Q}^{n\times(r-1)}$ and $b \in \mathbb{Q}^n$ such that $P = \{\, x \in \mathbb{R}^{r-1} \mid Ax + b \geq 0 \,\}$ is a full-dimensional polytope, and m rational points that span a full-dimensional polytope $S \subseteq P$ such that
   - **(a)** any d-dimensional RNMF (rational or irrational) of M determines d points that span a polytope Q with $S \subseteq Q \subseteq P$, and
   - **(b)** any d points (rational or irrational) that span a polytope Q with $S \subseteq Q \subseteq P$ determine a d-dimensional RNMF of M.
2. Let $A \in \mathbb{Q}^{n\times(r-1)}$ and $b \in \mathbb{Q}^n$ such that $P = \{\, x \in \mathbb{R}^{r-1} \mid Ax+b \geq 0 \,\}$ is a full-dimensional polytope. Let $S \subseteq P$ be a full-dimensional polytope spanned by $s_1, \ldots, s_m \in \mathbb{Q}^{r-1}$. Then matrix $M \in \mathbb{Q}^{n\times m}$ with $M^i = As_i + b$ for $i \in [m]$ satisfies (a) and (b).

Importantly, the correspondences (a) and (b) preserve rationality. In the full version we detail the reduction from point 2 above, thereby filling in a small gap in the proof of [11].

▶ **Example 3** ([11, Example 1])**.** Using the geometric interpretation of restricted nonnegative rank it follows easily that, in general, we may have $\operatorname{rank}(M) < \operatorname{rank}_+(M) < \operatorname{rrank}_+(M)$. Let *3D-cube* NPP be the NPP instance where the inner and outer polytope are the standard 3D cube, i.e., $P = S = \{\, x \in \mathbb{R}^3 \mid x_i \in [0,1],\ 1 \leq i \leq 3 \,\}$. The only nested polytope is $Q = P$. The corresponding restricted NMF problem consists of the following matrix $M \in \mathbb{R}_+^{6\times 8}$:

$$M = \begin{pmatrix} 0&0&0&0&1&1&1&1 \\ 1&1&1&1&0&0&0&0 \\ 0&0&1&1&0&0&1&1 \\ 1&1&0&0&1&1&0&0 \\ 0&1&0&1&0&1&0&1 \\ 1&0&1&0&1&0&1&0 \end{pmatrix}.$$

We have $\operatorname{rrank}_+(M) = 8$ and $\operatorname{rank}(M) = 4$. Since $\operatorname{rank}_+(M)$ is bounded above by the number of rows in M, we have $\operatorname{rank}_+(M) \leq 6$. It is shown in [11] that $\operatorname{rank}_+(M) = 6$.

3 Coverability of Labelled Markov Chains

In this section, we establish a connection between RNMF and the coverability relation for labelled Markov chains. We thereby answer an open question posed in 1971 by Paz [15] about the nature of minimal covering labelled Markov chains.

A *labelled Markov chain* (*LMC*) is a tuple $\mathcal{M} = (n, \Sigma, \mu)$ where $n \in \mathbb{N}$ is the number of states, Σ is a finite alphabet of labels, and function $\mu : \Sigma \to [0,1]^{n\times n}$ specifies the transition matrices and is such that $\sum_{\sigma\in\Sigma} \mu(\sigma)$ is a row-stochastic matrix. The intuitive behaviour of the LMC $\mathcal{M}$ is as follows: When $\mathcal{M}$ is in state $i \in [n]$, it emits label σ and moves to state j, with probability $\mu(\sigma)_{i,j}$.

We extend the function μ to words by defining $\mu(\varepsilon) := I_n$ and $\mu(\sigma_1 \ldots \sigma_k) := \mu(\sigma_1) \cdots \mu(\sigma_k)$ for all $k \in \mathbb{N}$, and all $\sigma_1, \ldots, \sigma_k \in \Sigma$. Observe that $\mu(xy) = \mu(x) \cdot \mu(y)$ for all words $x, y \in \Sigma^*$. We view $\mu(w)$ for a word $w \in \Sigma^*$ as follows: if $\mathcal{M}$ is in state $i \in [n]$, it emits w and moves to state j in $|w|$ steps, with probability $\mu(w)_{i,j}$.

For $i \in [n]$ and $w \in \Sigma^*$, we write $pr_i^{\mathcal{M}}(w) := e_i^\top \cdot \mu(w) \cdot \mathbf{1}^{(n)}$ for the probability that, starting in state i, $\mathcal{M}$ emits word w. For example, in Figure 1 we have $pr_0^{\mathcal{M}}(a_1 b_1) = \frac{1}{12}$. More generally, for a given *initial distribution* π on the set of states $[n]$ (viewed as a stochastic row vector), we write $pr_\pi^{\mathcal{M}}(w) := \pi \cdot \mu(w) \cdot \mathbf{1}^{(n)}$ for the probability that $\mathcal{M}$ emits word w starting from state distribution π.

We say that an LMC $\mathcal{M}$ is *covered by* an LMC $\mathcal{M}'$, written as $\mathcal{M}' \geq \mathcal{M}$, if for every initial distribution π for $\mathcal{M}$ there exists a distribution π' for $\mathcal{M}'$ such that $pr_\pi^{\mathcal{M}}(w) = pr_{\pi'}^{\mathcal{M}'}(w)$ for all words $w \in \Sigma^*$.

The *backward matrix* of $\mathcal{M}$ is a matrix $\operatorname{Back}\mathcal{M} \in \mathbb{R}_+^{[n]\times\Sigma^*}$ where $(\operatorname{Back}\mathcal{M})_{i,w} = pr_i^{\mathcal{M}}(w)$ for every $i \in [n]$ and $w \in \Sigma^*$. The *rank* of $\mathcal{M}$ is defined by $\operatorname{rank}(\mathcal{M}) = \operatorname{rank}(\operatorname{Back}\mathcal{M})$. (Matrix $\operatorname{Back}\mathcal{M}$ is infinite, but since it has n rows, its rank is at most n.) It follows easily from the definition (see also [15, Theorem 3.1]) that $\mathcal{M}' \geq \mathcal{M}$ if and only if there exists a row-stochastic matrix A such that $A \cdot \operatorname{Back}\mathcal{M}' = \operatorname{Back}\mathcal{M}$.

LMCs can be seen as a special case of stochastic sequential machines, a class of probabilistic automata introduced and studied by Paz [15]. More specifically, they are stochastic sequential machines with a singleton input alphabet and Σ as output alphabet. In his seminal 1971 textbook on probabilistic automata [15], Paz asks the following question:

▶ **Question 4** (Paz [15], p. 38)**.** *If an n-state LMC $\mathcal{M}$ is covered by an n'-state LMC $\mathcal{M}'$ where $n' < n$, is $\mathcal{M}$ necessarily covered by some n^*-state LMC $\mathcal{M}^*$, where $n^* < n$, such that $\mathcal{M}^*$ and $\mathcal{M}$ have the same rank?*

In 1974, a positive answer to this question was claimed [3, Theorem 13]. In fact, the author of [3] makes a stronger claim, namely that the answer to Question 4 is yes, even if the inequality $n^* < n$ in Question 4 is replaced by $n^* \leq n'$. To the contrary, we show:

▶ **Theorem 5.** *The answer to Question 4 is negative.*

Theorem 5 falsifies the claim in [3]. In the full version we discuss in detail the mistake in [3]. To prove Theorem 5 we establish a tight connection between NMF and LMC coverability:

▶ **Proposition 6.** *Given a nonnegative matrix $M \in \mathbb{Q}_+^{n\times m}$ of rank r, one can compute in polynomial time an LMC $\mathcal{M} = (m+2, \Sigma, \mu)$ of rank $r+2$ such that for all $d \in \mathbb{N}$:*

(a) *any d-dimensional NMF $M = W \cdot H$ determines an LMC $\mathcal{M}' = (d+2, \Sigma, \mu')$ with $\mathcal{M}' \geq \mathcal{M}$ and $\operatorname{rank}(\mathcal{M}') = \operatorname{rank}(W) + 2$, and*

(b) *any LMC $\mathcal{M}' = (d+2, \Sigma, \mu')$ with $\mathcal{M}' \geq \mathcal{M}$ determines a d-dimensional NMF $M = W \cdot H$ with $\operatorname{rank}(\mathcal{M}') = \operatorname{rank}(W) + 2$.*

In particular, for all $d \in \mathbb{N}$ the inequality $\operatorname{rrank}_+(M) \leq d$ holds if and only if $\mathcal{M}$ is covered by some $(d+2)$-state LMC $\mathcal{M}'$ such that $\mathcal{M}'$ and $\mathcal{M}$ have the same rank.

Assuming Proposition 6 we can prove Theorem 5:

Proof of Theorem 5. Let $M \in \{0,1\}^{6\times 8}$ be the matrix from Example 3. Let $\mathcal{M} = (10, \Sigma, \mu)$ be the associated LMC from Proposition 6. Since $M = I_6 \cdot M$ is an NMF with inner dimension 6, by Proposition 6 (a) there is an LMC $\mathcal{M}' = (8, \Sigma, \mu')$ with $\mathcal{M}' \geq \mathcal{M}$. Towards a contradiction, suppose the answer to Question 4 were yes. Then $\mathcal{M}$ is also covered by some n^*-state LMC $\mathcal{M}^*$, where $n^* \leq 9$, such that $\mathcal{M}^*$ and $\mathcal{M}$ have the same rank. The last sentence of Proposition 6 then implies that $\operatorname{rrank}_+(M) \leq 7$. But this contradicts the equality $\operatorname{rrank}_+(M) = 8$ from Example 3. Hence, the answer to Question 4 is no. ◀

To prove Proposition 6 we adapt a reduction from NMF to the trace-refinement problem in Markov decision processes [10].

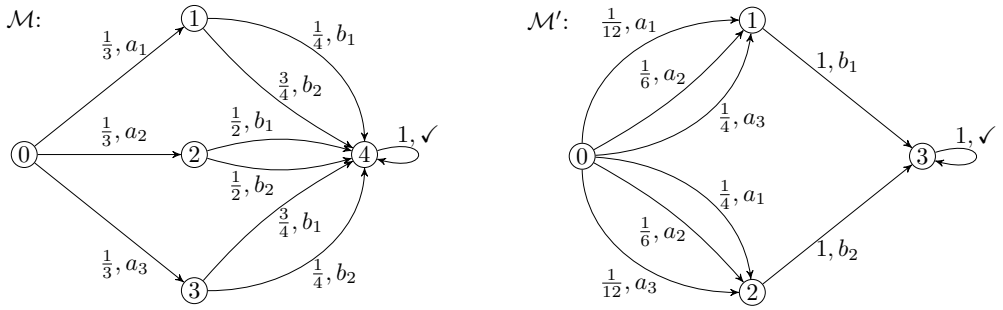

Figure 1 LMC $\mathcal{M}$ is constructed from matrix $M = \left(\begin{smallmatrix} 1/4 & 1/2 & 3/4 \\ 3/4 & 1/2 & 1/4 \end{smallmatrix}\right)$ whereas LMC $\mathcal{M}'$ is obtained by NMF $M = I_2 \cdot M$.

Proof sketch of Proposition 6. Let $M \in \mathbb{Q}_+^{n\times m}$ be a nonnegative matrix of rank r. As argued in Section 2.1, without loss of generality we may assume that M is column-stochastic and consider factorizations of M into column-stochastic matrices only.

We define an LMC $\mathcal{M} = (m+2, \Sigma, \mu)$ with $m+2$ states $\{0, 1, \ldots, m, m+1\}$. The alphabet is $\Sigma = \{a_1, \ldots, a_m\} \cup \{b_1, \ldots, b_n\} \cup \{\checkmark\}$ and the function μ, for all $i \in [m]$ and all $j \in [n]$, is defined by:

$$\mu(a_i)_{0,i} = \tfrac{1}{m}, \qquad \mu(b_j)_{i,m+1} = (M^\top)_{i,j} = M_{j,i}, \qquad \mu(\checkmark)_{m+1,m+1} = 1,$$

and all other entries of $\mu(a_i)$, $\mu(b_j)$, and $\mu(\checkmark)$ are 0. See Figure 1 for an example. We have:

$$\operatorname{Back}\mathcal{M} = \begin{array}{c} \begin{array}{ccccccccccc} \varepsilon & b_1 & \cdots & b_n & \checkmark & a_i & a_ib_j & b_1\checkmark & \cdots & b_n\checkmark & \checkmark^2 & \cdots \end{array} \\ \begin{pmatrix} 1 & 0 & \cdots & 0 & 0 & \frac{1}{m} & \frac{1}{m}M_{j,i} & 0 & \cdots & 0 & 0 & \cdots \\ 1 & M_{1,1} & \cdots & M_{n,1} & 0 & 0 & 0 & M_{1,1} & \cdots & M_{n,1} & 0 & \cdots \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \cdots \\ 1 & M_{1,m} & \cdots & M_{n,m} & 0 & 0 & 0 & M_{1,m} & \cdots & M_{n,m} & 0 & \cdots \\ 1 & 0 & \cdots & 0 & 1 & 0 & 0 & 0 & \cdots & 0 & 1 & \cdots \end{pmatrix} \end{array}.$$

Thus $\operatorname{rank}(\mathcal{M}) = \operatorname{rank}(\operatorname{Back}\mathcal{M}) \geq \operatorname{rank}(M) + 2$. The first $n+2$ columns (indexed by $\varepsilon, b_1, \ldots, b_n, \checkmark$) in $\operatorname{Back}\mathcal{M}$ span $\operatorname{Col}(\operatorname{Back}\mathcal{M})$. Therefore, $\operatorname{rank}(\mathcal{M}) = \operatorname{rank}(M) + 2 = r + 2$.

For $d \in \mathbb{N}$, let $M = W \cdot H$ for some column-stochastic matrices $W \in \mathbb{R}_+^{n\times d}$ and $H \in \mathbb{R}_+^{d\times m}$. Define an LMC $\mathcal{M}' = (d+2, \Sigma, \mu')$ where the states are $\{0, 1, \ldots, d, d+1\}$. The function μ', for all $i \in [m]$, $j \in [n]$, and $l \in [d]$, is defined by:

$$\mu'(a_i)_{0,l} = \tfrac{1}{m}H_{l,i}, \qquad \mu'(b_j)_{l,d+1} = W_{j,l}, \qquad \mu'(\checkmark)_{d+1,d+1} = 1,$$

and all other entries of $\mu'(a_i)$, $\mu'(b_j)$, and $\mu'(\checkmark)$ are 0. From the NMF $M = W \cdot H$ it follows that we can factor $\operatorname{Back}\mathcal{M}$ as follows:

$$\begin{pmatrix} 1 & 0 & \cdots & 0 & 0 \\ 0 & H_{1,1} & \cdots & H_{d,1} & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & H_{1,m} & \cdots & H_{d,m} & 0 \\ 0 & 0 & \cdots & 0 & 1 \end{pmatrix} \cdot \begin{array}{c} \begin{array}{ccccccccccc} \varepsilon & b_1 & \cdots & b_n & \checkmark & a_i & a_ib_j & b_j\checkmark & \checkmark^2 & \cdots \end{array} \\ \begin{pmatrix} 1 & 0 & \cdots & 0 & 0 & \frac{1}{m} & \frac{1}{m}M_{j,i} & 0 & 0 & \cdots \\ 1 & W_{1,1} & \cdots & W_{n,1} & 0 & 0 & 0 & W_{j,1} & 0 & \cdots \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \cdots \\ 1 & W_{1,d} & \cdots & W_{n,d} & 0 & 0 & 0 & W_{j,d} & 0 & \cdots \\ 1 & 0 & \cdots & 0 & 1 & 0 & 0 & 0 & 1 & \cdots \end{pmatrix} \end{array}$$

where the left factor is row-stochastic (as H is column-stochastic), and the right factor equals $\operatorname{Back}\mathcal{M}'$. It follows that $\mathcal{M}' \geq \mathcal{M}$. ◀

4 Restricted NMF of Rank-3 Matrices

In this section we consider rational matrices of rank at most 3. We show that for such matrices the restricted nonnegative ranks over $\mathbb{R}$ and $\mathbb{Q}$ are equal and we give a polynomial-time algorithm that computes a minimal-dimension RNMF over $\mathbb{Q}$.

▶ **Theorem 7.** *Given a matrix $M \in \mathbb{Q}_+^{n\times m}$ where $\operatorname{rank}(M) \leq 3$, there is a rational RNMF of M with inner dimension $\operatorname{rrank}_+(M)$ and it can be computed in polynomial time in the Turing model of computation.*

Using reduction 1 of Proposition 2, we can reduce in polynomial time the RNMF problem for rank-3 matrices to the 2-dimensional NPP, i.e., the nested polygon problem in the plane. As noted in Section 2.2, the correspondence between restricted nonnegative factorizations and nested polygons preserves rationality. Thus to prove Theorem 7 it suffices to prove:

▶ **Theorem 8.** *Given polygons $S \subseteq P \subseteq \mathbb{R}^2$ with rational vertices, there exists a minimum-vertex polygon Q nested between P and S that also has rational vertices. Moreover there is an algorithm that, given P and S, computes such a polygon in polynomial time in the Turing machine model.*

In fact, Aggarwal et al. [1] give an algorithm for the 2-dimensional NPP and prove that it runs in polynomial time in the RAM model with unit-cost arithmetic. However, they freely use trigonometric functions and do not address the rationality of the output of the algorithm nor its complexity in the Turing model. To prove Theorem 8 we show that, by adopting a suitable representation of the vertices of a nested polygon, the algorithm in [1] can be adapted so that it runs in polynomial time in the Turing model. We furthermore use this representation to prove that the minimum-vertex nested polygon identified by the resulting algorithm has rational vertices.

The remainder of the section is devoted to the proof of Theorem 8. We first recall some terminology from [1] and describe their algorithm.

A *supporting line segment* is a directed line segment, with its initial and final points on the boundary of the outer polygon P, that touches the inner polygon S on its left. A nested polygon with vertices on the boundary of P is said to be *supporting* if all but at most one of its edges are supporting line segments. A polygon nested between P and S is called *minimal* if it has the minimum number of vertices among all polygons nested between P and S. It is shown in [1, Lemma 4] that there is always a supporting polygon that is also minimal, and the algorithm given therein outputs such a polygon.

Let k be the number of vertices of a minimal nested polygon. Given a vertex v on the boundary of P, there is a uniquely defined supporting polygon Q_v with at most $k+1$ vertices. To determine Q_v one computes the supporting line segments $v_1v_2, \ldots, v_kv_{k+1}$, where $v_1 = v$; see Figure 2. Then Q_v is either the polygon with vertices $v_1, \ldots, v_k$ or the polygon with vertices $v_1, \ldots, v_{k+1}$. In the first case, Q_v is minimal. The idea behind the algorithm of [1] is to search along the boundary of P for an initial vertex v such that Q_v is minimal.

As a central ingredient for our proof of Theorem 8, we choose a convenient representation of the vertices of supporting polygons. To this end, we assume that the edges of P are oriented counter-clockwise, and we represent a vertex v on an edge pq of P by the unique $\lambda \in [0, 1]$ such that $v = (1 - \lambda)p + \lambda q$. We call this the *convex representation* of v.

Similar to [1], we associate with each supporting line segment uv a *ray function* r, such that if λ is the convex representation of u then $r(\lambda)$ is the convex representation of v. The same ray function applies for supporting line segments $u'v'$ with u' in a small enough interval containing u.

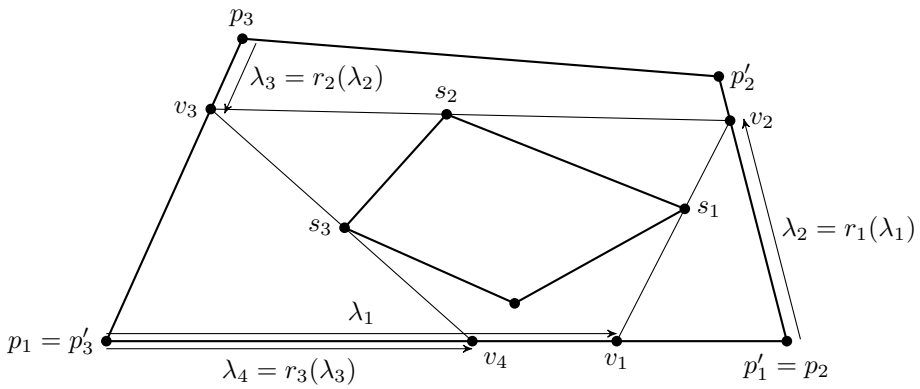

Figure 2 Supporting polygon Q_{v_1}. For every $i \in [3]$, vertex v_i lies on edge $p_i p_i'$ of P, and s_i is the point where the supporting line segment $v_i v_{i+1}$ touches the inner polygon S on its left.

In the following, when we say polynomial time, we mean polynomial time in the Turing model. To obtain a polynomial time bound, the key lemma is as follows:

▶ **Lemma 9.** *Consider bounded polygons $S \subseteq P \subseteq \mathbb{R}^2$ whose vertices are rational and of bit-length L. Then the ray function associated with a supporting line segment uv has the form $r(\lambda) = \frac{a\lambda+b}{c\lambda+d}$, where coefficients a, b, c, d are rational numbers with bit-length $O(L)$ that can be computed in polynomial time.*

Suppose that $v_1v_2, \ldots, v_kv_{k+1}$ is a sequence of k supporting line segments, with corresponding ray functions $r_1, \ldots, r_k$. Then $v_1, \ldots, v_k$ are the vertices of a minimal supporting polygon if and only if $(r_k \circ \ldots \circ r_1)(\lambda) \geq \lambda$, where λ is the convex representation of v_1.

It follows from [1] that, for each edge of P, one can compute in polynomial time a partition $\mathcal{I}$ of $[0, 1]$ into intervals with rational endpoints such that if λ_1, λ_2 are in the same interval $I \in \mathcal{I}$ then the points with convex representation λ_1 and λ_2 are associated with the same sequence of ray functions $r_1, \ldots, r_k$. Using Lemma 9 we can, for each interval $I \in \mathcal{I}$, compute these ray functions in polynomial time. Define the *slack function* $s(\lambda) = (r_k \circ \ldots \circ r_1)(\lambda) - \lambda$. In fact, this function has the form $s(\lambda) = \frac{a\lambda+b}{c\lambda+d} - \lambda$ for rational numbers a, b, c, d that are also computable in polynomial time. Then it is straightforward to check whether $s(\lambda) \geq 0$ has a solution $\lambda \in I$.

Next we show that if such a solution exists, then there exists a rational solution, which, moreover, can be computed in polynomial time. To this end, let $\lambda^* \in I$ be such that $s(\lambda^*) \geq 0$. If λ^* is on the boundary of I, then $\lambda^* \in \mathbb{Q}$. If λ^* is not on the boundary and is not an isolated solution, then there exists a rational solution in its neighbourhood. Lastly, let λ^* be an isolated solution not on the boundary. Then, λ^* is a root of both s and its derivative s'. For every $\lambda \in I$, we have

$$(c\lambda + d) \cdot s(\lambda) = a\lambda + b - \lambda \cdot (c\lambda + d).$$

Taking the derivative of the above equation with respect to λ, we get

$$c \cdot s(\lambda) + (c\lambda + d) \cdot s'(\lambda) = a - d - 2c\lambda. \tag{1}$$

Since $s(\lambda^*) = s'(\lambda^*) = 0$, from (1) we get $0 = a - d - 2c\lambda^*$. Note that $c \neq 0$ since otherwise $s \equiv 0$. Therefore, $\lambda^* = \frac{a-d}{2c} \in \mathbb{Q}$.

It follows that the vertex v represented by λ^* has rational coordinates computable in polynomial time. By computing $(r_i \circ \ldots \circ r_1)(\lambda^*)$ for $i \in [k]$, we can compute in polynomial time the convex representation of all vertices of the supporting polygon Q_v. Observe, in particular, that all vertices are rational. Hence we have proved Theorem 8.

5 Restricted NMF Requires Irrationality

Here we show that the restricted nonnegative ranks over $\mathbb{R}$ and $\mathbb{Q}$ are, in general, different.

▶ **Theorem 10.** *Let*

$$M = \begin{pmatrix} 1/8 & 1/2 & 17/22 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/2 & 3/4 & 7/12 \\ 3/4 & 3/4 & 3/11 & 2 & 1/2 & 1/6 \\ 1/4 & 1/4 & 8/11 & 1/4 & 19/8 & 55/24 \\ 1/2 & 1/8 & 1/11 & 1/8 & 15/16 & 17/16 \\ 11/16 & 5/16 & 7/44 & 1/16 & 7/32 & 43/96 \end{pmatrix} \in \mathbb{Q}_+^{6\times 6}.$$

The restricted nonnegative rank of M over $\mathbb{R}$ is 5. The restricted nonnegative rank of M over $\mathbb{Q}$ is 6.

Proof. Matrix M has an NMF $M = W \cdot H$ with inner dimension 5 with W, H as follows:

$$W = \begin{pmatrix} 0 & \frac{3+\sqrt{2}}{14} & \frac{11+\sqrt{2}}{14} & 0 & 0 \\ 0 & 0 & 0 & \frac{12-2\sqrt{2}}{17} & \frac{5}{7}+\frac{\sqrt{2}}{14} \\ 2-\sqrt{2} & 1 & \frac{3-\sqrt{2}}{7} & \frac{26+7\sqrt{2}}{17} & 0 \\ -1+\sqrt{2} & 0 & \frac{4+\sqrt{2}}{7} & \frac{21-12\sqrt{2}}{17} & \frac{39}{14}+\frac{5\sqrt{2}}{28} \\ \frac{\sqrt{2}}{2} & \frac{2}{7}-\frac{\sqrt{2}}{14} & 0 & \frac{7-4\sqrt{2}}{17} & \frac{33}{28}+\frac{\sqrt{2}}{56} \\ \frac{1}{2}+\frac{\sqrt{2}}{4} & \frac{15}{28}-\frac{\sqrt{2}}{14} & \frac{3-\sqrt{2}}{28} & 0 & \frac{3}{8}-\frac{\sqrt{2}}{16} \end{pmatrix},$$

$$H = \begin{pmatrix} \frac{1+\sqrt{2}}{4} & 0 & \frac{\sqrt{2}}{11} & \frac{1}{4}-\frac{\sqrt{2}}{8} & 0 & \frac{1}{6}+\frac{\sqrt{2}}{12} \\ \frac{3-\sqrt{2}}{4} & \frac{1}{2}+\frac{\sqrt{2}}{8} & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{2}-\frac{\sqrt{2}}{8} & 1-\frac{\sqrt{2}}{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{3}{4}+\frac{\sqrt{2}}{8} & \frac{13}{34}-\frac{7\sqrt{2}}{68} & 0 \\ 0 & 0 & 0 & 0 & \frac{21}{34}+\frac{7\sqrt{2}}{68} & \frac{5}{6}-\frac{\sqrt{2}}{12} \end{pmatrix}.$$

Since $\operatorname{rank}(M) = \operatorname{rank}(W) = 4$, the NMF $M = W \cdot H$ is restricted. This RNMF has been obtained by reducing, according to Proposition 2, an NPP instance, which we now describe.

Figure 3 shows the outer 3-dimensional polytope P with 6 faces. The polytope P is the intersection of the following half-spaces: $y \geq 0$ (blue), $z \geq 0$ (brown), $x \geq 0$ (pink), $-x + \frac{5}{2}z + 1 \geq 0$ (yellow), $-\frac{1}{2}x - y + \frac{1}{4}z + 1 \geq 0$ (green), $-\frac{1}{4}x - y - \frac{7}{8}z + 1 \geq 0$ (transparent front). The figure also indicates an interior polytope S spanned by 6 points (black dots): $s_1 = (\frac{3}{4}, \frac{1}{8}, 0)^\top$, $s_2 = (\frac{3}{4}, \frac{1}{2}, 0)^\top$, $s_3 = (\frac{3}{11}, \frac{17}{22}, 0)^\top$, $s_4 = (2, 0, \frac{1}{2})^\top$, $s_5 = (\frac{1}{2}, 0, \frac{3}{4})^\top$, $s_6 = (\frac{1}{6}, 0, \frac{7}{12})^\top$. In the following we discuss possible locations of 5 points q_1, q_2, q_3, q_4, q_5 that span a nested polytope Q. Since s_1, s_2, s_3 all lie on the (brown) face on the xy-plane, but not on a common line, at least 3 of the q_i must lie on the xy-plane. A similar statement holds for s_4, s_5, s_6 and the xz-plane. So at least one q_i, say q_1, must lie on the x-axis.

Suppose another q_i, say q_2, lies on the x-axis. Without loss of generality we can take $q_1 = (0, 0, 0)^\top$ and $q_2 = (1, 0, 0)^\top$, as all points in P on the x-axis are enclosed by these q_1, q_2.

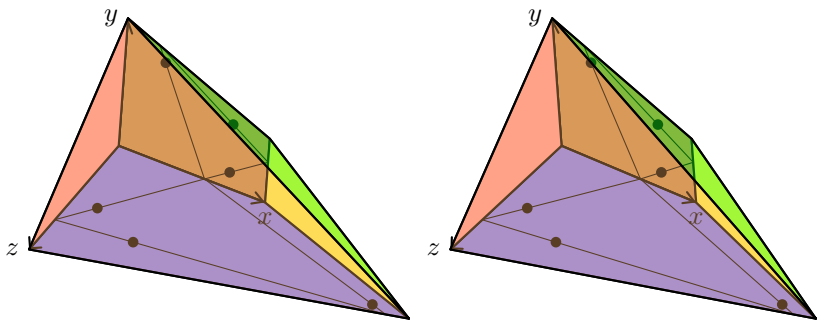

Figure 3 Instance of the nested polytope problem. The two images show orthogonal projections of a 3-dimensional outer polytope P. The black dots indicate 6 inner points (3 on the brown xy-face, and 3 on the blue xz-face) that span the interior polytope S. The two triangles on the xy-face and on the xz-face indicate the (unique) location of 5 points that span the nested polytope Q. The two slightly different projections are designed to create a 3-dimensional impression using stereoscopy. The "parallel-eye" technique should be used, see, e.g., [18]. See the full version for a "cross-eyed" variant.

Figure 4 provides a detailed view of the xy-plane. To enclose s_2, some $q \in \{q_3, q_4, q_5\}$ must also lie on the xy-plane and to the right of the line that connects $q_2 = (1,0,0)^\top$ and s_2. To enclose s_3, some $q' \in \{q_3, q_4, q_5\}$ must also lie on the xy-plane and to the left of the line that connects $q_1 = (0,0,0)^\top$ and s_3. If q and q' were identical then they would lie outside P – a contradiction. Hence 4 points (namely, q_1, q_2, q, q') are on the xy-plane. This leaves only one point, say q'', that is not on the xy-plane. To enclose s_4 (see the corresponding figure in the full version), point q'' must lie on the xz-plane and must lie to the right of the line that connects $q_2 = (1,0,0)^\top$ and s_4. To enclose s_6, point q'' must lie to the left of the line that connects $q_1 = (0,0,0)^\top$ and s_6. Hence q'' lies outside P – a contradiction.

Hence we have shown that only one point, say q_1, lies on the x-axis, and two points besides q_1, say q_2, q_3, lie on the xy-plane, and two points besides q_1, say q_4, q_5, lie on the xz-plane. Figure 4 indicates a possible location (q_1^*, q_2^*, q_3^*) of q_1, q_2, q_3. The figure illustrates that the x-coordinate of q_1^* must be at least $2 - \sqrt{2}$.

Figure 5 illustrates how to prove the same fact more formally, using the concept of a slack function (see Section 4): The slack function $s(\lambda)$ for the interval containing $2 - \sqrt{2}$ has a zero at $\lambda = 2 - \sqrt{2}$, with a sign change from negative to positive. An inspection of the intervals (of the partition $\mathcal{I}$ from Section 4) to the "left" of $2 - \sqrt{2}$ reveals that none of the corresponding slack functions $\tilde{s}$ satisfies $\tilde{s}(\lambda) \geq 0$ for $\lambda < 2 - \sqrt{2}$. Similarly, the x-coordinate of q_1^* must be *at most* $2 - \sqrt{2}$, see corresponding figures in the full version. Hence $q_1^* = (2 - \sqrt{2}, 0, 0)^\top$ is necessary. This uniquely (up to permutations) determines q_2^*, q_3^* and similarly the locations q_4^*, q_5^* of q_4, q_5. With the reduction from Proposition 2 this NPP solution determines the RNMF of M mentioned at the beginning of the proof. Since there is no 4-point solution of the NPP instance, we have $\operatorname{rrank}_+(M) = 5$. (Since $\operatorname{rank}(M) = 4$, Lemma 1 implies $\operatorname{rank}_+(M) = 5$.) Since there is no 5-point rational solution of the NPP instance, the restricted nonnegative rank of M over $\mathbb{Q}$ is 6. ◀

6 Conclusion and Future Work

We have shown that an optimal *restricted* nonnegative factorization of a rational matrix may require factors that have irrational entries. An outstanding open problem is whether the same holds for general nonnegative factorizations. An answer to this question will likely shed light on the issue of whether the nonnegative rank can be computed in NP.

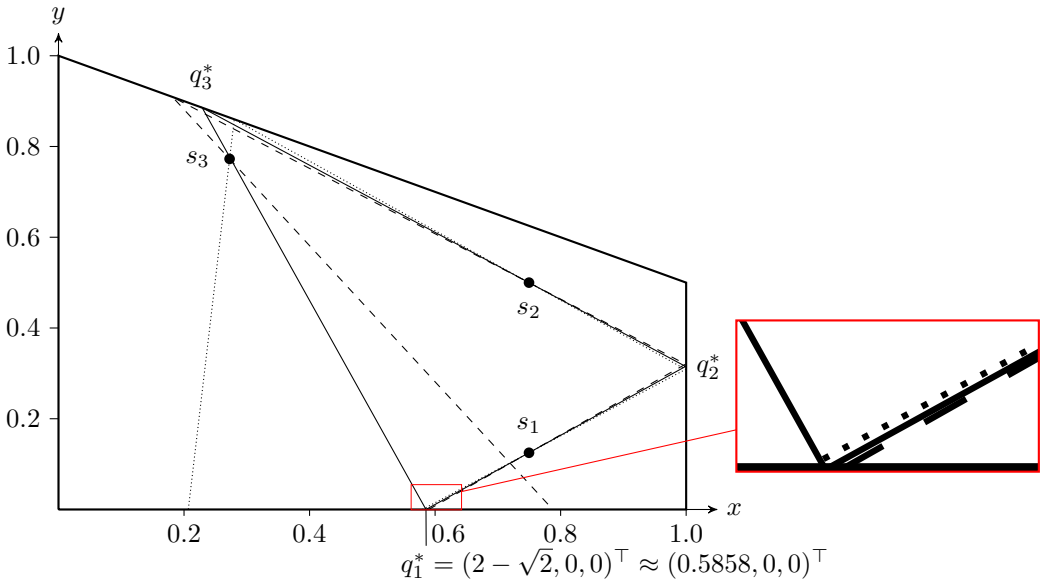

Figure 4 Detailed view of the xy-plane. The outer quadrilateral is one of 6 faces of P, the brown face in Figure 3. The points s_1, s_2, s_3 are among the 6 points that span the inner polytope S. The points q_1^*, q_2^*, q_3^* are among the 5 points that span the nested polytope Q. The area around q_1^* is zoomed in on the right-hand side. The picture illustrates that q_1^* cannot be moved left on the x-axis without increasing the number of vertices of the nested polytope: A dotted ray from a point slightly to the left of q_1^* is drawn through s_1. Its intersection with the line $x = 1$ is slightly below q_2^*. Following the algorithm of [1], the dotted ray is continued in a similar fashion, "wrapping around" s_2 and s_3, and ending on the x-axis at around $x \approx 0.2$, far left of the starting point. On the other hand, the dashed line illustrates that q_1^* could be moved right (considering only this face).

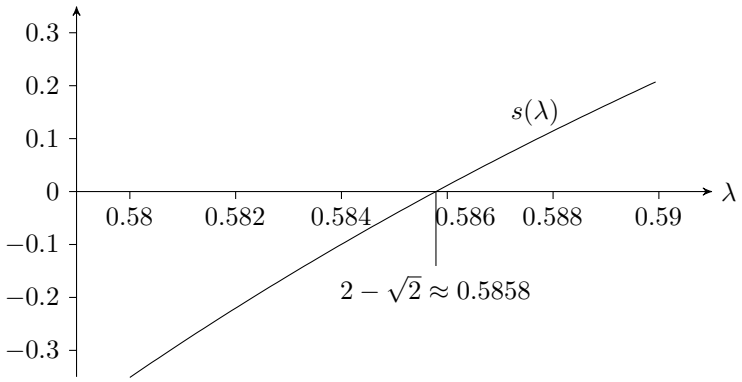

Figure 5 The slack function $s(\lambda) = \frac{52\lambda-30}{15\lambda-8} - \lambda$ corresponding to Figure 4. When $s(\lambda) < 0$, there is no nested triangle with vertex $(\lambda, 0, 0)$.

Another contribution of the paper has been to develop connections between nonnegative matrix factorization and probabilistic automata, thereby answering an old question concerning the latter. Pursuing this connection, and closely related to the above-mentioned open problem, one can ask whether, given a probabilistic automaton with rational transition probabilities, one can always find a minimal equivalent probabilistic automaton that also has rational transition probabilities.

Abstract

Herman's self-stabilization algorithm, introduced 25 years ago, is a well-studied synchronous randomized protocol for enabling a ring of N processes collectively holding any odd number of tokens to reach a stable state in which a single token remains. Determining the worst-case expected time to stabilization is the central outstanding open problem about this protocol. It is known that there is a constant h such that any initial configuration has expected stabilization time at most hN^2. Ten years ago, McIver and Morgan established a lower bound of $4/27 \approx 0.148$ for h, achieved with three equally-spaced tokens, and conjectured this to be the optimal value of h. A series of papers over the last decade gradually reduced the upper bound on h, with the present record (achieved in 2014) standing at approximately 0.156. In this paper, we prove McIver and Morgan's conjecture and establish that $h = 4/27$ is indeed optimal.

1 Introduction

The notion of *self-stabilization* was introduced in a seminal paper of Dijkstra [11], and rose to prominence a decade later, following (among others) an invited talk of Lamport during which he pointed out that "self-stabilization [is] a very important concept in fault tolerance" [22]. Both self-stabilization and fault tolerance have since become central themes in distributed computing (see, e.g., [12]), as recently witnessed by the award of the 2015 Edsger W. Dijkstra Prize in Distributed Computing to Michael Ben-Or and Michael Rabin for "starting the field of fault-tolerant randomized distributed algorithms" in the early 1980s.

In this paper, we examine an early self-stabilization algorithm known as Herman's Protocol [19], whose exact mathematical analysis has proven remarkably challenging over the two-and-a-half decades since its inception. This algorithm considers a ring of N processes

(or nodes), where each process either holds or doesn't hold a token. Starting from any initial configuration of K tokens, where K is required to be odd, Herman's algorithm proceeds as follows: at each time step, every process that holds a token either keeps it or passes it to its clockwise neighbor with probability 1/2. All updates happen synchronously, and if a process finds itself with two tokens (having simultaneously kept one and received one from its counterclockwise neighbor) then both tokens are annihilated. It is straightforward to see that, starting from an odd number of tokens and following this procedure, almost surely only one token eventually remains, at which point the ring is said to have *stabilized*.

Herman's original paper [19] presents the algorithm in a form amenable to implementation. Each process possesses a bit, which the process can read and write. Each process can also read the bit of its counterclockwise neighbor. In this representation, having the same bit as one's counterclockwise neighbor is interpreted as having a token. At each time step, each process compares its bit with the bit of its counterclockwise neighbor; if the bits differ, the process keeps its bit, whereas if the bits are the same, the process flips its bit with probability 1/2 and keeps it with probability 1/2. It is straightforward to verify that the bit-flipping version is an implementation of the token-passing version: in particular, a process flipping its bit corresponds to passing its token to its clockwise neighbor. If the number of processes is odd, by construction this bit representation forces the number of tokens to be odd as well, which justifies the assumption that K, the number of tokens, is always odd. In this paper we make no assumption about the parity of the number of *processes*, as we abstract from the bit implementation, and simply assume that the number of tokens is odd throughout.

Herman's original paper [19] showed that the expected time (number of synchronous steps) to stabilization is $O(N^2 \log N)$. The same paper also mentions an improved upper bound of $O(N^2)$ due to Dolev, Israeli, and Moran, without giving a proof or a further reference. In 2004, Fribourg et al. [16] established an upper bound of $2N^2$, and the following year Nakata [24] gave a tighter upper bound of $0.936N^2$ and exhibited an initial configuration with expected stablization time $\Omega(N^2)$. At the same time and independently, McIver and Morgan showed in [23] that the initial configuration consisting of three equally-spaced tokens has an expected stabilization time of exactly $\frac{4}{27}N^2$, and conjectured that this value is an upper bound on the expected time to stabilization starting from *any* initial configuration with *any* (odd) number of tokens. The conjecture is intriguing since increasing the initial number of tokens might be thought to lengthen the expected time to stabilization, due to the larger number of collisions required to achieve stabilization.

Nevertheless, McIver and Morgan's Herman-Protocol Conjecture is supported by considerable amount of experimental evidence [5], and in the intervening years a series of papers have gradually reduced the upper bound on the constant h such that stabilization from any initial configuration takes expected time at most hN^2: upper bounds of approximately 0.64, 0.521, 0.167, and 0.156 are given respectively in [21, 13, 14, 18], the last one provided last year by Haslegrave, and coming relatively close to McIver and Morgan's lower bound of $4/27 \approx 0.148$.

In this paper, we prove McIver and Morgan's conjecture and establish that $h = 4/27$ is indeed optimal. Writing T_z for the stabilization time starting from an initial configuration z, we seek to prove that $\mathbb{E}T_z \leq \frac{4}{27}N^2$. To this end, one of the key ideas is to work with a Lyapunov function $V(z)$ in lieu of the (more complicated) function $\mathbb{E}T_z$. The domain of the function V is *continuous*: a domain element describes a configuration in terms of the distances between adjacent tokens. Combinatorial arguments exploiting the highly symmetrical structure of $V(z)$ enable us to establish that, for an arbitrary configuration z,

we have $\mathbb{E}T_z \leq V(z)$, with equality holding for all three-token configurations. Finally, in what constitutes the most technically challenging part of this paper, we combine induction on the number of tokens with analytical techniques to show that V is bounded by $\frac{4}{27}N^2$. Taken together, we obtain $\mathbb{E}T_z \leq \frac{4}{27}N^2$, entailing the Herman-Protocol Conjecture.

The case of there being an *even* number K of tokens is equally natural from a mathematical point of view, although it does not correspond to a concrete bit-flipping protocol. It was established in [14] that the worst-case configuration in this variant is the equidistant *two*-token configuration, with an expected stabilization time of $\frac{1}{2}N^2$; the analysis underlying that result is considerably simpler than what is required in case the number of tokens is odd, as in the present paper.

Herman's protocol is also related to the notion of *coalescing random walks* [2, 8, 1]. There, one considers multiple independent random walks on $\mathbb{Z}^d$ (or on the vertices of a connected graph). When two walks meet, they coalesce into a new random walk. A protocol for self-stabilizing mutual exclusion based on such random walks was proposed in [20]. The expected coalescence time was studied in [7, 25, 6].

It is interesting to note that Herman's ring is closely related to widely-studied models of random walks and Brownian motion in statistical physics. Observe that by a simple modification of the formalism, one may equivalently view Herman's model as a ring in which tokens randomly move in discrete step in *any* direction, with pairwise collisions leading to annihilation; this precisely corresponds to Fisher's *vicious drunks* model [15] (with periodic boundary conditions). Similar models have been studied in chemical physics [10, 3, 28] and statistical mechanics [17, 26, 27], among others.

The rest of the paper is organized as follows. In Section 2 we review previous results in the literature that are relevant to our proof. In Section 3 we outline the structure of our proof, identifying two key lemmas, Lemma 8 and Lemma 9. Those are proved in [4] and Section 4, respectively.

Another solution of the conjecture, using different techniques, is independently shown in [9].

2 Relevant Previous Results

For the rest of the paper we fix the number N of processes. We assume that the number K of tokens is odd, and both N and K are at least 3.

Processes are numbered from 1 to N, clockwise, according to their position in the ring. A configuration with K tokens is formalized as a function $z : \{1, \ldots, K\} \to \{1, \ldots, N\}$ with $z(1) < \cdots < z(K)$, where the ith token ($i \in \{1, \ldots, K\}$) is held by the processor with the number $z(i)$. We write Z_K for the set of configurations with K tokens, and Z for the set of all possible configurations, that is, $Z = Z_1 \cup Z_3 \cup Z_5 \cup \ldots$

For a fixed initial configuration $z = z_0$ we write $(z_t)_{t\geq 0}$ for the stochastic process of configurations emanating from z. The *stabilization time* T_z is the smallest $t \geq 0$ such that $z_t \in Z_1$, i.e., the time until only one token is left. In this paper we focus on the expectation $\mathbb{E}T_z$. It is shown in [23] that if N is odd and a multiple of 3, then there is a configuration $z \in Z_3$ (with the 3 tokens maximally separated in an equilateral triangle) such that $\mathbb{E}T_z = \frac{4}{27}N^2$.

In this paper we show:

▶ **Theorem 1.** *We have $\mathbb{E}T_z \leq \frac{4}{27}N^2$ for all $z \in Z$.*

Equivalently, the Herman conjecture states that for all odd $K \geq 3$ and all $z \in Z_K$ we have $\mathbb{E}T_z \leq \frac{4}{27}N^2$. Only the case $K = 3$ was previously known [23].

The following proposition has been used in a similar form in various papers on Herman's protocol, for instance in [23, Lemma 5]. It bounds the stabilization time by a Lyapunov function V.

▶ **Proposition 2** (Bound by a Lyapunov function). *Given $z \in Z$, denote by $z' \in Z$ the random successor configuration of z. Let $V : Z \to \mathbb{R}$ be a function with*

$$\mathbb{E}(V(z') \mid z) \;\leq\; V(z) - 1 \qquad \text{for all } z \in Z \setminus Z_1, \text{ and} \tag{1}$$

$$0 \;\leq\; V(z) \qquad \text{for all } z \in Z_1. \tag{2}$$

Then $\mathbb{E}T_z \leq V(z)$ for all $z \in Z$. In particular, $V(z) \geq 0$ for all $z \in Z$.

Although this result is not new, we give a short proof based on a martingale argument. The proof is inspired by [18], and may provide some intuition.

Proof. Let $z \in Z$. Consider the stochastic process $(z_t)_{t\geq 0}$ of configurations emanating from $z = z_0$. Define $W_t := V(z_t) + t$. By (1) the process $(W_t)_{t\geq 0}$ is a supermartingale. The stabilization time $T_z = T_{z_0}$ is a stopping time with finite expectation, and the differences $|W_{t+1} - W_t|$ are bounded as the Markov chain reachable from z has finitely many states. Hence, the optional stopping theorem applies, yielding $\mathbb{E}W_{T_z} \leq \mathbb{E}W_0 = V(z)$. By definition of W_t we have $\mathbb{E}W_{T_z} = \mathbb{E}V(z_{T_z}) + \mathbb{E}T_z$. Since $z_{T_z} \in Z_1$, we have $\mathbb{E}T_z \leq \mathbb{E}W_{T_z}$ by (2). By combining the previous two inequalities, we obtain $\mathbb{E}T_z \leq V(z)$. ◀

Following [14, 18] we associate with a configuration $z \in Z_K$ the *gap vector* $\mathbf{g}(z) = (g_0, \ldots, g_{K-1}) \in \mathbb{N}^K$ by setting $g_0 := N + z(1) - z(K)$, and $g_i := z(i+1) - z(i)$ for $i \in \{1, \ldots, K-1\}$. Then $\mathbf{g}(z)/N$ lives in the so-called standard $(K-1)$-simplex $D^{(K)}$, defined by

$$D^{(K)} := \left\{ \mathbf{x} = (x_0, \ldots, x_{K-1}) \in [0,1]^K \;\mid\; x_0 + \cdots + x_{K-1} = 1 \right\}.$$

Towards a suitable Lyapunov function V we define the cubic polynomial $f_3^{(K)} : D^{(K)} \to [0, \infty)$ by

$$f_3^{(K)}(\mathbf{x}) := \sum_{\substack{0 \leq i_0 < i_1 < i_2 < K \\ i_2 - i_1,\ i_1 - i_0 \text{ odd}}} x_{i_0} x_{i_1} x_{i_2}.$$

For instance, we have $f_3^{(5)}(\mathbf{x}) = x_0x_1x_2 + x_0x_1x_4 + x_0x_3x_4 + x_1x_2x_3 + x_2x_3x_4$.

The following lemma was implicitly proved in previous works:

▶ **Lemma 3** (Lyapunov function V_3 [14, Page 240, Proof of Theorem 1] and [18, Theorem 4]). *Let $V_3 : Z \to [0, \infty)$ be defined by $V_3(z) := 4N^2 f_3^{(K)}(\mathbf{g}(z)/N)$ for $z \in Z_K$. Denote by $z' \in Z_1 \cup Z_3 \cup \ldots \cup Z_K$ the random successor configuration of $z \in Z_K$. Then $\mathbb{E}(V_3(z') \mid z) = V_3(z) - \frac{K-1}{2}$ for all $z \in Z_K$. Hence, by Proposition 2, $\mathbb{E}T_z \leq 4N^2 f_3^{(K)}(\mathbf{g}(z)/N)$.*

For $K = 3$ Lemma 3 gives $\mathbb{E}T_z \leq 4N^2 f_3^{(K)}(\mathbf{g}(z)/N) = \frac{4}{N} g_0 g_1 g_2$. In fact, for $K = 3$ it was shown before in [23] that $\mathbb{E}T_z$ is identically equal to $\frac{4}{N} g_0 g_1 g_2$, providing an exact formula for the expected stabilization time of configurations with three tokens. Lemma 3 suggests analyzing f_3:

▶ **Lemma 4** (Maximum of f_3 [14, Proof of Theorem 2], [18, Theorem 3]). *For all $K \geq 3$ odd we have*

$$\max_{\mathbf{x} \in D} f_3^{(K)}(\mathbf{x}) \;=\; f_3^{(K)}\left(\frac{1}{K}, \ldots, \frac{1}{K}\right) \;=\; \frac{1}{24}\left(1 - \frac{1}{K^2}\right).$$

By combining Lemmas 3 and 4 one obtains $\mathbb{E}T_z \leq \frac{N^2}{6}(1 - \frac{1}{K^2})$, which is the bound obtained in [14]. A slightly better bound is given in [18].

3 Proof of the Herman Conjecture

The function V_3 from Lemma 3 leaves room for improvement since $\mathbb{E}(V_3(z') \mid z) = V_3(z) - \frac{K-1}{2}$, which is strictly less than $V_3(z) - 1$ for $K > 3$. The idea for obtaining an optimal bound is to decrease the gap between $\frac{K-1}{2}$ and 1, by decreasing the Lyapunov function V. One could think that the scaled function $\frac{2}{K-1}V_3$ is also a Lyapunov function satisfying (1), but this is not true; in particular, note that the number of tokens K might be different for a configuration z and its successor z'. Since scaling does not work, we decrease the Lyapunov function by subtracting a quintic polynomial, as follows. Define a quintic polynomial $f_5^{(K)} : D^{(K)} \to [0, \infty)$, similar to $f_3^{(K)}$:

$$f_5^{(K)}(\mathbf{x}) = \sum_{\substack{0 \le i_0 < i_1 < \cdots < i_4 < K \\ i_4 - i_3, \ldots, i_1 - i_0 \text{ odd}}} x_{i_0} x_{i_1} x_{i_2} x_{i_3} x_{i_4}$$

For instance, $f_5^{(3)}(\mathbf{x}) = 0$, $f_5^{(5)}(\mathbf{x}) = x_0x_1x_2x_3x_4$, and $f_5^{(7)}(\mathbf{x}) = x_0x_1x_2x_3x_4 + x_0x_1x_2x_3x_6 + x_0x_1x_2x_5x_6 + x_0x_1x_4x_5x_6 + x_0x_3x_4x_5x_6 + x_1x_2x_3x_4x_5 + x_2x_3x_4x_5x_6$. We also define a polynomial $f^{(K)} : D^{(K)} \to [0, \infty)$:

$$f^{(K)}(\mathbf{x}) := f_3^{(K)}(\mathbf{x}) - \alpha f_5^{(K)}(\mathbf{x}) \qquad \text{with } \alpha := 24 \tag{3}$$

For example, $f^{(5)}(\mathbf{x}) = x_0x_1x_2 + x_0x_1x_4 + x_0x_3x_4 + x_1x_2x_3 + x_2x_3x_4 - \alpha x_0x_1x_2x_3x_4$. Throughout the paper we use α in the expression of $f^{(K)}$ for notational convenience. From now onwards we may drop the superscript K from the domain $D^{(K)}$ of the functions $f_3^{(K)}$, $f_5^{(K)}$ and $f^{(K)}$ to avoid notational clutter when K is understood.

The following properties of f are fundamental:

▶ **Lemma 5** (Symmetry and continuity properties). *The function f has the following properties.*

(a) *It is symmetric with respect to rotation:*

$$f(x_0, \ldots, x_{K-1}) = f(x_1, \ldots, x_{K-1}, x_0)$$

(b) *It is continuous: For $K \ge 5$ we have*

$$f^{(K)}(x_0, 0, x_2, x_3, \ldots, x_{K-1}) = f^{(K-2)}(x_0 + x_2, x_3, \ldots, x_{K-1}).$$

Analogous properties were shown for f_3 in [14]. Their proof carries over to f_5 and hence to f. The following lemma uses f to define a tighter Lyapunov function.

▶ **Lemma 6** (Lyapunov function V). *Define $V : Z \to [0, \infty)$ by $V(z) := 4N^2 f(\mathbf{g}(z)/N)$. Let $z \in Z$ and denote by z' the random successor configuration of z. Then $\mathbb{E}(V(z') \mid z) \le V(z) - 1$. Hence, by Proposition 2, $\mathbb{E}T_z \le 4N^2 f(\mathbf{g}(z)/N)$.*

We remark that a similar Lyapunov function has been investigated in [14, Equation (15)], but did not lead to a proof of the Herman conjecture. It seems that $V(z)$ needs to be chosen with great care, since even slight variations do not work.

Lemma 6 suggests analyzing f:

▶ **Lemma 7** (Maximum of f). *For all $K \ge 3$ odd we have*

$$\max_{\mathbf{x} \in D} f^{(K)}(\mathbf{x}) = \frac{1}{27}.$$

With this in hand our main result follows:

Proof of Theorem 1. Immediate by combining Lemmas 6 and 7. ◀

It remains to prove Lemmas 6 and 7.

3.1 Proof of Lemma 6

Towards Lemma 6 we show:

▶ **Lemma 8** (Lyapunov function V_5). *Define $V_5 : Z \to [0,\infty)$ by $V_5(z) := 4N^2 f_5(\mathbf{g}(z)/N)$. Let $K \geq 5$ and $z \in Z$ and denote by z' the random successor configuration of z. Then*

$$\mathbb{E}(V_5(z') \mid z) = V_5(z) + \frac{1}{32}\frac{(K-1)(K-3)}{N^2} - \frac{1}{2}(K-3) f_3\left(\frac{\mathbf{g}(z)}{N}\right).$$

The proof in [4] requires an analysis of correlations among the changes in gaps between tokens in each step of the protocol. Using Lemma 8 one can readily prove Lemma 6:

Proof of Lemma 6. For $K = 3$ the statement follows from Lemma 3. For $K \geq 5$ we have:

$$\begin{aligned}
\mathbb{E}(V(z') \mid z) &= \mathbb{E}((V_3(z') - 24V_5(z')) \mid z) && \text{by the definitions}\\
&= \mathbb{E}(V_3(z') \mid z) - 24\mathbb{E}(V_5(z') \mid z) && \text{linearity of expectation}\\
&= V_3(z) - \frac{K-1}{2} - 24V_5(z) - \frac{3}{4}\frac{(K-1)(K-3)}{N^2}\\
&\quad + 12(K-3) f_3\left(\frac{\mathbf{g}(z)}{N}\right) && \text{Lemmas 3 and 8}\\
&\leq V(z) - \frac{K-1}{2} + 12(K-3) f_3\left(\frac{\mathbf{g}(z)}{N}\right) && \text{since } K \geq 3\\
&\leq V(z) - \frac{K-1}{2} + \frac{K-3}{2} && \text{Lemma 4}\\
&= V(z) - 1
\end{aligned}$$

◀

3.2 Proof of Lemma 7

Towards Lemma 7 we show:

▶ **Lemma 9** (Local maxima of f). *Let $K \geq 5$ and odd. There is no $\mathbf{v} \in D^{(K)}$ in the interior of $D^{(K)}$ such that $\mathbf{v}$ is a local maximum and $f^{(K)}(\mathbf{v}) > \frac{1}{27}$.*

The proof in Section 4 involves a combinatorial analysis of inequalities arising from conditions on the derivatives of $f^{(K)}$. Using Lemma 9 one can readily prove Lemma 7:

Proof of Lemma 7. We proceed by induction on K. For the induction base we have $K = 3$. It is straightforward to check that the maximum of $f^{(3)}(\mathbf{x}) = f_3^{(3)}(\mathbf{x}) = x_0x_1x_2$ is $f^{(3)}(\frac{1}{3},\frac{1}{3},\frac{1}{3}) = \frac{1}{27}$.

For the induction step we have $K \geq 5$. Let $\mathbf{v} \in D^{(K)}$ with $f^{(K)}(\mathbf{v}) = \max_{\mathbf{x}\in D^{(K)}} f^{(K)}(\mathbf{x})$. If $\mathbf{v}$ is in the interior of $D^{(K)}$, then by Lemma 9 we have $f^{(K)}(\mathbf{v}) \leq \frac{1}{27}$. If $\mathbf{v}$ is at the boundary of $D^{(K)}$, then $v_i = 0$ for some i. By Lemma 5(a) we can assume that $v_1 = 0$. Using Lemma 5(b) the statement follows from the induction hypothesis. ◀

4 Proof of Lemma 9

In this section we prove Lemma 9. In Section 4.1 we state several properties that an interior local maximum of $f^{(K)}$ would have to satisfy. In Section 4.2 we prove Lemma 9 for $K = 5$ for a first taste of the general argument. In Section 4.3 we prove Lemma 9 for $K = 7$ to illustrate some fine points that occur only for larger values of K. In Section 4.4 we state some combinatorial facts needed for the general case. Finally, in Section 4.5 we prove Lemma 9.

4.1 Properties of an Interior Local Maximum

The following lemma is obtained by considering first and second derivatives of f evaluated at an interior local maximum.

▶ **Lemma 10.** *Let* $\mathbf{v}$ *be a local maximum of* $f^{(K)}$ *in the interior of* $D^{(K)}$ *and define* $c \in \mathbb{R}$ *by*

$$c \;=\; \sum_{\substack{1<i_2<K \\ i_2 \text{ even}}} v_{i_2} \;-\; \alpha \sum_{\substack{1<i_2<i_3<i_4<K \\ i_2,\, i_4 \text{ even} \\ i_3 \text{ odd}}} v_{i_2} v_{i_3} v_{i_4}\,. \tag{4}$$

This expression holds for the same value of c *if the indices are rotated by an arbitrary* k*: for all* j *the index* i_j *becomes* $(i_j + k) \bmod K$*. Further, we have*

$$\sum_{\substack{3\le i_3<i_4<K \\ i_3 \text{ odd} \\ i_4 \text{ even}}} v_{i_3} v_{i_4} \le \frac{1}{\alpha}\,. \tag{5}$$

Again, this inequality also holds when indices are rotated.

For example, for $K = 7$ we have $c = v_2 + v_4 + v_6 - \alpha(v_2v_3v_4 + v_2v_3v_6 + v_2v_5v_6 + v_4v_5v_6) = v_1 + v_3 + v_5 - \alpha(v_1v_2v_3 + v_1v_2v_5 + v_1v_4v_5 + v_3v_4v_5)$.

Proof of Lemma 10. The idea of the proof is as follows. We pick a particular direction in $D^{(K)}$, namely $\mathbf{d} = (-1, 0, 1, 0, 0, \ldots, 0)$, and consider the function $f(\mathbf{v} + \epsilon\mathbf{d})$ as a univariate function of ϵ. Since $\mathbf{v}$ is a local maximum, the first derivative must be zero and the second derivative must be nonpositive. Exploiting the fact that $v_i > 0$ for all i holds in the interior, we obtain (4) and (5), respectively. See [4] for the detailed proof. ◀

Let $S_j^{(K)}(\mathbf{x})$ denote the scalar product of $\mathbf{x}$ with a copy of itself rotated j times:

$$S_j^{(K)}(\mathbf{x}) := \sum_{i=0}^{K-1} x_i x_{i+j}$$

In all formulas it will be the case that the subscript of S is odd. Also, the superscript will be omitted when unimportant or understood from context.

▶ **Corollary 11.** *Let* $\mathbf{v}$ *be a local maximum of* $f^{(K)}$ *in the interior of* $D^{(K)}$*. Then the following inequality holds:*

$$\sum_{\substack{1\le i<K-2 \\ i \text{ odd}}} \frac{K-i-2}{2} S_i(\mathbf{v}) \quad\le\quad \frac{K}{\alpha}\,.$$

For example, for $K = 11$ we have $4S_1(\mathbf{v}) + 3S_3(\mathbf{v}) + 2S_5(\mathbf{v}) + S_7(\mathbf{v}) \le 11/\alpha$.

▶ **Lemma 12** (Bound for f_5)**.** *Suppose that* $\mathbf{v} \in D^{(K)}$ *satisfies* $f^{(K)}(\mathbf{v}) > \frac{1}{27}$*. Then* $\alpha f_5(\mathbf{v}) < \frac{1}{216}$*.*

Proof. By Lemma 4 we have $f_3(\mathbf{v}) \le \frac{1}{24}$ and hence $\alpha f_5(\mathbf{v}) = f_3(\mathbf{v}) - f(\mathbf{v}) < \frac{1}{24} - \frac{1}{27} = \frac{1}{216}$. ◀

4.2 Proof of Lemma 9 for $K = 5$

Let $K = 5$. Then

$$\begin{aligned} f(\mathbf{x}) &= f_3(\mathbf{x}) - \alpha f_5(\mathbf{x}) \\ &= x_0x_1x_2 + x_0x_1x_4 + x_0x_3x_4 + x_1x_2x_3 + x_2x_3x_4 - \alpha x_0x_1x_2x_3x_4 \end{aligned}$$

Towards a contradiction, suppose that there is a local maximum $\mathbf{v}$ with $f(\mathbf{v}) > \frac{1}{27}$ in the interior of D. By (4), the value

$$c = v_2 + v_4 - \alpha v_2v_3v_4 \tag{6}$$

is invariant under rotations. Indeed, $v_{2+k} + v_{4+k} - \alpha v_{2+k}v_{3+k}v_{4+k} \equiv c$ for all k, but we shall avoid explicitly mentioning rotations, for notational simplicity. Summing (6) over all K rotations we obtain:

$$5c = 2 - \alpha f_3(\mathbf{v}) \tag{7}$$

By (6) we have $v_0v_1c = v_0v_1v_2 + v_0v_1v_4 - \alpha f_5(\mathbf{v})$ and, summing over all K rotations,

$$cS_1(\mathbf{v}) = 2f(\mathbf{v}) - 3\alpha f_5(\mathbf{v}) \tag{8}$$

Moreover,

$$cS_1(\mathbf{v}) \overset{\text{Cor. 11}}{\leq} \frac{5c}{\alpha} \overset{(7)}{=} \frac{2}{\alpha} - f_3(\mathbf{v}) = \frac{2}{\alpha} - f(\mathbf{v}) - \alpha f_5(\mathbf{v}).$$

Combining this with (8) gives:

$$\frac{2}{\alpha} \geq 3f(\mathbf{v}) - 2\alpha f_5(\mathbf{v}) \overset{\text{Lemma 12}}{\geq} \frac{3}{27} - 2 \cdot \frac{1}{216}$$

This implies $\alpha \leq 216/11 \approx 19.6$, which is a contradiction as required (since $\alpha = 24$). ◀

4.3 Proof of Lemma 9 for $K = 7$

Let $K = 7$. Towards a contradiction, we suppose again that there is a local maximum $\mathbf{v}$ with $f(\mathbf{v}) > \frac{1}{27}$ in the interior of D. By (4), all K rotations of the following hold with the same $c \in \mathbb{R}$:

$$c = v_2 + v_4 + v_6 - \alpha(v_2v_3v_4 + v_2v_3v_6 + v_2v_5v_6 + v_4v_5v_6) \tag{9}$$

Summing (9) over K rotations we obtain:

$$7c = 3 - 2\alpha f_3(\mathbf{v}) \tag{10}$$

By (9) we have

$$v_0v_1c = v_0v_1v_2 + v_0v_1v_4 + v_0v_1v_6 - \alpha(v_0v_1v_2v_3v_4 + v_0v_1v_2v_3v_6 + v_0v_1v_2v_5v_6 + v_0v_1v_4v_5v_6) \tag{11}$$

and

$$\begin{aligned} v_0v_3c &= v_0v_3v_4 + v_0v_3v_6 - \alpha v_0v_3v_4v_5v_6 + v_0v_2v_3(1 - \alpha(v_3v_4 + v_3v_6 + v_5v_6)) \\ &\geq v_0v_3v_4 + v_0v_3v_6 - \alpha v_0v_3v_4v_5v_6 \end{aligned} \tag{12}$$

where the last inequality is by (5). Summing (11) and (12) over K rotations we obtain:

$$c\big(2S_1(\mathbf{v}) + S_3(\mathbf{v})\big) \;\geq\; 4f_3(\mathbf{v}) - 9\alpha f_5(\mathbf{v}) = 4f(\mathbf{v}) - 5\alpha f_5(\mathbf{v}) \tag{13}$$

Further we have:

$$c\big(2S_1(\mathbf{v}) + S_3(\mathbf{v})\big) \overset{\text{Cor. 11}}{\leq} \frac{7c}{\alpha} \overset{(10)}{=} \frac{3}{\alpha} - 2f_3(\mathbf{v}) \;=\; \frac{3}{\alpha} - 2f(\mathbf{v}) - 2\alpha f_5(\mathbf{v})$$

Combining this with (13) gives:

$$\frac{3}{\alpha} \;\geq\; 6f(\mathbf{v}) - 3\alpha f_5(\mathbf{v}) \overset{\text{Lemma 12}}{\geq} \frac{6}{27} - 3\cdot\frac{1}{216}$$

This leads to $\alpha \leq 14.4$, which is a contradiction as desired. ◀

4.4 Combinatorial Lemmas

In order to generalize the proofs from Sections 4.2 and 4.3 to any odd K, we state some combinatorial lemmas in this subsection. They are proved in [4].

In order to generalize (7) and (10) we show the following lemma:

▶ **Lemma 13.** *We have:*

$$\sum_{k=0}^{K-1} \sum_{\substack{1<i'_0<i'_1<i'_2<K \\ i'_0,\ i'_2\ even \\ i'_1\ odd}} x_{i'_0+k}x_{i'_1+k}x_{i'_2+k} = \frac{K-3}{2} \sum_{\substack{0\leq i_0<i_1<i_2<K \\ i_2-i_1,\ i_1-i_0\ odd}} x_{i_0}x_{i_1}x_{i_2} = \frac{K-3}{2} f_3^{(K)}(\mathbf{x})\,.$$

For example, if $K = 5$, then we obtain that summing the 5 rotations of $x_2x_3x_4$ gives $f_3^{(5)}(\mathbf{x})$. As another example, if $K = 7$, then we obtain that summing the 7 rotations of $x_2x_3x_4 + x_2x_3x_6 + x_2x_5x_6 + x_4x_5x_6$ gives $2f_3^{(7)}(\mathbf{x})$. These two instances of Lemma 13 help establish (7) and (10).

In order to generalize the inequality in (12) we need the following lemma:

▶ **Lemma 14.** *Let* $\mathbf{v}$ *be a local maximum of* $f^{(K)}$ *in the interior of* $D^{(K)}$*. If* i_1 *is odd and* $0 < i_1 < K$*, then the following inequality holds:*

$$v_0v_{i_1}\Bigg(\sum_{\substack{1<i_2<K \\ i_2\ even}} v_{i_2} - \sum_{\substack{1<i_2<i_3<i_4<K \\ i_2,i_4\ even \\ i_3\ odd}} \alpha v_{i_2}v_{i_3}v_{i_4}\Bigg) \geq v_0v_{i_1}\Bigg(\sum_{\substack{i_1<i_2<K \\ i_2\ even}} v_{i_2} - \sum_{\substack{i_1<i_2<i_3<i_4<K \\ i_2,i_4\ even \\ i_3\ odd}} \alpha v_{i_2}v_{i_3}v_{i_4}\Bigg)\,.$$

The inequality says that if we drop those terms that do not occur in $f_3^{(K)}$ or $f_5^{(K)}$, then we obtain a lower bound. The proof groups those terms that are not in either of $f_3^{(K)}$ or $f_5^{(K)}$, and then invokes (5) to show that their sum is nonnegative.

In order to generalize (8) and (13) we need Corollary 16 below, which is a consequence of the following lemma:

▶ **Lemma 15.** *Let* l *be an odd, positive integer. Then:*

$$\sum_{k=0}^{K-1} \sum_{\substack{1\leq i'_1<K-2 \\ i'_1\ odd}} \frac{K-i'_1-2}{2} \sum_{\substack{i'_1<i'_2<\cdots<i'_{l-1}<K \\ \forall j,\ i'_j\equiv j \pmod 2}} x_k x_{i'_1+k} \prod_{1<j<l} x_{i'_j+k} =$$

$$= \Big(\frac{l-1}{2}K - l\Big) \sum_{\substack{0\leq i_0<\cdots<i_{l-1}<K \\ i_j-i_{j-1}\ odd\ for\ 0<j<l}} \prod_{j=0}^{l-1} x_{i_j}$$

For example, if $K = 5$ and $l = 3$, then we have that summing 5 rotations of $x_0x_1x_2 + x_0x_1x_4$ gives $2f_3^{(5)}(\mathbf{x})$. As another example, if $K = 9$ and $l = 3$, then summing 9 rotations of $3x_0x_1(x_2 + x_4 + x_6 + x_8) + 2x_0x_3(x_4 + x_6 + x_8) + x_0x_5(x_6 + x_8)$ gives $6f_3^{(9)}(\mathbf{x})$.

▶ **Corollary 16.** *We have:*

$$\sum_{k=0}^{K-1} \sum_{\substack{1 \le i_1 < K-2 \\ i_1 \text{ odd}}} \frac{K - i_1 - 2}{2} \sum_{\substack{i_1 < i_2 < K \\ i_2 \text{ even}}} x_{0+k}x_{i_1+k}x_{i_2+k} = (K-3)f_3^{(K)}(\mathbf{x})$$

and also

$$\sum_{k=0}^{K-1} \sum_{\substack{1 \le i_1 < K-2 \\ i_1 \text{ odd}}} \frac{K - i_1 - 2}{2} \sum_{\substack{i_1 < i_2 < i_3 < i_4 < K \\ i_2, i_4 \text{ even} \\ i_3 \text{ odd}}} x_{0+k}x_{i_1+k}x_{i_2+k}x_{i_3+k}x_{i_4+k} = (2K-5)f_5^{(K)}(\mathbf{x})\,.$$

Proof. Instantiate Lemma 15 with $l = 3$ and, respectively, $l = 5$. ◀

4.5 Proof of Lemma 9

Towards a contradiction, suppose that there is a local maximum $\mathbf{v}$ with $f(\mathbf{v}) > \frac{1}{27}$ in the interior of D, i.e., $v_i > 0$ for all $i \in \{0, \ldots, K-1\}$. Summing up the K rotations of (4) and using Lemma 13, we obtain:

$$Kc \;=\; \frac{K-1}{2} - \frac{K-3}{2}\alpha f_3(\mathbf{v}) \tag{14}$$

Multiplying (4) on both sides by $\sum_{\substack{1 \le i_1 < K-2 \\ i_1 \text{ odd}}} \frac{K-i_1-2}{2} v_0v_{i_1}$ we obtain:

$$\begin{aligned} c \sum_{\substack{1 \le i_1 < K-2 \\ i_1 \text{ odd}}} \frac{K - i_1 - 2}{2} v_0v_{i_1} &= \sum_{\substack{1 \le i_1 < K-2 \\ i_1 \text{ odd}}} \frac{K - i_1 - 2}{2} v_0v_{i_1} \left(\sum_{\substack{1 < i_2 < K \\ i_2 \text{ even}}} v_{i_2} - \sum_{\substack{1 < i_2 < i_3 < i_4 < K \\ i_2,\, i_4 \text{ even} \\ i_3 \text{ odd}}} \alpha v_{i_2}v_{i_3}v_{i_4} \right) \\ &\ge \sum_{\substack{1 \le i_1 < K-2 \\ i_1 \text{ odd}}} \frac{K - i_1 - 2}{2} v_0v_{i_1} \left(\sum_{\substack{i_1 < i_2 < K \\ i_2 \text{ even}}} v_{i_2} - \sum_{\substack{i_1 < i_2 < i_3 < i_4 < K \\ i_2,\, i_4 \text{ even} \\ i_3 \text{ odd}}} \alpha v_{i_2}v_{i_3}v_{i_4} \right) \end{aligned}$$

using Lemma 14. Summing K rotations of this inequality yields:

$$\begin{aligned} c \sum_{\substack{1 \le i_1 < K-2 \\ i_1 \text{ odd}}} \frac{K - i_1 - 2}{2} S_{i_1}(\mathbf{v}) \;&\ge\; (K-3)f_3(\mathbf{v}) - (2K-5)\alpha f_5(\mathbf{v}) \\ &= (K-3)f(\mathbf{v}) - (K-2)\alpha f_5(\mathbf{v}) \end{aligned} \tag{15}$$

using Corollary 16. Further we have:

$$c \sum_{\substack{1 \le i_1 < K-2 \\ i_1 \text{ odd}}} \frac{K - i_1 - 2}{2} S_{i_1}(\mathbf{v}) \overset{\text{Cor. } 11}{\le} \frac{Kc}{\alpha} \overset{(14)}{=} \frac{K-1}{2\alpha} - \frac{K-3}{2} f_3(\mathbf{v})\,.$$

Combining this with (15) gives:

$$\frac{K-1}{2\alpha} \;\ge\; \frac{3K-9}{2} f(\mathbf{v}) - \frac{K-1}{2}\alpha f_5(\mathbf{v}) \overset{\text{Lemma } 12}{\ge} \frac{K-3}{2} \cdot \frac{1}{9} - \frac{K-1}{2} \cdot \frac{1}{216}\,.$$

This implies

$$\alpha \leq \frac{216(K-1)}{23K-71} < 19.7\,.$$

Since $\alpha = 24$, this leads to a contradiction as desired. ◀

5 Conclusions

In this paper we have proved the Herman-Protocol Conjecture formulated by McIver and Morgan in [23] a decade ago, which says that the worst-case initial configuration consists of three maximally-separated tokens, for N multiple of 3. This follows from our result that the worst-case self-stabilization time is at most $\frac{4}{27}N^2$, for any number of processes N and any odd number of tokens K.

The proof uses a Lyapunov function approach. To do so, we first find a suitable Lyapunov function and then show that its maximum is $\frac{4}{27}N^2$. Then we show that this function gives an upper bound for the self-stabilization time for *each* possible configuration in Herman's algorithm.

Abstract

Branching VASS (BVASS) generalise vector addition systems with states by allowing for special branching transitions that can non-deterministically distribute a counter value between two control states. A run of a BVASS consequently becomes a tree, and reachability is to decide whether a given configuration is the root of a reachability tree. This paper shows P-completeness of reachability in BVASS in dimension one, the first decidability result for reachability in a subclass of BVASS known so far. Moreover, we show that coverability and boundedness in BVASS in dimension one are P-complete as well.

1 Introduction

Vector addition systems with states (VASS), equivalently known as Petri nets, are a fundamental model of computation which comprise a finite-state controller with a finite number of counters ranging over the naturals. The number of counters is usually refereed to as the dimension of the VASS. A configuration $q(\boldsymbol{n})$ of a VASS in dimension d consists of a control state q and a valuation $\boldsymbol{n} \in \mathbb{N}^d$ of the counters. A transition of a VASS can increment and decrement counters and is enabled in a configuration whenever the resulting counter values are all non-negative, otherwise the transition is disabled. Consequently, VASS induce an infinite transition system. Three of the most fundamental decision problems for VASS are reachability, coverability and boundedness. Given a target configuration $q(\boldsymbol{n})$ and some

initial configuration, reachability is to decide whether starting in the initial configuration there exists a path ending in $q(\boldsymbol{n})$ in the induced infinite transition system. Coverability asks whether some configuration $q(\boldsymbol{n}')$ can be reached for some $\boldsymbol{n}' \geq \boldsymbol{n}$, where $\geq$ is defined component-wise. Boundedness is the problem to decide whether there are infinitely many different configurations reachable from a given starting configuration. Those decision problems find a plethora of applications, for instance in the verification of concurrent programs. Coverability can, for example, be used in order to validate mutual exclusion properties of shared-memory concurrent programs [6]; reachability is a key underlying decision problem in the verification of liveness properties of finite-data asynchronous programs [5]. Even though the complexity of coverability and boundedness are well-understood and known to be EXPSPACE-complete [12, 14], the precise complexity of reachability remains a major unsolved problem; a non-primitive recursive upper bound ($\mathbf{F}_{\omega^3}$) has only recently been established [11] and the best known lower bound is EXPSPACE [12].

The situation is even more dissatisfying when considering *branching extensions* of VASS. Such *branching VASS (BVASS)* are additionally equipped with special branching transitions of the form (q, p, p'). When in a configuration $q(\boldsymbol{n})$, a BVASS can simultaneously non-deterministically branch into configurations $p(\boldsymbol{m})$ and $p'(\boldsymbol{m}')$ such that $\boldsymbol{n} = \boldsymbol{m} + \boldsymbol{m}'$. Reachability of a configuration $q(\boldsymbol{n})$ then is to decide whether there exists a proof tree whose root is labelled with $q(\boldsymbol{n})$ and whose leaves are all labelled with designated target control states in which all counters have value zero; coverability and boundedness are defined analogously as above. While coverability and boundedness are known to be 2-EXPTIME-complete [3], reachability in BVASS is not known to be decidable, not even in any fixed dimension. Recently, non-elementary lower bounds for reachability in BVASS have been obtained [10]. Reachability in BVASS is closely related and in fact equivalent to decidability of the multiplicative-exponential fragment of linear logic [2], and also an underlying decision problem in various other applications for instance in computational linguistics, cryptographic protocol verification, data logics and concurrent program verification; see [10] for more details.

The primary contribution of this paper is to provide a polynomial-time algorithm for reachability in BVASS in dimension one (BVASS_1) and to show that reachability is in fact P-complete. To the best of our knowledge, we give the first decidability result for reachability in a fragment of BVASS. Let us remark that a decidability result, in particular with such low complexity is actually quite surprising. On the one hand, due to the infinite state space of BVASS_1 it is not immediate that reachability is decidable. In particular, the emptiness problem for conjunctive grammars over a unary alphabet, which can be seen as a slight generalisation of BVASS_1 with special alternating transitions that can simultaneously branch into two control states while retaining the same counter value (known as ABVASS_1), is undecidable [9]. On the other hand, if we disallow branching rules in ABVASS_1 and thus obtain AVASS_1 then reachability is PSPACE-complete [15, 8].

Due to the presence of only one single counter, it is possible to establish a small-model property and to show that if a configuration is reachable in a BVASS_1 then there exists a so-called reachability tree of exponential size. What causes a main challenge when establishing a polynomial-time algorithm is that this bound is optimal in the sense that, as we show in Section 3, there exist families of BVASS_1 whose reachability trees are inherently of exponential size, and which also contain an exponential number of different counter values. Consequently, reachability cannot be witnessed in polynomial time by explicitly constructing a witnessing reachability tree. Instead, in Section 4 we show that polynomial-time computable certificates for the reachability of a configuration suffice. These certificates have two parts: the first is

a table that, for certain $d > 0$ contains those pairs of control states q and residue classes r modulo d such that $q(n)$ is reachable for some sufficiently large n with $n \equiv r \bmod d$. This is called residue reachability and described in Section 4.1. The second part, described in Section 4.2, is a compressed collection of incomplete small reachability trees, so-called expandable partial reachability trees, whose leaves are either accepting configurations or have some ancestor node with the same control state and a strictly smaller counter. In the latter case, the corresponding subtree can be repeated arbitrarily often, which leaves some configuration with an arbitrarily large counter value in a certain residue class. This eventually enables us to witness the existence of a reachability tree via residue reachability.

In Section 5, we show that coverability and boundedness are P-complete for BVASS_1. For coverability, the upper bound follows easily via a reduction to reachability. For boundedness, this is not the case and we require a specifically tailored argument.

Due to space constraints, the proofs of some statements can be found in the technical report accompanying this article [7].

2 Preliminaries

We write $\mathbb{Z}$ and $\mathbb{N}$ for the sets of integers and non-negative integers, respectively, and define $[i,j] \stackrel{\text{def}}{=} \{i, i+1, \ldots, j-1, j\}$, for given integers $i < j$. For $d \geq 1$ we define $\mathbb{Z}_d \stackrel{\text{def}}{=} [0, d-1]$.

The set of finite words over alphabet A is denoted by A^* and the length of a word $w \in A^*$ is written as $|w|$. For two words $u, v \in A^*$, we say u is a *prefix* of v (written as $u \preceq v$) if $v = uw$ for some $w \in A^*$. It is a *strict prefix* ($u \prec v$) if $u \preceq v$ and $u \neq v$. We say u and v are *incomparable* if neither $u \preceq v$ nor $v \preceq u$. A set $U \subseteq A^*$ is *prefix-closed* if for all $u \in U$ and all $v \in A^*$ we have that $v \preceq u$ implies $v \in U$.

Let Σ be a set. A Σ-*labelled (finite) tree* is a mapping $T \colon U \to \Sigma$ where $U \subseteq A^*$ is a non-empty finite prefix-closed set of *nodes* for some finite set A. For $V \subseteq U$, we define $T(V) \stackrel{\text{def}}{=} \{T(v) \mid v \in V\}$. A *leaf* of T is a node $u \in U$ such that there is no $v \in U$ with $u \prec v$; every node of T that is not a leaf is called *inner node*. A node u is an *ancestor* (resp. *descendant*) of a node v if $u \preceq v$ (resp. $v \preceq u$) and a *strict ancestor* (resp. *strict descendant*) if $u \prec v$ (resp. $v \prec u$). For any node u we define the *subtree of T rooted at u* as $T^{\downarrow u} \colon u^{-1}U \to \Sigma$, where $u^{-1}U \stackrel{\text{def}}{=} \{x \in A^* \mid ux \in U\}$ and $T^{\downarrow u}(x) \stackrel{\text{def}}{=} T(ux)$. Note that $u^{-1}U$ is a prefix-closed subset of A. We define $h(u) \stackrel{\text{def}}{=} \max\{|x| \mid x \in u^{-1}U\}$ to be the *height* of the subtree rooted at u and and define $h(T) \stackrel{\text{def}}{=} h(\varepsilon)$. Note that $h(u) = 0$ if, and only if, u is a leaf. We say T is *binary* if $U \subseteq \{0,1\}^*$; in this case if for some node $u \in U$ we have that $u0 \in U$, then $u0$ the *left child* of u and if $u1 \in U$ we say that $u1$ is the *right child* of u.

2.1 Branching Vector Addition Systems

In the following, $\boldsymbol{n}$ and $\boldsymbol{z}$ will denote elements from $\mathbb{N}^k$ and $\mathbb{Z}^k$, respectively; addition on $\mathbb{Z}^k$ is defined component-wise.

▶ **Definition 1.** Let $k \geq 1$. A *k-dimensional branching vector addition system with states (BVASS_k)* is a tuple $\mathcal{B} = (Q, \Delta, F)$ where Q is a finite set of *control states*, $\Delta \subseteq Q^3 \cup (Q \times \{-1,0,1\}^k \times Q)$ is a finite set of *transitions*, and $F \subseteq Q$ is a set of *final states*. The *size* $|\mathcal{B}|$ of a BVASS is defined as $|\mathcal{B}| \stackrel{\text{def}}{=} |Q| + k \cdot |\Delta|$.

The semantics of BVASS is given in terms of reachability trees. A *partial reachability tree* of a BVASS_k $\mathcal{B}$ is a $Q \times \mathbb{N}^k$-labelled binary tree $T \colon U \to Q \times \mathbb{N}^k$, where each inner node $u \in U$ with $T(u) = (q, \boldsymbol{n})$ satisfies exactly one of the following conditions:

Figure 1 Illustration of the BVASS$_1$ $\mathcal{B}_n$. The reachability set of the control state q_n is the singleton set $\{2^n\}$, and a reachability tree for $q(0)$ contains all counter values between 0 and 2^n.

- $u0, u1 \in U$, and if $T(u0) = (p, \boldsymbol{n}_0)$ and $T(u1) = (p', \boldsymbol{n}_1)$, then $\boldsymbol{n} = \boldsymbol{n}_0 + \boldsymbol{n}_1$ and $(q, p, p') \in \Delta$; or
- $u0 \in U, u1 \notin U$, and if $T(u0) = (p, \boldsymbol{n}_0)$, then $\boldsymbol{n}_0 = \boldsymbol{n} + \boldsymbol{z}$ and $(q, \boldsymbol{z}, p) \in \Delta$.

Note that in the second condition, counter values can be seen as being propagated top down. A *reachability tree* is a partial reachability tree T where $T(u) \in F \times \{0\}^k$ for all leaves u of T. We call these nodes *accepting* nodes. For each $j \in \mathbb{N}$ we say that a partial reachability tree T is *j-bounded* if $T(u) \in Q \times [0, j]^k$ for all $u \in U$. We call $Q \times \mathbb{N}^k$ the set of *configurations* of $\mathcal{B}$ and for the sake of readability often write its elements $(q, \boldsymbol{n})$ as $q(\boldsymbol{n})$. We say that a configuration $q(\boldsymbol{n})$ is *reachable* if there exists a reachability tree T with $T(\varepsilon) = q(\boldsymbol{n})$. Note that in particular every configuration in $F \times \{0\}^k$ is reachable. The reachability set *reach*(q) of a control state q is defined as $\mathit{reach}(q) \stackrel{\text{def}}{=} \{\boldsymbol{n} \in \mathbb{N} \mid q(\boldsymbol{n}) \text{ is reachable}\}$. The decision problem that we mainly focus on in this paper is *reachability*, defined as follows:

Reachability in BVASS$_k$

INPUT: A BVASS$_k$ $\mathcal{B} = (Q, \Delta, F)$, a control state q and $\boldsymbol{n} \in \mathbb{N}^k$ encoded in unary.
QUESTION: Is $q(\boldsymbol{n})$ reachable?

Our main result is that reachability is P-complete in dimension one.

▶ **Theorem 2.** *Reachability in BVASS$_1$ is* P*-complete.*

3 Lower Bounds

As a warm-up exercise and in order to familiarise ourselves with BVASS$_1$, we begin with proving a couple of lower bounds for the reachability problem. First, it is not difficult to see that the reachability problem is P-hard via a reduction from the monotone circuit value problem (MCVP) [13]. By simulating $\vee$-gates of a Boolean by non-deterministic branching and $\wedge$-gates by splitting transitions, the following statement can easily be obtained.

▶ **Proposition 3.** *Let $\mathcal{C}$ be a Boolean circuit. There exists a logspace computable BVASS$_1$ $\mathcal{B}$ with a control state q such that $q(0)$ is reachable if, and only if, $\mathcal{C}$ evaluates to true.*

A challenging aspect when providing a polynomial-time upper bound for reachability in BVASS$_1$ is that reachability trees may be of exponential size and may contain an exponential number of nodes labelled with distinct counter values. To see this, consider the family $(\mathcal{B}_n)_{n \geq 0}$ of BVASS$_1$, where $\mathcal{B}_n \stackrel{\text{def}}{=} (Q_n, \Delta_n, F)$ and where $Q_n \stackrel{\text{def}}{=} \{q, q_f\} \cup \{q_0, \ldots, q_n\}$, $\Delta_n \stackrel{\text{def}}{=} \{(q, +1, q), (q, 0, q_n)\} \cup \{(q_i, q_{i-1}, q_{i-1}) \mid 0 < i \leq n\} \cup \{(q_0, -1, q_f)\}$ and $F \stackrel{\text{def}}{=} \{q_f\}$. The construction is illustrated in Figure 1. It is easily seen that $q_i(N)$ is reachable if, and only if, $N = 2^i$. Observe that $\mathit{reach}(q) = \{0, \ldots, 2^n\}$ is finite and that the reachability tree of $q(0)$ contains all counter values between 0 and 2^n. In particular, this allows us to obtain the following hardness result in which the updates of the BVASS$_1$ are from $\{-1, 0, +1\}$ (i.e. encoded in unary), but the initial configuration is given in binary, via a straight-forward reduction from the NP-complete Subset Sum problem [13].

▶ **Proposition 4.** *Reachability in $BVASS_1$ is* NP*-hard if the initial configuration $q(n)$ is given in binary.*

It is worth mentioning that the previous lemma enables us to derive as a corollary an NP-lower bound for reachability in BVASS_2. This is in contrast to VASS where there is no difference between the NL-completeness of reachability in dimensions one and two [16, 4].

▶ **Corollary 5.** *Reachability in $BVASS_2$ is* NP*-hard.*

4 Reachability in BVASS_1

Here, we show that reachability in BVASS_1 is decidable in polynomial time, thereby establishing the P upper bound claimed in Theorem 2. In the first part, we consider a variation of the reachability problem in which we are only interested in reaching configurations that are sufficiently large and lie in a certain residue class. Subsequently, we will apply this intermediate result for showing that reachability can be witnessed by small partial reachability trees. Finally, we put everything together in order to obtain a polynomial-time algorithm.

4.1 The Residue Reachability Problem

A cornerstone of our algorithm for reachability in BVASS_1 is the polynomial-time decidability of the following variant of the reachability problem for BVASS_1:

Residue Reachability for BVASS_1

INPUT: A BVASS_1 $\mathcal{B} = (Q, \Delta, F)$, a configuration $q_0(n_0)$ and $d \geq 1$, where n_0 and d are given in unary.

QUESTION: Does there exist some $n \geq n_0$ such that $q_0(n)$ is reachable and $n \equiv n_0 \bmod d$?

The main result of this section is that residue reachability for BVASS_1 is decidable in polynomial time. Notice that setting $d = 1$ allows for checking whether there exists some $n \geq n_0$ such that $q(n)$ is reachable. We first introduce some auxiliary definitions that allow us to abstract away concrete counter values of reachability trees. A *partial d-residue tree* is a binary tree $T\colon U \to Q \times \mathbb{Z}_d$, where each inner node $u \in U$ with $T(u) = (q, n)$ satisfies precisely one of the following conditions:

- **(i)** $u0, u1 \in U$, and if $T(u0) = (p, m_0)$ and $T(u1) = (p', m_1)$ then $n \equiv m_0 + m_1 \bmod d$ and $(q, p, p') \in \Delta$;
- **(ii)** $u0 \in U, u1 \notin U$, and if $T(u0) = (p, m)$ then $m = n + z \bmod d$ and $(q, z, p) \in \Delta$.

We call a configuration from $Q \times \mathbb{Z}_d$ a *residue configuration*. Given a set of configurations S, its *residue* is $S/\mathbb{Z}_d \stackrel{\text{def}}{=} \{(q, n \bmod d) \in Q \times \mathbb{Z}_d \mid q(n) \in S\}$. Likewise, given a partial reachability tree $T\colon U \to Q \times \mathbb{N}$, the *residue* $T/\mathbb{Z}_d$ *of* T is $T/\mathbb{Z}_d\colon U \to Q \times \mathbb{Z}_d$, where $T/\mathbb{Z}_d(u) \stackrel{\text{def}}{=} T(u)/\mathbb{Z}_d$ for all $u \in U$. Clearly, $T/\mathbb{Z}_d$ is a partial residue tree.

For the remainder of this section, fix some BVASS_1 $\mathcal{B} = (Q, \Delta, F)$, some configuration $q_0(n_0)$ and some $d \geq 1$, where n_0 and d are given in unary. In order to decide residue reachability, one might be tempted to start with an initial configuration and then to repeatedly apply transitions of $\mathcal{B}$ modulo d until the desired residue configuration is discovered. Such an approach would, however, not be sound as it may lead to residue configurations that, informally speaking, can only be obtained by forcing the counter to drop below zero. Also, the simple alternative of constructing a sufficiently large reachability tree is futile as it may be of exponential size, cf. Section 3. In order to balance between those two extremes, we introduce reachability trees in which all nodes except of the root are required to be bounded

by some value $j \in \mathbb{N}$: a partial reachability tree $T\colon U \to Q \times \mathbb{N}$ is *almost j-bounded* if $T(u) \in Q \times [0, j]$ for all $u \in U \setminus \{\varepsilon\}$. Note that every j-bounded partial reachability tree is almost j-bounded. The following constant will be particularly useful:

$$N \stackrel{\text{def}}{=} |Q| \cdot d.$$

Moreover, by S we denote the set of configurations for which there exists an (n_0+N)-bounded reachability tree and define for $i < j$:

$$S \stackrel{\text{def}}{=} \{(q, m) \in Q \times \mathbb{N} \mid q(m) \text{ has an } (n_0 + N)\text{-bounded reachability tree}\}$$
$$S[i, j] \stackrel{\text{def}}{=} S \cap Q \times [i, j].$$

▶ **Lemma 6.** *The set S is computable in polynomial time.*

For any set of residue configurations (modulo d) $V, W \subseteq Q \times \mathbb{Z}_d$, we define the following sets that contain the result of an application of a transition of $\mathcal{B}$ modulo d:

$$\Delta(V) \stackrel{\text{def}}{=} \{(q, r - z \bmod d) \mid (q, z, p) \in \Delta, (p, r) \in V\}$$
$$\Delta(V, W) \stackrel{\text{def}}{=} \{(q, r_0 + r_1 \bmod d) \mid (q, p_0, p_1) \in \Delta, (p_0, r_0) \in V, (p_1, r_1) \in W\}.$$

Next, we inductively define a sequence of sets $R_i \subseteq Q \times \mathbb{Z}_d$ for $i \geq 0$ whose fixed point will allow for deciding residue reachability. The set R_0 consists of those pairs of control states and residue classes that can be witnessed by a reachability tree that is almost $(n_0 + N)$-bounded and whose root has a counter value at least $n_0 + N$, and the R_i for $i > 0$ are obtained by application of Δ :

$$R_0 \stackrel{\text{def}}{=} \{(q, n \bmod d) \in Q \times \mathbb{Z}_d \mid n \geq n_0 + N,\ q(n) \text{ has an almost } (n_0 + N)\text{-bounded reachability tree}\}$$
$$R_{i+1} \stackrel{\text{def}}{=} R_i \cup \Delta(R_i) \cup \Delta(R_i, S/\mathbb{Z}_d) \cup \Delta(S/\mathbb{Z}_d, R_i) \cup \Delta(R_i, R_i).$$

Since the cardinality of each R_i is at most N, it is easily seen that the sequence $(R_i)_{i\geq 0}$ reaches a fixed point which can be computed in polynomial time.

▶ **Lemma 7.** *The fixed point $R \stackrel{def}{=} \bigcup_{i\geq 0} R_i$ equals R_N and is computable in polynomial time.*

In particular, R together with S yields the whole residue reachability set.

▶ **Lemma 8.** *The set $X \stackrel{def}{=} R \cup S[n_0, n_0+N]/\mathbb{Z}_d$ is computable in polynomial time. Moreover,*

$$X = \{(q, n \bmod d) \mid q \in Q, n \in \mathit{reach}(q), n \geq n_0\}.$$

Proof (sketch). Polynomial-time computability of X follows immediately from Lemmas 6 and 7. The proof of the stated equality is quite technical though not too difficult and can be found in the technical report [7]. The crucial part for the inclusion "$\subseteq$" is to show that for every $i \in [0, N]$ and each $(q, r) \in R_i$ there exists some $n \in \mathit{reach}(q)$ with $n \geq n_0 + N - i$ and $n \equiv r \bmod d$ by induction on i. For the converse inclusion the only interesting case is when a potential reachability tree T is not $(n_0 + N)$-bounded. One first shows that all $\prec$-maximal nodes u in T with $T(u) \notin S$ satisfy $T(u)/\mathbb{Z}_d \in R_0$ and uses the fact that $\Delta(R, R) \subseteq R$ and $\Delta(R) \subseteq R$ to conclude $T(\varepsilon)/\mathbb{Z}_d \in R$. ◀

The main result of this section now follows directly from Lemma 8.

▶ **Theorem 9.** *Residue reachability for $BVASS_1$ is decidable in polynomial time.*

4.2 Expandable Partial Reachability Trees

We now employ our result on residue reachability to show that small partial reachability trees suffice in order to witness reachability. The key idea is to identify branches of partial reachability trees that end in a leaf and which could, informally speaking, be copied or pumped an arbitrary number of times, thus achieving a counter value in the leaf that is large enough and lies in a certain residue class of some modulus. Residue reachability then witnesses that such a leaf could be completed in order to yield a reachability tree. For the remainder of this section, fix some BVASS_1 $\mathcal{B} = (Q, \Delta, F)$.

Let us first introduce a couple of auxiliary definitions. Given a partial reachability tree $T\colon U \to Q \times \mathbb{N}$ and $v, w \in U$, the *lowest common ancestor* of $v, w \in U$ is defined as

$$\mathit{lca}(v, w) \stackrel{\text{def}}{=} \max\{u \in U \mid u \preceq v \text{ and } u \preceq w\},$$

where the maximum is taken with respect to $\preceq$. Let $T(u) = q(n)$, we define functions $\mathit{state}(u) \stackrel{\text{def}}{=} q$ and $\mathit{counter}(u) \stackrel{\text{def}}{=} n$ that allow us to access the control state and the counter value at u, respectively.

▶ **Definition 10.** A node $v \in U$ is *increasing* if there is a proper ancestor $u \prec v$ such that $\mathit{state}(u) = \mathit{state}(v)$ and $\mathit{counter}(u) < \mathit{counter}(v)$; the maximal such u is called the *anchor* of v. We say that T is *exclusive* if the least common ancestor of any two distinct increasing leaves is a proper ancestor of at least one of their anchors. Finally, we call T *expandable* if

- T is exclusive,
- every leaf v of T is either accepting or an increasing leaf,
- every increasing leaf v with anchor u such that $T(v) = q(n)$ and $T(u) = q(m)$ induces a valid instance of the residue reachability problem, i.e., $q(l)$ is reachable for some $l \geq n$ and $l \equiv n \bmod (n - m)$.

A node u is said to be *exclusive* resp. *expandable* if $T^{\downarrow u}$ is.

Observe that nodes cannot be both accepting and increasing because increasing nodes have strictly positive counter values and accepting nodes must have counter value zero. Exclusive and non-exclusive partial reachability trees are illustrated in Figure 2(a).

The next lemma states a useful fact that directly follows from the pigeon-hole principle: whenever the counter increases on a branch by a certain amount then the branch contains an increasing node and its anchor.

▶ **Lemma 11.** *Let u and v be nodes of a partial reachability tree such that $u \prec v$ and $\mathit{counter}(u) + |Q| \leq \mathit{counter}(v)$. Then there exists an increasing node v' with anchor u' such that $u \preceq u' \prec v' \preceq v$.*

The following lemma shows that every reachability tree gives rise to an expandable reachability tree whose nodes have counter values bounded polynomially in $|\mathcal{B}|$.

▶ **Lemma 12.** *Suppose $q(n)$ is reachable and let $B \stackrel{def}{=} 2 \cdot |Q| + n$. Then there exists an expandable B-bounded partial reachability tree with root $q(n)$.*

Proof. Let T be a reachability tree with $T(\varepsilon) = q(n)$. We call a node w of T *large* if $\mathit{counter}(w) = B$. We obtain a partial reachability tree T' from T as follows. By Lemma 11, every large node w gives rise to at least one pair of nodes (u, v) such that $u \prec v \preceq w$ and v is an increasing node with anchor u. For every large node w that is minimal with respect to $\preceq$, we assign the maximal such pair $\mathit{pair}(w) \stackrel{\text{def}}{=} (u, v)$ with respect to the lexicographical ordering on nodes (more precisely, $(u, v) \preceq (u', v')$ if either, $u \prec u'$, or $u = u'$ and $v \preceq v'$).

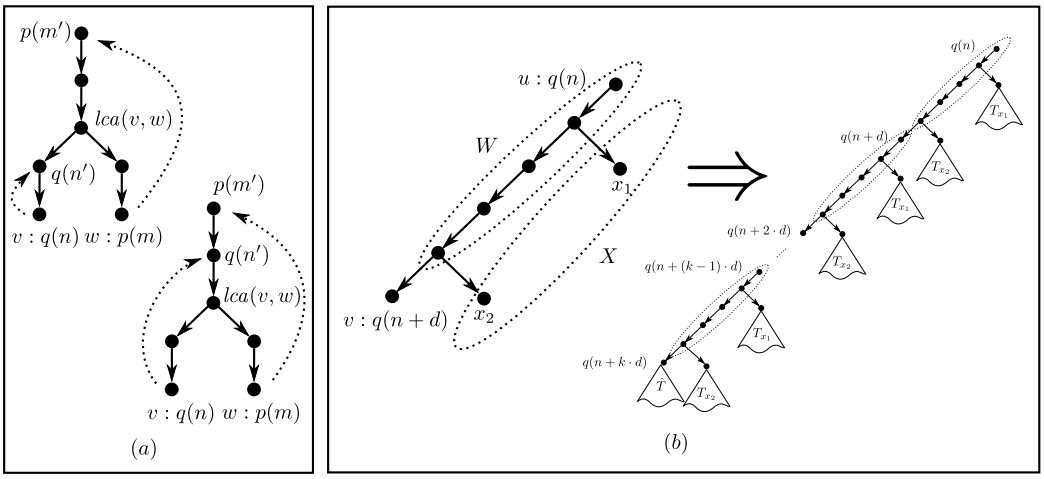

Figure 2 (a) Illustration an exclusive (top) and a non-exclusive (bottom) partial reachability tree. Here, v and w are pumping nodes and anchor relationships are depicted as dashed arrows. (b) Illustration of the pumping argument in Lemma 14.

Let $T' \colon U' \to Q \times \mathbb{N}$ denote the tree that one obtains from T by replacing all subtrees of T that are rooted at some node v such that $pair(w) = (u, v)$ for some minimal (with respect to $\preceq$) large node w in T by $\{v\}$ itself, i.e. such nodes v become leaves. We now prove that T' is B-bounded and exclusive:

- T' is B-bounded since the w above are chosen minimal with respect to $\preceq$ and hence $counter(u) \leq B$ for all nodes $u \in U'$.
- T' is exclusive, which can be seen as follows. Striving for a contradiction, suppose that T' is not exclusive. Then there are distinct increasing nodes v, v' with anchors u, u' such that $u, u' \preceq w \stackrel{\text{def}}{=} lca(v, v')$. Since $counter(w) = counter(w0) + counter(w1) \leq B$, we have $counter(w0) \leq B/2$ or $counter(w1) \leq B/2$, and assume without loss of generality that $counter(w0) \leq B/2$. Since $B - B/2 \geq |Q|$, by Lemma 11 there is another increasing node v'' with anchor u'' such that $w0 \preceq u'' \prec v''$, contradicting the assumed maximality of (u, v).
- Every leaf is accepting or increasing, by definition of T'.
- Finally, every increasing leaf u in T' induces a positive residue-reachability instance. Since T is a reachability tree, we have that $T(u)$ is reachable and thus $T'(u)$ is reachable. So in particular, it is reachable modulo $d = 1$, i.e. if $T'(u) = q(n)$, then we can choose $(q(n), 1)$ as the required valid instance of residue reachability. ◀

We now turn towards the converse direction and show that every expandable tree witnesses reachability. We first state an auxiliary lemma about structural properties of nodes in exclusive trees whose proof can be found in the technical report [7].

▶ **Lemma 13.** *For every node u of an expandable partial reachability tree the following hold:*

(i) *If u is the anchor of an increasing leaf v then u is expandable and all nodes w such that $u \prec w \preceq v$ are not expandable.*

(ii) *u has at most one child that is not expandable.*

The previous lemma enables us to show that an expandable partial reachability tree implies the existence of a reachability tree.

▶ **Lemma 14.** *Let $T\colon U \to Q \times \mathbb{N}$ be an expandable partial reachability tree. Then for all $u \in U$, $T(u)$ is reachable or u is not expandable.*

Proof. We prove the lemma by induction on $h(u)$. For the induction base, assume $h(u) = 0$, hence u is a leaf. Then u is either accepting and thus $T(u)$ is reachable, or u is not accepting and therefore an increasing leaf and so $T^{\downarrow u}$ is not expandable by Lemma 13(i).

For the induction step, suppose u is expandable. We distinguish two cases:

- *All children of u are expandable.* We only treat the case when u has two children, the case when u has one child follows as a special case. Since the children $u0$ and $u1$ of u are expandable, by the induction hypothesis there are reachability trees $T_0\colon U_0 \to Q \times \mathbb{N}$ and $T_1\colon U_1 \to Q \times \mathbb{N}$ with $T_0(\varepsilon) = T(u0)$ and $T_1(\varepsilon) = T(u1)$. We define the following tree $T_u\colon V \to Q \times \mathbb{N}$, where $V \stackrel{\text{def}}{=} \{0\}U_0 \cup \{1\}U_1 \cup \{\varepsilon\}$, $T_u(\varepsilon) \stackrel{\text{def}}{=} T(u)$ and $T_u(iv) \stackrel{\text{def}}{=} T_i(v)$ for all $i \in \{0,1\}$. Now T_u is a reachability tree, hence $T_u(\varepsilon) = T(u)$ is reachable.
- *Some child of u is not expandable.* For simplicity of presentation, let $u = \varepsilon$, the cases when $u \neq \varepsilon$ can be proven analogously. Moreover, let us assume that $T(u) = q(n)$. By Lemma 13(ii) there is at most one such child, without loss of generality let $u0 = 0$ be this child. Moreover, since u is expandable and $u0$ is not expandable it must hold that u is the anchor of some unique increasing leaf v, we may assume without loss of generality $v = u0^\ell$ for some $\ell \geq 1$. We must have $T(v) = q(n+d)$ for some $d \geq 1$. Let $W = \{0^i \mid i \in [0, \ell-1]\}$ be the set all nodes in T "on the path from u to v" without v. Let $X \stackrel{\text{def}}{=} \{0^i 1 \in U \mid i \in [0, \ell-1]\}$ be the set of all right children of nodes in W.
  By Lemma 13(i), all nodes in $\{0^i \mid i \in [1, \ell]\}$ are not expandable and consequently, Lemma 13(ii) implies that all nodes in X are expandable. Hence by induction hypothesis, for every $x \in X$ there is a reachability tree $T_x : U_x \to Q \times \mathbb{N}$ such that $T_x(\varepsilon) = T(x)$.
  It remains to show that $T(u) = q(n)$ is reachable. Since T is expandable there exists some $m \geq n+d$ such that $q(m)$ is reachable and $m \equiv n \bmod d$. Let us assume $m = n+d+k\cdot d$ for some $k \geq 0$ and let $\widehat{T}\colon Z \to Q \times \mathbb{N}$ be a reachability tree for $q(m)$.
  We construct the following reachability tree T' (formal definition below) for $q(n)$ as the tree one obtains from T by replacing the leaf v by the tree T repeatedly exactly k times and by adding to the counter values of the resulting nodes from 0^* in the i-th copy the counter value $i \cdot d$. This procedure is illustrated in Figure 2(b). Note that this process yields a partial reachability tree in which every leaf is accepting except for the leaf $0^{(k+1)\cdot\ell}$; therefore we replace this leaf by the tree $\widehat{T}\colon Z \to Q \times \mathbb{N}$. Recall that $T_x\colon U_x \to Q \times \mathbb{N}$ is a reachability tree for $T(x) = T_x(\varepsilon)$. Formally, we define $T'\colon \left(0^{(k+1)\cdot\ell}Z \cup \bigcup_{i=0}^{k} 0^{i\cdot\ell}(W \cup \bigcup\{xU_x \mid x \in X\})\right) \to Q \times \mathbb{N}$, where
  - $T'(0^{(k+1)\cdot\ell}z) \stackrel{\text{def}}{=} \widehat{T}(z)$ for all $z \in Z$,

  and for all $i \in [0,k]$ we put
  - $T'(0^{i\cdot\ell}w) \stackrel{\text{def}}{=} i\cdot d + T(w)$ for all $w \in W$, and
  - $T'(0^{i\cdot\ell}xy) \stackrel{\text{def}}{=} T_x(y)$ for all $x \in X$ and all $y \in U_x$.

  It easily checked that the result is a reachability tree for $T'(\varepsilon) = q(n)$. ◀

A consequence of the previous lemma is that in particular $T(\varepsilon)$ is reachable for every expandable partial reachability tree T. By combining Lemmas 12 and 14, we obtain the following characterisation of reachability in BVASS_1.

▶ **Proposition 15.** *A node $q(n)$ is reachable if, and only if, there exists an expandable B-bounded partial reachability tree T with $T(\varepsilon) = q(n)$, where $B \stackrel{def}{=} 2\cdot|Q| + n$.*

Algorithm 1 An alternating logspace procedure for reachability in BVASS_1.

```

19:                or AnchorReach(q(n), p2(m2)) and Reach(p1(m1))
20:        else let  t = (p, z, p′) ∈ Q × {−1, 0, 1} × Q
21:            return AnchorReach(q(n), p′(m + z))
```

4.3 The Algorithm

In this section, we provide an alternating logspace procedure for reachability in BVASS_1. This shows that reachability in BVASS_1 is decidable in deterministic polynomial time since alternating logspace equals deterministic polynomial time [1]. We employ the characterisation of reachability in BVASS_1 in terms of expandable B-bounded partial reachability of Proposition 15. First, by Theorem 9 we may assume the existence of an alternating logspace procedure for residue reachability in BVASS_1, i.e., an alternating logspace procedure $\textsc{ResidueReach}(q(n_0), d)$ that has an accepting computation if, and only if, $q(n)$ is reachable for some $n \geq n_0$ and $n \equiv n_0 \bmod d$. By application of this procedure, we show that one can construct an alternating logspace procedure $\textsc{Reach}(q(n))$ that takes a configuration $q(n)$ as input and that has an accepting computation if, and only if, there exists an expandable B-bounded partial reachability tree T with $T(\varepsilon) = q(n)$.

The idea is to simply to guess an expandable B-bounded partial reachability tree T in a top-down manner. The procedure Reach is defined above in Algorithm 1. First in Line 2, Reach rejects whenever the counter value n is not in $[0, B]$ and accepts if $q(n)$ is an accepting configuration (Line 3). Thus, subsequently we may assume that $n \in [0, B]$. In Line 4, we non-deterministically choose a transition $t \in \Delta$. If $t = (q, p_1, p_2) \in Q^3$ is a branching rule, we non-deterministically guess how n can be decomposed as $n = m_1 + m_2$. Moreover, we non-deterministically guess whether the currently processed inner node of T labelled by $q(n)$ will be an anchor of some pumping leaf "below." If not then we simply recursively call $\textsc{Reach}(p_1(m_1))$ and $\textsc{Reach}(p_2(m_2))$ (Line 7). Otherwise, $q(n)$ will be the anchor of some pumping leaf that is either in the subtree "rooted at" $p_1(m_1)$ (Line 8) or in the subtree "rooted at" $p_2(m_2)$ (Line 9). Speaking in terms of Lemma 13, either the inner node corresponding to configuration $p_1(m_1)$ is not exclusive or the one for $p_2(m_2)$ is not exclusive. Suppose $p_1(m_1)$ is not exclusive, we then call a procedure $\textsc{AnchorReach}(q(n), p(m_1))$ that takes two configurations as arguments and tacitly assumes the first argument $q(n)$ is the anchor and the second argument $p_1(m_1)$ corresponds to some inner node that lies between the anchor and the pumping leaf it will eventually correspond to.

In more detail, analogously to Reach the procedure AnchorReach first checks whether the counter values of its inputs both lie in $[0, B]$ (Line 13). If so it checks whether $p(m)$ corresponds to a valid pumping leaf of $q(n)$, i.e., it induces a positive instance of the residue reachability problem by invoking ResidueReach$(q(n), m - n)$ (Line 14). If not then a rule $t \in \Delta$ is non-deterministically chosen (Line 15), and in case t is a branching rule, it is non-deterministically chosen which "child" of $p(m)$ is not exclusive, the other child is simply checked for reachability by invoking procedure Reach (Lines 18 and 19).

Obviously, Reach and AnchorReach can be implemented in alternating logspace since the involved counter values lie in the interval $[-1, B + 1]$ and can hence be stored using a logarithmic number of bits.

5 Coverability and Boundedness

In this section, we show that the coverability and boundedness problem for BVASS_1 are also P-complete. The two problems are defined as follows:

Coverability and Boundedness in BVASS_1

INPUT: A BVASS_1 $\mathcal{B} = (Q, \Delta, F)$, a control state q and $n \in \mathbb{N}$ encoded in unary.
QUESTION: *Coverability:* Is there $m \geq n$ such that $q(m)$ is reachable?
Boundedness: Is $\mathit{reach}(q)$ finite?

If $q(n)$ is a positive instance of coverability then we call the configuration $q(n)$ *coverable*. A state q is *unbounded* whenever $\mathit{reach}(q)$ is unbounded (i.e. infinite).

Hardness for P is in both cases easily seen and similar to the P-hardness reduction from MCVP in Proposition 3.

Moreover, the P upper bound for coverability follows easily from the P upper bound for residue reachability since $q(n)$ is coverable if, and only if, the pair $(q(n), 1)$ is a positive instance of the residue reachability problem.

▶ **Theorem 16.** *Coverability in BVASS_1 is P-complete.*

The P upper bound for boundedness, however, cannot be derived immediately. In particular, as discussed in Section 3, there exists a family of BVASS_1 $(\mathcal{B}_n)_{n \geq 0}$ with some control state q such that $\mathit{reach}(q)$ is finite but of cardinality 2^n.

For the remainder of this section, fix some BVASS_1 $\mathcal{B} = (Q, \Delta, F)$. We first provide sufficient and necessary criteria that witness that a control state is unbounded. Call a node v in a reachability tree *decreasing* if there is an ancestor $u \prec v$ with $\mathit{state}(u) = \mathit{state}(v)$ and $\mathit{counter}(u) > \mathit{counter}(v)$. The following lemma, whose proof can be found in the technical report [7], shows that a reachability tree that contains some decreasing node witnesses that the control state at its root is unbounded.

▶ **Lemma 17.** *If a reachability tree T with $T(\varepsilon) = q(n)$ contains a decreasing node then q is unbounded.*

Conversely, the next lemma shows that a reachability tree whose root is labelled with a configuration with a sufficiently large counter value gives rise to a reachability tree which contains a decreasing node, informally speaking, shortly below its root.

▶ **Lemma 18.** *Suppose $n > 2^{|Q|}$ with $n \in \mathit{reach}(q)$. There exists a reachability tree $T \colon U \to Q \times \mathbb{N}$ for $q(n')$ where $n' \geq n$, and which contains a decreasing node v with $|v| \leq |Q|$.*

A consequence of the two previous lemmas is that q is unbounded if, and only if, $\mathit{reach}(q)$ contains some $n > 2^{|Q|}$. Even though the reachability trees in Lemma 18 are sufficient witnesses for unboundedness, they still contain much more information than necessary and are potentially of exponential size. In order to verify the existence of such a tree, exact counter values and in fact the subtrees rooted in v as well as all incomparable nodes can be abstracted away, as shown in the lemma below.

Let us write $\mathit{src}(t) \stackrel{\text{def}}{=} q$, $\mathit{trg}(t) \stackrel{\text{def}}{=} \{p, p'\}$ and $\mathit{eff}(t) \stackrel{\text{def}}{=} 0$, for the *source* and *target states* and the *effect* of a branching transition $t = (q, p, p') \in Q^3$, respectively. Similarly, for $t = (q, z, p)$ define $\mathit{src}(t) \stackrel{\text{def}}{=} q$, $\mathit{trg}(t) \stackrel{\text{def}}{=} \{p\}$ and $\mathit{eff}(t) \stackrel{\text{def}}{=} z$.

▶ **Lemma 19.** *A control state p_0 is unbounded if, and only if, there is a sequence of control states and transitions $p_0 t_1 p_1 t_2 \cdots t_k p_k$ with $k \leq |Q|$ and some index $j < k$ such that*

- **(i)** *$p_{i-1} = \mathit{src}(t_i)$ and $p_i \in \mathit{trg}(t_i)$ for all $1 \leq i \leq k$;*
- **(ii)** *$p_k = p_j$ and $p_i \neq p_j$ for all $0 \leq i < j$;*
- **(iii)** *$p(0)$ is coverable for every $p \in \bigcup_{i=1}^{k} \mathit{trg}(t_i)$; and*
- **(iv)** *for every $j < i \leq k$, there exists $n_i \leq |Q| + 1$ such that*
  1. *if $t_i = (p_{i-1}, p_i, p'_i) \in Q^3$ or $t_i = (p_{i-1}, p'_i, p_i) \in Q^3$ then $p'_i(n_i)$ is coverable, else $n_i = 0$,*
  2. *$\sum_{i=j+1}^{k} n_i > \sum_{i=j+1}^{k} \mathit{eff}(t_i)$.*

The last condition (iv) expresses that the cyclic suffix is consistent with the transition relation and guarantees a decreasing node.

Proof. If p_0 is unbounded, then by Lemma 18 we can take a reachability tree T containing a short decreasing node v, i.e., with $|v| \leq |Q|$. This decreasing node provides the claimed sequence: Conditions (i) and (ii) are immediate; for condition (iii) notice that for each mentioned state p some configuration $p(n)$ is reachable, as guaranteed by the respective subtree of T. This means in particular that $p(0)$ is coverable.

For (iv), first notice that the combined effect $\sum_{i=j+1}^{k} \mathit{eff}(t_i)$ of those transitions used between v (where $\mathit{state}(v) = p_k$) and its anchor (with state $p_j = p_k$) is bounded by $|v| = k \leq |Q|$. Secondly, as for condition (iii), we can assume that for all p'_i such that either $t_i = (p_{i-1}, p'_i, p_i) \in Q^3$ or $t_i = (p_{i-1}, p_i, p'_i) \in Q^3$, some configuration $p'_i(m_i)$ is reachable. For those $i \leq k$ where $t_i \notin Q^3$, let $m_i \stackrel{\text{def}}{=} 0$. Now, for all $j < i \leq k$, define $n_i \stackrel{\text{def}}{=} \min\{|Q| + 1, m_i\}$.

Case (iv)(a) holds immediately by definition of the n_i. To show Case (iv)(b) we distinguish two cases. In case $m_i \geq |Q| + 1$ for some such i it follows that $n_i = |Q| + 1$ and hence $\sum_{i=j+1}^{k} n_i \geq |Q| + 1 > \sum_{i=j+1}^{k} \mathit{eff}(t_i)$. Otherwise, if all $m_i < |Q| + 1$ then for all i it holds that $n_i = m_i$ and so $\sum_{i=j+1}^{k} m_i \leq \sum_{i=j+1}^{k} \mathit{eff}(t_i)$ contradicts that v is a decreasing node.

For the converse direction, assume a sequence as claimed above. Conditions (i)-(iii) imply the existence of a reachability tree for some $p_0(n)$. Condition (iv) ensures that there is such a tree with a decreasing node. We conclude by Lemma 17. ◀

Lemma 19 provides a characterisation of unbounded states that directly translates into an alternating logspace algorithm for the boundedness problem, similar to Algorithm 1, which yields the P upper bound. In particular, observe that a witnessing sequence satisfying Conditions (i) and (ii), as well as the numbers $n_i \leq |Q|+1$ can be guessed non-deterministically in logarithmic space. Moreover, Conditions (iii) and (iv) are decidable in polynomial time by Theorem 16.

▶ **Theorem 20.** *Boundedness in $BVASS_1$ is* P*-complete.*

Abstract

We study the almost-sure reachability problem in a distributed system obtained as the asynchronous composition of N copies (called processes) of the same automaton (called protocol), that can communicate via a shared register with finite domain. The automaton has two types of transitions: write-transitions update the value of the register, while read-transitions move to a new state depending on the content of the register. Non-determinism is resolved by a stochastic scheduler. Given a protocol, we focus on almost-sure reachability of a target state by one of the processes. The answer to this problem naturally depends on the number N of processes. However, we prove that our setting has a cut-off property: the answer to the almost-sure reachability problem is constant when N is large enough; we then develop an EXPSPACE algorithm deciding whether this constant answer is positive or negative.

1 Introduction

Verification of systems with many identical processes. It is a classical pattern in distributed systems to have a large number of identical components running concurrently (a.k.a. networks of processes). In order to verify the correctness of such systems, a naive option consists in fixing an upper bound on the number of processes, and applying classical verification techniques on the resulting system. This has several drawbacks, and in particular it gives no information whatsoever about larger systems. Another option is to

use parameterized-verification techniques, taking as a parameter the number of copies of the protocol in the system being considered. In such a setting, the natural question is to find and characterize the set of parameter values for which the system is correct. Not only the latter approach is more general, but it might also turn out to be easier and more efficient, since it involves orthogonal techniques.

Different means of communication lead to different models. A seminal paper on parameterized verification of such distributed systems is the work of German and Sistla [17]. In this work, the authors consider networks of processes all following the same finite-state automaton; the communication between processes is performed thanks to *rendez-vous* communication. Various related settings have been proposed and studied since then, which mainly differ by the way the processes communicate. Among those, let us mention broadcast communication [15, 10], token-passing [8, 2], message passing [6], shared register with ring topologies [1], or shared memory [16]. In his nice survey on such parameterized models [14], Esparza shows that minor changes in the setting, such as the presence of a controller in the system, might drastically change the complexity of the verification problems. The relative expressiveness of some of those models has been studied recently in [3], yielding several reductions of the verification problems for some of those classes of models.

Asynchronous shared-memory systems. We consider a communication model where the processes asynchronously access a shared register, and where read and write operations on this register are performed non-atomically. A similar model has been proposed by Hague in [18], where the behavior of processes is defined by a pushdown automaton. The complexity of some reachability and liveness problems for shared-memory models have then been established in [16] and [11], respectively. These works consider networks in which a specific process, called the leader, runs a different program, and address the problem whether, for some number of processes, the leader can satisfy a given reachability or liveness property. In the case where there is no leader, and where processes are finite-state, the parameterized control-state reachability problem (asking whether one of the processes can reach a given control state) can be solved in polynomial time, by adapting the approach of [9] for lossy broadcast protocols.

Fairness and cut-off properties. In this work, we further insert fairness assumptions in the model of parameterized networks with asynchronous shared memory, and consider reachability problems in this setting. There are different ways to include fairness in parameterized models. One approach is to enforce fairness expressed as a temporal-logic properties on the executions (e.g., any action that is available infinitely often must be performed infinitely often); this is the option chosen for parameterized networks with rendez-vous [17] and for systems with disjunctive guards (where processes can query the states of other processes) in [4]. We follow another choice, by equipping our networks with a stochastic scheduler that, at each step of the execution, assigns the same probability to the available actions of all the processes. From a high-level perspective, both forms of fairness are similar. However, expressing fairness via temporal logic allows for very regular patterns (e.g., round-robin execution of the processes), whereas the stochastic approach leads to consider all possible interleavings with probability 1. Under this stochastic scheduler assumption, we focus on almost-sure reachability of a given control state by any of the processes of the system. More specifically, as in [4], we are interested in determining the existence of a *cut-off*, i.e., an integer k such that networks with more than k processes almost-surely reach the target state. Deciding the existence and computing such cut-offs is important for at least two aspects: first, it ensures that the

system is correct for arbitrarily large networks; second, if we are able to derive a bound on the cut-off, then using classical verification techniques we can find the exact value of the cut-off and exactly characterize the sizes of the networks for which the behavior is correct.

Our contributions. We prove that for finite-state asynchronous shared-memory protocols with a stochastic scheduler, and for almost-sure reachability of some control state by some process of the network, there always exists a positive or negative cut-off; positive cut-offs are those above which the target state is reached with probability 1, while negative cut-offs are those above which the target state is reached with probability strictly less than 1. Notice that both cut-offs are not complement of one another, so that our result is not trivial.

We then prove that the "sign" (positive or negative) of a cut-off can be decided in EXPSPACE, and that this problem is PSPACE-hard. Finally, we provide lower and upper bounds on the values of the cut-offs, exhibiting in particular protocols with exponential (negative) cut-off. Notice how these results contrast with classical results in related areas: in the absence of fairness, reachability can be decided in polynomial time, and in most settings, when cut-offs exist, they generally have polynomial size [4, 13, 12].

2 Presentation of the model and of the considered problem

2.1 Preliminaries

Let S be a finite set. A multiset over S is a mapping $\mu\colon S \to \mathbb{N}$. The cardinality of a multiset μ is $|\mu| = \sum_{s\in S} \mu(s)$. The support $\overline{\mu}$ of μ is the subset $\nu \subseteq S$ s.t. for all $s \in S$, it holds $s \in \nu$ if, and only if, $\mu(s) > 0$. For $k \in \mathbb{N}$, we write $\mathbb{N}_k^S$ for the set of multisets of cardinality k over S, and $\mathbb{N}^S$ for the set of all multisets over S. For any $s \in S$ and $k \in \mathbb{N}$, we write s^k for the multiset where $s^k(s) = k$ and $s^k(s') = 0$ for all $s' \neq s$. We may write s instead of s^1 when no ambiguity may arise. A multiset μ is included in a multiset μ', written $\mu \sqsubseteq \mu'$, if $\mu(s) \leq \mu'(s)$ for all $s \in S$. Given two multisets μ and μ', their union $\mu \oplus \mu'$ is still a multiset s.t. $(\mu \oplus \mu')(s) = \mu(s) + \mu'(s)$ for all $s \in S$. Assuming $\mu \sqsubseteq \mu'$, the difference $\mu' \ominus \mu$ is still a multiset s.t. $(\mu' \ominus \mu)(s) = \mu'(s) - \mu(s)$.

A quasi-order $\langle A, \preceq\rangle$ is a *well quasi-order* (wqo for short) if for every infinite sequence of elements $a_1, a_2, \ldots$ in A, there exist two indices $i < j$ such that $a_i \preceq a_j$. For instance, for $n > 0$, $\langle \mathbb{N}^n, \leq\rangle$ (with lexicographic order) is a wqo. Given a set A with an ordering $\preceq$ and a subset $B \subseteq A$, the set B is said to be *upward closed* in A if for all $a_1 \in B$ and $a_2 \in A$, in case $a_1 \preceq a_2$, then $a_2 \in B$. The *upward-closure* of a set B (for the ordering $\preceq$), denoted by $\uparrow_{\preceq}(B)$ (or sometimes $\uparrow(B)$ when the ordering is clear from the context), is the set $\{a \in A \mid \exists b \in B \text{ s.t. } b \preceq a\}$. If $\langle A, \preceq\rangle$ is a wqo and B is an upward closed set in A, there exists a finite set of minimal elements $\{b_1, \ldots, b_k\}$ such that $B = \uparrow\{b_1, \ldots, b_k\}$.

2.2 Register protocols and associated distributed system

We focus on systems that are defined as the (asynchronous) product of several copies of the same protocol. Each copy communicates with the others through a single register that can store values from a finite alphabet.

▶ **Definition 1.** A *register protocol* is given by $\mathcal{P} = \langle Q, D, q_0, T\rangle$, where Q is a finite set of control locations, D is a finite alphabet of data for the shared register, $q_0 \in Q$ is an initial location, $T \subseteq Q \times \{R, W\} \times D \times Q$ is the set of transitions of the protocol. Here R means *read* the content of the shared register, while W means *write* in the register.

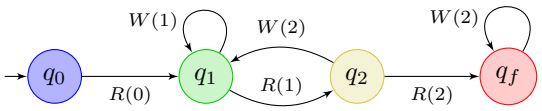

Figure 1 Example of a register protocol with $D = \{0, 1, 2\}$.

In order to avoid deadlocks, it is required that each location has at least one outgoing transition. We also require that whenever some R-transition (q, R, d', q') appears in T, then for all $d \in D$, there exists at least one $q_d \in Q$ such that $(q, R, d, q_d) \in T$. The size of the protocol $\mathcal{P}$ is given by $|Q| + |T|$.

▶ **Example 1.a.** *Figure 1 displays a small register protocol with four locations, over an alphabet of data* $D = \{0, 1, 2\}$. *In this figure (and in the sequel), omitted* R*-transitions (e.g., transitions* $R(1)$ *and* $R(2)$ *from* q_0*) are assumed to be self-loops. When the register contains* 0*, this protocol may move from initial location* q_0 *to location* q_1*. From there it can write* 1 *in the register, and then move to* q_2*. From* q_2*, as long as the register contains* 1*, the process can either stay in* q_2 *(with the omitted self-loop* $R(1)$*), or write* 2 *in the register and jump back to* q_1*. It is easily seen that if this process executes alone, it cannot reach state* q_f*.*

We now present the semantics of distributed systems associated with our register protocols. We consider the *asynchronous* composition of several copies of the protocol (the number of copies is not fixed a priori and can be seen as a parameter). We are interested in the behavior of such a composition under a fair scheduler. Such distributed systems involve two sources of non-determinism: first, register protocols may be non-deterministic; second, in any configuration, all protocols have at least one available transition, and non-determinism arises from the asynchronous semantics. In the semantics associated with a register protocol, non-determinism will be solved by a randomized scheduler, whose role is to select at each step which process will perform a transition, and which transition it will perform among the available ones. Because we will consider qualitative objectives (almost-sure reachability), the exact probability distributions will not really matter, and we will pick the uniform one (arbitrary choice). Note that we assume non-atomic read/write operations on the register, as in [18, 16, 11]. More precisely, when one process performs a transition, then all the processes that are in the same state are allowed to also perform the same transition just after, in fact write are always possible, and if a process performs a read of a specific value, since this read does not alter the value of the register, all processes in the same state can perform the same read (until one process performs a write). We will see later that dropping this hypothesis has a consequence on our results. We now give the formal definition of such a system.

The configurations of the distributed system built on register protocol $\mathcal{P} = \langle Q, D, q_0, T\rangle$ belong to the set $\Gamma = \mathbb{N}^Q \times D$. The first component of a configuration is a multiset characterizing the number of processes in each state of Q, whereas the second component provides the content of the register. For a configuration $\gamma = \langle \mu, d\rangle$, we denote by $st(\gamma)$ the multiset μ in $\mathbb{N}^Q$ and by $data(\gamma)$ the data d in D. We overload the operators defined over multisets; in particular, for a multiset δ over Q, we write $\gamma \oplus \delta$ for the configuration $\langle \mu \oplus \delta, d\rangle$. Similarly, we write $\overline{\gamma}$ for the support of $st(\gamma)$.

A configuration $\gamma' = \langle \mu', d'\rangle$ is a *successor* of a configuration $\gamma = \langle \mu, d\rangle$ if, and only if, there is a transition $(q, \mathsf{op}, d'', q') \in T$ such that $\mu(q) > 0$, $\mu' = \mu \ominus q \oplus q'$ and either $\mathsf{op} = R$ and $d = d' = d''$, or $\mathsf{op} = W$ and $d' = d''$. In that case, we write $\gamma \to \gamma'$. Note that since $\mu(q) > 0$ and $\mu' = \mu \ominus q \oplus q'$, we have necessarily $|\mu| = |\mu'|$. In our system, we assume that there is no creation or deletion of processes during an execution, hence the size of

configurations (i.e., $|st(\gamma)|$) remains constant along transitions. We write Γ_k for the set of configurations of size k. For any configuration $\gamma \in \Gamma_k$, we denote by $\mathrm{Post}(\gamma) \subseteq \Gamma_k$ the set of successors of γ, and point out that such a set is finite and non-empty.

Now, the *distributed system* $\mathcal{S}_\mathcal{P}$ associated with a register protocol $\mathcal{P}$ is a discrete-time Markov chain $\langle \Gamma, Pr \rangle$ where $Pr \colon \Gamma \times \Gamma \to [0,1]$ is the transition probability matrix defined as follows: for all γ and $\gamma' \in \Gamma$, we have $Pr(\gamma, \gamma') = \frac{1}{|\mathrm{Post}(\gamma)|}$ if $\gamma \to \gamma'$, and $Pr(\gamma, \gamma') = 0$ otherwise. Note that Pr is well defined: by the restriction imposed on the transition relation T of the protocol, we have $0 < |\mathrm{Post}(\gamma)| < \infty$ for all configuration γ, and hence we also get $\Sigma_{\gamma' \in \Gamma} Pr(\gamma, \gamma') = 1$. For a fixed integer k, we define the distributed system of size k associated with $\mathcal{P}$ as the finite-state discrete-time Markov chain $\mathcal{S}^k_\mathcal{P} = \langle \Gamma_k, \Pr_k \rangle$, where $\Pr_k$ is the restriction of Pr to $\Gamma_k \times \Gamma_k$.

We are interested in analyzing the behavior of the distributed system for a large number of participants. More precisely, we are interested in determining whether almost-sure reachability of a specific control state holds when the number of processes involved is large. We are therefore seeking a *cut-off* property, which we formalize in the following.

A finite path in the system $\mathcal{S}_\mathcal{P}$ is a finite sequence of configurations $\gamma_0 \to \gamma_1 \ldots \to \gamma_k$. In such a case, we say that the path starts in γ_0 and ends in γ_k. We furthermore write $\gamma \to^* \gamma'$ if, and only if, there exists a path that starts in γ and ends in γ'. Given a location q_f, we denote by $[\![\Diamond q_f]\!]$ the set of paths of the form $\gamma_0 \to \gamma_1 \ldots \to \gamma_k$ for which there is $i \in [0; k]$ such that $st(\gamma_i)(q_f) > 0$. Given a configuration γ, we denote by $\mathbb{P}(\gamma, [\![\Diamond q_f]\!])$ the probability that some paths starting in γ belong to $[\![\Diamond q_f]\!]$ in $\mathcal{S}_\mathcal{P}$. This probability is well-defined since the set of such paths is measurable (see e.g., [5]). Given a register protocol $\mathcal{P} = \langle Q, D, q_0, T \rangle$, an initial register value d_0, and a target location $q_f \in Q$, we say that q_f is almost-surely reachable for k processes if $\mathbb{P}(\langle q_0^k, d_0 \rangle, [\![\Diamond q_f]\!]) = 1$.

▶ **Example 1.b.** *Consider again the protocol depicted in Fig. 1, with initial register content* 0*. As we explained already, for $k = 1$, the final state is not reachable at all, for any scheduler (here as $k = 1$, the scheduler only has to solve non-determinism in the protocol).*

When $k = 2$, one easily sees that the final state is reachable: it suffices that both processes go to q_2 together, from where one process may write value 2 *in the register, which the other process can read and go to q_f. Notice that this does not ensure that q_f is reachable almost-surely for this k (and actually, it is not; see Example 1.c).*

We aim here at finding cut-offs for almost-sure reachability, i.e., we seek the existence of a threshold such that almost-sure reachability (or its negation) holds for all larger values.

▶ **Definition 2.** Fix a protocol $\mathcal{P} = \langle Q, D, q_0, T \rangle$, $d_0 \in D$, and $q_f \in Q$. An integer $k \in \mathbb{N}$ is a *cut-off for almost-sure reachability* (shortly a *cut-off*) for $\mathcal{P}$, d_0 and q_f if one of the following two properties holds:

- for all $h \geq k$, we have $\mathbb{P}(\langle q_0^h, d_0 \rangle, [\![\Diamond q_f]\!]) = 1$. In this case k is a *positive* cut-off;
- for all $h \geq k$, we have $\mathbb{P}(\langle q_0^h, d_0 \rangle, [\![\Diamond q_f]\!]) < 1$. Then k is a *negative* cut-off.

An integer k is a *tight* cut-off if it is a cut-off and $k - 1$ is not.

Notice that from the definition, cut-offs need not exist for a given distributed system. Our main result precisely states that cut-offs always exist, and that we can decide their nature.

▶ **Theorem 3.** *For any protocol $\mathcal{P}$, any initial register value d_0 and any target location q_f, there always exists a cut-off for almost-sure reachability, whose value is at most doubly-exponential in the size of $\mathcal{P}$. Whether it is a positive or a negative cut-off can be decided in* EXPSPACE*, and is* PSPACE*-hard.*

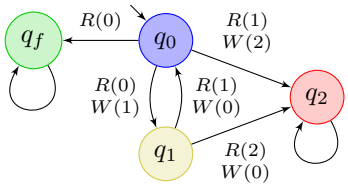

Figure 2 Example of a register protocol with atomic read/write operations.

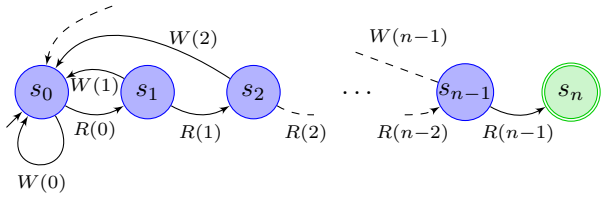

Figure 3 A "filter" protocol $\mathcal{F}_n$ for $n > 0$.

▶ Remark. When dropping the condition on non-atomic read/write operations, and allowing transitions with atomic read/write operations (i.e., one process is ensured to perform a read and a write operation without to be interrupted by another process), the existence of a cut-off (Theorem 3) is not ensured. This is demonstrated with the protocol of Fig. 2: one easily checks (e.g., inductively on the number of processes, since processes that end up in q_2 play no role anymore) that state q_f is reached with probability 1 if, and only if, the number of processes is odd.

3 Properties of register protocols

3.1 Example of a register protocol

We illustrate our model with a family of register protocols $(\mathcal{F}_n)_{n>0}$, depicted in Fig. 3. For a fixed n, protocol $\mathcal{F}_n$ has $n+1$ states and n different data; intuitively, in order to move from s_i to s_{i+1}, two processes are needed: one writes i in the register and goes back to s_0, and the second process can proceed to s_{i+1} by reading i. Since backward transitions to s_0 are always possible and since states can always exit s_0 by writing a 0 and reading it afterwards, no deadlock can ever occur so the main question remains to determine if s_n is reachable by one of the processes as we increase the number of initial processes. As shown in Lemma 4, the answer is positive: $\mathcal{F}_n$ has a tight linear positive cut-off; it actually behaves like a "filter", that can test if at least n processes are running together. We exploit this property later in Section 4.4.

▶ **Lemma 4.** *Fix $n \in \mathbb{N}$. The "filter" protocol $\mathcal{F}_n$, depicted in Fig. 3, with initial register value 0 and target location s_n, has a tight positive cut-off equal to n.*

3.2 Basic results

In this section, we consider a register protocol $\mathcal{P} = \langle Q, D, q_0, T\rangle$, its associated distributed system $\mathcal{S}_\mathcal{P} = \langle \Gamma, Pr\rangle$, an initial register value $d_0 \in D$ and a target state $q_f \in Q$. We define a partial order $\preceq$ over the set Γ of configurations as follows: $\langle \mu, d\rangle \preceq \langle \mu', d'\rangle$ if, and only if, $d = d'$ and $\overline{\mu} = \overline{\mu'}$ and $\mu \sqsubseteq \mu'$. Note that with respect to the classical order over multisets, we require here that the supports of μ and μ' be the same (we add in fact a finite information to hold for the comparison). We know from Dickson's lemma that $\langle \mathbb{N}^Q, \sqsubseteq\rangle$ is a wqo and since Q, D and the supports of multisets in $\mathbb{N}^Q$ are finite, we can deduce the following lemma.

▶ **Lemma 5.** *$\langle \Gamma, \preceq\rangle$ is a wqo.*

We will give some properties of register protocols, but first we introduce some further notations. Given a set of configuration $\Delta \subseteq \Gamma$, we define $\mathrm{Pre}^*(\Delta)$ and $\mathrm{Post}^*(\Delta)$ as follows:

$$\mathrm{Pre}^*(\Delta) = \{\gamma \in \Gamma \mid \exists \gamma' \in \Delta . \gamma \to^* \gamma'\} \qquad \mathrm{Post}^*(\Delta) = \{\gamma' \in \Gamma \mid \exists \gamma \in \Delta . \gamma \to^* \gamma'\}$$

We also define the set $[\![q_f]\!]$ of configurations we aim to reach as $\{\gamma \in \Gamma \mid st(\gamma)(q_f) > 0\}$. It holds that $\gamma \in \mathrm{Pre}^*([\![q_f]\!])$ if, and only if, there exists a path in $[\![\Diamond q_f]\!]$ starting in γ.

As already mentioned, when $\langle \mu, d\rangle \to \langle \mu', d'\rangle$ in $\mathcal{S}_{\mathcal{P}}$, the multisets μ and μ' have the same cardinality. This implies that given $k > 0$, the set $\mathrm{Post}^*(\{\langle q_0^k, d_0\rangle\})$ is finite (remember that Q and D are finite). As a consequence, for a fixed k, checking whether $\mathbb{P}(\langle q_0^k, d_0\rangle, [\![\Diamond q_f]\!]) = 1$ can be easily achieved by analyzing the finite-state discrete-time Markov chain $\mathcal{S}_{\mathcal{P}}^k$ [5].

▶ **Lemma 6.** *Let $k \geq 1$. Then $\mathbb{P}(\langle q_0^k, d_0\rangle, [\![\Diamond q_f]\!]) = 1$ if, and only if, $\mathrm{Post}^*(\{\langle q_0^k, d_0\rangle\}) \subseteq \mathrm{Pre}^*([\![q_f]\!])$.*

The difficulty here precisely lies in finding such a k and in proving that, once we have found one correct value for k, all larger values are correct as well (to get the cut-off property). Characteristics of register protocols provide us with some tools to solve this problem. We base our analysis on reasoning on the set of configurations reachable from initial configurations in $\uparrow\{\langle q_0, d_0\rangle\}$ (the upward closure of $\{\langle q_0, d_0\rangle\}$ w.r.t. $\preceq$), remember that since the order $\langle \Gamma, \preceq\rangle$ requires equality of support for elements to be comparable, we have that $\uparrow\{\langle q_0, d_0\rangle\} = \bigcup_{k\geq 1}\{\langle q_0^k, d_0\rangle\}$. We begin by showing that this set of reachable configurations and the set of configurations from which $[\![q_f]\!]$ is reachable are both upward-closed. Thanks to Lemma 5, they can be represented as upward closures of finite sets. To show that $\mathrm{Post}^*(\uparrow\{\langle q_0, d_0\rangle\})$ is upward-closed, we prove that register protocols enjoy the following monotonicity property. A similar property is given in [11] and derives from the non-atomicity of operations.

▶ **Lemma 7.** *Let γ_1, γ_2, and γ_2' be configurations in Γ. If $\gamma_1 \to^* \gamma_2$ and $\gamma_2 \preceq \gamma_2'$, then there exists $\gamma_1' \in \Gamma$ such that $\gamma_1' \to^* \gamma_2'$ and $\gamma_1 \preceq \gamma_1'$.*

$\mathrm{Pre}^*([\![q_f]\!])$ is also upward-closed, since if $[\![q_f]\!]$ can be reached from some configuration γ, it can also be reached by a larger configuration by keeping the extra copies idle. Thus:

▶ **Lemma 8.** $\mathrm{Post}^*(\uparrow\{\langle q_0, d_0\rangle\})$ *and* $\mathrm{Pre}^*([\![q_f]\!])$ *are upward-closed sets in* $\langle \Gamma, \preceq\rangle$.

3.3 Existence of a cut-off

From Lemma 8, and from the fact that $\langle \Gamma, \preceq\rangle$ is a wqo, there must exist two finite sequences of configurations $(\theta_i)_{1\leq i\leq n}$ and $(\eta_i)_{1\leq i\leq m}$ such that $\mathrm{Post}^*(\uparrow\{\langle q_0, d_0\rangle\}) = \uparrow\{\theta_1, \ldots, \theta_n\}$ and $\mathrm{Pre}^*([\![q_f]\!]) = \uparrow\{\eta_1, \ldots, \eta_m\}$. By analyzing these two sequences, we now prove that any register protocol has a cut-off (for any initial register value and any target location).

We let $\Delta, \Delta' \subseteq \Gamma$ be two upward-closed sets (for $\preceq$). We say that Δ *is included in* Δ' *modulo single-state incrementation* whenever for every $\gamma \in \Delta$, for every $q \in \overline{\gamma}$, there is some $k \in \mathbb{N}$ such that $\gamma \oplus q^k \in \Delta'$. Note that this condition can be checked using only comparisons between minimal elements of Δ and Δ'. In particular, we have the following lemma.

▶ **Lemma 9.** $\mathrm{Post}^*(\uparrow\{\langle q_0, d_0\rangle\})$ *is included in* $\mathrm{Pre}^*([\![q_f]\!])$ *modulo single-state incrementation if, and only if, for all $i \in [1; n]$, and for all $q \in \overline{\theta_i}$, there exists $j \in [1; m]$ such that $data(\theta_i) = data(\eta_j)$ and $\overline{\theta_i} = \overline{\eta_j}$ and $st(\eta_j)(q') \leq st(\theta_i)(q')$ for all $q' \in Q \setminus \{q\}$.*

Using the previous characterization of inclusion modulo single-state incrementation for $\mathrm{Post}^*(\uparrow\{\langle q_0, d_0\rangle\})$ and $\mathrm{Pre}^*([\![q_f]\!])$ together with the result of Lemma 6, we are able to provide a first characterization of the existence of a negative cut-off.

▶ **Lemma 10.** *If* $\mathrm{Post}^*(\uparrow\{\langle q_0, d_0\rangle\})$ *is not included in* $\mathrm{Pre}^*([\![q_f]\!])$ *modulo single-state incrementation, then* $\max_{1\leq i\leq n}(|st(\theta_i)|)$ *is a negative cut-off.*

We now prove that if the condition of Lemma 10 fails to hold, then there is a positive cut-off.In order to make our claim precise, for every $i \in [1; n]$ and for any $q \in \overline{\theta_i}$, we let $d_{i,q} = \max\{(|st(\eta_j)(q) - st(\theta_i)(q)|) \mid 1 \leq j \leq m \text{ and } \overline{\theta_i} = \overline{\eta_j}\}$.

▶ **Lemma 11.** *If* $\mathrm{Post}^*(\uparrow\{\langle q_0, d_0\rangle\})$ *is included in* $\mathrm{Pre}^*([\![q_f]\!])$ *modulo single-state incrementation, then* $\max_{1\leq i\leq n}(|st(\theta_i)| + \sum_{q\in\overline{\theta_i}} d_{i,q})$ *is a positive cut-off.*

The last two lemmas entail our first result:

▶ **Theorem 12.** *Any register protocol admits a cut-off (for any given initial register value and target state).*

4 Detecting negative cut-offs

We develop an algorithm for deciding whether a distributed system associated with a register protocol has a negative cut-off. Thanks to Theorem 12, this can also be used to detect the existence of a positive cut-off. Our algorithm relies on the construction and study of a *symbolic graph*, as we define below: for any given protocol $\mathcal{P}$, the symbolic graph has bounded size, but can be used to reason about *arbitrarily large* distributed systems built from $\mathcal{P}$. It will store sufficient information to decide the existence of a negative cut-off.

4.1 k-bounded symbolic graph

In this section, we consider a register protocol $\mathcal{P} = \langle Q, D, q_0, T\rangle$, its associated distributed system $\mathcal{S}_\mathcal{P} = \langle \Gamma, Pr\rangle$, an initial register value $d_0 \in D$, and a target location $q_f \in Q$ of $\mathcal{P}$. With $\mathcal{P}$, we associate a finite-state graph, called *symbolic graph of index* k, which for k large enough contains enough information to decide the existence of a negative cut-off.

▶ **Definition 13.** Let k be an integer. The *symbolic graph of index* k associated with $\mathcal{P}$ and d_0 is the transition system $\mathcal{G} = \langle V, v_0, E\rangle$ where

- $V = \mathbb{N}_k^Q \times 2^Q \times D$ contains triples made of a multiset of states of Q of size k, a subset of Q, and the content of the register; the multiset (called *concrete part*) is used to exactly keep track of a fixed set of k processes, while the subset of Q (the *abstract part*) encodes the support of the arbitrarily many remaining processes;
- $v_0 = \langle q_0^k, \{q_0\}, \{d_0\}\rangle$;
- transitions are of two types, depending whether they involve a process in the concrete part or a process in the abstract part. Formally, there is a transition $\langle \mu, S, d\rangle \to \langle \mu', S', d'\rangle$ whenever there is a transition $(q, O, d'', q') \in T$ such that $d = d' = d''$ if $O = R$ and $d' = d''$ if $O = W$, and one of the following two conditions holds:
  - either $S' = S$ and $q \sqsubseteq \mu$ (that is, $\mu(q) > 0$) and $\mu' = \mu \ominus q \oplus q'$;
  - or $\mu = \mu'$ and $q \in S$ and $S' \in \{S \setminus \{q\} \cup \{q'\}, S \cup \{q'\}\}$.

The symbolic graph of index k can be used as an abstraction of distributed systems made of at least $k + 1$ copies of $\mathcal{P}$: it keeps full information of the states of k processes, and only gives the support of the states of the other processes. In particular, the symbolic graph of index 0 provides only the states appearing in each configuration of the system.

▶ **Example 1.c.** *Consider the protocol depicted in Fig. 1. Its symbolic graph of index* 0 *is depicted in Fig. 4. Notice that the final state (representing all configurations containing* q_f*) is reachable from any state of this symbolic graph. However, our original protocol* $\mathcal{P}$ *of Fig. 1 does not have a positive cut-off (assuming initial register value* 0*): indeed, with*

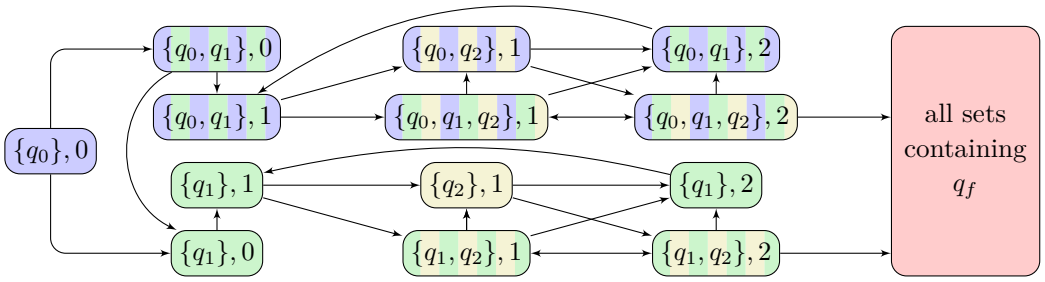

Figure 4 Symbolic graph (of index 0) of the protocol of Fig. 1 (self-loops omitted).

positive probability, a single process will go to q_1 and immediately write 1 in the register, thus preventing any other process to leave q_0; then one may check that the process in q_1 alone cannot reach q_f, so that the probability of reaching q_f from q_0^k is strictly less than 1, for any $k > 0$. This livelock is not taken into account in the symbolic graph of index 0, because from any configuration with support $\{q_0, q_1\}$ and register data equal to 1, the symbolic graph has a transition to the configuration with support $\{q_0, q_1, q_2\}$, which only exists in the concrete system when there are at least two processes in q_1. As we prove in the following, analyzing the symbolic graph for a sufficiently large index guarantees to detect such a situation.

For any index k, the symbolic graph achieves the following correspondence:

▶ **Lemma 14.** *Given two states $\langle \mu, S, d\rangle$ and $\langle \mu', S', d'\rangle$, there is a transition from $\langle \mu, S, d\rangle$ to $\langle \mu', S', d'\rangle$ in the symbolic graph $\mathcal{G}$ of index k if, and only if, there exist multisets δ and δ' with respective supports S and S', and such that $\langle \mu \oplus \delta, d\rangle \to \langle \mu' \oplus \delta', d'\rangle$ in $\mathcal{S}_\mathcal{P}$.*

4.2 Deciding the existence of a negative cut-off

We now explain how the symbolic graph can be used to decide the existence of a negative cut-off. Since $\mathrm{Pre}^*(\llbracket q_f \rrbracket)$ is upward-closed in $\langle \Gamma, \preceq\rangle$, there is a finite set of configurations $\{\eta_i = \langle \mu_i, d_i\rangle \mid 1 \le i \le m\}$ such that $\mathrm{Pre}^*(\llbracket q_f \rrbracket) = \uparrow\{\eta_i \mid 1 \le i \le m\}$. We let $K = \max\{st(\eta_i)(q) \mid q \in Q,\ 1 \le i \le m\}$, and show that for our purpose, it is enough to consider the symbolic graph of index $K \cdot |Q|$; we provide a bound on K in the next section.

▶ **Lemma 15.** *There is a negative cut-off for $\mathcal{P}$, d_0 and q_f if, and only if, there is a node in the symbolic graph of index $K \cdot |Q|$ that is reachable from $\langle q_0^{K\cdot|Q|}, \{q_0\}, d_0\rangle$ but from which no configuration involving q_f is reachable.*

Proof. We begin with the converse implication, assuming that there is a state $\langle \mu, S, d\rangle$ in the symbolic graph of index $K \cdot |Q|$ that is reachable from $(q_0^{K\cdot|Q|}, \{q_0\}, d_0)$ and from which no configuration in $\llbracket q_f \rrbracket$ is reachable. Applying Lemma 14, there exist multisets $\delta_0 = q_0^N$ and δ, with respective supports $\{q_0\}$ and S, such that $\langle \mu \oplus \delta, d\rangle$ is reachable from $\langle q_0^{K\cdot|Q|} \oplus \delta_0, d_0\rangle$. If location q_f was reachable from $\langle \mu \oplus \delta, d\rangle$ in the distributed system, then there would exist a path from $\langle \mu, S, d\rangle$ to a state involving q_f in the symbolic graph, which contradicts our hypothesis. By Lemma 7, it follows that such a configuration $\langle \mu \oplus \delta', d\rangle$ — which cannot reach q_f — can be reached from $\langle q_0^{K\cdot|Q|} \oplus q_0^{N'}, d_0\rangle$ for any $N' \ge N$: hence it cannot be the case that q_f is reachable almost-surely for any $N' \ge N$. Therefore there cannot be a positive cut-off, which implies that there is a negative one (from Theorem 12).

Conversely, if there is a negative cut-off, then for some $N > K \cdot |Q|$, the distributed system $\mathcal{S}_\mathcal{P}^N$ with N processes has probability less than 1 of reaching $\llbracket q_f \rrbracket$ from q_0^N. This system

being finite, there must exist a reachable configuration $\langle \mu, d \rangle$ from which q_f is not reachable [5]. Hence $\langle \mu, d \rangle \notin \mathrm{Pre}^*([\![q_f]\!])$, and for all $i \leq m$, there is a location q^i such that $\mu(q^i) < \mu_i(q^i) \leq K$. Then there must exist a reachable state $\langle \kappa, S, d \rangle$ of the symbolic graph of index $K \cdot |Q|$ for which $\kappa(q^i) = \mu(q^i)$ and $q^i \notin S$, for all $1 \leq i \leq m$: it indeed suffices to follow the path from $\langle q_0^N, d_0 \rangle$ to $\langle \mu, d \rangle$ while keeping track of the processes that end up in some q^i in the concrete part; this is possible because the concrete part has size at least $K \cdot |Q|$.

It remains to be proved that no state involving q_f is reachable from $\langle \kappa, S, d \rangle$ in the symbolic graph. If it were the case, then by Lemma 14, there would exist δ with support S such that $[\![q_f]\!]$ is reachable from $\langle \kappa \oplus \delta, d \rangle$ in the distributed system. Then $\langle \kappa \oplus \delta, d \rangle \in \mathrm{Pre}^*([\![q_f]\!])$, so that for some $1 \leq i \leq m$, $(\kappa \oplus \delta)(q^i) \geq \mu_i(q^i)$, which is not possible as $\kappa(q^i) < \mu_i(q^i)$ and q^i is not in the support S of δ. This contradiction concludes the proof. ◀

▶ Remark. Besides the existence of a negative cut-off, this proof also provides us with an upper bound on the tight cut-off, as we shall see in Section 5.

4.3 Complexity of the algorithm

We now consider the complexity of the algorithm that can be deduced from Lemma 15. Using results by Rackoff on the coverability problem in Vector Addition Systems [19], we can bound K – and consequently the size of the needed symbolic graph – by a *double-exponential* in the size of the protocol. Therefore, it suffices to solve a reachability problem in NLOGSPACE [20] on this doubly-exponential graph: this boils down to NEXPSPACE with regard to the protocol's size, hence EXPSPACE by Savitch's theorem [20].

▶ **Theorem 16.** *Deciding the existence of a negative cut-off is in* EXPSPACE.

4.4 PSPACE-hardness for deciding cut-offs

▶ **Theorem 17.** *Deciding the existence of a negative cut-off is* PSPACE*-hard.*

Our proof is based on the encoding of a linear-bounded Turing machine [20]: we build a register protocol for which there is a negative cut-off if, and only if, the machine reaches its final state q_{halt} with the tape head reading the last cell of the tape. Write n for the size of the tape of the Turing machine. We assume (without loss of generality) that the machine is deterministic, and that it accepts only if it ends in its halting state q_{halt} while reading the last cell of the tape. Our reduction works as follows: some processes of our network will first be assigned an index i in $[1; n]$ indicating the cell of the tape they shall encode during the simulation. The other processes are stuck in the initial location, and will play no role. The state q and position j of the head of the Turing machine are stored in the register. During the simulation phase, when a process is scheduled to play, it checks in the register whether the tape head is on the cell it encodes, and in that case it performs the transition of the Turing machine. If the tape head is not on the cell it encodes, the process moves to the target location (which we consider as the target for the almost-sure reachability problem). Finally, upon seeing (q_{halt}, n) in the register, all processes move to a $(n+1)$-filter protocol $\mathcal{F}_{n+1}$ (similar to that of Fig. 3) whose last location s_{n+1} is the aforementioned target location.

If the Turing machine halts, then the corresponding run can be mimicked with exactly one process per cell, thus giving rise to a finite run of the distributed system where n processes end up in the $(n+1)$-filter (and the other processes are stuck in the initial location); from there s_{n+1} cannot be reached. If the Turing machine does not halt, then assume that there is

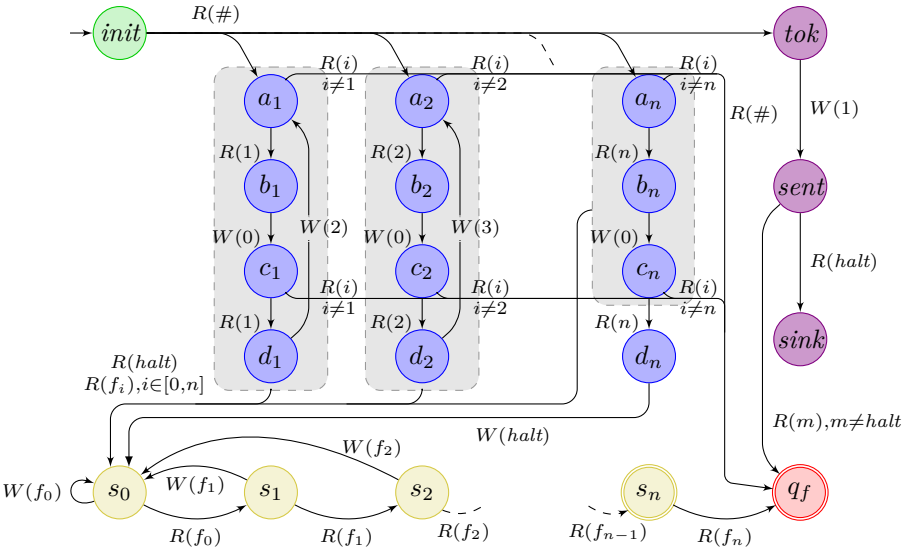

Figure 5 Simulating an exponential counter: grey boxes contain the nodes used to encode the bits of the counter; yellow nodes at the bottom correspond to the filter module from Fig. 3; purple nodes *tok*, *sent* and *sink* correspond to the second part of the protocol, and are used to produce tokens. Missing *read* edges are assumed to be self-loops.

an infinite run of the distributed system never reaching the target location. This run cannot get stuck in the simulation phase forever, because it would end up in a strongly connected component from which the target location is reachable. Thus this run eventually reaches the $(n+1)$-filter, which requires that at least $n+1$ processes participate in the simulation (because with n processes it would simulate the exact run of the machine, and would not reach q_{halt}, while with fewer processes the tape head could not go over cells that are not handled by a process). Thus at least $n+1$ processes would end up in the $(n+1)$-filter, and with probability 1 the target location should be reached.

5 Bounds on cut-offs

5.1 Existence of exponential tight negative cut-offs

We exhibit a family of register protocols that admits negative cut-off exponential in the size of the protocol. The construction reuses ideas from the PSPACE-hardness proof. Our register protocol has two parts: one part simulates a counter over n bits, and requires a *token* (a special value in the register) to perform each step of the simulation. The second part is used to generate the tokens (i.e., writing 1 in the register). Figure 5 depicts our construction. We claim that this protocol, with # as initial register value and q_f as target location, admits a negative tight cut-off larger than 2^n: in other terms, there exists $N > 2^n$ such that the final state will be reached with probability strictly less than 1 in the distributed system made of at least N processes (starting with # in the register), while the distributed system with 2^n processes will reach the final state almost-surely. In order to justify this claim, we explain now the intuition behind this protocol.

We first focus on the first part of the protocol, containing nodes named a_i, b_i, c_i, d_i and s_i. This part can be divided into three phases: the initialization phase lasts as long as the register contains #; the counting phase starts when the register contains *halt* for the first time; the simulation phase is the intermediate phase.

During the initialization phase, processes move to locations a_i and *tok*, until some process in *tok* writes 1 in the register (or until some process reaches q_f, using a transition from a_i to q_f while reading #). Write γ_0 for the configuration reached when entering the simulation phase (i.e., when 1 is written in the register for the first time). We assume that $st(\gamma_0)(a_i) > 0$ for some i, as otherwise all the processes are in *tok*, and they all will eventually reach q_f. Now, we notice that if $st(\gamma_0)(a_i) = 0$ for some i, then location d_n cannot be reached, so that no process can reach the counting phase. In that case, some process (and actually all of them) will eventually reach q_f. We now consider the case where $st(\gamma_0)(a_i) \geq 1$ for all i. One can prove (inductively) that d_i is reachable when $st(\gamma_0)(tok) \geq 2^i$. Hence d_n, and thus also s_0, can be reached when $st(\gamma_0)(tok) \geq 2^n$. Assuming q_f is not reached, the counting phase must never contain more than n processes, hence we actually have that $st(\gamma_0)(a_i) = 1$. With this new condition, s_0 is reached if, and only if, $st(\gamma_0)(tok) \geq 2^n$. When the latter condition is not true, q_f will be reached almost-surely, which proves the second part of our claim: the final location is reached almost-surely in systems with strictly less than $n + 2^n$ copies of the protocol.

We now consider the case of systems with at least $n + 2^n$ processes. We exhibit a finite execution of those systems from which no continuation can reach q_f, thus proving that q_f is reached with probability strictly less than 1 in those systems. The execution is as follows: during initialization, for each i, one process enters a_i; all other processes move to *tok*, and one of them write 1 in the register. The n processes in the simulation phase then simulate the consecutive incrementations of the counter, consuming one token at each step, until reaching d_n. At that time, all the processes in *tok* move to *sent*, and the process in d_n writes *halt* in the register and enters s_0. The processes in the simulation phase can then enter s_0, and those in *sent* can move to *sink*. We now have n processes in s_0, and the other ones in *sink*. According to Lemma 4, location q_f cannot be reached from this configuration, which concludes our proof.

▶ **Theorem 18.** *There exists a family of register protocols which, equipped with an initial register value and a target location, admit negative tight cut-offs whose size are exponential in the size of the protocol.*

▶ Remark. The question whether there exists protocols with exponential *positive* cut-offs remains open. The family of *filter* protocols described at Section 3.1 is an example of protocols with a linear positive cut-off.

5.2 Upper bounds on tight cut-offs

The results (and proofs) of Section 4 can be used to derive upper bounds on tight cut-offs. We make this explicit in the following theorem.

▶ **Theorem 19.** *For a protocol $\mathcal{P} = \langle Q, D, q_0, T\rangle$ equipped with an initial register value $d_0 \in D$ and a target location $q_f \in Q$, the tight cut-off is at most doubly-exponential in $|\mathcal{P}|$.*

6 Conclusions and future works

We have shown that in networks of identical finite-state automata communicating (non-atomically) through a single register and equipped with a fair stochastic scheduler, there always exists a cut-off on the number of processes which either witnesses almost-sure reachability of a specific control-state (positive cut-off) or its negation (negative cut-off). This cut-off determinacy essentially relies on the monotonicity induced by our model, which

allows to use well-quasi order techniques. By analyzing a well-chosen symbolic graph, one can decide in EXPSPACE whether that cut-off is positive, or negative, and we proved this decision problem to be PSPACE-hard. This approach allows us to deduce some doubly-exponential bounds on the value of the cut-offs. Finally, we gave an example of a network in which there is a negative cut-off, which is exponential in the size of the underlying protocol. Note however that no such lower-bound is known yet for positive cut-offs.

We have several further directions of research. First, it would be nice to fill the gap between the PSPACE lower bound and the EXPSPACE upper bound for deciding the nature of the cut-off. We would like also to investigate further atomic read/write operations, which generate non-monotonic transition systems, but for which we would like to decide whether there is a cut-off or not. Finally, we believe that our techniques could be extended to more general classes of properties, for instance, universal reachability (all processes should enter a distinguished state), or liveness properties.

Abstract

We propose a probabilistic Hoare logic aHL based on the union bound, a tool from basic probability theory. While the union bound is simple, it is an extremely common tool for analyzing randomized algorithms. In formal verification terms, the union bound allows flexible and compositional reasoning over possible ways an algorithm may go wrong. It also enables a clean separation between reasoning about probabilities and reasoning about events, which are expressed as standard first-order formulas in our logic. Notably, assertions in our logic are non-probabilistic, even though we can conclude probabilistic facts from the judgments.

Our logic can also prove accuracy properties for interactive programs, where the program must produce intermediate outputs as soon as pieces of the input arrive, rather than accessing the entire input at once. This setting also enables adaptivity, where later inputs may depend on earlier intermediate outputs. We show how to prove accuracy for several examples from the differential privacy literature, both interactive and non-interactive.

1 Introduction

Probabilistic computations arise naturally in many areas of computer science. For instance, they are widely used in cryptography, privacy, and security for achieving goals that lie beyond the reach of deterministic programs. However, the correctness of probabilistic programs can be quite subtle, often relying on complex reasoning about probabilistic events.

Accordingly, probabilistic computations present an attractive target for formal verification. A long line of research, spanning more than four decades, has focused on expressive formalisms for reasoning about general probabilistic properties both for purely probabilistic programs and for programs that combine probabilistic and non-deterministic choice (see, e.g., [35, 29, 34]).

More recent research investigates specialized formalisms that work with more restricted assertions and proof techniques, aiming to simplify formal verification. As perhaps the purest examples of this approach, some program logics prove probabilistic properties by working purely with non-probabilistic assertions; we call such systems *lightweight* logics.

* This work was partially supported by NSF grants TWC-1513694, CNS-1065060 and CNS-1237235, by EPSRC grant EP/M022358/1 and by a grant from the Simons Foundation (#360368 to Justin Hsu).

Examples include *probabilistic relational Hoare logic* [7] for proving the reductionist security of cryptographic constructions, and the related *approximate probabilistic relational Hoare logic* [8] for reasoning about differential privacy. These logics rely on the powerful abstraction of *probabilistic couplings* to derive probabilistic facts from non-probabilistic assertions [4].

Lightweight logics are appealing because they can leverage ideas for verifying deterministic programs, a rich and well-studied area of formal verification. However, existing lightweight logics apply only to relational verification: properties about the relation between two programs. In this paper, we propose a non-relational, lightweight logic based on the *union bound*, a simple tool from probability theory. For arbitrary properties $E_1, \ldots, E_n$, the union bound states that

$$\Pr\left[\cup_{i=1}^{n} E_i\right] \leq \sum_{i=1}^{n} \Pr[E_i]\,.$$

Typically, we think of the events E_i as *bad events*, describing different ways that the program may fail to satisfy some target property. Bad events can be viewed as propositions on single program states, so they can be represented as non-probabilistic assertions. For example, the formula $x > 10$ defines a bad event for x a program variable. If x stores the result from a random sample, this bad event models when the sample is bigger than 10. The union bound states that no bad events happen, except with probability at most the sum of the probabilities of each bad event.

The union bound is a ubiquitous tool in pen-and-paper proofs due to its flexible and compositional nature: to bound the probability of a collection of failures, consider each failure in isolation. This compositional style is also a natural fit for formal verification. To demonstrate this, we formalize a Hoare logic aHL based on the union bound for a probabilistic imperative language. The assertions in our logic are non-probabilistic, but judgments carry a numeric index for tracking the failure probability. Concretely, the aHL judgment

$$\vdash_{\beta} c : \Phi \Longrightarrow \Psi$$

states that every execution of a program c starting from an initial state satisfying Φ yields a distribution in which Ψ holds except with probability at most β. We define a proof system for the logic and show its soundness. We also define a sound embedding of aHL into standard Hoare logic, by instrumenting the program with ghost code that tracks the index β in a special program variable. This is a useful reduction that also applies to other lightweight logics [5].

Moreover, our logic applies both to standard algorithms and to *interactive* algorithms, a richer class of algorithms that is commonly studied in contexts such as *online learning* (algorithms which make predictions about the future input) and *streaming* (algorithms which operate on datasets that are too large to fit into memory by processing the input in linear passes). Informally, interactive algorithms receive their input in a sequence of chunks, and must produce intermediate outputs as soon as each chunk arrives. In some cases the input can be *adaptive*: later inputs may depend on earlier outputs. Besides enabling new classes of algorithms, interactivity allows more modularity. We can decompose programs into interacting parts, analyze each part in isolation, and reuse the components.

We demonstrate aHL on several algorithms satisfying *differential privacy* [14], a statistical notion of privacy which trades off between the privacy of inputs and the accuracy of outputs. Prior work on verifying private algorithms focuses on the privacy property for non-interactive algorithms (see, e.g. [37, 18, 8]). We provide the first verification of *accuracy* for both non-interactive and interactive algorithms. We note however that aHL, like the union bound, can be applied to a wide range of probabilistic programs beyond differential privacy.

2 A union bound logic

Before introducing the program logic, we will begin by reviewing a largely standard, probabilistic imperative language. We state the soundness of the logic and describe the embedding into Hoare logic. The semantics of the language and the proof of soundness are deferred to the appendix.

2.1 Language

We will work with a core imperative language with a command for random sampling from distributions, and procedure calls. The set of commands is defined as follows:

$\mathcal{C} ::=$	skip	noop
	$\mid \mathcal{X} \leftarrow \mathcal{E}$	deterministic assignment
	$\mid \mathcal{X} \xleftarrow{\$} \mathcal{D}(\mathcal{E})$	probabilistic assignment
	$\mid \mathcal{C}; \mathcal{C}$	sequencing
	$\mid \mathsf{if}\ \mathcal{E}\ \mathsf{then}\ \mathcal{C}\ \mathsf{else}\ \mathcal{C}$	conditional
	$\mid \mathsf{while}\ \mathcal{E}\ \mathsf{do}\ \mathcal{C}$	while loop
	$\mid \mathcal{X} \leftarrow \mathcal{F}(\mathcal{E})$	procedure call
	$\mid \mathcal{X} \leftarrow \mathcal{A}(\mathcal{E})$	external call

Here, $\mathcal{X}$ is a set of *variables*, $\mathcal{E}$ is a set of *expressions*, and $\mathcal{D}$ is a set of *distribution constructors*, which can be parameterized by standard expressions. Variables and expressions are typed, ranging over booleans, integers, lists, etc. The expression grammar is entirely standard, and we omit it.

We distinguish two kinds of procedure calls: $\mathcal{A}$ is a set of external procedure names, and $\mathcal{F}$ is a set of internal procedure names. We assume we have access to the code of internal procedures, but not the code of external procedures. We think of external procedures as controlled by some external *adversary*, who can select the next input in an interactive algorithm. Accordingly, external procedures run in an *external memory* separate from the main program memory, which is shared by all internal procedures.

For simplicity, procedures take a single argument, do not have local variables, and are not mutually recursive. A program consists of a sequence of procedures definitions, each of the following form:

$$\mathbf{proc}\ f(\mathbf{arg}_f)\{c; \mathbf{return}\ r;\}\,.$$

Here, f is a procedure name, $\mathbf{arg}_f \in \mathbf{Vars}$ is the formal argument of f, c is the function body and r is its return value. We assume that distinct procedure definitions do not bind the same procedure name and that the program variable $\mathbf{arg}_f$ can only appear in the body of f.

Before we define the program semantics, we first need to introduce a few definitions from probability theory.

▶ **Definition 1.** A discrete sub-distribution over a set A is defined by a *mass function* $\mu : A \to [0, 1]$ such that:

- the support $\mathrm{supp}(\mu)$ of μ – defined as $\{x \in A \mid \mu(x) \neq 0\}$ – is countable; and
- the weight $\mathrm{wt}(\mu)$ of μ – defined as $\sum_{x \in A} \mu(x)$ – satisfies $\mathrm{wt}(\mu) \leq 1$.

A *distribution* is a sub-distribution with weight 1. The probability of an event P w.r.t. μ, written $\Pr_\mu[P]$ (or $\Pr[P]$ when μ is clear from the context), is defined as $\sum_{x \in A | P(x)} \mu(x)$. When Φ is an assertion (assuming that $A \equiv \mathsf{State}$), we write $\Pr_\mu[\Phi]$ for $\Pr_\mu[\lambda m.\, m \models \Phi]$. Likewise, when $v \in A$, we write $\Pr_\mu[v]$ for $\Pr_\mu[\lambda x.\, x = v]$.

Commands are interpreted as a function from memories to sub-distributions over memories, where memories are finite maps from program and external variables to values. More formally, if State is the set of memories then the interpretation of c, written $[\![c]\!]$, is a function from State to $\mathbf{Distr}(\mathsf{State})$, where $\mathbf{Distr}(\mathsf{T})$ denotes the set of discrete sub-distributions over T. The definition of $[\![c]\!]$ enforces the separation between the internal and external states – only commands performing external procedure calls can act on the external memory. The interpretation of external procedure calls is parameterized by functions – one for each external procedure – of type $\mathsf{State}_{|\mathcal{A}} \to \mathbf{Distr}(\mathsf{State}_{|\mathcal{A}})$, where $\mathsf{State}_{|\mathcal{A}}$ is the set of memories *restricted* to the external variables. Thus, external procedures can only access the external memory.

2.2 Logic

Now that we have seen the programs, let us turn to the program logic. Our judgments are similar to standard Hoare logic with an additional numeric index representing the probability of failure. Concretely, the judgments are of the following form:

$$\vdash_\beta c : \Phi \Longrightarrow \Psi$$

where Φ and Ψ are first-order formulas over the program variables representing the pre- and post-condition, respectively. We stress that Φ and Ψ are *non-probabilistic* assertions: they do not mention the probabilities of specific events, and will be interpreted as properties of individual memories rather than distributions over memories. This is reflected by the validity relation for assertions: $m \models \Phi$ states that Φ is valid in the *single* memory m, rather than in a distribution over memories. Similarly, $\models \Phi$ states that Φ is valid in all (single) memories. By separating the assertions from the probabilistic features of our language, the assertions are simpler and easier to manipulate. The index β is a non-negative real number (typically, from the unit interval $[0, 1]$).

Now, we can define semantic validity for our judgments. In short, the index β will be an upper bound on the probability that the postcondition Ψ does not hold on the output distribution, assuming the precondition Φ holds on the initial memory.

▶ **Definition 2** (Validity). A judgment $\vdash_\beta c : \Phi \Longrightarrow \Psi$ is *valid* if for every memory m such that $m \models \Phi$, we have:

$$\Pr_{[\![c]\!](m)}[\neg\Psi] \leq \beta\,.$$

We present the main proof rules of our logic in Figure 1. The rule for random sampling [Rand] allows us to assume a proposition Ψ about the random sample provided that Ψ fails with probability at most β. This is a semantic condition which we introduce as an axiom for each primitive distribution.

The remaining rules are similar to the standard Hoare logic rules, with special handling for the index. The sequence rule [Seq] states that the failure probabilities of the two commands add together; this is simply the union bound internalized in our logic. The conditional rule [If] assumes that the indices for the two branch judgments are equal – which can always be achieved via weakening – keeping the same index for the conditional. Roughly, this is because only one branch of the conditional is executed. The loop rule [While] simply accumulates the failure probability β throughout the iterations; the side conditions ensure that the loop terminates in at most k iterations except with probability $k \cdot \beta$. To reason about procedure calls, standard (internal) procedure calls use the rule [Call], which substitutes the argument and return variables in the pre- and post-condition, respectively. External procedure calls

$$\frac{}{\vdash_0 \mathsf{skip} : \Phi \Longrightarrow \Phi}\ [\textsc{Skip}] \qquad \frac{}{\vdash_0 x \leftarrow e : \Phi[e/x] \Longrightarrow \Phi}\ [\textsc{Assn}]$$

$$\frac{\forall m.\, m \models \Phi \implies \Pr_{[\![x \xleftarrow{\$} d(e)]\!](m)}[\neg\Psi] \leq \beta}{\vdash_\beta x \xleftarrow{\$} d(e) : \Phi \Longrightarrow \Psi}\ [\textsc{Rand}]$$

$$\frac{\vdash_\beta c : \Phi \Longrightarrow \Phi' \quad \vdash_{\beta'} c' : \Phi' \Longrightarrow \Phi''}{\vdash_{\beta+\beta'} c; c' : \Phi \Longrightarrow \Phi''}\ [\textsc{Seq}] \qquad \frac{\vdash_\beta c : \Phi \wedge e \Longrightarrow \Psi \quad \vdash_\beta c' : \Phi \wedge \neg e \Longrightarrow \Psi}{\vdash_\beta \mathsf{if}\ e\ \mathsf{then}\ c\ \mathsf{else}\ c' : \Phi \Longrightarrow \Psi}\ [\textsc{If}]$$

Figure 1 Selected proof rules.

use the rule [Ext]. We do not have access to the implementation of the procedure; we know just the type of the return value.

The structural rules are also similar to the typical Hoare logic rules. The weakening rule [Weak] allows strengthening the precondition and weakening the postcondition as usual, but also allows increasing the index – this corresponds to allowing a possibly higher probability of failure. The frame rule [Frame] preserves assertions that do not mention variables modified by the command. The conjunction rule [And] is another instance of the union bound, allowing us to combine two postconditions while adding up the failure probabilities. The case rule [Or] is the dual of [And] and takes the maximum failure probability among two post-conditions when taking their disjunction. Finally, the rule [False] allows us to conclude false with failure probability 1: With probability at most 0, false holds in the final memory.

We can show that our proof system is sound with respect to the semantics; the proof is deferred to the appendix.

▶ **Theorem 3** (Soundness). *All derivable judgments* $\vdash_\beta c : \Phi \Longrightarrow \Psi$ *are valid.*

In addition, we can define a sound embedding into Hoare logic in the style of Barthe et al. [5]. Assuming a fresh program variable x_β of type $\mathbb{R}$, we can transform a command c

such that $\vdash_\beta c : \Phi \Longrightarrow \Psi$ to a new command $\lceil c \rceil$ and a proof of the standard Hoare logic judgment

$$\vdash \lceil c \rceil : \Phi \wedge x_\beta = 0 \implies \Psi \wedge x_\beta \leq \beta \,.$$

The command $\lceil c \rceil$ is obtained from c by replacing all probabilistic sampling $x \xleftarrow{\$} d(e)$ with a call to an abstract, non-probabilistic procedure call $x \leftarrow \text{Sample}^\diamond\,(d(e))$, whose specification models the postcondition of [Rand]:

$$\frac{\forall m.\, m \models \Phi \implies \Pr_{[\![x \xleftarrow{\$} d(e)]\!](m)}[\neg\Psi] \leq \iota}{\vdash x \leftarrow \text{Sample}^\diamond\,(d(e)) : \Phi \wedge x_\beta \leq \nu \implies \Psi \wedge x_\beta \leq \nu + \iota} \,.$$

3 Accuracy for differentially private programs

Now that we have presented our logic aHL, we will follow by verifying several examples. Though our system applies to programs from many domains, we will focus on programs satisfying *differential privacy*, a statistical notion of privacy proposed by Dwork et al. [14]. At a very high level, these programs take private data as input and add random noise to protect privacy. (Interested readers should consult a textbook [15] for a more detailed presentation.) In contrast to existing formal verification work, which verifies the privacy property, we will verify *accuracy*. This is just as important as privacy: the constant function is perfectly private but not very useful.

All of our example programs take samples from the Laplace distribution.

▶ **Definition 4.** The *(discrete) Laplace* distribution $\mathcal{L}_\epsilon(e)$ is parameterized by a scale parameter $\epsilon > 0$ and a mean e. The distribution ranges over the real numbers $\{\nu = k + e\}$ for k an integer, releasing ν with probability proportional to:

$$\Pr_{\mathcal{L}_\epsilon(e)}[\nu] \propto \exp\left(-\epsilon \cdot |\nu - e|\right).$$

This distribution satisfies a basic accuracy property.

▶ **Lemma 5.** *Let $\beta \in (0,1)$, and let ν be a sample from the distribution $\mathcal{L}_\epsilon(e)$. Then,*

$$\Pr_{\mathcal{L}_\epsilon(e)}\left[|\nu - e| > \frac{1}{\epsilon}\log\frac{1}{\beta}\right] < \beta \,.$$

Thus, the following sampling rule is sound for our system for every $\beta \in (0,1)$:

$$\frac{}{\vdash_\beta x \xleftarrow{\$} \mathcal{L}_\epsilon(e) : \top \Longrightarrow |x - e| \leq \frac{1}{\epsilon}\log\frac{1}{\beta}} \text{ [LapAcc]} \,.$$

Before presenting the examples, we will set some common notations and terminology. First, we consider a set db of databases,[1] a set query of queries, and primitive functions

$$\begin{array}{rcl} \mathsf{evalQ} & : & \mathsf{query} \to \mathsf{db} \to \mathbb{R} \\ \mathsf{invQ} & : & \mathsf{query} \to \mathsf{query} \\ \mathsf{negQ} & : & \mathsf{query} \to \mathsf{query} \\ \mathsf{size} & : & \mathsf{db} \to \mathbb{N} \\ \mathsf{error} & : & \mathsf{query} \to \mathsf{db} \to \mathsf{query} \end{array}$$

[1] The general setting of differential privacy is that the database contains private information that must be protected. However, this fact will not be important for proving accuracy.

satisfying

$$\begin{aligned} \mathsf{evalQ}(\mathsf{invQ}(q), d) &= -\mathsf{evalQ}(q, d) \\ \mathsf{evalQ}(\mathsf{negQ}(q), d) &= \mathsf{size}(d) - \mathsf{evalQ}(q, d) \\ \mathsf{evalQ}(\mathsf{error}(q, d_1), d_2) &= \mathsf{evalQ}(q, d_1) - \mathsf{evalQ}(q, d_2) \end{aligned}$$

Concretely, one can identify query with the functions $\mathsf{db} \to \mathbb{R}$ and obtain an easy realization of the above functions and axioms.

In some situations, we may need additional structure on the queries to prove the accuracy guarantees. In particular, a query q is *linear* if

- for every two databases d, d', we have $q(d + d') = q(d) + q(d')$ for a commutative and associative operator $+$ on databases; and
- for the database d_0 that is the identity of $+$, we have $q(d_0) = 0$.

Concretely, we can identify db with the set of multisets, $+$ with multiset union, and d_0 with the empty multiset.

3.1 Report-noisy-max

Our first example is the *Report-noisy-max* algorithm (see, e.g., Dwork and Roth [15]). Report-noisy-max is a variant of the *exponential mechanism* [32], which provides the standard way to achieve differential privacy for computations whose outputs lie in a finite (perhaps non-numeric) set $\mathcal{R}$. Both algorithms perform the same computations, except that the exponential mechanism adds *one-sided* Laplace noise whereas Report-noisy-max adds regular Laplace noise. Thus, accuracy for both algorithms is verified in essentially the same way. We focus on Report-noisy-max to avoid defining one-sided Laplace.

Report-noisy-max finds an element of a finite set $\mathcal{R}$ that approximately maximizes some *quality score* function qscore, which takes as input an element $r \in \mathcal{R}$ and a database d. Operationally, Report-noisy-max computes the quality score for each element of $\mathcal{R}$, adds Laplace noise, and returns the element with the highest (noisy) value. We can implement this algorithm with the following code, using syntactic sugar for arrays:

```
proc RNM(R, d) :
  flag ← 1; best ← 0;
  while R ≠ ∅ do
    r ← pick(R); noisy[r] ←$ L_{ε/2}(qscore(r, d));
    if (noisy[r] > best ∨ flag = 1) then
      flag ← 0; r* ← r; best ← noisy[r];
    R ← R \ {r};
return r*;
```

The scale $\epsilon/2$ of the Laplace distribution ensures an appropriate level of differential privacy under certain assumptions; we will not discuss privacy in the remainder.

▶ **Theorem 6.** *Let $\beta \in (0, 1)$, and let $res \in \mathcal{R}$ be the output of Report-noisy-max on input d and quality score* qscore*. Then, we have the following judgment:*

$$\vdash_\beta \mathrm{RNM} : \top \Longrightarrow \forall r \in \mathcal{R}.\ \mathsf{qscore}(res, d) > \mathsf{qscore}(r, d) - \frac{4}{\epsilon} \log \frac{|\mathcal{R}|}{\beta}\,.$$

where $|\mathcal{R}|$ denotes the size of $\mathcal{R}$. This corresponds to the existing accuracy guarantee for Report-noisy-max (see, e.g., Dwork and Roth [15]).

Roughly, this theorem states that while the result *res* may not be the element with the absolute highest quality score, its quality score is not far below the quality score of any other element. For a brief sanity check, note that the guarantee weakens as we increase the range $\mathcal{R}$, or decrease the failure probability β.

The proof of accuracy is based on an instantiation of the rule [LapAcc] with e set to $\mathsf{qscore}(r, d)$, β set to $\beta/|\mathcal{R}|$, and ϵ set to $\epsilon/2$. First, we can show

$$\vdash_{\beta/|\mathcal{R}|} c : \top \Longrightarrow |\mathit{noisy}[r] - \mathsf{qscore}(r, d)| < \frac{2}{\epsilon} \log \frac{|\mathcal{R}|}{\beta} .$$

where c is the loop body. Since the loop runs for $|\mathcal{R}|$ iterations, we also have

$$\vdash_{\beta} \text{RNM} : \top \Longrightarrow \forall r \in \mathcal{R}.\ |\mathit{noisy}[r] - \mathsf{qscore}(r, d)| < \frac{2}{\epsilon} \log \frac{|\mathcal{R}|}{\beta} .$$

In order to prove this judgment, the loop invariant quantifies over all previously seen $r \in \mathcal{R}$. Combined with a straightforward invariant showing that r^* stores the index of the current maximum (noisy) score, the above judgment suffices to prove the accuracy guarantee for Report-noisy-max (Theorem 6).

3.2 Sparse Vector algorithm

Our second example is the *Sparse Vector algorithm*, which indicates which numeric queries take value (approximately) above some threshold value (see, e.g., Dwork and Roth [15]). Simpler approaches can accomplish this task by releasing the noisy answer to all queries and then comparing with the threshold, but the resulting error then grows linearly with the total number of queries. Sparse Vector does not release the noisy answers, but the resulting error grows only *logarithmically* with the total number of queries – a substantial improvement. The differential privacy property of Sparse Vector was recently formally verified [6]; here, we consider the accuracy property.

In the non-interactive setting, the algorithm takes as input a list of queries $q_1, q_2, \ldots$, a database d, and a numeric threshold $t \in \mathbb{R}$.[2] First, we add Laplace noise to the threshold t to calculate the noisy threshold T. Then, we evaluate each query q_i on d, add Laplace noise, and check if the noisy value exceeds T. If so, we output $\top$; if not, we output $\bot$.

Sparse Vector also works in the *interactive* setting. Here, the algorithm is fed one query at a time, and must process this query (producing $\bot$ or $\top$) before seeing the next query. The input may be adaptive – future queries may depend on the answers to earlier queries.

We focus on the interactive version; the non-interactive version can be handled similar to Report-noisy-max. We break the code into two pieces. The first piece initializes variables and computes the noisy threshold, while the second piece accepts a single new query and returns the answer.

$$\begin{array}{l}
\mathsf{proc}\ \text{SV.}\textsc{Init}(T_{in}, \epsilon_{in}) : \\
\quad \epsilon \leftarrow \epsilon_{in}; \\
\quad T \xleftarrow{\$} \mathcal{L}_{\epsilon/2}(T_{in});
\end{array}
\qquad
\begin{array}{l}
\mathsf{proc}\ \text{SV.}\textsc{Step}(q) : \\
\quad a \xleftarrow{\$} \mathcal{L}_{\epsilon/4}(\mathsf{evalQ}(q, d)); \\
\quad \mathsf{if}\ (a < T)\ \mathsf{then}\ \{z \leftarrow \bot;\}\ \mathsf{else}\ \{z \leftarrow \top;\} \\
\mathsf{return}\ z;
\end{array}$$

[2] In some presentations, the algorithm is also parameterized by the maximum number k of queries to answer. This feature is important for privacy but not accuracy, so we omit it. It is not difficult to extend the accuracy proof for answering at most k queries.

The main procedure performs initialization, and then enters into an interactive loop between the external procedure $\mathcal{A}$ – which supplies the queries – and the Sparse Vector procedure SV.Step:

```
proc SV.main(Q, T, ε) :
  SV.Init(T, ε);
  u ← 0; ans[u] ← ⊥;
  while (u < Q) do
    u ← u + 1;
    q[u] ← A(ans[u − 1]);
    ans[u] ← SV.Step(q[u]);
return ans;
```

Sparse Vector satisfies the following accuracy guarantee.

▶ **Theorem 7.** *Let $\beta \in (0,1)$. We have*

$$\vdash_{\beta} \text{SV.main}(Q,T) : \top \Longrightarrow \forall j \in \{1,\ldots,Q\}.\ \Phi(q[j],d),\ \textit{where}$$

$$\Phi(q,d) \triangleq \left(res = \top \rightarrow \mathsf{evalQ}(q,d) > t - \frac{6}{\epsilon}\log\frac{Q+1}{\beta}\right) \wedge \left(res = \bot \rightarrow \mathsf{evalQ}(q,d) < t + \frac{6}{\epsilon}\log\frac{Q+1}{\beta}\right).$$

This judgment corresponds to the accuracy guarantee for Sparse Vector from (see, e.g., Dwork and Roth [15]). Note that the error term depends logarithmically on the total number of queries Q, a key feature of Sparse Vector.

To prove this theorem, we first specify the procedures SV.Init and SV.Step. For initialization, we have

$$\vdash_{\beta/(Q+1)} \text{SV.Init}(T,\epsilon) : \top \Longrightarrow \Phi_t \quad \text{where} \quad \Phi_t \triangleq |t-T| < \frac{2}{\epsilon}\log\frac{Q+1}{\beta} \wedge \epsilon = \epsilon_{in}\,.$$

For the interactive step, we have

$$\vdash_{\beta/(Q+1)} \text{SV.Step}(q) : \Phi_t \Longrightarrow \Phi_t \wedge \Phi(q,d)\,.$$

Combining these two judgments, we can prove accuracy for SV.main (Theorem 7).

3.3 Online Multiplicative Weights

Our final example demonstrates how we can use the union bound to analyze a complex combination of several interactive algorithms, yielding sophisticated accuracy proofs. We will verify the *Online Multiplicative Weights* (OMW) algorithm first proposed by Hardt and Rothblum [21] and later refined by Gupta et al. [20]. Like Sparse Vector, this interactive algorithm can handle adaptive queries while guaranteeing error logarithmic in the number of queries. Unlike Sparse Vector, OMW produces approximate answers to the queries instead of just a bit representing above or below threshold.

At a high level, OMW iteratively constructs a *synthetic* version of the true database. The user can present various linear queries to the algorithm, which applies the Sparse Vector algorithm to check whether the error of the synthetic database on this query is smaller than some threshold. If so, the algorithm simply returns the approximate answer. Otherwise, it

updates the synthetic database using the *multiplicative weights* update rule to better model the true database, and answers the query by adding Laplace noise to the true answer. An inductive argument shows that after enough updates, the synthetic database must be similar to the true database on *all* queries. At this point, we can answer all subsequent queries using the synthetic database alone.

In code, the following procedure implements the Online Multiplicative Weights algorithm.

```
proc MW-SV.MAIN(d, α, ϵ, Q, X, n) :
  η ← α/2n; T ← 2α; c ← 4n² ln(X)/α²;                    set parameters
  u ← 0; k ← 0; ans[k] ← ⊥;                               initialize variables
  mwdb ← MW.INIT(η, X, n); SV.INIT(T, ϵ/4c);              initialize MW and SV
  while (k < Q) do                                        main loop
    k ← k + 1;                                            increment count of queries
    q[k] ← 𝒜(ans[k − 1], mwdb);                           get next query
    approx ← evalQ(q[k], mwdb);                           calculate approx answer
    exact ← evalQ(q[k], d);                               calculate exact answer
    if (k ≥ c) then ans[k] ← approx;                      enough updates, use approx answer
    else
      err> ← error(q[k], mwdb); at ← SV.STEP(err>);       check if approx answer is high
      err< ← invQ(error(q[k], mwdb)); bt ← SV.STEP(err<); check if approx answer is low
      if (at ≠ ⊥ ∨ bt ≠ ⊥) then                           large error
        u ← u + 1;                                        increment count of updates
        if at ≠ ⊥ then up ← q[k];                         approx answer too high
        else up ← negQ(q[k]);                             approx answer too low
        mwdb ← MW.STEP(mwdb, up);                         update synthetic db
        ans[k] ←$ ℒ_{ϵ/2c}(exact);                        estimate true answer
      else                                                small error, do not update
        ans[k] ← approx;                                  answer using approx answer
return ans;
```

Online multiplicative weights satisfies the following accuracy guarantee.

▶ **Theorem 8.** *Let $\beta \in (0,1)$. Then,*

$$\vdash_\beta \text{MW-SV.MAIN}(d, \alpha, \epsilon, Q, X, n) : \alpha \geq \max(\alpha_{sv}, \alpha_{lap}) \implies \\ \forall j.\ j \in \{1, \ldots, Q\} \to |res[j] - \mathsf{evalQ}(q[j], d)| \leq \alpha,$$

$$\textit{where} \quad \gamma \triangleq 4n^2 \ln(X)/\alpha^2, \quad \alpha_{sv} \triangleq \tfrac{24\gamma}{\epsilon} \log \tfrac{2(Q+1)}{\beta}, \quad \textit{and} \quad \alpha_{lap} \triangleq \tfrac{4\gamma}{\epsilon} \log \tfrac{2\gamma}{\beta}.$$

In words, the answers to all the supplied queries are within α of the true answer if α is sufficiently large. The above judgment reflects the accuracy guarantee first proved by Hardt and Rothblum [21] and later generalized by Gupta et al. [20].

The main routine depends on the *multiplicative weights* subroutine (MW), which maintains and updates the synthetic database. Roughly, MW takes as input the current synthetic database and a query where the synthetic database gives an answer that is far from the true answer. Then, MW improves the synthetic database to better model the true database. Our implementation of MW consists of two subroutines: MW.INIT initializes the synthetic database, and MW.STEP updates the current database with a query that has high error. The code for these subroutines is somewhat technical, and we will not present it here.

Instead, we will present their specifications, which are given in terms of an expression $\Psi(x, d)$ where x is the current synthetic database and d is the true database. We omit the definition of Ψ and focus on its three key properties:

- $\Psi(x, d) \geq 0$;
- $\Psi(x, d)$ is initially bounded for the initial synthetic database; and
- $\Psi(x, d)$ decreases each time we update the synthetic database.

Functions satisfying these properties are often called *potential functions*.

The first property follows from the definition of Ψ, while the second and third properties are reflected by the specifications of the MW procedures. Concretely, we can bound the initial value of Ψ with the following specification for MW.INIT:

$$\vdash_0 \text{MW.INIT}(\eta, X, n) : \top \Longrightarrow \Psi(res, d) \leq \ln X \,.$$

We can also show that Ψ decreases with the following specification for MW.STEP:

$$\vdash_0 \text{MW.STEP}(x, q) : \top \Longrightarrow \Psi(x, d) - \Psi(res, d) \geq \eta(\mathsf{evalQ}(q, x) - \mathsf{evalQ}(q, d))/n - \eta^2 \,.$$

We make two remarks. First, these specifications crucially rely on the fact that q is a linear query. Second, both procedures are deterministic. For such procedures, the fragment of aHL with index $\beta = 0$ corresponds precisely to standard Hoare logic.

Now, let us briefly consider the key points in proving the main specification (Theorem 8). First, the key part of the invariant for the main loop is $\Psi(mwdb, d) \leq \log X - u \cdot \alpha^2/4n^2$. Roughly, Ψ is initially at most $\log X$ by the specification for MW.INIT, and every time we call MW.STEP we decrease Ψ by at least $\alpha^2/4n^2$ if the update query up has error at least α. Since Ψ is always non-negative, we can find at most c queries with high error – after c updates, the synthetic database $mwdb$ must give accurate answers on all queries.

Prior to making c updates, there are two cases for each query. If at least one of the Sparse Vector calls returns above threshold, we set the update query up to be $q[u]$ if the approximate answer is too high, otherwise we set up to be the negated query $\mathsf{neqQ}(q[u])$ if the approximate answer is too low. With this choice of update query, we can show that

$$\mathsf{evalQ}(up, mwdb) - \mathsf{evalQ}(up, d) \geq \alpha$$

so Ψ decreases by at least $\alpha^2/4n^2$. Then, we answer the original query $q[u]$ by adding Laplace noise, so our answer is also within α of the true answer. Otherwise, if both Sparse Vector calls return below threshold, then the query $q[u]$ is answered well by our approximation $mwdb$ and there is no need to update $mwdb$ or access the real database d.

The above reasoning assumes that Sparse Vector and the Laplace mechanisms are sufficiently accurate. To guarantee the former, notice that the Sparse Vector subroutine will process at most $2Q$ queries, so we assume that α is larger than the error α_{sv} guaranteed by Theorem 7 for $2Q$ queries and failure probability $\beta/2$. To guarantee the latter, notice that we sample Laplace noise at most c times – once for each update step – so we assume that α is larger than the error α_{lap} guaranteed by [LapAcc] for failure probability $\beta/2c$; by a union bound, all Laplace noises are accurate except with probability $\beta/2$. Taking $\alpha \geq \max(\alpha_{sv}, \alpha_{lap})$, both accuracy guarantees hold except with probability at most β, and we have the desired proof of accuracy for OMW (Theorem 8).

4 Related work

The semantics of probabilistic programming languages has been studied extensively since the late 70s. Kozen's seminal paper [28] studies two semantics for a core probabilistic imperative language. Other important work investigates using monads to structure the semantics of probabilistic languages; e.g. Jones and Plotkin [24]. More recent works study the semantics of

probabilistic programs for applications like statistical computations [9], probabilistic inference for machine learning [10], probabilistic modeling for software defined networks [17], and more.

Likewise, deductive techniques for verifying probabilistic programs have a long history. Ramshaw [35] proposes a program logic with basic assertions of the form $\Pr[E] = p$. Hart el al. [22], Sharir et al. [39] propose a method using intermediate assertions and invariants for proving general properties of probabilistic programs. Kozen [29] introduces PPDL, a logic that can reason about expected values of general measurable functions. Morgan et al. [34] (see McIver and Morgan [31] for an extended account) propose a verification method based on computing *greatest pre-expectations*, a probabilistic analogue of Dijkstra's weakest pre-conditions. Hurd et al. [23] formalize their approach using the HOL theorem prover. Other approaches based on interactive theorem provers include the work of Audebaud and Paulin-Mohring [1], who axiomatize (discrete) probability theory and verify some examples of randomized algorithms using the Coq proof assistant. Gretz et al. [19] extend the work of Morgan et al. [34] with a formal treatment of conditioning. More recently, Rand and Zdancewic [36] formalize another Hoare logic for probabilistic programs using the Coq proof assistant. Barthe et al. [3] implement a general-purpose logic in the EasyCrypt framework, and verify a representative set of randomized algorithms. Kaminski et al. [25] develop a weakest precondition logic to reason about expected run-time of probabilistic programs.

Most of these works support general probabilistic reasoning and additional features like non-determinism, so they most likely could formalize the examples that we consider. However, our logic aHL aims at a sweet spot in the design space, combining expressivity with simplicity of the assertion language. The design of aHL is inspired by existing *relational* program logics, such as pRHL [7] and apRHL [8]. These logics support rich proofs about probabilistic properties with purely non-probabilistic assertions, using a powerful coupling abstraction from probability theory [4] rather than the union bound.

Finally, there are many algorithmic techniques for verifying probabilistic programs. Probabilistic model-checking is a successful line of research that has delivered mature and practical tools and addressed a broad range of case studies; Baier and Katoen [2], Katoen [26], Kwiatkowska et al. [30] cover some of the most interesting developments in the field. Abstract interpretation of probabilistic programs is another rich source of techniques; see e.g. Cousot and Monerau [13], Monniaux [33]. Katoen et al. [27] infer linear invariants for the pGCL language of Morgan et al. [34]. There are several approaches based on martingales for reasoning about probabilistic loops; Chakarov and Sankaranarayanan [11, 12] use martingales for inferring expectation invariants, while Ferrer Fioriti and Hermanns [16] use martingales for analyzing probabilistic termination. Sampson et al. [38] use a mix of static and dynamic analyses to check probabilistic assertions for probabilistic programs.

5 Conclusion and perspective

We propose aHL, a lightweight probabilistic Hoare logic based on the union bound. Our logic can prove properties about bad events in cryptography and accuracy of differentially private mechanisms. Of course, there are examples that we cannot verify. For instance, reasoning involving independence of random variables, a common tool when analyzing randomized algorithms, is not supported. Accordingly, a natural next step is to explore logical methods for reasoning about independence, or to embed aHL into a more general system like pGCL.

The Decidable Properties of Subrecursive Functions

Mathieu Hoyrup

LORIA, Inria, Villers-lès-Nancy, France
mathieu.hoyrup@inria.fr

Abstract

What can be decided or semidecided about a primitive recursive function, given a definition of that function by primitive recursion? What about subrecursive classes other than primitive recursive functions? We provide a complete and explicit characterization of the decidable and semidecidable properties. This characterization uses a variant of Kolmogorov complexity where only programs in a subrecursive programming language are allowed. More precisely, we prove that all the decidable and semidecidable properties can be obtained as combinations of two classes of basic decidable properties: (i) the function takes some particular values on a finite set of inputs, and (ii) every finite part of the function can be compressed to some extent.

1 Introduction

What can be decided about a function $f : \mathbb{N} \to \mathbb{N}$ if f is represented by a program computing it? What can be semidecided?

In the 50's, many computability theory results have been proved in order to answer these questions. The answers depend on the class of functions considered.

Partial computable functions.

For the class of partial computable functions, Rice [11] proved that no non-trivial property is decidable, and Shapiro [12] refined it by characterizing the semidecidable properties. These results show that having a program computing f does not give more information than having an oracle giving the values of f, in the sense that the two presentations induce the same classes of decidable and semidecidable properties. In other words, the only way of exploiting a program computing f is to execute it on any input to obtains the values of f. Hence the code of the program contains no more information than a black-box containing the program.

Total computable functions

For the class of total computable functions, Kreisel, Lacombe, Shœnfield [8] and independently Ceitin [2] characterized the decidable properties. Again they are the same whether the function is presented by a program or by an oracle.

However, Friedberg [4] showed that the semidecidable properties of total computable functions do not admit such a characterization. In that case, having a program computing

f gives more information than having the values of f. In [6] we proved that the extra information is simply the size of the program. A remaining open problem is to obtain a nice characterization of the semidecidable properties of total computable functions, when they are presented by programs.

Subrecursive classes

In this paper we investigate the case of a subrecursive class, i.e. a class of total computable functions that can be effectively enumerated. Examples of such classes are the primitive recursive functions, complexity classes such as FPTIME, or the class of provably total functions in Peano Arithmetic. Here the function in the class is presented by a program in a restricted programming language. As for the whole class of total computable functions, the semidecidable properties are not the same if the function is presented by an oracle. However we obtain a characterization of the semidecidable properties, when the function is presented by a subrecursive program. This characterization uses a version of Kolmogorov complexity restricted to a subrecursive programming language. This is the main result of the paper.

We also prove that the semidecidable properties of total computable functions do not admit an analogous characterization.

We also discuss the difference between having an oracle giving the values of a function, and a black-box containing a program computing that function. The difference is that no assumption is made on the time it takes for the oracle to answer, while a program in a black-box has particular halting times. We show that in general it does not make any difference, but we also show a situation where the halting times of the black-box can be exploited.

1.1 Notations

Let $\mathbb{N}^*$ be the set of finite sequences of natural numbers and $\mathbb{N}^{\mathbb{N}}$ the Baire space of functions from $\mathbb{N}$ to $\mathbb{N}$. Given $f \in \mathbb{N}^{\mathbb{N}}$ and $n \in \mathbb{N}$, $f\restriction_n$ denotes the finite sequence $(f(0), \dots, f(n-1)) \in \mathbb{N}^*$. We say that $f \in \mathbb{N}^{\mathbb{N}}$ extends $v = (v_0, \dots, v_{n-1}) \in \mathbb{N}^*$ if $f(0) = v_0, \dots, f(n-1) = v_{n-1}$, i.e. if $f\restriction_n = v$. We denote by $[v] \subseteq \mathbb{N}^{\mathbb{N}}$ the set of all extensions of v and call it a cylinder. The Baire space is endowed with the topology whose open sets are unions of cylinders. An effective open set is the union of a computable sequence of cylinders.

2 Decidable and semidecidable properties

In this paper, a *subrecursive class of functions* is simply a class $\mathscr{C}$ of total computable functions that can be computably enumerated: there is a numbering $\mathscr{C} = \{f_i : i \in \mathbb{N}\}$ such that f_i is computable uniformly in i, i.e. the mapping $(i, n) \mapsto f_i(n)$ is computable. If $f \in \mathscr{C}$ then a $\mathscr{C}$-index of f is any i such that $f = f_i$ (a function may have several indices). There are usually many ways of indexing such a class, and they may induce different decidable properties. A thorough investigation about indexings of subrecursive classes can be found in [7].

Examples of subrecursive classes are: the primitive recursive functions, the class FPTIME of polynomial-time computable functions, the class of provably total computable functions in Peano arithmetic. A numbering of a class can be obtained from a numbering of the programs in a subrecursive programming language, or a restricted model of computation. Hence having an index of a function is usually equivalent to having a program for that function, in the restricted language. Famous examples of restricted programming language are: definitions

by primitive recursion, LOOP programming language [10], polynomially clocked Turing machines, proofs of totality in Peano Arithmetic.

Observe that two programming languages admitting computable translation procedures in both directions induce the same decidable and semidecidable properties. This is for instance the case of definitions by primitive recursion and LOOP programs.

Let $A \subseteq \mathscr{C}$. First observe that the property $f \in A$ is semidecidable given f by an oracle exactly when A is the intersection of an effective open subset of the Baire space with $\mathscr{C}$. Indeed, when the machine semideciding $f \in A$ accepts f in finite time so it has only read a finite segment of f hence it will accept all functions in some cylinder $[f\restriction_n]$. The property $f \in A$ is decidable given f by an oracle exactly when both A and $\mathscr{C} \setminus A$ are the intersections of effective open sets with $\mathscr{C}$.

The goal of this paper is to obtain a similar understanding of the decidable and semidecidable sets $A \subseteq \mathscr{C}$, when $f \in \mathscr{C}$ is presented by a $\mathscr{C}$-index rather than an oracle.

In order to investigate this problem we introduce a notion of Kolmogorov complexity adapted to the class $\mathscr{C}$.

▶ **Definition 1.** The $\mathscr{C}$-complexity of $f : \mathbb{N} \to \mathbb{N}$ is

$$K_{\mathscr{C}}(f) = \begin{cases} \min\{i : f_i = f\} & \text{if } f \in \mathscr{C}, \\ +\infty & \text{otherwise.} \end{cases}$$

If $v = (v_0, \dots, v_n)$ is a finite sequence of natural numbers then its $\mathscr{C}$-complexity is

$$K_{\mathscr{C}}(v) = \min\{i : f_i \text{ extends } v\} = \min\{K_{\mathscr{C}}(f) : f \in [v]\}.$$

If no f_i extends v then $K_{\mathscr{C}}(v) = +\infty$. Observe that for $f : \mathbb{N} \to \mathbb{N}$, $K_{\mathscr{C}}(f\restriction_n)$ is nondecreasing and converges to $K_{\mathscr{C}}(f)$ (which may be infinite). By the assumptions on $\mathscr{C}$, the quantity $K_{\mathscr{C}}(v)$ is computable from v (when it is finite – in, general, the predicate $K_{\mathscr{C}}(v) = i$ is decidable), contrary to usual Kolmogorov complexity which is upper semicomputable only. However $K_{\mathscr{C}}$ usually does not belong to the class $\mathscr{C}$ (modulo encoding of $\mathbb{N}^*$ in $\mathbb{N}$).

It may seem more consistent with usual notions of Kolmogorov complexity (see e.g. [9]) to take for instance $\log(i)$ instead of i in the definition, or to use a machine that is universal for the class $\mathscr{C}$ and define $K_{\mathscr{C}}$ in terms of the size of its inputs. All these choices are equally acceptable and lead exactly to the same result. The important point is that for each such notion of complexity K', an upper bound on $K_{\mathscr{C}}(f)$ can be uniformly computed from any upper bound on $K'(f)$ and vice-versa. Here we take the simplest definition of complexity following directly from the enumeration of $\mathscr{C}$, to avoid technicality.

2.1 An index gives more information than an oracle

Kreisel-Lacombe-Shœnfield/Ceitin's theorem implies that the properties of total computable functions that are decidable from indices are also decidable from oracles. In essence, Rice's theorem states the same for the class of partial computable functions. In general the situation is different when restricting to some subrecursive class: there exist properties that are decidable from indices but not from oracles.

Let us first give a concrete class of such properties. A *computable order* is a non-decreasing unbounded computable function $h : \mathbb{N} \to \mathbb{N}$, such as $\lfloor \log(n) \rfloor$, n^2 or 2^n for instance.

▶ **Definition 2.** Let $\mathscr{C}$ be a subrecursive class of functions and h a computable order. We define the set $A_{\mathscr{C},h}$ of $(\mathscr{C}, h)$-*anticomplex* functions as

$$A_{\mathscr{C},h} = \{f : \mathbb{N} \to \mathbb{N} : \forall n, K_{\mathscr{C}}(f\restriction_n) \leq h(n)\}.$$

We borrow the terminology from [3], where the notion of anti-complex set is defined in terms of usual Kolmogorov complexity, and is studied from a computability-theoretic perspective.

▶ **Proposition 3.** For $f \in \mathscr{C}$, the property $f \in A_{\mathscr{C},h}$ is decidable given any $\mathscr{C}$-index of f.

Proof. Given an index i for f, one has $K_{\mathscr{C}}(f\restriction_n) \leq K_{\mathscr{C}}(f) \leq i$ for all n, so f belongs to $A_{\mathscr{C},h}$ if and only if $K_{\mathscr{C}}(f\restriction_n) \leq h(n)$ for all n such that $h(n) < i$. This property is decidable as $K_{\mathscr{C}}(f\restriction_n)$ is computable from i and n and only a finite number of values of n has to be checked. ◀

Note that it is important that h be unbounded. One can easily show that if for each $g \in \mathscr{C}$ the set $\{j \in \mathbb{N} : f_j = g\}$ is not decidable (usual subrecursive classes satisfy this condition), then when h is bounded the property $f \in A_{\mathscr{C},h}$ is not decidable given any $\mathscr{C}$-index of f.

In general $A_{\mathscr{C},h}$ is no more decidable if instead of an index of f one is only given f as oracle.

▶ **Proposition 4.** If $\mathscr{C}$ is dense in $\mathbb{N}^{\mathbb{N}}$ then $A_{\mathscr{C},h}$ has empty interior in $\mathscr{C}$ (i.e. does not contain the intersection of a cylinder with $\mathscr{C}$), therefore $A_{\mathscr{C},h}$ is not semidecidable when the input function is given as oracle.

Proof. For each $u = (u_0, \dots, u_{n-1}) \in \mathbb{N}^*$, there exist only finitely many $i \in \mathbb{N}$ such that $K_{\mathscr{C}}(u_0, \dots, u_{n-1}, i) \leq h(n+1)$. Take any i outside this finite set: the cylinder $[u_0, \dots, u_{n-1}, i]$ is disjoint from $A_{\mathscr{C},h}$ but intersects $\mathscr{C}$, so $[u] \cap \mathscr{C}$ is not contained in $A_{\mathscr{C},h}$. ◀

All the usual subrecursive classes are dense in $\mathbb{N}^{\mathbb{N}}$. Observe that in computational complexity theory, one is more often interested in classes of *problems* rather than *functions*. Hence $\mathscr{C}$ could be the class of characteristic functions of subsets of $\mathbb{N}$ in some complexity class, such as P. In that case, $\mathscr{C}$ is not dense in $\mathbb{N}^{\mathbb{N}}$, however it is dense in $\{0,1\}^{\mathbb{N}}$ and a similar result holds.

▶ **Proposition 5.** The same result holds if $\mathscr{C}$ is dense in $\{0,1\}^{\mathbb{N}}$ and h is sufficiently small.

Proof. Let g be a computable order such that the number of finite sequences v such that $K_{\mathscr{C}}(v) \leq k$ is bounded by $g(k)$. If $K_{\mathscr{C}}$ is the notion of complexity from Definition 1 then one can take $g(k) = k + 1$. For other notions of complexity based on length of binary programs, one could take $g(k) = 2^{k+1}$ instead.

Let h be a computable order such that $g \circ h(n) = o(2^n)$ (take for instance $h(n) = n$ in our case). Given $u \in \{0,1\}^*$, there exists $n \geq |u|$ such that $g \circ h(n) < 2^{n-|u|}$. By definition of g there are at most $g(h(n)) < 2^{n-|u|}$ finite sequences v such that $K_{\mathscr{C}}(v) \leq h(n)$. As there exist $2^{n-|u|}$ binary extensions of u of length n, at least one of them satisfies $K_{\mathscr{C}}(v) > h(n)$. Hence $[v] \cap \mathscr{C}$ is disjoint from $A_{\mathscr{C},h}$ and non-empty, so $A_{\mathscr{C},h}$ does not contain $[u] \cap \mathscr{C}$. ◀

The result does not hold for any class $\mathscr{C}$: if $\mathscr{C}$ is the class of constant functions, numbered in the obvious way, then having an oracle for $f \in \mathscr{C}$ is equivalent to having a $\mathscr{C}$-index of f. This class has the particular property that all the functions in $\mathscr{C}$ are isolated from each other and as we now show this is the only obstruction to generalizing Propositions 4 and 5. We recall that a function f is not isolated in $\mathscr{C}$ if for each $p \in \mathbb{N}$ there exists some $g \neq f$ in $\mathscr{C}$ such that $g\restriction_p = f\restriction_p$.

▶ **Proposition 6.** If $\mathscr{C}$ contains a function f that is not isolated in $\mathscr{C}$ then there is a computable order h such that f belongs to $A_{\mathscr{C},h}$ but not to its interior, therefore $A_{\mathscr{C},h}$ is not semidecidable when the input function is given as oracle.

Hence having an index for $f \in \mathscr{C}$ usually gives more information than having an access to f via an oracle, as it enables to decide more properties of f. What is the additional information? Having an index for f obviously bounds $K_{\mathscr{C}}(f)$, and we now show that in a sense this is the only additional information.

First observe that the proof of Proposition 3 actually shows that $A_{\mathscr{C},h}$ remains decidable if one is given f via an oracle *together with an upper bound on* $K_{\mathscr{C}}(f)$. This is the case of every decidable, and even semidecidable property.

▶ **Proposition 7.** Let $A \subseteq \mathscr{C}$ be such that the problem $f \in A$ is semidecidable given a $\mathscr{C}$-index of f. Then the problem $f \in A$ is semidecidable given an access to f as oracle together with any upper bound on $K_{\mathscr{C}}(f)$.

Proof. Given f and $k \geq K_{\mathscr{C}}(f)$, one can progressively reject all numbers $i \leq k$ such that $f_i \neq f$. In parallel one can progressively accept all numbers $i \leq k$ that are accepted by the semidecision procedure for A. Wait for a stage when every number $i \leq k$ is accepted or rejected. If this happens then accept f. ◀

If one defines $\mathscr{C}_k = \{f : K_{\mathscr{C}}(f) \leq k\} = \{f_i : i \leq k\}$ then Proposition 7 implies the existence of uniformly effective open sets $U_k \subseteq \mathbb{N}^{\mathbb{N}}$ such that $A \cap \mathscr{C}_k = U_k \cap \mathscr{C}_k$ for all $k \in \mathbb{N}$. Indeed, U_k is defined as the union of finite prefixes of oracles f read and accepted by the machine semideciding A, given k as upper bound on $K_{\mathscr{C}}(f)$.

It was proved in [6] that such a result also holds for the class of total computable functions and much more general classes of computable objects. The proof given here in the case of a subrecursive class $\mathscr{C}$ is much easier because we only deal with total programs (every f_i is total, so one can always recognize whether $f_i \neq f$).

2.2 The main result

We can now state our main result: the cylinders and the sets of anticomplex functions are the basic decidable properties, from which all decidable and semidecidable properties can be obtained.

▶ **Theorem 8.** *Let $\mathscr{C}$ be a subrecursive class and $A \subseteq \mathscr{C}$. The following conditions are equivalent:*

1. *The property $f \in A$ is semidecidable given a $\mathscr{C}$-index of f,*
2. *A is an effective union of sets of the form $[v] \cap A_{\mathscr{C},h}$, i.e.*

$$A = \mathscr{C} \cap \bigcup_n ([v_i] \cap A_{\mathscr{C},h_i})$$

for some computable sequences of finite words $v_i \in \mathbb{N}^*$ and orders $h_i : \mathbb{N} \to \mathbb{N}$.

Proof. We prove that 1. implies 2., the other direction being a direct consequence of Proposition 3. We slightly reformulate the property $A_{\mathscr{C},h}$, using the following sets. Recall the sets $\mathscr{C}_k = \{f_i : i \leq k\}$ defined after Proposition 7. For $k, n \in \mathbb{N}$ let

$$\mathscr{C}_k^n = \bigcup_{u \in \mathbb{N}^n : K_{\mathscr{C}}(u) \leq k} [u] = \bigcup_{f \in \mathscr{C}_k} [f\restriction_n] = \bigcup_{i \leq k} [f_i\restriction_n].$$

Observe that $f \in A_{\mathscr{C},h}$ if and only if $f \in \mathscr{C}_{h(n)}^n$ for all n.

Assume that condition 1. in the statement of the theorem holds. By Proposition 7 there exist uniformly effective open sets $U_k \subseteq \mathbb{N}^{\mathbb{N}}$ such that $A \cap \mathscr{C}_k = U_k \cap \mathscr{C}_k$. One can take $U_{k+1} \subseteq U_k$, replacing U_k with $U_k \cup U_{k+1} \cup \ldots$ if necessary. It follows that $A = \mathscr{C} \cap \bigcap_k U_k$.

Given $k \in \mathbb{N}$ and $v \in \mathbb{N}^*$ such that $[v] \subseteq U_{k+1}$, we now build a computable order h such that $[v] \cap \mathscr{C}_{k+1} \subseteq [v] \cap A_{\mathscr{C},h} \cap \mathscr{C} \subseteq A$. In order to obtain the announced families v_i and h_i to cover the whole set A, we will simply start from all possible $k \in \mathbb{N}$ and all v in the effective enumeration of U_{k+1}.

We now define h, by first constructing a kind of inverse of h. More precisely we define a computable increasing sequence n_i such that for all i,

$$[v] \cap \mathscr{C}_{k+1}^{n_1} \cap \ldots \cap \mathscr{C}_{k+i}^{n_i} \subseteq U_{k+i+1}.$$

The base case $i = 0$ is satisfied as $[v] \subseteq U_{k+1}$. Once $n_1, \ldots, n_i$ have been defined,

$$\begin{aligned}[v] \cap \mathscr{C}_{k+1}^{n_1} \cap \ldots \cap \mathscr{C}_{k+i}^{n_i} \cap \mathscr{C}_{k+i+1} &\subseteq U_{k+i+1} \cap \mathscr{C}_{k+i+1} \\ &\subseteq A \\ &\subseteq U_{k+i+2}.\end{aligned}$$

The left-hand side is a finite set. For each f in that set, there is $n \in \mathbb{N}$ such that $[f\restriction_n] \subseteq U_{k+i+2}$. As the set is finite there is a single n that works for each f in the finite set. As this finite set is computable, such a n can be computed. We then define $n_{i+1} > n_i$ such that

$$[v] \cap \mathscr{C}_{k+1}^{n_1} \cap \ldots \cap \mathscr{C}_{k+i}^{n_i} \cap \mathscr{C}_{k+i+1}^{n_{i+1}} \subseteq U_{k+i+2}.$$

We then have

$$[v] \cap \mathscr{C}_{k+1} \subseteq [v] \cap \bigcap_{i \geq 1} \mathscr{C}_{k+i}^{n_i} \cap \mathscr{C} \subseteq \bigcap_n U_n \cap \mathscr{C} = A. \tag{1}$$

Let h be the computable order defined by $h(n) = k + \min\{i \geq 1 : n \leq n_i\}$. We claim, as announced, that

$$[v] \cap \mathscr{C}_{k+1} \subseteq [v] \cap A_{\mathscr{C},h} \cap \mathscr{C} \subseteq A.$$

The first inequality is straightforward: $h(n) \geq k + 1$ for all n, so $\mathscr{C}_{k+1} \subseteq A_{\mathscr{C},h}$.

To prove the second inequality, observe that if $g \in A_{\mathscr{C},h}$ then for all i, $K_{\mathscr{C}}(g\restriction_{n_i}) \leq h(n_i) = k + i$, i.e. $g \in \bigcap_{i \geq 1} \mathscr{C}_{k+i}^{n_i}$, and then use (1). ◀

A set $A \subseteq \mathscr{C}$ is then decidable from $\mathscr{C}$-indices if and only if both A and $\mathscr{C} \setminus A$ can be expressed as effective unions of sets $[v] \cap A_{\mathscr{C},h}$.

A further question

Each effective numbering of a class $\mathscr{C}$ induces particular classes of decidable and semidecidable properties. What can be said about the properties that are decidable or semidecidable for *every* effective numbering of $\mathscr{C}$? The least we can say is that any property of total functions that is Markov decidable, i.e. decidable given an arbitrary index of the total function, is also decidable for every effective numbering of $\mathscr{C}$ (see next section for more information about Markov computability), and similarly for semidecidable properties. Does the converse also holds? In a sequel to this paper we will show that it does not: in reasonable subrecursive classes, there exists a property that cannot be semidecided from arbitrary indices, but is semidecidable in any effective total numbering of the class.

2.3 The whole class of total computable functions

By the Kreisel-Lacombe-Shœnfield/Ceitin theorem, the properties of total computable functions that are Markov decidable, i.e., decidable from indices coincide with the ones that are decidable from oracles, hence are generated by cylinders. However Friedberg showed that is it not the case for Markov semidecidable properties. Can we obtain a characterization of these properties as in the case of subrecursive classes?

We leave this problem open, but we show that the analog of Theorem 8 does not hold. We first introduce the analog of Definition 2. Here, φ_i is some Gödel numbering of the partial computable functions.

▶ **Definition 9.** If $v = (v_0, \dots, v_n) \in \mathbb{N}^*$ then its *complexity* is

$$K(v) = \min\{i : \varphi_i \text{ extends } v\}.$$

Let h be a computable order. We define the set A_h of *h-anticomplex* functions as

$$A_h = \{f : \mathbb{N} \to \mathbb{N} : \forall n, K(f\restriction_n) \leq h(n)\}.$$

Again, the property $f \in A_h$ is semi-decidable (but this time not decidable) from any index of the total computable function f, but it is not semidecidable if f is given by an oracle. Observe that in the definition of $K(v)$, one considers all *partial* computable functions extending v. A direct analog of Definition 1 would be to consider *total* functions only. However the resulting anticomplexity property would not be semidecidable.

We now prove that the sets of anticomplex functions do not generate all the semidecidable properties.

▶ **Theorem 10.** *There is a semidecidable property of total computable functions that does not contain any non-empty set* $[v] \cap A_h$.

Proof. Let $t(j,i)$ be a partial computable function such that if φ_j is total then $t(j,i)$ is defined for all i. Define the set

$$B = \bigcap_i B_i \text{ where } B_i = \bigcup_{j \leq i} [\varphi_j\restriction_{t(j,i)}]$$

where $[\varphi_j\restriction_{t(j,i)}]$ is empty if $t(j,i)$ is not defined or φ_j is not defined on the first $t(j,i)$ inputs. The property $f \in B$ is semidecidable from indices of f. Indeed, if φ_i is total then $\varphi_i \in B \iff \varphi_i \in B_0 \cap \ldots \cap B_{i-1}$, which is semidecidable.

We now take $t(j,i)$ to be the halting time of $\varphi_j(i)$ plus $i+1$. We prove that the corresponding set B does not contain any non-empty set $[v] \cap A_h$. Let h be some computable order. We want to build a function f in $A_h \setminus B$, i.e. in $A_h \setminus B_b$ for some $b \in \mathbb{N}$.

▶ **Lemma 11.** *Given* $a, b \in \mathbb{N}$ *one can compute* $m = m(a,b)$ *such that if* $[\varphi_a\restriction_m] \setminus B_b$ *is non-empty then it contains some* f *such that* $K(f) \leq h(m)$.

Proof. The idea is simply that for $a, b, m \in \mathbb{N}$, if $[\varphi_a\restriction_m] \setminus B_b$ is non-empty then it contains a function whose complexity can be controlled. Indeed, while such a function cannot be effectively found as the set B_b is only enumerable, it becomes possible if some extra bits of information about B_b are provided.

Consider an algorithm that on inputs a, b, M and $p \leq b+1$ tries to find a set $L \subseteq \{0, \dots, b\}$ of p elements such that for all $j \in L$, $\varphi_j\restriction_{t(j,b)}$ is defined, tests whether $[\varphi_a\restriction_M] \setminus \bigcup_{j \in L} [\varphi_j\restriction_{t(j,b)}]$ is non-empty and if it is so computes some total function f in that set (p is a guess about the number of cylinders in B_b).

The complexity of the output of the algorithm can be bounded in terms of the complexity of its inputs: there is a total computable function $m_0(a,b,e)$ such that if $M := \varphi_e(a,b)$ is defined and $p \leq b+1$ and the algorithm finds a function f, then $K(f) \leq m_0(a,b,e)$.

Now by the Recursion Theorem, there is e such that $\varphi_e(a,b) = \min\{m : h(m) \geq m_0(a,b,e)\}$. Let $m(a,b) = \varphi_e(a,b)$.

Applying the algorithm on inputs $a, b, m(a,b), p$ where p is the number of values of $j \leq b+1$ such that $\varphi_j\restriction_{t(j,b)}$ is defined (p is the "right guess") gives a function $f \in [\varphi_a\restriction_{m(a,b)}] \setminus B_b$ such that $K(f) \leq m_0(a,b,e) \leq h(m(a,b))$. ◀

We can make sure that $m(a,b) > b$ (in the proof above, take instead $\varphi_e(a,b) = \min\{m > b : h(m) \geq m_0(a,b,e)\}$).

▶ **Lemma 12.** *Let $a, b \in \mathbb{N}$ and $m = m(a,b)$. If $\varphi_a \in A_h$ and $[\varphi_a\restriction_m] \setminus B_b$ is non-empty then $[\varphi_a\restriction_m] \cap A_h \setminus B$ is non-empty.*

Proof. By Lemma 11 there exits $f \in [\varphi_a\restriction_m] \setminus B_b$ such that $K(f) \leq h(m)$. Of course, $f \notin B$ and we show that $f \in A_h$ i.e. that $K(f\restriction_i) \leq h(n)$ for all n.

For $n \leq m$, $K(f\restriction_n) = K(\varphi_a\restriction_n) \leq h(n)$ as $\varphi_a \in A_h$.

For $n \geq m$, $K(f\restriction_n) \leq K(f) \leq h(m) \leq h(n)$. ◀

▶ **Lemma 13.** *Let $v \in \mathbb{N}^*$ be such that $[v] \cap A_h \neq \emptyset$. There exist a, b such that $\varphi_a \in A_h$, $[\varphi_a\restriction_{m(a,b)}] \setminus B_b$ is non-empty and $[\varphi_a\restriction_{m(a,b)}] \subseteq [v]$.*

Proof. Define the computable function $b(a) = \min\{b \geq |v| : h(b) \geq a\}$. We now define a and will take $b := b(a)$.

Let $g \in [v] \cap A_h$. By the Recursion theorem, there is a such that

- For $i \neq b(a)$, $\varphi_a(i) = g(i)$,
- For $i = b(a)$, $\varphi_a(i)$ differs from each $\varphi_j(i)$ such that $j \leq b(a)$ and $\varphi_j(i)$ halts in at most $m(a, b(a))$ steps.

Let then $b = b(a)$.

▶ **Claim 14.** $\varphi_a \in A_h$, i.e. $K(\varphi_a\restriction_n) \leq h(n)$ for all n.

Indeed, for $n \leq b$ one has $K(\varphi_a\restriction_n) = K(g\restriction_n) \leq h(n)$ as $g \in A_h$. For $n > b$, $K(\varphi_a\restriction_n) \leq a \leq h(b) \leq h(n)$.

▶ **Claim 15.** Let $m = m(a,b)$. The set $[\varphi_a\restriction_m]$ is not contained in $B_b = \cup_{j \leq b}[\varphi_j\restriction_{t(j,b)}]$.

Indeed for each $j \leq b$:

- If $\varphi_j(b)$ halts in at most m steps then $\varphi_a(b) \neq \varphi_j(b)$ so $[\varphi_a\restriction_m]$ is disjoint from $[\varphi_j\restriction_{t(j,b)}]$ as both m and $t(j,b)$ are larger than b.
- If $\varphi_j(b)$ does not halt in at most m steps then $t(j,b)$ is either undefined or larger than m, so $\varphi_a\restriction_m$ does not contain $[\varphi_j\restriction_{t(j,b)}]$.

Finally, $[\varphi_a\restriction_{m(a,b)}] \subseteq [v]$ as $m(a,b) > b \geq |v|$ and $\varphi_a\restriction_{|v|} = g\restriction_{|v|} = v$. ◀

We can now conclude. If $[v] \cap A_h \neq \emptyset$ then applying Lemma 12 to a, b provided by Lemma 13 directly gives that $[v] \cap A_h \setminus B$ is non-empty, as it contains $[\varphi_a\restriction_{m(a,b)}] \cap A_h \setminus B$ which is non-empty. ◀

In other words, the complement of B is "so big" that its intersection with each A_h is dense in A_h.

We conjecture than there is no way of describing the semidecidable properties of total computable functions, using a parametrization by total computable functions. We say that a set W is extensional if when $\varphi_i = \varphi_j$ is total and $i \in W$, one has $j \in W$. An extensional c.e. set W represents the semidecidable property $\{\varphi_i : i \in W \text{ and } \varphi_i \text{ is total}\}$. Let $\mathrm{Tot} = \{i : \varphi_i \text{ is total}\}$.

▶ **Conjecture.** There is no computable function $h : \mathrm{Tot} \to \mathbb{N}$ such that

- For all $i \in \mathrm{Tot}$, $W_{h(i)}$ is extensional,
- Every semidecidable property is represented by some $W_{h(i)}$ with $i \in \mathrm{Tot}$.

3 Black-box or oracle?

In computer science one often makes the distinction between accessing a program via its *code*, or as a *black-box*. For instance, this distinction appears naturally when validating or evaluating the correctness of a program, either by proving that its code is correct, or testing its outputs on a bunch of inputs, without looking at its code.

As for programs of every day life, looking at the code usually gives much more information than looking at its outputs. What about the general case of arbitrary programs, where information can be obfuscated? What is the difference between reading the code of a program and running it as a black-box? Does one obtain the same information about the function it computes? What additional information does the code of a program contains, compared to a black-box containing the program?

The results presented here (e.g., Proposition 7) and in [6] may be seen as answers to these questions. However, strictly speaking our results involve *oracles* more than *black-boxes*, the difference being that a black-box hides an actual program while no assumption is put on an arbitrary oracle. Does it make a difference? Does a black-box containing a program computing a function f give more information about f than an arbitrary oracle for f? For instance, could the particular halting times of the program (measurable from outside the black-box) be exploited in some way?

In this section we present a few results that are partial answers to these questions.

We first prove a result suggesting that a black-box does not give more information than an arbitrary oracle.

3.1 Observing a Turing machine

Here we prove that if the program is a Turing machine and that we can observe its execution, without knowing the complete transition table, we do not have more information than from an oracle giving the outputs of the machine.

Observing the execution of the machine means that at each step one can see the configuration of the machine, i.e. the contents of the tapes, the positions of the heads and the internal state. However, one may never know the complete transition table and the number of states. Equivalently, the observer progressively obtains the content of the transition table (at least its reachable part), but if the table is incomplete he may never know it entirely.

More formally, let us assume that the set Q of states of a Turing machine is a subset of $\mathbb{N}$, but is not known by the observer. Σ is some known finite alphabet. Instead of having access to the transition table δ as a finite function from $Q \times \Sigma$ to $Q \times \Sigma \times \{\leftarrow, \downarrow, \rightarrow\}$, the

observer has access to δ as a partial function from $\mathbb{N} \times \Sigma \to \mathbb{N} \times \Sigma \times \{\leftarrow, \downarrow, \rightarrow\}$, defined on $Q \times \Sigma$ only. In particular no upper bound on the elements of Q is known.

▶ **Theorem 16.** *Let A be a set of total computable functions. The following are equivalent:*

1. *The problem $f \in A$ is semidecidable given an enumeration of a transition table of a Turing machine computing f,*
2. *The problem $f \in A$ is semidecidable given an oracle for f.*

Proof. The intuition is as follows. Assume that 1. holds. Given a total computable function f, there is a machine that outputs the same values as f on inputs $0, \ldots, n$ for some n, such that its transition table is accepted by the semidecision procedure and can be extended to the transition table of a machine computing g, for any g that coincides with f on $0, \ldots, n$. As a result, the cylinder $[f\restriction_n]$ is contained in A, which is open (and even effectively open).

Let $E \subseteq \mathbb{N}$ be a noncomputable c.e. set. The following claim is obvious.

▶ **Claim 17.** Given i, one can effectively build a machine M_i such that on input n, $M_i(n)$ halts on the same configuration as the initial one (in particular its input tape contains n), except that its state is q_1 if i is enumerated in E by stage n, q_0 otherwise. q_0 and q_1 are never reached before and there is no transition from these states.

Let N be a Turing machine with initial state q_0, all the other states being fresh (no common state with the machines M_i). Think of N as computing a total function f, but we do not need to assume that N is total.

▶ **Claim 18.** For each i one can effectively build a Turing machine, denoted $N \circ M_i$, such that $N \circ M_i(n)$ reaches q_1 if and only if i is enumerated in E by stage n, and $N \circ M_i$ computes the same function as N if $i \notin E$.

Proof. Given i, taking the union of the transition tables of N and M_i, with the initial state of M_i as initial state, one gets a Turing machine $N \circ M_i$ which first behaves as M_i, and then if $i \notin E$ behaves as N. ◀

We now prove that A is the intersection of an effective open set U with the class of total computable functions, which is equivalent to 2. in the statement of Theorem 16. For each machine N, look for $i \in E$ such that an enumeration of $N \circ M_i$ is accepted by the semidecision procedure. Compute n_0 such that i is enumerated in E at stage n_0. If N is defined on inputs $0, \ldots, n_0 - 1$, with output values $v_0, \ldots, v_{n_0-1}$ respectively then enumerate the cylinder $[v_0, \ldots, v_{n_0-1}]$ in U.

▶ **Claim 19.** A is contained in U.

Proof. Let $f \in A$ and N be a machine computing f. When $i \notin E$, $N \circ M_i$ computes f so any enumeration of its transition table is accepted by the semidecision procedure. As E is not computable, there must exist $i \in E$ such that an enumeration of the table of $N \circ M_i$ is also accepted. Let n_0 be such that i is enumerated in E at stage n_0. $N(n)$ is defined for every $n < n_0$ and outputs $f(n)$, so the cylinder enumerated in U is $[f\restriction_{n_0}]$. ◀

▶ **Claim 20.** Conversely, every computable function in U belongs to A.

Proof. Let $[v_0, \dots, v_{n_0-1}]$ be a cylinder enumerated in U. On inputs $n < n_0$, $N \circ M_i(n)$ outputs v_n, never reaching state q_1. On inputs $n \geq n_0$, $N \circ M_i$ ends in state q_1.

Let $g \in [v_0, \dots, v_{n_0-1}]$ and M_g be a machine computing g with initial state q_1, all the other states being fresh. Taking the union of the transition tables of $N \circ M_i$ and M_g, with the initial state of M_i as initial state, one gets a machine M'_g computing g. The enumeration of the table of $N \circ M_i$, accepted by the semidecision procedure, can be extended to an enumeration of the table of M'_g, which is then also accepted (the semidecision procedure halts before being able to distinguish between $N \circ M_i$ and M'_g). As a result, $g \in A$. ◀

The proof is complete: given f by an oracle, evaluate it successively on all inputs and look for a cylinder of U containing f. ◀

3.2 A difference between a black-box and an oracle

We now exhibit a difference between having a program in a black-box and an oracle.

Instead of deciding or semi-deciding properties, a usual task it to compute a function. In [6] it is proved that

▶ **Theorem 21** ([6]). *Let $F : X_c \to Y$ where X, Y are effective topological spaces and X_c is the set of computable elements of X. The following statements are equivalent:*

- *There is a Turing machine that computes $F(x)$ given any index of x as input,*
- *There is a Turing machine that computes $F(x)$ given any name for x and any $k \geq K(x)$ as input.*

We do not insist on the notion of effective topological space, which is essentially a topological space with a countable basis. The classes of partial computable functions or total computable functions are examples of effective topological spaces. A name for an element x is an infinite binary string encoding x in some canonical way, which we do not describe here (the interested reader may consult [13]).

The assumption about effective topological spaces is essential as there is a non-effective topological space Y for which the result fails, which is the class $\mathcal{O}(\mathbb{N}^{\mathbb{N}})$ of open subsets of $\mathbb{N}^{\mathbb{N}}$ (which is not countably-based for the appropriate topology). Here we take for X the class $\mathcal{P}$ of partial computable functions.

▶ **Theorem 22** ([6]). *There is a functional $F : \mathcal{P} \to \mathcal{O}(\mathbb{N}^{\mathbb{N}})$ such that:*

- *There is a Turing machine that computes $F(\varphi)$ given any index of φ as input,*
- *There is <u>no</u> Turing machine that computes $F(\varphi)$ given any name for φ and any $k \geq K(\varphi)$ as input.*

Computing an element of $\mathcal{O}(\mathbb{N}^{\mathbb{N}})$, i.e. and open set $U \subseteq \mathbb{N}^{\mathbb{N}}$, consists in enumerating a list of finite words $v_i \in \mathbb{N}^*$ such that U is the corresponding union of cylinders $\bigcup_i [v_i]$. A name for a partial function φ is an infinite binary sequence such that $\varphi(m) = n$ if and only if the block $01^{\langle n,m \rangle}0$ appears in the sequence ($\langle ., . \rangle$ is a computable bijection between $\mathbb{N}^2$ and $\mathbb{N}$).

Contrasting with Theorem 22 we now show that

▶ **Theorem 23.** *Let $F : \mathcal{P} \to \mathcal{O}(\mathbb{N}^{\mathbb{N}})$. The following statements are equivalent:*

- *There is a Turing machine that computes $F(\varphi)$ given any index of φ as input,*
- *There is a Turing machine that computes $F(\varphi)$ given an access to a black-box containing a program computing φ, and any upper bound onthe size of the program.*

The difference with the previous theorem is that:

- Contrary to an oracle producing a name, a black-box contains an actual program, with its particular halting times,

- For a particular program p computing a function φ, an upper bound on the size of p is always an upper bound on $K(\varphi)$ (the size of the shortest program computing φ), but not the converse. In particular the theorem fails if an upper bound on $K(\varphi)$ rather than the size of $|p|$ is provided.

Proof idea. The argument is essentially the same as in the proof of Proposition 7. The idea is that the observation of the black-box can be seen as a total computable function that, given an input and a time, tells whether the program on that input halts in that time.

Assume that F is computable from indices. Let φ be given by a black-box and k an upper bound on the size of the program in the black-box.

At each stage we will have a finite list L of programs, such that the program in the black-box belongs to this list. At the beginning, L is the set of programs whose size is bounded by k. We enumerate the intersection of the open sets $F(\varphi_i)$ for all $i \in L$. From time to time we may remove an element of L that we know is not the program in the black-box. Each time we change L, we restart the enumeration of the intersection of the open sets $F(\varphi_i)$ for all i in the new list L (a larger open set). Eventually the list L will contain only programs computing the actual function φ, so we will enumerate the right open set.

We now explain how we progressively remove programs from L. For each program (in the list or in the black-box), each input n and each number t, we can decide whether the program halts in t steps on input n. If for some n and t a program is inconsistent with the black-box (one halts in t steps on input n but not the other), then the program can be rejected. If for some n the program and the black-box both halt on n giving different outputs, we can also reject the program.

Observe that we do not really need to have a precise measure of the halting time of the black-box: if we know that the actual halting time t of a program and the measured halting time $\tilde{t}$ are related by $|t - \tilde{t}| \leq 10$, or $t/2 \leq \tilde{t} \leq 2t$ for instance, then we only rejects programs that do not respect this gap w.r.t. the black-box. ◀

4 Two remarks on The Intensional Content of Rice's Theorem

In this paper we have investigated the properties of functions that are semidecidable, when the function is presented as a program computing it. Such a property can be alternatively seen as a c.e. set of programs that is *extensional*, in the sense that two equivalent programs – two programs computing the same function – are both in the set or both outside the set.

Asperti [1] investigates the case when extensionality is understood in a weaker sense, i.e. for a stronger notion of equivalence: two programs are equivalent if they compute the same function *and* have similar complexities (running time, or space, more generally any measure of complexity in Blum's sense). Such classes of programs are called Complexity Cliques.

It is proved in [1] that under certain assumptions on the measure of complexity (which should "behave well" w.r.t. the s-m-n function, composition and parallel computation),

▶ **Theorem 24** (Asperti [1]). *No Complexity Clique of total functions and containing programs with non constant complexity can be c.e.*

It is asked in [1] whether the assumption about non-constant complexity is needed.

We make the simple observation that it is indeed necessary, because the set of Turing machines with constant time complexity is a c.e. Complexity Clique. Indeed, given $c \in \mathbb{N}$, it is decidable whether a given Turing machine always halts in c steps, because one only has to evaluate it on inputs of size at most $c + 1$, during c steps. Hence it is semidecidable whether a Turing machine has constant time complexity, by trying every possible c.

We also observe that the assumptions about the measure of complexity cannot be dropped either, as the class of one-tape Turing machines that run in linear time is a c.e. Complexity Clique. Indeed, it was recently proved by Gajser [5] that for each $c \in \mathbb{N}$, whether a one-tape Turing machine halts in time cn on inputs of size n is decidable (his result is more general as it applies to a larger class of time bounds in $o(n \log n)$). It gives an indirect proof that one-tape Turing machines and their running time do not satisfy the assumptions of [1].

Acknowledgements. We thank the anonymous referees for their useful comments that helped improving this article, and for suggesting the question at the end of Section 2.2.

Abstract

The outcomes of this paper are twofold.

Implicit complexity. We provide an implicit characterization of polynomial time computation in terms of ordinary differential equations: we characterize the class P of languages computable in polynomial time in terms of differential equations with polynomial right-hand side.

This result gives a purely continuous (time and space) elegant and simple characterization of P. We believe it is the first time such classes are characterized using only ordinary differential equations. Our characterization extends to functions computable in polynomial time over the reals in the sense of computable analysis.

Our results may provide a new perspective on classical complexity, by giving a way to define complexity classes, like P, in a very simple way, without any reference to a notion of (discrete) machine. This may also provide ways to state classical questions about computational complexity via ordinary differential equations.

Continuous-Time Models of Computation. Our results can also be interpreted in terms of analog computers or analog model of computation: As a side effect, we get that the 1941 General Purpose Analog Computer (GPAC) of Claude Shannon is provably equivalent to Turing machines both at the computability and complexity level, a fact that has never been established before. This result provides arguments in favour of a generalised form of the Church-Turing Hypothesis, which states that any physically realistic (macroscopic) computer is equivalent to Turing machines both at a computability and at a computational complexity level.

1 Introduction

The outcomes of this paper are twofold, and are concerning a priori not closely related topics.

Implicit Complexity: Since the introduction of the P and NP complexity classes, much work has been done to build a well-developed complexity theory based on Turing Machines. In particular, classical computational complexity theory is based on limiting resources used by Turing machines, like time and space. Another approach is implicit computational complexity. The term "implicit" in "implicit computational complexity" can sometimes be understood in various ways, but a common point of these characterizations is that they provide (Turing or equivalent) machine-independent alternative definitions of classical complexity.

Implicit characterization theory has gained enormous interest in the last decade. This has led to many alternative characterizations of complexity classes using recursive functions, function algebras, rewriting systems, neural networks, lambda calculus and so on.

However, most of – if not all – these models or characterizations are essentially discrete: in particular they are based on underlying discrete time models working on objects which are essentially discrete such as words, terms, etc. that can be considered as being defined in a discrete space.

Models of computation working on a continuous space have also been considered: they include Blum Shub Smale machines [4], and in some sense Computable Analysis [40], or quantum computers [17] which usually feature discrete-time and continuous-space. Machine-independent characterizations of the corresponding complexity classes have also been devised: see e.g. [10, 24]. However, the resulting characterizations are still essentially discrete, since time is still considered to be discrete.

In this paper, we provide a purely analog machine-independent characterization of the P class. Our characterization relies only on a simple and natural class of ordinary differential equations: P is characterized using ordinary differential equations (ODEs) with polynomial right-hand side. This shows first that (classical) complexity theory can be presented in terms of ordinary differential equations problems. This opens the way to state classical questions, such as P vs NP, as questions about ordinary differential equations.

Analog Computers: Our results can also be interpreted in the context of analog models of computation and actually originate as a side effect from an attempt to understand continuous-time analog models of computation, and if they could solve some problem more efficiently than classical models. Refer to [39] for a very instructive historical account of the history of Analog computers. See also [29, 9] for other discussions.

Indeed, in 1941, Claude Shannon introduced in [38] the General Purpose Analog Computer (GPAC) model as a model for the Differential Analyzer [11], a mechanical programmable machine, on which he worked as an operator. The GPAC model was later refined in [35], [23]. Originally it was presented as a model based on circuits (see Figure 1), where several units performing basic operations (e.g. sums, integration) are interconnected (see Figure 2).

However, Shannon himself realized that functions computed by a GPAC are nothing more than solutions of a special class of polynomial differential equations. In particular it can be shown that a function is computed by Shannon's model if and only if it is a (component of the) solution of an ordinary differential equations (ODEs) with polynomial right-hand side [38], [23]. In this paper, we consider the refined version presented in [23].

We note that the original model of the GPAC presented in [38], [23] is not equivalent to Turing machine based models. However, the original GPAC model performs computations

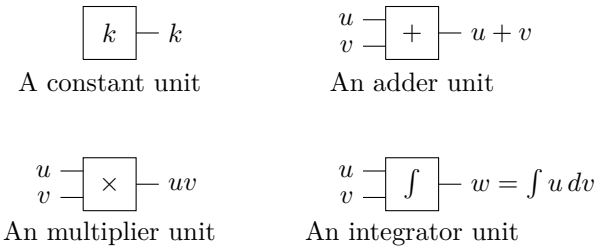

Figure 1 Circuit presentation of the GPAC: a circuit built from basic units.

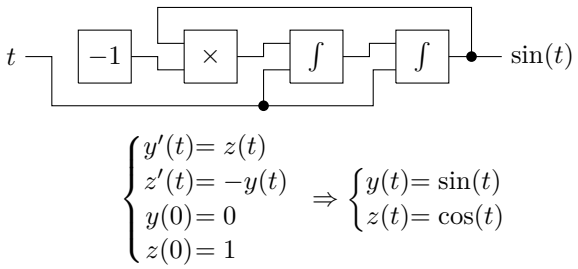

Figure 2 Example of GPAC circuit: computing sine and cosine with two variables.

in real-time: at time t the output is $f(t)$, which different from the notion used by Turing machines. In [19] a new notion of computation for the GPAC, which uses "converging computations" as done by Turing machines was introduced and it was shown in [5],[6] that using this new notion of computation, the GPAC and computable analysis are two equivalent models of computation at a computability level.

In that sense, our paper extends this latter result and proves that the GPAC and computable analysis are two equivalent models of computation, both at the computability and at the complexity level. We also provide as a side effect a robust way to measure time in the GPAC, or more generally in computations performed by ordinary differential equations: basically, by considering the length of the curve.

This paper is organized as follows. Section 2 gives our main definitions and results. Section 3 discusses the related work and consequences of our results. Section 4 gives a very high-level overview of the proof. It also contains more definitions and results so that the reader can understand the big steps of the proof.

2 Our Results

We consider the following class of differential equations:

$$y(0) = y_0 \qquad y'(t) = p(y(t)) \tag{1}$$

where $y : I \to \mathbb{R}^d$ for some interval $I \subset \mathbb{R}$ and where p is a vector of polynomials. Such systems are sometimes called PIVP, for polynomial initial value problems [21]. Observe that there is always a unique solution to the PIVP, which is analytic, defined on a maximum interval of life I containing y_0, which we refer to as "the solution".

Our crucial and key idea is that, when using PIVPs to compute a function f, the complexity should be measured as the length of the solution curve of the PIVP computing the function f. We recall that the length of a curve $y \in C^1(I, \mathbb{R}^n)$ defined over some interval $I = [a, b]$ is given by $\text{len}_y(a, b) = \int_I \|y'(t)\|\, dt$, where $\|y\|$ refers to the infinite norm of y.

We assume the reader familiar with the notion of polynomial time computable function $f : [a, b] \to \mathbb{R}$ (see [40] for an introduction to computable analysis). We take $\mathbb{R}_+ = [0, +\infty[$ and denote by $\mathbb{R}_P$ the set of polynomial time computable reals. For any vector y, $y_{i\dots j}$ refers to the vector $(y_i, y_{i+1}, \dots, y_j)$. For any sets X and Z, $f :\subseteq X \to Z$ refers to any function $f : Y \to Z$ where $Y \subseteq X$ and $\operatorname{dom} f$ refers to the domain of definition of f.

▶ Remark (The space $\mathbb{K}$ of the coefficients). In this paper, the coefficients of all considered polynomials will belong to $\mathbb{K}$. Formally, $\mathbb{K}$ needs to a be *generable field*, as introduced in [33]. However, without a significant loss of generality, the reader can consider that $\mathbb{K} = \mathbb{R}_P$ which is the set of polynomial time computable real numbers. All the reader needs to know about $\mathbb{K}$ is that it is a field and it is stable by generable functions (introduced in Section 4.2), meaning that if $\alpha \in \mathbb{K}$ and f is generable then $f(\alpha) \in \mathbb{K}$. It is shown in [33] that there exists a small generable field $\mathbb{R}_G$ lying somewhere between $\mathbb{Q}$ and $\mathbb{R}_P$, with expected strict inequality on both sides.

Our main results (the class AP is defined in Definition 3, and the notion of language recognized by a continuous system is given in Definition 4) are the following. Let us recall that $\mathrm{P}(\mathbb{R})$ is the class of polynomial time computable real functions, as defined in [27].

▶ **Theorem 1** (An implicit characterization of $\mathrm{P}(\mathbb{R})$). *Let $a, b \in \mathbb{R}_P$. A function $f : [a, b] \to \mathbb{R}$ is computable in polynomial time iff its belongs to the class* AP*.*

▶ **Theorem 2** (An implicit characterization of P). *A decision problem (language) $\mathcal{L}$ belongs to class* P *if and only if it is analog-recognizable.*

▶ **Definition 3** (Complexity Class AP). We say that $f :\subseteq \mathbb{R}^n \to \mathbb{R}^m$ is in AP if and only if there exists a vector p of polynomials with $d \geqslant m$ variables and a vector q of polynomials with n variables, both with coefficients in $\mathbb{K}$, and a bivariate polynomial Ω such that for any $x \in \operatorname{dom} f$, there exists (a unique) $y : \mathbb{R}_+ \to \mathbb{R}^d$ satisfying for all $t \in \mathbb{R}_+$:

- $y(0) = q(x)$ and $y'(t) = p(y(t))$ ▶ y satisfies a PIVP
- for all $\mu \in \mathbb{R}_+$, if $\mathrm{len}_y(0, t) \geqslant \Omega(\|x\|, \mu)$ then $\|y_{1..m}(t) - f(x)\| \leqslant e^{-\mu}$ ▶ $y_{1..m}$ converges to $f(x)$
- $\mathrm{len}_y(0, t) \geqslant t$ ▶ technical condition: the length grows at least linearly with time[1]

Intuitively, a function f belongs to AP if there is a PIVP that approximates f with a polynomial length to reach a given level of approximation.

In definition 3, the PIVP was given its input x as part of the initial condition: this is very natural because x was a real number. In the following, we will characterize languages with differential equations. Since a language is made up of words, we need to discuss how to represent (encode) a word with a real number. We fix a finite alphabet $\Gamma = \{0, .., k-2\}$ and define the encoding[2] $\psi(w) = \left(\sum_{i=1}^{|w|} w_i k^{-i}, |w|\right)$ for a word $w = w_1 w_2 \dots w_{|w|}$.

▶ **Definition 4** (Analog recognizability). A language $\mathcal{L} \subseteq \Gamma^*$ is called *analog-recognizable* if there exists a vector q of bivariate polynomials and a vector p of polynomials with d variables,

[1] This is a technical condition required for the proof. This can be weakened, for example to $\left\|y'(t)\right\| = \|p(y(t))\| \geqslant \frac{1}{\mathrm{poly}(t)}$. The technical issue is that if the speed of the system becomes extremely small, it might take an exponential time to reach a polynomial length, and we want to avoid such "unatural" cases. This is satisfied by all examples of computations we know [39].

[2] Other encodings may be used, however, two crucial properties are necessary: (i) $\psi(w)$ must provide a way to recover the length of the word, (ii) $\|\psi(w)\| \approx \mathrm{poly}(|w|)$ in other words, the norm of the encoding is roughly the size of the word.

both with coefficients in $\mathbb{K}$, and a polynomial $\Omega : \mathbb{R}_+ \to \mathbb{R}_+$, such that for all $w \in \Gamma^*$ there is a (unique) $y : \mathbb{R}_+ \to \mathbb{R}^d$ such that for all $t \in \mathbb{R}_+$:

- $y(0) = q(\psi(w))$ and $y'(t) = p(y(t))$ ▶ y satisfies a differential equation
- if $|y_1(t)| \geqslant 1$ then $|y_1(u)| \geqslant 1$ for all $u \geqslant t$ ▶ the decision is stable
- if $w \in \mathcal{L}$ (resp. $\notin \mathcal{L}$) and $\text{len}_y(0,t) \geqslant \Omega(|w|)$ then $y_1(t) \geqslant 1$ (resp. $\leqslant -1$) ▶ decision
- $\text{len}_y(0,t) \geqslant t$ ▶ technical condition

Intuitively this definition says that a language is analog-recognizable if there is a PIVP such that, if the initial condition is set to be (the encoding of) some word $w \in \Gamma^*$, then by using a portion of *polynomial length* of the curve, we are able to tell if this word should be accepted or rejected, by watching to which region of the space the trajectory will go: the value of y_1 determines if the word has been accepted or not, or if the computation is still in progress.

3 Discussion

Extensions. Our characterizations of the polynomial time can easily be extended to characterizations of deterministic complexity classes above polynomial time. For example, EXPTIME can be shown to correspond to the case where polynomial Ω is replaced by some exponential function.

▶ **Theorem 5.** *Let a and b in $\mathbb{R}_P$. A function $f : [a,b] \to \mathbb{R}$ is computable in exponential time iff its belongs to the class $f \in$ AEXP.*

▶ **Definition 6** (Definition of the complexity class AEXP for continuous systems)**.** We say that $f :\subseteq \mathbb{R}^n \to \mathbb{R}^m$ is in AEXP if and only if there exists a vector p of polynomial functions with d variables, a vector q of polynomial with n variables, both with coefficients in $\mathbb{K}$, an exponential function $\Omega : \mathbb{R}_+^2 \to \mathbb{R}_+$ such that for any $x \in \text{dom}\, f$, there exists (a unique) $y : \mathbb{R}_+ \to \mathbb{R}^d$ satisfying for all $t \in \mathbb{R}_+$:

- $y(0) = q(x)$ and $y'(t) = p(y(t))$ for all $t \geqslant 0$ ▶ y satisfies a PIVP
- for any $\mu \in \mathbb{R}_+$, if $\text{len}_y(0,t) \geqslant \Omega(\|x\|, \mu)$ then $\|y_{1..m}(t) - f(x)\| \leqslant e^{-\mu}$ ▶ $y_{1..m}$ converges
- $\|y'(t)\| \geqslant 1$ ▶ technical condition: The length grows at least linearly with time[3]

Applications to computational complexity. We believe these characterizations to really open a new perspective on classical complexity, as we indeed provide a natural definition (through previous definitions) of P for decision problems and of polynomial time for functions over the reals using analysis only i.e. ordinary differential equations and polynomials, no need to talk about any (discrete) machinery like Turing machines. This may open ways to characterize other complexity classes like NP or PSPACE. In the current settings of course NP can be viewed as an existential quantification over our definition, but we are obviously talking about "natural" characterizations, not involving unnatural quantifiers (for e.g. a concept of analysis like ordinary differential inclusions).

As a side effect, we also establish that solving ordinary differential equations with polynomial right-hand side leads to P- (or EXPTIME-)complete problems, when the length of the solution curve is taken into account. In an less formal way, this is stating that ordinary

[3] This is a technical condition required for the proof. This can be weakened, for example to $\|p(y(t))\| \geqslant \frac{1}{\text{poly}(t)}$. The technical issue is that the speed of the system becomes extremely small, it might take an exponential time to reach a polynomial length, and we want to avoid such "unatural" cases.

differential equations can be solved by following the solution curve (as most numerical analysis method do), but that for general (and even right-hand side polynomial) ODEs, no better method can work, unless some famous complexity questions do not hold. Note that our results only deal with ODEs with a polynomial right-hand side and that we do not know what happens for ODEs with analytic right-hand sides over unbounded domains. There are some results (see e.g. [31]) which show that ODEs with analytic right-hand sides can be computed locally in polynomial time. However these results do not apply to our setting since we need to compute the solution of ODEs over arbitrary large domains, and not only locally.

Applications to continuous-time analog models. PIVPs are known to correspond to functions that can be generated by the GPAC of Claude Shannon [38].

Defining a robust (time) complexity notion for continuous time systems is a well known open problem [9] with no generic solution provided to this day. In short, the difficulty is that the naive idea of using the time variable of the ODE as measure of "time complexity" is problematic, since time can be arbitrarily contracted in a continuous system due to the "Zeno phenomena" (e.g. by using functions like arctan which contract the whole real line into a bounded set). It follows that all computable languages can then be computed by a continuous system in time $O(1)$ (see e.g. [36], [37], [30], [7], [8], [1], [12], [15], [13], [14]).

With that respect, we solve this open problem by stating that the "time complexity" should be measured by the length of the solution curve of the ODE. Doing so, we get a robust notion of time complexity for PIVP systems. Indeed, the length is a geometric property of the curve and is thus "invariant" by rescaling. Notice that this is not sufficient to get robustness: the fact that we restrict to PIVP systems is crucial because more general ODEs are usually hard to simulate (e.g. see [26]). This explains why all previous attempts of a general complexity for general sytems failed in some sense [9]. Super-Turing "Zeno phenomena" can still happen with general ODEs, but not with PIVPs.

Applications to algorithms. We also believe that transferring the notion of time complexity to a simple consideration about length of curves allows for very elegant and nice proofs of polynomiality of many methods for solving continuous but also discrete problems. For example, the zero of a function f can easily be computed by considering the solution of $y' = -f(y)$ under reasonable hypotheses on f. More interestingly, this may also covers many interior-point methods or barrier methods where the problem can be transformed into the optimization of some continuous function (see e.g. [25, 16, 3, 28]).

Related work. We believe no purely continuous-time definition of P has ever been stated before. One direction of our characterization is based on a polynomial time algorithm (in the length of the curve) to solve PIVPs over unbounded time domains, such a result strengthens all existings results on the complexity of solving ODEs over unbounded time domains. In the converse direction, our proof requires a way to simulate a Turing machine using PIVP systems with a polynomial length, a task whose difficulty is discussed below, and still something that has never been done up to date.

Attempts to derive a complexity theory for continous-time systems include [18]. However, the theory developped there is not intended to cover generic dynamical systems but only specific systems that are related to Lyapunov theory for dynamical systems. The global minimizers of particular energy functions are supposed to give solutions of the problem. The structure of such energy functions leads to the introduction of problem classes U and NU, with the existence of complete problems for theses classes.

Another attempt is [2], also focussed on a very specific type of systems: dissipative flow models. The proposed theory is nice but non-generic. This theory has been used in several papers from the same authors to study a particular class of flow dynamics [3] for solving linear programming problems.

Both approaches are not at all intended to cover generic ODEs, and none of them is able to relate the obtained classes to classical classes from computational complexity.

Up to our knowledge, the most up to date survey about continuous time computation are [9, 29].

Relating computational complexity problems (like the P vs NP question) to problems of analysis has already been the motivation of series of works. In particular, Félix Costa and Jerzy Mycka have a series of work (see e.g. [32]) relating the P vs NP question to questions in the context of real and complex analysis. Their approach is very different: they do so at the price of a whole hierarchy of functions and operators over functions. In particular, they can use multiple times an operator which solves ordinary differential equations before defining an element of $DAnalog$ e $NAnalog$ (the counterparts of P and NP introduced in their paper), while in our case we do not need the multiple application of this kind of operator: we only need to use *one* application of such operator (i.e. we only need to solve one ordinary differential equations with polynomial right-hand side).

We also mention that Friedman and Ko (see [27]) proved that polynomial time computable functions are closed under maximization and integration if and only if some open problems of computational complexity (like P = NP for the maximization case) hold. The complexity of solving Lipschitz continuous ordinary differential equation has been proved to be polynomial-space complete by Kawamura [26].

All the results of this paper are fully developped in the PhD thesis of Amaury Pouly [33].

4 Overview of the proof

To show our main results (Theorem 1 and Theorem 2), we need to show two implications: (i) if a function $f : [a, b] \to \mathbb{R}$ (resp. a language $\mathcal{L}$) is polynomial time computable, then it belongs to AP (resp. it is analog-recognizable) and (ii) if a function $f : [a, b] \to \mathbb{R}$ belongs to AP (resp. a language $\mathcal{L}$ is analog-recognizable) then it is polynomial time computable (resp. belongs to P).

The second implication (ii) is proved by computing the solution of a PIVP system using some numerical algorithm. If a function $f : [a, b] \to \mathbb{R}$ in AP can be computed (up to some given accuracy) by following the solution curve of its associated ODE up to a reasonable (polynomial) amount of the length of the curve, the numerical simulation of its associated ODE will use a reasonable (polynomial) amount of resources to simulate this bounded portion of the solution curve. Hence the function f will be computed (up to some given accuracy, as usual in Computable Analysis) by a Turing machine in polynomial time. A similar idea can be used for showing the implication (ii) for P and analog-recognizable languages.

The idea sketched above gives the intuition of the proof but the usual ODE solving algorithms cannot be used here since (1) they are only guaranteed to compute the solution of an ODE with a given accuracy over a bounded time domain, but here we need to compute this solution over an unbounded time domain[4] which introduce further complications and (2)

[4] Note that while f has domain of definition $[a, b]$, from Definition 3 f is approximated by a PIVP whose solution is defined over the unbounded time domain $\mathbb{R}$

we need polynomial complexity in the length of the curve, which is not a classical measure of complexity.

The first implication (i) is proved by simulating Turing machines with PIVPs and by showing that these simulations can be performed by using a reasonable (polynomial) amount of resources (length of the solution curve) if the Turing machine runs in polynomial time.

Some simulation of Turing machines with PIVPs was already performed e.g. in [6], [22]. Basically one has to simulate the behavior of a Turing machine with a continuous system. This is problematic since Turing machines behave discretely (e.g. "if x happens then do A, otherwise do B") and one only has access to continuous (analytic) functions. This can be solved by *approximating* discontinuous functions with continuous functions to obtain an approximation of the transition function of the Turing machine. Then, by using special techniques, one can iterate the new (now continuous) transition function to simulate the step-by-step evolution of the Turing machine. Here we have one new difficult problem to tackle (not covered in previous papers like [6] and [22]) because we must ensure that everything can be done using only a reasonable (polynomial) amount of the length of the solution curve of the PIVP. In particular, this constraint rules out particularly simple techniques like integer encodings of the tape and error correction, as used in the previously mentioned papers.

At a high level, our proof relies on considerations about (polynomial length) *ODE programming*: we prove that it is possible to "program" with polynomial length ODE systems that keep some variable fixed, do assignement, iterate some functions, compute limits, etc. We use those basic operations and basic functions with PIVPs (e.g. $\min, \max$, continuous approximation of rounding, etc.) to create more complex functions and operations that simulate the transition function of a given Turing machine and its iterations. To be sure that the more complex functions still satisfy all the properties we want (e.g. that they belong to AP), we prove several closure properties: in particular, we prove very strong and elegant equivalent definitions of class AP.

For reasons of lack of space, we do not detail all these operators and functions, but we sketch the proof of a few properties and some key ideas of our techniques. We use the following notation: when p is a polynomial, Σp is the sum of the absolute values of its coefficients and $\deg(p)$ its degree. If p is a vector of polynomials, we extend those notions by taking the maximum for each component.

4.1 Polytime analog computability implies polytime computability

We start by sketching the proof of the "only if" direction of Theorem 2, and then of Theorem 1. Recall that a real function is polynomial time computable if given arbitrary approximations of the input, we can produce arbitrary approximations of the output in polynomial time. As it is customary, we proceed in two steps. We first show that the function has a polynomial modulus of continuity. This allows us to restrict the problem to rational inputs of controlled size.

▶ **Theorem 7** (Modulus of continuity). *If $f \in \mathrm{AP}$, then f admits a polynomial modulus of continuity: there exists a polynomial $\mho : \mathbb{R}_+^2 \to \mathbb{R}_+$ such that for all $x, y \in \operatorname{dom} f$ and $\mu \in \mathbb{R}_+$:*

$$\|x - y\| \leqslant e^{-\mho(\|x\|,\mu)} \quad \Rightarrow \quad \|f(x) - f(y)\| \leqslant e^{-\mu}.$$

We then show that the solution of a such a PIVP can be approximated in polynomial time. For this, will need the following theorem to get the complexity of numerically solving this PIVP. The idea of the proof is detailled below.

▶ **Theorem 8** (Complexity of Solving PIVP[34]). *If* [5] $y : \mathbb{R} \to \mathbb{R}^d$ *satisfies for all* $t \geqslant 0$.

$$y(0) = y_0 \qquad y'(t) = p(y(t)). \tag{2}$$

Then $y(t)$ *can be computed with precision* $2^{-\mu}$ *in time bounded by*

$$\mathrm{poly}(\deg(p), \mathrm{len}_y(0,t), \log \|y_0\|, \log \Sigma p, \mu)^d. \tag{3}$$

More precisely, there exists a Turing machine $\mathcal{M}$ *such that for any oracle* $\mathcal{O}$ *representing*[6] (y_0, p, t) *and any* $\mu \in \mathbb{N}$, $\left\|\mathcal{M}^{\mathcal{O}}(\mu) - \mathrm{PIVP}(y_0, p, t)\right\| \leqslant 2^{-\mu}$ *if* $y(t)$ *exists, and the number of steps of the machine is bounded by* (3) *for all such oracles.*

General Idea. Assume that $\mathcal{L}$ is analog-recognizable in the sense of Definition 4, using corresponding notations d, q, p, Ω. Let $w \in \Gamma^*$ and consider the following system: $y(0) = q(\psi(w))$, $y'(t) = p(y(t))$. We show that we can decide in time polynomial in $|w|$ whether $w \in \mathcal{L}$ or not. Theorem 8 can be used to conclude that we can compute $y(t) \pm e^{-\mu}$ in time polynomial in $\log \|q(\psi(w))\|, \mu$ and $\mathrm{len}_y(0,t)$. Recall that $\|\psi(w)\| = |w|$ and that the system is guaranteed to give an answer as soon as $\mathrm{len}_y(0,t) \geqslant \Omega(|w|)$. This means that it is enough to compute $y(t^*)$, where t^* satisfies $\mathrm{len}_y(0,t^*) \geqslant \Omega(|w|)$, with precision $1/2$ to distinguish between $y_1(t) \geqslant 1$ and $y_1(t) \leqslant -1$. Since $\mathrm{len}_y(0,t) \geqslant t$, thanks to the technical condition of the definition, we know that we can find a $t^* \leqslant \Omega(|w|)$. Note that $\mathrm{len}_y(0, \Omega(|w|))$ might not be polynomial in $|w|$ so we cannot simply compute $y(\Omega(|w|))$.

Fortunately, the proof of Theorem 8 provides us with an algorithm that solves the PIVP by making small time steps, and at each step the length cannot increase by more than a constant. This means that we can run algorithm to compute $y(\Omega(|w|))$ and stop it as soon as the length is greater than $\Omega(|w|)$. Let t^* be the time at which the algorithm stops. Then the running time of the algorithm will be polynomial in t^*, μ and $\mathrm{len}_y(0,t^*) \leqslant \Omega(|w|) + \mathcal{O}(1)$. Finally, thanks to the technical condition, $t^* \leqslant \mathrm{len}_y(0,t^*)$, this algorithm has running time polynomial in $|w|$.

The proof of Theorem 1 is established using the same principle based on Theorem 8, observing in addition that functions in AP can easily be approximated by considering only their value on rationals, since they have a polynomial modulus of continuity, as shown by the following theorem.

It thus appears that the true remaining difficulty lies in proving Theorem 8. An important point is that none of the classical methods for solving ordinary differential equations are polynomial time over unbounded time domains. Indeed, no method of fixed order r is polynomial in variable t over the whole domain $\mathbb{R}$.[7] For more information, we refer the reader to [34].

▶ Remark. Observe that the solution of the following PIVP $y_1' = y_1, y_2' = y_1 y_2, y_3' = y_2 y_3, \ldots, y_n' = y_{n-1} y_n$ is a tower of n exponentials. Its solution can be computed in polynomial time over any fixed compact $[a,b]$ [31]. However, the solution cannot be computed in polynomial time over $\mathbb{R}$, as just writing this value in binary cannot ever been done in polynomial time. Hence, the solution of a PIVP cannot be computed in polynomial time, over $\mathbb{R}$, in the general case. A key feature of our method is that we are searching methods polynomial in the length of the curve, which is not a classical framework.

[5] The existence of a solution y up to a given time is undecidable [20] so we have to assume existence.
[6] See [27] for more details. In short, the machine can ask arbitrary approximation of y_0, p and t to the oracle. The polynomial is represented by the finite list of coefficients.
[7] This is why most studies restricts to a compact domain.

4.2 Polytime computability implies polytime analog computability

The idea of the proof of the "if" directions is to simulate a Turing machine using a PIVP. But this is far from trivial since we need to do it with a polynomial length.

About generable functions. The following concept can be attributed to [38]: a function $f : \mathbb{R} \to \mathbb{R}$ is said to be a PIVP function if there exists a system of the form (1) with $f(t) = y_1(t)$ for all t, where y_1 denotes first component of the vector y defined in $\mathbb{R}^d$. We need in our proof to extend the concept to talk about (i) multivariable functions and (ii) the growth of these functions. The following class and closure properties can be seen as extensions of results from [21].

▶ **Definition 9** (Polynomially bounded generable function)**.** Let $d, e \in \mathbb{N}$, I be an open and connected subset of $\mathbb{R}^d$ and $f : I \to \mathbb{R}^e$. We say that $f \in$ GPVAL if and only if there exists a polynomial $\mathtt{sp} : \mathbb{R} \to \mathbb{R}_+$, $n \geqslant e$, a $n \times d$ matrix p consisting of polynomials with coefficients in $\mathbb{K}$, $x_0 \in \mathbb{K}^d$, $y_0 \in \mathbb{K}^n$ and $y : I \to \mathbb{R}^n$ satisfying for all $x \in I$:

- $y(x_0) = y_0$ and $J_y(x) = p(y(x))$ ▶ y satisfies a differential equation[8]
- $f(x) = y_{1..e}(x)$ ▶ f is a component of y
- $\|y(x)\| \leqslant \mathtt{sp}(\|x\|)$ ▶ y is polynomially bounded

▶ **Lemma 10** (Closure properties of GPVAL)**.** *Let $f :\subseteq \mathbb{R}^d \to \mathbb{R}^n \in$ GPVAL and $g :\subseteq \mathbb{R}^e \to \mathbb{R}^m \in$ GPVAL. Then $f + g$, $f - g$, fg and $f \circ g$ are in* GPVAL*.*

▶ **Lemma 11** (Generable functions are closed under ODE)**.** *Let $d \in \mathbb{N}$, $J \subseteq \mathbb{R}$ an interval, $f :\subseteq \mathbb{R}^d \to \mathbb{R}^d$ in* GPVAL*, $t_0 \in \mathbb{K} \cap J$ and $y_0 \in \mathbb{K}^d \cap \operatorname{dom} f$. Assume there exists $y : J \to \operatorname{dom} f$, and a polynomial $\overline{\mathtt{sp}} : \mathbb{R}_+ \to \mathbb{R}_+$ satisfying for all $t \in J$:*

$$y(t_0) = y_0 \qquad y'(t) = f(y(t)) \qquad \|y(t)\| \leqslant \overline{\mathtt{sp}}(t)$$

Then $y \in$ GPVAL *and it is unique.*

It follows that many polynomially bounded usual analytic[9] functions are in the class GPVAL. The inclusion GPVAL $\subset$ AP holds for functions whose domain is simple enough. However, the inclusion GPVAL $\subset$ AP is strict[10], since functions like the inverse of the Gamma function $\Gamma(x) = \int_0^\infty t^{x-1}e^{-t}dt$ or Riemann's Zeta function $\zeta(x) = \sum_{k=0}^\infty \frac{1}{k^x}$ are not differentially algebraic [38] but belong to AP.

Robustness of AP. A very strong key argument of our proof is that the notion of computability given by Definition 3 is actually very robust and can be stated in many equivalent ways. A key point is that the definition can be weakened and strengthened. The following theorem shows that we weaken the definition without changing the class. Since it might not be obvious to the reader, we emphasize that this notion is a priori weaker (thus AP is a priori larger than AWP). Indeed, (i) the system accepts errors in the input (ii) the system does not even converge, but merely approximates the output, doing the best it can given the input error.

[8] J_y denotes the Jacobian matrix of y.
[9] Functions from GPVAL are necessarily analytic, as solutions of an analytic ODE are analytic.
[10] Even with functions with star domains with a vantage point.

▶ **Theorem 12** (Weak Computability). AP = AWP *where* AWP *corresponds to the class of functions* $f :\subseteq \mathbb{R}^n \to \mathbb{R}^m$ *such that there are some polynomials* $\Omega : \mathbb{R}_+^2 \to \mathbb{R}_+$ *and* $\Upsilon : \mathbb{R}_+^3 \to \mathbb{R}_+$, $d \in \mathbb{N}$, $p, q \in \mathrm{GPVAL}$, *such that for any* $x \in \mathrm{dom}\, f$ *and* $\mu \in \mathbb{R}_+$, *there exists (a unique)* $y : \mathbb{R}_+ \to \mathbb{R}^d$ *satisfying for all* $t \in \mathbb{R}_+$*:*

- $y(0) = q(x, \mu)$ *and* $y'(t) = p(y(t))$ ▶ *y satisfies a PIVP*
- *if* $t \geqslant \Omega(\|x\|, \mu)$ *then* $\|y_{1..m}(t) - f(x)\| \leqslant e^{-\mu}$ ▶ *$y_{1..m}$ approximates $f(x)$ within $e^{-\mu}$*
- $\|y(t)\| \leqslant \Upsilon(\|x\|, \mu, t)$ ▶ *$y(t)$ is polynomially bounded*

The proof of Theorem 12, however, is quite involved: first p and q can be equivalently assumed to be polynomials instead of functions in GPVAL above, from Lemma 11. Then AP $\subset$ AWP, follows from the fact that this is possible to rescale the system using the length of the curve as a new variable to make sure it does not grow faster than a polynomial time, we get what is needed. The other direction (AWP $\subset$ AP) is really harder: the first step is to transform a computation into a computation that tolerates small perturbations of the dynamics (AWP $\subset$ ARP). The second problem is to avoid that the system explodes for inputs not in the domain of the function, or for too big perturbation of the dynamics perturbations on inputs (ARP $\subset$ ASP). As a third step, we allow the system to have its inputs (input and precision) changed during the computation and the system has a maximum delay to react to these changes (ASP $\subset$ AXP). Finally, as a fourth step, we add a mechanism that feeds the system with the input and some precision. By continuously increasing the precision with time, we ensure that the system will converge when the input is stable. The result of these 4 steps is the following lemma, yielding a nice notion of online-computation (AXP $\subset$ AOP). Equality AP = AWP = AOP follows because time and length are related for polynomially bounded systems. The notion of online computability is an example of a priori strengthening of our notion of computation; yet it still corresponds to the same class of function. Intuitively, a function is online computable if, on any (long enough) time interval where the input is almost constant, the system converges (after some delay) the output of the function. Of course, the output will have some error that is related to the input error (due to the input not being exactly constant).

▶ **Lemma 13** (Online computability). AWP $\subset$ AOP*, where* AOP *corresponds to the class of functions* $f :\subseteq \mathbb{R}^n \to \mathbb{R}^m$ *such that for polynomials* $\Upsilon, \Omega, \Lambda : \mathbb{R}_+^2 \to \mathbb{R}_+$*, there exists* $\delta \geqslant 0$, $d \in \mathbb{N}$ *and* $p \in \mathbb{K}^d[\mathbb{R}^d \times \mathbb{R}^n]$ *and* $y_0 \in \mathbb{K}^d$ *such that for any* $x \in C^0(\mathbb{R}_+, \mathbb{R}^n)$*, there exists (a unique)* $y : \mathbb{R}_+ \to \mathbb{R}^d$ *satisfying for all* $t \in \mathbb{R}_+$*:*

- $y(0) = y_0$ *and* $y'(t) = p(y(t), x(t))$
- $\|y(t)\| \leqslant \Upsilon\big(\sup_{u \in [t-\delta, t]} \|x(u)\|, t\big)$
- *For any* $I = [a, b]$*, if there exists* $\bar{x} \in \mathrm{dom}\, f$ *and* $\bar{\mu} \geqslant 0$ *such that for all* $t \in I$, $\|x(t) - \bar{x}\| \leqslant e^{-\Lambda(\|\bar{x}\|, \bar{\mu})}$ *then* $\|y_{1..m}(u) - f(\bar{x})\| \leqslant e^{-\bar{\mu}}$ *whenever* $a + \Omega(\|\bar{x}\|, \bar{\mu}) \leqslant u \leqslant b$.

ODE Programming. With the closure properties of AP, programming with (polynomial length) ODE becomes a rather pleasant exercise, once the logic is understood. For example, simulating the assignement $y := g_\infty$ corresponds to dynamics $y(0) = y_0$, $y'(t) = \mathrm{reach}(\phi(t), y(t), g(t)) + E(t)$, for a fixed function reach $\in$ GPVAL, tolerating bounded error $E(t)$ on dynamics, and g fluctuating around g_∞. Other example: from a AP system computing f, just adding the corresponding AOP-equations for g, yields a PIVP computing $g \circ f$, by feeding output of the system computing f to the (online) input of g.

Turing machines. Consider a Turing machine $\mathcal{M} = (Q, \Sigma, b, \delta, q_0, q_\infty)$. A (instantaneous) configuration of M can be seen as a tuple $c = (x, \sigma, y, q)$ where $x \in \Sigma^*$ is the part of the

tape at left of the head, $y \in \Sigma^*$ is the part at the right, $\sigma \in \Sigma$ is the symbol under the head and $q \in Q$ the current state. Let $\mathcal{C}_{\mathcal{M}}$ be the set of configurations of $\mathcal{M}$, and $\mathcal{M}$ denotes the function mapping a configuration to its next configuration. In order to simulate a machine, we encode configurations with real numbers as follows. Recall that $\Gamma = \{0, 1, \ldots, k-2\}$ and let $\langle c \rangle = (0.x, \sigma, 0.y, q) \in \mathbb{Q} \times \Sigma \times \mathbb{Q} \times Q$ where $0.x = x_1 k^{-1} + x_2 k^{-2} + \cdots + x_{|x|} k^{-|x|} \in \mathbb{Q}$ with $x = x_1 x_2 \ldots x_{|x|}$.

▶ **Theorem 14** (Robust Real Step). *For any machine $\mathcal{M}$, there is some function $\langle \mathcal{M} \rangle \in$ AP such that for all $c \in \mathcal{C}_{\mathcal{M}}$, $\mu \in \mathbb{R}_+$ and $\bar{c} \in \mathbb{R}^4$, if $\|\langle c \rangle - \bar{c}\| \leqslant \frac{1}{2k^2} - e^{-\mu}$ then $\|\langle \mathcal{M} \rangle (\bar{c}, \mu) - \langle \mathcal{M}(c) \rangle\| \leqslant k \|\langle c \rangle - \bar{c}\|$.*

The difficulty of the proof is that one step of Turing machine with our encoding naturally involves computing the integer and fractional parts of a number. These operations are discontinuous and thus cannot be done in AP in full generality. This is solved by proving that a continuous and good enough "fractional part" like-function is in AP (and avoids constructions from [21]).

Iterating Functions. A key point for proving the main result is to show that it is possible to iterate a function using a PIVP under some specific hypotheses. The proof consists in building by ODE programming an ordinary differential equation using three variables y, z and w updating in a cycle to be repeated n times. At all time, y is an online component of the system computing $f(w)$. During the first stage of the cycle, w stays still and y converges to $f(w)$. During the second stage of the cycle, z copies y while w stays still. During the last stage, w copies z thus effectively computing one iterate. This computes all the iterates $f(x), f^{[2]}(x), \ldots$. The crucial point of this process is the error estimation, to guarantee that the system does not diverge, while keeping polynomial length. One of the key assumption to ensure this is for f to admit a specific kind of modulus of continuity. The other key assumption is an effective "openness" of the iteration domain.

▶ **Theorem 15** (Closure by iteration). *Let $I \subseteq \mathbb{R}^m$, $(f : I \to \mathbb{R}^m) \in$ AP, $\eta \in [0, 1/2[$ and assume that there exists a family of subsets $I_n \subseteq I$, for all $n \in \mathbb{N}$ and polynomials $\mho : \mathbb{R}_+ \to \mathbb{R}_+$ and $\Pi : \mathbb{R}_+^2 \to \mathbb{R}_+$ such that:*

- *for all $n \in \mathbb{N}$, $I_{n+1} \subseteq I_n$ and $f(I_{n+1}) \subseteq I_n$*
- *for all $x \in I_n$, $\left\|f^{[n]}(x)\right\| \leqslant \Pi(\|x\|, n)$*
- *for all $x \in I_n$, $y \in \mathbb{R}^m, \mu \in \mathbb{R}_+$, if $\|x - y\| \leqslant e^{-\mho(\|x\|)-\mu}$ then $y \in I$ and $\|f(x) - f(y)\| \leqslant e^{-\mu}$.*

Define $f_\eta^*(x, u) = f^{[n]}(x)$ for $x \in I_n$, $u \in [n - \eta, n + \eta]$ and $n \in \mathbb{N}$. Then $f_\eta^* \in$ AP.

The iteration of the (transition) functions given by Theorem 14 leads to a way to emulate any function computable in polynomial time.

At a high level, the "if" direction of Theorem 2 then follows. Indeed, decidability can be seen as the computability of some particular function with boolean output.

For the "if" direction of Theorem 1, there are further nontrivial obstacles to overcome. Given $x \in [a, b]$ and $\mu \in \mathbb{N}$, we want to compute an approximation of $f(x) \pm 2^{-\mu}$ and take the limit when $\mu \to \infty$. To compute f, we will use a polynomial time computable function g that computes f over rationals, and m a modulus of continuity. All we have to do is simulate g with input $\tilde{x}$ and μ, where $\tilde{x} = x \pm 2^{-m(\mu)}$ because we can only feed the machine with a finite input of course. The remaining nontrivial part of the proof is how to obtain the encoding of $\tilde{x}$ from x and μ. Indeed, the encoding is a discrete quantity whereas x is real number, so by a simple continuity argument, one can see that no such function can exist. The trick is

the following: from x and μ, we can compute two encodings ψ_1 and ψ_2 such that at least one of them is valid, and we know which one it is. So we are going to simulate g on both inputs and then select the result. Again, the select operation cannot be done continuously unless we agree to "mix" both results, i.e. we will compute $\alpha g(\psi_1) + (1-\alpha)g(\psi_2)$. The trick is to ensure that $\alpha = 1$ or 0 when only one encoding is valid, $\alpha \in]0,1[$ when both are valid (by "when" we mean with respect to x). This way, a mixing of both will ensure continuity but in fact when both encodings are valid, the outputs are nearly the same so we are still computing f. Obtaining such encodings ψ_1 and ψ_2 is also nontrivial and requires more uses of the closure by iteration property.

Algorithmic Complexity for the Realization of an Effective Subshift By a Sofic*

Mathieu Sablik[1] and Michael Schraudner[2]

Abstract

Realization of d-dimensional effective subshifts as projective sub-actions of $d + d'$-dimensional sofic subshifts for $d' \geq 1$ is now well known [6, 4, 2]. In this paper we are interested in qualitative aspects of this realization. We introduce a new topological conjugacy invariant for effective subshifts, the speed of convergence, in view to exhibit algorithmic properties of these subshifts in contrast to the usual framework that focuses on undecidable properties.

Introduction

A d-dimensional subshift is a set of colorings of $\mathbb{Z}^d$ by a finite set of colors in which a set of forbidden patterns never appear. The simplest class, called subshifts of finite type, corresponds at finite sets of forbidden patterns. In dimension 2, they are equivalent to the usual notion of tilings introduced by Wang [16]. Applying a block map on a subshift of finite type, one obtains a sofic subshift which can be characterized, in dimension 1, by a set of forbidden patterns accepted by a finite automaton [17].

For multidimensional subshifts, we can consider their stability according to another dynamical operation: projective subaction which consists of restricting the configurations of a subshift to a sublattice of $\mathbb{Z}^d$. The smallest class stable under this operation which contains the class of sofic shifts is the set of effective subshifts defined by a set of forbidden patterns enumerated by a Turing machine. A consequence of the main result of [6] states that every d-dimensional effective subshift can be obtained via projective subaction of a $d+2$-dimensional sofic. This result was improved in [4, 2] to hold for $d+1$-dimensional sofics.

These three classes evoked are stable by conjugacy and underline links between dynamical characterization and computability property of their set of forbidden patterns. Other classes are exhibited in [1], using forbidden patterns recursively enumerated by Turing machine with oracle. In this article, we introduce new conjugacy invariant classes which subdivide the class of effective subshift based on the speed of convergence of the realization via projective subaction. In contrast to the usual framework that focuses on undecidable properties and their position relatively to some hierarchies [7, 15, 9, 10], the approach proposed here emphasizes the algorithmic properties of subshifts using time and space complexity.

In [14], the authors characterize one-dimensional sofic subshifts obtained by a projective subaction of subshift of finite type. It appears a difference between certain types of sofic subshifts, according to whether their realization can be stable or unstable that is to say if a bounded strip around the central one is necessary to obtain the desired sofic subshift or whether there is no bounds which guarantee to the central row to be in the subshift. This approach is inspired by the notion of stable and unstable limit-set for cellular automata [12].

In this article, we would like to go beyond the dichotomy stable vs unstable realization and try to quantify this notion. We introduce the notion of speed of convergence of the realization of an effective subshift by projective subaction of a sofic. This is defined as the function which, for a given integer k, returns the width of the strip necessary to obtain the language of the effective subshift up to a word of size k in the central rows.

Given an effective subshift, we study the set of speeds of convergence which realizes it as projective subaction. Modulo an equivalence relation this set is invariant under conjugacy (Sections 1.3). In Section 2 we compare the general constructions of realization of an effective subshift given in [6, 2] and we propose a quicker construction if the effective subshift has a periodic point. Moreover we show that when the dimension of the sofic increase the convergence is quicker. These results give upper bounds for realization by sofic, but is also possible to obtain lower bounds (see Section 3). In Section 4 we present some examples of different classes which exhibit the optimality of the different previous results.

1 Definitions and first properties

1.1 Classes of subshifts

Subshifts. Let $\mathcal{A}$ be a finite alphabet, a *configuration* x is an element of $\mathcal{A}^{\mathbb{Z}^d}$. Let $\mathbb{U}$ be a finite subset of $\mathbb{Z}^d$, denote $x_{\mathbb{U}}$ the *restriction* of x to $\mathbb{U}$. A *d-dimensional pattern* of support $\mathbb{U}$ is an element $p \in \mathcal{A}^{\mathbb{U}}$. Denote by $\mathcal{A}^*$ the set of d-dimensional patterns and $p \in \mathcal{A}^{\mathbb{U}}$ *appears* in a configuration x, denoted by $p \sqsubset x$, if there exists $\mathbf{i} \in \mathbb{Z}^d$ such that $p = x_{\mathbf{i}+\mathbb{U}}$.

For the product topology, $\mathcal{A}^{\mathbb{Z}^d}$ is a compact metric space on which $\mathbb{Z}^d$ acts by translation via the shift map σ defined for all $\mathbf{i} \in \mathbb{Z}^d$ by $\sigma^{\mathbf{i}}(x)_{\mathbf{j}} = x_{\mathbf{i}+\mathbf{j}}$ for all $x \in \mathcal{A}^{\mathbb{Z}^d}$ and $\mathbf{j} \in \mathbb{Z}^d$. The $\mathbb{Z}^d$-dynamical system $(\mathcal{A}^{\mathbb{Z}^d}, \sigma)$ is called the *fullshift* and a *subshift* is a σ-invariant closed subset of $\mathcal{A}^{\mathbb{Z}^d}$. Let $\mathbf{T} \subset \mathcal{A}^{\mathbb{Z}^d}$ be a subshift, define $\mathcal{L}(\mathbf{T}) = \{p \in \mathcal{A}^* : \exists x \in \mathbf{T} \text{ such that } p \sqsubset x\}$ the *language of* $\mathbf{T}$ and $\mathcal{L}_n(\mathbf{T}) = \{p \in \mathcal{A}^{[0,n-1]^d} : p \in \mathcal{L}(\mathbf{T})\}$ the *square language of size* n.

Finite type condition. Let F be a set of patterns, define the *subshift of forbidden patterns* F by $\mathbf{T}_F = \left\{x \in \mathcal{A}^{\mathbb{Z}^d} : \forall p \in F,\, p \not\sqsubset x\right\}$. Every subshift can be defined in this way and this allows to define classes of subshifts according to the complexity of F. Let $\mathbf{T}$ be a subshift,

- $\mathbf{T}$ is a *subshift of finite type* if there exists a finite set of patterns F such that $\mathbf{T} = \mathbf{T}_F$;
- $\mathbf{T}$ is an *effective subshift* if there exists a recursively enumerable set of patterns F (that is to say enumerated by a Turing machine) such that $\mathbf{T} = \mathbf{T}_F$.

Factor. A *block map* is a continuous function $\pi : \mathcal{A}^{\mathbb{Z}^d} \to \mathcal{B}^{\mathbb{Z}^d}$ such that $\pi \circ \sigma^{\mathbf{i}} = \sigma^{\mathbf{i}} \circ \pi$ for all $\mathbf{i} \in \mathbb{Z}^d$. Equivalently, there exists a local function $\overline{\pi} : \mathcal{A}^{\mathbb{U}} \longrightarrow \mathcal{B}$ where $\mathbb{U} \subset \mathbb{Z}^d$ is a finite set called *neighborhood* such that $\pi(x)_{\mathbf{i}} = \overline{\pi}(x_{\mathbf{i}+\mathbb{U}})$ for all $x \in \mathcal{A}^{\mathbb{Z}^d}$ and $\mathbf{i} \in \mathbb{Z}^d$.

Let $\mathbf{T} \subset \mathcal{A}^{\mathbb{Z}^d}$ be a subshift and $\pi : \mathcal{A}^{\mathbb{Z}^d} \to \mathcal{B}^{\mathbb{Z}^d}$ a block map, then $\pi(\mathbf{T}) \subset \mathcal{B}^{\mathbb{Z}^d}$ is a subshift called *factor subshift* of $\mathbf{T}$ by π which is called the *factor map*. A subshift $\mathbf{T}$ is called *sofic* if there exists a subshift of finite type $\mathbf{T}_F$ and a factor map π such that $\mathbf{T} = \pi(\mathbf{T}_F)$. The factor map π can be considered letter to letter.

Two subshifts $\mathbf{T}$ and $\mathbf{T}'$ are *conjugate* if there exists a bijective factor map $\psi : \mathbf{T} \longrightarrow \mathbf{T}'$. The different classes of subshifts defined here (finite type, sofic and effective subshifts) are stable under conjugacy.

Projective subactions. Let $\mathbf{T} \subseteq \mathcal{A}^{\mathbb{Z}^d}$ be a subshift and $d' < d$, the *projective subdynamics* of $\mathbf{T}$ of dimension d' is the subshift $\mathbf{SA}_{d'}(\mathbf{T})$ where $\mathbf{SA}_{d'} : \mathcal{A}^{\mathbb{Z}^d} \longrightarrow \mathcal{A}^{\mathbb{Z}^{d'}}$ is defined by $\mathbf{SA}_{d'}(x) = x_{\mathbb{Z}^{d'} \times \{\mathbf{0}\}}$ for all $x \in \mathcal{A}^{\mathbb{Z}^d}$.

▶ **Theorem 1.** *[6, 2, 4] Let $\Sigma \subset \mathcal{A}^{\mathbb{Z}^d}$ be an effective subshift, then the $d+1$-dimensional subshift $\widetilde{\Sigma} = \{x \in \mathcal{A}^{\mathbb{Z}^{d+1}} : \exists y \in \Sigma \text{ such that } x_{\mathbb{Z}^d \times \{i\}} = y \text{ for all } i \in \mathbb{Z}\}$ is sofic.*

In particular there exists a subshift of finite type $\mathbf{T} \subset \mathcal{B}^{\mathbb{Z}^{d+1}}$ and a factor map $\pi : \mathcal{B}^{\mathbb{Z}^{d+1}} \to \mathcal{A}^{\mathbb{Z}^{d+1}}$, which can be considered letter to letter, such that $\mathbf{SA}_d(\pi(\mathbf{T})) = \Sigma$.

1.2 Speed of convergence

Approximation row. Let F be a finite set of d-dimensional forbidden patterns on $\mathcal{B}$ and $d' < d$. Define $\mathbb{B}_n = \{k_{d'+1}\mathbf{e_{d'+1}}, \dots, k_d\mathbf{e_d} : (k_{d'+1}, \dots, k_d) \in [-n, n]^{d-d'}\}$ where $\mathbf{e_1}, \dots, \mathbf{e_d}$ are the canonical vectors of $\mathbb{Z}^d$ and denote $\mathrm{Proj}_{\mathbf{i}} : \mathcal{B}^{\mathbb{B}_n} \longrightarrow \mathcal{B}$ the projection according to the coordinates $\mathbf{i} \in \mathbb{B}_n$.

One considers the *n-approximation row of* $\mathbf{T}_F \subset (\mathcal{B}^{\mathbb{B}_n})^{\mathbb{Z}^{d'}}$ the d'-dimensional subshift of finite type defined by the finite condition where no patterns of F appears in the row of width n. Formally, it is defined by:

$$\mathbf{T}_F^{n,d\to d'} = \left\{ x \in \left(\mathcal{B}^{\mathbb{B}_n}\right)^{\mathbb{Z}^{d'}} : \forall p \in F, p \not\sqsubset \left(\mathrm{Proj}_{\mathbf{j}}(x_{\mathbf{i}})\right)_{(\mathbf{i},\mathbf{j}) \in \mathbb{Z}^{d'} \times \mathbb{B}_n} \right\}.$$

Let $\pi : \mathcal{B}^{\mathbb{Z}^d} \to \mathcal{A}^{\mathbb{Z}^d}$ be a factor map. One has $\mathbf{SA}_{d'}(\pi(\mathbf{T}_F)) = \bigcap_{n\in\mathbb{N}} \mathbf{SA}_{d'}\left(\pi\left(\mathbf{T}_F^{n,d\to d'}\right)\right)$ where for n sufficiently large $\mathbf{SA}_{d'}\left(\pi\left(\mathbf{T}_F^{n,d\to d'}\right)\right)$ denote the central row of $\pi\left(\mathbf{T}_F^{n,d\to d'}\right)$.

Speed of convergence. By definition of $\mathbf{T}_F^{n,d\to d'}$, if $u \in \mathcal{L}\left(\mathbf{SA}_{d'}(\pi(\mathbf{T}_F))\right)$, then $u \in \mathcal{L}\left(\mathbf{SA}_{d'}\left(\pi\left(\mathbf{T}_F^{n,d\to d'}\right)\right)\right)$. We want to quantify the reciprocal, that is to say given a k, find the smallest n such that $u \notin \mathcal{L}_k(\mathbf{SA}_{d'}(\pi(\mathbf{T}_F))) \implies u \notin \mathcal{L}_k\left(\mathbf{SA}_{d'}\left(\pi(\mathbf{T}_F^{n,d\to d'})\right)\right)$. This allows to quantify when a word is forbidden by the local rules F in the approximation row. The *speed of convergence as sofic* of the cover $\mathbf{T}_F$ with the factor π is the following function:

$$\begin{array}{rccl} \varphi_{F,\pi,d\to d'} : & \mathbb{N} & \longrightarrow & \mathbb{N} \\ & k & \longmapsto & \min\{n \in \mathbb{N} : u \notin \mathcal{L}_k(\mathbf{SA}_{d'}(\pi(\mathbf{T}_F))) \\ & & & \qquad \implies u \notin \mathcal{L}_k\left(\mathbf{SA}_{d'}\left(\pi(\mathbf{T}_F^{n,d\to d'})\right)\right)\}. \end{array}$$

$\varphi_{F,\pi,d\to d'}(k)$ corresponds to the minimum size of the row to detect a forbidden pattern in the effective subshift realized as projective subaction of $\pi(\mathbf{T}_F)$.

▶ **Example 2.** Consider the following set of 2-dimensional forbidden patterns

$$F = \left\{ \begin{array}{ccc} \begin{smallmatrix} \bar{\alpha} \\ \beta\, a \end{smallmatrix}, & \begin{smallmatrix} \beta \\ a\, a \end{smallmatrix}, & \begin{smallmatrix} \\ a\, \$ \end{smallmatrix}, \\ \begin{smallmatrix} \bar{\alpha} \\ b\, \bar{\gamma} \end{smallmatrix}, & \begin{smallmatrix} \bar{\gamma} \\ b\, \bar{b} \end{smallmatrix}, & \begin{smallmatrix} \\ \$\, \bar{b} \end{smallmatrix} \end{array} \right. \quad \text{such that} \quad \left. \begin{array}{l} \bar{\alpha} \in \{ a, \bar{b} \}, \\ \beta \in \{ \$, \bar{b} \}, \\ \bar{\gamma} \in \{ \$, a \}. \end{array} \right\}.$$

$\mathbf{SA}_1(\mathbf{T}_F)$ is the subshift where $\{\$a^nb^m\$, \$a^nb^ma, ba^nb^m\$, ba^nb^ma : m \neq n\}$ are the forbidden patterns. The idea is that in a configuration of $\mathbf{T}_F$, if a line contains $\$a^nb^m\$$ with

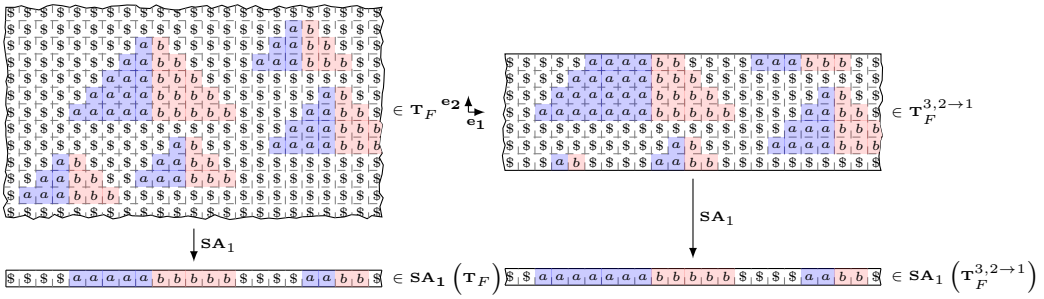

Figure 1 Application of $\mathbf{SA}_1$ under a configuration of $\mathbf{T}_F$ and $\mathbf{T}_F^{3,2\to1}$.

$n \neq m$ then the next line in the direction $\mathbf{e_2}$ contains $\$a^{n-1}b^{m-1}\$$ and recursively. Thus the pattern $a\$$ or $\$b$ appear and the configuration considered is excluded (see Figure 1).

In $\mathbf{T}_F^{n,2\to1}$ there is only n lines to detect a forbidden pattern so $\mathbf{SA}_1\left(\mathbf{T}_F^{n,2\to1}\right)$ is the subshift where the forbidden patterns are $\{\$a^pb^m\$, \$a^pb^ma, ba^pb^m\$, ba^pb^ma \ : \ m \neq p \text{ and } \max(p,m) \leq n\}$. We deduce that $\varphi_{F,\mathrm{Id},2\to1}(n) = \lfloor \frac{n}{2} \rfloor$. In Section 4 we will see that it is possible to obtain $\mathbf{SA}_1\left(\mathbf{T}_F\right)$ thanks to another sofic but with a better speed.

1.3 Subshift (φ, d)-realizable by sofic

A speed of convergence is in $\mathcal{F}$, the set of non-decreasing functions from $\mathbb{N}$ to $\mathbb{N}$. Denote

$$\mathcal{F}_{\Sigma,d\to d'}^{Sofic} = \left\{\varphi \in \mathcal{F} : \exists F \underset{\text{finite}}{\subset} \mathcal{B}^* \text{ and } \pi : \mathcal{B} \to \mathcal{A} \text{ with } \varphi = \varphi_{F,\pi,d\to d'} \text{ and } \mathbf{SA}_{d'}\left(\pi(\mathbf{T}_F)\right) = \Sigma\right\}.$$

By Theorem 1, $\mathcal{F}_{\Sigma,d\to d'}^{Sofic} \neq \emptyset$ if and only if Σ is effective. Using the fact that a sofic subshift can superpose different layers and delete them with the factor, it is easy to verify that $\mathcal{F}_{\Sigma,d\to d'}^{Sofic}$ is stable by min, max, multiplication by an integer, division by an integer, addition and multiplication. Moreover $\mathcal{F}_{\Sigma,d\to d'}^{Sofic} \subset \mathcal{F}_{\Sigma,d+1\to d'}^{Sofic}$.

Invariance of (φ, d)-realizable subshift under conjugacy. We need to introduce a preorder relation on $\mathcal{F}$. We say that $\varphi \prec \varphi'$ if there exists $r, M \in \mathbb{N}$ such that $\varphi(k) \leq M\varphi'(k+r)$ for all $k \in \mathbb{N}$. We say that $\varphi \sim \varphi'$ if $\varphi \prec \varphi'$ and $\varphi' \prec \varphi$. Multiplication by M comes from the fact that a given speed can be improved by division by an integer and addition by r allows stability by conjugacy.

A d'-dimensional subshift Σ is (φ, d)-*realizable by projective subaction of sofic* if there exist a finite set of d-dimensional forbidden patterns F and a factor π such that $\mathbf{SA}_{d'}\left(\pi(\mathbf{T}_F)\right) = \Sigma$ and $\varphi_{F,\pi,d\to d'} \prec \varphi$. The subshift Σ is *sharp* (φ, d)-*realizable* if moreover $\varphi \prec \varphi'$ for all $\varphi' \in \mathcal{F}_{\Sigma,d\to d'}^{Sofic}$.

▶ **Proposition 3.** *Let Σ and Σ' be two conjugated d'-dimensional subshfits. The subshift Σ is (φ, d)-realizable by projective subaction of a sofic if and only if it is the same for Σ'.*

Proof. Let $\psi : \Sigma \longrightarrow \Sigma'$ be the conjugation map of neighborhood $\mathbb{U} = [-r, r]^{d'}$. The local function can be extended in a function $\psi : \mathcal{A}^{\mathbb{Z}^d} \longrightarrow \mathcal{B}^{\mathbb{Z}^d}$ of neighborhood $\mathbb{U} = [-r, r]^{d'} \times \{\mathbf{0}\}$.

Let $\mathbf{T}_F$ be a subshift of finite type and π be a factor such that $\mathbf{SA}_{d'}\left(\pi(\mathbf{T}_F)\right) = \Sigma$, one

has $\mathbf{SA}_{d'}(\psi \circ \pi(\mathbf{T}_F)) = \Sigma'$. Let $u \in \mathcal{B}^{[0,k-1]^{d'}}$ and $\varphi = \varphi_{F,\pi,d\to d'}$, one has

$$\begin{aligned} u \notin \mathcal{L}(\Sigma') &\implies \left\{v \in \mathcal{A}^{[-r,k+r-1]^{d'}} : \psi(v) = u\right\} \not\subset \mathcal{L}(\Sigma) \\ &\implies \left\{v \in \mathcal{A}^{[-r,k+r-1]^{d'}} : \psi(v) = u\right\} \not\subset \mathcal{L}\left(\mathbf{SA}_{d'}\left(\pi\left(\mathbf{T}_F^{\varphi(k+2r),d\to d'}\right)\right)\right) \\ &\implies u \notin \mathcal{L}\left(\mathbf{SA}_{d'}\left(\psi \circ \pi\left(\mathbf{T}_F^{\varphi(k+2r),d\to d'}\right)\right)\right) \end{aligned}$$

Thus $\varphi_{F,\psi\circ\pi,d\to d'}(k) \leq \varphi_{F,\pi,d\to d'}(k+2r)$, the reciprocal is obtained using ψ^{-1}. ◀

2 Speed of convergence in general constructions

2.1 Notion of Turing machines

A *k-tapes Turing machine* $\mathcal{M} = (k, Q, \Gamma, \#, q_0, \delta, Q_F)$ is defined by:

- Γ a finite alphabet, with a blank symbol $\# \in \Gamma$. Initially, k infinite memory tapes represented as an element of $(\Gamma^k)^{\mathbb{Z}}$, are filled with $\#$, except for a finite prefix on the first tape (the input), and a computing head is located on the first letter of the tape;
- Q the finite set of states of the head and $q_0 \in Q$ is the initial state;
- $\delta : Q \times \Gamma^k \to Q \times \Gamma^k \times \{\leftarrow, \cdot, \rightarrow\}^k$ the transition function. Given the state of the head and the letter associated, it reads on the tape, depending on its position, the head can change state, replace the letter and move by one cell at most.
- $Q_F \subset Q$ the set of final states, when a final state is reached, the computation stops and the output is the value currently written on the tape.

Turing machines are a very robust model of computation, there exist several variants in the literature which are equivalent from a decidability point of view. Nevertheless these modifications on the definition are not without effects on the time and space complexities (time unit is one application of the transition function, space unit is one cell of the tape). To detect forbidden patterns in the projective subaction, one of the fundamental construction is the use of laical rules to encode Turing machine computations. In this article we choose to use the basic version of $\mathcal{M}$ but the reader should have in mind that it is possible to improve time and space complexities, using by instance these non-exhaustive acceleration techniques:

- **Compare-Copy:** compare or copy instantaneously a word between two markers between two tapes;
- **Transfer head:** transfer instantaneously the head to another cell of the tape marked by a special symbol;
- **Fill:** fill instantaneously a part of a tape with a periodic pattern.

Let F be a recursively enumerable set of forbidden patterns, then the complementary of $\mathcal{L}(\mathbf{T}_F)$ in $\mathcal{A}^*$, denoted $\mathcal{L}(\mathbf{T}_F)^c$ is also recursively enumerable. Consider $\mathcal{M}_{\mathcal{L}(\mathbf{T}_F)^c}$ be a Turing machine which enumerates $\mathcal{L}(\mathbf{T}_F)^c$, denote

- $\mathrm{Dtime}_{\mathcal{M}_{\mathcal{L}(\mathbf{T}_F)^c}}(k)$ the maximal time needed by the Turing machine $\mathcal{M}_{\mathcal{L}(\mathbf{T}_F)^c}$ to know if a pattern of size k is not in the language of $\mathbf{T}_F$;
- $\mathrm{Dspace}_{\mathcal{M}_{\mathcal{L}(\mathbf{T}_F)^c}}(k)$ the maximal space needed by the Turing machine $\mathcal{M}_{\mathcal{L}(\mathbf{T}_F)^c}$ to know if a pattern of size k is not in the language of $\mathbf{T}_F$ (only the space necessary for the computation is taken in consideration and the input is considered in an auxiliary tape).

▶ Remark. $\mathrm{Dtime}_{\mathcal{M}_{\mathcal{L}(\mathbf{T}_F)^c}}$ and $\mathrm{Dspace}_{\mathcal{M}_{\mathcal{L}(\mathbf{T}_F)^c}}$ are not computable if $\mathcal{L}(\mathbf{T}_F)^c$ is not recursive.

Let F be a set of patterns and $\mathcal{M}_F$ a Turing machine, called *enumerative Turing machine of* F, with the following behavior: it starts on the empty tape and successively writes the patterns of F on its tape. A set of finite patterns F *forbids the pattern* w if $w \notin \mathcal{L}(\mathbf{T}_F)$. Let $\mathcal{M}_F$ be an enumerative Turing machine of F, denote $\mathrm{Dtime}^{\mathrm{enu}}_{\mathcal{M}_F}(k)$ (resp. $\mathrm{Dspace}^{\mathrm{enu}}_{\mathcal{M}_F}(k)$) the smallest time (resp. the smallest space) taken by the Turing machine $\mathcal{M}_F$ such that the subset $F_{\mathrm{Dtime}^{\mathrm{enu}}_{\mathcal{M}_F}(k)}$ of F (resp. $F_{\mathrm{Dspace}^{\mathrm{enu}}_{\mathcal{M}_F}(k)} \subset F$) generated at this time (resp. at this space) forbid all the words of $\mathcal{L}_k(\mathbf{T}_F)^c$.

2.2 Speed of convergence for previous constructions

In this section, we give some elements to determine the speed of convergence given by the construction of [6] and [2]. The idea is to "program" a d-dimensional subshift of finite type, denoted $\mathbf{T}_{\mathtt{Final}}$ whose projective subaction is a given effective subshift $\Sigma \subset \mathcal{A}^{\mathbb{Z}}$ where $d = 3$ in [6] and $d = 2$ in [2]. In the two constructions, $\mathbf{T}_{\mathtt{Final}}$ is constituted by three layers:

- the first one is $\mathcal{A}^{\mathbb{Z}^d}$ and contains different copies of the same configuration $y \in \mathcal{A}^{\mathbb{Z}}$ superposed on additional directions, the additional finite type conditions check if $y \in \Sigma$;
- the second is $\mathbf{T}_{\mathtt{Grid}} \subset \mathcal{A}^{\mathbb{Z}^d}_{\mathtt{Grid}}$ and constructs a grid which allows to implement well initialized Turing machine in all configurations with different sizes for time and space;
- the third is $\mathbf{T}_{\mathcal{M}} \subset \mathcal{A}^{\mathbb{Z}^d}_{\mathcal{M}}$ and checks if no forbidden pattern appears: the purpose is to implement a Turing machine $\mathcal{M}_F$ which enumerates forbidden patterns which define Σ and an additional procedure $\mathcal{M}_{\mathtt{Search}}$ which checks if the patterns produced appear in the configuration of the first layer (if it is the case, the Turing machine enters in a special state which is forbidden by $\mathbf{T}_{\mathtt{Final}}$).

Thus $x \in \mathbf{T}_{\mathtt{Final}} \subset \mathcal{A}^{\mathbb{Z}^d} \times \mathbf{T}_{\mathtt{Grid}} \times \mathbf{T}_{\mathcal{M}}$ if and only if there exists $y \in \Sigma$ such that $y = \pi(x)_{\mathbf{i}+\mathbb{Z}\mathbf{e_1}}$ for all $\mathbf{i} \in \langle \mathbf{e_2}, \dots, \mathbf{e_d} \rangle_{\mathbb{Z}}$ where π is the factor on the first layer which deletes computation states. In particular $\Sigma = \mathbf{SA}_1(\pi(\mathbf{T}_{\mathtt{Final}}))$ but moreover Σ is conjugate to a sub-action of $\pi(\mathbf{T}_{\mathtt{Final}})$. This result is stronger that just realization by projective subaction and allows to construct local rules for exotic tilings [3, 5].

In the two articles, $\mathbf{T}_{\mathrm{Grid}}$ is defined by a substitution. Mozes' result [13] gives local rules which force a cell to be in a super tile of order n well formed without considering the whole configuration. To determine $\varphi_{F_{\mathtt{Final}},\pi,d\to 1}$, it is sufficient to analyze the size in $\mathbf{T}_{\mathtt{Grid}}$ necessary for that $\mathcal{M}_F$ enumerates patterns of size k and all zones are checked by the additional procedure $\mathcal{M}_{\mathtt{Search}}$. This depends of $\mathrm{Dtime}^{\mathrm{enu}}_{\mathcal{M}_F}(k)$ and $\mathrm{Dspace}^{\mathrm{enu}}_{\mathcal{M}_F}(k)$.

Speed of convergence in the construction of [6]. As it is described in Section 4 of [6], $\mathbf{T}_{\mathtt{Grid}}$ gives a rectangular partition of $\mathbb{Z}^3$ generated by $\widehat{W}_3 \times \widehat{W}_5$ where $\widehat{W}_3$ and $\widehat{W}_5$ are obtained by a substitution. Thus for $s, t \in \mathbb{N}$ there exists $\mathbb{M} \subset \mathbb{Z}$ such that for all $i \in \mathbb{M}$, the slice $\{i\} \times \mathbb{Z}^2$ is partitioned into rectangles of size $3^s \times 5^t$ which delimits computation zones. Moreover $\mathbb{M}$ does not have gap bigger than $3^s 5^t$. To copy the initial configuration onto the first layer, we need an approximation row of width $O(3^s 5^t)$ to detect a forbidden word enumerated in space less than 3^s and in time less than 5^t. One deduces that

$$(k \longmapsto \varphi_{F_{\mathtt{Final}},\pi,3\to 1}) \sim \left(k \longmapsto \mathrm{Dspace}^{\mathrm{enu}}_{\mathcal{M}_F}(k)\mathrm{Dtime}^{\mathrm{enu}}_{\mathcal{M}_F}(k)\right).$$

Speed of convergence in the construction of [2]. As it is described in Section 2, Fact 2.4, of [2], $\mathbf{T}_{\mathtt{Grid}}$ defines fractured zone of computation to implement the Turing machine of size $2^n \times 2^{2^n}$, the first coordinate according to $\mathbf{e_1}$ corresponds to the space and the second according to $\mathbf{e_2}$ corresponds to the time. By the substitution rules and the clock rules, this fractured zone of computation is included in a pattern of $\mathbf{T}_{\mathtt{Grid}}$ of size $4^n \times (2^{n+2^n})$

and every row $\mathbf{T}_{\texttt{Final}}^{2^{n+2^n},2\to1}$ contains such computation zone every 4^n cells. Since the time to cheek if a forbidden pattern of size k appears in the responsibility zone ($n^2 2^n$ steep in direction $\mathbf{e_2}$ by Fact 3.4 of [2]) is negligible according to the time given to the Turing machine to compute forbidden patterns (2^{n+2^n} steep in direction $\mathbf{e_2}$), one deduces that $(k \mapsto \varphi_{F_{\texttt{Final}},\pi,2\to1}(k)) \sim \left(k \mapsto 2^{n(k)+2^{n(k)}}\right)$ where $n(k) = \min\{n : \text{Dspace}^{\text{enu}}_{\mathcal{M}_F}(k) < 2^n\}$. So

$$(k \longmapsto \varphi_{F_{\texttt{Final}},\pi,2\to1}) \sim \left(k \longmapsto \text{Dspace}^{\text{enu}}_{\mathcal{M}_F}(k) 2^{\text{Dspace}^{\text{enu}}_{\mathcal{M}_F}(k)}\right).$$

2.3 A more efficient construction

In the particular case where Σ is an effective subshift with a periodic configuration, the construction can be highly simplified and the speed of convergence is improved. In a few words, the same type of construction with different layers is built, however the computation checks if no forbidden patterns appear only in one line, the other lines are mapped into the periodic configuration by the factor map. Thus the computation zones do not need to be fractionated and simplified layer $\mathbf{T}_{\texttt{Grid}}$ allows a computation in real time.

▶ **Theorem 4.** *Let $\Sigma \subset \mathcal{A}^{\mathbb{Z}^d}$ be an effective subshift of dimension d with a periodic point ($^\infty w^\infty \in \Sigma$) defined by a set F of forbidden patterns enumerated by a Turing machine $\mathcal{M}_F$. Then there exists a subshift of finite type $\mathbf{T}_{F_{Final}}$ of dimension $d+1$ and a factor map π such that $\mathbf{SA}_d(\pi(\mathbf{T}_{F_{Final}})) = \Sigma$ and $\varphi_{F_{Final},\pi,d+1\to d} \sim Dtime^{enu}_{\mathcal{M}_F}$.*

Proof. Assume that $\mathcal{M}_F$ enumerates patterns of F on the first tape separated by the symbol \$ and that the tapes of $\mathcal{M}$ are onesided. The different layers of $\mathbf{T}_{F_{\texttt{Final}}}$ are:

- **Layer 1:** The first layer is $\mathbf{T}_{\texttt{Line}} \subset ((\mathcal{A} \times \{$  $\}) \cup \{$ $\})^{\mathbb{Z}^2}$ the subshift of finite type such that for $x \in \mathbf{T}_{\texttt{Line}}$ there is at most one $i \in \mathbb{Z}$ such that $\mathbf{SA}_1\left(\sigma^{i\mathbf{e_2}}(x)\right) =^\infty$ $^\infty$ and for all $j \neq i$ one has $\mathbf{SA}_1\left(\sigma^{j\mathbf{e_2}}(x)\right) \in \{\sigma^k(^\infty w^\infty) : k \in \mathbb{Z}\} \times \{$  $\}^{\mathbb{Z}}$.
- **Layer 2:** The second layer is the subshift $\mathbf{T}_{\texttt{Config}} = \{x \in \mathcal{A}^{\mathbb{Z}^2} : \sigma^{\mathbf{e_1}-\mathbf{e_2}}(x) = x\}$, the configuration is shifted in view to scan two adjacent areas (and their frontier) during the comparison.
- **Layer 3:** The third layer is the subshift of finite type $\mathbf{T}_{\texttt{Grid}} \subset \{$  $\}^{\mathbb{Z}^2}$ such that on each line of $x \in \mathbf{T}_{\texttt{Grid}}$, the two colors alternates and this alternation is repeated above until it crosses a line which contains the symbol $*$. In this case the transitions red/blue become monochromatic and the transitions blue/red force the alternation. Thus the sequences of monochromatic colors become larger. We remark that if a line contains the periodic configuration $^\infty$ ( $)^\infty$, then all lines below contain this periodic configuration and above, if we have crossed n times a line with the symbol $*$, we obtain a line with the periodic configuration $^\infty$($^{2^n}$ $^{2^n})^\infty$ (see Figure 2).
- **Layer 4:** Denote $\mathcal{A}_{\mathcal{M}} = ((Q \times \Gamma) \cup \Gamma)^k$ where k is the number of tapes, the fourth layer is a subshift of finite type $\mathbf{T}_{\mathcal{M}} \subset \mathcal{A}_{\mathcal{M}}^{\mathbb{Z}^2}$ where the local rules are given by the transition rules δ of $\mathcal{M}_F$.
- **Layer 5:** The fifth layer is the full-shift $\mathbf{T}_{\texttt{Compar}} = \{$  $\}^{\mathbb{Z}^2}$.

To obtain the subshift of finite type $\mathbf{T}_{\texttt{Final}} \subset \mathbf{T}_{\texttt{Line}} \times \mathbf{T}_{\texttt{Config}} \times \mathbf{T}_{\texttt{Grid}} \times \mathbf{T}_{\mathcal{M}} \times \mathbf{T}_{\texttt{Compar}}$ we add a finite set of forbidden patterns $F_{\texttt{SynchroLine}} \cup F_{\texttt{Init}} \cup F_{\texttt{Extend}} \cup F_{\texttt{Compar}}$ which codes the interaction between the different layers. These local rules are:

- **Rules $F_{\texttt{SynchroLine}}$:** These rules imply that if a line $^\infty$  $^\infty$ appears in the layer $\mathbf{T}_{\texttt{Line}}$ of a configuration, then it is synchronized with a periodic point $^\infty$  $^\infty$ or $^\infty$  $^\infty$ in the layer $\mathbf{T}_{\texttt{Grid}}$.

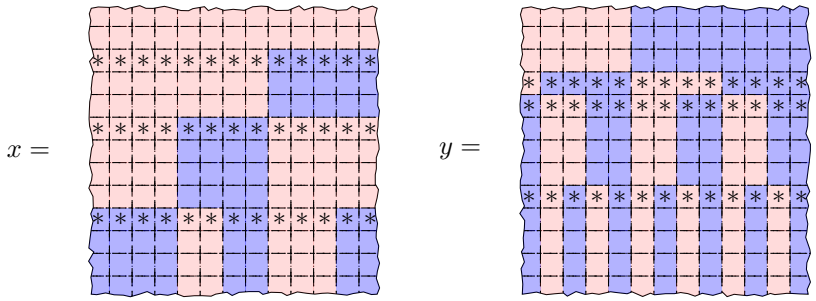

Figure 2 x and y are two examples of configurations of $\mathbf{T}_{\texttt{Grid}}$ and y contains $^{\infty}$ ( )$^{\infty}$.

- **Rules $F_{\texttt{Init}}$:** They imply that the initialization state appears in the layer $\mathbf{T}_{\mathcal{M}}$ on each cell in correspondence to the line $^{\infty}$ $^{\infty}$ in the layer $\mathbf{T}_{\texttt{Line}}$.
- **Rules $F_{\texttt{Extend}}$:** They imply that if a computation needs more space, the symbol $*$ appears in the layer $\mathbf{T}_{\texttt{Grid}}$ (thus the computation zones is doubled) and the tape in the layer $\mathbf{T}_{\mathcal{M}}$ corresponding to the old red zone is erased (to have only one computation by computation zone). Thus the space allowed by a Turing machine is doubled if the head was in a blue zone.
- **Rules $F_{\texttt{Compar}}$:** They imply that if a forbidden pattern appears in the enumeration obtained in $\mathbf{T}_{\mathcal{M}}$ then it is compared with the corresponding pattern which appears in $\mathbf{T}_{\texttt{Config}}$. If the two patterns coincide then the configuration is forbidden in $\mathbf{T}_{\texttt{Final}}$.

Define the factor map $\pi_{\texttt{Final}} : \mathbf{T}_{\texttt{Final}} \to \mathcal{A}^{\mathbb{Z}^2}$ such that for $x \in \mathbf{T}_{\texttt{Final}}$ and $\mathbf{i} \in \mathbb{Z}^2$, $\pi(x)_{\mathbf{i}}$ is the cell of the layer $\mathbf{T}_{\texttt{Config}}$ if we are in the line $^{\infty}$ $^{\infty}$ in $\mathbf{T}_{\texttt{Config}}$ and the cell corresponding to the periodic orbit of $\mathbf{T}_{\texttt{Line}}$ if not.

For $x \in \Sigma$ it is easy to construct $y \in \mathbf{T}_{\texttt{Final}}$ such that $\mathbf{SA}_1(\pi_{\texttt{Final}}(y)) = x$. Reciprocally, consider $y \in \mathbf{T}_{\texttt{Final}}$. If $\pi_{\texttt{Line}}(y)_{(0,0)} \neq$ then $\mathbf{SA}_1(\pi_{\texttt{Final}}(y)) =^{\infty} w^{\infty} \in \Sigma$. If $\pi_{\texttt{Line}}(y)_{(0,0)} =$, we consider u a sub-pattern of $x = \mathbf{SA}_1(\pi_{\texttt{Final}}(y))$ of size n. Assume that $u \notin \mathcal{L}(\Sigma)$, so there exists a word $w \sqsubset x$ enumerated by $\mathcal{M}$ in time $t_F(n) = \text{Dtime}^{\text{enu}}_{\mathcal{M}}(n)$ and space $s_F(n) = \text{Dspace}^{\text{enu}}_{\mathcal{M}}(n)$ such that $w \sqsubset u$. By construction of $\mathbf{T}_{\texttt{Final}}$, one has $\mathbf{SA}_1\left(\pi_{\texttt{Grid}}(\sigma^{t_F(n)}(y))\right) =^{\infty}$ ($^{2^k}$ $^{2^k}$)$^{\infty}$ where $k = \min\{k' : s_F(n) < 2^{k'}\}$. Since the configuration is shifted on $\mathbf{T}_{\texttt{Config}}$ and compared instantaneously thanks to $\mathbf{T}_{\texttt{Compar}}$, we conclude there exists k' such that $t_F(n) \leq k' \leq t_F(n) + 2^{1+min\{k:s_F(n)<2^k\}}$ where the word w is detected in the line $y_{\mathbb{Z},k'}$. By the condition $F_{\texttt{Compar}}$ this is impossible.

Thus $\mathbf{SA}_{\mathbf{e}_1\mathbb{Z}}\left(\pi_{\texttt{Final}}(\mathbf{T}_{\texttt{Final}})\right) = \Sigma$ and $\varphi_{F,\pi,2\to1}(k) = t_F(k) + 2^{1+\min\{n:s_F(k)<2^n\}}$ for all $k \in \mathbb{N}$. In particular $\varphi_{F,\pi,2\to1} \sim \max(\text{Dtime}^{\text{enu}}_{\mathcal{M}_F}, \text{Dspace}^{\text{enu}}_{\mathcal{M}_F}) = \text{Dtime}^{\text{enu}}_{\mathcal{M}_F}$. ◀

2.4 Increase the dimension to increase the speed

Generally, properties studied on subshifts of finite type exhibit a gap between dimension one and dimension two. The most famous is the undecidability of the domino problem in dimension $d \geq 2$. In this section we exhibit a gap which appears in an algorithmic point of view.

▶ **Theorem 5.** *Let $\Sigma \subset \mathcal{A}^{\mathbb{Z}^d}$ be a subshift which is $(\varphi, d+d')$-realizable by projective subaction of a sofic then it is $(\varphi^{\frac{d'}{d''}}, d+d'')$-realizable by projective subaction of a sofic for $d'' \geq d'$.*

Proof. Let $\Sigma \subset \mathcal{A}^{\mathbb{Z}}$ be an effective subshift. Consider $\mathbf{T}_F \subset \mathcal{B}^{\mathbb{Z}^2}$ a subshift of finite type such that $\mathbf{SA}_1(\pi(\mathbf{T}_F)) = \Sigma$. Denote $\varphi = \varphi_{F,\pi,2\to1}$. One constructs $\mathbf{T}_{F'} \subset \mathcal{B}'^{\mathbb{Z}^3}$ a subshift of finite

type and $\pi' : \mathcal{B}' \to \mathcal{A}$ a factor map such that $\mathbf{SA}_1(\pi'(\mathbf{T}_{F'})) = \Sigma$ and $\varphi_{F',\pi',3\to1} \in \Theta(\sqrt{\varphi})$. This prove the Theorem for $d = 1$, $d' = 1$ and $d'' = 2$.

Construction of a tangled grid. Consider the alphabet $\mathcal{C}$ formed by  ,  ,  , their rotations and their symmetrized about to the axis, thus $\mathrm{card}(\mathcal{C}) = 3 \times 4 \times 2 = 24$ and define the following substitution on $\mathcal{C}$ (modulo rotations and symmetries):

s: 
By iterating substitution s on a letter $a \in \mathcal{C}$, we construct for every $n \in \mathbb{N}$ the pattern $s^n(a)$ called the *super-tile of order n and type a*. The substitutive subshift defined by

$$\mathbf{T}_s = \left\{ x \in \mathcal{C}^{\mathbb{Z}^2} : u \sqsubset x \text{ if there exists } n \in \mathbb{N} \text{ and } a \in \mathcal{C} \text{ which verifies } u \sqsubset s^n(a) \right\},$$

is sofic according to Mozes' result [13]. Thus there exists a finite set of forbidden patterns F_s and a factor map $\pi_s : \mathcal{C}_s \to \mathcal{C}$ such that $\pi_s(\mathbf{T}_{F_s}) = \mathbf{T}_s$. In the Mozes' construction the local rules F_s force every super tile of order n to be assembled in a super tile of order $n+1$. Thus if $p \in \mathcal{C}_s^{[-k,k]^2}$ does not contain patterns of F_s, then the center letter $p_{\mathbf{0}}$ is in a super-tile of order n such that $2^n \leq k < 2^{n+1}$. In this super tile, the arrows form a connected tangled segment of size 2^{n^2}.

Construction of a three-dimensional sofic subshift which realizes Σ. Consider the subshift of finite type $\mathbf{T}_{F'} \subset \mathcal{B}'^{\mathbb{Z}^3}$ where $\mathcal{B}' = \mathcal{B} \times \mathcal{C}_s$ such that

- for all $i \in \mathbb{Z}$ the $\mathbb{Z}^2$-configuration $\pi_{\mathcal{C}_s}(x)_{i\mathbf{e_1}+\mathbb{Z}^2}$ is an element of $\mathbf{T}_s$;
- the 2-dimensional forbidden patterns of F are transfered in 3-dimensional forbidden patterns where the second coordinate is wrapped following the tangled grid (see Figure 3).

Let π' be the application of π following the tangled grid, we obtain $\mathbf{SA}_1(\pi'(\mathbf{T}_{F'})) = \Sigma$.

$\pi'(\mathbf{T}_{F'})$ has the expected speed of convergence. By definition of the speed of convergence, for any $u \in \mathcal{A}^k$, if $u \notin \Sigma$ then $u \notin \mathcal{L}\left(\pi\left(\mathbf{SA}_1\left(\mathbf{T}_F^{\varphi(k),2\to1}\right)\right)\right)$.

Let $z \in \mathbf{T}_{F'}^{2\left\lceil\sqrt{\varphi(k)}\right\rceil,3\to1}$. The condition F_s verified on $z_{\{0\}\times\left[-2\left\lceil\sqrt{\varphi(k)}\right\rceil,2\left\lceil\sqrt{\varphi(k)}\right\rceil\right]^2}$ implies that $z_{\mathbf{0}}$ is included in a super-tile of order $n = \left\lfloor \log_2\left(\left\lceil\sqrt{\varphi(k)}\right\rceil\right)\right\rfloor$. One deduces that $z_{\mathbf{0}}$ is in the center of a segment constituted following the arrows of $\mathcal{C}$ of amplitude $\left(2^{\left\lfloor\log_2\left(\left\lceil\sqrt{\varphi(k)}\right\rceil\right)\right\rfloor}\right)^2$. Like the local transitions F are transfered, there exists $y \in \mathbf{SA}_1\left(\mathbf{T}_F^{\varphi(k),2\to1}\right)$ which correspond to z in the wrapped zone. Thus $u \notin \mathcal{L}\left(\mathbf{T}_{F'}^{2\left\lceil\sqrt{\varphi(k)}\right\rceil,3\to1}\right)$ that is to say $\varphi_{F',\pi',3\to1} \prec \sqrt{\varphi}$. In the same way the reverse holds and so $\varphi_{F',\pi',3\to1} \succ \sqrt{\varphi}$. ◀

▶ Remark. Exemples of Section 4 show that this theorem is optimal.

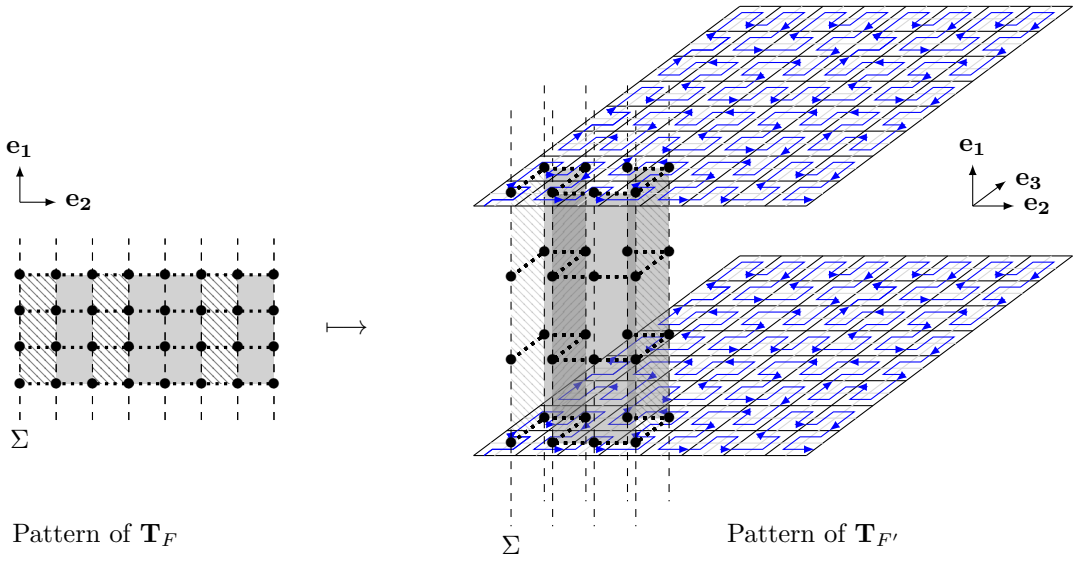

Figure 3 Pattern of $\mathbf{T}_F$ wrapped following the tangled grid in a pattern of $\mathbf{T}_{F'}$. The subshift Σ is obtained taking factor π or π' and projective subaction following $\mathbf{e_1}$.

3 Lower bounds for the speed of convergence of a subshift

3.1 Combinatorial lower bounds

Let Σ be a one dimensional subshift and let $u \in \mathcal{A}^*$, the *follower set of word of size* k of u is $\mathrm{Fol}_\Sigma^k(u) = \{v \in \mathcal{L}_k(\Sigma) : uv \in \mathcal{L}(\Sigma)\}$. If $u \notin \mathcal{L}(\Sigma)$ then $\mathrm{Fol}_\Sigma^k(u) = \emptyset$. Moreover one has $\mathrm{card}(\{\mathrm{Fol}_\Sigma^{k_2}(u) : u \in \mathcal{A}^{k_1}\}) \leq \mathrm{card}(\mathcal{A})^{k_1}$.

▶ **Theorem 6.** *Let $\Sigma \subset \mathcal{A}^{\mathbb{Z}}$ be an one dimensional effective subshift and $\varphi \in \mathcal{F}_{\Sigma,d}^{Sofic}$ with $d \geq 2$. Then there exists a constant M such that for all $k_1, k_2 \in \mathbb{N}$ one has:*

$$M\varphi_{F,\pi,d\to 1}(k_1+k_2) \geq \left(\log(card(\{Fol_\Sigma^{k_2}(u) : u \in \mathcal{A}^{k_1}\}))\right)^{\frac{1}{d-1}}.$$

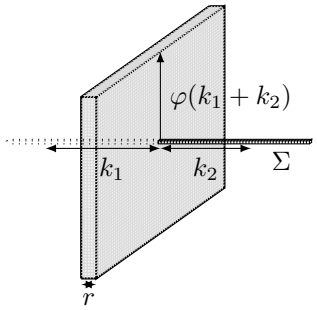
Proof. Assume that $\Sigma = \mathbf{SA}_1(\pi(\mathbf{T}_F))$ and $\varphi = \varphi_{F,\pi,d\to 1}$. For $u \in \mathcal{L}_{k_1}(\Sigma)$, one has

$$\mathrm{Fol}_\Sigma^{k_2}(u) = \Big\{\mathbf{SA}_1(\pi(x))_{[0,k_2-1]} \in \mathcal{A}^{k_2} : x \in \mathbf{T}_F^{\varphi(k_1+k_2),d\to 1} \text{ such that } \mathbf{SA}_1(\pi(x))_{[-k_1,-1]} = u\Big\}.$$

Let r such that the support of every pattern of F is included in $[0, r-1]^d$. For $x \in \mathbf{T}_F^{\varphi(k_1+k_2),d\to 1} \subset \mathcal{B}^{\mathbb{Z}^d}$ such that $\mathbf{SA}_1(\pi(x))_{[-k_1,-1]} = u \in \mathcal{A}^{k_1}$, the knowledge of $x_{[-r,-1]\times[-\varphi(k_1+k_2),\varphi(k_1+k_2)]^{d-1}}$ is sufficient to determine which set of $\{\mathrm{Fol}_\Sigma^{k_2}(u') : u' \in \mathcal{A}^{k_1}\}$ is allowed to complete $u \in \mathcal{A}^{k_1}$ by a word $v \in \mathcal{A}^{k_2}$ such that

$$uv \in \mathcal{L}_{k_1+k_2}(\mathbf{SA}_1\left(\pi(\mathbf{T}_F^{\varphi(k_1+k_2),d\to 1}\right)) = \mathcal{L}_{k_1+k_2}(\Sigma).$$

Thus $\mathrm{card}(\{\mathrm{Fol}_\Sigma^{k_2}(u) : u \in \mathcal{A}^{k_1}\}) \leq \mathcal{B}^{r(2\varphi(k_1+k_2)+1)^{d-1}}$.



◀

3.2 Computational lower bounds

▶ **Theorem 7.** *Let $\Sigma \subset \mathcal{A}^{\mathbb{Z}}$ be an one dimensional effective subshift and $\varphi \in \mathcal{F}_{\Sigma,d}^{Sofic}$. There exists a Turing machine $\mathcal{M}$ whose the domaine is $\mathcal{L}(\Sigma)^c$ such that*

- $\max(\log, (\varphi_{F,\pi,d\to 1})^{d-1}) \succ \log \circ Dtime_{\mathcal{M}}$;
- $(\varphi_{F,\pi,d\to 1})^{d-1} \succ Dspace_{\mathcal{M}}$.

Since $\mathcal{L}(\Sigma)^c$ is not necessarily recursive, $\mathrm{Dtime}_{\mathcal{M}}$ and $\mathrm{Dspace}_{\mathcal{M}}$ are not necessarily computable.

Proof. Let F be a finite set of forbidden patterns of maximal size r such that $\Sigma = \mathbf{SA}_1(\pi(\mathbf{T}_F))$ and $\varphi = \varphi_{F,\pi,d\to 1}$. Denote $\mathbb{B}_n = \{k_2\mathbf{e_2} + \cdots + k_d\mathbf{e_d} : (k_2, \ldots, k_d) \in [-n, n]^{d-1}\}$ and $\mathbf{T}^m = \mathbf{T}_F^{m,d\to 1}$. One has $\mathcal{L}_k\left(\mathbf{SA}_1\left(\pi(\mathbf{T}^{\varphi(k)})\right)\right) = \mathcal{L}_k(\Sigma)$ and $\mathbf{T}^{\varphi(k)} \subset \left(\mathcal{B}^{\mathbb{B}_{\varphi(k)}}\right)^{\mathbb{Z}}$ is a one-dimensional subshift of finite type of order r. This subshift can be represented by a graph where the vertices are $\left(\mathcal{B}^{\mathbb{B}_{\varphi(k)}}\right)^r \cap \mathcal{L}(\mathbf{T}^{\varphi(k)})$ and there is an edge from u to v if the two words coincide except for the extremal letters (see [11]). Thus this graph has at most $\mathrm{card}(\mathcal{B})^{r(2\varphi(k))^{d-1}}$ vertices and can be viewed as an automaton which accepts words of $\mathcal{L}(\pi(\mathbf{T}^{\varphi(k)}))$, this takes a linear time in the size of the graph.

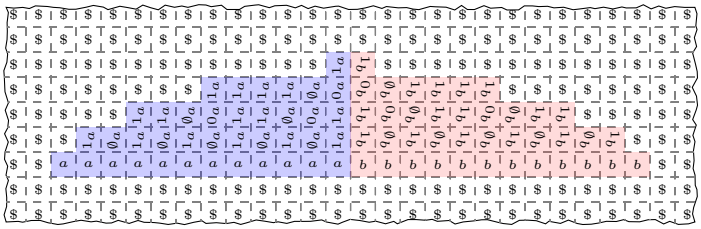
To determine if $u \notin \mathcal{L}(\Sigma)$, it is sufficient that $u \notin \mathcal{L}(\mathbf{SA}_1(\pi(\mathbf{T}^m)))$ for some $m \in \mathbb{N}$. We implement an algorithm which explores the graph generated by $\mathbf{T}^m$ for each $m \in \mathbb{N}$ and search if u is accepted with the corresponding automaton. One knows if $u \in \mathcal{L}(\mathbf{SA}_1(\pi(\mathbf{T}^m)))$ in time $O(k\,\mathrm{card}(\mathcal{A})^{r(2m)^{d-1}})$. This algorithm halts on $u \notin \mathcal{L}(\Sigma)$ in time

$$\mathrm{Dtime}_{\mathcal{M}}(k) \leq M\,k \sum_{m=1}^{\varphi(k)} \mathrm{card}(\mathcal{A})^{r(2m)^{d-1}} \leq M\,k\,\varphi(k)\mathrm{card}(\mathcal{A})^{r(2\varphi(k))^{d-1}}$$

Since $\varphi(k) \leq \varphi^{d-1}(k)$, it follows that $\max(\log, \varphi^{d-1}) \succ \log \circ \mathrm{Dtime}_{\mathcal{M}}$.We deduce the first point of the theorem.

To prove the second point, the naive procedure to find a configuration of $\mathbf{SA}_1(\pi(\mathbf{T}^m))$ which contains u in the center is to start from an element of $\left(\mathcal{B}^{\mathbb{B}_n}\right)^r \cap \mathcal{L}(\mathbf{T}^m)$ and complete it respecting the condition F until it finds again a one-sided periodic orbit. To be sure to explore all the orbits it is possible to order them lexicographically. Thus, the algorithm just needs to know the last orbit checked, this needs $r(2m)^{d-1}$ space to know if $u \in \mathcal{L}(\mathbf{SA}_1(\pi(\mathbf{T}^m)))$. If $u \notin \mathcal{L}(\Sigma)$, the algorithm halts when it explores $\left(\mathcal{B}^{\mathbb{B}_n}\right)^r \cap \mathcal{L}(\mathbf{T}^{\varphi(k)})$. So there exists $M > 0$ such that $M(\varphi(k))^{d-1} \geq \mathrm{Dspace}_{\mathcal{M}}(k)$. We recall that the word u is written on an annex tape which is only used for the reading and which is not counted in $\mathrm{Dspace}_{\mathcal{M}}$. ◀

▶ Remark. These theorems do not generalize to dimension 2: Theorem 6 uses a characterization of one dimensional sofic subshifts with follower sets and Theorem 7 is blocked by the undecidability of emptiness of two-dimensional subshifts of finite type.



A configuration of $\mathbf{T}_{F_{\log}}$

Figure 4 A configuration of $\mathbf{T}_{F_{\log}}$.

4 Some classes of speed of convergence and perspectives

In this section we give the sharp realization of some one-dimensional subshifts.

▶ **Sofic subshift.** A subshift is constant-realizable by sofic if and only if it is sofic (see [14]).

▶ **Gap under constant-realizable.** If a subshift $\Sigma \subset \mathcal{A}^{\mathbb{Z}}$ is $(\varphi, 2)$-realizable by sofic with $\varphi \in o(\log(\log(n)))$ then this subshift is sofic. Indeed, by Theorem 7, $\mathcal{L}(\Sigma)^c$ can be recognized in space $o(\log(\log(n)))$, thus $\mathcal{L}(\Sigma)^c$ is rational (see [8]), that is to say Σ is sofic.

Let $\mathcal{L} \subset \mathcal{A}^*$ be a language and $\$ \notin \mathcal{A}$. Define the subshift $\mathbf{T}(\mathcal{L}) = \mathbf{T}_{F_{\mathcal{L}}} \subset \mathcal{A}'^{\mathbb{Z}}$ where $\mathcal{A}' = \mathcal{A} \cup \{\$\}$ and $F = \{\$u\$: u \notin \mathcal{L}\}$. If $\mathcal{L}$ is effective then $\mathbf{T}(\mathcal{L})$ is an effective subshift.

▶ **log-realizable.** Consider $\mathcal{L}_= = \{a^n b^n : n \in \mathbb{N}\}$. The subshift $\mathbf{T}(\mathcal{L}_=) \subset \{a, b, \$\}^{\mathbb{Z}}$ is sharp $((\log)^{\frac{1}{d-1}}, d)$-realizable by sofic for $d \geq 2$. Theorem 6 gives the lower bound since

$$\mathrm{card}(\{\mathrm{Fol}^n_\Sigma(u) : u \in \mathcal{A}^n\}) \geq \mathrm{card}(\{\mathrm{Fol}^k_\Sigma(\$a^k) : k \in [0, n-1]\}) = n.$$

For $d = 2$, the upper bound is obtained considering the subshift of finite type $\mathbf{T}_{F_{\log}} \subset \{a, b, \$, 0_a, 1_a, \emptyset_a, 0_b, 1_b, \emptyset_b\}^{\mathbb{Z}^2}$ where $F_{\log}$ are the forbidden patterns of shape $\mathbb{U} =$  which do not appear in the configuration represented in Figure 4. The factor π maps \$ on \$, $\{0_a, 1_a, \emptyset_a\}$ on a and $\{0_b, 1_b, \emptyset_b\}$ on b. The idea is to implement counters which grow when going from \$'s region and compare them at the frontier. The upper bound for $d \geq 3$ is obtained using Theorem 5.

In the same way the subshift $\mathbf{T}(\mathcal{L}_{\mathrm{square}})$ defined with the langage $\mathcal{L}_{\mathrm{square}} = \{a^n b^{n^2} : n \in \mathbb{N}\}$ is sharp $((\log)^{\frac{1}{d-1}}, d)$-realizable by sofic.

▶ **Linear-realizable.** For $u \in \{0,1\}^*$, define $\overline{u}$ the miror of u. Consider $\mathcal{L}_{\mathrm{palin}} = \{u\overline{u} : u \in \{0,1\}^*\}$, the subshift $\mathbf{T}(\mathcal{L}_{\mathrm{palin}}) \subset \{0, 1, \$\}^{\mathbb{Z}}$ is sharp $((\mathrm{Id})^{\frac{1}{d-1}}, d)$-realizable by projective subaction of sofic for $d \geq 2$ where $\mathrm{Id} : k \mapsto k$. Theorem 6 gives the lower bound.

For $d = 2$, the upper bound is obtained considering the subshift $\mathbf{T}_{F_{\mathrm{lin}}} \subset \{\$, 0_l, 1_l, 0_r, 1_r\}^{\mathbb{Z}^2}$ where F_{lin} are the patterns of shape $\mathbb{U} =$  or which do not appear in the configuration represented in Figure 5. The factor π maps \$ on \$, $\{0_l, 0_r\}$ on 0 and $\{1_l, 1_r\}$ on 1. The principle is to compare vertically the two words of $\{0,1\}^*$. The upper bound for $d \geq 3$ is obtained using Theorem 5.

▶ **Dspace$_{\mathcal{M}}$ realizable.** Let $\mathcal{L}$ be a computable language in space $\mathrm{Dspace}_{\mathcal{M}}$ and $\# \notin \mathcal{L}$. Consider $\mathcal{L}' = \{u\#^{\mathrm{Dtime}_{\mathcal{M}}(|u|)}\}$, then $\mathbf{T}(\mathcal{L}')$ is sharp $(\mathrm{Dspace}_{\mathcal{M}}, 2)$-realizable (the time of the Turing machine is coded following $\mathbf{e_1}$ in the sofic which realizes $\mathbf{T}(\mathcal{L}')$).

▶ **Substitutive subshift.** Let s be a one-dimensional substitution, $\mathbf{T}_s \cup \{^\infty a^\infty\}$ is sharp $(\log, 2)$-realisable. The lower bound is given by Theorem 6 and the upper bound follows from the sofic subshift where elements of $\mathbf{T}_s$ are in at most in one row. If it appears, this row is de-substituted in the next row in direction $\mathbf{e_2}$.

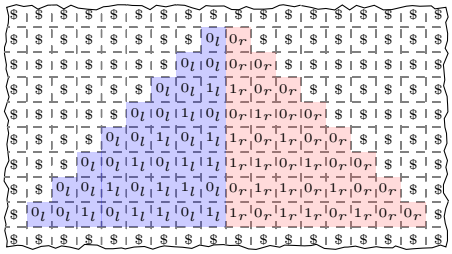


Figure 5 A configuration of $\mathbf{T}_{F_{\text{lin}}}$.

▶ **No-computable realization.** Consider the recursively enumerable set $F = \{01^n0 : n \text{ such that the Turing machine of number } n \text{ halts}\}$. Then $\varphi \in \mathcal{F}_{\Sigma,2}^{Sofic}$ is larger than any recursive function, otherwise it is possible to decide if the Turing machine of number n halts.

▶ **Perspectives.** This article highlights the importance of algorithmic properties and optimality in the realization of effective subshifts by sofic. Particularly, the last section exhibits the existence of different subclasses of effective subshift but does not present systematic study: characterization of classes of subshifts with the same speed of convergence, links between dynamical properties and speed of convergence, sharp realization for effective subshift without periodic point (as the substitutive subshift $\mathbf{T}_s$)...

Abstract

Higher-order grammars are an extension of regular and context-free grammars, where non-terminals may take parameters. They have been extensively studied in 1980's, and restudied recently in the context of model checking and program verification. We show that the class of unsafe order-(n+1) word languages coincides with the class of frontier languages of unsafe order-n tree languages. We use intersection types for transforming an order-(n+1) word grammar to a corresponding order-n tree grammar. The result has been proved for safe languages by Damm in 1982, but it has been open for unsafe languages, to our knowledge. Various known results on higher-order grammars can be obtained as almost immediate corollaries of our result.

1 Introduction

Higher-order grammars are an extension of regular and context-free grammars, where non-terminals may take trees or (higher-order) functions on trees as parameters. They were extensively studied in the 1980's [6, 7, 8], and recently reinvestigated in the context of model checking [10, 17] and applied to program verification [11].

The present paper shows that the class of unsafe order-$(n+1)$ word languages coincides with the class of "frontier languages" of unsafe order-n tree languages. Here, the frontier of a tree is the sequence of symbols that occur in the leaves of the tree from left to right, and the frontier language of a tree language consists of the frontiers of elements of the tree language. The special case where $n = 0$ corresponds to the well-known fact that the frontier language of a regular tree language is a context-free language. The result has been proved by Damm [6] for grammars with the safety restriction (see [16] for a nice historical account of the safety restriction), but it has been open for unsafe grammars, to our knowledge.[1]

Damm's proof relied on the safety restriction (in particular, the fact that variable renaming is not required for safe grammars [3]) and does not apply (at least directly) to the case of unsafe grammars. We instead use intersection types to transform an order-$(n+1)$ word grammar $\mathcal{G}$ to an order-n tree grammar $\mathcal{G}'$ such that the frontier language of $\mathcal{G}'$ coincides

with the language generated by $\mathcal{G}$. Intersection types have been used for recent other studies of higher-order grammars and model checking [11, 13, 12, 15, 19, 18, 14, 20]; our proof in the present paper provides even more evidence that intersection types are a versatile tool for studies of higher-order grammars. Compared with the previous work on intersection types for higher-order grammars, the technical novelties include: (i) our intersection types (used in Section 3) are mixtures of non-linear and linear intersection types and (ii) our type-based transformation involves global restructuring of terms. These points have made the correctness of the transformations non-trivial and delicate.

As stressed by Damm [6] at the beginning of his paper, the result will be useful for analyzing properties of higher-order languages by induction on the order of grammars. Our result allows properties on (unsafe) order-n languages to be reduced to those on order-$(n-1)$ tree languages, and then the latter may be studied by investigating those on the path languages of order-$(n-1)$ tree languages, which are order-$(n-1)$ word languages.

The rest of this paper is structured as follows. Section 2 reviews the definition of higher-order grammars, and states the main result. Sections 3 and 4 prove the result by providing the (two-step) transformations from order-$(n+1)$ word grammars to order-n tree grammars. Section 5 discusses applications of the result. Section 6 discusses related work and Section 7 concludes the paper. For the space restriction, we omit some details and proofs, which are found in the full version [2].

2 Preliminaries

This section defines higher-order grammars and the languages generated by them, and then explains the main result. Most of the following definitions follow those in [13].

A higher-order grammar consists of non-deterministic rewriting rules of the form $A \to t$, where A is a non-terminal and t is a simply-typed λ-term that may contain non-terminals and terminals (tree constructors).

▶ **Definition 1** (types and terms)**.** The set of *simple types*,[2] ranged over by κ, is given by: $\kappa ::= \mathtt{o} \mid \kappa_1 \to \kappa_2$. The order and arity of a simple type κ, written $\mathtt{order}(\kappa)$ and $\mathtt{ar}(\kappa)$, are defined respectively by:

$$\mathtt{order}(\mathtt{o}) = 0 \qquad \mathtt{order}(\kappa_1 \to \kappa_2) = \max(\mathtt{order}(\kappa_1) + 1, \mathtt{order}(\kappa_2))$$
$$\mathtt{ar}(\mathtt{o}) = 0 \qquad \mathtt{ar}(\kappa_1 \to \kappa_2) = 1 + \mathtt{ar}(\kappa_2)$$

The type $\mathtt{o}$ describes trees, and $\kappa_1 \to \kappa_2$ describes functions from κ_1 to κ_2. The set of *λ-terms*, ranged over by t, is defined by: $t ::= x \mid A \mid a \mid t_1\, t_2 \mid \lambda x : \kappa.t$. Here, x ranges over variables, A over symbols called non-terminals, and a over symbols called terminals. We assume that each terminal a has a fixed arity; we write Σ for the map from terminals to their arities. A term t is called an *applicative term* (or simply a *term*) if it does not contain λ-abstractions. A (simple) type environment $\mathcal{K}$ is a sequence of type bindings of the form $x : \kappa$ such that if $\mathcal{K}$ contains $x : \kappa$ and $x' : \kappa'$ in different positions then $x \neq x'$. In type environments, non-terminals are also treated as variables. A λ-term t has type κ under $\mathcal{K}$ if $\mathcal{K} \vdash_{\mathtt{ST}} t : \kappa$ is derivable from the following typing rules.

$$\frac{}{\mathcal{K}, x : \kappa, \mathcal{K}' \vdash_{\mathtt{ST}} x : \kappa} \qquad \frac{}{\mathcal{K} \vdash_{\mathtt{ST}} a : \underbrace{\mathtt{o} \to \cdots \to \mathtt{o}}_{\Sigma(a)} \to \mathtt{o}}$$

[2] We sometimes call simple types *sorts* in this paper, to avoid confusion with intersection types introduced later for grammar transformations.

$$\frac{\mathcal{K} \vdash_{\mathtt{ST}} t_1 : \kappa_2 \to \kappa \qquad \mathcal{K} \vdash_{\mathtt{ST}} t_2 : \kappa_2}{\mathcal{K} \vdash_{\mathtt{ST}} t_1\, t_2 : \kappa} \qquad \frac{\mathcal{K},\, x : \kappa_1 \vdash_{\mathtt{ST}} t : \kappa_2}{\mathcal{K} \vdash_{\mathtt{ST}} \lambda x : \kappa_1.t : \kappa_1 \to \kappa_2}$$

We call t a (finite, Σ-ranked) *tree* if t is an applicative term consisting of only terminals, and $\vdash_{\mathtt{ST}} t : \mathtt{o}$ holds. We write $\mathbf{Tree}_\Sigma$ for the set of Σ-ranked trees, and use the meta-variable π for a tree.

We often omit type annotations and just write $\lambda x.t$ for $\lambda x : \kappa.t$. We consider below only well-typed λ-terms of the form $\lambda x_1.\cdots\lambda x_k.t$, where t is an applicative term. We are now ready to define higher-order grammars.

▶ **Definition 2** (higher-order grammar)**.** A *higher-order grammar* is a quadruple $(\Sigma, \mathcal{N}, \mathcal{R}, S)$, where (i) Σ is a ranked alphabet; (ii) $\mathcal{N}$ is a map from a finite set of non-terminals to their types; (iii) $\mathcal{R}$ is a finite set of *rewriting rules* of the form $A \to \lambda x_1.\cdots\lambda x_\ell.t$, where $\mathcal{N}(A) = \kappa_1 \to \cdots \to \kappa_\ell \to \mathtt{o}$, t is an applicative term, and $\mathcal{N}, x_1 : \kappa_1, \ldots, x_\ell : \kappa_\ell \vdash_{\mathtt{ST}} t : \mathtt{o}$ holds for some $\kappa_1, \ldots, \kappa_\ell$. (iv) S is a non-terminal called *the start symbol*, and $\mathcal{N}(S) = \mathtt{o}$. The *order* of a grammar $\mathcal{G}$, written $\mathtt{order}(\mathcal{G})$, is the largest order of the types of non-terminals. We sometimes write $\Sigma_\mathcal{G}, \mathcal{N}_\mathcal{G}, \mathcal{R}_\mathcal{G}, S_\mathcal{G}$ for the four components of $\mathcal{G}$.

For a grammar $\mathcal{G} = (\Sigma, \mathcal{N}, \mathcal{R}, S)$, the rewriting relation $\longrightarrow_\mathcal{G}$ is defined by:

$$\frac{(A \to \lambda x_1.\cdots\lambda x_k.t) \in \mathcal{R}}{A\, t_1 \cdots t_k \longrightarrow_\mathcal{G} [t_1/x_1, \ldots, t_k/x_k]t} \qquad \frac{t_i \longrightarrow_\mathcal{G} t_i' \qquad i \in \{1, \ldots, k\} \qquad \Sigma(a) = k}{a\, t_1 \cdots t_k \longrightarrow_\mathcal{G} a\, t_1 \cdots t_{i-1}\, t_i'\, t_{i+1} \cdots t_k}$$

Here, $[t_1/x_1, \ldots, t_k/x_k]t$ is the term obtained by substituting t_i for the free occurrences of x_i in t. We write $\longrightarrow_\mathcal{G}^*$ for the reflexive transitive closure of $\longrightarrow_\mathcal{G}$.

The *tree language generated by* $\mathcal{G}$, written $\mathcal{L}(\mathcal{G})$, is the set $\{\pi \in \mathbf{Tree}_{\Sigma_\mathcal{G}} \mid S \longrightarrow_\mathcal{G}^* \pi\}$. We call a grammar $\mathcal{G}$ a *word grammar* if all the terminal symbols have arity 1 except the special terminal $\mathtt{e}$, whose arity is 0. The *word language* generated by a word grammar $\mathcal{G}$, written $\mathcal{L}_\mathtt{w}(\mathcal{G})$, is $\{a_1 \cdots a_n \mid a_1(\cdots(a_n\, \mathtt{e})\cdots) \in \mathcal{L}(\mathcal{G})\}$. The frontier word of a tree π, written $\mathbf{leaves}(\pi)$, is the sequence of symbols in the leaves of π. It is defined inductively by: $\mathbf{leaves}(a) = a$ when $\Sigma(a) = 0$, and $\mathbf{leaves}(a\, \pi_1 \cdots \pi_k) = \mathbf{leaves}(\pi_1) \cdots \mathbf{leaves}(\pi_k)$ when $\Sigma(a) = k > 0$. The *frontier language* generated by $\mathcal{G}$, written $\mathcal{L}_\mathtt{leaf}(\mathcal{G})$, is the set: $\{\mathbf{leaves}(\pi) \mid S \longrightarrow_\mathcal{G}^* \pi \in \mathbf{Tree}_{\Sigma_\mathcal{G}}\}$. In our main theorem, we assume that there is a special nullary symbol $\mathtt{e}$ and consider $\mathtt{e} \in \mathcal{L}_\mathtt{leaf}(\mathcal{G})$ as the empty word ε; i.e., we consider $\mathcal{L}^\varepsilon_\mathtt{leaf}(\mathcal{G})$ defined by:

$$\mathcal{L}^\varepsilon_\mathtt{leaf}(\mathcal{G}) := (\mathcal{L}_\mathtt{leaf}(\mathcal{G}) \setminus \{\mathtt{e}\}) \cup \{\varepsilon \mid \mathtt{e} \in \mathcal{L}_\mathtt{leaf}(\mathcal{G})\}.$$

We note that the classes of order-0 and order-1 word languages coincide with those of regular and context-free languages respectively. We often write $A\, x_1 \cdots x_k \to t$ for the rule $A \to \lambda x_1.\cdots\lambda x_k.t$. When considering the frontier language of a tree grammar, we assume, without loss of generality, that the ranked alphabet Σ has a unique binary symbol $\mathtt{br}$, and that all the other terminals have arity 0.

▶ **Example 3.** Consider the order-2 (word) grammar $\mathcal{G}_1 = (\{\mathtt{a} : 1, \mathtt{b} : 1, \mathtt{e} : 0\}, \{S : \mathtt{o}, F : (\mathtt{o} \to \mathtt{o}) \to \mathtt{o}, A : (\mathtt{o} \to \mathtt{o}) \to (\mathtt{o} \to \mathtt{o}), B : (\mathtt{o} \to \mathtt{o}) \to (\mathtt{o} \to \mathtt{o})\}, \mathcal{R}_1, S)$, where $\mathcal{R}_1$ consists of:

$$S \to F\, \mathtt{a} \qquad S \to F\, \mathtt{b} \qquad A\, f\, x \to \mathtt{a}(f\, x) \qquad B\, f\, x \to \mathtt{b}(f\, x),$$
$$F\, f \to f(f\, \mathtt{e}) \qquad F\, f \to F\, (A\, f) \qquad F\, f \to F\, (B\, f).$$

S is reduced, for example, as follows.

$$S \longrightarrow F\, \mathtt{b} \longrightarrow F\, (A\, \mathtt{b}) \longrightarrow (A\, \mathtt{b})(A\, \mathtt{b}\, \mathtt{e}) \longrightarrow \mathtt{a}\, (\mathtt{b}\, (A\, \mathtt{b}\, \mathtt{e})) \longrightarrow \mathtt{a}(\mathtt{b}\, (\mathtt{a}(\mathtt{b}\, \mathtt{e}))).$$

The word language $\mathcal{L}_{\mathtt{w}}(\mathcal{G}_1)$ is $\{ww \mid w \in \{\mathtt{a},\mathtt{b}\}^+\}$.

Consider the order-1 (tree) grammar $\mathcal{G}_2 = (\{\mathtt{br}\!:\!2, \mathtt{a}\!:\!0, \mathtt{b}\!:\!0, \mathtt{e}\!:\!0\}, \{S\!:\!\mathtt{o}, F\!:\!\mathtt{o}\to\mathtt{o}\}, \mathcal{R}_2, S)$, where $\mathcal{R}_2$ consists of:

$$S \to F\,\mathtt{a} \qquad S \to F\,\mathtt{b} \qquad F\,f \to \mathtt{br}\,f\,f \qquad F\,f \to F(\mathtt{br}\,\mathtt{a}\,f) \quad F\,f \to F(\mathtt{br}\,\mathtt{b}\,f).$$

The frontier language $\mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}_2)$ coincides with $\mathcal{L}_{\mathtt{w}}(\mathcal{G}_1)$ above.

The following is the main theorem we shall prove in this paper.

▶ **Theorem 4.** *For any order-$(n+1)$ word grammar $\mathcal{G}$ ($n \geq 0$), there exists an order-n tree grammar $\mathcal{G}'$ such that $\mathcal{L}_{\mathtt{w}}(\mathcal{G}) = \mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}')$.*

The converse of the above theorem also holds:

▶ **Theorem 5.** *For any order-n tree grammar $\mathcal{G}'$ such that no word in $\mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}')$ contains $\mathtt{e}$, there exists a word grammar $\mathcal{G}$ of order at most $n+1$ such that $\mathcal{L}_{\mathtt{w}}(\mathcal{G}) = \mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}')$.*

Since the construction of $\mathcal{G}$ is easy, we sketch it here; For $n \geq 1$, the grammar $\mathcal{G}$ is obtained by (i) changing the arity of each nullary terminal a ($\neq \mathtt{e}$) to one, i.e., $\Sigma_{\mathcal{G}}(a) := 1$, (ii) replacing the terminal $\mathtt{e}$ with a new non-terminal E of type $\mathtt{o}\to\mathtt{o}$, defined by $E\,x \to x$, and also the unique binary terminal $\mathtt{br}$ with a new non-terminal Br of type $(\mathtt{o}\to\mathtt{o})\to(\mathtt{o}\to\mathtt{o})\to(\mathtt{o}\to\mathtt{o})$, defined by $Br\,f\,g\,x \to f(g\,x)$, (iii) applying η-expansion to the right hand side of each (original) rule to add an order-0 argument, and (iv) adding new start symbol S' with rule $S' \to S\,\mathtt{e}$. For example, given the grammar $\mathcal{G}_2$ above, the following grammar is obtained:

$$\begin{array}{l} S' \to S\,\mathtt{e} \qquad S\,x \to F\,\mathtt{a}\,x \qquad S\,x \to F\,\mathtt{b}\,x \\ F\,f\,x \to Br\,f\,f\,x \qquad F\,f\,x \to F(Br\,\mathtt{a}\,f)\,x \qquad F\,f\,x \to F(Br\,\mathtt{b}\,f)\,x \\ E\,x \to x \qquad Br\,f\,g\,x \to f(g\,x). \end{array}$$

Theorem 4 is proved by two-step grammar transformations, both of which are based on intersection types. In the first step, we transform an order-$(n+1)$ word grammar $\mathcal{G}$ to an order-n tree grammar $\mathcal{G}''$ such that $\mathcal{L}_{\mathtt{w}}(\mathcal{G}) = \mathcal{L}_{\mathtt{leaf}}(\mathcal{G}'')\!\uparrow_{\mathtt{e}}$, where $\mathcal{L}\!\uparrow_{\mathtt{e}}$ is the word language obtained from $\mathcal{L}$ by removing all the occurrences of the special terminal $\mathtt{e}$; that is, the frontier language of $\mathcal{G}''$ is almost the same as $\mathcal{L}_{\mathtt{w}}(\mathcal{G})$, except that the former may contain multiple occurrences of the special, dummy symbol $\mathtt{e}$. In the second step, we clean up the grammar to eliminate $\mathtt{e}$ (except that a singleton tree $\mathtt{e}$ may be generated when $\epsilon \in \mathcal{L}_{\mathtt{w}}(\mathcal{G})$). The first and second steps shall be formalized in Sections 3 and 4 respectively.

For the target of the transformations, we use the following extended terms, in which a *set* of terms may occur in an argument position:

$$\begin{array}{rl} u \text{ (extended terms)} & ::= x \mid A \mid a \mid u_0 U \mid \lambda x.u \\ U & ::= \{u_1, \ldots, u_k\}\ (k \geq 1). \end{array}$$

Here, $u_0\,u_1$ is interpreted as just a shorthand for $u_0\{u_1\}$. Intuitively, $\{u_1,\ldots,u_k\}$ is considered a non-deterministic choice $u_1 + \cdots + u_k$, which (lazily) reduces to u_i non-deterministically. The typing rules are extended accordingly by:

$$\frac{\mathcal{K} \vdash_{\mathtt{ST}} u_0 : \kappa_1 \to \kappa \qquad \mathcal{K} \vdash_{\mathtt{ST}} U : \kappa_1}{\mathcal{K} \vdash_{\mathtt{ST}} u_0\,U : \kappa} \qquad\qquad \frac{\mathcal{K} \vdash_{\mathtt{ST}} u_i : \kappa \text{ for each } i \in \{1,\ldots,k\}}{\mathcal{K} \vdash_{\mathtt{ST}} \{u_1,\ldots,u_k\} : \kappa}$$

An *extended higher-order grammar* is the same as a higher-order grammar, except that each rewriting rule in $\mathcal{R}$ may be of the form $\lambda x_1 \cdots \lambda x_\ell.u$, where u may be an applicative extended term. The reduction rule for non-terminals is replaced by:

$$\frac{(A \to \lambda x_1 \cdots \lambda x_k.u) \in \mathcal{R} \qquad u' \in [U_1/x_1, \ldots, U_k/x_k]u}{A\,U_1 \cdots U_k \longrightarrow_{\mathcal{G}} u'}$$

where the substitution θu is defined by:

$$\theta a = \{a\} \qquad \theta x = \begin{cases} \theta(x) & (\text{if } x \in dom(\theta)) \\ \{x\} & (\text{otherwise}) \end{cases}$$
$$\theta(u_0 U) = \{v(\theta U) \mid v \in \theta u_0\} \qquad \theta\{u_1, \ldots, u_k\} = \theta u_1 \cup \cdots \cup \theta u_k\,.$$

Also, the other reduction rule is replaced by the following two rules:

$$\frac{u \longrightarrow_{\mathcal{G}} u' \qquad i \in \{1, \ldots, k\} \qquad \Sigma(a) = k}{a\,U_1 \cdots U_{i-1}\,\{u\}\,U_{i+1} \cdots U_k \longrightarrow_{\mathcal{G}} a\,U_1 \cdots U_{i-1}\,\{u'\}\,U_{i+1} \cdots U_k}$$

$$\frac{u \in U_i \qquad U_i \text{ is not a singleton} \qquad i \in \{1, \ldots, k\} \qquad \Sigma(a) = k}{a\,U_1 \cdots U_k \longrightarrow_{\mathcal{G}} a\,U_1 \cdots U_{i-1}\,\{u\}\,U_{i+1} \cdots U_k}$$

Note that unlike in the extended grammar introduced in [13], there is no requirement that each u_i in $\{u_1, \ldots, u_k\}$ is used at least once. Thus, the extended syntax does not change the expressive power of grammars. A term set $\{u_1, \ldots, u_k\}$ can be replaced by $A\,x_1 \cdots x_\ell$ with the rewriting rules $A\,x_1 \cdots x_\ell \to u_i$, where $\{x_1, \ldots, x_\ell\}$ is the set of variables occurring in some of $u_1, \ldots, u_k$. In other words, for any order-n extended grammar $\mathcal{G}$, there is an (ordinary) order-n grammar $\mathcal{G}'$ such that $\mathcal{L}(\mathcal{G}) = \mathcal{L}(\mathcal{G}')$.

3 Step 1: from order-$(n+1)$ grammars to order-n tree grammars

In this section, we show that for any order-$(n+1)$ grammar $\mathcal{G} = (\Sigma, \mathcal{N}, \mathcal{R}, S)$ such that $\Sigma(\mathtt{e}) = 0$ and $\Sigma(a) = 1$ for every $a \in dom(\Sigma) \setminus \{\mathtt{e}\}$, there exists an order-$n$ grammar $\mathcal{G}'$ such that $\Sigma_{\mathcal{G}'} = \{\mathtt{br} \mapsto 2, \mathtt{e} \mapsto 0\} \cup \{a \mapsto 0 \mid \Sigma(a) = 1\}$ and $\mathcal{L}_{\mathtt{w}}(\mathcal{G}) = \mathcal{L}_{\mathtt{leaf}}(\mathcal{G}')\uparrow_{\mathtt{e}}$.

For technical convenience, we assume below that, for every type κ occurring in $\mathcal{N}_{\mathcal{G}}(A)$ for some A, if κ is of the form $\mathtt{o} \to \kappa'$, then $\mathtt{order}(\kappa') \leq 1$. This does not lose generality, since any function $\lambda x : \mathtt{o}.t$ of type $\mathtt{o} \to \kappa'$ with $\mathtt{order}(\kappa') > 1$ can be replaced by the term $\lambda x' : \mathtt{o} \to \mathtt{o}.[x'\mathtt{e}/x]t$ of type $(\mathtt{o} \to \mathtt{o}) \to \kappa'$ (without changing the order of the term), and any term t of type $\mathtt{o}$ can be replaced by the term $K\,t$ of type $\mathtt{o} \to \mathtt{o}$, where K is a non-terminal of type $\mathtt{o} \to \mathtt{o} \to \mathtt{o}$, with rule $K\,x\,y \to x$. See [2] for the details of this transformation.

The basic idea of the transformation is to remove all the order-0 arguments (i.e., arguments of tree type $\mathtt{o}$). This reduces the order of each term by 1; for example, terms of types $\mathtt{o} \to \mathtt{o}$ and $(\mathtt{o} \to \mathtt{o}) \to \mathtt{o}$ will respectively be transformed to those of types $\mathtt{o}$ and $\mathtt{o} \to \mathtt{o}$. Order-0 arguments can indeed be removed as follows. Suppose we have a term $t_1\,t_2$ where $t_1 : \mathtt{o} \to \mathtt{o}$. If t_1 does not use the order-0 argument t_2, then we can simply replace $t_1\,t_2$ with $t_1^{\#}$ (where $t_1^{\#}$ is the result of recursively applying the transformation to t_1). If t_1 uses the argument t_2, the word generated by $t_1\,t_2$ must be of the form $w_1 w_2$, where w_2 is generated by t_2; in other words, t_1 can only append a word to the word generated by t_2. Thus, $t_1\,t_2$ can be transformed to $\mathtt{br}\;t_1^{\#}\;t_2^{\#}$, which can generate a tree whose frontier coincides with $w_1 w_2$ (if $\mathtt{e}$ is ignored). As a special case, a constant word $\mathtt{a}\,\mathtt{e}$ can be transformed to $\mathtt{br}\;\mathtt{a}\;\mathtt{e}$. As a little more complex example, consider the term $A\,(\mathtt{b}\,\mathtt{e})$, where A is defined by $A\,x \to \mathtt{a}\,x$. Since A uses the argument, the term $A\,(\mathtt{b}\,\mathtt{e})$ is transformed to $\mathtt{br}\;A\;(\mathtt{br}\;\mathtt{b}\;\mathtt{e})$. Since A no longer takes an argument, we substitute $\mathtt{e}$ for x in the body of the rule for A (and apply the transformation recursively to $\mathtt{a}\,\mathtt{e}$). The resulting rule for A is: $A \to \mathtt{br}\;\mathtt{a}\;\mathtt{e}$. Thus, the

term after the transformation generates the tree $\mathtt{br}\,(\mathtt{br}\,\mathtt{a}\,\mathtt{e})\,(\mathtt{br}\,\mathtt{b}\,\mathtt{e})$. Its frontier word is $\mathtt{aebe}$, which is equivalent to the word $\mathtt{ab}$ generated by the original term, up to removals of $\mathtt{e}$; recall that redundant occurrences of $\mathtt{e}$ will be removed by the second transformation. Note that the transformation sketched above depends on whether each order-0 argument is actually used or not. Thus, we introduce intersection types to express such information, and define the transformation as a type-directed one.

Simple types are refined to the following intersection types.

$$\delta ::= \mathtt{o} \mid \sigma \to \delta \qquad \sigma ::= \delta_1 \wedge \cdots \wedge \delta_k \quad (k \geq 0)$$

We write $\top$ for $\delta_1 \wedge \cdots \wedge \delta_k$ when $k = 0$. We assume some total order $<$ on intersection types, and require that $\delta_1 < \cdots < \delta_k$ whenever $\delta_1 \wedge \cdots \wedge \delta_k$ occurs in an intersection type. Intuitively, $(\delta_1 \wedge \cdots \wedge \delta_k) \to \delta$ describes a function that uses an argument according to types $\delta_1, \ldots, \delta_k$, and the returns a value of type δ. As a special case, the type $\top \to \mathtt{o}$ describes a function that ignores an argument, and returns a tree. Thus, according to the idea of the transformation sketched above, if x has type $\top \to \mathtt{o}$, $x\,t$ would be transformed to x; if x has type $\mathtt{o} \to \mathtt{o}$, $x\,t$ would be transformed to $\mathtt{br}\;x\;t^{\#}$. In the last example above, the type $\mathtt{o} \to \mathtt{o}$ should be interpreted as a function that uses the argument *just once*; otherwise the transformation to $\mathtt{br}\;x\;t^{\#}$ would be incorrect. Thus, the type $\mathtt{o}$ should be treated as a linear type, for which weakening and dereliction are disallowed. In contrast, we need not enforce, for example, that a value of the intersection type $\mathtt{o} \to \mathtt{o}$ should be used just once. Therefore, we classify intersection types into two kinds; one called *balanced*, which may be treated as non-linear types, and the other called *unbalanced*, which must be treated as linear types. For that purpose, we introduce two refinement relations $\delta ::_{\mathrm{b}} \kappa$ and $\delta ::_{\mathrm{u}} \kappa$; the former means that δ is a balanced intersection type of sort κ, and the latter means that δ is an unbalanced intersection type of sort κ. The relations are defined as follows, by mutual induction; k may be 0.

$$\frac{\delta_j ::_{\mathrm{u}} \kappa \qquad j \in \{1, \ldots, k\} \qquad \delta_i ::_{\mathrm{b}} \kappa \ (\text{for each } i \in \{1, \ldots, k\} \setminus \{j\})}{\delta_1 \wedge \cdots \wedge \delta_k ::_{\mathrm{u}} \kappa} \qquad \frac{\delta_i ::_{\mathrm{b}} \kappa \ (\text{for each } i \in \{1, \ldots, k\})}{\delta_1 \wedge \cdots \wedge \delta_k ::_{\mathrm{b}} \kappa}$$

$$\frac{}{\mathtt{o} ::_{\mathrm{u}} \mathtt{o}} \qquad \frac{\sigma ::_{\mathrm{b}} \kappa \qquad \delta ::_{\mathrm{u}} \kappa'}{\sigma \to \delta ::_{\mathrm{u}} \kappa \to \kappa'} \qquad \frac{\sigma ::_{\mathrm{u}} \kappa \qquad \delta ::_{\mathrm{u}} \kappa'}{\sigma \to \delta ::_{\mathrm{b}} \kappa \to \kappa'} \qquad \frac{\sigma ::_{\mathrm{b}} \kappa \qquad \delta ::_{\mathrm{b}} \kappa'}{\sigma \to \delta ::_{\mathrm{b}} \kappa \to \kappa'}$$

A type δ is called *balanced* if $\delta ::_{\mathrm{b}} \kappa$ for some κ, and called *unbalanced* if $\delta ::_{\mathrm{u}} \kappa$ for some κ. Intuitively, unbalanced types describe trees or closures that contain the end of a word (i.e., symbol $\mathtt{e}$). Intersection types that are neither balanced nor unbalanced are considered ill-formed, and excluded out. For example, the type $\mathtt{o} \to \mathtt{o} \to \mathtt{o}$ (as an intersection type) is ill-formed; since $\mathtt{o}$ is unbalanced, $\mathtt{o} \to \mathtt{o}$ must also be unbalanced according to the rules for arrow types, but it is actually balanced. Note that, in fact, no term can have the intersection type $\mathtt{o} \to \mathtt{o} \to \mathtt{o}$ in a word grammar. We write $\delta :: \kappa$ if $\delta ::_{\mathrm{b}} \kappa$ or $\delta ::_{\mathrm{u}} \kappa$.

We introduce a type-directed transformation relation $\Gamma \vdash t : \delta \Rightarrow u$ for terms, where Γ is a set of type bindings of the form $x : \delta$, called a *type environment*, t is a source term, and u is the image of the transformation, which may be an extended term. We write $\Gamma_1 \cup \Gamma_2$ for the union of Γ_1 and Γ_2; it is defined only if, whenever $x : \delta \in \Gamma_1 \cap \Gamma_2$, δ is balanced. In other words, unbalanced types are treated as linear types, whereas balanced ones as non-linear (or idempotent) types. We write $\mathbf{bal}(\Gamma)$ if δ is balanced for every $x : \delta \in \Gamma$.

The relation $\Gamma \vdash t : \delta \Rightarrow u$ is defined inductively by the following rules.

$$\frac{\mathbf{bal}(\Gamma)}{\Gamma, x : \delta \vdash x : \delta \Rightarrow x_\delta} \ (\textsc{Tr1-Var}) \qquad \frac{A :: \mathcal{N}(A) \qquad \mathbf{bal}(\Gamma)}{\Gamma \vdash A : \delta \Rightarrow A_\delta} \ (\textsc{Tr1-NT})$$

$$\frac{\mathbf{bal}(\Gamma)}{\Gamma \vdash \mathtt{e} : \mathtt{o} \Rightarrow \mathtt{e}} \quad (\textsc{Tr1-Const0}) \qquad \frac{\Sigma(a) = 1 \qquad \mathbf{bal}(\Gamma)}{\Gamma \vdash a : \mathtt{o} \to \mathtt{o} \Rightarrow a} \quad (\textsc{Tr1-Const1})$$

$$\frac{\begin{array}{c}\Gamma_0 \vdash s : \delta_1 \wedge \cdots \wedge \delta_k \to \delta \Rightarrow v \\ \Gamma_i \vdash t : \delta_i \Rightarrow U_i \text{ and } \delta_i \neq \mathtt{o} \text{ (for each } i \in \{1, \ldots, k\})\end{array}}{\Gamma_0 \cup \Gamma_1 \cup \cdots \cup \Gamma_k \vdash st : \delta \Rightarrow v U_1 \cdots U_k} \quad (\textsc{Tr1-App1})$$

$$\frac{\Gamma_0 \vdash s : \mathtt{o} \to \delta \Rightarrow V \qquad \Gamma_1 \vdash t : \mathtt{o} \Rightarrow U}{\Gamma_0 \cup \Gamma_1 \vdash st : \delta \Rightarrow \mathtt{br}\, V\, U} \quad (\textsc{Tr1-App2})$$

$$\frac{\Gamma \vdash t : \delta \Rightarrow u_i \text{ (for each } i \in \{1, \ldots, k\}) \qquad k \geq 1}{\Gamma \vdash t : \delta \Rightarrow \{u_1, \ldots, u_k\}} \quad (\textsc{Tr1-Set})$$

$$\frac{\begin{array}{c}\Gamma, x : \delta_1, \ldots, x : \delta_k \vdash t : \delta \Rightarrow u \qquad x \notin dom(\Gamma) \\ \delta_i \neq \mathtt{o} \text{ for each } i \in \{1, \ldots, k\}\end{array}}{\Gamma \vdash \lambda x.t : \delta_1 \wedge \cdots \wedge \delta_k \to \delta \Rightarrow \lambda x_{\delta_1} \cdots \lambda x_{\delta_k}.u} \quad (\textsc{Tr1-Abs1})$$

$$\frac{\Gamma, x : \mathtt{o} \vdash t : \delta \Rightarrow u}{\Gamma \vdash \lambda x.t : \mathtt{o} \to \delta \Rightarrow [\mathtt{e}/x_{\mathtt{o}}]u} \quad (\textsc{Tr1-Abs2})$$

In rule (Tr1-Var), a variable is replicated for each type. This is because the image of the transformation of a term substituted for x is different depending on the type of the term; accordingly, in rule (Tr1-Abs1), bound variables are also replicated, and in rule (Tr1-App1), arguments are replicated. In rule (Tr1-NT), a non-terminal is also replicated for each type. In rules (Tr1-Const0) and (Tr1-Const1), constants are mapped to themselves; however, the arities of all the constants become 0. In these rules, Γ may contain only bindings on balanced types.

In rule (Tr1-App1), the first premise indicates that the function s uses the argument t according to types $\delta_1, \ldots, \delta_k$. Since the image of the transformation of t depends on its type, we replicate the argument to $U_1, \ldots, U_k$. For each type δ_i, the result of the transformation is not unique (but finite); thus, we represent the image of the transformation as a *set* U_i of terms. (Recall the remark at the end of Section 2 that a set of terms can be replaced by an ordinary term by introducing auxiliary non-terminals.) For example, consider a term $A(x\,y)$. It can be transformed to $A_{\delta_1 \to \delta}\{x_{\delta_0 \to \delta_1} y_{\delta_0}, x_{\delta_0' \to \delta_1} y_{\delta_0'}\}$ under the type environment $\{x : \delta_0 \to \delta_1, x : \delta_0' \to \delta_1, y : \delta_0, y : \delta_0'\}$. Note that k in rule (Tr1-App1) (and also (Tr1-Abs1)) may be 0, in which case the argument disappears in the image of the transformation.

In rule (Tr1-App2), as explained at the beginning of this section, the argument t of type $\mathtt{o}$ is removed from s and instead attached as a sibling node of the tree generated by (the transformation image of) s. Accordingly, in rule (Tr1-Abs2), the binder for x is removed and x in the body of the abstraction is replaced with the empty tree $\mathtt{e}$. In rule (Tr1-Set), type environments are shared. This is because $\{u_1, \ldots, u_k\}$ represents the choice $u_1 + \cdots + u_k$; unbalanced (i.e. linear) values should be used in the same manner in $u_1, \ldots, u_k$.

The transformation rules for rewriting rules and grammars are given by:

$$\frac{\emptyset \vdash \lambda x_1. \cdots \lambda x_k.t : \delta \Rightarrow \lambda x_1'. \cdots \lambda x_\ell'.u \qquad \delta :: \mathcal{N}(A)}{(A\, x_1\, \cdots\, x_k \to t) \Rightarrow (A_\delta\, x_1'\, \cdots\, x_\ell' \to u)} \quad (\textsc{Tr1-Rule})$$

$$\frac{\Sigma' = \{\mathtt{br} \mapsto 2, \mathtt{e} \mapsto 0\} \cup \{a \mapsto 0 \mid \Sigma(a) = 1\} \quad \mathcal{N}' = \{A_\delta : [\![\delta :: \kappa]\!] \mid \mathcal{N}(A) = \kappa \wedge \delta :: \kappa\} \quad \mathcal{R}' = \{r' \mid \exists r \in \mathcal{R}. r \Rightarrow r'\}}{(\Sigma, \mathcal{N}, \mathcal{R}, S) \Rightarrow (\Sigma', \mathcal{N}', \mathcal{R}', S_{\mathtt{o}})} \quad (\textsc{Tr1-Gram})$$

Here, $[\![\delta :: \kappa]\!]$ is defined by:

$$[\![\delta :: \kappa]\!] = \mathtt{o} \qquad (\text{if } \mathtt{order}(\kappa) \leq 1)$$
$$[\![(\delta_1 \wedge \cdots \wedge \delta_k \to \delta) :: (\kappa_0 \to \kappa)]\!] = [\![\delta_1 :: \kappa_0]\!] \to \ldots \to [\![\delta_k :: \kappa_0]\!] \to [\![\delta :: \kappa]\!] \qquad (\text{if } \mathtt{order}(\kappa_0 \to \kappa) > 1)$$

▶ **Example 6.** Recall the grammar $\mathcal{G}_1$ in Example 3. For the term $\lambda f.\lambda x.\mathtt{a}(f\,x)$ of the rule for A, we have the following derivation:

$$\dfrac{\dfrac{\dfrac{}{\emptyset \vdash \mathtt{a} : \mathtt{o} \to \mathtt{o} \Rightarrow \mathtt{a}}\ \textsc{Const1} \quad \dfrac{\dfrac{}{f : \mathtt{o} \to \mathtt{o} \vdash f : \mathtt{o} \to \mathtt{o} \Rightarrow f_{\mathtt{o}\to\mathtt{o}}}\ \textsc{Var} \quad \dfrac{}{x : \mathtt{o} \vdash x : \mathtt{o} \Rightarrow x_{\mathtt{o}}}\ \textsc{Var}}{f : \mathtt{o} \to \mathtt{o}, x : \mathtt{o} \vdash f\,x : \mathtt{o} \Rightarrow \mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, x_{\mathtt{o}}}\ \textsc{App2}}{f : \mathtt{o} \to \mathtt{o}, x : \mathtt{o} \vdash \mathtt{a}(f\,x) : \mathtt{o} \Rightarrow \mathtt{br}\,\mathtt{a}\,(\mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, x_{\mathtt{o}})}\ \textsc{App2}}{f : \mathtt{o} \to \mathtt{o} \vdash \lambda x.\mathtt{a}(f\,x) : \mathtt{o} \to \mathtt{o} \Rightarrow \mathtt{br}\,\mathtt{a}\,(\mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, \mathtt{e})}\ \textsc{Abs2}}{\emptyset \vdash \lambda f.\lambda x.\mathtt{a}(f\,x) : (\mathtt{o} \to \mathtt{o}) \to \mathtt{o} \to \mathtt{o} \Rightarrow \lambda f_{\mathtt{o}\to\mathtt{o}}.\mathtt{br}\,\mathtt{a}\,(\mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, \mathtt{e})}\ \textsc{Abs1}$$

Notice that the argument x has been removed, and the result of the transformation has type $\mathtt{o} \to \mathtt{o}$. The whole grammar is transformed to the grammar consisting of the following rules.

$$S_{\mathtt{o}} \to F_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}}\,\mathtt{a} \qquad S_{\mathtt{o}} \to F_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}}\,\mathtt{b}$$
$$A_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}\to\mathtt{o}}\, f_{\mathtt{o}\to\mathtt{o}} \to \mathtt{br}\,\mathtt{a}\,(\mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, \mathtt{e}) \qquad B_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}\to\mathtt{o}}\, f_{\mathtt{o}\to\mathtt{o}} \to \mathtt{br}\,\mathtt{b}\,(\mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, \mathtt{e})$$
$$F_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}}\, f_{\mathtt{o}\to\mathtt{o}} \to \mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\,(\mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, \mathtt{e}) \qquad F_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}}\, f_{\mathtt{o}\to\mathtt{o}} \to F_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}}(A_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}\to\mathtt{o}}\, f_{\mathtt{o}\to\mathtt{o}})$$
$$F_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}}\, f_{\mathtt{o}\to\mathtt{o}} \to F_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}}(B_{(\mathtt{o}\to\mathtt{o})\to\mathtt{o}\to\mathtt{o}}\, f_{\mathtt{o}\to\mathtt{o}}).$$

Here, we have omitted rules that are unreachable from $S_{\mathtt{o}}$. For example, the rule

$$F_{(\top\to\mathtt{o})\wedge(\mathtt{o}\to\mathtt{o})\to\mathtt{o}}\, f_{\top\to\mathtt{o}}\, f_{\mathtt{o}\to\mathtt{o}} \to \mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, f_{\top\to\mathtt{o}}$$

may be obtained from the following derivation, but it is unreachable from $S_{\mathtt{o}}$, since F is never called with an argument of type $(\top \to \mathtt{o}) \wedge (\mathtt{o} \to \mathtt{o})$.

$$\dfrac{\dfrac{\dfrac{}{f : \mathtt{o} \to \mathtt{o} \vdash f \Rightarrow f_{\mathtt{o}\to\mathtt{o}}}\ \textsc{Var} \quad \dfrac{\dfrac{}{f : \top \to \mathtt{o} \vdash f : \top \to \mathtt{o} \Rightarrow f_{\top\to\mathtt{o}}}\ \textsc{Var}}{f : \top \to \mathtt{o} \vdash f\,\mathtt{e} : \mathtt{o} \Rightarrow f_{\top\to\mathtt{o}}}\ \textsc{App1}}{f : \top \to \mathtt{o}, f : \mathtt{o} \to \mathtt{o} \vdash f(f\,\mathtt{e}) : \mathtt{o} \Rightarrow \mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, f_{\top\to\mathtt{o}}}\ \textsc{App2}}{\emptyset \vdash \lambda f.f(f\,\mathtt{e}) : (\top \to \mathtt{o}) \wedge (\mathtt{o} \to \mathtt{o}) \to \mathtt{o} \Rightarrow \lambda f_{\top\to\mathtt{o}}.\lambda f_{\mathtt{o}\to\mathtt{o}}.\mathtt{br}\, f_{\mathtt{o}\to\mathtt{o}}\, f_{\top\to\mathtt{o}}}\ \textsc{Abs1}$$

The following theorem states the correctness of the first transformation.

▶ **Theorem 7.** *Let $\mathcal{G}$ be an order-$(n+1)$ word grammar. If $\mathcal{G} \Rightarrow \mathcal{G}''$, then $\mathcal{G}''$ is an (extended) grammar of order at most n. Furthermore, $\mathcal{L}_{\mathtt{w}}(\mathcal{G}) = \mathcal{L}_{\mathtt{leaf}}(\mathcal{G}'')\uparrow_{\mathtt{e}}$.*

4 Step 2: removing dummy symbols

We now describe the second step for eliminating redundant symbols $\mathtt{e}$, which have been introduced by (Tr1-Abs2). By the remark at the end of Section 2, we assume that the result of the first transformation is an ordinary grammar, not containing extended terms. We also assume that $\mathtt{br}$ occurs only in the fully applied form. This does not lose generality, because otherwise we can replace $\mathtt{br}$ by a new non-terminal Br and add the rule $Br\,x\,y \to \mathtt{br}\,x\,y$.

The idea of the transformation is to use intersection types to distinguish between terms that generate trees consisting of only $\mathtt{br}$ and $\mathtt{e}$, and those that generate trees containing other arity-0 terminals. We assign the type $\mathtt{o}_\epsilon$ to the former terms, and $\mathtt{o}_+$ to the latter. A term $\mathtt{br}\,t_0\,t_1$ is transformed to (i) $\mathtt{br}\,t_0^\#\,t_1^\#$ if both t_0 and t_1 have type $\mathtt{o}_+$ (where $t_i^\#$ is the image of the transformation of t_i), (ii) $t_i^\#$ if t_i has type $\mathtt{o}_+$ and t_{1-i} has type $\mathtt{o}_\epsilon$, and (iii) $\mathtt{e}$ if both t_0 and t_1 have type $\mathtt{o}_\epsilon$. As in the transformation of the previous section, we replicate each non-terminal and variable for each intersection type. For example, the nonterminal $A : \mathtt{o} \to \mathtt{o}$ defined by $A\,x \to x$ would be replicated to $A_{\mathtt{o}_+\to\mathtt{o}_+}$ and $A_{\mathtt{o}_\epsilon\to\mathtt{o}_\epsilon}$.

We first define the set of intersection types by:

$$\xi ::= \mathtt{o}_\epsilon \mid \mathtt{o}_+ \mid \xi_1 \wedge \cdots \wedge \xi_k \to \xi$$

We assume some total order $<$ on intersection types, and require that whenever we write $\xi_1 \wedge \cdots \wedge \xi_k$, $\xi_1 < \cdots < \xi_k$ holds. We define the refinement relation $\xi :: \kappa$ inductively by: (i) $\mathtt{o}_\epsilon :: \mathtt{o}$, (ii) $\mathtt{o}_+ :: \mathtt{o}$, and (iii) $(\xi_1 \wedge \cdots \wedge \xi_k \to \xi) :: (\kappa_1 \to \kappa_2)$ if $\xi :: \kappa_2$ and $\xi_i :: \kappa_1$ for every $i \in \{1, \ldots, k\}$. We consider only types ξ such that $\xi :: \kappa$ for some κ. For example, we forbid an ill-formed type like $\mathtt{o}_+ \wedge (\mathtt{o}_+ \to \mathtt{o}_+) \to \mathtt{o}_+$.

We introduce a type-based transformation relation $\Xi \vdash t : \xi \Rightarrow u$, where Ξ is a type environment (i.e., a set of bindings of the form $x : \xi$), t is a source term, ξ is the type of t, and u is the result of transformation. The relation is defined inductively by the rules below.

$$\frac{}{\Xi, x : \xi \vdash x : \xi \Rightarrow x_\xi}\ (\textsc{Tr2-Var}) \qquad \frac{}{\Xi \vdash \mathtt{e} : \mathtt{o}_\epsilon \Rightarrow \mathtt{e}}\ (\textsc{Tr2-Const0}) \qquad \frac{\Sigma(a) = 0 \qquad a \neq \mathtt{e}}{\Xi \vdash a : \mathtt{o}_+ \Rightarrow a}\ (\textsc{Tr2-Const1})$$

$$\frac{\Xi \vdash t_0 : \xi_0 \Rightarrow u_0 \qquad \Xi \vdash t_1 : \xi_1 \Rightarrow u_1 \qquad (u, \xi) = \begin{cases} (\mathtt{br}\,u_0\,u_1, \mathtt{o}_+) & \text{if } \xi_0 = \xi_1 = \mathtt{o}_+ \\ (u_i, \mathtt{o}_+) & \text{if } \xi_i = \mathtt{o}_+ \text{ and } \xi_{1-i} = \mathtt{o}_\epsilon \\ (\mathtt{e}, \mathtt{o}_\epsilon) & \text{if } \xi_0 = \xi_1 = \mathtt{o}_\epsilon \end{cases}}{\Xi \vdash \mathtt{br}\,t_0\,t_1 : \xi \Rightarrow u}\ (\textsc{Tr2-Const2})$$

$$\frac{\xi :: \mathcal{N}(F) \qquad A\,x_1\,\cdots\,x_k \to t \in \mathcal{R} \qquad \emptyset \vdash \lambda x_1.\cdots\lambda x_k.t : \xi \Rightarrow \lambda y_1.\cdots\lambda y_\ell.u}{\Xi \vdash A : \xi \Rightarrow A_\xi}\ (\textsc{Tr2-NT})$$

$$\frac{\Xi \vdash s : \xi_1 \wedge \cdots \wedge \xi_k \to \xi \Rightarrow v \qquad \Xi \vdash t : \xi_i \Rightarrow U_i \text{ (for each } i \in \{1, \ldots, k\})}{\Xi \vdash st : \xi \Rightarrow vU_1 \cdots U_k}\ (\textsc{Tr2-App})$$

$$\frac{\Xi \vdash t : \xi \Rightarrow u_i \text{ (for each } i \in \{1, \ldots, k\}) \qquad k \geq 1}{\Xi \vdash t : \xi \Rightarrow \{u_1, \ldots, u_k\}}\ (\textsc{Tr2-Set})$$

$$\frac{\Xi, x : \xi_1, \ldots, x : \xi_k \vdash t : \xi \Rightarrow u}{\Xi \vdash \lambda x.t : \xi_1 \wedge \cdots \wedge \xi_k \to \xi \Rightarrow \lambda x_{\xi_1} \cdots \lambda x_{\xi_k}.u}\ (\textsc{Tr2-Abs})$$

The transformation of rewriting rules and grammars is defined by:

$$\frac{\emptyset \vdash \lambda x_1.\cdots\lambda x_k.t : \xi \Rightarrow \lambda x'_1.\cdots\lambda x'_\ell.t' \qquad \xi :: \mathcal{N}(A)}{(A \to \lambda x_1.\cdots\lambda x_k.t) \Rightarrow (A_\xi \to \lambda x'_1.\cdots\lambda x'_\ell.t')}\ (\textsc{Tr2-Rule})$$

$$\frac{\begin{array}{c}\mathcal{N}' = \{A_\xi : [\![\xi]\!] \mid \mathcal{N}(A) = \kappa \wedge \xi :: \kappa\} \\ \mathcal{R}' = \{r' \mid \exists r \in \mathcal{R}.r \Rightarrow r'\} \cup \{S' \to S_{\mathtt{o}_\epsilon}, S' \to S_{\mathtt{o}_+}\}\end{array}}{(\Sigma, \mathcal{N}, \mathcal{R}, S) \Rightarrow (\Sigma, \mathcal{N}', \mathcal{R}', S')}\ (\textsc{Tr2-Gram})$$

Here, $[\![\xi]\!]$ is defined by:

$$[\![\mathtt{o}_\epsilon]\!] = [\![\mathtt{o}_+]\!] = \mathtt{o} \qquad [\![\,\xi_1 \wedge \cdots \wedge \xi_k \to \xi]\!] = [\![\xi_1]\!] \to \cdots \to [\![\xi_k]\!] \to [\![\xi]\!]$$

We explain some key rules. In (Tr2-Var) we replicate a variable for each type, as in the first transformation. The rules (Tr2-Const0) and (Tr2-Const1) are for nullary constants, which are mapped to themselves. We assign type $\mathtt{o}_\epsilon$ to $\mathtt{e}$ and $\mathtt{o}_+$ to the other constants. The rule (Tr2-Const2) is for the binary tree constructor $\mathtt{br}$. As explained above, we eliminate terms that generate empty trees (those consisting of only $\mathtt{br}$ and $\mathtt{e}$). For example, if $\xi_0 = \mathtt{o}_\epsilon$ and $\xi_1 = \mathtt{o}_+$, then t_0 may generate an empty tree; thus, the whole term is transformed to u_1.

The rule (Tr2-NT) replicates a terminal for each type, as in the case of variables. The middle and rightmost premises require that there is some body t of A that can indeed be transformed according to type ξ. Without this condition, for example, A defined by the rule $A \to A$ would be transformed to $A_{\mathtt{o}_\epsilon}$ by $\emptyset \vdash A : \mathtt{o}_\epsilon \Rightarrow A_{\mathtt{o}_\epsilon}$, but $A_{\mathtt{o}_\epsilon}$ diverges and does not produce an empty tree. That would make the rule (Tr2-Const2) unsound: when a source term is $\mathtt{br}\,A\,\mathtt{a}$, it would be transformed to $\mathtt{a}$, but while the original term does not generate a tree, the result of the transformation does. In short, the two premises are required to ensure that whenever $\emptyset \vdash t : \mathtt{o}_\epsilon \Rightarrow u$ holds, t can indeed generate an empty tree. In (Tr2-App), the argument is replicated for each type. Unlike in the transformation in the previous section, type environments can be shared among the premises, since linearity does not matter here. The other rules for terms are analogous to those in the first transformation.

In rule (Tr2-Gram) for grammars, we prepare a start symbol S' and add the rules $S' \to S_{\mathtt{o}_\epsilon}, S' \to S_{\mathtt{o}_+}$. We remark that the rewriting rule for $S_{\mathtt{o}_\epsilon}$ (resp. $S_{\mathtt{o}_+}$) is generated only if the original grammar generates an empty (resp. non-empty) tree. For example, in the extreme case where $\mathcal{R} = \{S \to S\}$, we have $\mathcal{R}' = \{S' \to S_{\mathtt{o}_\epsilon}, S' \to S_{\mathtt{o}_+}\}$, without any rules to rewrite $S_{\mathtt{o}_\epsilon}$ or $S_{\mathtt{o}_+}$.

▶ **Example 8.** Let us consider the grammar $\mathcal{G}_3 = (\Sigma, \mathcal{N}, \mathcal{R}, S)$ where $\mathcal{N} = \{S : \mathtt{o}, A : \mathtt{o} \to \mathtt{o}, B : \mathtt{o} \to \mathtt{o}, F : \mathtt{o} \to \mathtt{o}\}$, and $\mathcal{R}$ consists of:

$$S \to F\,\mathtt{a} \qquad S \to F\,\mathtt{b} \qquad A\,f \to \mathtt{br}\,\mathtt{a}\,(\mathtt{br}\,f\,\mathtt{e}) \qquad B\,f \to \mathtt{br}\,\mathtt{b}\,(\mathtt{br}\,f\,\mathtt{e})$$
$$F\,f \to \mathtt{br}\,f\,(\mathtt{br}\,f\,\mathtt{e}) \qquad F\,f \to F(A\,f) \qquad F\,f \to F(B\,f)$$

It is the same as the grammar obtained in Example 6, except that redundant subscripts on non-terminals and variables have been removed. The body of the rule for A is transformed as follows.

$$\dfrac{\dfrac{}{f : \mathtt{o}_+ \vdash \mathtt{a} : \mathtt{o}_+ \Rightarrow \mathtt{a}}\ \textsc{Const1} \qquad \dfrac{\dfrac{\dfrac{}{f : \mathtt{o}_+ \vdash f : \mathtt{o}_+ \Rightarrow f_{\mathtt{o}_+}}\ \textsc{Var} \quad \dfrac{}{f : \mathtt{o}_+ \vdash \mathtt{e} : \mathtt{o}_\epsilon \Rightarrow \mathtt{e}}\ \textsc{Const0}}{f : \mathtt{o}_+ \vdash \mathtt{br}\,f\,\mathtt{e} : \mathtt{o}_+ \Rightarrow f_{\mathtt{o}_+}}\ \textsc{Const2}}{f : \mathtt{o}_+ \vdash \mathtt{br}\,\mathtt{a}\,(\mathtt{br}\,f\,\mathtt{e}) : \mathtt{o}_+ \Rightarrow \mathtt{br}\,\mathtt{a}\,f_{\mathtt{o}_+}}\ \textsc{Const2}}{\emptyset \vdash \lambda f.\mathtt{br}\,\mathtt{a}\,(\mathtt{br}\,f\,\mathtt{e}) : \mathtt{o}_+ \to \mathtt{o}_+ \Rightarrow \lambda f_{\mathtt{o}_+}.\mathtt{br}\,\mathtt{a}\,f_{\mathtt{o}_+}}\ \textsc{Abs}$$

The whole rules are transformed to:

$$S' \to S_{\mathtt{o}_+} \qquad S' \to S_{\mathtt{o}_\epsilon} \qquad S_{\mathtt{o}_+} \to F_{\mathtt{o}_+ \to \mathtt{o}_+}\,\mathtt{a} \qquad S_{\mathtt{o}_+} \to F_{\mathtt{o}_+ \to \mathtt{o}_+}\,\mathtt{b}$$
$$A_{\mathtt{o}_+ \to \mathtt{o}_+}\,f_{\mathtt{o}_+} \to \mathtt{br}\,\mathtt{a}\,f_{\mathtt{o}_+} \qquad B_{\mathtt{o}_+ \to \mathtt{o}_+}\,f_{\mathtt{o}_+} \to \mathtt{br}\,\mathtt{b}\,f_{\mathtt{o}_+} \qquad F_{\mathtt{o}_+ \to \mathtt{o}_+}\,f_{\mathtt{o}_+} \to \mathtt{br}\,f_{\mathtt{o}_+}\,f_{\mathtt{o}_+}$$
$$F_{\mathtt{o}_+ \to \mathtt{o}_+}\,f_{\mathtt{o}_+} \to F_{\mathtt{o}_+ \to \mathtt{o}_+}(A_{\mathtt{o}_+ \to \mathtt{o}_+}\,f_{\mathtt{o}_+}) \qquad F_{\mathtt{o}_+ \to \mathtt{o}_+}\,f_{\mathtt{o}_+} \to F_{\mathtt{o}_+ \to \mathtt{o}_+}(B_{\mathtt{o}_+ \to \mathtt{o}_+}\,f_{\mathtt{o}_+})$$

Here, we have omitted rules on non-terminals unreachable from S'.

The following theorem claims the correctness of the transformation. The proof is given in [2]. The main theorem (Theorem 4) follows from Theorems 7, 9, and the fact that any order-m grammar with $m < n$ can be converted to an order-n grammar by adding a dummy non-terminal of order n.

▶ **Theorem 9.** *Let $\mathcal{G} = (\Sigma, \mathcal{N}, \mathcal{R}, S)$ be an order-n tree grammar. If $\mathcal{G} \Rightarrow \mathcal{G}'$, then $\mathcal{G}'$ is a tree grammar of order at most n, and $\mathcal{L}_{\mathtt{leaf}}(\mathcal{G})\uparrow_{\mathtt{e}} = \mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}')$.*

5 Applications

5.1 Unsafe order-2 word languages = safe order-2 word languages

As mentioned in Section 1, many of the earlier results on higher-order grammars [6, 10] were for the subclass called *safe* higher-order grammars. In safe grammars, the (simple) types of terms are restricted to *homogeneous types* [6] of the form $\kappa_1 \to \cdots \to \kappa_k \to \mathtt{o}$, where $\mathtt{order}(\kappa_1) \geq \cdots \geq \mathtt{order}(\kappa_k)$, and arguments of the same order must be supplied simultaneously. For example, if A has type $(\mathtt{o} \to \mathtt{o}) \to (\mathtt{o} \to \mathtt{o}) \to \mathtt{o}$, then the term $f\,(A\,f\,f)$ where $f : \mathtt{o} \to \mathtt{o}$ is valid, but $g\,(A\,f)$ where $g : ((\mathtt{o} \to \mathtt{o}) \to \mathtt{o}) \to \mathtt{o}, f : \mathtt{o} \to \mathtt{o}$ is not: the partial application $A\,f$ is disallowed, since A expects another order-1 argument. *Unsafe* grammars (which are just called higher-order grammars in the present paper) are higher-order grammars without the safety restriction.

For order-2 word languages, Aehlig et al. [1] have shown that safety is not a genuine restriction. Our result in the present paper provides an alternative, short proof. Given an unsafe order-2 word grammar $\mathcal{G}$, we can obtain an equivalent order-1 grammar $\mathcal{G}'$ such that $\mathcal{L}_{\mathtt{w}}(\mathcal{G}) = \mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}')$. Note that $\mathcal{G}'$ is necessarily safe, since it is order-1 and hence there are no partial applications. Now, apply the backward transformation sketched in Section 2 to obtain an order-2 word grammar $\mathcal{G}''$ such that $\mathcal{L}_{\mathtt{w}}(\mathcal{G}'') = \mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}')$. By the construction of the backward transformation, $\mathcal{G}''$ is clearly a safe grammar: Since the type of each term occurring in $\mathcal{G}'$ is $\mathtt{o} \to \cdots \to \mathtt{o} \to \mathtt{o}$, the type of the corresponding term of $\mathcal{G}''$ is $(\mathtt{o} \to \mathtt{o}) \to \cdots \to (\mathtt{o} \to \mathtt{o}) \to (\mathtt{o} \to \mathtt{o})$. Since all the arguments of type $\mathtt{o}$ are applied simultaneously in $\mathcal{G}'$, all the arguments of type $\mathtt{o} \to \mathtt{o}$ are also applied simultaneously in $\mathcal{G}''$. Thus, for any unsafe order-2 word grammar, there exists an equivalent safe order-2 word grammar.

5.2 Diagonal problem

The diagonal problem [5] asks, given a (word or tree) language L and a set S of symbols, whether for all n, there exists $w_n \in L$ such that $\forall a \in S. |w_n|_a \geq n$. Here, $|w|_a$ denotes the number of occurrences of a in w. A decision algorithm for the diagonal problem can be used for computing downward closures [21], which in turn have applications to program verification. Hague et al. [9] recently showed that the diagonal problem is decidable for safe higher-order word languages, and Clemente et al. [4] extended the result for unsafe tree languages. For the single letter case of the diagonal problem (where $|S| = 1$), we can obtain an alternative proof as follows. First, following the approach of Hague et al. [9], we can use logical reflection to reduce the single letter diagonal problem for an unsafe order-n tree language to that for the path language of an unsafe order-n tree language. We can then use our transformation to reduce the latter to the single letter diagonal problem for an unsafe order-$(n-1)$ tree language.

5.3 Context-sensitivity of order-3 word languages

By using the result of this paper and the context-sensitivity of order-2 tree languages [13], we can prove that any order-3 word language is context-sensitive, i.e., the membership problem for an order-3 word language can be decided in non-deterministic linear space. Given an order-3 word grammar $\mathcal{G}$, we first construct a corresponding order-2 tree grammar $\mathcal{G}'$ in

advance. Given a word w, we can construct a tree π whose frontier word is w one by one, and check whether $\pi \in \mathcal{L}(\mathcal{G}')$. Since the size of π is linearly bounded by the length $|w|$ of w, $\pi \stackrel{?}{\in} \mathcal{L}(\mathcal{G}')$ can be checked in space linear with respect to $|w|$. Thus, $w \in \mathcal{L}_{\mathtt{w}}(\mathcal{G})$ can be decided in non-deterministic linear space (with respect to the size of w).

6 Related Work

As already mentioned in Section 1, higher-order grammars have been extensively studied in 1980's [6, 7, 8], but most of those results have been for safe grammars. In particular, Damm [6] has shown an analogous result for safe grammars, but his proof does not extend to the unsafe case.

As also mentioned in Section 1, intersection types have been used in recent studies of (unsafe) higher-order grammars. In particular, type-based transformations of grammars and λ-terms have been studied in [14, 13, 4]. Clement et al. [4], independently from ours, gave a transformation from an order-$(n+1)$ "narrow" tree language (which subsumes a word language as a special case) to an order-n tree language; this transformation preserves the number of occurrences of each symbol in each tree. When restricted to word languages, our result is stronger in that our transformation is guaranteed to preserve the order of symbols as well, and does not add any additional leaf symbols (though they are introduced in the intermediate step); consequently, our proofs are more involved. They use different intersection types, but the overall effect of their transformation seems similar to that of our first transformation. Thus, it may actually be the case that their transformation also preserves the order of symbols, although they have not proved so.

7 Conclusion

We have shown that for any unsafe order-$(n+1)$ word grammar $\mathcal{G}$, there exists an unsafe order-n tree grammar $\mathcal{G}'$ whose frontier language coincides with the word language $\mathcal{L}_{\mathtt{w}}(\mathcal{G})$. The proof is constructive in that we provided (two-step) transformations that indeed construct $\mathcal{G}'$ from $\mathcal{G}$. The transformations are based on a combination of linear/non-linear intersection types, which may be interesting in its own right. As Damm [6] suggested, we expect the result to be useful for further studies of higher-order languages; in fact, we have discussed a few applications of the result.

Acknowledgments. We would like to thank Takeshi Tsukada for helpful discussions and thank Pawel Parys for information about the related work [4].

Abstract

Starting from Boolean algebras of languages closed under quotients and using duality theoretic insights, we derive the notion of *Boolean spaces with internal monoids* as recognisers for arbitrary formal languages of finite words over finite alphabets. This leads to recognisers and syntactic spaces in a setting that is well-suited for applying tools from Stone duality as applied in semantics.

The main focus of the paper is the development of topo-algebraic constructions pertinent to the treatment of languages given by logic formulas. In particular, using the standard semantic view of quantification as projection, we derive a notion of *Schützenberger product* for Boolean spaces with internal monoids. This makes heavy use of the Vietoris construction – and its dual functor – which is central to the coalgebraic treatment of classical modal logic.

We show that the unary Schützenberger product for spaces yields a recogniser for the language of all models of the formula $\exists x.\Phi(x)$, when applied to a recogniser for the language of all models of $\Phi(x)$. Further, we generalise global and local versions of the theorems of Schützenberger and Reutenauer characterising the languages recognised by the binary Schützenberger product.

Finally, we provide an equational characterisation of Boolean algebras obtained by local Schützenberger product with the one element space based on an Egli-Milner type condition on generalised factorisations of ultrafilters on words.

1 Introduction

This contribution lies at the interface of two distinct areas: one in semantics concerned with modelling binding of variables, and the other in the theory of formal languages and the search for separation results for complexity classes based on a generalisation of the algebraic theory of regular languages [22, 12]. In semantics of propositional and modal logics, Stone duality and coalgebraic logic have had great success, but in the presence of quantifiers more

general categorical semantics is required. Quantifiers change the set of free variables in a formula, leading to a notion of indexing formulas by their contexts of free variables. In the theory of regular languages, classes of models indexed by finite alphabets have long been studied in the form of varieties of languages [5]. There, one considers Boolean algebras of languages closed under quotients over a category of finite alphabets with monoid morphisms between the corresponding finitely generated monoids. This paper is intended as a first step towards establishing a connection between categorical semantics of logics and fibrational approaches in language theory.

We follow the line set by [7, 8] and [9], which exploits the connection between the algebraic theory of formal languages and Stone duality, see also [2, 1]. In this paper we are interested in the effect that first-order quantifiers have at the level of the algebraic recognisers. This is well understood in the regular case, where a plethora of powerful tools, in the form of Schützenberger, Maltsev, and block products of finite (and profinite) monoids, is used. Beyond the regular setting, we take as a departure point classes of languages equipped with actions of the free monoid over a finite set and the standard view of existential quantification as projection, and we derive – via Stone duality – our notion of recognisers and of unary Schützenberger product. Our analysis arrives at an extension of the Schützenberger product, which was originally introduced in [19] as a means of studying the concatenation product of regular languages and was further extended in [21] and [16] to arbitrary arity and to ordered monoids, respectively. Reutenauer [18], and Pin [15] in the ordered setting, have provided exact characterisations of the regular languages accepted by the Schützenberger product.

In the setting of regular languages, equations have played an essential rôle in providing decidability results for varieties of languages and various generalisations thereof. For classes of arbitrary languages decidability is not to be expected and separation of classes is the main focus. For this reason soundness becomes more important than completeness per se. However, complete axiomatisations are useful for obtaining decidability results for the class of regular languages within a fragment. See [9] for an example and for further motivation relative to the study of circuit complexity classes.

Contributions and Structure. After some preliminaries on Stone duality and actions by monoids, Section 3 introduces our notion of recognisers and main objects of study, the *Boolean spaces with internal monoids*. In Section 4 we analyse the relation between recognisers for a language L_Φ, corresponding to a formula Φ with one free first-order variable x, and recognisers for the existentially quantified language $L_{\exists x.\Phi}$. To this end, in Section 4.1 we introduce a unary version of the Schützenberger product, $\Diamond M$, for a discrete monoid M and prove that if M recognises L_Φ, then $\Diamond M$ recognises $L_{\exists x.\Phi}$. In Section 4.2 we extend the unary Schützenberger product, and the results in Section 4.1, to Boolean spaces with internal monoids (noting this can be done for semigroups as well). We end the section with a characterisation of the languages recognised by the unary Schützenberger product $(\Diamond X, \Diamond S)$ of a Boolean space with an internal semigroup (X, S) (see Theorem 14). In Section 5 we introduce the binary Schützenberger product of Boolean spaces with internal monoids. Theorems 16 and 18 extend results of Reutenauer in the regular setting and establish the connection with concatenation product for arbitrary languages. Finally, in Section 6 we provide a completeness result for the Boolean algebra recognised by the local version of the Schützenberger product of a space with the one element space.

2 Preliminaries

2.1 Stone duality for Boolean algebras

Let $(\mathcal{B}, \wedge, \vee, \neg, 0, 1)$ be a Boolean algebra. Recall that a subset $\mu \subseteq \mathcal{B}$ is a *filter* of $\mathcal{B}$ if it satisfies the following conditions:

- non-emptiness: $1 \in \mu$,
- upward closure: if $L \in \mu$ and $N \in \mathcal{B}$ satisfies $L \leq N$, then $N \in \mu$,
- closure under finite meets: if $L, N \in \mu$, then $L \wedge N \in \mu$.

A filter $\mu \subseteq \mathcal{B}$ is *proper* if $\mu \neq \mathcal{B}$. *Ultrafilters* are those for which $L \in \mu$ or $\neg L \in \mu$ for each $L \in \mathcal{B}$. In the Boolean algebra $\mathcal{P}(S)$, an example of an ultrafilter is given, for each $s \in S$, by the *principal ultrafilter* associated with the element s, namely

$$\uparrow s := \{b \in \mathcal{P}(S) \mid s \in b\}. \tag{1}$$

Let $X_{\mathcal{B}}$ be the collection of all the ultrafilters of $\mathcal{B}$. The fundamental insight of Stone is that, equipped with an appropriate topology, one may recover $\mathcal{B}$ from $X_{\mathcal{B}}$. For $L \in \mathcal{B}$ set

$$\widehat{L} := \{\mu \in X_{\mathcal{B}} \mid L \in \mu\}. \tag{2}$$

Then the family $\{\widehat{L} \mid L \in \mathcal{B}\}$ forms a basis of open sets for a topology σ on $X_{\mathcal{B}}$, and the topological space $(X_{\mathcal{B}}, \sigma)$ is called the *dual space* of the Boolean algebra $\mathcal{B}$. The topology σ is compact, Hausdorff, and admits a basis of *clopen* sets (i.e. sets that are both open and closed) since the complement of $\widehat{L}$ is $\widehat{\neg L}$. Compact Hausdorff spaces that admit a basis of clopen sets are known as *Boolean* (or *Stone*) *spaces*. The collection of clopens of a Boolean space X (equipped with set-theoretic operations) constitutes a Boolean algebra, known as the *dual algebra* of X. These processes are, up to natural equivalence, inverse to each other. Given a morphism of Boolean algebras $h\colon \mathcal{A} \to \mathcal{B}$, the inverse image map on their power sets $h^{-1}\colon \mathcal{P}(\mathcal{B}) \to \mathcal{P}(\mathcal{A})$ sends ultrafilters to ultrafilters and provides the continuous map from the dual space of $\mathcal{B}$ to the dual space of $\mathcal{A}$. Similarly, the inverse image map of a continuous map $f\colon X \to Y$ provides the morphism from the dual algebra of Y to that of X. In this correspondence, quotient algebras correspond to embeddings as (closed) subspaces, and inclusions as subalgebras correspond to quotient spaces. In category-theoretic terms, this establishes a contravariant equivalence between the category of Boolean spaces and continuous maps, and the category of Boolean algebras and their morphisms. This is the content of the celebrated Stone duality for Boolean algebras [20, Theorems 67 and 68].

We end this section with an example of a Boolean algebra and its dual space which will play a key rôle in the sequel. Let S be a set. Then $\mathcal{P}(S)$ is a Boolean algebra and its dual space, denoted by $\beta(S)$, is known as the *Stone-Čech compactification* of the set S. We remark that the map $\iota\colon S \to \beta(S)$, mapping an element s to the principal ultrafilter $\uparrow s$ of (1), is injective and embeds S, with the discrete topology, as a dense subspace of $\beta(S)$. Henceforth, we will consider S as a subspace of $\beta(S)$, identifying $s \in S$ with $\uparrow s$, thus suppressing the embedding ι. The space $\beta(S)$ is characterised by the following *universal property*: if X is a compact Hausdorff space and $f\colon S \to X$ is any function, then there is a (unique) continuous function $g\colon \beta(S) \to X$ such that the following diagram commutes.

$$\begin{array}{ccc} S & \hookrightarrow & \beta(S) \\ & \searrow^{f} & \downarrow{\scriptstyle g} \\ & & X \end{array} \tag{3}$$

Consequently, if T is a discrete space, any function $f\colon S \to T$ can be extended to a continuous map $\beta(f)\colon \beta(S) \to \beta(T)$. Explicitly, the latter is given, for each $\mu \in \beta(S)$ and $L \in \mathcal{P}(T)$, by

$$L \in \beta(f)(\mu) \quad \text{if, and only if,} \quad f^{-1}(L) \in \mu.$$

2.2 Monoid actions

Let $(M, \cdot, 1)$ be a monoid, and X be a set. A function $\lambda\colon M \times X \to X$ is called a *left action* of M on X provided

- for all $x \in X$, $\lambda(1, x) = x$,
- for all $m, m' \in M$ and $x \in X$, $\lambda(m \cdot m', x) = \lambda(m, \lambda(m', x))$.

Similarly, one can define a *right action* $\rho\colon X \times M \to X$ of M on X. For each $m \in M$, we refer to the function $\lambda_m\colon X \to X$ given by $\lambda_m(x) := \lambda(m, x)$ (respectively to the function $\rho_m\colon X \to X$ given by $\rho_m(x) := \rho(x, m)$) as the *component* of the action λ at m (respectively, of the action ρ at m). A pair consisting of left and right actions λ, ρ of M on X is said to be *compatible* if, for all $m, m' \in M$, $\lambda_m \circ \rho_{m'} = \rho_{m'} \circ \lambda_m$. We call such a pair of compatible actions a *biaction* of M on X (or an *M-biaction* on X).

▶ **Example 1.** Any monoid M can be seen as acting on itself on the left and on the right. The component of the left action at $m \in M$ is the multiplication on the left by m, and the component of the right action is the multiplication on the right by m. The compatibility of the two actions amounts precisely to the associativity of the monoid operation.

▶ **Example 2.** Consider $\mathbb{N}$, the free monoid on one generator. As observed in Example 1, for each $n \in \mathbb{N}$ we have components $\lambda_n, \rho_n\colon \mathbb{N} \to \mathbb{N}$ of compatible left and right actions of $\mathbb{N}$ on itself. By the universal property (3) of the Stone-Čech compactification, we obtain continuous components $\beta(\lambda_n), \beta(\rho_n)\colon \beta(\mathbb{N}) \to \beta(\mathbb{N})$ of a biaction of $\mathbb{N}$ on $\beta(\mathbb{N})$. However the set $\beta(\mathbb{N})$ is not equipped with a continuous monoid operation, see [11, Chapter 4].

3 Recognition by spaces with dense monoids

We start by showing how our main objects of study (see Definition 3 below) arise naturally by considering duals of Boolean algebras of languages closed under certain operations known as quotients by words. Let Σ be a finite alphabet. Instantiating the monoid in Example 1 with the free monoid Σ^* on Σ, we obtain a biaction of Σ^* on itself. The components of the left and right actions are given by concatenation, and they will be denoted by

$$\lambda_w\colon \Sigma^* \to \Sigma^*,\ u \mapsto wu \quad \text{and} \quad \rho_w\colon \Sigma^* \to \Sigma^*,\ u \mapsto uw.$$

By discrete duality, i.e. by applying the contravariant power set functor, we obtain right and left Σ^*-actions on $\mathcal{P}(\Sigma^*)$ given by $\lambda_w^{-1}\colon \mathcal{P}(\Sigma^*) \to \mathcal{P}(\Sigma^*)$, and respectively, by $\rho_w^{-1}\colon \mathcal{P}(\Sigma^*) \to \mathcal{P}(\Sigma^*)$. These are the well-known *left quotients* and *right quotients* of language theory given, respectively, by

$$L \mapsto \{u \mid wu \in L\} =: w^{-1}L \quad \text{and} \quad L \mapsto \{u \mid uw \in L\} =: Lw^{-1}.$$

It is immediate that the λ_w^{-1} and ρ_w^{-1} are homomorphisms and compatible Σ^*-actions.

Dualising again, we see that the space $\beta(\Sigma^*)$ is equipped with (compatible and continuous) left and right Σ^*-actions given, for all $w \in \Sigma^*$, by $\beta(\lambda_w)$ and $\beta(\rho_w)$, respectively. By abuse of notation and for ease of readability, we will denote these actions again by λ_w, respectively ρ_w. We notice that the pair $(\beta(\Sigma^*), \Sigma^*)$ exhibits the following structure:

- a Boolean space $\beta(\Sigma^*)$,
- a dense subspace Σ^* equipped with a monoid structure,
- a biaction of Σ^* on $\beta(\Sigma^*)$ with continuous components extending that of Σ^* on itself.

Now, consider a Boolean subalgebra $\mathcal{B}$ of $\mathcal{P}(\Sigma^*)$ closed under left and right quotients by words. Then the maps λ_w^{-1} and ρ_w^{-1} restrict to Boolean algebra morphisms on $\mathcal{B}$, yielding the following commutative diagrams.

$$\begin{array}{ccc} \mathcal{P}(\Sigma^*) & \xrightarrow{\lambda_w^{-1}} & \mathcal{P}(\Sigma^*) \\ \uparrow & & \uparrow \\ \mathcal{B} & \xrightarrow{\lambda_w^{-1}} & \mathcal{B} \end{array} \qquad \begin{array}{ccc} \mathcal{P}(\Sigma^*) & \xrightarrow{\rho_w^{-1}} & \mathcal{P}(\Sigma^*) \\ \uparrow & & \uparrow \\ \mathcal{B} & \xrightarrow{\rho_w^{-1}} & \mathcal{B} \end{array} \tag{4}$$

Let $X_{\mathcal{B}}$ denote the dual space of the Boolean algebra $\mathcal{B}$. The embedding $\mathcal{B} \hookrightarrow \mathcal{P}(\Sigma^*)$ dually corresponds to a quotient $\tau\colon \beta(\Sigma^*) \twoheadrightarrow X_{\mathcal{B}}$. The space $X_{\mathcal{B}}$ also admits left and right Σ^*-actions induced by the duals of the maps λ_w^{-1}, respectively ρ_w^{-1}, from (4). We thus obtain

$$\begin{array}{ccc} \beta(\Sigma^*) & \xrightarrow{\lambda_w} & \beta(\Sigma^*) \\ \tau\downarrow & & \downarrow\tau \\ X_{\mathcal{B}} & \xrightarrow{\lambda_w} & X_{\mathcal{B}} \end{array} \qquad \begin{array}{ccc} \beta(\Sigma^*) & \xrightarrow{\rho_w} & \beta(\Sigma^*) \\ \tau\downarrow & & \downarrow\tau \\ X_{\mathcal{B}} & \xrightarrow{\rho_w} & X_{\mathcal{B}} \end{array} \tag{5}$$

Then $M := \tau[\Sigma^*]$ is a dense subspace of $X_{\mathcal{B}}$, and we have the following commutative diagram.

$$\begin{array}{ccc} \beta(\Sigma^*) & \xrightarrow{\tau} & X_{\mathcal{B}} \\ \uparrow & & \uparrow \\ \Sigma^* & \xrightarrow{\tau} & M \end{array} \tag{6}$$

We observe that the pair $(X_{\mathcal{B}}, M)$ exhibits the same kind of structure as $(\beta(\Sigma^*), \Sigma^*)$:

- a Boolean space $X_{\mathcal{B}}$,
- a dense subspace M equipped with a monoid structure,
- a biaction of M on $X_{\mathcal{B}}$ with continuous components extending the biaction of M on itself.

Indeed, recall that $X_{\mathcal{B}}$ is equipped with left and right Σ^*-actions which are preserved by the map τ by commutativity of (5). The Σ^*-actions on $X_{\mathcal{B}}$ restrict to Σ^*-actions on M, which are preserved by the restriction of τ. The monoid structure on M is then defined as follows. For any $m \in M$ pick $w_m \in \Sigma^*$ satisfying $\tau(w_m) = m$. Such an element exists because M is the image of Σ^* by τ. For $m, m' \in M$, set $m \cdot m' := \lambda_{w_m}(m')$. It is easily seen that the latter operation is well-defined and provides a monoid structure on M which makes the restriction of τ a monoid morphism.

As first introduced in [8], we will be using dual spaces equipped with actions as recognisers. The examples above motivate the following definition.

▶ **Definition 3.** A *Boolean space with an internal monoid* is a pair (X, M) consisting of

- a Boolean space X,
- a dense subspace M equipped with a monoid structure,
- a biaction of M on X with continuous components extending the biaction of M on itself.

▶ Remark. The recognisers introduced in [8] are monoids equipped with a uniform space structure, namely the Pervin uniformity given by a Boolean algebra of subsets of the monoid,

so that the biaction of the monoid on itself has uniformly continuous components. Such an object was called a *semiuniform monoid*. One may show that the completion of a semiuniform monoid is a Boolean space with an internal monoid. Conversely, given a Boolean space with an internal monoid (X, M), the Pervin uniformity on M induced by the dual of X is a semiuniform monoid, and these two constructions are inverse to each other.

We are interested in maps between pairs (X, M) and (Y, N), i.e. continuous maps $X \to Y$ which preserve the additional structure.

▶ **Definition 4.** A *morphism* between two Boolean spaces with internal monoids (X, M) and (Y, N) is a continuous map $f\colon X \to Y$ such that f restricts to a monoid morphism $M \to N$.

Morphisms, as just defined, are in fact also biaction-preserving maps.

▶ **Lemma 5.** *Let $f\colon (X, M) \to (Y, N)$ be a morphism of Boolean spaces with internal monoids. Then f preserves the actions, i.e. for every $m \in M$*

$$f \circ \lambda_m = \lambda_{f(m)} \circ f \quad \text{and} \quad f \circ \rho_m = \rho_{f(m)} \circ f.$$

▶ **Example 6.** The map $\tau\colon (\beta(\Sigma^*), \Sigma^*) \to (X_{\mathcal{B}}, M)$ of (6) is a morphism of Boolean spaces with internal monoids.

▶ Remark. The map $L \mapsto \widehat{L}$ of (2) establishes a one-to-one correspondence between the elements of $\mathcal{P}(\Sigma^*)$ and the clopens of $\beta(\Sigma^*)$. Thus, we will sometimes blur the distinction between recognition of a language L and recognition of the corresponding clopen $\widehat{L}$.

▶ **Definition 7.** Let Σ be a finite alphabet, and let $L \subseteq \Sigma^*$ be a language. We say that L (or $\widehat{L}$) is *recognised by the morphism* $f\colon (\beta(\Sigma^*), \Sigma^*) \to (X, M)$ if there is a clopen $C \subseteq X$ such that $\widehat{L} = f^{-1}(C)$. Moreover, the language L is *recognised by the space* (X, M) if there is a morphism $(\beta(\Sigma^*), \Sigma^*) \to (X, M)$ recognising L. Similarly, we say that a morphism (or a space) recognises a Boolean algebra if it recognises all its elements.

▶ Remark. In general, a morphism $(\beta(\Sigma^*), \Sigma^*) \to (X, M)$ with *infinite* M, recognises (in the sense of Definition 7) far less languages than the induced monoid morphism $\Sigma^* \to M$. On the other hand, a finite monoid M may be seen as a space with an internal monoid, in which the space component is the monoid itself, equipped with the discrete topology. A morphism $(\beta(\Sigma^*), \Sigma^*) \to (M, M)$ yields in particular a monoid morphism $\Sigma^* \to M$. Conversely, a monoid morphism $h\colon \Sigma^* \to M$ extends uniquely to a continuous map $\beta h\colon \beta(\Sigma^*) \to M$ whose restriction to Σ^* is a monoid morphism. Thus the notion of recognition introduced here extends the usual notion for regular languages, but is finer-grained in the non-regular setting.

4 A unary variant of the Schützenberger product

4.1 Logical motivation: existentially quantified languages

Consider the free monoid Σ^* over a finite alphabet Σ. A word $w \in \Sigma^*$ may be seen as a structure based on the set $\{0, \dots, |w| - 1\}$,[1] equipped minimally with a unary predicate for each letter $a \in \Sigma$, which holds at i if and only if $w_i = a$. Now given a formula Φ (in a language interpretable over words as structures), assumed for simplicity to have only one free first-order variable x, we will see the set L_Φ of all words satisfying Φ as a language in the

[1] Here, as usual, $|w| \in \mathbb{N}$ denotes the length of the word $w = w_0 \cdots w_{|w|-1} \in \Sigma^*$.

extended alphabet $\Sigma \times 2$. In the terminology of [22], L_Φ consists of $\{x\}$-structures, which correspond to words in the subset $(\Sigma \times \{0\})^*(\Sigma \times \{1\})(\Sigma \times \{0\})^*$ of the free monoid $(\Sigma \times 2)^*$. An $\{x\}$-structure satisfies Φ provided the underlying word in the alphabet Σ satisfies Φ under the interpretation in which x points to the unique position marked with a 1. Notice that $(\Sigma \times \{0\})^*(\Sigma \times \{1\})(\Sigma \times \{0\})^*$ is isomorphic to the set $\Sigma^* \otimes \mathbb{N}$ of words in Σ^* with a marked spot defined by

$$\Sigma^* \otimes \mathbb{N} := \{(w, i) \in \Sigma^* \times \mathbb{N} \mid i < |w|\}.$$

Throughout this section we will make use of the following three maps

$$\gamma_0 \colon \Sigma^* \to (\Sigma \times 2)^*, \qquad \gamma_1 \colon \Sigma^* \otimes \mathbb{N} \to (\Sigma \times 2)^*, \qquad \pi \colon \Sigma^* \otimes \mathbb{N} \to \Sigma^*.$$

- The map $\gamma_0 \colon \Sigma^* \to (\Sigma \times 2)^*$ is the embedding given by $w \mapsto w^0$, where w^0 has the same length as w and

$$(w^0)_j := (w_j, 0) \quad \text{for each} \quad j < |w|.$$

- The map $\gamma_1 \colon \Sigma^* \otimes \mathbb{N} \to (\Sigma \times 2)^*$ is the embedding given by $(w, i) \mapsto w^{(i)}$, where $w^{(i)}$ has the same length as w and

$$(w^{(i)})_j := \begin{cases} (w_j, 0) & \text{if} \quad i \neq j < |w| \\ (w_i, 1) & \text{if} \quad i = j. \end{cases}$$

- The map $\pi \colon \Sigma^* \otimes \mathbb{N} \to \Sigma^*$ is the projection on the first coordinate.

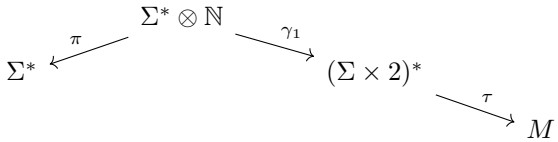
▶ Remark. The language $L_{\exists x.\Phi}$ is obtained as $\pi[\gamma_1^{-1}(L_\Phi)]$. More generally, given a language $L \subseteq (\Sigma \times 2)^*$, we shall denote $\pi[\gamma_1^{-1}(L)] \subseteq \Sigma^*$ by $L_\exists$.

▶ Remark. Notice that, unlike γ_0, the maps γ_1 and π are not monoid morphisms. Indeed, $\Sigma^* \otimes \mathbb{N}$ does not have a suitable monoid structure. However, $\Sigma^* \otimes \mathbb{N}$ does have a Σ^*-biaction structure. For $v \in \Sigma^*$, the components of the left and right actions are given by

$$\lambda_v(w, i) := (vw, i + |v|),$$
$$\rho_v(w, i) := (wv, i).$$

It is clear that both γ_1 and π preserve the Σ^*-actions.

Assume that the language L_Φ is recognised by a monoid morphism $\tau \colon (\Sigma \times 2)^* \to M$. We have the following pair of functions[2] with domain $\Sigma^* \otimes \mathbb{N}$



which gives rise to a relation $R \colon \Sigma^* \nrightarrow M$ given by

$$(w, m) \in R \quad \text{if, and only if,} \quad \exists (w, i) \in \pi^{-1}(w).\ (\tau \circ \gamma_1)(w, i) = m.$$

[2] Notice that this is not a relational morphism in the sense of Tilson's definition given in [5], since the domain $\Sigma^* \otimes \mathbb{N}$ does not have a compatible monoid structure.

Though π is not injective, it does have *finite preimages*. As will be crucial in what follows, this allows us to represent R as a function (which, in general, is not a monoid morphism)

$$\xi_1 \colon \Sigma^* \to \mathcal{P}_{fin}(M), \quad w \mapsto \{\tau(w^{(i)}) \mid 0 \leq i < |w|\} \tag{7}$$

where $\mathcal{P}_{fin}(M)$ denotes the set of finite subsets of M. Consider the monoid structure on $\mathcal{P}_{fin}(M)$ with union as the multiplication, and the empty set as unit. Notice that the monoid M acts on $\mathcal{P}_{fin}(M)$ both to the left and to the right, and the two actions are compatible. The left action $M \times \mathcal{P}_{fin}(M) \to \mathcal{P}_{fin}(M)$ is given, for $m \in M$ and $S \in \mathcal{P}_{fin}(M)$, by $m \cdot S := \{m \cdot s \mid s \in S\}$. Similarly, the right action is given by $S \cdot m := \{s \cdot m \mid s \in S\}$.

▶ **Definition 8.** We define the *unary Schützenberger product* $\Diamond M$ of M as the bilateral semidirect product $\mathcal{P}_{fin}(M) * M$ of the monoids $(\mathcal{P}_{fin}(M), \cup)$ and $(M, \cdot)$. Explicitly, the underlying set of this monoid is the Cartesian product $\mathcal{P}_{fin}(M) \times M$, and the multiplication $*$ on $\mathcal{P}_{fin}(M) * M$ is given by

$$(S, m) * (T, n) := (S \cdot n \cup m \cdot T, m \cdot n).$$

Note that the projection onto the second coordinate, $\pi_2 \colon \Diamond M \to M$, is a monoid morphism.

▶ **Proposition 9.** *If $\tau \colon (\Sigma \times 2)^* \to M$ is a monoid morphism recognising L_Φ, then there exists a monoid morphism*

$$\xi \colon \Sigma^* \to \Diamond M$$

that recognises the language $L_{\exists x.\Phi}$ and makes the following diagram commute.

$$\begin{array}{ccc} \Sigma^* & \xrightarrow{\ \xi\ } & \Diamond M \\ {\scriptstyle \gamma_0}\downarrow & & \downarrow{\scriptstyle \pi_2} \\ (\Sigma \times 2)^* & \xrightarrow{\ \tau\ } & M \end{array}$$

Proof idea. The map ξ is obtained by pairing $\xi_1 \colon \Sigma^* \to \mathcal{P}_{fin}(M)$ of (7) and $\tau \circ \gamma_0 \colon \Sigma^* \to M$. Explicitly,

$$w \mapsto (\{\tau(w^{(i)}) \mid 0 \leq i < |w|\}, \tau(w^0)).$$

One may show that the map ξ is a monoid morphism with respect to the concatenation on Σ^* and the multiplication $*$ on the semidirect product $\mathcal{P}_{fin}(M) * M$. Now let V be a subset of M such that $L_\Phi = \tau^{-1}(V)$, and consider the set $\diamond V \subseteq \mathcal{P}_{fin}(M)$ defined as $\{S \in \mathcal{P}_{fin}(M) \mid S \cap V \neq \emptyset\}$. Then $\xi^{-1}(\diamond V \times M)$ is precisely $L_{\exists x.\Phi}$. ◀

▶ Remark. In [21] Straubing generalised the Schützenberger product for any finite number of monoids. Using his construction, the unary Schützenberger product of M is simply M, and hence is different from $\Diamond M$ introduced above. For the connection between closure under concatenation product and first-order quantification in the regular setting, see [14].

▶ Remark. For lack of space, we have chosen to just 'pull Definition 8 (and consequently also the upcoming Definition 11) out of a hat'. However, by a careful analysis of how quotients in $\mathcal{P}(\Sigma^*)$ of languages $L_\exists$ are calculated, relative to corresponding calculations in $\mathcal{P}((\Sigma \times 2)^*)$, one may simply derive by duality that the operation given here is the right one.

4.2 The Schützenberger product for one space $\Diamond X$

In this section we assume that the language $L_\Phi \subseteq (\Sigma \times 2)^*$ is recognised by a morphism of Boolean spaces with internal monoids $\tau\colon (\beta(\Sigma \times 2)^*, (\Sigma \times 2)^*) \to (X, M)$. Notice that in this case we have a pair of continuous maps

$$\begin{array}{ccccc} & & \beta(\Sigma^* \otimes \mathbb{N}) & & \\ & \overset{\beta\pi}{\swarrow} & & \overset{\beta\gamma_1}{\searrow} & \\ \beta(\Sigma^*) & & & & \beta(\Sigma \times 2)^* \\ & & & & \overset{\tau}{\searrow} \\ & & & & X \end{array} \tag{8}$$

which, as before, yields a relation $\beta(\Sigma^*) \nrightarrow X$. We would like to describe this relation as a continuous map on $\beta(\Sigma^*)$. To this end, we need an analogue for spaces of the finite power set construction. This is provided by the *Vietoris space construction* (see [10, Section B.1] for further details).

▶ **Definition 10.** Let X be a Boolean space. The *Vietoris space* $\mathcal{V}(X)$ is the Boolean space with underlying set $\{K \subseteq X \mid K \text{ is closed in } X\}$, and topology generated by the subbasis consisting of the sets, for V clopen in X, of the form

$$\Box V := \{K \in \mathcal{V}(X) \mid K \subseteq V\} \quad \text{and} \quad \Diamond V := \{K \in \mathcal{V}(X) \mid K \cap V \neq \emptyset\}.$$

Just as in the monoid case, diagram (8) yields a map

$$\xi_1\colon \beta(\Sigma^*) \to \mathcal{V}(X)$$

defined as the composition $\tau \circ \beta\gamma_1 \circ (\beta\pi)^{-1}$, or equivalently as the unique continuous extension of the map $\xi_1\colon \Sigma^* \to \mathcal{P}_{fin}(M)$ defined in (7).

▶ **Definition 11.** We define the *unary Schützenberger product* of a Boolean space with an internal monoid (X, M) as the pair $(\Diamond X, \Diamond M)$, where $\Diamond X$ is the space $\mathcal{V}(X) \times X$ equipped with the product topology and $\Diamond M$ is as in Definition 8.

▶ **Lemma 12.** *The unary Schützenberger product $(\Diamond X, \Diamond M)$ of (X, M) is a Boolean space with an internal monoid.*

Proof Idea. Recall that M is a dense subspace of X. It follows by [13, Theorem 4, p. 163] that $\mathcal{P}_{fin}(M)$ is a dense subspace of $\mathcal{V}(X)$. Thus the monoid $\Diamond M$ is a dense subspace of $\Diamond X$. Next we define the actions of $\Diamond M$ on $\Diamond X$ as follows:

$$l_{(S,m)}(T, x) := (\{\lambda_s(x) \mid s \in S\} \cup \lambda_m[T], \lambda_m(x)),$$
$$r_{(S,m)}(T, x) := (\{\rho_s(x) \mid s \in S\} \cup \rho_m[T], \rho_m(x)).$$

It is not difficult to see that the above maps are the unique continuous extensions to $\Diamond X$ of the multiplication by (S, m), to the left and to the right, on $\Diamond M$. ◀

The projection $\pi_2\colon \Diamond X \to X$ is a morphism of Boolean spaces with internal monoids.

▶ **Proposition 13.** *If $\tau\colon (\beta(\Sigma \times 2)^*, (\Sigma \times 2)^*) \to (X, M)$ is a morphism of Boolean spaces with internal monoids recognising L_Φ, then there is a morphism $\xi\colon (\beta(\Sigma^*), \Sigma^*) \to (\Diamond X, \Diamond M)$ recognising $L_{\exists x.\Phi}$ and such that the following diagram commutes.*

$$\begin{array}{ccc} \beta(\Sigma^*) & \xrightarrow{\xi} & \Diamond X \\ {\scriptstyle \beta\gamma_0}\downarrow & & \downarrow{\scriptstyle \pi_2} \\ \beta(\Sigma \times 2)^* & \xrightarrow{\tau} & X \end{array}$$

All the constructions introduced so far can be carried out for semigroups. In particular, we can consider Boolean spaces with internal semigroups as recognisers of languages in $\mathcal{P}(\Sigma^+)$. Along the lines of Definition 8, we introduce the unary Schützenberger product $\Diamond S$ of a semigroup S as the bilateral semidirect product of the semigroups $(\mathcal{P}^+_{fin}(S), \cup)$ and $(S, \cdot)$, where $\mathcal{P}^+_{fin}(S)$ denotes the family of finite non-empty subsets of S. Similarly, at the level of spaces, in the Vietoris construction we will consider only non-empty closed subsets.

Now, write $\mathcal{B}(X, \Sigma)$ for the Boolean algebra of languages in $\mathcal{P}(\Sigma^+)$ recognised by the Boolean space with an internal semigroup (X, S), and note that the latter Boolean algebra is always closed under quotients. Moreover, given a language $L \subseteq (\Sigma \times 2)^+$, recall that $L_\exists$ denotes the language $\pi[\gamma_1^{-1}(L)]$.

▶ **Theorem 14.** *Let (X, S) be a Boolean space with an internal semigroup, and let $\mathcal{B}(X, \Sigma{\times}2)_\exists$ denote the Boolean subalgebra closed under quotients of $\mathcal{P}(\Sigma^+)$ generated by the family $\{L_\exists \mid L \in \mathcal{B}(X, \Sigma \times 2)\}$. Then $\mathcal{B}(\Diamond X, \Sigma)$ coincides with the Boolean algebra generated by the union of $\mathcal{B}(X, \Sigma)$ and $\mathcal{B}(X, \Sigma \times 2)_\exists$.*

The proof of this theorem hinges on the fact that the first components of the recognising morphisms evaluate to non-empty subsets. An analogous statement can be formulated for monoids, but we would have to restrict the recognising morphisms when defining $\mathcal{B}(\Diamond X, \Sigma)$.

5 A variant of the Schützenberger product for two spaces

Given two monoids $(M, \cdot), (N, \cdot)$, the Schützenberger product $\Diamond(M, N)$ can be defined as the monoid $\mathcal{P}_{fin}(M \times N) \times M \times N$ whose operation is given by

$$(S, m_1, n_1) \cdot (T, m_2, n_2) := (m_1 \cdot T \cup S \cdot n_2, m_1 \cdot m_2, n_1 \cdot n_2).$$

Now, consider two Boolean spaces with internal monoids (X, M) and (Y, N). We define the space $\Diamond(X, Y)$ as the product $\mathcal{V}(X \times Y) \times X \times Y$. It is clear that the monoid $\Diamond(M, N)$ is dense in $\Diamond(X, Y)$. Moreover, the left action of $\Diamond(M, N)$ on itself can be extended to $\Diamond(X, Y)$ by setting, for any $(S, m_1, n_1) \in \Diamond(M, N)$,

$$\lambda_{(S,m_1,n_1)} \colon \Diamond(X, Y) \to \Diamond(X, Y),\ (Z, x, y) \mapsto (m_1 Z \cup Sy, \lambda_{m_1}(x), \lambda_{n_1}(y)), \tag{9}$$

where

$$m_1 Z := \{(\lambda_{m_1}(x), y) \in X \times Y \mid (x, y) \in Z\} \quad \text{and} \quad Sy := \{(m, \lambda_n(y)) \in X \times Y \mid (m, n) \in S\}.$$

Similarly, the right action can be defined by

$$\rho_{(S,m_1,n_1)} \colon \Diamond(X, Y) \to \Diamond(X, Y),\ (Z, x, y) \mapsto (Z n_1 \cup xS, \rho_{m_1}(x), \rho_{n_1}(y)), \tag{10}$$

where

$$Z n_1 := \{(x, \rho_{n_1}(y)) \in X \times Y \mid (x, y) \in Z\} \quad \text{and} \quad xS := \{(\rho_m(x), n) \in X \times Y \mid (m, n) \in S\}.$$

It is easy to see that we obtain a biaction of $\Diamond(M, N)$ on $\Diamond(X, Y)$. Furthermore,

▶ **Lemma 15.** *The biaction of $\Diamond(M, N)$ on $\Diamond(X, Y)$ defined in (9) and (10) has continuous components. Thus $(\Diamond(X, Y), \Diamond(M, N))$ is a Boolean space with an internal monoid.*

The next three results establish the connection between concatenation of possibly non-regular languages and the Schützenberger product of Boolean spaces with internal monoids. We thus extend the theorems of Schützenberger [19] and Reutenauer [18].

▶ **Theorem 16** (Reutenauer's theorem, global version). *Consider Boolean spaces with internal monoids (X, M) and (Y, N). Let $\mathcal{L}$ be the Boolean algebra generated by all the Σ^*-languages of the form L_1, L_2 and $L_1 a L_2$, where L_1 (respectively L_2) is recognised by X (respectively Y) and $a \in \Sigma$. Then a Σ^*-language is recognised by $X \Diamond Y$ if, and only if, it belongs to $\mathcal{L}$.*

Proof Idea. Suppose the languages L_1, L_2 are recognised by morphisms $\phi_1 \colon (\beta(\Sigma^*), \Sigma^*) \to (X, M)$ and $\phi_2 \colon (\beta(\Sigma^*), \Sigma^*) \to (Y, N)$, respectively, and fix $a \in \Sigma$. By abuse of notation, call $\phi_1 \times \phi_2 \colon \beta(\Sigma^* \times \{a\} \times \Sigma^*) \to X \times Y$ the unique continuous extension of the product map $\Sigma^* \times \{a\} \times \Sigma^* \to X \times Y$ whose components are $(w, a, w') \mapsto \phi_1(w)$ and $(w, a, w') \mapsto \phi_2(w')$. Let $\zeta_a \colon \beta(\Sigma^*) \to \mathcal{V}(X \times Y)$ be the continuous function induced by the diagram

$$\begin{array}{ccc} & \beta(\Sigma^* \times \{a\} \times \Sigma^*) & \\ {\scriptstyle \beta c}\swarrow & & \searrow{\scriptstyle \phi_1 \times \phi_2} \\ \beta(\Sigma^*) & & X \times Y \end{array} \tag{11}$$

just as for diagram (8), where $c \colon \Sigma^* \times \{a\} \times \Sigma^* \to \Sigma^*$ is the concatenation map $(w, a, w') \mapsto waw'$. One can prove that the map ζ_a is a morphism recognising L_1, L_2 and $L_1 a L_2$.

Conversely, for any morphism $\langle \zeta, \phi_1, \phi_2 \rangle \colon (\beta(\Sigma^*), \Sigma^*) \to (X \Diamond Y, M \Diamond N)$ and clopens $C_1 \subseteq X$, $C_2 \subseteq Y$, we must prove that $\zeta^{-1}(\Diamond(C_1 \times C_2)) \cap \Sigma^* \in \mathcal{L}$. One observes that each

$$L_{C_1 \times C_2, a} := \{w \in \Sigma^* \mid \exists u, v \in \Sigma^* \text{ s.t. } w = uav \text{ and } \phi_1(u)\zeta(a)\phi_2(v) \in \Diamond(C_1 \times C_2)\}$$

is in the Boolean algebra $\mathcal{L}$. Then $\zeta^{-1}(\Diamond(C_1 \times C_2)) \cap \Sigma^* = \bigcup_{a \in \Sigma} L_{C_1 \times C_2, a}$. ◀

The next corollary follows at once by Theorem 16, by noting that $L_1 L_2 = \bigcup_{a \in \Sigma} L_1 a (a^{-1} L_2)$ whenever L_2 does not contain the empty word and $L_1 L_2 = \bigcup_{a \in \Sigma} L_1 a (a^{-1} L_2) \cup L_1$ otherwise.

▶ **Corollary 17.** *The Boolean space with an internal monoid $(\Diamond(X, Y), \Diamond(M, N))$ recognises the concatention $L_1 L_2$ of languages L_1, L_2 recognised by (X, M) and (Y, N), respectively.*

Finally, the following local statement is a direct consequence of the proof of Theorem 16.

▶ **Theorem 18** (Reutenauer's theorem, local version). *Consider morphisms $\phi_1 \colon (\beta(\Sigma^*), \Sigma^*) \to (X, M)$ and $\phi_2 \colon (\beta(\Sigma^*), \Sigma^*) \to (Y, N)$. Let $\mathcal{L}$ be the Boolean algebra generated by all the Σ^*-languages of the form L_1, L_2 and $L_1 a L_2$, where L_1 (respectively L_2) is recognised by ϕ_1 (respectively ϕ_2) and $a \in \Sigma$. Then a Σ^*-language is recognised by the morphism*

$$\langle \langle \zeta_a \rangle_{a \in \Sigma}, \phi_1, \phi_2 \rangle \colon \beta(\Sigma^*) \to \mathcal{V}(X \times Y)^{\Sigma} \times X \times Y$$

where $\zeta_a \colon \beta(\Sigma^*) \to \mathcal{V}(X \times Y)$ is induced by diagram (11) if, and only if, it belongs to $\mathcal{L}$.

6 Ultrafilter equations

Identifying simple equational bases for the Boolean algebras of languages recognised by Schützenberger products, in terms of the equational theories of the input Boolean algebras, is an important step in studying classes built up by repeated application of quantification or language concatenation. See e.g. [17, 3] for examples of such work in the regular setting.

As a proof-of-concept and first step, we provide a fairly easy completeness result for the Boolean algebra recognised by the local version of a Schützenberger product of a space with the one element space. First we introduce notation for the dual construction, see Theorem 18.

▶ **Definition 19.** Let $\mathcal{B}_1$ and $\mathcal{B}_2$ be Boolean algebras of Σ^*-languages closed under quotients. We define the *binary Schützenberger sum* of $\mathcal{B}_1$ and $\mathcal{B}_2$ to be the Boolean algebra of languages

$$\mathcal{B}_1 \Diamond\!\!\!\!\!+ \mathcal{B}_2 := \langle \mathcal{B}_1 \cup \mathcal{B}_2 \cup \{L_1 a L_2 \mid L_1 \in \mathcal{B}_1,\ L_2 \in \mathcal{B}_2,\ a \in \Sigma\}\rangle.$$

Note that this Boolean algebra is also closed under quotients.

Let $\mathcal{B} \subseteq \mathcal{P}(\Sigma^*)$ be a Boolean algebra closed under quotients. We give equations for $\mathcal{B}\Diamond\!\!\!\!\!+2$. Recall that an equation for a Boolean subalgebra of $\mathcal{P}(\Sigma^*)$ is a pair $\mu \approx \nu$, where $\mu, \nu \in \beta(\Sigma^*)$, and that $L \in \mathcal{P}(\Sigma^*)$ *satisfies the ultrafilter equation* $\mu \approx \nu$ provided

$$L \in \mu \quad \text{if, and only if,} \quad L \in \nu.$$

A Boolean subalgebra of $\mathcal{P}(\Sigma^*)$ satisfies an ultrafilter equation provided each of its elements satisfies it. For background and more details on equations see e.g. [7, 9, 6]. Now, set

$$f_a \colon \Sigma^* \otimes \mathbb{N} \to \Sigma^*,\ (w,i) \mapsto w(a@i) \quad \text{and} \quad f_r \colon \Sigma^* \otimes \mathbb{N} \to \Sigma^*,\ (w,i) \mapsto w_{|i} = w_0 \cdots w_{i-1}$$

where $a \in \Sigma$ and $w(a@i)$ denotes the word obtained by replacing the ith letter of the word $w = w_0 \cdots w_{|w|-1}$ by an a.

The intuition is that the extension βf_a will allow us to *factor* an ultrafilter at an occurrence of the letter a, whereas the extension βf_r gives us access to the prefix of this factorisation.

▶ **Definition 20.** Let $\mathcal{E}(\mathcal{B}\Diamond\!\!\!\!\!+2)$ denote the set of all equations $\mu \approx \nu$ so that

- $\mu \approx \nu$ holds in $\mathcal{B}$;
- for each $\gamma \in \beta(\Sigma^* \otimes \mathbb{N})$ so that $\mu = \beta f_a(\gamma)$, there exists $\delta \in \beta(\Sigma^* \otimes \mathbb{N})$ such that $\nu = \beta f_a(\delta)$ and the equation $\beta f_r(\gamma) \approx \beta f_r(\delta)$ holds in $\mathcal{B}$;
- for each $\delta \in \beta(\Sigma^* \otimes \mathbb{N})$ so that $\nu = \beta f_a(\delta)$, there exists $\gamma \in \beta(\Sigma^* \otimes \mathbb{N})$ such that $\mu = \beta f_a(\gamma)$ and the equation $\beta f_r(\gamma) \approx \beta f_r(\delta)$ holds in $\mathcal{B}$.

▶ **Theorem 21.** *The ultrafilter equations in $\mathcal{E}(\mathcal{B}\Diamond\!\!\!\!\!+2)$ characterise the Boolean algebra $\mathcal{B}\Diamond\!\!\!\!\!+2$.*

The proof of Theorem 21 relies on the following two lemmas.

▶ **Lemma 22.** *Let $\gamma \in \beta(\Sigma^* \otimes \mathbb{N})$. If $\mu = \beta f_a(\gamma)$ and $L \in \beta f_r(\gamma)$, then $La\Sigma^* \in \mu$.*

▶ **Lemma 23.** *Let $\mathscr{F} \subseteq \mathcal{P}(\Sigma^*)$ be a proper filter, $\mu \in \beta(\Sigma^*)$ and $a \in \Sigma$. If $La\Sigma^* \in \mu$ for all $L \in \mathscr{F}$, then there exists $\gamma \in \beta(\Sigma^* \otimes \mathbb{N})$ such that $\mu = \beta f_a(\gamma)$ and $\mathscr{F} \subseteq \beta f_r(\gamma)$.*

Proof Idea for Theorem 21. Soundness follows easily from the lemmas. For completeness notice that, by repeated use of compactness, $K \in \mathcal{P}(\Sigma^*)$ belongs to $\mathcal{B}\Diamond\!\!\!\!\!+2$ if and only if for each $\mu \in \widehat{K}$, the clopen $\widehat{K}$ extends the set

$$C_\mu := \bigcap\{\widehat{L} \mid L \in \mathcal{B},\ L \in \mu\} \cap \bigcap\{\widehat{La\Sigma^*} \mid a \in \Sigma, L \in \mathcal{B}, La\Sigma^* \in \mu\} \cap \bigcap\{(\widehat{La\Sigma^*})^c \mid a \in \Sigma, L \in \mathcal{B}, La\Sigma^* \notin \mu\}.$$

Finally one shows, again using the lemmas, that $\mu \approx \nu \in \mathcal{E}(\mathcal{B}\Diamond\!\!\!\!\!+2)$ for any $\nu \in C_\mu$. ◀

7 Conclusion

The concepts of recognition and of syntactic monoid, stemming from the algebraic theory of regular languages, inherently arise in the setting of Stone/Priestley duality for Boolean algebras and lattices with additional operations, see [7]. Reasoning by analogy, this led in

[8] to generalisations of recognition and syntactic objects for arbitrary languages of finite words. In *loc. cit.* this was achieved in the setting of monoids equipped with uniform space structures, the so called *semiuniform monoids*. In this paper we naturally arrive at an isomorphic notion of recogniser – Boolean spaces with internal monoids – which is however more amenable to existing tools from duality theory.

Our first contribution is setting up the right framework that allows us to extend to the non-regular setting algebraic constructions whose logical counterpart is adding a layer of quantifier depth. We should mention that both the Schützenberger and the block product are algebraic constructions that can be used for this purpose in the regular case. However, for technical reasons, extending the former to Boolean spaces with internal monoids is more natural. The unary Schützenberger product that we introduce (which actually does not appear in the (pro)finite monoid literature to the best of our knowledge) arises naturally via duality for the Boolean algebra with quotients generated by the languages $L_\exists$, for L coming from some Boolean algebra $\mathcal{B}$. Moreover, our framework can be easily extended to the case of bounded distributive lattices, one would just need to use the Vietoris functor on spectral spaces instead. A comparison between our unary Schützenberger product and the block product introduced in [12] for finitely typed monoids remains a topic for future investigation.

Furthermore, Theorem 14 of Section 4.2 and Theorem 16 of Section 5, provide characterisations of the languages accepted by our unary and binary Schützenberger products of Boolean spaces. Finally, in Section 6 we derive a preliminary result on equations. Theorem 21 on equational completeness is by no means the final word, but rather a first stepping stone in this direction. In the regular setting, as well as in the special cases treated in [9] and [4], much smaller subsets of $\mathcal{E}(\mathcal{B}\Diamond\!\!\!\!\!\!+2)$ have been shown to provide complete axiomatisations. We expect that a notion akin to the derived categories of profinite monoid theory [23] have to be developed, and we expect the remainder of the Stone-Čech compactification to play a key rôle in this.

Acknowledgements. We are grateful to Olivier Carton, Thomas Colcombet, Andreas Krebs and Jean-Éric Pin for helpful discussions on the block and Schützenberger products, and to Jean-Éric Pin for sharing an unpublished note on profinite equations and one-step products.

Logic of Local Inference for Contextuality in Quantum Physics and Beyond*

Abstract

Contextuality in quantum physics provides a key resource for quantum information and computation. The topological approach in [Abramsky and Brandenburger, New J. Phys., 2011, Abramsky et al., CSL 2015, 2015] characterizes contextuality as "global inconsistency" coupled with "local consistency", revealing it to be a phenomenon also found in many other fields. This has yielded a logical method of detecting and proving the "global inconsistency" part of contextuality. Our goal is to capture the other, "local consistency" part, which requires a novel approach to logic that is sensitive to the topology of contexts. To achieve this, we formulate a logic of local inference by using context-sensitive theories and models in regular categories. This provides a uniform framework for local consistency, and lays a foundation for high-level methods of detecting, proving, and moreover using contextuality as computational resource.

1 Introduction

Quantum physics provides quantum computing with immense advantage over classical computing. Among its non-classical properties, non-locality is known to be a basis for quantum communication (see [19]). It is in fact a special case of a property called *contextuality*, which recent studies [22, 10] suggest is an essential source of the computational power of quantum computers. This motivates the search for structural, higher-level expressions of contextuality that are independent of the formalism of quantum mechanics.

The conception of contextuality that originated in [11] exploits the structure of *presheaf*: As was shown in [11], a certain type of contextuality of a quantum system amounts to the absence of global sections from presheaves modelling the behaviors of the system. The recent, "sheaf-theoretic" approach [3] expands this insight by viewing contextuality in more general terms, as a matter of *topology* in data of measurements and outcomes: A wider range of contextuality is then characterized as the "global inconsistency" of the "locally consistent".

This has on the one hand shown that contextual phenomena can be found in various other fields such as relational database theory (see [1]), and on the other hand made it possible to apply various tools – sheaf theory, cohomology, linear algebra, for instance – to contextuality. One idea that has emerged is to formulate contextuality argument in logical terms [2]: One describes a presheaf model using logical formulas, and proves its contextuality by deriving contradiction from the formulas.

This method, however, only shows the global inconsistency of a given set of formulas; we know them to be locally consistent only because they describe a locally consistent model that is given. Nonetheless, when designing ways of exploiting contextuality, we may well first obtain a set of formulas or a specification, and then check if there is a model satisfying it. This requires a logic in which consistency means local consistency. The chief goal of this paper is to deliver such a new logic of local inference. The two logics – one for global inconsistency and the other for local consistency – together lay a foundation for high-level logical methods of not only showing but also using contextuality as resource.

Section 2 reviews the sheaf approach to contextuality, which takes presheaves valued in **Sets**. Then section 3 defines what we call "inchworm logic", a novel logic of local inference for contextual models. We formulate this on the basis of regular logic, since its vocabulary captures the essence of local inference. Semantics is provided for this logic in section 4, where we generalize **Sets**-valued presheaf models to ones valued in any regular category **S**. This encompasses cases that prove useful and powerful in applications: E.g., presheaves of abelian groups, R-modules, etc. serve the purpose of cohomology; indeed, Čech cohomology is used to detect the contextuality of **Sets**-valued presheaves [2]. This paper gives a uniform way of using **S**-valued presheaves directly as models of contextual logic.

2 Contextual Models

We first review the idea behind the formalism of [2], stressing that it applies to more settings than just quantum ones. The idea captures contextuality as a matter of topological nature, which we illustrate with a simplicial formulation equivalent to the presheaf formulation of [2]. We also present a modification of the latter that can readily be generalized in section 4.

2.1 Topological Models for Contextuality

The formalism of [3] concerns variables and values in general. Their bare-bones structure consists of a set X of variables and, for each $x \in X$, a set A_x of possible values of x. So we have an X-indexed family of sets A_x. This can model various settings in which we make queries against a system and it answers, as observed in [1, 2]; e.g.,

- We measure properties $x \in X$ of a physical system and it gives back outcomes $a \in A_x$.
- A relational database has attributes $x \in X$, and $a \in A_x$ are possible data values for x.
- $x \in X$ are sentences of propositional logic and a set of models assign to them boolean values $a \in A_x = \mathbf{2}$. Or $x \in X$ may simply be boolean variables.

We often make a query regarding several variables in combination; a set $U \subseteq X$ of variables the query concerns forms a *context* in which the system gives back a result. Contexts play essential rôles in the following two kinds of constraints, (a) on answers and (b) on queries.

(a) When we make a query in a context U, the system returns (one or a set of) tuples $s \in \prod_{x \in U} A_x$ of values. It then has the subset $A_U \subseteq \prod_{x \in U} A_x$ of "admissible" tuples that can be part of query results, and it is often the information on A_U that we want. E.g.,

- From a relational database we retrieve data with an attribute list U, and the database returns the relation A_U on sets A_x $(x \in U)$ as a table.

- Given a set of models and a set U of sentences, A_U is the set of combinations of values that U can take; e.g., a pair $\varphi, \neg\varphi \in U$ only take values $(1,0)$ or $(0,1)$.
- We may measure a physical system in various states and find that some set U of quantities always satisfy a certain equation that characterizes A_U.

(A tuple $s \in \prod_{x\in U} A_x$ is a dependent function, so it is formally a set of the form $\{\, (x, s(x)) \mid x \in U \text{ and } s(x) \in A_x \,\}$; but we may refer to it as "$(s(x), s(y), \dots)$ over $(x, y, \dots)$".)

(b) We have the family $\mathcal{C} \subseteq \mathcal{P}X$ of contexts in which queries can be made and answered. We may not be able to make a query in a context $V \subseteq X$ (i.e. $V \notin \mathcal{C}$) for reasons such as:

- V may have too many variables to deal with feasibly.
- A database schema may have no table encompassing all the attributes in V.
- Quantum mechanics may deem it impossible to measure all the properties in V at once.

In these examples, if queries can be made in a context U, they can be in any $V \subseteq U$; we also assume that queries can be made in $\{x\}$ for any $x \in X$, but only in finite U. So $\mathcal{C}$ is an (abstract) *simplicial complex* on X, i.e. a $\subseteq$-downward closed subfamily of $\mathcal{P}_{\text{fin}}X$ with $\bigcup_{U\in\mathcal{C}} U = X$. Also, if a tuple s of values is admissible, so is any $t \subseteq s$. Hence, whenever $V \subseteq U \in \mathcal{C}$, the projection of tuples $-|_V : \prod_{x\in U} A_x \to \prod_{x\in V} A_x :: s \mapsto s|_V$ restricts to $A_{V\subseteq U} : A_U \to A_V$. Thus $A : \mathcal{C}^{\text{op}} \to \mathbf{Sets}$ forms a presheaf on the poset $\mathcal{C}$.

In fact, A is a *separated* presheaf. Generally, for any subfamily $\mathcal{C}$ of $\mathcal{P}X$ closed under binary intersection, whenever $\bigcup_i U_i = U \in \mathcal{C}$ for $U_i \in \mathcal{C}$, a presheaf P on $\mathcal{C}$ has the map $\langle P_{U_i\subseteq U}\rangle_i : P_U \to \prod_i P_{U_i} :: s \mapsto (s|_{U_i})_i$ land in the set of *matching families* for $(U_i)_i$,

$$\text{Match}_{(U_i)_i,P} = \{\, (t_i)_i \in \textstyle\prod_i P_{U_i} \mid t_j|_{U_j\cap U_k} = t_k|_{U_j\cap U_k} \text{ for every pair } j,k \,\}.$$

Then P is called separated if each of these $\langle P_{U_i\subseteq U}\rangle_i$ is injective, and a *sheaf* if each of those $\langle P_{U_i\subseteq U}\rangle_i : P_U \to \text{Match}_{(U_i)_i,P}$ is bijective (see [17]). Yet, on a simplicial complex $\mathcal{C}$, separated presheaves and sheaves have simpler descriptions:

▶ **Fact 1.** A presheaf P on a simplicial complex $\mathcal{C}$ is a sheaf iff $P_U = \prod_{x\in U} P_x$ for all $U \in \mathcal{C}$. And P is separated iff it is a subpresheaf of a sheaf, i.e. iff $P_U \subseteq \prod_{x\in U} P_x$ for all $U \in \mathcal{C}$.

This shows that our A above is a separated presheaf, but not generally a sheaf. So let us write $\mathbf{sPsh}(\mathcal{C})$ for the full subcategory of $\mathbf{Sets}^{\mathcal{C}^{\text{op}}}$ of separated presheaves. Note that every sheaf F has $F_\varnothing = 1$, a singleton. A separated presheaf P has $P_\varnothing = 1$, too, unless it is the empty presheaf $U \mapsto \varnothing$, i.e. the model is inconsistent in every context (hence modelling, e.g., a physical system that never produces outcomes in any context of measurements).

2.2 Presheaves and Bundles

The constraints (a) and (b) above are, indeed, matters of topology; this idea will be useful in subsection 2.3. Given a separated presheaf A as in subsection 2.1, its underlying family of X-indexed sets $(A_x)_{x\in X}$ is equivalent to a set over X, viz. $\pi : \sum_{x\in X} A_x \to X :: (x, a) \mapsto x$, by $\mathbf{Sets}^X \simeq \mathbf{Sets}/X$. The base X comes with a simplicial complex $\mathcal{C}$, but so does $\sum_{x\in X} A_x$, taking tuples $s \in A_U$ as simplices, i.e. $\mathcal{A} = \bigcup_{U\in\mathcal{C}} A_U$. And π is a *simplicial map*, or a *bundle* of simplicial complexes, since $s \in A_U \subseteq \mathcal{A}$ implies $\pi[s] = U \in \mathcal{C}$. On the other hand, any given bundle $\pi : \mathcal{A} \to \mathcal{C}$ has a family of $A_U = \{\, s \in \mathcal{A} \mid \pi[s] = U \,\}$ and $A_{V\subseteq U} : s \mapsto s|_V$.

A simplicial map $\pi : \mathcal{A} \to \mathcal{C}$ is called *non-degenerate* if $\pi|_s$ is injective for every $s \in \mathcal{A}$. Our π above is non-degenerate, because every $s \in A_U$ is a *local section* of the bundle π, meaning $s : U \to \sum_{x\in X} A_x$ such that $\pi \circ s = 1_U$. Let us write **Simp** and **ndSimp** for the categories of simplicial maps and of non-degenerate ones, respectively. It is easy to check that for every simplicial complex $\mathcal{C}$, the slice category $\mathbf{ndSimp}/\mathcal{C}$ is a full subcategory of

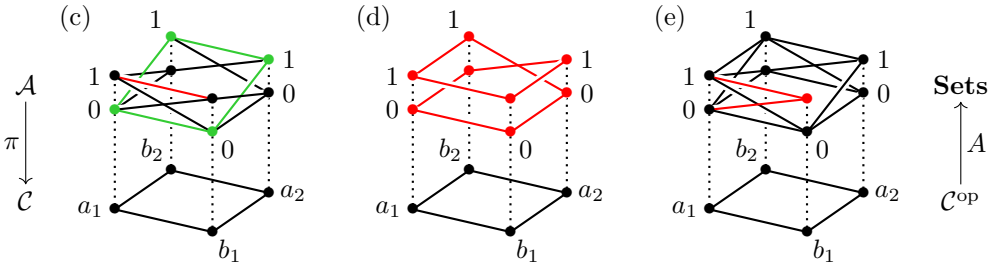

Figure 1 Bundles for (c) the Hardy model and (d) the PR-box

Simp/$\mathcal{C}$; i.e., it is the category of non-degenerate bundles and simplicial maps over $\mathcal{C}$. Then, extending $\mathbf{Sets}^X \simeq \mathbf{Sets}/X$, the correspondence described above gives

▶ **Fact 2.** $\mathbf{sPsh}(\mathcal{C}) \simeq \mathbf{ndSimp}/C$ for any simplicial complex $\mathcal{C}$.

So here is a topological reading of (a) and (b). Each $U \in \mathcal{C}$ is a local, small enough region of the space X of variables. The topology on the space $\mathcal{A}$ of values then distinguishes those tuples $s \in \prod_{x \in U} A_x$ in A_U from the others and deems the former to be continuous sections. We refer to objects of $\mathbf{sPsh}(\mathcal{C})$ and $\mathbf{ndSimp}/C$ interchangeably as *topological models*.

2.3 Contextuality in Physics, Databases, and More

Given a non-degenerate bundle $\pi : \mathcal{A} \to \mathcal{C}$ over a simplicial complex $\mathcal{C}$ on X, consider a *global section* of it, i.e. $g \in \prod_{x \in X} A_x$ such that $g|_U \in A_U$ for all $U \in \mathcal{C}$. It is an assignment of values to all the variables that satisfies every constraint on combinations of values. E.g., in classical logic, the models are exactly the global sections; so the consistency of a sentence x means that $(x, 1)$ is part of a global section. Then, in the physical setting, it may seem natural to similarly think of global sections g as states of the system, assigning values to all the quantities – so, although we can only make a query locally in a context $U \in \mathcal{C}$, the system in a state g actually has a value $g(x)$ assigned to every quantity x, and the answer we receive in the context U is simply $g|_U$. This assumption, that any section we observe is part of a context-independent global section, holds not just in classical logic but also in classical physics – but breaks down in quantum physics, precisely when contextuality arises.

Figure 1 shows "Bell-type" scenarios in which Alice and Bob measure properties of a system, perhaps a quantum one. The base $\mathcal{C}$ expresses constraints of type (b) above: Alice can make at most one of two measurements a_1 and a_2 at a time, so she chooses one; similarly Bob chooses from b_1 and b_2 – so there are four possible combinations of measurements, indicated by the four edges of $\mathcal{C}$. Alice and Bob repeat measurements in different contexts, and learn that each $x \in X = \{a_1, a_2, b_1, b_2\}$ has two possible outcomes 0 and 1, but that some combinations of outcomes are never obtained. $\mathcal{A}$ expresses these constraints, of type (a), with edges indicating possible combinations. E.g., $\mathcal{A}$ of (c) deems every joint outcome of (a_1, b_1) possible, with $A_{\{a_1,b_1\}} = \mathbf{2} \times \mathbf{2}$; but $(0, 0)$ is not a possible joint outcome of (a_2, b_2).

The models in Figure 1 all violate the classical assumption above, and are examples of

▶ **Definition 3** ([2])**.** A topological model is said to be *logically contextual* if not all of its local sections extend to global ones, and *strongly contextual* if it has no global section at all.

(c) of Figure 1 represents an example of logical contextuality due to [9] that is realizable in quantum physics. It has several global sections, e.g. the one marked in green; call it g. So, when Alice and Bob measure (a_1, b_1) and observe $(0, 0)$, the classical explanation is possible

that the system was in the state g and had outcomes $g(x)$ assigned to all the measurements $x \in X$, and that Alice and Bob have simply retrieved that information on U. On the other hand, the local section in red, $(1,1)$ over (a_1, b_1), does not extend to any global section. This means that the classical explanation is simply impossible for this joint outcome. Furthermore, the classical explanation is never possible in the strongly contextual (d). This model, called the *PR box* [21], is not quantum-realizable (though it plays an important rôle in the quantum information literature), but quantum physics exhibits many instances of strong contextuality.

The upshot is that contextuality consists in *global inconsistency coupled with local consistency*: A section $s \in A_U$ is consistent locally, in the sense of satisfying the constraint on query results in the context U, but it may be inconsistent globally, in the sense of contradicting all the other constraints and thereby failing to extend to a global section.

The general definition of contextuality in terms of global sections can also be applied to relational databases: Contextuality then corresponds exactly to the absence of a universal relation [1]. In fact, the natural join $\bowtie_{U \in \mathcal{C}} A_U = \{\, g \in \prod_{x \in X} A_x \mid g|_U \in A_U \text{ for all } U \in \mathcal{C} \,\}$ of relations A_U (which is the largest of universal relations if there are any) is, simply by definition, the set of global sections.

2.4 No-Signalling Principle

Not just there being local sections, local consistency involves more – viz. a constraint that is called the *no-signalling* principle in the physical setting [7]. For a topological model A, it amounts to the condition that every $A_{U \subseteq V} : A_V \to A_U :: s \mapsto s|_U$ is a surjection.

An example violating no-signalling is (e) of Figure 1: $A_{\{b_1\} \subseteq \{a_2, b_1\}} : A_{\{a_2, b_1\}} \to A_{\{b_1\}}$ is not surjective. Suppose Alice and Bob make measurements, Bob chooses b_1, and he observes 1, which is not in the image of $A_{\{b_1\} \subseteq \{a_2, b_1\}}$. This means that Bob has received the signal from Alice (no matter how far away she may be!) that she has chosen a_1 and not a_2.

To see why no-signalling should be part of local consistency, regard $\mathcal{A}$ in (e) as representing a relational database. It has tables $A_{\{a_1, b_1\}}$ and $A_{\{a_2, b_1\}}$; but, when queried about the attribute b_1, they yield different results of projection, differing in whether 1 is in or not. Thus, no-signalling means the consistency of projections (see [1]). Indeed, as we will see in subsection 4.3, no-signalling means a sort of coherence of A as a semantic model of logic.

▶ **Definition 4.** We say that a separated presheaf $A : \mathcal{C}^{\mathrm{op}} \to \mathbf{Sets}$ is no-signalling if it satisfies (1), and that a non-degenerate bundle $\pi : \mathcal{A} \to \mathcal{C}$ is no-signalling if it satisfies (2):

(1) Every $A_{U \subseteq V} : A_V \to A_U$ is a surjection.

(2) If $\pi[s] \subseteq U$ for $s \in \mathcal{A}$ and $U \in \mathcal{C}$, then there is some $t \in \mathcal{A}$ such that $s \subseteq t$ and $\pi[t] = U$.

Clearly, (1) and (2) coincide via $\mathbf{sPsh}(\mathcal{C}) \simeq \mathbf{ndSimp}/\mathcal{C}$. Hence their full subcategories of no-signalling models are equivalent. Note that (1) or (2) implies $A_U \neq \varnothing$ for all $U \in \mathcal{C}$, if $A_\varnothing \neq \varnothing$. So, while the empty model is no-signalling, all the other, nonempty no-signalling models (which are, essentially, the "empirical models" of [2]) are locally consistent.

3 Contextual Logics

3.1 Contextuality Argument: Logic of Global Inconsistency

Viewing A_U as representing a constraint on assignments of values to variables $x \in U$, we can describe a topological model A using formulas in contexts $U \in \mathcal{C}$ of variables. E.g., the assignments of $(0,0)$ and $(1,1)$ to (x, y) satisfy the equation $x \oplus y = 0$, where $\oplus$ is for XOR,

i.e. addition modulo 2; the assignments $(0,1)$ and $(1,0)$ satisfy $x \oplus y = 1$. Therefore the PR box, (d) of Figure 1, satisfies the following set of equations:

$$a_1 \oplus b_1 = 0, \quad a_1 \oplus b_2 = 0, \quad a_2 \oplus b_1 = 0, \quad a_2 \oplus b_2 = 1 \tag{3}$$

These are in fact inconsistent: Their right-hand sides sum to 1, but the left to 0 regardless of the values of variables (since each variable occurs twice). This is to say that no global assignment of values satisfies all the constraints of A_U, i.e., that A is strongly contextual.

A family of arguments of this sort, using XOR (or parity) equations, has been given to show the strong contextuality of a range of quantum examples; the first instance in literature was in [18] for the GHZ state [8]. This sort of so-called "all-vs-nothing argument" was formalized and generalized in [2]. On the other hand, one may also adopt more expressive languages, such as Boolean formulas, to express a wider range of constraints.

Formulas can also be used to show logical (and not strong) contextuality. E.g., the Hardy model, (c) of Figure 1, satisfies the antecedents of

$$\neg a_1 \vee \neg b_2, \quad \neg a_2 \vee \neg b_1, \quad a_2 \vee b_2 \quad \vdash \quad \neg a_1 \vee \neg b_1 \tag{4}$$

but not the consequent, due to the contextual section $(1,1)$ over (a_1, b_1). This shows that this local section can be part of no global assignment satisfying all the constraints.

Yet this kind of contextuality argument needs some reflection. The inconsistency of a set Γ of formulas, $\Gamma \vdash \bot$, does not mean that Γ has no model; in fact, the PR box, (d) of Figure 1, satisfies all the equations in (3). In the same vein, the derivability $\Gamma \vdash \varphi$ does not mean that every model of Γ satisfies φ; the Hardy model (c) satisfies Γ but not φ of (4). So the logic of $\vdash$ here is *not* sound with respect to contextual models – indeed, that is the whole point of the argument. Invalidating $\vdash$ precisely means contextuality: $\Gamma \vdash \bot$ really means that no global section satisfies Γ; it is why any model of Γ has no global section. $\Gamma \vdash \varphi$ means that every global section satisfying Γ satisfies φ; it is why any model satisfying Γ but not φ must have local sections (viz. ones not satisfying φ) that fail to extend to global sections.

In this sense, the logic of $\vdash$ here is a "global logic" of global sections. We should then note that this logic, by itself, says very little about local consistency. To see this, consider:

$$a_1 \oplus b_1 = 0, \quad a_1 \oplus b_1 = 1 \tag{5}$$

This set of equations is, like (3), inconsistent. It is, however, inconsistent not just globally but also locally: Not only does no global section satisfy both equations, no local section over the context $\{a_1, b_1\}$ does; a model A satisfies (5) only if $A_{\{a_1,b_1\}} = \varnothing$ (the physical system can give no outcomes to the measurements a_1, b_1). Yet the global logic does not tell us why (3) is locally consistent whereas (5) is not. Thus the kind of argument above is really a "global-inconsistency argument": It shows contextuality only because we already know the formulas to be locally consistent, having obtained them as descriptions of some model.

3.2 "Inchworm Logic" of Local Inference

$\Gamma \vdash \bot$ of (5) means local inconsistency over $\{a_1, b_1\}$ since both equations in Γ are in the context $\{a_1, b_1\}$. Turning $\Gamma, \varphi \vdash \bot$ into the form of inference, if Γ, φ are in the context U, $\Gamma \vdash \neg\varphi$ gives local entailment over U. E.g., the antecedents of $a_1 = 0$, $b_1 = 0 \vdash a_1 \oplus b_1 = 0$ rule out all the sections over (a_1, b_1) except $(0,0)$, which satisfies the consequent.

Indeed, local inference can be carried out across different contexts, validly in no-signalling models, subject to one constraint. To see this, expand the base $\mathcal{C}$ in Figure 1 from (f) of

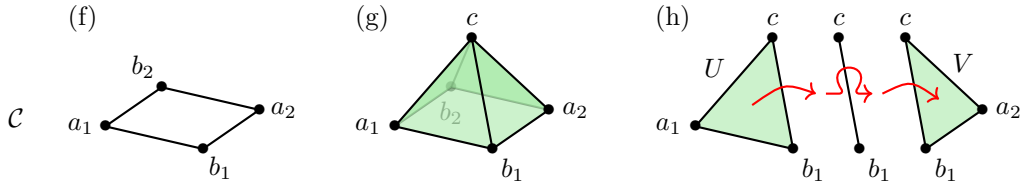

Figure 2 Charlie and an inchworm

Figure 2 to (g), where the four triangles are in $\mathcal{C}$ – so a new experimenter, Charlie, can make his measurement c along with Alice and Bob.

Now rewrite the locally consistent (3) in the inference form (6) (we replace $x \oplus y = 0$ with simpler $x = y$) and compare it to (7):

$$a_1 = b_1, \quad a_1 = b_2, \quad a_2 = b_1 \quad \vdash \quad a_2 = b_2 \tag{6}$$

$$a_1 = b_1, \quad a_1 = c, \quad a_2 = b_1 \quad \vdash \quad a_2 = c \tag{7}$$

(7) is valid in no-signalling models, whereas (6) is not (the PR box is a countermodel, as it is a model for (3)). The only difference is c replacing b_2 – this tiny difference, however, enables us to obtain (7) in the following two steps:

$$\dfrac{\dfrac{a_1 = b_1 \qquad a_1 = c}{b_1 = c}\,U \qquad a_2 = b_1}{a_2 = c}\,V \tag{8}$$

The first step is within the context $U = \{a_1, b_1, c\}$, hence valid locally: Every section over U satisfying the antecedents satisfies the consequent. Similarly, the second step is valid within $V = \{a_2, b_1, c\}$. The key aspect is that the formula in the middle, $b_1 = c$, can be in the context $U \cap V$ and so in U or in V. The upshot is that information gets passed on from a larger context U to a smaller $U \cap V$ and then to another larger V – just like the locomotion of an inchworm, if (h) of Figure 2 helps to visualize it. Crucially, the no-signalling property is essential when the inchworm moves from a larger context to a smaller: E.g., the first step of (8) concludes that every section over $\{a_1, b_1, c\}$ satisfies $b_1 = c$; but then, in the absence of no-signalling, there may be a section over $\{b_1, c\}$ violating $b_1 = c$ without extending to $\{a_1, b_1, c\}$. We will discuss the semantic rôle of no-signalling further in subsection 4.3.

3.3 Formalizing the Inchworm

We formalize and generalize the idea of "inchworm inference". As in the example in subsection 3.2, an inchworm logic is obtained by constraining a global logic. We assume this logic to be (at least) regular, i.e. to have $\top$, $\wedge$, and $\exists$, for the reasons explained shortly.

▶ **Definition 5.** Let $\mathcal{L}$ be a language of regular logic (or richer) whose variables include X. For each $x \in X$, write T_x for the type of x, and then, for each $\bar{x} \subseteq X$, write $\Phi_{\bar{x}}$ for the set of formulas in the context $\bar{x} : T_{\bar{x}}$. Given a simplicial complex $\mathcal{C}$ on X, the *$\mathcal{C}$-contextual fragment* of $\mathcal{L}$ is $\Phi_{\mathcal{C}} = \bigcup_{U \in \mathcal{C}} \Phi_U$. By a *$\mathcal{C}$-contextual language* $\mathcal{L}_{\mathcal{C}}$, we simply mean a pair of such $\mathcal{L}$ and $\Phi_{\mathcal{C}}$. Now let $\mathbb{T}$ be a regular theory in $\mathcal{L}$ given by an entailment relation $\vdash$ (which is *not* required to be binary). Then the inchworm fragment of $\vdash$ in $\mathcal{L}_{\mathcal{C}}$ is the entailment relation $\vdash_{\mathcal{C}}$ on $\Phi_{\mathcal{C}}$ defined inductively by the following. We write $\Gamma_U = \Gamma \cap \Phi_U$.

(9) $\Gamma \vdash_{\mathcal{C}} \varphi$ if there is $U \in \mathcal{C}$ such that $\varphi \in \Phi_U$ and $\Gamma_U \vdash \varphi$.

(10) If $\Gamma \vdash_{\mathcal{C}} \varphi$ and $\Delta, \varphi \vdash_{\mathcal{C}} \psi$ then $\Gamma, \Delta \vdash_{\mathcal{C}} \psi$.

(9) expresses the idea that $\vdash$ within a single context is valid locally as well. In (10), note that the first two instances of $\vdash_{\mathcal{C}}$ may be witnessed by different contexts. Observe also that $\Gamma \vdash_{\mathcal{C}} \varphi$ entails $\Gamma \vdash \varphi$; thus $\vdash_{\mathcal{C}}$ is a fragment of $\vdash$.

▶ **Example 6.** Let $\mathcal{L}$ have T as a basic type; 0, 1 be constants of type T; and $\oplus$ be a function symbol of type $\oplus : T \times T \to T$. Let $T_x = T$ for all $x \in X$. So, e.g., $x : T, y : T \mid x \oplus y = 1$ makes sense, and is in $\Phi_{\{x,y\}}$. This gives equations of the kind relevant to the examples in subsection 3.1. Note that $\Phi_{\mathcal{C}}$ is a union. E.g., for (f) of Figure 2, $a_i = 0$ is in $\Phi_{\{a_i\}} \subseteq \Phi_{\mathcal{C}}$ for both $i = 1, 2$, but $a_1 = 0 \wedge a_2 = 0$ is *not* in $\Phi_{\mathcal{C}}$ since $\{a_1, a_2\} \notin \mathcal{C}$.

We assume $\mathcal{L}$ to have $\top$ and $\wedge$, so that pieces of information can be combined within the same context. The inchworm moves from a smaller context U to a larger V via the order embedding $i : (\Phi_U, \vdash_U) \hookrightarrow (\Phi_V, \vdash_V)$, and from V to U via the left adjoint $\exists_{V \setminus U}$ of i. Then $\exists_{V \setminus U} \dashv i$ means that, for any $\varphi \in \Phi_V$, $\exists_{V \setminus U}.\varphi \in \Phi_U$ encapsulates all and only the information that φ entails on U. We also have $\exists_{V \setminus U} \circ i \cong 1$, so a piece of information that can be both about U and about V undergoes no change when carried across U and V.

4 Contextual Semantics in Regular Categories

Our definition of model using a sheaf generalizes by replacing **Sets** with any category $\mathbf{S}$ with finite limits, since the base $\mathcal{C}$ is a simplicial complex. Yet, for the sake of no-signalling, we moreover need $\mathbf{S}$ to be regular. References on regular categories and their categorical logic include [20, 5, 12]. We then lay out how to model the inchworm logic in $\mathbf{S}$.

4.1 Topological Models in Regular Categories

Let $\mathcal{C}$ be a simplicial complex on a set X, and $\mathbf{S}$ be a category with finite limits. By a presheaf on $\mathcal{C}$ valued in $\mathbf{S}$, we mean any contravariant functor $P : \mathcal{C}^{\mathrm{op}} \to \mathbf{S}$. Then the definitions of separated presheaf and sheaf generalize straightforwardly to

▶ **Definition 7.** We say that an $\mathbf{S}$-valued presheaf P on $\mathcal{C}$ is separated if the arrow $\langle P_{U_i \subseteq U} \rangle_i : P_U \to \prod_i P_{U_i}$ is monic whenever $\bigcup_i U_i = U$, and a sheaf if, whenever $\bigcup_i U_i = U$, $\langle P_{U_i \subseteq U} \rangle_i$ is an equalizer as follows, where $p_j : \prod_i P_{U_i} \to P_{U_j}$ and $p_k : \prod_i P_{U_i} \to P_{U_k}$ are the projections.

$$P_U \rightarrowtail \prod_i P_{U_i} \rightrightarrows \prod_{j,k} P_{U_j \cap U_k}$$

with the parallel pair $\langle P_{U_j \cap U_k \subseteq U_j} \circ p_j \rangle_{j,k}$ and $\langle P_{U_j \cap U_k \subseteq U_k} \circ p_k \rangle_{j,k}$.

Again, every sheaf F has $F_\varnothing = 1$, the terminal object of $\mathbf{S}$, and every separated presheaf P has $P_\varnothing \rightarrowtail 1$. Also, for simpler descriptions, Fact 1 generalizes to

▶ **Fact 8.** An $\mathbf{S}$-valued presheaf P on a simplicial complex $\mathcal{C}$ is a sheaf iff $P_U = \prod_{x \in U} P_x$ for all $U \in \mathcal{C}$. And P is separated iff it is a subpresheaf of a sheaf, i.e. iff each $\langle P_{\{x\} \subseteq U} \rangle_{x \in U} : P_U \to \prod_{x \in U} P_x$ is monic, i.e. iff each P_U is a relation in $\mathbf{S}$ on $(P_x)_{x \in U}$.

Next we define the no-signalling property for $\mathbf{S}$-valued separated presheaves. In doing so, we need to choose from several generalizations of the notion of surjection in (1) of Definition 4; the one that serves our purpose is the one that provides semantics for $\exists : \Phi_V \rightleftarrows \Phi_U : i$ in the inchworm logic. This is the principal reason we need $\mathbf{S}$ to be regular; then, in $\mathbf{S}$, every arrow $f : C \to D$ gives rise to the adjoint pair $\exists_f \dashv f^{-1}$, $\exists_f : \mathrm{Sub}_{\mathbf{S}}(C) \rightleftarrows \mathrm{Sub}_{\mathbf{S}}(D) : f^{-1}$ (e.g. [5, Lemma 2.5]), and moreover $\exists_f \circ f^{-1} = 1_{\mathrm{Sub}(D)}$ (and so f^{-1} is an order embedding) if f is a regular epi (essentially, [12, Corollary D1.2.8]). Therefore the right generalization of Definition 4 is the following Definition 9, with an alternative description in Fact 10.

▶ **Definition 9.** A separated presheaf A on a simplicial complex $\mathcal{C}$ valued in a regular category $\mathbf{S}$ is said to be no-signalling if every $A_{U\subseteq V} : A_V \to A_U$ is a regular epi.

▶ **Fact 10.** Let F be a sheaf on a simplicial complex $\mathcal{C}$. Then a family $(i_U : A_U \rightarrowtail F_U)_{U\in\mathcal{C}}$ of subobjects forms a subpresheaf of F, and hence a separated presheaf, iff $A_V \leqslant {F_{U\subseteq V}}^{-1}(A_U)$, or equivalently $\exists_{F_{U\subseteq V}}(A_V) \leqslant A_U$, whenever $U \subseteq V \in \mathcal{C}$. Moreover, a separated presheaf $i : A \rightarrowtail F$ is no-signalling iff $\exists_{F_{U\subseteq V}}(A_V) = A_U$ whenever $U \subseteq V \in \mathcal{C}$.

4.2 Global Inconsistency in Regular Categories

Definition 3 of contextuality for **Sets**-valued presheaves can now extend to ones valued in any regular category $\mathbf{S}$. Let A be an $\mathbf{S}$-valued separated presheaf on a simplicial complex $\mathcal{C}$ on X. It is a subpresheaf of a sheaf F on $\mathcal{C}$. In fact, let us assume, just in this subsection, that X is finite (or that $\mathbf{S}$ is complete); then, by Fact 8 (or a straightforward generalization), F extends uniquely to a sheaf on $\mathcal{P}X$, viz. $F : U \mapsto \prod_{x\in U} F_x$. Then the set of global sections of A – i.e. the natural join $\bowtie A$ of the relations $A_U \subseteq F_U$ – generalizes to the $\mathbf{S}$-valued case:

▶ **Fact 11.** Given any $\mathbf{S}$-valued separated presheaf A, let F be a sheaf such that $i : A \rightarrowtail F$ and, using A_U as predicates in the internal language of $\mathbf{S}$, define

$$\bowtie A = [\![\, \bar{x} : F_X \mid \textstyle\bigwedge_{U\in\mathcal{C}} A_U(F_{U\subseteq X}\bar{x}) \,]\!] = \textstyle\bigwedge_{U\in\mathcal{C}} {F_{U\subseteq X}}^{-1}(A_U) \rightarrowtail F_X.$$

Then $\bowtie A$ is the limit of A as a diagram in $\mathbf{S}$.

For each $U \in \mathcal{C}$, write $\rho_U : \bowtie A \to A_U$ for the restriction of $F_{U\subseteq X}$ to $\bowtie_A$; it generalizes the restriction of global sections to local sections over U. Definition 3 then extends to

▶ **Definition 12.** An $\mathbf{S}$-valued separated presheaf A is said to be logically contextual if not every $\rho_U : \bowtie A \to A_U$ is a regular epi. A is moreover said to be strongly contextual if $\bowtie A$ is not well-supported, i.e. if the unique arrow $!_{\bowtie A} : \bowtie A \to 1$ is not a regular epi.

Rewriting this in the internal language of $\mathbf{S}$, the strong contextuality of A means that $\mathbf{S}$ fails $\exists\bar{x} : F_X.\bowtie A(\bar{x})$, i.e., that no global section $\bar{x}$ satisfies all the constraints A_U. The logical contextuality means that $\bar{x} : F_V \mid A_V(\bar{x}) \vdash \exists\bar{y} : F_{X\setminus V}.\bowtie A(\langle\bar{x},\bar{y}\rangle)$ fails in $\mathbf{S}$ for some $V \in \mathcal{C}$, i.e., that not every local section $\bar{x}$ over V satisfying A_V extends to a global section $\langle\bar{x},\bar{y}\rangle$ satisfying all A_U.

4.3 Contextual Interpretation

In Definition 5 we defined a contextual language $\mathcal{L}_\mathcal{C}$ and logic $\vdash_\mathcal{C}$ simply as a global language $\mathcal{L}$ and logic $\vdash$ paired with their contextual fragments. Our definition of an interpretation of them in regular categories goes in parallel.

▶ **Definition 13.** Given a contextual language $\mathcal{L}_\mathcal{C} = (\mathcal{L}, \Phi_\mathcal{C})$, an interpretation of it in a regular category $\mathbf{S}$ is simply an interpretation $[\![-]\!]$ of $\mathcal{L}$ in $\mathbf{S}$. The images of T_x and Φ_U then play special rôles: For each $\bar{x} \in \mathcal{C}$, we have

- $[\![T_{\bar{x}}]\!] = \prod_{x\in\bar{x}} [\![T_x]\!]$; therefore $[\![T_-]\!] : \mathcal{C}^{\mathrm{op}} \to \mathbf{S}$ forms a sheaf by Fact 8.
- Moreover, $[\![\, \bar{x} : T_{\bar{x}} \mid \varphi \,]\!] \rightarrowtail [\![T_{\bar{x}}]\!]$ for each $\varphi \in \Phi_{\bar{x}}$.

So we may write $([\![-]\!], F)$ for the interpretation $[\![-]\!]$, where F is the sheaf $F : \bar{x} \mapsto [\![T_{\bar{x}}]\!]$. We may also write $[\![\varphi]\!]_{\bar{x}} \rightarrowtail F_{\bar{x}}$ for $[\![\, \bar{x} : T_{\bar{x}} \mid \varphi \,]\!]$.

▶ **Example 14.** Expanding Example 6, take $[\![-]\!]$ in **Sets** with $[\![T]\!] = \mathbf{2}$ and the obvious $[\![0]\!]$, $[\![1]\!]$, and $[\![\oplus]\!]$. Then we have a sheaf $[\![T_-]\!] : U \mapsto \mathbf{2}^U$ and, e.g., $[\![\, x : T, y : T \mid x \oplus y = 0 \,]\!] \rightarrowtail [\![T_{\{x,y\}}]\!] = \mathbf{2} \times \mathbf{2}$ is an equalizer of $[\![\oplus]\!], [\![0]\!] \circ ! : \mathbf{2} \times \mathbf{2} \to \mathbf{2}$.

An interpretation $[\![-]\!]$ of $\mathcal{L}$ is said to model a sequent $\Gamma \vdash \varphi$ if some finite $\Delta \subseteq \Gamma$ has $\bigwedge_{\psi\in\Delta}[\![\psi]\!]_U \leqslant [\![\varphi]\!]_U$. This makes sense whether $U \in \mathcal{C}$ or not. Nevertheless, if $U \notin \mathcal{C}$, then $\bigwedge_{\psi\in\Delta}[\![\psi]\!]_U \leqslant [\![\varphi]\!]_U$ only means the global entailment and not the local one. Take, e.g.,

▶ **Example 15.** Expanding Example 14, the model A of the PR box, (d) of Figure 1, is a subpresheaf of $[\![T\_]\!]$ described by (3): E.g. $A_{\{a_i,b_1\}} = [\![\, a_1 \oplus b_1 = 0 \,]\!]_{\{a_1,b_1\}} \rightarrowtail \mathbf{2}\times\mathbf{2}$. Then the global inconsistency, and strong contextuality in particular, of the equations Γ in (3) means $\bowtie A = \bigcap_{\varphi\in\Gamma}[\![\varphi]\!]_X \subseteq [\![\bot]\!]_X = \varnothing$. Yet Γ is locally consistent, modelled by the PR box.

This is why, to model the inchworm logic of local inference, we need a presheaf on different contexts $U \in \mathcal{C}$, as opposed to an intersection in a single context $V \notin \mathcal{C}$, to the left of $\leqslant$.

▶ **Definition 16.** Suppose $([\![-]\!], F)$ is an interpretation of a contextual language $\mathcal{L}_\mathcal{C}$. Then let us say that a subpresheaf $A \rightarrowtail F$ is a *pre-model* in $([\![-]\!], F)$ of a formula $\varphi \in \Phi_U$ in a context $U \in \mathcal{C}$, and write $A \vDash_U \varphi$, to mean that $A_U \leqslant [\![\varphi]\!]_U$.

▶ **Fact 17.** If $A \leqslant B$ for subpresheaves A and B of F, then $B \vDash_U \varphi$ implies $A \vDash_U \varphi$.

Note, however, that this notion of pre-model is context-dependent and concerns formulas in contexts as opposed to formulas *per se*. When $U \subseteq V \in \mathcal{C}$ and $\varphi \in \Phi_U$, Fact 10 yields

(11) $A \vDash_U \varphi$ entails $A \vDash_V \varphi$ (because $\exists_{F_{U\subseteq V}}(A_V) \leqslant A_U \leqslant [\![\varphi]\!]_U$ entails $A_V \leqslant {F_{U\subseteq V}}^{-1}[\![\varphi]\!]_U = [\![\varphi]\!]_V$).

(12) Suppose A is no-signalling. Then $A \vDash_V \varphi$ entails $A \vDash_U \varphi$. (This is because $A_V \leqslant [\![\varphi]\!]_V = {F_{U\subseteq V}}^{-1}[\![\varphi]\!]_U$ implies $A_U = \exists_{F_{U\subseteq V}}(A_V) \leqslant [\![\varphi]\!]_U$.)

If A is not no-signalling, (12) may fail, and then inchworm inference fails. E.g., in (8), the first step purports to show that, if $A \vDash_U a_1 = b_1$ and $A \vDash_U a_1 = c$, then $A \vDash_U b_1 = c$ and so $A \vDash_{U\cap V} b_1 = c$; but the "and so" step here requires (12). In this sense, no-signalling means the context-independent coherence of a presheaf as a model of formulas. Therefore

▶ **Definition 18.** A pre-model A is called a (no-signalling) *model* if it is no-signalling. Then we say that A is a model of a formula $\varphi \in \Phi_\mathcal{C}$, and write $A \vDash \varphi$, to mean that A is a pre-model of φ in any suitable context, i.e., that $A_U \leqslant [\![\varphi]\!]_U$ for every $U \in \mathcal{C}$ such that $\varphi \in \Phi_U$.

▶ **Theorem 19.** *Let $[\![-]\!]$ be an interpretation of $\mathcal{L}_\mathcal{C}$ that models a theory $\vdash$ in $\mathcal{L}$. Then the inchworm logic $\vdash_\mathcal{C}$ of $\vdash$ is sound with respect to the no-signalling models in $[\![-]\!]$: If $\Gamma \vdash_\mathcal{C} \varphi$, then $A \vDash \varphi$ for every no-signalling model A of Γ in $[\![-]\!]$.*

4.4 The Inchworm and No-Signalling

Subsection 4.3 primarily concerned how given presheaves modelled formulas. We showed in particular that no-signalling validated inchworm inference. Let us discuss, on the other hand, how the description by given formulas yields a model. This shows the other direction of the connection between no-signalling and the inchworm, from the latter to the former.

We say a set $\Gamma \subseteq \Phi_\mathcal{C}$ of formulas of $\mathcal{L}_\mathcal{C}$ is $\mathcal{C}$-*finite* if Γ_U is finite for each $U \in \mathcal{C}$.

▶ **Definition 20.** Let $([\![-]\!], F)$ be an interpretation of $\mathcal{L}_\mathcal{C}$. Given any $\mathcal{C}$-finite $\Gamma \subseteq \Phi_\mathcal{C}$, define $\mathbb{M}_F(\Gamma)$ as a family $(\mathbb{M}_F(\Gamma)_U = \bigwedge_{\varphi\in\Gamma_U}[\![\varphi]\!]_U \rightarrowtail F_U)_{U\in\mathcal{C}}$ of subobjects of F_U.

▶ **Fact 21.** $\mathbb{M}_F(\Gamma)$ is the largest subpresheaf A of F such that $A \vDash_U \Gamma_U$ for each $U \in \mathcal{C}$.

$\mathbb{M}_F(\Gamma)$ generally fails to be no-signalling (take the first step of (8) as an example again). Yet the description by Γ sometimes manages to give a no-signalling $\mathbb{M}_F(\Gamma)$.

▶ **Fact 22.** Let $(\llbracket - \rrbracket, F)$ be an interpretation of $\mathcal{L}_\mathcal{C}$ that models a theory $\vdash$ in $\mathcal{L}$. We say $\Gamma \subseteq \Phi_\mathcal{C}$ is *inchworm-saturated* if $\Gamma_V \vdash \varphi$ implies $\Gamma_U \vdash \exists_{V \setminus U}. \varphi$ whenever $U \subseteq V \in \mathcal{C}$ and $\varphi \in \Phi_V$. Now, if a $\mathcal{C}$-finite Γ is inchworm-saturated, then $\mathbb{M}_F(\Gamma)$ is no-signalling.

When Γ is inchworm-saturated, it may not be deductively closed, but the inchworm cannot bring a new piece of information ψ to a context U from another V, since ψ follows from the information Γ_U that U already has. Fact 22 means that, if Γ is inchworm-saturated and if each Γ_U finite and consistent (and has $\mathbb{M}_F(\Gamma)_U$ nonempty or well-supported), then Γ is locally consistent, modelled by a no-signalling model $\mathbb{M}_F(\Gamma)$. E.g., (3) is inchworm-saturated, with each context consistent, so it gives the PR box, (d) of Figure 1, as $\mathbb{M}_F(\Gamma)$.

On the other hand, even when a description Γ is not inchworm-saturated and $\mathbb{M}_F(\Gamma)$ fails to be no-signalling, the inchworm can carve out the "no-signalling interior" of $\mathbb{M}_F(\Gamma)$, if Γ can be saturated in finite (or $\mathcal{C}$-finite) steps.

▶ **Theorem 23.** *Let $(\llbracket - \rrbracket, F)$ be an interpretation of $\mathcal{L}_\mathcal{C}$ that models a theory $\vdash$ in $\mathcal{L}$. Given $\Gamma \subseteq \Phi_\mathcal{C}$, suppose there is a $\mathcal{C}$-finite and inchworm-saturated $\Delta \subseteq \Phi_\mathcal{C}$ such that $\Gamma \subseteq \Delta$ and $\Gamma \vdash_\mathcal{C} \varphi$ for all $\varphi \in \Delta$. Then $\mathbb{M}_F(\Delta)$ is the largest no-signalling subpresheaf of $\mathbb{M}_F(\Gamma)$.*

E.g., A in (e) of Figure 1 is $\mathbb{M}_F(\Gamma)$ given by $\Gamma = \{\varphi\}$ for $\varphi = (a_2 \wedge \neg b_1) \vee (\neg a_2 \wedge \neg b_1)$; since φ cannot be in the context $\{b_1\}$, $\Gamma_{\{b_1\}} = \varnothing$ and $A_{\{b_1\}} = \mathbf{2}$. Yet $\varphi \vdash \neg b_1$, so $\Gamma \vdash_\mathcal{C} \neg b_1$, and $\Delta = \Gamma \cup \{\neg b_1\}$ is inchworm-saturated, with $\neg b_1 \in \Delta_{\{b_1\}}$. Hence, by Theorem 23, the inchworm carves out a no-signalling $\mathbb{M}_F(\Delta)$ by removing the red sections from (e). Indeed, in many applications (e.g. all the examples in sections 2 and 3), the theory $\vdash$ satisfies

(13) Given any $\Gamma \subseteq \Phi_\mathcal{C}$ (that may not be $\mathcal{C}$-finite), for each $U \in \mathcal{C}$ there is a finite $\Delta_U \subseteq \Gamma_U$ such that $\Delta_U \vdash \varphi$ for all $\varphi \in \Gamma_U$.

This guarantees the supposition of Theorem 23: Given any $\mathcal{C}$-finite $\Gamma \subseteq \Phi_\mathcal{C}$, take its $\vdash_\mathcal{C}$-deductive closure $\Gamma^* = \{\, \varphi \mid \Gamma \vdash_\mathcal{C} \varphi \,\}$ as Γ in (13) and obtain Δ_U; then $\Delta = \Gamma \cup \bigcup_{U \in \mathcal{C}} \Delta_U$ is such as in Theorem 23. Therefore Theorem 23 applies and leads to a family of completeness results organized by Lemma 24, which transfers a completeness theorem of a global theory to its inchworm fragment. It yields, e.g., Theorem 25, since any (global) regular theory has a "conservative model" in a "classifying category" (e.g. [5, Proposition 6.4]).

▶ **Lemma 24.** *Suppose that a theory $\vdash$ in $\mathcal{L}$ satisfies* (13)*, and that $\llbracket - \rrbracket$ is a conservative model of $\vdash$, meaning that, for any $\Gamma \subseteq \Phi_\mathcal{C}$, $\bigwedge_{\psi \in \Delta} \llbracket \psi \rrbracket_U \leqslant \llbracket \varphi \rrbracket_U$ for some $\Delta \subseteq \Gamma$ if but also only if $\Gamma \vdash \varphi$. Then $\Gamma \vdash_\mathcal{C} \varphi$ iff $A \vDash \varphi$ for every no-signalling model A of Γ in $\llbracket - \rrbracket$.*

▶ **Theorem 25.** *Let $\vdash$ be a regular theory satisfying* (13)*. Then, for any $\Gamma \subseteq \Phi_\mathcal{C}$, $\Gamma \vdash_\mathcal{C} \varphi$ iff $A \vDash \varphi$ for every no-signalling model A of Γ in every model $\llbracket - \rrbracket$ of $\vdash$ in any regular category.*

4.5 Completion for Completeness

Generally, (13) may fail and the inchworm saturation may not be attained in finite steps.

▶ **Example 26.** In Figure 1, replace each $A_x = \mathbf{2}$ with $\mathbb{Z}$, and let $\Gamma = \{\, a_1 = b_2, b_1 = a_1, a_2 = b_1, b_2 = a_2 + 1, b_2 > 0 \,\}$ in the obvious $\mathcal{L}$ and $\vdash$. Then $\Gamma \vdash_\mathcal{C} a_1 > 0, b_1 > 0, a_2 > 0, b_2 > 1, \ldots, x > n$ for every $x \in X$ and $n \in \mathbb{N}$, whereas $\Gamma \nvdash_\mathcal{C} \bot$ (although the empty presheaf is the only no-signalling model of Γ). So there cannot be any such Δ as in Theorem 23. (Note that the topology of $\mathcal{C}$ is essential: E.g., if we take $\mathcal{C} = \mathcal{P}X$ instead, then $\Gamma \vdash_\mathcal{C} \bot$ by $\Gamma \vdash \bot$.)

Thus, even if Γ is finite, the set $\{\, \llbracket \varphi \rrbracket_U \mid \varphi \in \Gamma^*{}_U \,\}$ may have no minimum (though it is lowerbounded by $\exists_{F_U \subseteq X} (\bigwedge_{\psi \in \Gamma} \llbracket \psi \rrbracket_X)$ if X is finite); then, in a regular category in general, $\bigwedge_{\varphi \in \Gamma^*{}_U} \llbracket \varphi \rrbracket_U$ may not exist. So, instead of the semilattice $\mathrm{Sub}_\mathbf{S}(F_U)$ of subobjects, let us

use a completion of it, viz. the semilattice $\mathrm{Filt}(\mathrm{Sub}_{\mathbf{S}}(F_U))$ of filters in $\mathrm{Sub}_{\mathbf{S}}(F_U)$, and assign a filter of subobjects, instead of a subobject, to each $U \in \mathcal{C}$.

▶ **Definition 27.** Suppose $([\![-]\!], F)$ is an interpretation of a contextual language $\mathcal{L}_{\mathcal{C}}$. Then, by a *filter model* in $([\![-]\!], F)$, we mean a presheaf $G : \mathcal{C}^{\mathrm{op}} \to \mathbf{Sets}$ such that

- $G_U \in \mathrm{Filt}(\mathrm{Sub}_{\mathbf{S}}(F_U))$ for every $U \in \mathcal{C}$.
- For $U \subseteq V \in \mathcal{C}$, $G_U = \{\, S \rightarrowtail F_U \mid {F_{U\subseteq V}}^{-1}(S) \in G_V \,\} = \{\, \exists_{F_{U\subseteq V}}(S) \rightarrowtail F_U \mid S \in G_V \,\}$, so $G_{U\subseteq V} : G_V \to G_U :: S \mapsto \exists_{F_{U\subseteq V}}(S)$ is a surjection.

We say G models φ, and write $G \vDash \varphi$, to mean that $[\![\varphi]\!]_U \in G_U$ whenever $\varphi \in \Phi_U$.

Then we have the filter versions of Theorem 19, Fact 22, and completeness results organized by Lemma 24. Observe that every (no-signalling) model A is a "principal" filter model, $U \mapsto \uparrow A_U = \{\, S \rightarrowtail F \mid A_U \leqslant S \,\}$; so Theorem 28 is stronger than Theorem 19.

▶ **Theorem 28.** *Let $[\![-]\!]$ be a model of a theory $\vdash$ in $\mathcal{L}$. Then the inchworm logic $\vdash_{\mathcal{C}}$ of $\vdash$ is sound with respect to the filter models in $[\![-]\!]$: If $\Gamma \vdash_{\mathcal{C}} \varphi$, then $G \vDash \varphi$ for every filter model G of Γ in $[\![-]\!]$.*

▶ **Fact 29.** Let $([\![-]\!], F)$ be a model of a theory $\vdash$ in $\mathcal{L}$. Given any $\Gamma \subseteq \Phi_{\mathcal{C}}$, the family $\mathbb{FM}_F(\Gamma) = (\{\, S \rightarrowtail F_U \mid [\![\varphi]\!]_U \leqslant S \text{ for some } \varphi \in {\Gamma^*}_U \,\})_{U\in\mathcal{C}}$ is a filter model of Γ in $([\![-]\!], F)$. Moreover, for any filter model G of Γ in $([\![-]\!], F)$, $\mathbb{FM}_F(\Gamma)_U \subseteq G_U$ for each $U \in \mathcal{C}$.

▶ **Lemma 30.** *Suppose $[\![-]\!]$ is a conservative model of a theory $\vdash$ in $\mathcal{L}$. Then $\Gamma \vdash_{\mathcal{C}} \varphi$ iff $G \vDash \varphi$ for every filter model G of Γ in $[\![-]\!]$.*

5 Conclusion

Let us conclude the paper by discussing connections and applications between the framework of this paper and other approaches or other fields as future work. First of all, categorical logic has a long tradition (since [16]) of viewing local truth as a modal operator. Indeed, the logic of local information in this paper is closely related to the dynamic-logical characterization of contextuality in [13]. There is also a connection to model theory. For instance, the similarity between inchworm inference and Craig interpolation should be obvious; indeed, by defining Φ_U more generally as a "language in the vocabulary U", we can prove a stronger version of Robinson's joint consistency theorem (see [6, subsection 4.1.1]) that is sensitive to the topology of $\mathcal{C}$.

As explained in section 2, presheaf models can model Boolean valuations. This enables us to transfer and apply techniques from satisfiability problems to quantum contextuality as computational resource. Another connection is to the structure of valuation algebra, which is used for local computation [14]. In fact, our presheaf models can also be formulated in terms of valuation algebras, as a $\mathcal{C}$-indexed family of valuations satisfying certain conditions. We can expect these connections to help extend local computation to situations in classical computing where contextual phenomena arise.

The generality of taking presheaves in regular categories is also expected to facilitate applications. In cohomology, it is typical to use presheaves valued in regular categories, such as presheaves of abelian groups, R-modules, etc. Therefore the framework of this paper applies to the logic of local inference within such presheaves. One can also take regular categories of structures that are used for other purposes such as modelling processes in quantum physics. In addition, the connection to logical paradoxes [2] is also relevant. As shown in [15, 4], regular categories provide background for self-referential and other fixpoint paradoxes; so our formalism will unify the two perspectives on paradoxes.

Abstract

We consider minimization problems for natural parameters of word transducers: the number of passes performed by two-way transducers and the number of registers used by streaming transducers. We show how to compute in ExpSpace the minimum number of passes needed to implement a transduction given as sweeping transducer, and we provide effective constructions of transducers of (worst-case optimal) doubly exponential size. We then consider streaming transducers where concatenations of registers are forbidden in the register updates. Based on a correspondence between the number of passes of sweeping transducers and the number of registers of equivalent concatenation-free streaming transducers, we derive a minimization procedure for the number of registers of concatenation-free streaming transducers.

1 Introduction

Regular word functions extend the robust family of regular languages, preserving many of its characterizations and algorithmic properties. A word function maps words over a finite input alphabet to words over a finite output alphabet. Regular word functions have been studied in the early seventies, in the form of (deterministic) two-way finite state automata with output [1]. Engelfriet and Hoogeboom [8] later showed that monadic second-order definable graph transductions, restricted to words, are an equivalent model – this justifies the notation "regular" word functions, in the spirit of classical results in automata theory and logic by Büchi, Elgot, Rabin and others. Recently, Alur and Cerný [2] proposed an enhanced version of one-way transducers called streaming transducers, and showed that they equivalent to the two previous models. A streaming transducer processes the input word from left to right, and stores (partial) output words in finitely many, write-only registers. A variant of streaming transducers extended by stacks has been introduced in [3] and shown to capture precisely the monadic-second order definable tree transductions.

Two-way and streaming transducers raise new and challenging questions about storage requirements. The classical storage measure for automata is state complexity. State space minimization of two-way transducers is however poorly understood, even in the simpler setting of automata (cf. related work). But there are more meaningful parameters for transducer minimization. One such parameter for streaming transducers is the number of registers, and for two-way transducers it is the number of times the transducer needs to re-process the input word. These parameters measure the required storage capacity in a more realistic way than the number of control states. For example, a two-way transducer that needs to process a very large input with several passes has much larger memory requirements in practice than the memory needed for storing the states. Ideally, the input is processed one-way, hence in one pass only, as in the streaming setting. But not every transduction can be implemented by a one-way, finite state transducer without additional memory.

The register minimization problem has been considered by Alur and Raghothaman in [4], for a special family of deterministic streaming transducers: the output alphabet is unary, and the updates are additions/subtractions of registers by constants. For two-way transducers, Filiot et al. showed how to decide whether a transducer is equivalent to some one-way transducer [10]. The decision procedure of [10] is non-elementary, and we provided in [5] an elementary decision procedure and construction of equivalent one-way transducers in the special case of *sweeping* transducers: head reversals are only allowed at the extremities of the input. Sweeping transducers are strictly less expressive than two-way transducers, as shown e.g. by the transduction mapping inputs of the form $u_1\#u_2\#\cdots\#u_n$, where the words u_i contain no occurrence of $\#$, to $u_n\cdots u_2u_1$.

In this paper we extend our results from [5] by showing how to compute in ExpSpace the *minimal number of passes* needed by a non-deterministic, functional sweeping transducer. It turns out that sweeping transducers have the same expressive power as bounded-reversal two-way transducers, and as *concatenation-free* streaming transducers – transducers where concatenation of registers is not allowed in the updates. Since the transformations between the sweeping and streaming models preserve the relationship between the number of passes and the number of registers, we reduce the *minimization problem for registers* of concatenation-free streaming transducers to the minimization of the number of passes of sweeping transducers, and thus solve the former problem.

Related work. As already mentioned, succinctness questions about two-way automata are still challenging. A longstanding open problem is whether non-deterministic two-way automata are exponentially more succinct than deterministic two-way automata. It is only known that this is the case for deterministic sweeping automata [13].

Regular transductions behave also nicely in terms of expressiveness: first-order definable transductions are known to be equivalent to transductions defined by aperiodic streaming transducers [11] and by aperiodic two-way transducers [6].

Besides [4], the closest work to ours is [7], that shows how to compute the minimal number of registers of deterministic streaming transducers with register updates of the form $x := y \cdot v$, where v is a word and x, y are registers. These transducers are as expressive as one-way transducers. However, the focus of [7] is different from ours, since the outputs can be formed over any infinitary group. Moreover, the works [4, 7] consider deterministic transducers, which require in general more registers than non-deterministic functional ones. The proof techniques are based on variants of a property that has been studied for one-way transducers (the twinning property), and are quite different from ours.

Overview. After introducing two-way and streaming transducers in Section 2, and showing some basic properties, we recall in Section 3 the key characterization of one-way definability from [5]. Section 4 presents the main result on minimization of sweeping transducers. Finally, Section 5 concludes with a logical characterization for sweeping transducers. A longer version of the paper is available at `https://hal.archives-ouvertes.fr/hal-01274992`.

2 Preliminaries

Here we introduce the transducers we are interested in: two-way and streaming transducers.

Two-way transducers. A *two-way transducer* is a tuple $T = (Q, \Sigma, \Delta, I, E, F)$, where Q is a finite set of states, Σ (resp. Δ) is a finite input (resp. output) alphabet, I (resp. F) is a subset of Q representing the initial (resp. final) states, and $E \subseteq Q \times \Sigma \times \Delta^\star \times Q \times \{\mathsf{left}, \mathsf{right}\}$ is a finite set of transition rules describing, for each state and input symbol, the possible output string, target state, and direction of movement. To enable distinguished transitions at the extremities of the input word, we use two special symbols $\rhd$ and $\lhd$ and assume that the input of a two-way transducer is of the form $u = a_1 \dots a_n$, with $n \geq 2$, $a_1 = \rhd$, $a_n = \lhd$, and $a_i \neq \rhd, \lhd$ for all $i = 2, \dots, n-1$.

Given an input word u, we call *positions* the places between the symbols of u, where the head of a transducer can lie. We can identify the positions of $u = a_1 \dots a_n$ with the numbers $1, \dots, n-1$, where each number x is seen as the position between a_x and a_{x+1}. Since here we deal with *two-way* devices, a position can be visited several times along a run. Formally, we associate the states of the transducer with *locations*, namely, with pairs (x, y), where x is a position and y is a non-negative integer, called *level*. For convenience, we assume that, from a location at even level, the transducer can either move to the next position to the right, without changing the level, or perform a reversal, that is, increment the level by 1 and keep the same position; symmetrically, from a location at odd level, the transducer can either move leftward, without changing the level, or perform a reversal. Locations are ordered according to the following order: $\ell \leq \ell'$ if $\ell = (x, y), \ell' = (x', y')$ and one of the following holds: (1) $y < y'$, or (2) $y = y'$ even and $x \leq x'$, or (3) $y = y'$ odd and $x \geq x'$.

Formally, we define a run on $u = a_1 \dots a_n$ as a sequence of locations, labeled by states and connected by edges, hereafter called *transitions*. The state at a location $\ell = (x, y)$ of a run ρ is denoted $\rho(\ell)$. The transitions must connect pairs of locations $\ell \leq \ell'$ that are either at adjacent positions and on the same level, or at the same position and on adjacent levels. Each transition is labeled with a pair a/v consisting of an input symbol a and a word v produced as output. There are four types of transitions:

$$(x, 2y+1) \xleftarrow{a_{x+1}/v} (x+1, 2y+1) \qquad (x, 2y) \xrightarrow{a_{x+1}/v} (x+1, 2y)$$

$$a_{x+1}/v \circlearrowright \begin{matrix}(x+1, 2y+2)\\(x+1, 2y+1)\end{matrix} \qquad \begin{matrix}(x, 2y+1)\\(x, 2y)\end{matrix} \circlearrowleft a_{x+1}/v$$

The upper left (resp. upper right) transition can occur in a run ρ of T on u provided that $\big(\rho(x+1, 2y+1), a_{x+1}, v, \rho(x, 2y+1), \mathsf{left}\big)$ (resp. $\big(\rho(x, 2y), a_{x+1}, v, \rho(x+1, 2y), \mathsf{right}\big)$) is a valid transition rule of T and a_{x+1} is the $(x+1)$-th symbol of u (assuming that first symbol is $\rhd$). Similarly, the lower left (resp. lower right) transition are called *reversals*, and can occur in a run ρ if $\big(\rho(x+1, 2y+1), a_{x+1}, v, \rho(x+1, 2y+2), \mathsf{right}\big)$ (resp. $\big(\rho(x, 2y), a_{x+1}, v, \rho(x, 2y+1), \mathsf{left}\big)$) is a valid transition rule of T and a_{x+1} is the $(x+1)$-th symbol of u.

We say that a run on $u = a_1 \dots a_n$ is *successful* if it starts with an initial state, either at location $(1, 0)$ or at location $(n-1, 1)$, and ends in a final state, at some location of the form $(1, y_{\mathsf{max}})$ or $(n-1, y_{\mathsf{max}})$. The output produced by a run ρ is the concatenation of the words produced by its transitions, and it is denoted by $\mathsf{out}(\rho)$.

Crossing sequences. An important notion associated with runs of two-way automata is that of crossing sequence. Intuitively, this is a tuple of states that label those locations of a run that visit the same position. Formally, given a successful run ρ of a two-way transducer on input $u = a_1 \dots a_n$, the *crossing sequence of ρ at a position $x \in \{1, \dots, n-1\}$* is the tuple $\rho|x = \big(\rho(x, y_0), \dots, \rho(x, y_h)\big)$, where $y_0 < \dots < y_h$ are all and only the levels of the locations of ρ at position x. The classical transformation of two-way finite state automata into equivalent one-way automata [12] uses crossing sequences.

Properties of two-way transducers. We say that a two-way transducer is

- *sweeping* if every run performs the reversals only at the extremities of the input word, i.e. when reading the symbols $\triangleright$ or $\triangleleft$;
- *L-sweeping* if it is sweeping and all successful runs start at the leftmost location $(1, 0)$;
- *R-sweeping* if it is sweeping and all successful runs start at the rightmost location $(n–1, 1)$;
- *k-pass* if every successful run visits every position of the input at most k times;
- *k-reversal* if every successful run performs at most k reversals;
- *one-way* if it is 1-pass, L-sweeping.

A transducer is *functional* if it produces at most one output on each input. It is called *unambiguous* if it admits at most one successful run on each input. These notions will have the same meaning for streaming transducers, defined later. Clearly, every unambiguous transducer is functional. The converse is not true in general, but we will see later that we can transform the functional transducers considered in this paper so as to enforce unambiguity.

It is easy to see that every unambiguous transducer with n states is $2n$-pass. For functional transducers we can restrict ourselves to considering only *normalized* runs, namely, runs that never visit the same position twice with the same state and the same direction. The reason is that functionality guarantees that every factor of a successful run that starts and ends at the same position and with the same state produces the empty output.

Hereafter, we silently assume that all transducers are *functional* and all successful runs are *normalized*. As a consequence the length of the crossing sequences of the successful runs of a transducer can be bounded by $2n$, where n is the number of states of the transducer.

For streaming transducers, we can observe the following. Every k-pass R-sweeping transducer can be transformed into an equivalent $(k+1)$-pass L-sweeping transducer. It is also easy to disambiguate functional sweeping transducers, that is, transform them into equivalent unambiguous sweeping transducers, without increasing the number of passes. For this it suffices to fix a total order on the successful runs, e.g. the lexicographic order, and restrict to runs that are minimal among those over the same input.

The following proposition shows an interesting correspondence between the number of passes of sweeping transducers and the number of reversals of two-way transducers.

▶ **Proposition 1.** *Every k-pass sweeping transducer is also $(k-1)$-reversal. Conversely, every $(k-1)$-reversal two-way transducer can be transformed in* 2ExpTime *into an equivalent unambiguous k-pass sweeping transducer. The transformation can be performed in* ExpTime *if the $(k-1)$-reversal transducer is unambiguous.*

Streaming transducers. Streaming transducers can implement the same transductions as two-way transducers [2, 8], but they do so using a single left-to-right pass and a fixed set of registers that can store words over the output alphabet.

Formally, a *streaming transducer* is a tuple $T = (Q, \Sigma, \Delta, R, U, I, E, F)$, where Q is a finite set of states, Σ (resp. Δ) is a finite input (resp. output) alphabet, R is a finite set of registers disjoint from Δ, U is a finite set of *updates* for the registers, namely, functions from R to $(R \uplus \Delta)^\star$, I is a subset of Q representing the initial states, $E \subseteq Q \times \Sigma \times U \times Q$ is a finite set of transition rules, describing, for each state and input symbol, the possible updates and target states, and $F : Q \rightharpoonup (R \uplus \Delta)^\star$ is a partial output function.

A well-behaved class of streaming transducers [2] is obtained by restricting the allowed types of updates and partial output functions to be copyless. A streaming transducer $T = (Q, \Sigma, \Delta, R, U, I, E, F)$ is *copyless* if (1) for every update $f \in U$, every register $z \in R$ appears at most once in $f(z_1) \cdot \ldots \cdot f(z_k)$, where $R = \{z_1, \ldots, z_k\}$, and (2) for every state $q \in Q$, every register $z \in R$ appears at most once in $F(q)$. Hereafter we assume that all streaming transducers are copyless.

To define the semantics of a streaming transducer $T = (Q, \Sigma, \Delta, R, U, I, E, F)$, we introduce *valuations* of registers in R. These are functions of the form $g : R \to \Delta^\star$. Valuations can be homomorphically extended to words over $R \cup \Delta$ and to updates, as follows. For every valuation $g : R \to \Delta^\star$ and every word $w \in (R \cup \Delta)^\star$, we let $g(w)$ be the word over Δ obtained from w by replacing every occurrence of a register z with its valuation $g(z)$. Similarly, for every valuation $g : R \to \Delta^\star$ and every update $f : R \to (R \cup \Delta)^\star$, we denote by $g \circ f$ the valuation that maps each register z to the word $g(f(z))$.

A *configuration* of T is a pair state-valuation (q, g). This configuration is said to be initial if $q \in I$ and $g(z) = \varepsilon$ for all registers $z \in R$. When reading a symbol a, the transducer can move from a configuration (q, g) to a configuration (q', g') if there exists a transition rule $(q, a, f, q') \in E$ such that $g' = g \circ f$. We denote this by $(q, g) \xrightarrow[T]{a} (q', g')$.

A *run* of T on $u = a_1 \ldots a_n$ is a sequence of configurations and transitions of the form $\sigma = (q_0, g_0) \xrightarrow[T]{a_1} (q_1, g_1) \xrightarrow[T]{a_2} \ldots \xrightarrow[T]{a_n} (q_n, g_n)$. The run ρ is *successful* if the partial output function F is defined on the last state q_n. In this case, the *output* of T on u is $g_n(F(q_n))$.

Properties and relationships with sweeping transducers. Functional and unambiguous streaming transducers are defined as in the two-way case. A streaming transducer is *k-register* if it uses at most k registers. As we did for two-way transducers, we assume that all streaming transducers are functional.

It is known that (functional) streaming transducers capture precisely the transductions definable by deterministic two-way transducers or, equally, by monadic second-order logic (so-called MSO transductions) [2, 8]. Moreover, differently from two-way transducers, non-deterministic streaming transducers can be determinized. This happens at the cost of increasing the number of registers.

▶ **Definition 2.** A streaming transducer $T = (Q, \Sigma, \Delta, R, U, I, E, F)$ is *concatenation-free* if $f(z) \in \Delta^\star \cdot (R \cup \{\varepsilon\}) \cdot \Delta^\star$, for all registers $z \in R$ and all updates $f \in U$.

Intuitively, a concatenation-free streaming transducer forbids register updates with two or more registers inside a right-hand side. We note that concatenation-free streaming transducers can also be determinized effectively. Moreover, it is easy to see that allowing boundedly many updates with concatenations does not change the expressiveness of the model, as one can remove any occurrence of an update with concatenations by introducing new registers.

The following proposition shows a tight correspondence between the number of registers of the concatenation-free streaming transducers and the number of passes of the sweeping transducers. Note that the proposition considers sweeping transducers that start from the rightmost position. A slightly weaker correspondence holds for L-sweeping transducers, since any sweeping transducer can be made L-sweeping (resp. R-sweeping) by increasing the number of passes by 1.

▶ **Proposition 3.** *Every concatenation-free streaming transducer with k registers can be transformed in* ExpTime *into an equivalent unambiguous $2k$-pass R-sweeping transducer. The transformation is in* Ptime *if the streaming transducer is unambiguous.*

Conversely, every k-pass R-sweeping transducer can be transformed in 2ExpTime *into an equivalent unambiguous concatenation-free streaming transducer with $\lceil \frac{k}{2} \rceil$ registers. The transformation is in* ExpTime *if the sweeping transducer is unambiguous.*

Based on the above proposition, the problem of minimizing the number of registers in a concatenation-free streaming transducer reduces to the problem of minimizing the number of passes performed by a sweeping transducer. We will thus focus on the latter problem: in Section 4, we consider the decidability and complexity of the following problem, called *k-pass sweeping definability problem*: given a functional sweeping transducer S and a number $k \in \mathbb{N}$, decide whether S has an equivalent k-pass sweeping transducer.

3 One-way definability

In [5] we gave an effective characterization of sweeping transducers that are *one-way definable*, i.e., equivalent to some one-way transducer. This can be seen as a special case of the problem that we are considering here, and some of the technical tools developed in [5] will be used later. We briefly recall some definitions and results related to this characterization. Hereafter we assume that S is an L-sweeping transducer and ρ a successful run of S.

Intercepted factors. An *interval* of positions of the run ρ has the form $I = [x_1, x_2]$, with $x_1 < x_2$. We say that an interval $I = [x_1, x_2]$ *contains* (resp., *strongly contains*) another interval $I' = [x'_1, x'_2]$ if $x_1 \leq x'_1 \leq x'_2 \leq x_2$ (resp., $x_1 < x'_1 \leq x'_2 < x_2$). We say that a factor of ρ is *intercepted* by an interval $I = [x_1, x_2]$ if it is maximal among the factors of ρ that visit only positions in I and that never make a reversal (recall that reversals in sweeping transducers can only occur at the extremities of the input word).

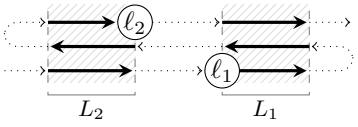
Pumping loops. A *loop* of a run ρ is an interval $L = [x_1, x_2]$ of positions such that the crossing sequences $\rho|x_1$ and $\rho|x_2$ are equal. If L is a loop of ρ, we can obtain new runs by replicating any number of times the factors of ρ intercepted by L and, simultaneously, the factor of the input word u between positions x_1 and x_2. This operation is called *pumping* and is formally defined as follows. Let $L = [x_1, x_2]$ be a loop of a run ρ on u. The run obtained by pumping n times the loop L is the sequence $\mathsf{pump}^n_L(\rho) = \underbrace{\alpha_1 \, \boldsymbol{\beta_1^n} \, \gamma_1}_{\text{1st pass}} \; \underbrace{\alpha_2 \, \boldsymbol{\beta_2^n} \, \gamma_2}_{\text{2nd pass}} \; \cdots \; \underbrace{\alpha_k \, \boldsymbol{\beta_k^n} \, \gamma_h}_{k\text{-th pass}}$ where k is the number of passes performed by ρ, β_i is the factor intercepted by L at the i-th level, α_i is the factor intercepted either by $[1, x_1]$ or by $[x_2+1, |u|]$ at the i-th level, depending on whether this level is even or odd, and, symmetrically, γ_i is the factor intercepted either by $[x_2+1, |u|]$ or by $[1, x_1]$ at the i-th level, depending on whether this level is even or odd. We also define $\mathsf{pump}^n_L(u) = u[1, x_1] \cdot \boldsymbol{\big(u[x_1+1, x_2]\big)^n} \cdot u[x_2+1, |u|]$ and we observe that $\mathsf{pump}^n_L(\rho)$ is a valid run on $\mathsf{pump}^n_L(u)$.

It is convenient to introduce some notation for pumping runs on multiple loops. If the loops are pairwise non-overlapping this can be done by simply pumping each loop separately, since the order in which we pump the loops does not really matter. The situation is a bit more complicated when some loops overlap. In particular, when pumping a loop L of ρ, several copies of the original locations of ρ are introduced, and with this several copies of other loops may appear (think, for example, of a loop L' that is contained in L). We say that a location $\tilde{\ell}$ in $\mathsf{pump}^n_L(\rho)$ *corresponds* to ℓ in ρ if $\tilde{\ell}$ is one of the copies of ℓ that is introduced when pumping ρ on L. We extend this correspondence to sets of locations and loops. With a slight abuse of notation, we denote by $\mathsf{pump}^{n_2}_{L_2}(\mathsf{pump}^{n_1}_{L_1}(\rho))$ the run obtained by first pumping n_1 times the loop L_1 in ρ, and then pumping n_2 times *every loop* that corresponds to L_2 in $\mathsf{pump}^{n_1}_{L_1}(\rho)$ (note that the copies of L_2 in $\mathsf{pump}^{n_1}_{L_1}(\rho)$ are pairwise non-overlapping). It is routine to check that the two runs $\mathsf{pump}^{n_2}_{L_2}(\mathsf{pump}^{n_1}_{L_1}(\rho))$ and $\mathsf{pump}^{n_1}_{L_1}(\mathsf{pump}^{n_2}_{L_2}(\rho))$ are isomorphic. This allows us to use the shorthand $\mathsf{pump}^{\overline{n}}_{\overline{L}}(\rho)$ to denote runs obtained from ρ by pumping the loops $\overline{L} = L_1, \ldots, L_m$ with the numbers $\overline{n} = n_1, \ldots, n_m$, respectively.

Inversions. The notion of inversion is crucial for characterizing one-way definability [5]. Let L be a loop of ρ. A location ℓ_1 is called an *entry point of* L if it is the first location of a factor intercepted by L. Similarly, a location ℓ_2 is called an *exit point of* L if it is the last location of a factor intercepted by L. Note that every entry/exit point of $L = [x_1, x_2]$ occurs either at position x_1 or at position x_2.

▶ **Definition 4.** An *inversion* of a run ρ is a pair of locations ℓ_1 and ℓ_2 for which there exist two loops $L_1 = [x_1, x'_1]$ and $L_2 = [x_2, x'_2]$ such that (also refer to the figure on the right):

- ℓ_1 is an entry point of L_1 and ℓ_2 is an exit point of L_2,
- $\ell_1 < \ell_2$ and $x_2 \leq x'_1$,
- for both $i = 1$ and $i = 2$, the factor intercepted by L_i and visiting ℓ_i has non-empty output, and no other loop strongly contained in L_i has the same property as L_i w.r.t. this factor.



We say that the loops L_1 and L_2 are the *witnessing loops* of the inversion (ℓ_1, ℓ_2).

Periodic words. A word w is said to have *period* p if $w \in u^* v$ for some word u of length p and some prefix v of u. For example, $w = abc\,abc\,ab$ has period $p = 3$.

We are interested into factors of the outputs of S that are periodic, with uniformly bounded periods. To do this, we fix the constant $e_S = c_S \cdot |Q|^{2|Q|}$, where c_S is the maximum number of symbols output by a single transition of S and Q is the state space of S. The crux in [5] is the following property:

▶ **Proposition 5** (Prop. 7 in [5]). *If S is a one-way definable L-sweeping transducer and (ℓ_1, ℓ_2) is an inversion of a successful run ρ of S, then $\mathsf{out}(\rho[\ell_1, \ell_2])$ has period at most e_S.*

The above result justifies the following definition: let $L_S \subseteq \mathrm{dom}(S)$ be the language of those words u that induce a successful run ρ of S such that, for all inversions (ℓ_1, ℓ_2) of ρ, $\mathsf{out}(\rho[\ell_1, \ell_2])$ is periodic with period at most e_S. We denote by $S|_{L_S}$ the transducer S restricted to inputs from L_S. One-way definability is characterized as follows:

▶ **Theorem 6** (Th. 1 in [5]). *An L-sweeping transducer S is one-way definable if and only if $L_S = dom(S)$. Moreover, given an L-sweeping transducer S, one can construct in doubly exponential time a one-way transducer T that is equivalent to $S|_{L_S}$.*

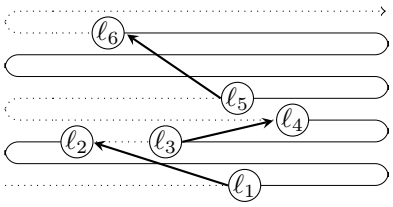
4 k-pass sweeping definability

We begin by defining the objects that need to be considered for characterizing *k-pass definability*, i.e., whether a sweeping transducer is equivalent to some k-pass sweeping transducer. Let S be an L-sweeping transducer. The idea is to consider factors of runs of S that can be simulated alternatively from left to right and from right to left. We begin by introducing a notion of inversion that looks symmetric to Definition 4: a *co-inversion* is defined as above, with $x_1 \leq x'_2$ replacing $x_2 \leq x'_1$. In other words, for an inversion we exclude the case where L_2 is *after* L_1, whereas for a co-inversion we exclude that L_2 is *before* L_1. We then combine inversions and co-inversions, as follows:

▶ **Definition 7.** A *k-inversion* of ρ is a sequence $\bar{\ell} = (\ell_1, \ell_2), \ldots, (\ell_{2k-1}, \ell_{2k})$ such that:

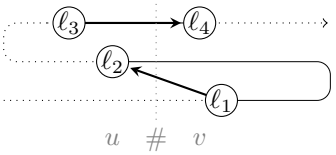
- $\ell_1 < \ell_2 < \ldots < \ell_{2k-1} < \ell_{2k}$ are distinct locations in ρ,
- for all even $i \in \{0, \ldots, k-1\}$, $(\ell_{2i+1}, \ell_{2i+2})$ is an inversion of ρ,
- for all odd $i \in \{0, \ldots, k-1\}$, $(\ell_{2i+1}, \ell_{2i+2})$ is a co-inversion of ρ.

An example of a 3-inversion is depicted to the right.



We say that $\bar{\ell}$ is *safe* if $\mathsf{out}(\rho[\ell_{2i+1}, \rho_{2i+2}])$ has period at most e_S, for *some* $i \in \{0, \ldots, k-1\}$. We denote by $L_S^{(k)}$ the language of words $u \in \mathrm{dom}(S)$ such that all k-inversions of all successful runs of S on u are safe.

▶ **Example 8.** Consider the 3-pass transducer that on input $u\#v$, with $u, v \in \{a, b\}^*$, outputs $(ab)^{|uvv|}(ba)^{|uuv|}$. This transduction can also be realized in 2 passes. This means that every 2-inversion is safe. For example, the 2-inversion depicted to the right is safe, as the output $\rho[\ell_3, \ell_4]$ is periodic.



Note that the definition of 1-inversion is the same as Definition 4, and hence $L_S^{(1)} = L_S$. In particular, by Theorem 6, we know that S is one-way definable iff $L_S^{(1)} = \mathrm{dom}(S)$. The generalization of this result is provided in Theorem 9 below: k-pass definability is equivalent to k-inversions being all safe, in the same way as one-way definability is equivalent to all inversions having periodic output.

▶ **Theorem 9.** *A sweeping transducer S is k-pass L-sweeping definable iff $L_S^{(k)} = dom(S)$, and this can be decided in* ExpSpace*. Moreover, given a sweeping transducer S, one can construct in* 2ExpTime *an unambiguous k-pass L-sweeping transducer T equivalent to $S|_{L_S^{(k)}}$.*

An analogous result for deciding k-pass *R-sweeping* definability can be derived by symmetry, by mirroring the input and reversing the computation. We also observe that, for $k = 1$, the above theorem improves the previous 2ExpSpace upper bound from [5] for deciding one-way definability of a sweeping transducer S. Concerning the doubly exponential size of an equivalent k-pass L-sweeping transducer, we observe that this is optimal, as in [5] we have shown that there are sweeping transducers S such that any equivalent one-way transducer has size at least doubly exponential in S.

Before turning to the proof of Theorem 9, we list some simple consequences of this theorem and of Propositions 1 and 3.

▶ **Corollary 10.**

- *One can compute in* ExpSpace *the minimum number of passes needed to implement a transduction given as a sweeping transducer.*

- *One can compute in* 3ExpSpace *the minimum number of reversals needed to implement a transduction given as a bounded-reversal two-way transducer. The complexity is* 2ExpSpace *if the given two-way transducer is unambiguous.*
- *One can compute in* 2ExpSpace *the minimum number of registers needed to implement a transduction given as a concatenation-free streaming transducer. The complexity is* ExpSpace *if the given streaming transducer is unambiguous.*

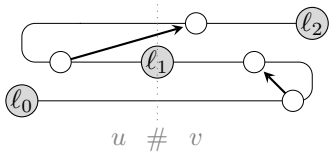
The proof of Theorem 9 is split into two parts. The first part, called "soundness", deals with the construction of the k-pass L-sweeping transducer T of the second claim. Since $L_S^{(k)} = \mathrm{dom}(S)$ implies that T is equivalent to S, this construction also proves the right-to-left direction of the first claim. Moreover, as a side result, we prove that whether $L_S^{(k)} = \mathrm{dom}(S)$ holds is decidable in ExpSpace. The second part, called "completeness", deals with the left-to-right direction of the first claim.

Soundness. We show how to construct from S a k-pass L-sweeping transducer T equivalent to $S|_{L_S^{(k)}}$. The idea is to consider a successful run ρ of S on a word $u \in L_S^{(k)}$, and divide it into k factors. We then simulate each factor of the run in a single pass, alternatively from left to right and from right to left, using [5]. First we need the notion of *k-factorizations*:

▶ **Definition 11.** A *k-factorization* of a successful run ρ of S is any sequence of locations $\overline{\ell} = \ell_0, \ell_1, \ldots, \ell_k$ of ρ such that:

- $\ell_0 \leq \ell_1 \leq \ldots \leq \ell_k$, ℓ_0 is the first location of ρ, and ℓ_k is the last location of ρ,
- for all even indexes i, with $0 \leq i < k$, and all inversions (ℓ, ℓ') of ρ, with $\ell_i \leq \ell \leq \ell' \leq \ell_{i+1}$, the word $\mathsf{out}(\rho[\ell, \ell'])$ has period at most e_S,
- for all odd indexes i, with $1 \leq i < k$, and all co-inversions (ℓ, ℓ') of ρ, with $\ell_i \leq \ell \leq \ell' \leq \ell_{i+1}$, the word $\mathsf{out}(\rho[\ell, \ell'])$ has period at most e_S.

▶ **Example 12.** We consider the transducer of Example 8 and we depict a 2-factorization of a run of it (gray nodes). All the inversions between ℓ_0 and ℓ_1, and all the co-inversions between ℓ_1 and ℓ_2, must be periodic. Note that the run does contain non-periodic inversions (e.g. those crossing ℓ_1), and hence it does not admit a 1-factorization.



The following lemma shows that we can reason equally in terms of safe k-inversions (Definition 7) and in terms of k-factorizations.

▶ **Lemma 13.** *For every word $u \in dom(S)$, we have that $u \in L_S^{(k)}$ if and only if all successful runs of S on u admit k-factorizations.*

Next we show that being a k-factorization is a *regular* property. To formalize this, we need to explain how to encode runs and sequences of locations as annotations of the underlying input. Formally, given a word $u \in \mathrm{dom}(S)$, a successful run ρ of S on u, and a tuple of locations $\overline{\ell} = \ell_1, \ldots, \ell_m$ in ρ, we denote by $\langle u, \rho, \overline{\ell} \rangle$ the word obtained by annotating each position $1 \leq x < |u|$ of u with the crossing sequence $\rho|x$ and with the m-tuple $\overline{y} = (y_1(x), \ldots, y_m(x))$, where each $y_i(x)$ is either the level of ℓ_i or $\perp$, depending on whether ℓ_i is at position x or not. Based on this encoding, we can define the language $F_S^{(k)}$ of all words of the form $\langle u, \rho, \overline{\ell} \rangle$, where ρ is a successful run of S on u and $\overline{\ell} = \ell_0, \ldots, \ell_k$ is a k-factorization of ρ. Lemma 14 below proves that this language is regular. In fact, in order to better handle the complexity of our characterization, the lemma shows that both $F_S^{(k)}$ and its complement $\overline{F}_S^{(k)}$ are recognized by automata of doubly exponential size.

▶ **Lemma 14.** *The language $F_S^{(k)}$ and its complement $\overline{F}_S^{(k)}$ are recognized by non-deterministic finite state automata of size double exponential w.r.t. S.*

Using the above encodings, we can also relativize the outputs produced by the transducer S to factors of successful runs. More precisely, we denote by S_{factors} the transducer that reads words of the form $\langle u, \rho, \ell_1, \ell_2\rangle$ and outputs words of the form $\mathsf{out}(\rho[\ell_1, \ell_2])$, provided that ρ is a successful run of S on u and ℓ_1, ℓ_2 are two locations in it. Note that S_{factors} does not check that the input is well-formed, in particular, that ρ is a successful run of S on u. Because of this, the number of states of S_{factors} is polynomial in the number of states of S, and a succinct representation of S_{factors} can be produced in polynomial time.

Now, it is easy to construct a k-pass L-sweeping transducer T equivalent to $S|_{L_S^{(k)}}$, as claimed in Theorem 9. The idea is that, on reading the input u, the transducer T guesses a successful run ρ on u and a k-factorization $\overline{\ell} = \ell_0, \ldots, \ell_k$ of ρ – this can be done using the encoding $\langle u, \rho, \overline{\ell}\rangle$ and Lemma 14. While guessing these objects, T performs k passes and outputs $T_0(\langle u, \rho, \ell_0, \ell_1\rangle) \cdot T_1(\langle u, \rho, \ell_1, \ell_2\rangle) \cdot \ldots \cdot T_{k-1}(\langle u, \rho, \ell_{k-1}, \ell_k\rangle)$, where each T_i is the 1-pass sweeping transducer obtained by applying Theorem 6 to S_{factor} (as usual, some mirroring is required for dealing with the odd indexes i). The only technical detail, here, is that different objects $\rho, \overline{\ell}$ may be guessed along the different passes of T. If this happens, the output produced by T might not be equal to that of S. We can overcome this problem by exploiting disambiguation, namely, by guessing canonical encodings $\langle u, \rho, \overline{\ell}\rangle$ in the language $F_S^{(k)}$. For example, we can fix a lexicographic ordering on these encodings and commit to always guessing the least encoding among those that agree on the input word u. This requires reasoning with both the language $F_S^{(k)}$ and its complement $\overline{F}_S^{(k)}$. By Lemma 14, the two languages are recognized by automata of doubly exponential size in S, and hence T can be constructed in doubly exponential time from S. As a matter of fact, the transducer T that we just constructed is also unambiguous.

We conclude this part by showing how to decide in exponential space if $L_S^{(k)} = \text{dom}(S)$. In fact, as we already know that $L_S^{(k)} \subseteq \text{dom}(S)$, it suffices to decide only the containment $L_S^{(k)} \supseteq \text{dom}(S)$. We know from Lemma 13 that the language $L_S^{(k)}$ coincides with the projection of $F_S^{(k)}$ on the underlying words u. Thus, we have $L_S^{(k)} \supseteq \text{dom}(S)$ if and only if $\overline{F}_S^{(k)} \cap D = \emptyset$, where $D = \{\langle u, \rho, \overline{\ell}\rangle \ : \ u \in \text{dom}(S)\}$. A close inspection of the construction of the automaton for $\overline{F}_S^{(k)}$ shows that the emptiness of $\overline{F}_S^{(k)} \cap D$ can be decided in ExpSpace.

Completeness. Here we prove the left-to-right direction of the first claim of Theorem 9. We suppose that S is an L-sweeping transducer and T is an equivalent k-pass L-sweeping transducer. We fix, once and for all, a successful run ρ of S on u and a k-inversion $\overline{\ell} = (\ell_1, \ell_2), \ldots, (\ell_{2k-1}, \ell_{2k})$ of ρ.

The goal is to prove that $\overline{\ell}$ is safe, namely, that the factor of the output produced between the locations of some (co-)inversion $(\ell_{2i+1}, \ell_{2i+2})$ of $\overline{\ell}$ is periodic, with uniformly bounded period. The main idea is to try to find a factor $\mathsf{out}(\rho[\ell_{2i+1}, \ell_{2i+2}])$ that is entirely covered by the output produced along a single pass of the equivalent transducer T, and apply a suitable generalization of Proposition 5. Informally, this works by pumping the output $\mathsf{out}(\rho[\ell_{2i+1}, \ell_{2i+2}])$ through repeating the witnessing loops of $(\ell_{2i+1}, \ell_{2i+2})$. In a similar way, we pump the output produced along a single pass of T. Then, by analyzing how the former outputs are covered by the latter outputs, we deduce the periodicity of $\mathsf{out}(\rho[\ell_{2i+1}, \ell_{2i+2}])$.

The main difficulty in formalizing the above idea lies in the fact that the k passes of the supposed transducer T cannot be identified directly on the run ρ of S. Therefore we need to reason in a proper way about *families* of factors associated with (co-)inversions inside pumped runs. Below, we introduce some terminology and notation to ease this task.

Recall that $\overline{\ell} = (\ell_1, \ell_2), \ldots, (\ell_{2k-1}, \ell_{2k})$ is a k-inversion of the run ρ. For all $i = 0, \ldots, k-1$, let L_{2i+1} and L_{2i+2} be the witnessing loops of $(\ell_{2i+1}, \ell_{2i+2})$. For a given tuple of numbers $\overline{n} = (n_1, \ldots, n_{2k}) \in \mathbb{N}^{2k}$, we define $\rho^{\overline{n}} = \mathsf{pump}^{\overline{n}}_{\overline{L}}(\rho)$, where $\overline{L} = L_1, \ldots, L_{2k}$ and $\overline{n} = n_1, \ldots, n_{2k}$ (recall that this is the run obtained by pumping the loops $L_1, \ldots, L_{2k}$ respectively $n_1, \ldots, n_{2k}$ times, as described in Section 3). Similarly, we denote by $u^{\overline{n}}$ the word parsed by the pumped run $\rho^{\overline{n}}$.

We would like to map the inversions and co-inversions of $\overline{\ell}$ on the pumped runs $\rho^{\overline{n}}$. Consider an inversion $(\ell_{2i+1}, \ell_{2i+2})$, for some $i \in \{1, \ldots, 2k\}$ (the case of a co-inversion is similar). Recall that when pumping loops in ρ, several copies of the original locations may be introduced. In particular, among the copies of the inversion $(\ell_{2i+1}, \ell_{2i+2})$ that appear in the pumped run $\rho^{\overline{n}}$, we will consider the maximal one, which is identified by taking the *first* copy $\tilde{\ell}_{2i+1}$ of ℓ_{2i+1} and the *last* copy $\tilde{\ell}_{2i+2}$ of ℓ_{2i+2}. For the sake of brevity, we say that $(\tilde{\ell}_{2i+1}, \tilde{\ell}_{2i+2})$ is the inversion of $\rho^{\overline{n}}$ that *corresponds* to $(\ell_{2i+1}, \ell_{2i+2})$.

We can now define the key objects for our reasoning, that is, the factors of the output of a pumped run $\rho^{\overline{n}}$ that correspond in the original run ρ to the factors produced between the locations of the (co-)inversions of $\overline{\ell}$. Formally, for every $2k$-tuple $\overline{n}$ of natural numbers and every index $i = 0, \ldots, k-1$, we define

$$v^{\overline{n}}(i) \;=\; \mathsf{out}\big(\rho^{\overline{n}}[\tilde{\ell}_{2i+1}, \tilde{\ell}_{2i+2}]\big)$$

where $(\tilde{\ell}_{2i+1}, \tilde{\ell}_{2i+2})$ is the (co-)inversion of $\rho^{\overline{n}}$ that corresponds to $(\ell_{2i+1}, \ell_{2i+2})$. Below we highlight the relevant factors inside the output produced by S on $u^{\overline{n}}$:

$$S(u^{\overline{n}}) \;=\; \mathsf{out}\big(\rho^{\overline{n}}[\tilde{\ell}_0, \tilde{\ell}_1]\big) \cdot \boldsymbol{v^{\overline{n}}(0)} \cdot \mathsf{out}\big(\rho^{\overline{n}}[\tilde{\ell}_2, \tilde{\ell}_3]\big) \cdot \boldsymbol{v^{\overline{n}}(1)} \cdot \ldots \cdot \boldsymbol{v^{\overline{n}}(k-1)} \cdot \mathsf{out}\big(\rho^{\overline{n}}[\tilde{\ell}_{2k}, \tilde{\ell}_{2k+1}]\big) \quad (1)$$

where $\tilde{\ell}_0$ is the first location of $\rho^{\overline{n}}$, $\tilde{\ell}_{2k+1}$ is the last location of $\rho^{\overline{n}}$.

In a similar way, we can factorize the output produced by the k-pass L-sweeping transducer T when reading the input $u^{\overline{n}}$. However, the focus here is on the factors of the output produced along each pass. Formally, given $\overline{n} \in \mathbb{N}^{2k}$, we let $\sigma^{\overline{n}}$ be some successful run of T on $u^{\overline{n}}$. For every $j = 0, \ldots, k-1$, we let ℓ'_j be the first location of $\sigma^{\overline{n}}$ at level j. We further let ℓ'_k be the last location of $\sigma^{\overline{n}}$, which is at level $k-1$. We then define

$$w^{\overline{n}}(j) \;=\; \mathsf{out}\big(\sigma^{\overline{n}}[\ell'_j, \ell'_{j+1}]\big)$$

and factorize the output of T on $u^{\overline{n}}$ as follows:

$$T(u^{\overline{n}}) \;=\; \boldsymbol{w^{\overline{n}}(0)} \cdot \boldsymbol{w^{\overline{n}}(1)} \cdot \ldots \cdot \boldsymbol{w^{\overline{n}}(k-1)}. \quad (2)$$

The next step is to exploit the hypothesis that S and T are equivalent. This means that Equations (1) and (2) represent the same word. From this we derive that, for any given $\overline{n} \in \mathbb{N}^{2k}$, at least one of the words $v^{\overline{n}}(i)$ highlighted in Equation (1) is a factor of the word $w^{\overline{n}}(i)$ highlighted in Equation (2). However, what is the index i for which this coverability relation holds depends on the parameter $\overline{n}$. In order to enable a reasoning similar to that of Proposition 5, we need to find a single index i such that, for "sufficiently many" parameters $\overline{n}$, $v^{\overline{n}}(i)$ is a factor of $w^{\overline{n}}(i)$. The definition below, formalizes what we mean precisely by "sufficiently many" $\overline{n}$ – intuitively, we require that specific coordinates of $\overline{n}$ are unbounded, as well the differences between these coordinates.

▶ **Definition 15.** Let $\mathcal{P}(\overline{n})$ denote an arbitrary property of tuples $\overline{n} \in \mathbb{N}^{2k}$. Further let h, h' be two distinct coordinates in $\{1, \ldots, 2k\}$. We say that $\mathcal{P}(\overline{n})$ holds *unboundedly on the coordinates* h, h' *of* $\overline{n}$ if, for all numbers $n_0 \in \mathbb{N}$, there exist $\overline{n}_1, \overline{n}_2 \in \mathbb{N}^{2k}$ such that:

- $\mathcal{P}(\overline{n}_1)$ and $\mathcal{P}(\overline{n}_2)$ hold,
- $\overline{n}_1[h] \geq n_0$ and $\overline{n}_1[h'] - \overline{n}_1[h] \geq n_0$,
- $\overline{n}_2[h'] \geq n_0$ and $\overline{n}_2[h] - \overline{n}_2[h'] \geq n_0$.

We recall that each factor $v^{\overline{n}}(i)$ is associated with the (co-)inversion $(\ell_{2i+1}, \ell_{2i+2})$, and that the corresponding components $\overline{n}[2i+1]$ and $\overline{n}[2i+2]$ of the parameter $\overline{n}$ denote the number of times the witnessing loops L_{2i+1} and L_{2i+2} are pumped in $\rho^{\overline{n}}$. The specific properties we are interested in are the following ones, for $i = 0, \ldots, k-1$:

$\mathcal{P}_i(\overline{n})$ = "$v^{\overline{n}}(i)$ *is a factor of* $w^{\overline{n}}(i)$".

It is not difficult to see that for every tuple $\overline{n} \in \mathbb{N}^{2k}$, $\mathcal{P}_i(\overline{n})$ holds for some $i \in \{0, \ldots, k-1\}$. From this, using a suitable counting argument, we can prove the crucial lemma below.

▶ **Lemma 16.** *There exists an index* $i \in \{0, \ldots, k-1\}$ *such that the property* $\mathcal{P}_i(\overline{n})$ = "$v^{\overline{n}}(i)$ is a factor of $w^{\overline{n}}(i)$" *holds unboundedly on the coordinates* $2i+1$ *and* $2i+2$ *of* $\overline{n}$.

The last piece of the puzzle consists of generalizing the statement of Proposition 5. The idea is that we can replace the hypothesis that S is one-way definable by the weaker assumption of Lemma 16. That is, if $\mathcal{P}_i(\overline{n})$ holds unboundedly on the coordinates $2i+1$ and $2i+2$ of $\overline{n}$, we can still use the same arguments based on pumping and Fine-Wilf's Theorem as in Proposition 5, in order to deduce that the output $\mathsf{out}(\rho[\ell_{2i+1}, \ell_{2i+2}])$ between the locations of the (co-)inversion is periodic:

▶ **Proposition 17.** *If the property* $\mathcal{P}_i(\overline{n})$ = "$v^{\overline{n}}(i)$ is a factor of $w^{\overline{n}}(i)$" *holds unboundedly on the coordinates* $2i+1$ *and* $2i+2$ *of* $\overline{n}$*, then the output* $\mathsf{out}(\rho[\ell_{2i+1}, \ell_{2i+2}])$ *produced between the locations of the (co-)inversion* $(\ell_{2i+1}, \ell_{2i+2})$ *is periodic, with period* e_S*. In particular, the* k*-inversion* $\overline{\ell} = (\ell_1, \ell_2), \ldots, (\ell_{2k-1}, \ell_{2k})$ *is safe.*

To conclude, we assumed that the L-sweeping transducer S is equivalent to a k-pass L-sweeping transducer T. We considered a successful run ρ of S and an arbitrary k-inversion $\overline{\ell}$ of it. By Lemma 16, we know that there is an index $i \in \{0, \ldots, k-1\}$ for which the property $\mathcal{P}_i(\overline{n})$ = "$v^{\overline{n}}(i)$ *is a factor of* $w^{\overline{n}}(i)$" holds unboundedly on the coordinates $2i+1$ and $2i+2$ of $\overline{n}$. From this, by applying Proposition 17, we derive that the k-inversion $\overline{\ell}$ is safe. This proves the left-to-right direction of the first claim of Theorem 9. ◀

5 Sweeping transducers and MSO

We provide a logical characterization of sweeping transducers. For this we will consider restricted forms of transductions definable in monadic-second order logic (MSO) [8].

MSO transductions are described by specifying the output (seen as a relational structure) from a fixed number of copies of the input. Formally, an *MSO transduction with m copies* consists of an MSO sentence Φ_{dom}, some unary MSO formulas $\Phi^i_a(x)$, one for each $i \in \{1, \ldots, m\}$ and $a \in \Delta$, and some binary MSO formulas $\Phi^{i,j}_{\leq}(x, y)$, one for each $i, j \in \{1, \ldots, m\}$. Intuitively, the sentence Φ_{dom} tells whether the transduction is defined on some input u. The unary formula $\Phi^i_a(x)$ tells whether the element x of the i-th copy of the input belongs to the output and is labeled with the letter a. The formula $\Phi^{i,j}_{\leq}(x, y)$ tells whether, in the produced output, the element x of the i-th copy of the input precedes the element y of the j-th copy of the input. Note that the sentence Φ_{dom} can easily guarantee that, whenever the output is defined, it is well-formed, namely, it is a word. For the sake of simplicity, we assume that $\Phi^i_a(x)$ *entails* Φ_{dom}, namely, for all words u and all positions x, $u \models \Phi^i_a(x)$ implies $u \models \Phi_{\text{dom}}$. Similarly, we assume that $\Phi^{i,j}_{\leq}(x, y)$ entails $\Phi^i(x)$ and $\Phi^j(y)$.

▶ **Definition 18.** Let T be an MSO transduction with m copies. We say that T is

- *order-preserving* if each formula $\Phi^{i,j}_{\leq}(x,y)$ entails $x \leq y$;
- *order-inversing* if each formula $\Phi^{i,j}_{\leq}(x,y)$ entails $x \geq y$;
- *k-phase* if there is a partition $I_0, I_1, \ldots, I_{k-1}$ of the set of indexes $\{1,\ldots,m\}$ such that $I_0 < I_1 < \ldots < I_{k-1}$, namely, $i < j$ for all $0 \leq h < h' < k$, $i \in I_h$, and $j \in I_{h'}$, and each formula $\Phi^{i,j}_{\leq}(x,y)$ entails $x \leq y$ if h is even, or $x \geq y$ otherwise.

We know from [9] that order-preserving MSO transductions capture precisely the one-way definable transductions. We obtain:

▶ **Theorem 19.** *k-phase MSO transductions have the same expressive power as functional, k-pass L-sweeping transducers.*

6 Conclusions

We showed that sweeping transducers, bounded-reversal transducers, and concatenation-free streaming transducers define the same subclass of regular word transductions. Our main result is an effective characterization of transductions definable by sweeping transducers with a fixed number of passes. As a consequence we obtained a procedure that minimizes the number of registers in a concatenation-free sweeping transducer.

We believe that similar results can be proven for two-way (non-sweeping) transducers, using a refined version of the constructions presented here. In this respect, an interesting open problem is to characterize the two-way transducers that are equivalent to sweeping transducers, but with an arbitrary (unspecified) number of passes.

Abstract

Linear acceleration theorems are known for most computational models. Although such results have been proved for two-dimensional cellular automata working on specific neighborhoods, no general construction was known. We present here a technique of linear acceleration for all two-dimensional languages recognized by cellular automata working on complete neighborhoods.

1 Introduction

Cellular automata (CA) were initially introduced by S. Ulam and J. von Neumann [14] in the 1960s to study self-reproduction in discrete dynamical systems. They are massively parallel systems consisting of an infinite array of cells. Cells evolve synchronously depending on the states of their neighbors according to a uniform deterministic rule. Although initially considered in two dimensions, the definition can be adapted to any dimensional cellular space and even more general uniform graphs [8].

Soon after their introduction, they were shown to be computationally universal [9, 1]. As a computation model, they have been extensively studied as one-dimensional language recognizers [11, 3] but are also very well suited to the study of two-dimensional "picture languages" [10, 12, 13].

The neighborhood of a cellular automaton defines the underlying communications graph of the cells. Although most of the existing work on two-dimensional cellular automata focuses on the von Neumann (4 closest neighbors) and Moore (8 closest neighbors) neighborhoods, understanding how the choice of the neighborhood affects the algorithmic capabilities of the model is a key to understanding parallel computation.

Linear acceleration theorems are well known for most of the commonly considered computation models. It was first proved for one-dimensional cellular automata working on the standard neighborhood and two-dimensional cellular automata on von Neumann's neighborhood by W. T. Beyer [2], inspired by similar constructions for sequential input cellular automata [3, 5, 6]. The one-dimensional case was later generalized by J. Mazoyer and N. Reimen for arbitrary neighborhoods [7]. As for two-dimensional neighborhoods, V. Terrier extended the construction to the Moore neighborhood [12] and then to the slightly more general class of neighborhoods whose convex hull has at most one vertex in the positive quarter plane [13].

In this paper, we prove a general linear acceleration result for all complete neighborhoods on two-dimensional cellular automata.

The main theorem is stated in Section 3 and proved in Sections 4 to 7. Sections 4 and 6 describe the two main elements of the construction (compression of the input and accelerated simulation of the original automaton respectively). Section 5 presents a technique to perform a sequence of tasks on a cellular automaton without the need for synchronization at the start of each new task, used in the proof of the theorem to combine sections 4 and 6. Although this technique is elementary and has been used in previous publications (a special case was used by W. T. Beyer in 1969 [2]), reviews of previous articles seem to indicate that it is not common knowledge. It is therefore presented here in a separate section and stated generally in the hopes that it can be easily reused in future publications.

The construction presented in this article is similar in several ways to previously published constructions, most notably those of V. Terrier in [13]. Significant improvements include compression of the input in *almost* optimal time (Section 4, specifically Subsection 4.2) and a more general simulation technique (Section 6).

2 Definitions

2.1 Cellular Automata

▶ **Definition 1** (Cellular Automaton)**.** A *cellular automaton* (CA) is a quadruple $\mathcal{A} = (d, \mathcal{Q}, \mathcal{N}, \delta)$ where

- $d \in \mathbb{N}$ is the dimension of the automaton ;
- $\mathcal{Q}$ is a finite set whose elements are called *states* ;
- $\mathcal{N}$ is a finite subset of $\mathbb{Z}^d$ called *neighborhood* of the automaton ;
- $\delta : \mathcal{Q}^{\mathcal{N}} \to \mathcal{Q}$ is the *local transition function* of the automaton.

▶ **Definition 2** (Configuration)**.** A *d-dimensional configuration* $\mathfrak{C}$ over the set of states $\mathcal{Q}$ is a mapping from $\mathbb{Z}^d$ to $\mathcal{Q}$. The elements of $\mathbb{Z}^d$ will be referred to as *cells*.

Given a CA $\mathcal{A} = (d, \mathcal{Q}, \mathcal{N}, \delta)$, a configuration $\mathfrak{C} \in \mathcal{Q}^{\mathbb{Z}^d}$ and a cell $c \in \mathbb{Z}^d$, we denote by $\mathcal{N}_{\mathfrak{C}}(c)$ the neighborhood of c in $\mathfrak{C}$:

$$\mathcal{N}_{\mathfrak{C}}(c) : \left\{ \begin{array}{ccc} \mathcal{N} & \to & \mathcal{Q} \\ n & \mapsto & \mathfrak{C}(c+n) \end{array} \right.$$

From the local transition function δ of a CA $\mathcal{A} = (d, \mathcal{Q}, \mathcal{N}, \delta)$, we can define the *global transition function of the automaton* $\Delta : \mathcal{Q}^{\mathbb{Z}^d} \to \mathcal{Q}^{\mathbb{Z}^d}$ obtained by applying the local rule on all cells :

$$\Delta(\mathfrak{C}) = \left\{ \begin{array}{ccc} \mathbb{Z}^d & \to & \mathcal{Q} \\ c & \mapsto & \delta(\mathcal{N}_{\mathfrak{C}}(c)) \end{array} \right.$$

The action of the global transition rule makes $\mathcal{A}$ a dynamical system over the set $\mathcal{Q}^{\mathbb{Z}^d}$. Because of this dynamic, in the following we will identify the CA $\mathcal{A}$ with its global rule so that $\mathcal{A}(\mathfrak{C})$ is the image of a configuration $\mathfrak{C}$ by the action of the CA $\mathcal{A}$, and more generally $\mathcal{A}^t(\mathfrak{C})$ is the configuration resulting from applying t times the global rule of the automaton from the initial configuration $\mathfrak{C}$.

▶ **Definition 3** (Quiescent and Permanent States)**.** For a given CA $\mathcal{A}$, we say that a state q is *quiescent* if a cell in state q remains in this state if all its neighbors are also in q. We say that q is *permanent* if a cell in state q remains in that state regardless of the state of its neighbors.

In this article we will only consider 2-dimensional cellular automata (2DCA). From now on the set of cells will always be $\mathbb{Z}^2$.

2.2 Neighborhoods

Throughout the article, we use the additive notation for vector sums, the power notation for neighborhood composition and the product notation for scalar product:

▶ **Definition 4** (Vector Sum). Given two neighborhoods $\mathcal{N}_1$ and $\mathcal{N}_2$ and a cell $c \in \mathbb{Z}^2$, we define the vector sums $\mathcal{N}_1 + \mathcal{N}_2 = \{x + y \mid x \in \mathcal{N}_1, y \in \mathcal{N}_2\}$ and $c + \mathcal{N}_1 = \{c + x \mid x \in \mathcal{N}_1\}$.

▶ **Definition 5** (Neighborhood Powers). Given a neighborhood $\mathcal{N}$, we define

$$\mathcal{N}^0 = \{0\} \tag{1}$$

$$\forall k \in \mathbb{N}, \quad \mathcal{N}^{k+1} = \mathcal{N} + \mathcal{N}^k \tag{2}$$

▶ **Definition 6** (Scalar product). Given a neighborhood $\mathcal{N}$ and an integer $k \in \mathbb{Z}$, we define the scalar product $k\mathcal{N} = \{kx \mid x \in \mathcal{N}\}$.

▶ **Definition 7** (Complete Neighborhood). A neighborhood $\mathcal{N}$ is said to be *complete* if

$$\bigcup_{k \in \mathbb{N}} \mathcal{N}^k = \mathbb{Z}^2$$

▶ **Definition 8** (Convex Hull and Convex Neighborhood). The *convex hull* of a neighborhood $\mathcal{N}$ is the smallest convex polygon $\mathrm{CH}(\mathcal{N}) \subset \mathbb{R}^2$ such that $\mathcal{N} \subseteq \mathrm{CH}(\mathcal{N})$. Moreover a neighborhood $\mathcal{N}$ is said to be *convex* if it contains all points of integer coordinates in its convex hull: $\mathcal{N} = \mathrm{CH}(\mathcal{N}) \cap \mathbb{Z}^2$.

▶ Remark. If $\mathcal{N}$ is a convex neighborhood, $\mathcal{N}^p$ is also convex for any $p \in \mathbb{N}$.

2.3 Two-Dimensional Language Recognition

▶ **Definition 9** (Picture). For $n, m \in \mathbb{N}$ and Σ a finite alphabet, an (n, m)-*picture* (picture of width n and height m) over Σ is a mapping

$$p : [\![0, n-1]\!] \times [\![0, m-1]\!] \to \Sigma$$

$\Sigma^{n,m}$ denotes the set of all (n, m)-pictures over Σ and $\Sigma^{*,*} = \bigcup_{n,m \in \mathbb{N}} \Sigma^{n,m}$ the set of all pictures over Σ. A *picture language* over Σ is a set of pictures over Σ.

▶ **Definition 10** (Picture Configuration). Given an (n, m)-picture p over Σ, we define the *picture configuration* associated to p with quiescent state $q_0 \notin \Sigma$ as

$$\mathfrak{C}_{p,q_0} : \begin{cases} \mathbb{Z}^2 & \to & \Sigma \cup \{q_0\} \\ x, y & \mapsto & \begin{cases} p(x, y) & \text{if } (x, y) \in [\![0, n-1]\!] \times [\![0, m-1]\!] \\ q_0 & \text{otherwise} \end{cases} \end{cases}$$

▶ **Definition 11** (Picture Recognizer). Given a picture language L over an alphabet Σ, we say that a 2DCA $\mathcal{A} = (2, \mathcal{Q}, \mathcal{N}, \delta)$ such that $\Sigma \subseteq \mathcal{Q}$ recognizes L with quiescent state $q_0 \in \mathcal{Q} \setminus \Sigma$, accepting state $q_a \in \mathcal{Q}$ and rejecting state $q_r \in \mathcal{Q}$ in time $\tau : \mathbb{N}^2 \to \mathbb{N}$ if q_a and q_r are permanent states and for any picture p (of size $n \times m$), starting from the picture configuration $\mathfrak{C}_{p,q_0}$ at time 0, the origin cell of the automaton at time $\tau(n, m)$ is in state q_a if $p \in L$ and state q_r if $p \notin L$.

▶ **Definition 12** (Real Time). Given a complete neighborhood $\mathcal{N}$, the real time function $\mathrm{RT}_{\mathcal{N}} : \mathbb{N}^2 \to \mathbb{N}$ associated to $\mathcal{N}$ is defined as

$$\mathrm{RT}_{\mathcal{N}}(n, m) = \min\{t \mid [\![0, n-1]\!] \times [\![0, m-1]\!] \subseteq \mathcal{N}^t\}$$

3 The Main Theorem

Most of the article will be dedicated to the proof of the following theorem

▶ **Theorem 13** (Linear Acceleration). *For any complete neighborhood $\mathcal{N}$, any real number $\epsilon > 0$, any finite alphabet Σ and any language $L \subseteq \Sigma^{*,*}$, if L is recognized by a 2DCA working on $\mathcal{N}$ in time*

$$(n, m) \mapsto \mathrm{RT}_{\mathcal{N}}(n, m) + f(n, m)$$

for some function $f : \mathbb{N}^2 \to \mathbb{N}$ then L can be recognized in time

$$(n, m) \mapsto \lceil (1 + \epsilon) \mathrm{RT}_{\mathcal{N}}(n, m) + \epsilon f(n, m) \rceil$$

by a 2DCA with neighborhood $\mathcal{N}$.

▶ **Corollary 14.** *For any complete neighborhood $\mathcal{N}$, any language recognized in time $(n, m) \mapsto k \mathrm{RT}_{\mathcal{N}}(n, m)$ for some $k > 1$ can be recognized in time $(n, m) \mapsto (1 + \epsilon) \mathrm{RT}_{\mathcal{N}}(n, m)$ for any real number $\epsilon > 0$.*

To prove Theorem 13, we consider a 2DCA $\mathcal{A}$ working on a complete neighborhood $\mathcal{N}$ and describe the construction of a 2DCA $\mathcal{A}'$ working on the same neighborhood that simulates the behavior of $\mathcal{A}$ in a way that enables it to recognize the same language as $\mathcal{A}$ in a linearly shorter time.

3.1 Preliminary Remarks

The following observations will greatly simplify the proof of Theorem 13.

▶ **Claim 15.** *It is sufficient to prove Theorem 13 up to an additive constant, meaning that we only need to prove that L can be recognized in time*

$$(n, m) \mapsto (1 + \epsilon) \mathrm{RT}_{\mathcal{N}}(n, m) + \epsilon f(n, m) + O(1)$$

Proof. Consider that we have this weaker result. To get rid of the $O(1)$ term simply choose $\epsilon' < \epsilon$. For any $C > 0$, for (n, m) large enough we have

$$(1 + \epsilon) \mathrm{RT}_{\mathcal{N}}(n, m) + \epsilon f(n, m) > (1 + \epsilon') \mathrm{RT}_{\mathcal{N}}(n, m) + \epsilon' f(n, m) + C$$

The automaton can handle all the finitely many inputs of small size in real time. ◀

▶ **Claim 16.** *It is sufficient to prove Theorem 13 for all complete convex neighborhoods.*

Proof. Consider a complete neighborhood $\mathcal{N}$ and let $\mathcal{N}'$ be the convex neighborhood having same convex hull as $\mathcal{N}$. The real time functions $\mathrm{RT}_{\mathcal{N}}$ and $\mathrm{RT}_{\mathcal{N}'}$ differ by at most a constant. Moreover a CA on $\mathcal{N}$ can simulate the behavior of a CA on $\mathcal{N}'$ with a loss of at most a constant number of steps and conversely (see [4] for more details).

The property from the theorem therefore translates directly from one neighborhood to the other with at most a constant difference that can be ignored according to Claim 15. ◀

From now on we will consider that $\mathcal{N}$ is a convex neighborhood.

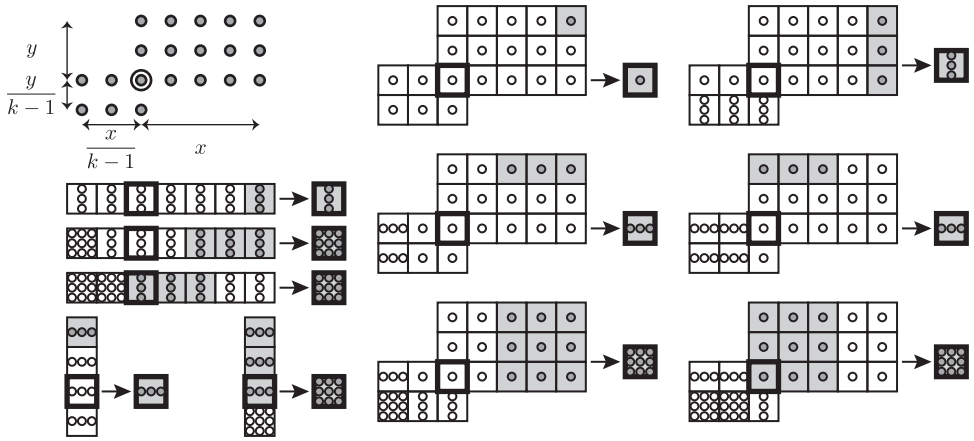

Figure 1 Rules for the compression by a factor 3 of inputs of ratio $\frac{n}{m} = 2$ with the neighborhood represented in the top left. The information that the cell takes as its new state is represented in grey. Information travels towards the bottom left. By looking down and left a cell determines if the information from the top right should simply pass through (first case) or if some of its neighbors are already full in which case it should start packing information. Left column shows simplified rules for which the cell has already packed information in one of the directions and therefore only the neighbors in the remaining direction are significant.

4 Compression of the Input

The first phase of the construction is to compress the input by a factor $k > \frac{1}{\epsilon}$. We want to move the states of the initial configuration towards the origin, packing them in groups of $k \times k$ as illustrated by Figure 2.

Although such compressions are relatively simple to perform on the von Neumann and Moore neighborhoods, on a more general neighborhood it is not possible to know in which direction the information should travel to move towards the origin at optimal speed. In general, the optimal travel direction depends on the proportion $\frac{n}{m}$ of the input.

We first show that if the proportion of the input is fixed, compression can be done in optimal time on any complete neighborhood. Then, by performing a finite number of compressions in parallel, each assuming a different proportion, we show that any input is close enough to one of these assumed proportions to be compressed in "nearly optimal" time, which will be sufficient for the proof of Theorem 13.

4.1 Compression of an Input of Constrained Proportion

If the size of the input is known to be of proportion $\frac{n}{m} = \alpha$ for some fixed rational α, we can perform a compression by a factor k with a neighborhood such as the one illustrated on the top left of Figure 1 with $\frac{x}{y} = \alpha$. On such a neighborhood, compressing the input is simply a matter of transferring the states from the top right to the bottom left, packing them in groups of $(1 \times k)$, $(k \times 1)$ or $(k \times k)$ when they cannot go any further in one or both directions (see Figures 1 and 2). The compression is completed in time $\lceil \frac{k-1}{k} \mathrm{RT} \rceil$.

Note that in order to compress by a factor k, the cell must be able to see $\frac{1}{k-1}$ times as far towards the left and bottom as it sees towards the right and top in order to properly determine when it should start packing states. Because the convex hull of a complete neighborhood $\mathcal{N}$ contains an open set around the origin (otherwise $(\mathcal{N}^p)_{p\in\mathbb{N}}$ would not expand in all directions), it contains its homothetic image of ratio $-\frac{1}{k_0-1}$ for some k_0 (see Figure 3). On such a neighborhood compression by any factor $k \geq k_0$ is possible.

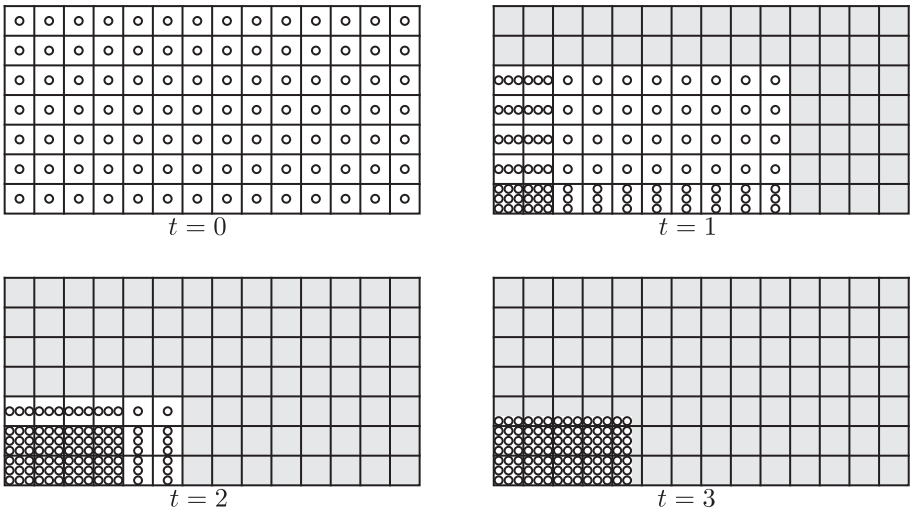

Figure 2 Compression of an input of size (14×7) with the neighborhood and rules from Figure 1.

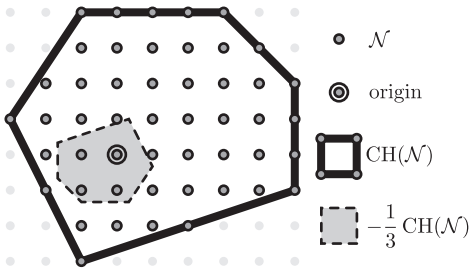

Figure 3 An example neighborhood on which a compression by a factor $k = 4$ is possible.

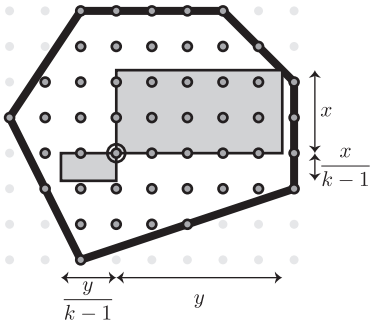

Figure 4 The area of the neighborhood that will be used for the compression of inputs of proportion $\frac{n}{m} = 2$ by a factor $k = 4$.

To compress inputs of proportion $\frac{n}{m} = \alpha$ on some complete neighborhood $\mathcal{N}$, we consider the largest rectangle $[0, x] \times [0, y]$ with $x, y \in \mathbb{Q}$ and $\frac{x}{y} = \alpha$ included in the convex hull of $\mathcal{N}$ (see Figure 4). For all $k \geq k_0$, the rectangle $[-\frac{x}{k-1}, 0] \times [-\frac{y}{k-1}, 0]$ is also in the convex hull of $\mathcal{N}$.

These rectangles have rational but not necessarily integer dimensions. If we consider the neighborhood $\mathcal{N}^p$ for some large p, all is scaled up by a factor p and the corresponding rectangles can be made of integer dimensions. The real time function on inputs of proportion α for $\mathcal{N}^p$ is equal to the real time function of the neighborhood containing only the two rectangles (of integer coordinates). The compression algorithm described by Figures 1 and 2 therefore finishes in time $\frac{k-1}{k}\,\mathrm{RT}_{\mathcal{N}^p} + O(1)$ on $\mathcal{N}^p$. An automaton working on $\mathcal{N}$ can simulate one step of an automaton working on $\mathcal{N}^p$ in p time steps, and since $\mathrm{RT}_{\mathcal{N}^p} = \lceil \frac{1}{p}\,\mathrm{RT}_{\mathcal{N}} \rceil$, the compression can be completed on $\mathcal{N}$ in time $\frac{k-1}{k}\,\mathrm{RT}_{\mathcal{N}} + O(1)$.

4.2 Compression of General Input

Let us now consider inputs of arbitrary proportions. As discussed in the previous subsection, for inputs of proportion α the optimal direction in which the information should travel for

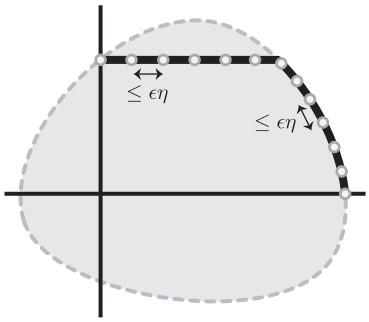

Figure 5 Choosing the set S of proportions that will be used by $\mathcal{A}'$ for compressions. The thick line is the set of corners of maximal rectangles for all possible proportions. Along this line, we pick a finite set of points at intervals of at most $\epsilon\eta$.

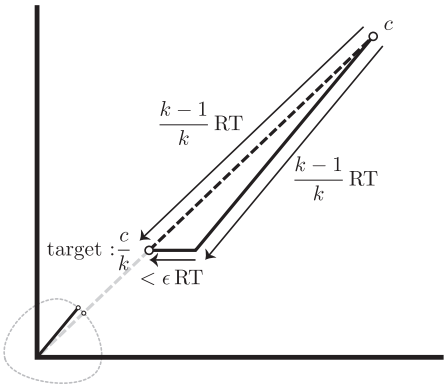

Figure 6 Compression of an input of arbitrary proportion. The optimal direction for the compression is represented by a dashed line. The closest chosen direction is represented by a solid line inside the neighborhood. It is at a distance at most $\epsilon\eta$ of the optimal vector. The travel path of the farthest cell of the input is represented as a solid black line, made of an initial segment along the almost-optimal direction and an extra segment to compensate for the deviation.

a compression is defined by the diagonal of the largest rectangle $[0, x] \times [0, y]$ with $\frac{x}{y} = \alpha$ included in the convex hull of $\mathcal{N}$. The first thing to note is that since $\mathcal{N}$ is complete, there exists $\eta > 0$ such that $[0, \eta] \times [0, \eta] \subseteq \mathrm{CH}(\mathcal{N})$ and hence all maximal rectangles in $\mathrm{CH}(\mathcal{N})$ have at least one dimension greater than η. The corners (x, y) of such maximal rectangles all lie on a line. Let us pick a finite set S of rational points on this line from one extremity to the other with distance at most $\epsilon\eta$ between two consecutive points (see Figure 5).

For each proportion $\alpha = \frac{x}{y}$ with $(x, y) \in S$, $\mathcal{A}'$ performs a compression of the input as described in the previous subsection. All compressions take place at the same time in parallel. Note that even if the proportion of the input is not exactly that for which the compression is optimized, the input is still compressed properly although not as quickly.

Let us prove that one of the compressions that are run by the automaton compresses the input in time at most $(\frac{k-1}{k} + \epsilon)\,\mathrm{RT}$. A compression along the vector corresponding exactly to the proportion of the input would take a time $\frac{k-1}{k}\,\mathrm{RT}$. A compression along one of the vectors in S that is closest to the optimal vector (at distance at most $\epsilon\eta$) puts all states from the input within a distance at most $\epsilon\eta\,\mathrm{RT}$ from their destination in time $\frac{k-1}{k}\,\mathrm{RT} + O(1)$. By choosing the closest vector properly amongst the two choices, the remaining distance can be travelled in time at most $\epsilon\,\mathrm{RT} + O(1)$ as illustrated by Figure 6 (information travels at speed at least η in one of the dimensions).

For any possible input, at least one of the compressions completes in time at most $(\frac{k-1}{k} + \epsilon)\,\mathrm{RT} + O(1)$.

5 Transition

After the input has been compressed, the automaton $\mathcal{A}'$ should immediately start simulating the behavior of $\mathcal{A}$, k steps at a time. However the cells of $\mathcal{A}'$ receive the compressed input at different times. If we wanted all the cells to start the next phase at the same time, we would

require some synchronization scheme such as a firing-squad synchronization algorithm but this would take a linear time. Instead, we show that synchronization is not required to start the accelerated simulation as each cell of the automaton proceeds with the next phase as soon as the relevant information is available.

This technique is very general and can be used in numerous situations where a cellular automaton performs a computation by executing a series of separate tasks one after the other without having to spend time synchronizing all cells. In its general form, it can be stated in the following way:

▶ **Proposition 17** (Passive Synchronization). *Given a CA $\mathcal{A}$ of any dimension working on a complete neighborhood $\mathcal{N}$, there exists a CA $\mathcal{A}'$ working on the same neighborhood $\mathcal{N}$ that can simulate the behavior of $\mathcal{A}$ on any input even if the configuration is given asynchronously in such a way that each cell of $\mathcal{A}'$ computes states of the simulated automaton at least as fast as if the computation had started synchronously when the last cell receives its input.*

Formally, if we denote by $\mathcal{Q}$ the states of $\mathcal{A}$, $\mathcal{A}'$ has states $\{\perp\} \cup (\mathcal{Q} \times \mathcal{Q}')$ where $\perp$ is a permanent state (cannot be changed by the transition rule of the automaton) and $\mathcal{Q}'$ is a set of extra working states containing a default state ν. The cells of $\mathcal{A}'$ are initially in state $\perp$ and considered inactive*. Before each transition of the automaton, any number of inactive cells of $\mathcal{A}'$ might be* activated *by some external action over which $\mathcal{A}'$ has no control. Activating a cell c changes its state to $(\mathfrak{C}(c), \nu)$ where $\mathfrak{C}$ is the input of the simulated automaton $\mathcal{A}$.*

If there exists a time t_0 at which all cells have been activated then for any cell c the projection on $\mathcal{Q}$ of the state of c in $\mathcal{A}'$ at time $(t_0 + t)$ is the state of c in the evolution of $\mathcal{A}$ from the configuration $\mathfrak{C}$ at time t' for some $t' \geq t$.

Proof. The idea is to make all cells of $\mathcal{A}'$ compute one step of $\mathcal{A}$ whenever they have enough information to do so, while remembering their past states that other cells might need at a later time.

When a cell c is activated, it receives the initial state $\mathfrak{C}(c)$ and we say that its *simulated time* is 0. From that point on, it looks at its neighbors and waits for all of them to be activated. When this happens, it sees all initial states in its neighborhood and can compute the next state in the evolution of $\mathcal{A}$, increasing its simulated time to 1. As time passes it keeps watching its neighbors until all of them are also at a simulated time at least equal to its own, which means that it has all the information necessary to compute the next step and increase its simulated time further.

Let us prove that this process can be carried out with finitely many states. First, notice that since $\mathcal{N}$ is complete, there exists $\tau \in \mathbb{N}$ such that $-\mathcal{N} \subseteq \mathcal{N}^\tau$. In order to compute its state for a simulated time $(\tau + t)$ a cell c needs to have had access to the state at the simulated time t of all cells in $(c + \mathcal{N}^\tau)$ which includes the set $(c - \mathcal{N})$ of cells that have c in their neighborhood. This means that a cell cannot be more than τ steps ahead in its simulation than the cells that have it in their neighborhood, which implies that the difference of simulated times between two neighbor cells is at most τ. If each cell stores the value of its simulated time modulo $(2\tau + 1)$, it is possible for a cell to know the relative difference in simulated time with all cells in its neighborhood. Furthermore, it is sufficient that a cell remembers its last τ simulated states to be sure that when a cell c at simulated time t looks at its neighbors that are more advanced in the simulation it can see their simulated state at time t.

Finally, we prove by induction that at time $(t_0 + t)$ all cells have a simulated time at least t. This is obviously true at time t_0 since all cells have been activated. By induction, at time

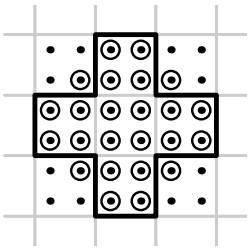

Figure 7 Compression of factor $k = 2$ with the von Neumann neighborhood. The thick line represents $\rho(c+\mathcal{N})$, the states that are visible to the central cell in one step. The circles represent $\rho(c) + \mathcal{N}^k$, the states that should be known to compute two steps of the original automaton on the states that the central cell holds.

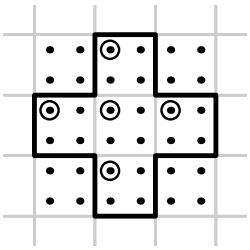

Figure 8 The thick line represents $\rho(c + \mathcal{N})$. The circles represent the cells in $(c' + k\mathcal{N})$ for some c' in $\rho(c)$ (the one in the top left).

$(t_0 + t)$ for any cell at simulated time t all its neighbors are at least at simulated time t so it can compute a new step of the simulation, which proves that at time $(t_0 + t + 1)$ all cells have a simulated time of at least $(t + 1)$.

Note that this process is such that the cells who are behind in their simulation can compute new states without delay, whereas the ones ahead wait for their neighbors to catch up. ◀

In the following section we describe how $\mathcal{A}'$ can simulate k steps of $\mathcal{A}$ at a time starting from a compressed input. We assume that all cells complete the compression and start the simulation synchronously when the last cell receives its compressed information. Using Proposition 17, we can connect the two constructions (cells are *activated* for the simulation when they receive their compressed input) and ensure that the origin is always at least as advanced in its computation as if the simulation had started synchronously.

6 Simulation on a Compressed Input

Let us denote by ρ the function that maps a cell of $\mathcal{A}'$ to the set of cells of $\mathcal{A}$ whose states it receives after the compression of a factor k :

$$\forall c \in \mathbb{Z}^2, \quad \rho(c) = \{kc + (x, y) \mid x, y \in [\![0, k-1]\!]\}$$

and extend the notation to sets of cells by $\rho(S) = \bigcup_{c \in S} \rho(c)$.

The states of $\mathcal{A}$ that are held in the neighborhood of a cell c in $\mathcal{A}'$ are the ones corresponding to the cells of $\mathcal{A}$ in $\rho(c + \mathcal{N})$. To be able to compute k steps of the original automaton, the cell c in $\mathcal{A}'$ needs to be able to see in its neighborhood the states corresponding to the cells $(\rho(c) + \mathcal{N}^k)$ of $\mathcal{A}$. Although this is the case for simple rectangular neighborhoods, it is not true for some neighborhoods (see Figure 7).

What is true however is that $\rho(c) + k\mathcal{N} \subseteq \rho(c + \mathcal{N})$ since for any $v \in \mathcal{N}$ if the state of a cell c' in $\mathcal{A}$ is held by a cell c in $\mathcal{A}'$ after compression of the input, the cell $(c + v)$ in $\mathcal{A}'$ holds the state of $(c' + kv)$ in $\mathcal{A}$ (see Figure 8).

▶ **Lemma 18.** $\forall k \in \mathbb{N}, \exists \alpha \in \mathbb{N}, \quad \mathcal{N}^\alpha + k\mathcal{N} = \mathcal{N}^\alpha + \mathcal{N}^k$

Proof. The inclusion $\mathcal{N}^\alpha + k\mathcal{N} \subseteq \mathcal{N}^\alpha + \mathcal{N}^k$ is obvious for any α. As for the converse, choose α such that $\alpha + k > |\mathcal{N}|(k-1)$. Any $x \in \mathcal{N}^\alpha + \mathcal{N}^k$ can be written as the sum of $(\alpha + k)$

elements of $\mathcal{N}$ and therefore at least one of these elements appears at least k times, which proves that $x \in \mathcal{N}^\alpha + k\mathcal{N}$. ◀

By Lemma 18, we can choose α such that $\mathcal{N}^\alpha + k\mathcal{N} = \mathcal{N}^\alpha + \mathcal{N}^k$. We now modify the behavior of $\mathcal{A}'$ so that during the first α steps of the computation, before starting the compression, all cells gather the initial states contained in their $\mathcal{N}^\alpha$ neighborhood. From here onwards, each cell performs all of the computation as described earlier on all the states it holds : a cell c holds at time $(\alpha + t)$ the states that would have been on all the cells in $(c + \mathcal{N}^\alpha)$ at time t on the automaton $\mathcal{A}'$ as described until now. At time $(\alpha + t)$ the cells in $(c + \mathcal{N})$ as a whole hold all the states that would have been on the cells in $(c + \mathcal{N}^{\alpha+1})$ at time t, which is exactly what is needed to compute the states of all cells in $(c + \mathcal{N}^\alpha)$ at time $(t + 1)$. This extra step adds a constant time α to the computation of the automaton[1].

After the initial gathering and compression of the input, the cell c in $\mathcal{A}'$ holds the initial states in $\mathcal{A}$ for the cells in $(\rho(c) + \mathcal{N}^\alpha)$. Let us show by induction that this is enough to simulate the behavior of $\mathcal{A}'$ with a linear speed-up of factor k. Assume that at time $(t_0 + t)$, any cell c of $\mathcal{A}'$ holds the states at time t for the cells of $\mathcal{A}$ in $(\rho(c) + \mathcal{N}^\alpha)$.

This means that the cells in the neighborhood $(c + \mathcal{N})$ of c in $\mathcal{A}'$ at time $(t_0 + t)$ hold the states at time t in $\mathcal{A}$ of the cells in $\rho(c + \mathcal{N}) + \mathcal{N}^\alpha$. By Lemma 18, we have

$$\rho(c + \mathcal{N}) + \mathcal{N}^\alpha \quad \supseteq \quad \rho(c) + k\mathcal{N} + \mathcal{N}^\alpha \quad \supseteq \quad \rho(c) + \mathcal{N}^{\alpha+k}$$

which shows that cell c in $\mathcal{A}'$ at time $(t_0 + t)$ sees enough information to compute the states in $\mathcal{A}$ for the cells in $(\rho(c) + \mathcal{N}^\alpha)$ at time $(t + k)$.

7 Total time

We have completed the description of the behavior of the automaton $\mathcal{A}'$. Let us now evaluate the total time taken to recognize the language L recognized by $\mathcal{A}$ in time $\mathrm{RT}_\mathcal{N} + f$.

The compression of the input takes a time $(\frac{k-1}{k} + \epsilon)\,\mathrm{RT}_\mathcal{N} + O(1)$. The simulation of $\mathcal{A}$ from a fully compressed input takes a time $\frac{1}{k}(\mathrm{RT}_\mathcal{N} + f) + O(1)$ for some $k \geq \frac{1}{\epsilon}$, and Proposition 17 shows that no time is lost by completing the compression asynchronously (the time of the compression is the time at which the last cell is correctly compressed).

The total time for the simulation of $\mathcal{A}$ is therefore

$$(\frac{k-1}{k} + \epsilon)\,\mathrm{RT}_\mathcal{N} + \frac{1}{k}(\mathrm{RT}_\mathcal{N} + f) + O(1) \leq (1 + \epsilon)\,\mathrm{RT}_\mathcal{N} + \epsilon f + O(1)$$

By Claim 15, the $O(1)$ term can be eliminated, which concludes the proof of Theorem 13.

8 Conclusion

The linear acceleration presented in this article is slightly weaker than the previously known results on a limited class of neighborhoods (which contains the von Neumann and Moore neighborhoods). On these neighborhoods, as well as all one-dimensional complete neighborhoods, any language that can be recognized in time $(\mathrm{RT} + f)$ can be recognized in time $(\mathrm{RT} + \epsilon f)$ for any $\epsilon > 0$.

[1] The constant time α is actually not lost since the origin holds the states that would be on the cells in $\mathcal{N}^\alpha$, which enables it to compute its own state α time steps ahead. However, for the purpose of proving Theorem 13, adding a constant time to the computation is irrelevant.

Although the difference is only significant if $f = o(\mathrm{RT})$, it would be interesting to know whether this stronger statement can be proved for general two-dimensional complete neighborhoods. This would either require an optimal-time compression of the input or a completely different construction skipping the compression altogether.

As we currently understand it, optimal-time compression seems unlikely on general neighborhoods. The problem is that states from the initial configuration should move towards the origin in the optimal direction permitted by the neighborhood. Before receiving any information from the axes, a cell has no way of knowing the precise direction to the origin. If the neighborhood's convex hull has more than one vertex in the positive quarter of the plane, moving along any of the directions permitted by the neighborhood might be sub-optimal, as oppposed to the case of the Moore neighborhood in which going diagonally at first is never sub-optimal and by the time it is necessary to change direction to go either horizontally or vertically information is received from the axes.

If only one cell needs to send its information towards the origin, the problem can be solved by spreading the information in all directions and spreading symmetric signals from the origin. It is however not possible to implement this for all cells at the same time with finitely many states.

Acknowledgments. The authors would like to thank Jacques Mazoyer for his helpful conversations and inspiring ideas at the start of the work that led to this article.

hellis@cs.ioc.ee

Abstract

We present a reinterpretation of the Kameda-Weiner method of finding a minimal nondeterministic finite automaton (NFA) of a language, in terms of atoms of the language. We introduce a method to generate NFAs from a set of languages, and show that the Kameda-Weiner method is a special case of it. Our method provides a unified view of the construction of several known NFAs, including the canonical residual finite state automaton and the atomaton of the language.

1 Introduction

Nondeterministic finite automata (NFAs), introduced by Rabin and Scott [11] in 1959, have played a major role in the theory and applications of finite automata. In particular, the problem of finding NFAs with the minimal number of states has received much attention. Different approaches have been used over the years when trying to solve this problem, of which the work done by Kameda and Weiner [10] in 1970 seems to be among the most classical ones. Kameda and Weiner studied the problem of NFA minimization using a matrix based on the states of the minimal deterministic finite automata (DFAs) for a given language and its reverse. They suggested a method of finding a minimal NFA using grids of this matrix.

We present a reinterpretation of the Kameda-Weiner method, using the recently introduced atoms of regular languages [3, 5], and continuing the work started by Brzozowski and Tamm in [4], where the Kameda-Weiner method was formulated in terms of quotients and atoms of a language. We show that the matrix used by Kameda and Weiner can be viewed as the *quotient-atom* matrix of the language, and that any maximal grid of this matrix can be seen as the set of atoms that the grid involves. We also show that, instead of applying the rather complicated *intersection rule* of the Kameda-Weiner method, to construct an NFA corresponding to a cover of the matrix, consisting of maximal grids, one can use sets of atoms associated with grids, and form an NFA based on these sets. We note that essentially the same approach to the Kameda-Weiner method, which uses projections of grids (corresponding to sets of atoms), has been presented by Champarnaud and Coulon [6].

Furthermore, we generalize the idea of constructing an NFA using sets of atoms. Namely, we introduce a method to generate NFAs from a set of languages, and show that the

Kameda-Weiner method of constructing a minimal NFA is a special case of this method. The introduced method provides a unified view of the construction of several known NFAs including, for example, the canonical residual finite state automaton and the átomaton of the language.

The structure of the rest of the paper is as follows. In Section 2, we provide definitions for automata, quotients, and atoms of a regular language, and recall some results related to atoms. Section 3 describes the Kameda-Weiner method of finding a minimal NFA of a language and shows how the Kameda-Weiner construction of an NFA can be expressed in terms of atoms. In Section 4, we introduce a method to generate NFAs from a set of languages and present a few examples of known NFAs that can be constructed using this method. In Section 5, we show that the NFA minimization method presented by Kameda and Weiner is a special case of generating an NFA by our method. Section 6 concludes the paper.

2 Automata, Quotients, and Atoms of Regular Languages

A *nondeterministic finite automaton (NFA)* is a quintuple $\mathcal{N} = (Q, \Sigma, \delta, I, F)$, where Q is a finite, non-empty set of *states*, Σ is a finite non-empty *alphabet*, $\delta : Q \times \Sigma \to 2^Q$ is the *transition function*, $I \subseteq Q$ is the set of *initial states*, and $F \subseteq Q$ is the set of *final states*. We extend the transition function to functions $\delta' : Q \times \Sigma^* \to 2^Q$ and $\delta'' : 2^Q \times \Sigma^* \to 2^Q$, using δ for all these functions. An NFA $\mathcal{N}' = (Q', \Sigma', \delta', I', F')$ is a *subautomaton* of $\mathcal{N}$ if $Q' \subseteq Q$, $\Sigma' \subseteq \Sigma$, $I' \subseteq I$, $F' \subseteq F$, and $q \in \delta'(p, a)$ implies $q \in \delta(p, a)$ for every $p, q \in Q'$ and $a \in \Sigma'$.

The *language accepted* by an NFA $\mathcal{N}$ is $L(\mathcal{N}) = \{w \in \Sigma^* \mid \delta(I, w) \cap F \neq \emptyset\}$. The *right language* of a state q of $\mathcal{N}$ is $L_{q,F}(\mathcal{N}) = \{w \in \Sigma^* \mid \delta(q, w) \cap F \neq \emptyset\}$. A state is *empty* if its right language is empty. The *left language* of a state q of $\mathcal{N}$ is $L_{I,q} = \{w \in \Sigma^* \mid q \in \delta(I, w)\}$. A state is *unreachable* if its left language is empty. An NFA is *trim* if it has no empty or unreachable states. If $\mathcal{N}_1 = (Q_1, \Sigma, \delta_1, I_1, F_1)$ and $\mathcal{N}_2 = (Q_2, \Sigma, \delta_2, I_2, F_2)$ are NFAs, then a map φ from Q_1 into Q_2 is a *morphism* from $\mathcal{N}_1$ into $\mathcal{N}_2$ if and only if $\varphi(I_1) \subseteq I_2$, $\varphi(F_1) \subseteq F_2$, and $q \in \delta_1(p, a)$ implies $\varphi(q) \in \delta_2(\varphi(p), a)$.

A *deterministic finite automaton (DFA)* is a quintuple $\mathcal{D} = (Q, \Sigma, \delta, q_0, F)$, where Q, Σ, and F are as in an NFA, $\delta : Q \times \Sigma \to Q$ is the transition function, and q_0 is the initial state.

The following three operations on automata are commonly used: the *determinization* operation D applied to an NFA $\mathcal{N}$, yielding a DFA $\mathcal{N}^D$, obtained by the well-known subset construction, the *reversal* operation R which, when applied to an NFA $\mathcal{N}$, yields an NFA $\mathcal{N}^R$, where the sets of the initial and the final states of $\mathcal{N}$ are interchanged and all transitions are reversed, and the *trimming* operation T which, when applied to an NFA $\mathcal{N}$, results in an NFA $\mathcal{N}^T$ where all unreachable and empty states are removed.

The *left quotient*, or simply *quotient*, of a language L by a word $w \in \Sigma^*$ is the language $w^{-1}L = \{x \in \Sigma^* \mid wx \in L\}$. There is one *initial* quotient, $\varepsilon^{-1}L = L$. A quotient is *final* if it contains ε. It is well known that there is a one-to-one correspondence between the set of states $Q = \{q_0, \ldots, q_{n-1}\}$ of the minimal DFA $\mathcal{D} = (Q, \Sigma, \delta, q_0, F)$ accepting L and the set of quotients $\{K_0, \ldots, K_{n-1}\}$ of L, such that $L_{q_i,F}(\mathcal{D}) = K_i$ for $i = 0, \ldots, n-1$.

An *atom* of a regular language L with quotients $K_0, \ldots, K_{n-1}$ is any non-empty language of the form $\widetilde{K_0} \cap \cdots \cap \widetilde{K_{n-1}}$, where $\widetilde{K_i}$ is either K_i or $\overline{K_i}$, and $\overline{K_i}$ is the complement of K_i with respect to Σ^*. Thus atoms of L are regular languages uniquely determined by L and they define a partition of Σ^*. They are pairwise disjoint and every quotient of L (including L itself) is a union of atoms. Also, every quotient of an atom of L is a union of atoms. It has been noticed that atoms are exactly the classes of the *left congruence* of L [9] defined as

follows: for $x, y \in \Sigma^*$, x is equivalent to y if for every $u \in \Sigma^*$, $ux \in L$ if and only if $uy \in L$. This idea was used in [2], where this equivalence is called the *atom congruence*.

A regular language L with n quotients has at most 2^n atoms. An atom is *initial* if it has L (rather than $\overline{L}$) as a term; it is *final* if it contains ε. There is exactly one final atom, the atom $\widehat{K_0} \cap \cdots \cap \widehat{K_{n-1}}$, where $\widehat{K_i} = K_i$ if $\varepsilon \in K_i$, and $\widehat{K_i} = \overline{K_i}$ otherwise. Let $A = \{A_0, \ldots, A_{m-1}\}$ be the set of atoms of L, let I_A be the set of initial atoms, and let A_{m-1} be the final atom. If $\overline{K_0} \cap \cdots \cap \overline{K_{n-1}}$ is an atom, then it is called the *negative* atom, all the other atoms are *positive*.

We use a one-to-one correspondence $A_i \leftrightarrow \mathbf{A}_i$ between atoms A_i of a language L and the states $\mathbf{A}_i$ of the NFA $\mathcal{A}$ defined as follows [5]:

▶ **Definition 1.** The *átomaton* of L is the NFA $\mathcal{A} = (\mathbf{A}, \Sigma, \alpha, \mathbf{I}_A, \{\mathbf{A}_{m-1}\})$, where $\mathbf{A} = \{\mathbf{A}_i \mid A_i \in A\}$, $\mathbf{I}_A = \{\mathbf{A}_i \mid A_i \in I_A\}$, and $\mathbf{A}_j \in \alpha(\mathbf{A}_i, a)$ if and only if $A_j \subseteq a^{-1}A_i$, for all $\mathbf{A}_i, \mathbf{A}_j \in \mathbf{A}$ and $a \in \Sigma$.

The right language of any state $\mathbf{A}_i$ of the átomaton is the atom A_i [5].

The next theorem is a slightly modified version of the result by Brzozowski [1]:

▶ **Theorem 2.** *If an NFA $\mathcal{N}$ has no empty states and $\mathcal{N}^R$ is deterministic, then $\mathcal{N}^D$ is minimal.*

Since it was shown in [5] that $\mathcal{A}^R$ is a minimal DFA for the reverse language of L, we know by Theorem 2 that $\mathcal{A}^R$ is isomorphic to $\mathcal{D}^{RD}$, where $\mathcal{D}$ is the minimal DFA of L. Thus, $\mathcal{A}$ is isomorphic to $\mathcal{D}^{RDR}$.

A new class of NFA's was defined in [5] as follows: an NFA $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ is *atomic* if for every $q \in Q$, the right language $L_{q,F}(\mathcal{N})$ of q is a union of atoms of $L(\mathcal{N})$. Also, it was shown that for any NFA $\mathcal{N}$, $\mathcal{N}^D$ is a minimal DFA if and only if $\mathcal{N}^R$ is atomic.

3 NFA Minimization by Kameda and Weiner

Kameda and Weiner [10] have developed a theory of NFA minimization. They used minimal DFAs for a language L and its reverse L^R to form a matrix, and based on the grids in this matrix, a minimal NFA was found. We note that the biclique edge cover technique presented by Gruber and Holzer [8] as a lower bound method for the size of a minimal NFA, uses another representation of the same matrix.

We present main principles of the Kameda-Weiner method, using mostly our terminology and notation. Kameda and Weiner [10] consider a trim minimal DFA $\mathcal{D} = (Q, \Sigma, \delta, q_0, F)$ with Q of cardinality p, and its reversed determinized and trim version $\mathcal{D}^{RDT}$; the set of states of $\mathcal{D}^{RDT}$ is a subset S of cardinality r of $2^Q \setminus \emptyset$. They then form an $p \times r$ matrix T where the rows correspond to non-empty states $q_i \in Q$ of $\mathcal{D}$, which is the trim minimal DFA of a language L, and columns, to states $S_j \in S$ of $\mathcal{D}^{RDT}$, which is the trim minimal DFA of the language L^R by Theorem 2. The entry $t_{i,j}$ of the matrix T is 1 if $q_i \in S_j$, and 0 otherwise.

We use $\mathcal{D}^{RDRT}$, the trim átomaton, instead of $\mathcal{D}^{RDT}$, since the state sets of these two automata are identical. Interpret the rows of the matrix as non-empty quotients of L and columns, as positive atoms of L. Then $t_{i,j} = 1$ if and only if quotient K_i contains atom A_j as a subset, and it is clear that every regular language defines a unique such matrix, which we will call the *quotient-atom matrix*.

The ordered pair (K_i, A_j) is a *point* of T if $t_{i,j} = 1$. A *grid* g of T is the direct product $g = P \times R$ of a set P of quotients with a set R of atoms, such that every atom in R is a

subset of every quotient in P. If $g = P \times R$ and $g' = P' \times R'$ are two grids of T, then $g \subseteq g'$ if and only if $P \subseteq P'$ and $R \subseteq R'$. Thus $\subseteq$ is a partial order on the set of all grids of T, and a grid is *maximal* if it is not contained in any other grid. We say that a grid $g = P \times R$ is *horizontally maximal* if for any grid $g' = P \times R'$, $R' \subseteq R$. Similarly, a grid $g = P \times R$ is *vertically maximal* if for any grid $g' = P' \times R$, $P' \subseteq P$. Clearly, any maximal grid is both horizontally and vertically maximal.

A *cover* G of T is a set $G = \{g_0, \ldots, g_{k-1}\}$ of grids, such that every point (K_i, A_j) belongs to some grid g_i in G. A *minimal cover* has the minimal number of grids.

Let f_G be the function that assigns to every non-empty quotient K_i the subset of a cover G, consisting of grids $g = P \times R$ such that $K_i \in P$. The NFA constructed by the Kameda-Weiner method is $\mathcal{N}_G = (G, \Sigma, \eta_G, I_G, F_G)$, where G is a cover consisting of maximal grids, $I_G = f_G(K_0)$ is the set of grids corresponding to the initial quotient K_0, and F_G is defined by $g \in F_G$ if and only if $g \in f_G(K_i)$ implies that K_i is a final quotient. For every grid $g = P \times R$ and $a \in \Sigma$, we can compute $\eta_G(g, a)$ by the formula $\eta_G(g, a) = \bigcap_{K_i \in P} f_G(a^{-1}K_i)$. It is said that the NFA $\mathcal{N}_G$ is obtained from $\mathcal{D}$ by the *intersection rule*, using the (grid) cover G.

It may be the case that $\mathcal{N}_G$ does not accept the language L. A cover G is called *legal* if $L(\mathcal{N}_G) = L$. To find a minimal NFA of a language L, the method in [10] tests the covers of the quotient-atom matrix of L in the order of increasing size to see if they are legal. The first legal NFA is a minimal one.

Next, we will interpret the Kameda-Weiner method in terms of atoms. For this, we first show the relationship between maximal grids and certain sets of atoms. Let us start with the following definition:

▶ **Definition 3.** Let R be a set of atoms and let $U(R) = \bigcup_{A_j \in R} A_j$ be the union of these atoms. We define the *maximized* version of $U(R)$ to be the language $max(U(R)) = \bigcap_{U(R) \subseteq K_i} K_i$. We say that the set R is *maximal* if $max(U(R)) = U(R)$.

The following proposition is an easy observation:

▶ **Proposition 4.** *Let R be a set of atoms. Then*
1. $U(R) \subseteq max(U(R))$,
2. $max(max(U(R))) = max(U(R))$.

▶ **Proposition 5.** *Let R_i and R_j be sets of atoms. The following properties hold:*
1. *If $U(R_i) \subseteq U(R_j)$, then $max(U(R_i)) \subseteq max(U(R_j))$.*
2. *For every $a \in \Sigma$, $max(a^{-1}U(R_i)) \subseteq a^{-1}max(U(R_i))$.*

Proof. To prove the first claim, let $U(R_i) \subseteq U(R_j)$. Then it is easy to see that the inclusion $\{K_h \mid U(R_i) \subseteq K_h\} \supseteq \{K_k \mid U(R_j) \subseteq K_k\}$ holds, implying that also the inclusion $\bigcap_{U(R_i) \subseteq K_h} K_h \subseteq \bigcap_{U(R_j) \subseteq K_k} K_k$ holds. Thus, $max(U(R_i)) \subseteq max(U(R_j))$.

To prove the second property, consider the set of quotients K_h such that $U(R_i) \subseteq K_h$. Since $U(R_i) \subseteq K_h$ implies that $a^{-1}U(R_i) \subseteq a^{-1}K_h$ holds, it is clear that the inclusion $\{a^{-1}K_h \mid U(R_i) \subseteq K_h\} \subseteq \{K_k \mid a^{-1}U(R_i) \subseteq K_k\}$ holds. This implies that also the inclusion $\bigcap_{a^{-1}U(R_i) \subseteq K_k} K_k \subseteq \bigcap_{U(R_i) \subseteq K_h} a^{-1}K_h$ holds. Since $\bigcap_{U(R_i) \subseteq K_h} a^{-1}K_h = a^{-1} \bigcap_{U(R_i) \subseteq K_h} K_h$, we get that $max(a^{-1}U(R_i)) \subseteq a^{-1}max(U(R_i))$. ◀

Next, we will see that any maximal grid can be considered as a maximal set of atoms it involves.

▶ **Proposition 6.** *For any grid $g = P \times R$, $U(R) \subseteq \bigcap_{K_i \in P} K_i$ holds.*

Proof. For any grid $g = P \times R$, it holds that for every $K_i \in P$ and $A_j \in R$, $A_j \subseteq K_i$, implying that $U(R) \subseteq \bigcap_{K_i \in P} K_i$. ◀

▶ **Proposition 7.** *A grid $g = P \times R$ is horizontally maximal if and only if the equality $\bigcap_{K_i \in P} K_i = U(R)$ holds.*

Proof. For any grid $g = P \times R$, the inclusion $U(R) \subseteq \bigcap_{K_i \in P} K_i$ holds by Proposition 6. Let g be a horizontally maximal grid. Then there is no grid $g' = P \times R'$, such that $R \subset R'$. That is, there is no $A_l \in \{A_0, \ldots, A_{m-1}\} \setminus R$, such that $U(R) \cup A_l \subseteq \bigcap_{K_i \in P} K_i$ would hold. Since every quotient is a disjoint union of atoms, every intersection of quotients is also a union of atoms. Therefore, the equality $\bigcap_{K_i \in P} K_i = U(R)$ holds.

Conversely, if $\bigcap_{K_i \in P} K_i = U(R)$, then for every grid $g' = P \times R'$, the inclusion $R' \subseteq R$ holds. Thus, the grid $g = P \times R$ is horizontally maximal. ◀

▶ **Corollary 8.** *A grid $g = P \times R$ is horizontally maximal if and only if the set R is maximal.*

Proof. Let $g = P \times R$ be a horizontally maximal grid. By Proposition 7, this means that the equality $\bigcap_{K_i \in P} K_i = U(R)$ holds. Since $max(U(R)) = \bigcap_{U(R) \subseteq K_i} K_i$, it is clear that $max(U(R)) = U(R)$. Thus, R is maximal. ◀

▶ **Corollary 9.** *A grid $g = P \times R$ is maximal if and only if P is a maximal set of quotients such that the equality $\bigcap_{K_i \in P} K_i = U(R)$ holds.*

According to Corollaries 8 and 9, any maximal grid involves a maximal set of atoms and the set of quotients, such that the intersection of these quotients is the union of the atoms involved.

As the main result of this section, we will prove the following theorem which shows how the construction of the NFA $\mathcal{N}_G$ can be expressed in terms of atoms:

▶ **Theorem 10.** *Let $G = \{g_0, \ldots, g_{k-1}\}$ be a cover consisting of maximal grids $g_i = P_i \times R_i$, $i = 0, \ldots, k-1$, and let $\mathcal{N}_G = (G, \Sigma, \eta_G, I_G, F_G)$ be the corresponding NFA, obtained by the intersection method. It holds that $g_i \in I_G$ if and only if $U(R_i) \subseteq L$, and $g_i \in F_G$ if and only if $\varepsilon \in U(R_i)$. For any $g_i, g_j \in G$ and $a \in \Sigma$, $g_j \in \eta_G(g_i, a)$ if and only if the inclusion $U(R_j) \subseteq a^{-1}U(R_i)$ holds.*

Proof. The set I_G of initial states of $\mathcal{N}_G$ consists of those grids that intersect the initial quotient $K_0 = L$. That is, for every grid $g_i \in G$, $g_i \in I_G$ if and only if $U(R_i) \subseteq L$ holds.

The set F_G of final states of $\mathcal{N}_G$ is the set of grids that intersect only the final quotients. Equivalently, for any $g_i \in G$, it holds that $g_i \in F_G$ if and only if $U(R_i)$ includes the final atom. The latter is equivalent to having $\varepsilon \in U(R_i)$.

Next, let $g_j \in \eta_G(g_i, a)$ for some $g_i, g_j \in G$ and $a \in \Sigma$. By the intersection rule, it holds that $\eta_G(g_i, a) = \bigcap_{K_h \in P_i} f(a^{-1}K_h)$. That is, $g_j \in \eta_G(g_i, a)$ if and only if $g_j \in f(a^{-1}K_h)$ for every $K_h \in P_i$. This implies that $g_j \in \eta_G(g_i, a)$ if and only if $a^{-1}K_h \in P_j$ holds for every $K_h \in P_i$.

It is clear that if $a^{-1}K_h \in P_j$ holds for every $K_h \in P_i$, then the inclusion $\bigcap_{K_k \in P_j} K_k \subseteq \bigcap_{K_h \in P_i} a^{-1}K_h$ holds. And conversely, if $\bigcap_{K_k \in P_j} K_k \subseteq \bigcap_{K_h \in P_i} a^{-1}K_h$, then since by Corollary 9, P_j is a maximal set of quotients such that the equality $\bigcap_{K_k \in P_j} K_k = U(R_j)$ holds, it must be that $a^{-1}K_h \in P_j$ for $K_h \in P_i$. Thus, $a^{-1}K_h \in P_j$ for $K_h \in P_i$ if and only if the inclusion $\bigcap_{K_k \in P_j} K_k \subseteq \bigcap_{K_h \in P_i} a^{-1}K_h$ holds. Because of the equality $\bigcap_{K_h \in P_i} a^{-1}K_h = a^{-1}\bigcap_{K_h \in P_i} K_h$, we get the equivalent condition $\bigcap_{K_k \in P_j} K_k \subseteq a^{-1}\bigcap_{K_h \in P_i} K_h$. Using Corollary 9, we get the inclusion $U(R_j) \subseteq a^{-1}U(R_i)$. ◀

Theorem 10 provides another way of constructing the NFA $\mathcal{N}_G$ from a given set of maximal grids covering the quotient-atom matrix: instead of applying the intersection rule to get transitions of $\mathcal{N}_G$, one can use the sets of atoms corresponding to the grids, and apply quotients of unions of the atoms involved. This can be done using the transition function of the átomaton.

We mention that basically the same approach to the Kameda-Weiner method has been presented by Champarnaud and Coulon [6]. They used projections of grids, consisting of subsets of the state set of the DFA $\mathcal{D}^{RDT}$, to construct an NFA similarly as in Theorem 10.

In the next section, we will generalize this idea of using sets of atoms (or unions of atoms) of a language L, to construct NFAs for L.

4 Generating Automata by a Set of Languages

In this section, we introduce a method to generate NFAs from a set of languages.

Let L be a regular language, and let $K = \{K_0, \ldots, K_{n-1}\}$ be the set of quotients of L. A set $\{L_0, \ldots, L_{k-1}\}$ of languages is a *cover* of the quotients of L, or simply, a cover for L, if every quotient K_j of L is a union of some L_i's. We note that since L is the quotient of itself by the empty word ε, L is a union of some L_i's.

We define the NFA based on a cover $\{L_0, \ldots, L_{k-1}\}$ as follows:

▶ **Definition 11.** The NFA generated by a cover $\{L_0, \ldots, L_{k-1}\}$ for L is defined by $\mathcal{G} = (Q, \Sigma, \delta, I, F)$, where $Q = \{q_0, \ldots, q_{k-1}\}$, $I = \{q_i \mid L_i \subseteq L\}$, $F = \{q_i \mid \varepsilon \in L_i\}$, and $q_j \in \delta(q_i, a)$ if and only if $L_j \subseteq a^{-1}L_i$ for all $q_i, q_j \in Q$ and $a \in \Sigma$.

▶ **Lemma 12.** *For all states q_i, q_j of NFA $\mathcal{G}$ and for any word $w \in \Sigma^+$, $q_j \in \delta(q_i, w)$ if and only if $L_j \subseteq w^{-1}L_i$.*

Proof. We prove the statement by induction on the length of w. If $w = a$ for some $a \in \Sigma$, then the lemma holds by Definition 11.

Now, let $w = ua$, where $u \in \Sigma^+$ and $a \in \Sigma$, and assume that the lemma holds for u, that is, for all states q_i, q_j of $\mathcal{G}$, $q_j \in \delta(q_i, u)$ if and only if $L_j \subseteq u^{-1}L_i$. Consider a state q_i, and let $q_k \in \delta(q_i, ua)$. Then there is a state q_j, such that $q_j \in \delta(q_i, u)$ and $q_k \in \delta(q_j, a)$. Equivalently, by the induction assumption and Definition 11, respectively, the inclusions $L_j \subseteq u^{-1}L_i$ and $L_k \subseteq a^{-1}L_j$ hold. Hence $L_k \subseteq a^{-1}L_j \subseteq a^{-1}(u^{-1}L_i) = (ua)^{-1}L_i$. Thus, $q_k \in \delta(q_i, ua)$ if and only if $L_k \subseteq (ua)^{-1}L_i$. ◀

▶ **Proposition 13.** *The following properties hold for NFA $\mathcal{G}$:*

1. *$L_{q_i,F}(\mathcal{G}) \subseteq L_i$ for every $q_i \in Q$.*
2. *$L(\mathcal{G}) \subseteq L$.*

Proof. 1. Consider a state q_i of $\mathcal{G}$. Let $w \in L_{q_i,F}(\mathcal{G})$. If $w = \varepsilon$, then $q_i \in F$, and $\varepsilon \in L_i$ by Definition 11. If $w \in \Sigma^+$, then there is some q_j such that $q_j \in F$ and $q_j \in \delta(q_i, w)$. By Lemma 12, $L_j \subseteq w^{-1}L_i$ and $\varepsilon \in L_j$ implying that $w \in L_i$.

2. Since $L(\mathcal{G})$ is the union of right languages of the initial states of $\mathcal{G}$, the claim follows from Definition 11 and Part 1. ◀

▶ **Lemma 14.** *If $a^{-1}L_i$ is a union of L_j's for every L_i and $a \in \Sigma$, then $w^{-1}L_i$ is a union of L_j's for every L_i and $w \in \Sigma^+$.*

Proof. Let $a^{-1}L_i$ be a union of L_j's for every L_i and $a \in \Sigma$, that is, $a^{-1}L_i = \bigcup_{j \in J_{i,a}} L_j$ for some $J_{i,a} \subseteq \{0, \ldots, k-1\}$. We prove the statement by induction on the length of w. If $w = a$ for some $a \in \Sigma$, then the lemma trivially holds.

Now, let $w = ua$, where $u \in \Sigma^+$ and $a \in \Sigma$, and assume that the lemma holds for u, that is, $u^{-1}L_i = \bigcup_{j \in J_{i,u}} L_j$ for some $J_{i,u} \subseteq \{0, \ldots, k-1\}$. Then $(ua)^{-1}L_i = a^{-1}(u^{-1}L_i) = a^{-1}(\bigcup_{j \in J_{i,u}} L_j) = \bigcup_{j \in J_{i,u}} a^{-1}L_j = \bigcup_{j \in J_{i,u}} \bigcup_{h \in J_{j,a}} L_h$. Thus, $(ua)^{-1}L_i$ is a union of L_h's. ◀

▶ **Proposition 15.** *Let $\mathcal{G} = (Q, \Sigma, \delta, I, F)$ be the NFA generated by a cover $\{L_0, \ldots, L_{k-1}\}$ for L. The equality $L_{q_i,F}(\mathcal{G}) = L_i$ holds for every $q_i \in Q$ if and only if $a^{-1}L_i$ is a union of L_j's for every L_i and $a \in \Sigma$.*

Proof. First, let the equality $L_{q_i,F}(\mathcal{G}) = L_i$ hold for every $q_i \in Q$. Let us consider any L_i and $a \in \Sigma$. Then it holds that $a^{-1}L_i = a^{-1}L_{q_i,F}(\mathcal{G}) = \bigcup_{q_j \in \delta(q_i,a)} L_{q_j,F}(\mathcal{G}) = \bigcup_{L_j \subseteq a^{-1}L_i} L_j$.

Conversely, assume that $a^{-1}L_i$ is a union of L_j's for every L_i and $a \in \Sigma$. Let us consider any state q_i of $\mathcal{G}$. By Proposition 13, the inclusion $L_{q_i,F}(\mathcal{G}) \subseteq L_i$ holds, so we only have to show that $L_i \subseteq L_{q_i,F}(\mathcal{G})$. Let w be any word in L_i. If $w = \varepsilon$, then $q_i \in F$, and so $w \in L_{q_i,F}(\mathcal{G})$. If $w \in \Sigma^+$, then by Lemma 14, $w^{-1}L_i$ is a union of L_j's. Since $w \in L_i$, there must be some L_j such that $L_j \subseteq w^{-1}L_i$ and $\varepsilon \in L_j$. By Lemma 12, there is some $q_j \in F$ such that $q_j \in \delta(q_i, w)$. Therefore $w \in L_{q_i,F}(\mathcal{G})$, and we conclude that $L_{q_i,F}(\mathcal{G}) = L_i$. ◀

▶ **Proposition 16.** *Let $\mathcal{G} = (Q, \Sigma, \delta, I, F)$ be the NFA generated by a cover $\{L_0, \ldots, L_{k-1}\}$ for L. If $a^{-1}L_i$ is a union of L_j's for every L_i and $a \in \Sigma$, then $\mathcal{G}$ accepts L.*

Proof. If $a^{-1}L_i$ is a union of L_j's for every L_i and $a \in \Sigma$, then by Proposition 15, $L_{q_i,F}(\mathcal{G}) = L_i$ holds for every $q_i \in Q$. Since $L(\mathcal{G}) = \bigcup_{q_i \in I} L_{q_i,F}(\mathcal{G}) = \bigcup_{L_i \subseteq L} L_i = L$, the equality $L(\mathcal{G}) = L$ holds. ◀

We present four examples of covers for the language L and the corresponding NFAs generated by these covers, where the condition of Proposition 16 holds, ensuring that the generated NFA accepts L:

▶ **Example 17.** Consider the set $K = \{K_0, \ldots, K_{n-1}\}$ of quotients of L as a cover for L. Let $\mathcal{G}_K$ be the NFA generated by the set K. Since for every quotient K_i and $a \in \Sigma$ there exists some quotient K_j such that $a^{-1}K_i = K_j$, we know by Proposition 16 that $\mathcal{G}_K$ accepts L. It is well known that the states of the minimal DFA correspond to the quotients of L. However, the NFA $\mathcal{G}_K$ is isomorphic to the *saturated* version [7] of the minimal DFA of L.

▶ **Example 18.** Consider the set $K' \subseteq K$ of *prime* quotients of L, that is, those non-empty quotients of L which are not unions of other quotients, as a cover for L. Let $\mathcal{G}_{K'}$ be the NFA generated by the set K'. Since every quotient of L is a union of some prime quotients of L, it is clear that for every prime quotient K'_i and $a \in \Sigma$, $a^{-1}K'_i$ is a union of prime quotients. Thus, $\mathcal{G}_{K'}$ accepts L by Proposition 16. The NFA $\mathcal{G}_{K'}$ is known as the *canonical residual finite state automaton (canonical RFSA)* [7] of L.

▶ **Example 19.** Consider the set $A = \{A_0, \ldots, A_{m-1}\}$ of atoms of L. The set of atoms is a cover for L, because every quotient of L is a union of atoms [5]. The NFA $\mathcal{G}_A$, generated by the set A, is the átomaton of L (cf. Definition 1). It is known that for every atom A_i and $a \in \Sigma$, $a^{-1}A_i$ is a union of atoms [5]. Thus, the condition of Proposition 16 holds, and $\mathcal{G}_A$ accepts L.

▶ **Example 20.** Let $A_0, \ldots, A_{m-1}$ be the atoms of L. Consider the set $M = \{M_0, \ldots, M_{m-1}\}$ of the maximized versions of atoms, that is, $M_i = max(A_i)$ for $i = 0, \ldots, m-1$. Clearly, if $A_i \subseteq K_j$ for some atom A_i and quotient K_j, then the inclusion $M_i \subseteq K_j$ holds by Definiton 3. Thus, the set M is a cover for L. The NFA $\mathcal{G}_M$, generated by the set M, is the *maximized átomaton* [13] of L. Since for any $M_i \in M$ and $a \in \Sigma$, $a^{-1}M_i = \bigcup_{A_j \subseteq M_i} a^{-1}A_j$, and because $a^{-1}A_j$ is a union of atoms [5], we get that $a^{-1}M_i$ is a union of atoms. By [13, Proposition 2, Part 4], the inclusion $A_j \subseteq a^{-1}M_i$ holds if and only if $M_j \subseteq a^{-1}M_i$ holds. We conclude that $a^{-1}M_i$ is a union of M_j's, and by Proposition 16, $\mathcal{G}_M$ accepts L.

However, we note that the condition of Proposition 16 is not necessary for the generated NFA to accept L.

▶ **Proposition 21.** *If $\mathcal{N}$ is a trim NFA accepting L, with the set $\{L_0, \ldots, L_{k-1}\}$ of the right languages of its states, then this set is a cover for L.*

Proof. By determinizing $\mathcal{N}$, the quotients of L are formed as unions of some L_i's. ◀

▶ **Proposition 22.** *Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be a trim NFA of L, with the set $\{L_0, \ldots, L_{k-1}\}$ of the right languages of its states, and let $\mathcal{G} = (Q', \Sigma, \delta', I', F')$ be the NFA generated by the set $\{L_0, \ldots, L_{k-1}\}$. Let $\varphi : Q \to Q'$ be the mapping assigning to every state q of $\mathcal{N}$, the state q'_i of $\mathcal{G}$, such that $L_i = L_{q,F}(\mathcal{N})$. Then φ is a morphism from $\mathcal{N}$ into $\mathcal{G}$.*

Proof. Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be a trim NFA accepting L, with the set $\{L_0, \ldots, L_{k-1}\}$ of the right languages of its states. By Proposition 21, the set $\{L_0, \ldots, L_{k-1}\}$ is a cover for L. Let $\mathcal{G} = (Q', \Sigma, \delta', I', F')$ be the NFA generated by the set $\{L_0, \ldots, L_{k-1}\}$, with $Q' = \{q'_0, \ldots, q'_{k-1}\}$. Let $\varphi : Q \to Q'$ be the mapping assigning to every state q of $\mathcal{N}$, the state q'_i of $\mathcal{G}$, such that $L_i = L_{q,F}(\mathcal{N})$. We note that there may be some states p and q of $\mathcal{N}$, such that $p \neq q$ and $L_{p,F}(\mathcal{N}) = L_{q,F}(\mathcal{N})$, so φ is a many-to-one correspondence. We show that φ is a morphism from $\mathcal{N}$ into $\mathcal{G}$.

First, if $q \in I$ is an initial state of $\mathcal{N}$, then there is some L_i, such that $L_i = L_{q,F}(\mathcal{N})$ and $L_i \subseteq L$, which implies that the corresponding state q'_i of $\mathcal{G}$ is also initial, that is, $\varphi(q) \in I'$.

Similarly, if $q \in F$, then there is some L_i, such that $L_i = L_{q,F}(\mathcal{N})$ and $\varepsilon \in L_i$, implying that $q'_i \in F'$, that is, $\varphi(q) \in F'$.

If $q \in \delta(p, a)$ holds for some states $p, q \in Q$ and $a \in \Sigma$, then there are some L_i and L_j, such that $L_i = L_{p,F}(\mathcal{N})$, $L_j = L_{q,F}(\mathcal{N})$, and $L_j \subseteq a^{-1}L_i$. It is implied that $q'_j \in \delta'(q'_i, a)$, that is, $\varphi(q) \in \delta'(\varphi(p), a)$. We conclude that φ is a morphism from $\mathcal{N}$ into $\mathcal{G}$. ◀

▶ **Theorem 23.** *If there is a trim NFA accepting L, with the set $\{L_0, \ldots, L_{k-1}\}$ of the right languages of its states, then the NFA generated by the cover $\{L_0, \ldots, L_{k-1}\}$ for L is such an NFA.*

Proof. Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be a trim NFA accepting L, with the set $\{L_0, \ldots, L_{k-1}\}$ of the right languages of its states. By Proposition 21, the set $\{L_0, \ldots, L_{k-1}\}$ is a cover for L. Let $\mathcal{G} = (Q', \Sigma, \delta', I', F')$ be the NFA generated by the set $\{L_0, \ldots, L_{k-1}\}$, with $Q' = \{q'_0, \ldots, q'_{k-1}\}$. By Proposition 22, there is a morphism $\varphi : Q \to Q'$ from $\mathcal{N}$ into $\mathcal{G}$, such that $\varphi(q) = q'_i$ for some $q \in Q$ and $q'_i \in Q'$ if and only if $L_{q,F}(\mathcal{N}) = L_i$.

The morphism φ implies that for every state $q \in Q$, with its right language $L_{q,F}(\mathcal{N}) = L_i$ for some L_i, the inclusion $L_{q,F}(\mathcal{N}) \subseteq L_{q'_i,F'}(\mathcal{G})$, that is, $L_i \subseteq L_{q'_i,F'}(\mathcal{G})$ holds. Since by Proposition 13, Part 1, the inclusion $L_{q'_i,F'}(\mathcal{G}) \subseteq L_i$ holds, the equality $L_{q'_i,F'}(\mathcal{G}) = L_i$ must hold. Also, the morphism φ implies that the inclusion $L(\mathcal{N}) \subseteq L(\mathcal{G})$ holds. Since by Proposition 13, Part 2, $L(\mathcal{G}) \subseteq L$, and we assumed that $L(\mathcal{N}) = L$, we conclude that $\mathcal{G}$ accepts L. ◀

Theorem 23 shows that our method to generate NFAs from a set of languages is indeed general. That is, if one is interested in finding an NFA for a given language, such that the states of that NFA correspond to certain languages, this method can be used to generate such an NFA if it exists. If the generated NFA is not such an NFA, then it does not exist.

To conclude this section, we point out three cases which can occur if a cover $\{L_0, \ldots, L_{k-1}\}$ for L is used to generate an NFA $\mathcal{G}$:

First, the NFA $\mathcal{G}$ accepts L, and the right language of every state q_i of $\mathcal{G}$ is L_i. This case is described by Propositions 15 and 16.

In the second case, the NFA $\mathcal{G}$ accepts L, but the right language of some state q_i of $\mathcal{G}$ is not L_i. The third case is when $\mathcal{G}$ does not accept L. Characterization of the last two cases is an interesting problem for further study.

5 Generating Automata by Atomic Languages

Let L be a regular language, with its quotients $K_0, \ldots, K_{n-1}$ and atoms $A_0, \ldots, A_{m-1}$.

▶ **Definition 24.** A language L_i is *atomic* with regard to L if L_i is a union of atoms of L.

Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be a trim NFA accepting L, with $Q = \{q_0, \ldots, q_{k-1}\}$. For every state q_i of $\mathcal{N}$, we define an atomic language $B_i = \bigcup_{L_{q_i,F}(\mathcal{N}) \cap A_h \neq \emptyset} A_h$ as the union of all atoms of L which intersect with the right language of q_i. In other words, B_i is the smallest atomic language that contains the right language of state q_i. Clearly, if $L_{q_i,F}(\mathcal{N}) \subseteq K_j$ holds for some quotient K_j of L, then, because every quotient is a union of atoms, $B_i \subseteq K_j$ holds as well. Since by Proposition 21, the set of right languages of the states of $\mathcal{N}$ forms a cover for L, the set of B_i's has the same property. We note that there may be some states q_i and q_j of $\mathcal{N}$, such that $q_i \neq q_j$, but $B_i = B_j$. Let the set of distinct B_i's be B.

Let $\mathcal{G}_B = (Q_B, \Sigma, \delta_B, I_B, F_B)$ be the NFA generated by the cover B for the language L. We note that $|Q_B| \leqslant |Q|$. Let $\varphi_{atom} : Q \to Q_B$ be the mapping assigning to state q_i of $\mathcal{N}$, the state q_{B_i} of $\mathcal{G}_B$, such that $B_i = \bigcup_{L_{q_i,F}(\mathcal{N}) \cap A_h \neq \emptyset} A_h$.

▶ **Proposition 25.** *The mapping φ_{atom} is a morphism from $\mathcal{N}$ into $\mathcal{G}_B$.*

Proof. First, if $q_i \in I$ is initial, then $L_{q_i,F}(\mathcal{N}) \subseteq L$, and since L is a union of (initial) atoms, the inclusion $B_i \subseteq L$ holds, implying that q_{B_i} is also initial, that is, $\varphi_{atom}(q_i) \in I_B$.

Similarly, if $q_i \in F$, then $\varepsilon \in L_{q_i,F}(\mathcal{N})$, implying that $\varepsilon \in B_i$, and thus $q_{B_i} \in F_B$, that is, $\varphi_{atom}(q_i) \in F_B$.

It remains to be shown that for all states $q_i, q_j \in Q$ and $a \in \Sigma$, if $q_j \in \delta(q_i, a)$ holds, then $\varphi_{atom}(q_j) \in \delta_B(\varphi_{atom}(q_i), a)$ holds as well. Let $q_j \in \delta(q_i, a)$ for some $q_i, q_j \in Q$ and $a \in \Sigma$. Then the inclusion $L_{q_j,F}(\mathcal{N}) \subseteq a^{-1}L_{q_i,F}(\mathcal{N})$ holds. Because of $L_{q_i,F}(\mathcal{N}) \subseteq B_i$, the inclusion $L_{q_j,F}(\mathcal{N}) \subseteq a^{-1}B_i$ holds. Since it is known that any quotient of a union of atoms is some union of atoms, $a^{-1}B_i$ is a union of atoms. Consequently, $L_{q_j,F}(\mathcal{N}) \subseteq B_j \subseteq a^{-1}B_i$ holds, implying that $q_{B_j} \in \delta_B(q_{B_i}, a)$, that is, $\varphi_{atom}(q_j) \in \delta_B(\varphi_{atom}(q_i), a)$.

We conclude that φ_{atom} is a morphism from $\mathcal{N}$ into $\mathcal{G}_B$. ◀

▶ **Corollary 26.** *For every state q_i of $\mathcal{N}$, the inclusion $L_{q_i,F}(\mathcal{N}) \subseteq L_{q_{B_i},F_B}(\mathcal{G}_B)$ holds. Also, $L(\mathcal{G}_B) = L$.*

Proof. The morphism $\varphi_{atom} : Q \to Q_B$ implies that for every $q_i \in Q$, the inclusion $L_{q_i,F}(\mathcal{N}) \subseteq L_{q_{B_i},F_B}(\mathcal{G}_B)$ holds, and also that $L(\mathcal{N}) \subseteq L(\mathcal{G}_B)$ holds.

Since $L(\mathcal{N}) = L$, and we know by Proposition 13 that $L(\mathcal{G}_B) \subseteq L$, we conclude that $L(\mathcal{G}_B) = L$. ◀

▶ **Corollary 27.** *If there is a one-to-one correspondence between the sets Q and B, then the NFA $\mathcal{N}$ is isomorphic to a subautomaton of $\mathcal{G}_B$.*

Next, for every atomic language B_i we consider its maximized version, the language $C_i = max(B_i) = \bigcap_{B_i \subseteq K_j} K_j$. Clearly, C_i is also atomic, and $B_i \subseteq C_i$. If the inclusion $B_i \subseteq K_j$ holds for some quotient K_j, then by the definition of C_i, $C_i \subseteq K_j$ holds as well. Since the set of B_i's forms a cover for L, so does the set of corresponding C_i's. We note that there may be some B_i and B_j, such that $B_i \neq B_j$, but $C_i = C_j$. Let the set of distinct C_i's be C.

Let $\mathcal{G}_C = (Q_C, \Sigma, \delta_C, I_C, F_C)$ be the NFA generated by the cover C for the language L. We note that $|Q_C| \leqslant |Q_B|$. Let $\varphi_{max} : Q_B \to Q_C$ be the mapping assigning to state q_{B_i} of $\mathcal{G}_B$, the state q_{C_i} of $\mathcal{G}_C$.

▶ **Proposition 28.** *The mapping φ_{max} is a morphism from $\mathcal{G}_B$ into $\mathcal{G}_C$.*

Proof. First, if $q_{B_i} \in I_B$, then $B_i \subseteq L$. Since C_i is a subset of the same quotients as B_i, $C_i \subseteq L$, implying that $q_{C_i} \in I_C$. If $q_{B_i} \in F_B$, then $\varepsilon \in B_i$, and since $B_i \subseteq C_i$, it holds that $\varepsilon \in C_i$, so we get $q_{C_i} \in F_C$.

We also have to show that if $q_{B_j} \in \delta_B(q_{B_i}, a)$ holds for some states q_{B_i} and q_{B_j} of $\mathcal{G}_B$ and $a \in \Sigma$, then $q_{C_j} \in \delta_C(q_{C_i}, a)$ for the corresponding states q_{C_i} and q_{C_j} of $\mathcal{G}_C$. Indeed, if $q_{B_j} \in \delta_B(q_{B_i}, a)$, then $B_j \subseteq a^{-1}B_i$. By Proposition 5, Part 1, we know that $max(B_j) \subseteq max(a^{-1}B_i)$, and by Part 2, the inclusion $max(a^{-1}B_i) \subseteq a^{-1}max(B_i)$ holds. Since $C_i = max(B_i)$ and $C_j = max(B_j)$, we get that $C_j \subseteq a^{-1}C_i$ holds. Thus, $q_{C_j} \in \delta_C(q_{C_i}, a)$.

We conclude that φ_{max} is a morphism from $\mathcal{G}_B$ into $\mathcal{G}_C$. ◀

▶ **Corollary 29.** *For every state q_{B_i} of $\mathcal{G}_B$, the inclusion $L_{q_{B_i},F_B}(\mathcal{G}_B) \subseteq L_{q_{C_i},F_C}(\mathcal{G}_C)$ holds. Also, $L(\mathcal{G}_C) = L$.*

Proof. The morphism $\varphi_{max} : Q_B \to Q_C$ implies that for every $q_{B_i} \in Q_B$, the inclusion $L_{q_{B_i},F_B}(\mathcal{G}_B) \subseteq L_{q_{C_i},F_C}(\mathcal{G}_C)$ holds, and also that $L(\mathcal{G}_B) \subseteq L(\mathcal{G}_C)$ holds.

Since $L(\mathcal{G}_B) = L$ by Corollary 26, and $L(\mathcal{G}_C) \subseteq L$ by Proposition 13, we conclude that $L(\mathcal{G}_C) = L$. ◀

▶ **Corollary 30.** *If there is a one-to-one correspondence between the sets B and C, then the NFA $\mathcal{G}_B$ is isomorphic to a subautomaton of $\mathcal{G}_C$.*

Based on the results above, we can state the following theorem:

▶ **Theorem 31.** *There is a morphism $\varphi_{max} \circ \varphi_{atom}$ from a trim NFA $\mathcal{N}$ into the NFA $\mathcal{G}_C$, generated by the set C of languages $C_i = max(\bigcup_{L_{q_i,F}(\mathcal{N}) \cap A_h \neq \emptyset} A_h)$, where q_i is a state of $\mathcal{N}$, with $L(\mathcal{G}_C) = L(\mathcal{N})$. Moreover, if there is a one-to-one correspondence between the states of $\mathcal{N}$ and $\mathcal{G}_C$, then $\mathcal{N}$ is isomorphic to a subautomaton of $\mathcal{G}_C$.*

The following theorem shows that the NFA minimization method presented by Kameda and Weiner is a special case of generating an NFA:

▶ **Theorem 32.** *Let $G = \{g_0, \ldots, g_{k-1}\}$ be a set of maximal grids, with $g_i = P_i \times R_i$, forming a cover of the quotient-atom matrix of L. The NFA $\mathcal{N}_G$, obtained by the Kameda-Weiner method using G, is isomorphic to the NFA $\mathcal{G}_C$, generated by the set $C = \{C_0, \ldots, C_{k-1}\}$ of languages $C_i = U(R_i)$, $i = 0, \ldots, k-1$.*

Proof. Let $G = \{g_0, \ldots, g_{k-1}\}$ be a set of maximal grids $g_i = P_i \times R_i$, forming a cover of the quotient-atom matrix of L. Let $\mathcal{N}_G = (G, \Sigma, \eta_G, I_G, F_G)$ be the NFA obtained by the intersection method using G, and let $\mathcal{G}_C = (Q_C, \Sigma, \delta_C, I_C, F_C)$ be the NFA generated by the set $C = \{C_0, \ldots, C_{k-1}\}$, where $C_i = U(R_i)$ for $i = 0, \ldots, k-1$. We show that $\mathcal{N}_G$ is isomorphic to $\mathcal{G}_C$ by applying Theorem 10.

First, by Theorem 10, for every grid $g_i \in G$, it holds that $g_i \in I_G$ if and only if the inclusion $U(R_i) \subseteq L$ holds, that is, $C_i \subseteq L$. Since this is equivalent to the condition $q_{C_i} \in I_C$, there is a one-to-one correspondence between the sets I_G and I_C.

Also, it holds that $g_i \in F_G$ if and only if $\varepsilon \in U(R_i)$, that is, $\varepsilon \in C_i$. This is equivalent to the condition $q_{C_i} \in F_C$. Thus, there is a one-to-one correspondence between the sets F_G and F_C.

It remains to show that $g_j \in \eta_G(g_i, a)$ if and only if $q_{C_j} \in \delta_C(q_{C_i}, a)$ for all $g_i, g_j \in G$ and $a \in \Sigma$. Indeed, by Theorem 10, $g_j \in \eta_G(g_i, a)$ holds if and only if the inclusion $U(R_j) \subseteq a^{-1}U(R_i)$ holds, that is, $C_j \subseteq a^{-1}C_i$. On the other hand, by Definition 11, $q_{C_j} \in \delta_C(q_{C_i}, a)$ if and only if $C_j \subseteq a^{-1}C_i$, where $q_{C_i}, q_{C_j} \in Q_C$ and $a \in \Sigma$. Therefore, $g_j \in \eta_G(g_i, a)$ holds if and only if $q_{C_j} \in \delta_C(q_{C_i}, a)$ holds for all $g_i, g_j \in G$ and $a \in \Sigma$. ◀

▶ **Corollary 33.** *There exists an atomic NFA with the right languages $C_0, \ldots, C_{k-1}$, such that the set of atoms contained in every C_i is maximal, if and only if the Kameda-Weiner method finds it.*

Proof. Follows from Theorem 23 and Theorem 32. ◀

▶ **Corollary 34.** *There is a morphism from any trim NFA $\mathcal{N}$ into the NFA $\mathcal{N}_G$ obtained by the Kameda-Weiner method using the set G of maximal grids, corresponding to the maximal sets of atoms associated to the right languages of $\mathcal{N}$.*

Proof. Follows from Theorem 31 and Theorem 32. ◀

As a special case, if $\mathcal{N}$ is a minimal NFA, then by Theorem 31, $\mathcal{N}$ is isomorphic to a subautomaton of the NFA $\mathcal{G}_C$ generated by the set C of the maximized atomic languages of the right languages of $\mathcal{N}$, or equivalently, as by Theorem 32, of the NFA $\mathcal{N}_G$ obtained by the Kameda-Weiner method, using the corresponding maximal grids.

This indeed ensures that if one considers covers of the quotient-atom matrix, starting from the smallest cover, and produces NFAs according to the Kameda-Weiner method, or equivalently, generates NFAs, using unions of atoms corresponding to the grids in the cover, the first obtained NFA which accepts the given language, is a minimal NFA.

As we mentioned earlier, Champarnaud and Coulon [6] have presented an approach to the Kameda-Weiner method which, similarly to our method, finds NFAs corresponding to grid covers, using projections of grids (corresponding to sets of atoms). We note that they also used grid extensions and automaton morphisms, similarly to our theory. However, we point out that our theory explicitly shows that atoms of regular languages have an important role in the Kameda-Weiner method.

We also mention that Sengoku's method [12] of constructing NFAs is related to atoms; it yields atomic NFAs. However, we note that by a result proved in [5], not every language has an atomic minimal NFA.

6 Conclusions

We presented a reinterpretation of the Kameda-Weiner method for NFA minimization, and generalized it by introducing a method to generate NFAs by certain sets of languages. We hope that our contributions provide a useful insight into the difficult problem of NFA minimization, to obtain a better understanding of this problem.

We also think that the introduced method of generating NFAs is of interest on its own as exemplified in Section 4. This method provides a unified view of the construction of several known NFAs, including the canonical RFSA and the átomaton of the language.

Abstract

Designing query languages for graph structured data is an active field of research, where expressiveness and efficient algorithms for query evaluation are conflicting goals. To better handle dynamically changing data, recent work has been done on designing query languages that can compare values stored in the graph database, without hard coding the values in the query. The main idea is to allow variables in the query and bind the variables to values when evaluating the query. For query languages that bind variables only once, query evaluation is usually NP-complete. There are query languages that allow binding inside the scope of Kleene star operators, which can themselves be in the scope of bindings and so on. Uncontrolled nesting of binding and iteration within one another results in query evaluation being PSPACE-complete.

We define a way to syntactically control the nesting depth of iterated bindings, and study how this affects expressiveness and efficiency of query evaluation. The result is an infinite, syntactically defined hierarchy of expressions. We prove that the corresponding language hierarchy is strict. Given an expression in the hierarchy, we prove that it is undecidable to check if there is a language equivalent expression at lower levels. We prove that evaluating a query based on an expression at level i can be done in level i of the polynomial time hierarchy. Satisfiability of quantified Boolean formulas can be reduced to query evaluation; we study the relationship between alternations in Boolean quantifiers and the depth of nesting of iterated bindings.

1 Introduction

Graph structures representing data have found many applications like semantic web [11], social networks [19] and biological networks [13]. Theoretical models of such data typically have a graph with nodes representing entities and edges representing relations among them. One reason for the popularity of these models is their flexibility in handling semi-structured data. While traditional relational databases impose rigid structures on the relations between

data elements, graph databases are better equipped to handle data in which relations are not precisely known and/or developing dynamically.

A fundamental query language for such models is Regular Path Queries (RPQs), which is now part of the W3C recommendation [18]. An RPQ consists of a regular expression. Suppose a communication network is modeled by a graph, where nodes represent servers and edges labeled ℓ represent links between them. Evaluating the RPQ ℓ^* on this graph results in the set of pairs of nodes between which there exists a route. Suppose each link has a priority and we need pairs of connected nodes where all intermediate links have the same priority. We can hard code the set of priorities in the query. If the set of priorities is not static, a querying mechanism which avoids hard coding is better. Every edge can be labeled by a supplementary data value (priority of the link, in this example) and we want query languages that can compare data values without hard coding them in the syntax. Nodes can also carry data values. In generic frameworks, there is no a priori bound on the number of possible data values and they are considered to be elements of an infinite domain. Graph databases with data values are often called data graphs in theory and property graphs in practice.

One way to design querying languages for data graphs is to extend RPQs using frameworks that handle words on infinite alphabets [16, 15, 12, 23]. Expressiveness and efficient algorithms for query evaluation are conflicting goals for designing such languages. We study a feature common to many of these languages, and quantify how it affects the trade-off between expressiveness and complexity of query evaluation. Variable finite automata [10] and parameterized regular expressions [2] are conservative extensions of classical automata and regular expressions. They have variables, which can be bound to letters of the alphabet at the beginning of query evaluation. The query evaluation problem is NP-complete for these languages. Regular expressions with binding (REWBs) [15] is an extended formalism where binding of variables to values can happen inside a Kleene star, which can itself be in the scope of another binding operator and so on. Allowing binding and iteration to occur inside each other's scope freely results in the query evaluation problem being PSPACE-complete. Here we study how the expressiveness and complexity of query evaluation vary when we syntactically control the depth of nesting of iterated bindings.

Contributions

1. We syntactically classify REWBs according to the depth of nesting of iterated bindings.
2. The resulting hierarchy of data languages is strict, and so is the expressiveness of queries.
3. It is undecidable to check if a given REWB has a language equivalent one at lower levels.
4. An REWB query in level i can be evaluated in Σ_i in the polynomial time hierarchy.
5. For lower bounds, we consider quantified Boolean formulas with some restrictions on quantifications and reduce their satisfiability to query evaluation, with some restrictions on the queries.

For proving strictness of the language hierarchy, we build upon ideas from the classic star height hierarchy [9]. Universality of REWBs is known to be undecidable [17, 12]. We combine techniques from this proof with tools developed for the language hierarchy to prove the third result above. The Σ_i upper bound for query evaluation involves complexity theoretic arguments based on the same tools. In the reductions from satisfiability of quantified Boolean formulas to the query evaluation problem, the relation between the number of alternations (in the Boolean quantifiers) and the depth of nesting (of iterated bindings in REWBs) is not straight forward. We examine this relation closely in the framework of parameterized complexity theory, which is suitable for studying the effect of varying the structure of input instances on the complexity.

Related work: The quest for efficient evaluation algorithms and expressive languages to query graph databases, including those with data values, is an active area of research; [1] is a recent comprehensive survey. Numerous formalisms based on logics and automata exist for handling languages over infinite alphabets [20]. In [16], the suitability of these formalisms as query languages has been studied, zeroing in on register automata mainly for reasons of efficient evaluation. The same paper introduced regular expressions with memory and proved that they are equivalent to register automata. REWBs [15] have slightly less expressive power but have better scoping structure for the binding operator. Properties of these expressions have been further studied in [12]. In [14], XPath has been adapted to query data graphs. Pebble automata have been adapted to work with infinite alphabets in [17]. A strict language hierarchy based on the number of pebbles allowed in pebble automata has been developed in [22]. Many questions about comparative expressiveness of register and pebble automata are open [17]. Fixed-point logics can be used to define languages over infinite alphabets [4]. These logics can use the class successor relation, which relates two positions with the same data value if no intermediate position carries the same value. Expressiveness of these logics increase [6, 5], when the number of alternations between standard successor relation and class successor relation increase.

2 Preliminaries

2.1 Data Languages and Querying Data Graphs

We follow the notation of [15]. Let Σ be a finite alphabet and $\mathcal{D}$ a countably infinite set. The elements of $\mathcal{D}$ are called *data values*. A *data word* is a finite string over the alphabet $\Sigma \times \mathcal{D}$. We will write a data word as $\binom{a_1}{d_1}\binom{a_2}{d_2}\ldots\binom{a_n}{d_n}$, where each $a_i \in \Sigma$ and $d_i \in \mathcal{D}$. A set of data words is called a *data language*.

An extension of standard regular expressions, called *regular expressions with binding (REWB)*, has been defined in [15]. Here, data values are compared using variables. For a set $\{x_1, x_2, \ldots, x_k\}$ of variables, the set of conditions $\mathcal{C}_k$ is the set of Boolean combinations of $x_i^{=}$ and $x_i^{\neq}$ for $i \in \{1, \ldots, k\}$. A data value $d \in \mathcal{D}$ and a partial valuation $\nu : \{x_1, \ldots, x_k\} \to \mathcal{D}$ satisfies the condition $x_i^{=}$ (written as $d, \nu \models x_i^{=}$) if $\nu(x_i) = d$. The satisfaction for other Boolean operators are standard.

▶ **Definition 2.1** (Regular expressions with binding (REWB) [15])**.** Let Σ be a finite alphabet and $\{x_1, \ldots, x_k\}$ a set of variables. Regular expressions with binding over $\Sigma[x_1, \ldots, x_k]$ are defined inductively as: $r := \varepsilon \mid a \mid a[c] \mid r + r \mid r \cdot r \mid r^* \mid a \downarrow_x (r)$ where $a \in \Sigma$ is a letter in the alphabet, $c \in \mathcal{C}_k$ is a condition on the variables and $x \in \{x_1, \ldots, x_k\}$ is a variable.

We call $\downarrow_x$ the *binding operator*. In the expression $a \downarrow_x (r)$, the expression r is said to be the *scope* of the binding $\downarrow_x$. A variable x in an expression is *bound* if it occurs in the scope of a binding $\downarrow_x$. Otherwise it is *free*. We write $fv(r)$ to denote the set of free variables in r and $r(\bar{x})$ to denote that $\bar{x}$ is the sequence of all free variables. The semantics of an REWB $r(\bar{x})$ over the variables $\{x_1, \ldots, x_k\}$ is defined with respect to a partial valuation $\nu : \{x_1, \ldots, x_k\} \to \mathcal{D}$ of the variables. A valuation ν is *compatible* with $r(\bar{x})$ if $\nu(\bar{x})$ is defined.

▶ **Definition 2.2** (Semantics of REWB)**.** Let $r(\bar{x})$ be an REWB over $\Sigma[x_1, \ldots, x_k]$ and let $\nu : \{x_1, \ldots, x_k\} \to \mathcal{D}$ be a valuation of variables compatible with $r(\bar{x})$. The language of data words $L(r, \nu)$ defined by $r(\bar{x})$ with respect to ν is given as follows:

r	$L(r,\nu)$	r	$L(r,\nu)$	r	$L(r.\nu)$
ε	$\{\varepsilon\}$	a	$\{\binom{a}{d} \mid d \in \mathcal{D}\}$	$a[c]$	$\{\binom{a}{d} \mid d, \nu \models c\}$
$r_1 + r_2$	$L(r_1,\nu) \cup L(r_2,\nu)$	$r_1 \cdot r_2$	$L(r_1,\nu) \cdot L(r_2,\nu)$	r_1^*	$(L(r_1,\nu))^*$
$a \downarrow_{x_i} (r_1)$	$\bigcup_{d\in\mathcal{D}}\{\binom{a}{d}\} \cdot L(r_1, \nu[x_i \to d])$				

where $\nu[x_i \to d]$ denotes the valuation which is the same as ν except for x_i which is mapped to d. An REWB r defines the data language $L(r) = \bigcup_{\nu \text{ compatible with } r} L(r,\nu)$.

For example, the REWB $a \downarrow_x (b[x^=]^*)$ defines the set of data words of the form ab^* with all positions having the same data value. The REWB $(a \downarrow_x (b[x^=]))^*$ defines the set of data words of the form $\binom{a}{d_1}\binom{b}{d_1}\binom{a}{d_2}\binom{b}{d_2}\cdots\binom{a}{d_n}\binom{b}{d_n}$.

▶ **Definition 2.3** (Data graphs). A *data graph* G over a finite alphabet Σ and an infinite set of data values $\mathcal{D}$ is a pair (V, E) where V is a finite set of vertices, and $E \subseteq V \times \Sigma \times \mathcal{D} \times V$ is a set of edges which carry labels from $\Sigma \times \mathcal{D}$.

We do not have data values on vertices, but they can be introduced without affecting the results. A *regular data path query* is of the form $Q = x \xrightarrow{r} y$ where r is an REWB. Evaluating Q on a data graph G results in the set $Q(G)$ of pairs of nodes $\langle u, v\rangle$ such that there exists a data path from u to v and the sequence of labels along the data path forms a data word in $L(r)$. Evaluating a regular data path query on a data graph is known to be PSPACE-complete in general and NLOGSPACE-complete when the query is of constant size [15]. We sometimes identify the query Q with the expression r and write $r(G)$ for $Q(G)$. A query r_1 is said to be contained in another query r_2 if for every data graph G, $r_1(G) \subseteq r_2(G)$. It is known from [12, Proposition 3.5] that a query r_1 is contained in the query r_2 iff $L(r_1) \subseteq L(r_2)$. Hence, if a class E_2 of REWBs is more expressive than the class E_1 in terms of defining data languages, E_2 can also express more queries than E_1.

2.2 Parameterized Complexity

The size of queries are typically small compared to the size of databases. To analyze the efficiency of query evaluation algorithms, the size of the input can be naturally split into the size of the query and the size of the database. Parameterized complexity theory is a formal framework for dealing with such problems. An instance of a parameterized problem is a pair (x, k), where x is an encoding of the input structure on which the problem has to be solved (e.g., a data graph and a query), and k is a parameter associated with the input (e.g., the size of the query). A parameterized problem is said to be in the parameterized complexity class Fixed Parameter Tractable (FPT) if there is a computable function $f : \mathbb{N} \to \mathbb{N}$, a constant $c \in \mathbb{N}$ and an algorithm to solve the problem in time $f(k)|x|^c$.

We will see later that the query evaluation problem is unlikely to be in FPT, when parameterized by the size of the regular data path query. There are many parameterized complexity classes that are unlikely to be in FPT, like W[SAT], W[P], AW[SAT] and AW[P]. To place parameterized problems in these classes, we use FPT-reductions.

▶ **Definition 2.4** (FPT reductions). A FPT reduction from a parameterized problem Q to another parameterized problem Q' is a mapping R such that:

1. For all instances (x, k) of parameterized problems, $(x, k) \in Q$ iff $R(x, k) \in Q'$.
2. There exists a computable function $g : \mathbb{N} \to \mathbb{N}$ such that for all (x, k), say with $R(x, k) = (x', k')$, we have $k' \leqslant g(k)$.
3. There exist a computable function $f : \mathbb{N} \to \mathbb{N}$ and a constant $c \in \mathbb{N}$ such that R is computable in time $f(k)|x|^c$.

3 Nesting Depth of Iterated Bindings and Expressive Power

A binding $\downarrow_x$ along with a condition $[x^{=}]$ or $[x^{\neq}]$ is used to constrain the possible data values that can occur at certain positions in a data word. A binding inside a star — an *iterated binding* — imposes the constraint arbitrarily many times. For instance, the expression $r_1 := (a_1 \downarrow_{x_1} (b_1[x_1^{=}]))^*$ defines data words in $(a_1 b_1)^*$ where every a_1 has the same data value as the next b_1. We now define a syntactic mechanism for controlling the nesting depth of iterated bindings. The restrictions result in an infinite hierarchy of expressions. The expressions at level i are generated by F_i in the grammar below, defined by induction on i.

$$F_0 ::= \varepsilon \mid a \mid a[c] \mid F_0 + F_0 \mid F_0 \cdot F_0 \mid F_0^*$$
$$E_i ::= F_{i-1} \mid E_i + E_i \mid E_i \cdot E_i \mid a \downarrow_{x_j} (E_i)$$
$$F_i ::= E_i \mid F_i + F_i \mid F_i \cdot F_i \mid F_i^*$$

where $i \geqslant 1$, $a \in \Sigma$, c is a condition in $\mathcal{C}_k$ and $x_j \in \{x_1, \ldots, x_k\}$. Intuitively, E_i can add bindings over iterations (occurring in F_{i-1}) and F_i can add iterations over bindings (occurring in E_i). The nesting depth of iterated bindings in an expression in F_i is therefore i. The union of all expressions at all levels equals the set of REWBs. In this paper, we use subscripts to denote the levels of expressions and superscripts to denote different expressions in a level: so e_5^1 is some expression in E_5, f_3^2 is some expression in F_3.

We now give a sequence of expressions $\{r_i\}_{i \geqslant 1}$ such that each r_i is in F_i but no language equivalent expression exists in F_{i-1}. For technical convenience, we use an unbounded number of letters from the finite alphabet and an unbounded set of variables. The results can be obtained with a constant number of letters and variables.

▶ **Definition 3.1.** Let $\{a_1, b_1, a_2, b_2, \ldots\}$ be an alphabet and $\{x_1, x_2, \ldots\}$ a set of variables. We define r_1 to be $(a_1 \downarrow_{x_1} (b_1[x_1^{=}]))^*$. For $i \geqslant 2$, define $r_i := (a_i \downarrow_{x_i} (r_{i-1} b_i[x_i^{=}]))^*$.

From the syntax, it can be seen that each r_i is in F_i. To show that $L(r_i)$ cannot be defined by any expression in F_{i-1}, we will use an "automaton view" of the expression, as this makes pigeon-hole arguments simpler. No automata characterizations are known for REWBs in general; the restrictions on the binding and star operators in the expressions of a given level help us build specific automata in stages.

Standard finite state automata can be converted to regular expressions by considering generalized non-deterministic finite automata, where transitions are labeled with regular expressions instead of a single letter (see e.g., [21, Lemma 1.32]). The language of an expression f_i^1 can be accepted by such an automaton, where transitions are labeled with expressions in E_i. We will denote this automaton by $\mathcal{A}(f_i^1)$. Similarly, the language of an expression e_i^1 can be accepted by an automaton whose transitions are labeled with expressions in F_{i-1} or with $a \downarrow_x$. We will denote this automaton by $\mathcal{A}(e_i^1)$. There are no cycles in $\mathcal{A}(e_i^1)$, since e_i^1 can not use the Kleene $*$ operator except inside expressions in F_{i-1}. The runs of $\mathcal{A}(e_i^1)$ are sequences of pairs of a state and a valuation for variables. The valuations are updated after every transition with a label of the form $a \downarrow_x$. Formal semantics are given in Appendix A of the full version of this paper, which also contains all the proofs in detail.

We will prove that $L(r_i)$ cannot be defined by any expression in E_i (and hence not by any expression in F_{i-1}). We first define the following sequence of words, which will be used in the proof. Let $\{d[j_1, j_2] \in \mathcal{D} \mid j_1, j_2 \in \mathbb{N}\}$ be a set of data values such that $d[j_1, j_2] \neq d[j_1', j_2']$

if $\langle j_1, j_2\rangle \neq \langle j_1', j_2'\rangle$. For every $n \geqslant 1$, define the words:

$$u_{1,n} := \binom{a_1}{d[1,1]}\binom{b_1}{d[1,1]}\binom{a_1}{d[1,2]}\binom{b_1}{d[1,2]} \cdots \binom{a_1}{d[1,n^2]}\binom{b_1}{d[1,n^2]}$$

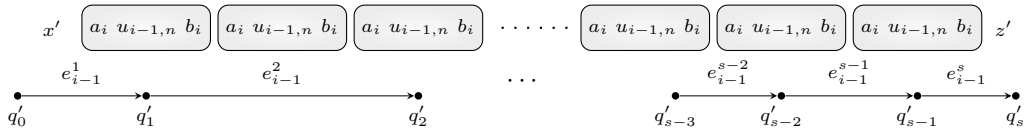
$$u_{i,n} := \binom{a_i}{d[i,1]}u_{i-1,n}\binom{b_i}{d[i,1]}\binom{a_i}{d[i,2]}u_{i-1,n}\binom{b_i}{d[i,2]}\cdots\binom{a_i}{d[i,n^2]}u_{i-1,n}\binom{b_i}{d[i,n^2]}$$

for all $i \geqslant 2$

In order to prove that $L(r_i)$ cannot be defined by any expression in E_i, we will show the following property: if $u_{i,n}$ occurs as a sub-word of a word w in the language of a "sufficiently small" expression e_i^1, then the same expression accepts a word where some a_j and a matching b_j have different data values. Let $Mismatch_{i,n}$ be the set of all data words obtained from $u_{i,n}$ by modifying the data values so that there exist two positions p, p' with $p < p'$ and a $j \leqslant i$ such that: p contains $\binom{a_j}{d}$ and p' contains $\binom{b_j}{d'}$ with $d \neq d'$; moreover between positions p and p', b_j does not occur in the word. We consider expressions in which no two occurrences of the binding operator use the same variable. For an expression e, let $|\mathcal{A}(e)|$ denote the number of states in the automaton $\mathcal{A}(e)$ and $|var(e)|$ denote the number of variables in e.

▶ **Lemma 3.2.** *Let e_i^1 be an expression and let $n \in \mathbb{N}$ be greater than $(|\mathcal{A}(e)| + 1)$ and $(|var(e)| + 1)$ for every sub-expression e of e_i^1. Let ν be a valuation of $fv(e_i^1)$ and let x, z be data words. Then: $xu_{i,n}z \in L(e_i^1, \nu) \implies x\bar{u}_{i,n}z \in L(e_i^1, \nu)$ for some $\bar{u}_{i,n} \in Mismatch_{i,n}$.*

Proof idea. By induction on i. Suppose $xu_{i,n}z \in L(e_i^1, \nu)$. The run of $\mathcal{A}(e_i^1)$ on $xu_{i,n}z$ consists of at most n transitions, since the automaton is acyclic and has at most n states. Each of the (at most) n transitions reads some sub-word in the language of some sub-expression f_{i-1}^1, while the whole word consists of n^2 occurrences of $a_i u_{i-1,n} b_i$. Hence, at least one sub word consists of n occurrences of $a_i u_{i-1,n} b_i$. A run of $\mathcal{A}(f_{i-1}^1)$ on such a sub-word is shown below.



Every transition of this run reads sub-words in the language of some sub-expression e_{i-1}^j. If some transition of this run reads an entire sub-word $u_{i-1,n}$ (as in transition $q_1' \longrightarrow q_2'$), then we can create a mismatch inside this $u_{i-1,n}$ by induction hypothesis. Otherwise, none of the transitions read an a_i and the corresponding b_i together (as in $q_{s-2}' \longrightarrow q_{s-1}'$ in the figure). None of the b_is is compared with the corresponding a_i, so the data value of one of the b_is can be changed to create a mismatch. The resulting data word will be accepted provided the change does not result in a violation of some condition. Since the range of the valuation has at most $(n-1)$ distinct values, one of the n b_is is safe for changing the data value. ◀

▶ **Theorem 3.3.** *For any i, the language $L(r_i)$ cannot be defined by any expression in E_i.*

Proof. Suppose r_i is equivalent to an expression e_i^1. Pick an n bigger than $|\mathcal{A}(e)|$ and $|fv(e)|$ for every sub-expression e of e_i^1. The word $u_{i,n}$ belongs to $L(r_i)$ and hence $L(e_i^1)$. By Lemma 3.2, we know that if this is the case, then $\bar{u}_{i,n} \in L(r_i)$ for some word $\bar{u}_{i,n} \in Mismatch_{i,n}$. But $L(r_i)$ cannot contain words with a mismatch. A contradiction. ◀

Given an expression at some level, it is possible that its language is defined by an expression at lower levels. Next we show that it is undecidable to check this.

▶ **Theorem 3.4.** *Given an expression in F_{i+1}, checking if there exists a language equivalent expression in F_i is undecidable.*

Proof idea. By reduction from Post's Correspondence Problem (PCP). The basic idea is from the proof of undecidability of universality of REWBs and related formalisms [17, 15]. For an instance $\{(u_1, v_1), \ldots, (u_n, v_n)\}$ of PCP, a solution (if it exists) can be encoded by a data word of the form $w_1 \# r_i \# w_2$, where w_1 is made up of u_i's, w_2 is made up of v_i's and r_i is from Definition 3.1. To ensure that such a data word indeed represents a solution, we need to match up the u_i's in w_1 with the v_i's in w_2, which can be done through matching data values. Consider the language of data words of the form $w_1' \# r_i \# w_2'$ that are *not* solutions of the given PCP instance. This language can be defined by an expression Δ in E_{i+1}, which compares data values in the left of $\# r_i \#$ with those on the right side, to catch mismatches. We can prove that no equivalent expression exists in lower levels, using techniques used in Lemma 3.2. On the other hand, if the given PCP instance does not have a solution, no data word encodes a solution, so the given language is defined by $\Sigma^* r_i \Sigma^*$, which is in F_i. ◀

4 Complexity of Query Evaluation

In this section, we will study how the depth of nesting of iterated bindings affects the complexity of evaluating queries. An instance of the query evaluation problem consists of a data graph G, an REWB e, a valuation ν for $fv(e)$ and a pair $\langle u, v \rangle$ of nodes in G. The goal is to check if u is connected to v by a data path in $L(e, \nu)$.

4.1 Upper Bounds

An expression in F_i can be thought of as a standard regular expression (without data values) over the alphabet of its sub-expressions. This is the main idea behind our upper bound results. The main result proves that evaluating queries in E_i can be done in Σ_i in the polynomial time hierarchy.

▶ **Lemma 4.1.** *With an oracle for evaluating E_i queries, F_i queries can be evaluated in polynomial time.*

Proof idea. Suppose the query f_i^1 is to be evaluated on the data graph G and f_i^1 consists of the sub-expressions $e_i^1, \ldots, e_i^m$ in E_i. For every j, add an edge labeled e_i^j between those pairs $\langle v_1, v_2 \rangle$ of nodes of G for which $\langle v_1, v_2 \rangle$ is in the evaluation of e_i^j on G. Evaluating the sub-expressions can be done with the oracle. Now f_i^1 can be treated as a standard regular expression over the finite alphabet $\{e_i^1, \ldots, e_i^m\}$, and can be evaluated in polynomial time using standard automata theoretic techniques. ◀

▶ **Theorem 4.2.** *For queries in E_i, the evaluation problem belongs to Σ_i.*

Proof idea. Since bindings in E_i are not iterated, each binding is performed at most once. The data value for each variable is guessed non-deterministically. The expression can be treated as a standard regular expression over its sub-expressions and the guessed data values. The sub-expressions are in F_{i-1}, which can be evaluated in polynomial time (Lemma 4.1) with an oracle for evaluating queries in E_{i-1}. This argument will not work in general for arbitrary REWBs — bindings that are nested deeply inside iterations and other bindings may occur more than polynomially many times in a single path. ◀

Next we consider the query evaluation problem with the size of the query as the parameter. An instance of the *parameterized weighted circuit satisfiability* problem consists of a Boolean circuit and the parameter $k \in \mathbb{N}$. The goal is to check if the circuit can be satisfied by a truth assignment of weight k (i.e., one that sets exactly k propositional atoms to true). The class W[P] is the set of all parameterized problems which are FPT-reducible to the weighted circuit satisfiability problem.

▶ **Theorem 4.3.** *Evaluating REWB queries in E_1, parameterized by the size of the query is in* W[P].

Proof idea. It is proved in [3, Lemma 7, Theorem 8] that a parameterized problem is in W[P] iff there is a non-deterministic Turing machine that takes an instance (x, k) and decides the answer within $f(k)|x|^c$ steps, of which at most $f(k)\log|x|$ are non-deterministic (for some computable function f and a constant c). Such a Turing machine exists for evaluating REWB queries in E_1, using the steps outlined in the proof idea of Theorem 4.2. ◀

Thus, the number of non-deterministic steps needed to evaluate an E_1 query depends only logarithmically on the size of the data graph. It is also known that W[P] is contained in the class PARA-NP — the class of parameterized problems for which there are deterministic algorithms taking instances (x, k) and computing an equivalent instance of the Boolean satisfiability problem in time $f(k)|x|^c$. Hence, we can get an efficient reduction to the satisfiability problem, on which state of the art SAT solvers can be run. Many hard problems in planning fall into this category [7].

We next consider the parameterized complexity of evaluating queries at higher levels. The parameterized class *uniform*-XNL is the class of parameterized problems Q for which there exists a computable function $f : \mathbb{N} \to \mathbb{N}$ and a non-deterministic algorithm that, given a pair (x, k), decides if $(x, k) \in Q$ in space at most $f(k)\log|x|$ [3, Proposition 18].

▶ **Theorem 4.4.** *Evaluating REWB queries, with size of the query as parameter, is in uniform-*XNL.

Proof idea. Let k be the size of the query e_i^1 to be evaluated, on a data graph with n nodes. Suppose a pair of nodes is connected by a data path w in $L(e_i^1)$. Iterations in e_i^1 can only occur inside its F_{i-1} sub-expressions. Hence w consists of at most k sub-paths, each sub-path w_j in the language of some sub-expression f_{i-1}^j. When f_{i-1}^j is considered as a standard regular expression over its sub-expressions (in E_{i-1}), there are no bindings. By a standard pigeon hole principle argument, we can infer that w_j consists of at most kn sub-paths, each one in the language of some sub-expression e_{i-1}^1. This argument can be continued to prove that w is of length at most $(k^2n)^i$. The existence of such a path can be guessed and verified by a non-deterministic Turing machine in space $\mathcal{O}(ik^2 \log n)$. ◀

4.2 Lower Bounds

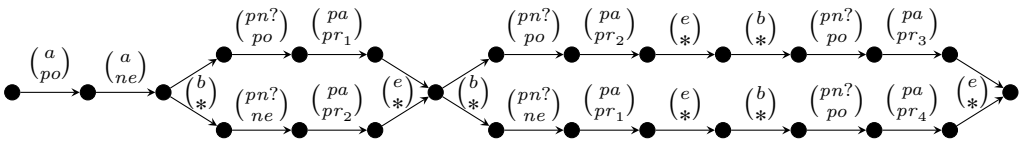
We obtain our lower bounds by reducing various versions of the Boolean formula satisfiability problem to query evaluation. We begin by describing a schema for reducing the problem of evaluating a Boolean formula on a given truth assignment to the problem of evaluating a query on a data graph. The basic ideas for the gadgets we construct below are from [15, proofs of Proposition 2, Theorem 5]. We will need to build on these ideas to address finer questions about the complexity of query evaluation.

Suppose the propositional atoms used in the Boolean formula are among $\{pr_1, \ldots, pr_n\}$. We use $pr_1, \ldots, pr_n$ also as data values. An edge labeled $\binom{pa}{pr_j}$ indicates the propositional

atom pr_j occurring in a sub-formula. The data values po and ne appear on edges labeled with the letter $pn?$, to indicate if a propositional atom appears positively or negatively. The symbol $*$ denotes an arbitrary data value different from all others. We will assume that the Boolean formula is in negation normal form, i.e., negation only appears in front of propositional atoms. This restriction does not result in loss of generality, since any Boolean formula can be converted into an equi-satisfiable one in negation normal form with at most linear blowup in the size. The data graph is a series parallel digraph with a source and a sink, defined as follows by induction on the structure of the Boolean formula.

- Positively occurring propositional atom pr_j: $\cdot \xrightarrow{\binom{b}{*}} \cdot \xrightarrow{\binom{pn?}{po}} \cdot \xrightarrow{\binom{pa}{pr_j}} \cdot \xrightarrow{\binom{e}{*}} \cdot$.
- Negatively occurring propositional atom pr_j: $\cdot \xrightarrow{\binom{b}{*}} \cdot \xrightarrow{\binom{pn?}{ne}} \cdot \xrightarrow{\binom{pa}{pr_j}} \cdot \xrightarrow{\binom{e}{*}} \cdot$.
- $\phi_1 \wedge \cdots \wedge \phi_r$: inductively construct the data graphs for the conjuncts, then do a standard serial composition, by fusing the sink of one graph with the source of the next one.
- $\phi_1 \vee \cdots \vee \phi_r$: inductively construct the data graphs for the disjuncts, then do a standard parallel composition, by fusing all the sources into one node and all the sinks into another node.
- After the whole formula is handled, the source of the resulting graph is fused with the sink of the following graph: $\cdot \xrightarrow{\binom{a}{po}} \cdot \xrightarrow{\binom{a}{ne}} \cdot$.

Let G_ϕ denote the data graph constructed above for formula ϕ. The data graph G_ϕ is shown below for $\phi = (pr_1 \vee \neg pr_2) \wedge ((pr_2 \wedge pr_3) \vee (\neg pr_1 \wedge pr_4))$.



The query uses $x_1, \ldots, x_k$ to remember the propositional atoms that are set to true.

$$e_{eval}[k] := a \downarrow_{x_{po}} (a \downarrow_{x_{ne}} (\quad (1)$$
$$(b(pn?[x^{=}_{po}] \cdot pa[x^{=}_1 \vee \cdots \vee x^{=}_k] + pn?[x^{=}_{ne}] \cdot pa[x^{\neq}_1 \wedge \cdots \wedge x^{\neq}_k])e)^* \ )) \ .$$

▶ **Lemma 4.5.** *Let ϕ be a Boolean formula over the propositional atoms $pr_1, \ldots, pr_n$ and $\nu : \{x_1, \ldots, x_k\} \to \{pr_1, \ldots, pr_n, *\}$ be a valuation. The source of G_ϕ is connected to its sink by a data path in $L(e_{eval}[k], \nu)$ iff ϕ is satisfied by the truth assignment that sets exactly the propositions in $\{pr_1, \ldots, pr_n\} \cap Range(\nu)$ to true.*

Proof idea. The two bindings in the beginning of $e_{eval}[k]$ forces x_{po}, x_{ne} to contain po, ne respectively. A positively occurring propositional atom generates a data path of the form $\cdot \xrightarrow{\binom{b}{*}} \cdot \xrightarrow{\binom{pn?}{po}} \cdot \xrightarrow{\binom{pa}{pr_j}} \cdot \xrightarrow{\binom{e}{*}} \cdot$, which can only be in the language of the expression $b \cdot pn?[x^{=}_{po}] \cdot pa[x^{=}_1 \vee \cdots \vee x^{=}_k]e$. This forces pr_j to be contained in one of $x_1, \ldots, x_k$. Similar arguments works for negatively occurring atoms. Rest of the proof is by induction on the structure of the formula. ◀

▶ **Theorem 4.6.** *For queries in E_1, the evaluation problem is* NP*-hard.*

Proof idea. To check if a Boolean formula ϕ is satisfiable, evaluate the query $a \downarrow_{x_1} a \downarrow_{x_2} \cdots a \downarrow_{x_n} e_{eval}[n]$ on the data graph $\cdot \xrightarrow{\binom{a}{pr_1/*}} \cdot \xrightarrow{\binom{a}{pr_2/*}} \cdots \xrightarrow{\binom{a}{pr_n/*}} \cdot - G_\phi \to \cdot$. Here, $\xrightarrow{\binom{a}{pr_j/*}}$ denotes two edges in parallel, one labeled with $\binom{a}{pr_j}$ and another with $\binom{a}{*}$. ◀

Evaluating queries in E_1 is NP-complete, evaluating REWB queries in general is PSPACE-complete and evaluating queries in E_i is in Σ_i. To prove a corresponding Σ_i lower bound, one would need to simulate Σ_i computations using queries with bounded depth of nesting of iterated bindings. However, this does not seem to be possible. We take a closer look at this in the rest of the paper. Finding the exact complexity of evaluating queries in E_i remains open.

We now extend our satisfiability-to-query evaluation schema to handle Boolean quantifiers. Let $PR = \{pr_1, \ldots, pr_n\}$ be a set of propositional atoms. To handle existential Boolean quantifiers, we build a new graph and a query. These gadgets build on earlier ideas to bring out the difference in the role played by the data graph and the query while reducing satisfiability to query evaluation. The new graph $G[\exists k/PR] \circ G$, is as follows: $\cdot \xrightarrow{\binom{a_1}{pr_1}} \cdot \xrightarrow{\binom{a_1}{pr_2}} \cdots \xrightarrow{\binom{a_1}{pr_n}} \cdot - G \rightarrow \cdot$. We assume that the letter a_1 is not used inside G, which is equal to G_ϕ for some Boolean formula ϕ. The new query $e[\exists k] \circ e$ is defined as follows:

$$e[\exists k] \circ e := a_1^* a_1 \downarrow_{x_1} a_1^* a_1 \downarrow_{x_2} a_1^* \cdots a_1^* a_1 \downarrow_{x_k} a_1^* e \tag{2}$$

where $e = e_{eval}[k]$ for some $k \in \mathbb{N}$.

We now give a parameterized lower bound for evaluating E_1 queries. An instance of the *weighted satisfiability* problem consists of a Boolean formula (not necessarily in Conjunctive Normal Form) and a parameter $k \in \mathbb{N}$. The goal is to check if the formula is satisfied by a truth assignment of weight k. The class W[SAT] is the set of all parameterized problems that are FPT-reducible to the weighted satisfiability problem (see [8, Chapter 25]).

▶ **Lemma 4.7.** *Let ϕ be a Boolean formula over the set PR of propositions and $k \in \mathbb{N}$. We can construct in polynomial time a data graph G and an REWB e_1^1 satisfying the following conditions.*

1. *The source of G is connected to its sink by a data path in $L(e_1^1)$ iff ϕ has a satisfying assignment of weight k.*
2. *The size of e_1^1 depends only on k.*

Proof idea. The required data graph is $G[\exists k/PR] \circ G_\phi$ and e_1^1 is $e[\exists k] \circ e_{eval}[k]$. The data path $\cdot \xrightarrow{\binom{a_1}{pr_1}} \cdot \xrightarrow{\binom{a_1}{pr_2}} \cdots \xrightarrow{\binom{a_1}{pr_n}} \cdot$ in the graph $G[\exists k/PR] \circ G_\phi$ has to be in the language of $a_1^* a_1 \downarrow_{x_1} a_1^* a_1 \downarrow_{x_2} a_1^* \cdots a_1^* a_1 \downarrow_{x_k} a_1^*$. This induces a valuation ν' which maps $\{x_1, \ldots, x_k\}$ injectively into PR, denoting the k propositions that are set to true. With this the data path continues from the source of G_ϕ to its sink. Rest of the proof follows from Lemma 4.5. ◀

▶ **Theorem 4.8.** *Evaluating REWB queries in E_1, parameterized by the size of the query is hard for* W[SAT] *under* FPT *reductions.*

Proof. The reduction given in Lemma 4.7 is a FPT reduction from the weighted satisfiability problem to the problem of evaluating E_1 queries , parameterized by the size of the query. ◀

Finally we extend our gadgets to handle universal Boolean quantifiers. These gadgets build upon the previous ideas and bring out the role of nested iterated bindings when satisfiability is reduced to query evaluation. We would first like to check if the source of some graph G is connected to its sink by a data path in the language of some REWB e, for every possible injective valuation $\nu : \{x_1, \ldots, x_k\} \rightarrow PR$. We will now design some data graphs and expressions to achieve this. Let *skip* be a letter not used in G. The data graphs $G_0, \ldots, G_k$ are as shown in Figure 1.

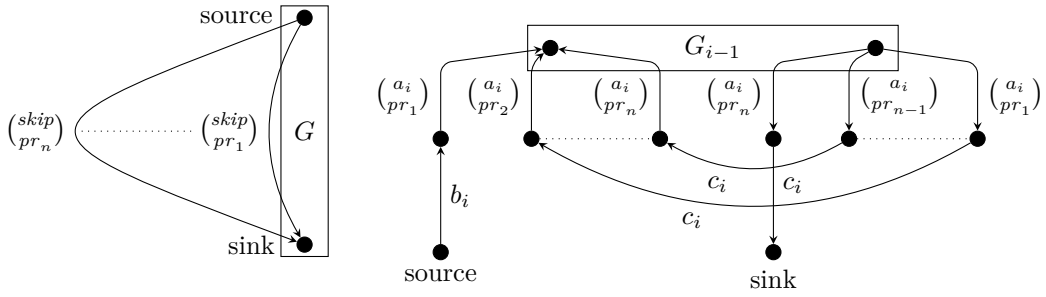


Figure 1 Data graphs G_0 (left) and G_i (right).

The expressions $e^0, \ldots, e^k$ are as follows.

$$e^0 := e + \bigdoublebarwedge_{1 \leqslant i < j \leqslant k} skip[x_i^{=} \wedge x_j^{=}] \qquad e^i := b_i(a_i \downarrow_{x_i} (e^{i-1} a_i[x_i^{=}])c_i)^* \tag{3}$$

The graph G_0 and the expression e^0 are designed to ensure that the source of G is connected to its sink by a path in $L(e, \nu)$, unless ν is not injective, in which case G can be bypassed by one of the edges labeled $\binom{skip}{pr_j}$ introduced in G_0. The graph G_i and the expression e_i are designed to ensure that any path from the source of G_i to its sink has to go through G_{i-1} multiple times, once for each pr_j stored in the variable x_i. The nesting depth of iterated bindings in the expression e^i is one more than that of e^{i-1}.

Suppose ν is a partial valuation of some variables, whose domain does not intersect with $\{x_1, \ldots, x_k\}$. We denote by $\nu[\{x_1, \ldots, x_k\} \to PR]$ the set of valuations ν' that extend ν such that $\text{domain}(\nu') = \text{domain}(\nu) \cup \{x_1, \ldots, x_k\}$ and $\{\nu'(x_1), \ldots, \nu'(x_k)\} \subseteq PR$. We additionally require that ν' is injective on $\{x_1, \ldots, x_k\}$ when we write $\nu[\{x_1, \ldots, x_k\} \xrightarrow{1:1} PR]$.

▶ **Lemma 4.9.** *Let $i \in \{1, \ldots, k\}$ and ν_i be a valuation for $fv(e^i) \backslash \{x_1, \ldots, x_i\}$. The source of G_i is connected to its sink by a data path in $L(e^i, \nu_i)$ iff for every $\nu \in \nu_i[\{x_1, \ldots, x_i\} \to PR]$, there is a data path in $L(e^0, \nu)$ connecting the source of G_0 to its sink.*

Proof idea. The data path has to begin with $b_i\binom{a_i}{pr_1}$ in the language of $b_i a_i \downarrow_{x_i}$, forcing x_i to store pr_1. Then the path has to traverse G_{i-1} using e^{i-1}. At the sink of G_{i-1}, the path is forced to take $\binom{a_i}{pr_1}c_i$ to satisfy the condition in $a_i[x_i^{=}]c_i$. This forces the path to start again in $\binom{a_i}{pr_2}$ and so on. ◀

We write $G[\forall k/PR] \circ G$ and $e[\forall k] \circ e$ to denote the graph G_k and REWB e^k constructed above. We implicitly assume that the variables $x_1, \ldots, x_k$ are not bound inside e. We can always rename variables to ensure this. If e is in E_i, then $e[\forall k] \circ e$ is in F_{i+k-1}.

▶ **Lemma 4.10.** *Let ν be a valuation for $fv(e) \backslash \{x_1, \ldots, x_k\}$ for some REWB e. The source of $G[\forall k/PR] \circ G$ is connected to its sink by a data path in $L(e[\forall k] \circ e, \nu)$ iff for all $\nu' \in \nu[\{x_1, \ldots, x_k\} \xrightarrow{1:1} PR]$, the source of G is connected to its sink by a data path in $L(e, \nu')$.*

Proof idea. Lemma 4.9 ensures that there is a path $w_{\nu'}$ in $L(e^0, \nu')$ connecting the source of G_0 to its sink for every valuation $\nu' \in \nu[\{x_1, \ldots, x_k\} \to PR]$. From Figure 1, $w_{\nu'}$ can either be a *skip* edge, or a path through G. By definition, e^0 allows a skip edge to be taken only when two variables among $x_1, \ldots, x_k$ have the same data value. Hence for valuations ν' that are injective on $\{x_1, \ldots, x_k\}$, $w_{\nu'}$ is in $L(e, \nu')$. ◀

If ϕ is a partially quantified Boolean formula with the propositional atoms in PR occurring freely, we write $\exists^k PR\ \phi$ to denote that atoms in PR are existentially quantified with the constraint that exactly k of them should be set to true. We write $\forall^k PR\ \phi$ to denote that atoms in PR are universally quantified and that only those assignments that set exactly k of the atoms to true are to be considered. An instance of the *weighted quantified satisfiability* problem consists of a Boolean formula ϕ over the set PR of propositional atoms, a partition $PR_1, \ldots, PR_\ell$ of PR and numbers $k_1, \ldots, k_\ell$. The goal is to check if $(\exists^{k_1} PR_1 \forall^{k_2} PR_2 \cdots \phi)$ is true.

▶ **Lemma 4.11.** *Given an instance of the weighted quantified satisfiability problem, We can construct in polynomial time a data graph G and an REWB $e^1_{1+k_2+k_4+\cdots}$ satisfying the following conditions.*

1. *The source of G is connected to its sink by a data path in $L(e^1_{1+k_2+k_4+\cdots})$ iff the given instance of the weighted quantified satisfiability problem is a yes instance.*
2. *The size of $e^1_{1+k_2+k_4+\cdots}$ depends only on $k_1, \ldots, k_\ell$.*

Proof idea. The required data graph G is $G[\exists k_1/PR_1] \circ G[\forall k_2/PR_2] \circ \cdots \circ G_\phi$ and the required REWB $e^1_{1+k_2+k_4+\cdots}$ is $e[\exists k_1] \circ e[\forall k_2] \circ \cdots \circ e_{eval}[k_1 + \cdots + k_\ell]$. We assume that $\circ$ associates to the right, so $G_1 \circ G_2 \circ G_3$ is $G_1 \circ (G_2 \circ G_3)$ and $e^1 \circ e^2 \circ e^3$ is $e^1 \circ (e^2 \circ e^3)$. Correctness follows from Lemma 4.10 and Lemma 4.5. ◀

The weighted quantified satisfiability problem is parameterized by $\ell + k_1 + \cdots + k_\ell$. The class AW[SAT] is the set of parameterized problems that are FPT-reducible to the weighted quantified satisfiability problem (see [8, Chapter 26]).

▶ **Theorem 4.12.** *Evaluating REWB queries, parameterized by the size of the query is hard for* AW[SAT] *under* FPT *reductions.*

Proof. The reduction given in Lemma 4.11 is a FPT reduction from the weighted quantified satisfiability problem to the problem of evaluating REWB queries, with query size as the parameter. ◀

5 Summary and Open Problems

We have proved that increasing the depth of nesting of iterated bindings in REWBs increase expressiveness. Given an REWB, it is undecidable to check if its language can be defined with another REWB with smaller depth of nesting of iterated bindings. The complexity of query evaluation problems are summarized in the following table, followed by a list of technical challenges to be overcome for closing the gaps.

Query level	Evaluation	Parameterized complexity, query size is parameter
E_1	NP-complete	(?2)W[SAT] lower bound, W[P] upper bound
E_i, $i > 1$	(?1), Σ_i upper bound	(?3)
Unbounded	PSPACE-complete [15]	(?4)AW[SAT] lower bound, uniform-XNL upper bound

1. Suppose we want to check the satisfiability of a Σ_2 Boolean formula over $(n_e + n_u)$ propositional atoms of which the first n_e atoms are existentially quantified and the last n_u are universally quantified. With currently known techniques, reducing this to query evaluation results in an REWB in $E_{(n_u+1)}$. Hence, with bounded nesting depth, we cannot even prove a Σ_2 lower bound.

2. Weighted formula satisfiability, complete for W[SAT], can be simulated with series-parallel graphs. Queries in E_1 do not seem to be powerful enough for weighted circuits.
3. Without parameterization, the Σ_i upper bound is obtained by an oracle hierarchy of NP machines. With parameterization, an oracle hierarchy of W[P] machines does not correspond to any parameterized complexity class. See [3, Section 4] for discussions on subtle points which make classical complexity results fail in parameterized complexity.
4. As in point 2, here one might hope for a AW[P] lower bound, which is quantified weighted circuit satisfiability (stronger than AW[SAT], which is quantified weighted formula satisfiability). Even if this improvement can be made, there is another classical complexity result not having analogous result in parameterized complexity: not much is known about the relation between parameterized alternating time bounded class (AW[P]) and parameterized space bounded class (uniform-XNL).

Abstract

We extend the notion of *distributed decision* in the framework of distributed network computing, inspired by recent results on so-called *distributed graph automata*. We show that, by using distributed decision mechanisms based on the interaction between a *prover* and a *disprover*, the size of the certificates distributed to the nodes for certifying a given network property can be drastically reduced. For instance, we prove that minimum spanning tree can be certified with $O(\log n)$-bit certificates in n-node graphs, with just one interaction between the prover and the disprover, while it is known that certifying MST requires $\Omega(\log^2 n)$-bit certificates if only the prover can act. The improvement can even be exponential for some simple graph properties. For instance, it is known that certifying the existence of a nontrivial automorphism requires $\Omega(n^2)$ bits if only the prover can act. We show that there is a protocol with two interactions between the prover and the disprover enabling to certify nontrivial automorphism with $O(\log n)$-bit certificates. These results are achieved by defining and analysing a *local hierarchy* of decision which generalizes the classical notions of *proof-labelling schemes* and *locally checkable proofs*.

1 Introduction

This paper is tackling the long-standing issue of characterizing the power of local computation in the framework of distributed network computing [27]. Our concern is the ability to design *local* algorithms, defined as distributed algorithms in which every node of a network (i.e., every computing entity in the system) can compute its output after having consulted only nodes in its vicinity. That is, communications proceed along the links of the network, and, in a local algorithm, every node must output after having exchanged information with nodes at constant distance only. A *construction* task consists, for the nodes of a network $G = (V, E)$ where each node u is given an input $x(u)$, to collectively and concurrently compute a collection

$y(u)$, $u \in V$, of individual outputs, such that (G, x, y) satisfies some property characterizing the task to be solved. For instance, the minimum-weight spanning tree (MST) task consists, given the weights $x(u)$ of all the incident edges of every node u, in computing a subset $y(u)$ of edges incident to u such that the set $\{y(u), u \in V\}$ forms a MST in G. Similarly, the maximal independent set (MIS) task consists of computing $y(u) \in \{0, 1\}$, $u \in V$, such that the set $\{u \in V : y(u) = 1\}$ forms an MIS. It is an easy observation that the MST task cannot be solved locally as the weights of far-away edges may impact the output of a node. In a seminal result Linial showed that the same is true for MIS [24]: there is no local algorithm for constructing an MIS, even on an n-node ring. Nevertheless, there are many construction tasks that can be solved locally, such as approximate solutions of NP-hard graph problems (see, e.g., [8, 21, 22, 23]). In general it is Turing-undecidable whether or not a construction task can be solved locally [26].

Interestingly, the Turing-undecidability result of Naor and Stockmeyer [26] concerning the locality of construction tasks holds even if one restricts the question to properties that can be locally decided. A distributed *decision* task [1, 13] consists, given an input $x(u)$ to every node in a network G, in deciding whether (G, x) satisfies some given property. An instance is accepted by a distributed algorithm if and only if every node individually accepts (i.e., every node u outputs $y(u) = \text{true}$). For instance, proper colouring can easily be decided locally by having each node merely comparing its colour with the ones of its neighbours. On the contrary, deciding whether a collection of edges defined by $\{x(u), u \in V\}$ forms a MST is not possible locally (in fact, even separating paths from cycles is not possible locally). Similarly to the sequential computing setting, there are strong connections between the construction variant of a task and the ability to locally decide the legality of a given candidate solution for the same task, as illustrated by, e.g., the derandomization results in [6, 26], and the approximation algorithms in [29]. These connections have motivated work focusing on the basic question: what can be decided locally? This paper is aiming at pushing further our current knowledge on this question.

Two specific lines of work have motivated our approach of local decision in this paper. The first line of research is related to the notion of *proof-labelling schemes* introduced by Korman et al. [20], who showed that while not all graph properties can be decided locally, they can all be *verified* locally, with the help of local *certificates* provided by a prover. Unfortunately, there are natural graph properties (e.g., the existence of a non-trivial automorphism) which require $\Omega(n^2)$-bit certificates to be verified by any local distributed algorithm [16]. Göös and Suomela introduced the more practical class LogLCP of all graph properties that can be verified using certificates of size $O(\log n)$ bits [16], i.e., merely the size required to store the identities of the nodes. The class LogLCP contains non locally decidable properties such as hamiltonicity and non-bipartiteness. LogLCP even contains graph properties that are not in NP. Also, all existential-MSO graph properties are shown to be in LogLCP.

The second line of research which motivated our approach is the study of *distributed graph automata*. In particular, [28] recently proved that an analogue of the polynomial hierarchy, where sequential polynomial-time computation is replaced by distributed local computation, turns out to coincide with MSO. However, while this result is important for our understanding of the computational power of finite automata, the model does not quite fit with the standard model of distributed computing aiming at capturing the power of large-scale computer networks (see, e.g., [27]). Indeed, on the one hand, the model in [28] is somewhat weaker than desired, by assuming a finite-state automaton at each node instead of a Turing machine, and by assuming anonymous computation instead of the presence of unique node identities. On the other hand, the very same model is also stronger than the standard

model, by assuming a decision-making mechanism based on an arbitrary mapping from the collection of all node states to $\{\text{true}, \text{false}\}$. Instead, the classical distributed decision mechanism is based on the logical conjunction of the individual decisions. This is crucial as this latter decision mechanism provides the ability for every node rejecting the current instance to raise an alarm, and/or to launch a recovery procedure, without having to collect all of the individual decisions.

In this paper, our objective is to push further the study initiated in [16] on the LogLCP class, by adopting the approach of [28]. Indeed, LogLCP can be seen as the first level Σ_1 of a *local hierarchy* $(\Sigma_k, \Pi_k)_{k\geq 0}$, where $\Sigma_0 = \Pi_0 = \mathsf{LD}$, the class of properties that can be locally decided [13], and, for $k \geq 1$, Σ_k is the class of graph properties for which there exists a local algorithm A such that, for every instance (G, x),

$$(G, x) \text{ is legal } \iff \exists \ell_1 \forall \ell_2 \exists \ell_3 \ldots Q\ell_k : A(G, x, \ell_1, \ell_2, \ldots, \ell_k) \text{ accepts}$$

with k alternations of quantifiers, and where Q is the universal quantifier if k is even, and the existential quantifier otherwise. (Π_k is defined similarly as Σ_k, but starting with a universal quantifier). The ℓ_i's are called *labelling functions*, assigning a label $\ell_i(v) \in \{0,1\}^*$ to every node v, such that, for every node v, $|\ell_i(v)| = O(\log n)$ in n-node networks. Our aim is to analyze the local hierarchy in the general context of distributed network computing [27], where each node has an identity which is unique in the network, every node has the computational power of a Turing machine, and where the acceptance of an instance by an algorithm is defined as the logical conjunction of the individual decisions of the nodes.

1.1 Our Results

We study a hierarchy $(\Sigma_k, \Pi_k)_{k\geq 0}$ of local decision which represents a natural extension of proof-labelling scheme, as well as of locally checkable proof, with succinct certificates (i.e., of size $O(\log n)$ bits). In addition to its conceptual interest, this hierarchy might have some practical impact. Indeed, any level k of the hierarchy can be viewed as a game between a *prover* and a *disprover*, who play in turn by alternating k times. Roughly, on legal instances, the prover aims at assigning distributed certificates responding to any attempt of the disprover to demonstrate that the instance is illegal, and vice-versa on illegal instances. The referee judging the correctness of the collection of certificates produced by the players is a local distributed algorithm. For instance, the extensively studied class Σ_1 includes problems whose solutions are such that their legality can be certified by a prover using distributed certificates. Instead, the class Π_2 includes problems whose solutions are such that their legality can be certified by a prover against any other candidate solution provided by a disprover, both using distributed certificates.

We show that many problems have succinct proofs in the hierarchy. Actually, climbing up the hierarchy enables to reduce drastically the size of the certificates. For instance, we show a quadratic improvement for MST, which requires locally checkable proofs of $\Omega(\log^2 n)$ bits, while MST stands at the second level of our hierarchy. That is, there is a Π_2-protocol for MST using distributed certificates of $O(\log n)$ bits. For graph properties such as nontrivial automorphism, the improvement can even be exponential in term of certificate size, by relaxing the verification from locally checkable proofs with $\Omega(n^2)$ bits proofs to Σ_3 (with $O(\log n)$ bits proofs). More generally, many natural optimization problems are on the second level of our hierarchy. On the other hand, we also show that there are simple (Turing-computable) languages outside the local hierarchy. This latter property illustrates the impact of insisting on compact $O(\log n)$-bits certificates: there are graph properties that cannot be

locally certified via a finite number of interactions between a prover and a disprover using succinct certificates.

In addition, we prove several results regarding the structure of the hierarchy. In particular, we show that if the hierarchy collapses partially at any level, then it collapses all the way down to that level. On the other hand, we prove that the hierarchy does not collapse to the first level (i.e., the first and second levels are distinct). Distributed decision is naturally asymmetric, that is, reversing the individual decision of the algorithm at each node does not correctly reverse the global decision of the algorithm. As a consequence, it is not necessarily the case that co-$\Sigma_k = \Pi_k$, and vice-versa. However, we show that one additional level of quantifiers is always sufficient to reverse a decision (i.e., to decide the complement of a language). Finally, we show that, for every graph property at the intersection of a level-k class and the complement of this class, there is a protocol deciding that property at level k with *unanimous* decision, for both legal and illegal instances.

All our positive results hold in the classical CONGEST model (in which every edge can transmit at most $O(\log n)$ bits at each round), while all our negative results hold in the more liberal LOCAL model (in which there are no constraints on the amount of bits that can be sent through an edge at each round).

All proofs missing from this extended abstract can be found in [7].

1.2 Related Work

Several forms of "local hierarchies" have been investigated in the literature, with the objective of understanding the power of local computation, or for the purpose of designing verification mechanisms for fault-tolerant computing. In particular, as we already mentioned, [28] has investigated the case of *distributed graph automata*, where nodes are anonymous finite automata, and where the decision function is a global interpretation of all the individual outputs of the nodes. In this context, it was proved that the local hierarchy is exactly captured by the MSO formulas on graphs.

The picture is radically different in the framework in which the computing entities are Turing machines with pairwise distinct identities, and where the decision function is the logical conjunction of all the individual boolean outputs. In [13], the authors investigated the local hierarchy in which the certificates must not depend on the identity-assignment to the nodes. Under such *identity-oblivious* certificates, there are distributed languages outside Σ_1. However, all languages are in the probabilistic version of Σ_1, that is, in Σ_1 where the correctness of the verification is only stochastically guaranteed with constant probability. In [11], it is proved that Σ_1 is exactly captured by the set of distributed languages that are closed under lift. (A configuration (G', x') is a t-lift of a configuration (G, x) if there is an input-preserving mapping from $V(G')$ to $V(G)$ which preserves the t-neighbourhood of the nodes in these graphs). Interestingly, in the same framework as [13] but where the decision function is a global interpretation of the all the individual outputs, instead of the logical conjunction of individual boolean outputs, [3, 4] proved that the local hierarchy collapses to Σ_1. Also, in the same framework as [13], but where the certificates may depend on the identity assignment, all distributed languages are in Σ_1 (see [20]).

In [16], the authors proved that, to be placed in the first level Σ_1 of the local hierarchy, there are distributed languages on graphs (e.g., the existence of a nontrivial automorphism) which require to exchange certificates of size $\Omega(n^2)$ bits among neighbours, which is enough to trivially decide any problem. Similarly, [18, 20] has proved that certifying Minimum-weight Spanning Tree (MST) requires to exchange certificates on $\Theta(\log^2 n)$ bits, which can be costly in networks with limited bandwidth, i.e., under the CONGEST model [27]. In [19], it is

proved that the size of the certificates for MST can be decreased to $O(\log n)$ bits, but to the expense of $O(\log n)$ rounds of communication. Recently, [25] has proved that the amount of communication between nodes (but not necessarily the size of the certificates) for verifying general network configurations can be exponentially decreased if using randomization, and [9] analyzed in depth the certificate size for s-t connectivity and acyclicity.

It is also worth mentioning the role of the node identities in distributed decision. For instance, after noticing that the identities are leaking information to the nodes about the size of the network (e.g., at least one node has an ID at least $n-1$ in n-node network), it was recently proved that restricting the algorithms to be identity-oblivious reduces the ability to decide languages locally in Σ_0 (see [10]), while this is not the case for Σ_1 (see [11]). Recently, [12] characterized the "power of the IDs" in local distributed decision. In [5], the authors discussed what can be computed in an anonymous networks, and showed that the answer to this question varies a lot depending on the commitment of the nodes to their first computed output value, i.e., whether it is revocable or not. In the context of local decision, the output is assumed to be irrevocable.

In general, we refer to [32] for a recent survey on local distributed computing, and we refer to [14, 15] for distributed decision in the context of asynchronous crash-prone systems with applications to runtime verification, and to [2] for distributed decision in contexts where nodes have the ability to share non classical resources (e.g., intricate quantum bits).

2 Local Decision

Let $G = (V, E)$ denote an undirected graph, where V is the set of nodes, and E is the set of edges. The subgraph induced by nodes at distance (i.e., number of hops) at most t from a node v is denoted by $B_G(v, t)$. All graphs considered in this paper are assumed to be connected (for non connected graphs, our results apply separately to each connected components). The number of nodes in the graph is denoted by n. In every graph $G = (V, E)$, each node $v \in V$ is assumed to have a name from the set $\{1, \ldots, N\}$, denoted by $\mathrm{id}(v)$, where N is polynomial in n. In other words, all identities are stored on $O(\log n)$ bits. In a fixed graph, all names are supposed to be pairwise distinct.

Distributed languages. A *distributed language* L is a set of pairs (G, x), where G is a graph and x is a function that assigns some local input $x(v)$ to each node v. We assume that all inputs $x(v)$ are polynomial in n, and thus can be stored locally on $O(\log n)$ bits. The following are typical examples of distributed languages:

- 3-COLOURING: (G, x) such that x encodes a proper 3-colouring of G;
- 3-COLOURABILITY: graphs that can be properly 3-coloured;
- NTA: graphs with a nontrivial automorphism;
- PLANARITY: planar graphs.

The *complement* $\bar{L}$ of a distributed language L is defined as the set $\bar{L} = \{(G, x) : (G, x) \notin L\}$. For instance, the complement of 3-COLOURING is NON-3-COLOURING, consisting of all pairs (G, x) such that x is not a proper 3-colouring of G.

Labellings. A *labelling* ℓ is a function $\ell \colon V(G) \to \{0,1\}^*$, assigning a bit string to each node. If, for every graph G and every node $v \in V(G)$, $\ell(v) \in \{0,1\}^k$, we say that the labelling ℓ is of size k. In this paper, we are mostly interested in labellings of logarithmic size in the number of nodes in the input graph.

Local algorithms. We use the standard LOCAL model of distributed computing [27, 24]. In this model each node $v \in V(G)$ is a computational entity that has direct communication links to other nodes, represented by the edges of G. Every node runs the same algorithm. In this paper, all algorithms are deterministic. Nodes communicate with each other in synchronous communication rounds. During each round, every node is allowed to (1) send a message to each of its neighbours, (2) receive a message from each of its neighbours, and (3) perform individual computation. At some point every node has to halt and produce a local output. The number of rounds until all nodes have halted is the *running time* of an algorithm.

A *local* algorithm is a distributed algorithm A for which there exists a constant t such that, for every instance (G, x), the running time of A in (G, x) is at most t. Since the most a node can do in t communication rounds is to gather all the information available in its local neighbourhood $B_G(v, t)$, a local algorithm A can be defined as a (computable) function from all possible labelled local neighbourhoods to some output set. Given an ordered set $\bar{\ell} = (\ell_1, \ell_2, \ldots, \ell_k)$ of labellings, for some $k \geq 0$, and given an instance (G, x), we denote by $A(G, v, x, \bar{\ell})$ the output of v in algorithm A running in G with input x and labelling $\bar{\ell}$.

Local decision. In *distributed decision*, the output of each node v corresponds to its own individual decision. That is, each node either *accepts* or *rejects*. Globally, the instance (G, x) is accepted if and only if every node accepts individually. In other words, the global acceptance is subject to the logical conjunction of all the individual acceptances. For the sake of simplifying the presentation, $A(G, v, x, \bar{\ell}) = 1$ (resp., $A(G, v, x, \bar{\ell}) = 0$) denotes the fact that v accepts (resp., rejects) in an execution of algorithm A on (G, x) labelled with $\bar{\ell}$. We say that A accepts if $A(G, v, x, \bar{\ell}) = 1$ for every node $v \in V(G)$, and rejects otherwise. We will use the shorthand $A(G, x, \bar{\ell}) = 1$ to denote that $\forall v \in V(G), A(G, v, x, \bar{\ell}) = 1$, and $A(G, x, \bar{\ell}) = 0$ to denote that $\exists v \in V(G), A(G, v, x, \bar{\ell}) = 0$.

The first class in the local hierarchy considered in this paper is *local decision*, denoted by LD. A language L is in LD if there exists a local algorithm A, such that for all graphs G, and all possible inputs x on G, we have that $(G, x) \in L \iff A(G, x)$ accepts.

As an example, deciding whether x is a 3-colouring of G is in LD, but deciding whether G is 3-colourable is not. Note that LD does not refer to any labellings. The algorithm A runs solely on graphs G with possible inputs to the nodes.

Example: certifying spanning trees. In a graph G, a *spanning tree* can be encoded as a distributed data-structure x such that, for every $v \in V(G)$, $x(v)$ encodes the identity of one of v's neighbours (its parent in the tree), but one node r for which $x(r) = \perp$ (this node is the root of the tree). Deciding whether x is a spanning tree of G is not in LD. However, a spanning tree can be *certified* locally as follows (see [1, 17]). Given a spanning tree x of G rooted at node r, a *prover* assigns label $\ell(v) = (\mathrm{id}(r), d(v))$ to each node v, where $d(v)$ is the distance of v to the root r in the spanning tree x. Such a label is on $O(\log n)$ bits. The verification algorithm A at node v checks that v agrees on $\mathrm{id}(r)$ with all its neighbours, and that $d(x(v)) = d(v) - 1$. If both tests are passed, then v accepts, otherwise it rejects. It follows that Algorithm A accepts if and only if x is a spanning tree of G. Now we can also accumulate counters, such as the number of nodes in the graph, toward the root. This ability to certify spanning trees and to use them to carry information is a simple but powerful tool that will be used throughout the paper.

3 The Local Hierarchy

We generalize the various classes of distributed decision from previous work into a hierarchy of distributed decision classes, in a way analogous to the polynomial hierarchy (in particular, our class Σ_1^{LD} is equal to[1] the class logLCP introduced by Göös and Suomela [16]).

3.1 Definition

We first define an infinite hierarchy $\{(\Sigma_k^{\mathsf{LD}})_{k\geq 0}, (\Pi_k^{\mathsf{LD}})_{k\geq 0}\}$ of classes. For the sake of simplifying the notation, each of these classes is now abbreviated in Σ_k or Π_k. Informally, each class can be defined by a game between two players, called the *prover* and the *disprover*, who can assign labels to the nodes. The nodes take these labels as additional inputs when running their local algorithm A. Both players are given the language L, the instance (G, x), and the algorithm A. The goal of the prover is to make the nodes accept the instance, whereas the disprover wants it to be rejected. In Σ_k (resp., Π_k), with $k > 0$, the prover (resp., disprover) goes first, and assigns an $O(\log n)$-bit label to each node. Then, the players alternate, assigning $O(\log n)$-bit labels to each node in turn, until k labels $\ell_1, \ell_2, \ldots, \ell_k$ are assigned. A language L is in the corresponding class if there exists a local algorithm A such that, for all instances (G, x), the prover has a winning strategy if and only if $(G, x) \in L$. In other words, the algorithm is such that if $(G, x) \in L$, no matter how the disprover assigns its own labels, the prover can make A accept. Conversely, if $(G, x) \notin L$, then the disprover has a winning strategy and thus it can force A to reject. Such a combination local algorithm A and prover-disprover pair is called a *decision protocol* for L in the corresponding class. Equivalently, we define $\mathsf{LD} = \Sigma_0 = \Pi_0$, and, for $k > 0$, Σ_k is defined as the set of languages L for which there exists $c \geq 0$, and a local algorithm A such that

$$(G, x) \in L \iff \exists \ell_1 \, \forall \ell_2 \ldots \mathrm{Q}\, \ell_k, A(G, x, \ell_1, \ell_2, \ldots, \ell_k) = 1,$$

where Q is the existential (resp., universal) quantifier if k is odd (resp., even), and every label ℓ_i is of size at most $c \log n$. The class Π_k is defined similarly, except that the acceptance condition is: $(G, x) \in L \iff \forall \ell_1 \, \exists \ell_2 \ldots \mathrm{Q}\, \ell_k, A(G, x, \ell_1, \ell_2, \ldots, \ell_k) = 1$.

▶ Remark. For both Σ_k and Π_k, the equivalence should hold *for every identity-assignment* to the nodes with identities in $[1, N]$, where N is a fixed function polynomial in n. Indeed, the membership of an instance (G, x) to a language is independent of the identities given to the nodes. On the other hand, the labels given by the prover and the disprover may well depend on the actual identities of the nodes in the graph where the decision algorithm A is run. This is for instance the case of the protocol for certifying spanning trees described in the previous section, establishing that SPANNING-TREE $\in \Sigma_1$.

3.2 The odd-even collapsing and the Λ_k-hierarchy

Interestingly, the ending universal quantifier in both Σ_{2k} and Π_{2k+1} does not help. The class Π_1 turns out to be just slightly stronger than LD. Specifically, we prove the following result.

▶ **Theorem 1.** *For every $k \geq 1$, $\Sigma_{2k} = \Sigma_{2k-1}$ and $\Pi_{2k+1} = \Pi_{2k}$. Moreover, $\mathsf{LD} \subseteq \Pi_1 \subseteq \mathsf{LD}^{\#\mathrm{node}}$, that is, local decision with access to an oracle providing each node with the number of nodes in the graph.*

[1] If fact, Σ_1^{LD} is equal to LogLCP as defined by Göös and Suomela [16] when one restricts computation to be performed by Turing Machines ([16] makes no assumption on the computational power of the nodes).

Proof. The result follows from the fact that an existential quantification on labels of size $O(\log n)$ bit is sufficient to provide the nodes with the exact size of the graph. This can be certified by accumulating subtree counters along a spanning tree (see Section 2 [16]).

▶ **Claim 1.** *Let $L = \{(G, x) : \text{for every } v \in V(G),\ x(v) = |V(G)|\}$. We have that $L \in \Sigma_1$.*

We show how to use this mechanism in the case of Σ_{2k}, for $k > 0$. Let $L \in \Sigma_{2k}$, and let A be a t-round local algorithm such that:

$$(G, x) \in L \iff \exists \ell_1\, \forall \ell_2\, \ldots \exists \ell_{2k-1}\, \forall \ell_{2k}, A(G, x, \ell_1, \ell_2, \ldots, \ell_{2k}) = 1.$$

Recall that all labellings ℓ_i, $i = 1, \ldots, 2k$, are of size at most $c \log n$ for some $c \geq 0$. We construct an algorithm A' that simulates A for a protocol that does not need the last universal quantifier on ℓ_{2k}. The first labelling ℓ'_1 consists of some correct ℓ_1 for A, with the aforementioned additional label that encodes a spanning tree x' (rooted at an arbitrary node) and the value of the number of nodes in G. Regarding the remaining labellings, for each ℓ_{2i-1} assigned by the disprover, the prover assigns ℓ_{2i} as in the protocol for A, ignoring the bits padded to ℓ_1 for creating ℓ'_1. After the labellings have been assigned, each node v gathers its radius-t neighbourhood. Then, it virtually assigns every possible combination of $(c \log n)$-bit labellings $\ell_{2k}(u)$ to each node $u \in B_G(v, t)$, and simulates A at v to check whether it accepts or rejects with this labelling. If every simulation accepts, then A' accepts at v, else it rejects. Since every node generates all possible ℓ_{2k} labellings in its neighbourhood, we get that

$$(G, x) \in L \iff \exists \ell'_1\, \forall \ell_2\, \ldots \exists \ell_{2k-1}, A'(G, \ell_1, \ell_2, \ldots, \ell_{2k-1}) \text{ accepts},$$

which places L in Σ_{2k-1}. The proof of $\Pi_{2k+1} = \Pi_{2k}$ is similar by using the first existential quantifier (which appears in second position) to certify the number of nodes in the graph. For the case of Π_1, the nodes use the number of nodes provided by the oracle. ◀

A consequence of Theorem 1 is that only of the classes Σ_k for odd k, and Π_k for even k, are worth investigating.

▶ **Definition 2.** We define the classes $(\Lambda_k)_{k \geq 0}$ as follows: $\Lambda_k = \begin{cases} \Sigma_k & \text{if } k \text{ is odd;} \\ \Pi_k & \text{otherwise.} \end{cases}$

In particular, $\Lambda_0 = \Pi_0 = \mathsf{LD}$. By definition, we get $\Lambda_k \subseteq \Lambda_{k+1}$ for every $k \geq 0$, as the distributed algorithm can simply ignore the first label.

▶ **Definition 3.** The local hierarchy is defined as $\mathsf{LH} = \cup_{k \geq 0} \Lambda_k$.

3.3 Complementary classes

We define the complement classes co-Λ_k, for $k \geq 0$, as co-$\Lambda_k = \{L : \bar{L} \in \Lambda_k\}$. Note that, due to the asymmetric nature of distributed decision (unanimous acceptance, but not rejection), simply reversing the individual decision of an algorithm deciding L is generally not appropriate to decide $\bar{L}$. Nevertheless, we show that an additional existential quantifier is sufficient to reverse any decision, implying the following theorem.

▶ **Theorem 4.** *For every $k \geq 0$,* co-$\Lambda_k \subseteq \Lambda_{k+1}$.

Proof. The proof uses a spanning tree certificate to reverse the decision, in a way similar to the proof that the complement of LD is contained in logLCP (i.e., according to our terminology, co-$\Lambda_0 \subseteq \Lambda_1$) due to Göös and Suomela [16]. Let $L \in \Lambda_k$, and let A be a t-round local algorithm deciding $L \in \Lambda_k$ using labels on at most $c \log n$ bits. We construct

an algorithm A' which simulates A, but uses an additional label ℓ_{k+1} to reverse the decisions made by A. Let us assume that k is even (as it will appear clear later, the proof is essentially the same for k odd). We have that

$$(G,x) \in L \iff \forall \ell_1 \, \exists \ell_2 \, \ldots \exists \ell_k, A(G,x,\ell_1,\ell_2,\ldots,\ell_k) = 1,$$

with all labels ℓ_i's of size at most $c \log n$ for some constant $c \geq 0$. In Algorithm A', the prover and the disprover essentially switch their roles. From the above, we have

$$(G,x) \notin L \iff \exists \ell_1 \, \forall \ell_2 \, \ldots \forall \ell_k \, \exists v \in G, A(G,v,x,\ell_1,\ell_2,\ldots,\ell_k) = 0.$$

The prover for A' always follows the disprover for A, and can always pick labellings $\ell_1, \ell_3, \ldots, \ell_{k-1}$ such that there is a rejecting node if and only if $(G,x) \notin L$. In the protocol for A', the prover sets ℓ_{k+1} to be a spanning tree rooted at one such rejecting node v. Every other node $u \neq v$ simply checks that ℓ_{k+1} constitutes a proper encoding of a spanning tree, and rejects if not. If all nodes $u \neq v$ accept, then ℓ_{k+1} is indeed a proper spanning tree, and it only remains to check that v rejects in A. To this end, the node v designated as the root of the spanning tree encoded by ℓ_{k+1} gathers all labellings in its radius-t neighbourhood, and computes $A(G,x,v,\ell_1,\ell_2,\ldots,\ell_k)$. If A rejects at v, we set A' to accept at v, and, otherwise, we set A' to reject at v.

As discussed in Section 2, the spanning tree can be encoded using $O(\log n)$ bits. All labellings $\ell_1, \ell_2, \ldots, \ell_k$ have size at most $c \log n$, therefore all labels of A' are of size at most $c' \log n$ for some $c' \geq c$. The protocol is correct, as a rejecting node exists in A if and only if $(G,x) \notin L$, and A' correctly accepts in this case. If $(G,x) \in L$, then we have that, for every choice the prover can make, the disprover can always choose its labellings so that A accepts. Thus, if the spanning tree ℓ_{k+1} is correct, the root of that tree will indeed detect that it is an accepting node in A, and so reject in A'. ◀

▶ **Corollary 5.** *For every $k \geq 0$, co-$\Lambda_k \subseteq$ co-Λ_{k+1}, and $\Lambda_k \subseteq$ co-Λ_{k+1}.*

Proof. If $L \in$ co-Λ_k, then, by definition, $\bar{L} \in \Lambda_k$, and thus also $\bar{L} \in \Lambda_{k+1}$, which implies that $L \in$ co-Λ_{k+1}. If $L \in \Lambda_k$, then $\bar{L} \in$ co-Λ_k, and thus, by Theorem 4, we get that $\bar{L} \in \Lambda_{k+1}$, which implies that $L \in$ co-Λ_{k+1}. ◀

The following theorem shows that, for every $k \geq 0$, and every language L in $\Lambda_k \cap$ co-Λ_k, there is an algorithm deciding L such that an instance $(G,x) \in L$ is accepted at all nodes, and an $(G,x) \notin L$ is rejected at all nodes.

▶ **Theorem 6.** *Let $k \geq 1$, and let $L \in \Lambda_k \cap$ co-Λ_k. Then there exists a local algorithm A such that, for every instance (G,x), and for every $v \in V(G)$,*

$$(G,x) \in L \iff \begin{cases} \forall \ell_1 \, \exists \ell_2 \, \forall \ell_3 \, \ldots \exists \ell_k, A(G,v,x,\ell_1,\ldots,\ell_k) = 1 & \text{if } k \text{ is even} \\ \exists \ell_1 \, \forall \ell_2 \, \ldots \exists \ell_k, A(G,v,x,\ell_1,\ldots,\ell_k) = 1 & \text{otherwise} \end{cases}$$

In Theorem 9 in the next section, we shall see several example of languages in $\Lambda_1 \cap$ co-Λ_1, in relation with classical optimization problems on graphs. By Theorem 6, all of these languages can be decided unanimously.

3.4 Separation results

From the previous results in this section, we get that the local hierarchy $\mathsf{LH} = \cup_{k \geq 0} \Lambda_k$ has a typical "crossing ladder" as depicted on Figure 1.

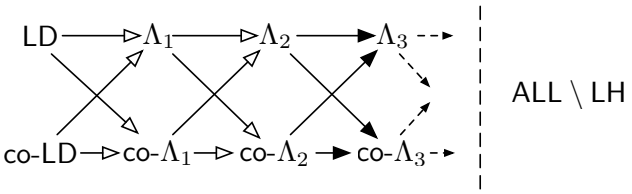

Figure 1 Structure of the local hierarchy. Arrows indicate inclusions, while hollow-headed arrows indicate strict inclusions.

In addition, we can show that some of the inclusions are strict. Indeed, it is known for long that LD is strictly included in Λ_1 (for instance, 2-COLOURABILITY $\in \Lambda_1 \setminus$ LD). Also, $\Lambda_0 \cup$ co-Λ_0 is strictly included in co-Λ_1. Indeed, for instance, NON-3-COLOURABILITY $\in$ co-$\Lambda_1 \setminus(\Lambda_0 \cup$ co-$\Lambda_0)$. Therefore, all inclusions between LD and co-LD and the classes at the first level are strict. Moreover, it is known [16] that NON-3-COLOURABILITY $\notin \Lambda_1$, implying that 3-COLOURABILITY $\notin$ co-Λ_1. On the other hand, both languages are in Λ_2, by application of Theorem 4. As a consequence, both are also in co-Λ_2. Therefore, all inclusions between the classes at the first and second levels are strict.

For $k \geq 2$, separating the classes at the kth level from the classes at the next level appears to be not straightforward. In particular, all classical counting arguments used to separate the three first levels (i.e., levels 0, 1, and 2) fail. On the other hand, we show that if $\Lambda_k = \Lambda_{k+1}$ for some k, then LH collapses to the kth level.

▶ **Theorem 7.** *If there exists $k \geq 0$ such that $\Lambda_k = \Lambda_{k+1}$, then $\Lambda_i = \Lambda_k$ for all $i > k$, that is,* LH *collapses at the kth level.*

Finally, we show that there are languages outside LH. In fact, this result holds, even if we restrict ourselves to languages with inputs 0 or 1 on oriented paths, i.e., with identity-assignment where nodes are given consecutive ID from 1 to n. The result follows from the fact that there are "only" $2^{2^{O(\log n)}}$ different local algorithms for such n-node instances at any fixed level of LH, while there are 2^{2^n} different languages on such instances.

▶ **Theorem 8.** *There exists a Turing-computable language on 0/1-labelled oriented paths that is outside* LH.

4 Positive results

In this section, we precisely identify the position of some relevant problems for distributed computing in the local hierarchy.

Optimization problems. Given an optimization problem π on graphs (e.g., finding a minimum dominating set), one defines two distinct distributed languages: the language OPT$_\pi$ (resp., ADM$_\pi$) is composed of all configurations (G, x) such that x encodes an optimal (resp., admissible) solution for π in graph G. Informally, in the context of optimization problems, the disprover aims at demonstrating that the current solution is not optimal or not admissible. Typically, the disprover does so by exhibiting a better solution or a proof of non-admissibility.

The minimum-weight spanning tree (MST) problem, which is one of the most studied problem in the context of network computing [18, 19, 20], is a typical example of optimization problems that we aim at considering in this section, but many other problems such as maximum independent set, max-cut, etc., are also of our interest. We show that, for any

optimization problem π, if deciding whether a candidate solution for π is admissible is "easy", and if the objective function for π has an additive form, then $\text{OPT}_\pi \in \text{co-}\Lambda_1$, and $\text{OPT}_\pi \in \Lambda_2$.

▶ **Theorem 9.** *Let π be an optimization problem on graphs. If the following two properties are satisfied:* (a) $\text{ADM}_\pi \in \Lambda_1 \cap \text{co-}\Lambda_1$, *and* (b) *the value to the objective function for π is the sum, over all nodes, of an individual value at each node which can be computed locally and encoded on $O(\log n)$ bits, then $\text{OPT}_\pi \in \text{co-}\Lambda_1$.*

Let us give concrete examples of problems satisfying hypotheses (a) and (b). In fact, most classical optimization problems are satisfying these hypotheses, and all the ones typically investigated in the framework of local computing (cf. the survey [32]) do satisfy (a) and (b).

▶ **Corollary 10.** *Let π be one of the following optimization problems: maximum independent set, minimum dominating set, maximum matching, max-cut, or min-cut. Then $\text{OPT}_\pi \in \text{co-}\Lambda_1$.*

The following corollary of Theorem 9 deals with two specific optimization problems, namely travelling salesman and MST. The former illustrates a significant difference between the local hierarchy defined from distributed graph automata in [28], and the one in this paper. Indeed, we show that travelling salesman is at the second level of our hierarchy, while it does not even belong to the graph automata hierarchy (as Hamiltonian cycle is not in MSO). Let TRAVELLING SALESMAN be the distributed language formed of all configurations (G, x) where G is a weighted graph, and x is an Hamiltonian cycle C in G of minimum weight (i.e., at node u, $x(u)$ is the pair of edges incident to u in C). Similarly, let MST be the distributed language formed of all configurations (G, x) where G is a weighted graph, and x is a MST T in G (i.e., at node u, $x(u)$ is the parent of u in T). Note that the case of MST is also particularly interesting. Indeed, MST is known to be in $\text{LCP}(\log^2(n))$ [18], but not in $\Lambda_1 = \text{LCP}(\log(n))$ [19]. Note also that, for MST, it is possible to trade locality for the size of the certificates, as it was established in [19] that one can use logarithmic certificates to certify MST in a logarithmic number of rounds. A consequence of Theorem 9 is the following.

▶ **Corollary 11.** $\text{MST} \in \text{co-}\Lambda_1$ *and* $\text{TRAVELLING SALESMAN} \in \text{co-}\Lambda_1$ *for weighted graphs with weights bounded by a polynomial in n.*

Non-trivial automorphism. The graph automorphism problem is the problem of testing whether a given graph has a nontrivial automorphism (i.e., an automorphism[2] different from the identity). Let NONTRIVIAL AUTOMORPHISM be the distributed language composed of the (connected) graphs that admit such an automorphism. It is known that this language is maximally hard for locally checkable proofs, in the sense that it requires proofs with size $\Omega(n^2)$ bits [16]. Nevertheless, we prove that this language is low in the local hierarchy.

▶ **Theorem 12.** $\text{NONTRIVIAL AUTOMORPHISM} \in \Lambda_3$.

Proof. The first label ℓ_1 at node u is an integer that is supposed to be the identity of the image of u by a nontrivial automorphism. Let us denote by $\phi : V(G) \to V(G)$ the mapping induced by ℓ_1. We are left with proving that deciding whether a given ϕ is a nontrivial automorphism of G is in Λ_2. Thanks to Theorem 4, it is sufficient to prove that this decision can be made in co-Λ_1. Thus let us prove that checking that (G, ϕ) is *not* a nontrivial automorphism is in Λ_1. If ϕ is the identity, then the certificate can just encode this

[2] Recall that $\phi : V(G) \to V(G)$ is an automorphism of G if and only if ϕ is a bijection, and, for every two nodes u and v, we have: $\{u, v\} \in E(G) \iff \{\phi(u), \phi(v)\} \in E(G)$.

information, and each node u checks that $\phi(u)$ is equal to its own ID. So assume now that ϕ is distinct from the identity, but is not an automorphism. To certify this, the prover assigns to each node a set of at most four spanning tree certificates, that "broadcast" to all nodes the identity of at most four nodes witnessing that ϕ is not an automorphism. Specifically, if $\phi(u) = \phi(v)$ with $u \neq v$, then the certificates are for three spanning trees, respectively rooted at u, v, and $\phi(u)$, and if $\{u, v\} \in E(G)$ is mapped to $\{\phi(u), \phi(v)\} \notin E(G)$, or $\{u, v\} \notin E(G)$ is mapped to $\{\phi(u), \phi(v)\} \in E(G)$, then the certificates are for four spanning trees, respectively rooted at $u, v, \phi(u)$, and $\phi(v)$. Checking such certificates can be done locally, and thus checking that (G, ϕ) is *not* a nontrivial automorphism is in Λ_1, and the claim follows. ◀

Problems from the polynomial hierarchy. As the local hierarchy LH is inspired by the polynomial hierarchy, it is natural to ask how their respective levels are connected. In this section, we show that some connections can indeed be established, for central problems in the polynomial hierarchy. For instance, let $k \geq 0$, and let us consider all (connected) graphs $G = (V, E)$ such that there exists $X \subseteq V$, $|X| \geq k$, such that, for every $S \subseteq X$, there is a cycle C in G containing all vertices in S, but none in $X \setminus S$. Such graphs have Cycle-VC-dimension, $\mathrm{VC}_{cycle}(G)$, at least k. Deciding whether, given G and k, we have $\mathrm{VC}_{cycle}(G) \geq k$ is Σ_3^P-complete [30, 31]. Let CYCLE-VC-DIMENSION be the distributed language composed of all configurations (G, k) such that all nodes of G have the same input k, and $\mathrm{VC}_{cycle}(G) \geq k$.

▶ **Theorem 13.** CYCLE-VC-DIMENSION $\in \Lambda_3$.

Proof. The existence of the set X can be certified setting a flag at each node in X, together with a tree T_X spanning X for proving that $|X| \geq k$. Given $S \subseteq X$, the cycle C can be certified in the same way as the Hamiltonian cycle in the proof of Corollary 11. ◀

We also show that the natural graph version QBF-SAT$_k$ of QBF-k-SAT is in Λ_k. Also, as a direct consequence of the fact that any language at level k of the distributed graph automata hierarchy [28] is at level at most $k + 1$ of LH, we get:

▶ **Theorem 14.** *All graph properties expressible in MSO are in* LH.

5 Conclusion

In this paper, we have defined and analyzed a local hierarchy LH of decision generalizing proof-labelling schemes and locally checkable proofs. Using this hierarchy, we have defined interactive local decision protocols enabling to decrease the size of the distributed certificates. We have defined the hierarchy for $O(\log n)$-bit size labels, mostly because this extends the class LogLCP in [16], and because this is consistent with the classical CONGEST model for distributed computation [27]. However, most of our results can be extended to labels on $O(B(n))$ bits, for $B(n)$ larger than $\log n$. In particular, it is worth noticing that the existence of a language L outside LH holds as long as $B = o(n)$.

The main open problem is whether LH has infinitely many levels, or whether it collapses at some level Λ_k. We know that the latter can only happen for $k \geq 2$, and thus it would be quite interesting to know whether $\Lambda_3 \neq \Lambda_2$. In particular, all the typical counting arguments used to separate Λ_2 from Λ_1, or, more generally, to give lower bounds on the label size in proof-labelling schemes or locally checkable proofs appear to be too weak for separating Λ_3 from Λ_2. A separation result for $\Lambda_3 \neq \Lambda_2$ would thus probably provide new tools and concepts for the design of space lower bounds in the framework of distributed computing.

Acknowledgements. We thank Jukka Suomela for pointing out that a counting argument can be used to find languages outside the local hierarchy, and Fabian Reiter for fruitful discussions about distributed graph automata.

Abstract

For $n \geq 3$, let (H_n, E) denote the n-th Henson graph, i.e., the unique countable homogeneous graph with exactly those finite graphs as induced subgraphs that do not embed the complete graph on n vertices. We show that for all structures Γ with domain H_n whose relations are first-order definable in (H_n, E) the constraint satisfaction problem for Γ is either in P or is NP-complete.

We moreover show a similar complexity dichotomy for all structures whose relations are first-order definable in a homogeneous graph whose reflexive closure is an equivalence relation.

Together with earlier results, in particular for the random graph, this completes the complexity classification of constraint satisfaction problems of structures first-order definable in countably infinite homogeneous graphs: all such problems are either in P or NP-complete.

1 Introduction

1.1 Constraint satisfaction problems

A *constraint satisfaction problem* (CSP) is a computational problem in which the input consists of a finite set of variables and a finite set of *constraints*, and where the question is whether there exists a mapping from the variables to some fixed domain such that all the constraints are satisfied. We can thus see the possible constraints as relations on the domain,

and in an instance of the CSP, we are asked to assign domain values to the variables such that certain specified tuples of variables become elements of certain specified relations.

When the domain is finite, and arbitrary constraints are permitted, then the CSP is NP-complete. However, when only constraints from a restricted set of relations on the domain are allowed in the input, there might be a polynomial-time algorithm for the CSP. The set of relations that is allowed to formulate the constraints in the input is often called the *constraint language*. The question which constraint languages give rise to polynomial-time solvable CSPs has been the topic of intensive research over the past years. It has been conjectured by Feder and Vardi [19] that CSPs for constraint languages over finite domains have a complexity dichotomy: they are either in P or NP-complete. This conjecture remains unsettled, although dichotomy is now known on substantial classes (for example when the domain has at most three elements [26, 17] or when the constraint language contains a single binary relation without sources and sinks [21, 1]). Various methods, combinatorial (graph-theoretic), logical, and universal-algebraic have been brought to bear on this classification project, with many remarkable consequences. A conjectured delineation for the dichotomy was given in the algebraic language in [18].

When the domain is infinite, the complexity of the CSP can be outside NP, and even undecidable [10]. But for natural classes of such CSPs there is often the potential for structured classifications, and this has proved to be the case for structures first-order definable over the order $(\mathbb{Q}, <)$ of the rationals [7] or over the integers with successor [8]. Another classification of this type has been obtained for CSPs where the constraint language is first-order definable over the random (Rado) graph [13], making use of structural Ramsey theory. This paper was titled 'Schaefer's theorem for graphs' and it can be seen as lifting the famous classification of Schaefer [26] from Boolean logic to logic over finite graphs, since the random graph is universal for the class of finite graphs.

1.2 Homogeneous graphs and their reducts

The notion of *homogeneity* from model theory plays an important role when applying techniques from finite-domain constraint satisfaction to constraint satisfaction over infinite domains. A relational structure is *homogeneous* if every isomorphism between finite induced substructures can be extended to an automorphism of the entire structure. Homogeneous structures are uniquely (up to isomorphism) given by the class of finite structures that embed into them. The structure $(\mathbb{Q}, <)$ and the random graph are among the most prominent examples of homogeneous structures. The class of structures that are definable over a homogeneous structure with finite relational signature is a very large generalisation of the class of all finite structures, and CSPs for those structures have been studied independently in many different areas of theoretical computer science, e.g. in temporal and spatial reasoning, phylogenetic analysis, computational linguistics, scheduling, graph homomorphisms, and many more; see [4] for references.

While homogeneous relational structures are abundant, there are remarkably few countably infinite homogeneous (undirected, irreflexive) *graphs*; they have been classified by Lachlan and Woodrow [23]. Besides the random graph mentioned earlier, an example of such a graph is the countable homogeneous *universal triangle-free* graph, one of the fundamental structures that appears in most textbooks in model theory. This graph is the up to isomorphism unique countable triangle-free graph (H_3, E) with the property that for every finite independent set $X \subseteq H_3$ and for every finite set $Y \subseteq H_3$ there exists a vertex $x \in H_3 \setminus (X \cup Y)$ such that x is adjacent to every vertex in X and to no vertex in Y.

Further examples of homogeneous graphs are the graphs (H_3, E), (H_4, E), (H_5, E), ..., called the *Henson graphs*, and their complements. Here, (H_n, E) for $n > 3$ is the generalisation

of the graph (H_3, E) above from triangles to cliques of size n. Finally, the list of Lachlan and Woodrow contains only one more family of infinite graphs, namely the graphs (C_n^s, E) whose reflexive closure Eq is an equivalence relation with n classes of equal size s, where $1 \leq n, s \leq \omega$ and either n or s equals ω, as well as their complements. We remark that (C_n^s, Eq) is itself homogeneous and first-order interdefinable with (C_n^s, E), and so we shall sometimes refer to the *homogeneous equivalence relations*.

All countable homogeneous graphs, and even all structures which are first-order definable over homogeneous graphs, are ω-*categorical*, that is, all countable models of their first-order theory are isomorphic. Moreover, all countably infinite homogeneous graphs Γ are *finitely bounded* in the sense that the *age* of Γ, i.e., the class of finite structures that embed into Γ, can be described by finitely many forbidden substructures. Finitely bounded homogeneous structures also share with finite structures the property of having a finite description: up to isomorphism, they are uniquely given by the finite list of forbidden structures that describes their age. Recent work indicates the importance of finite boundedness for complexity classification [2, 9], and it has been conjectured that all structures with a first-order definition in a finitely bounded homogeneous structure enjoy a complexity dichotomy, i.e., their CSP is either in P or NP-complete (cf. [15, 2]). The structures first-order definable in homogeneous graphs therefore provide the most natural class on which to test further the methods developed in [13] specifically for the random graph.

In this article we obtain a complete classification of the computational complexity of CSPs where all constraints have a first-order definition in one of the Henson graphs. We moreover obtain such a classification for CSPs where all constraints have a first-order definition in a countably infinite homogeneous graph whose reflexive closure is an equivalence relation, expanding earlier results for the special cases of one single equivalence class (so-called equality constraints [6]) and infinitely many infinite classes [16]. Together with the above-mentioned result on the random graph, this completes the classification of CSPs for constraints with a first-order definition in any countably infinite homogeneous graph, by Lachlan and Woodrow's classification.

Following an established convention [28, 11], we call a structure with a first-order definition in another structure Δ a *reduct* of Δ. That is, for us a reduct of Δ is as the classical definition of a reduct with the difference that we first allow a first-order expansion of Δ. With this terminology, the present article provides a complexity classification of the CSPs for all reducts of countably infinite homogeneous graphs. In other words, for every such reduct we determine the complexity of deciding its *primitive positive theory*, which consists of all sentences which are existentially quantified conjunctions of atomic formulas and which hold in the reduct. We remark that all reducts of such graphs can be defined by quantifier-free first-order formulas, by homogeneity and ω-categoricity.

For reducts of (H_n, E), the CSPs express computational problems where the task is to decide whether there exists a finite graph without any clique of size n that meets certain constraints. An example of a reduct whose CSP can be solved in polynomial time is $(H_n, \neq, \{(x, y, u, v) : E(x, y) \Rightarrow E(u, v)\})$, where $n \geq 3$ is arbitrary. As it turns out, for every CSP of a reduct of a Henson graph which is solvable in polynomial time, the corresponding reduct over the Rado graph, i.e., the reduct whose relations are defined by the same quantifier-free formulas, is also polynomial-time solvable. On the other hand, the CSP of the reduct $(H_n, \{(x, y, u, v) : E(x, y) \vee E(u, v)\})$ is NP-complete for all $n \geq 3$, but the corresponding reduct over the random graph can be decided in polynomial time.

Similarly, for reducts of the graph (C_n^s, E) whose reflexive closure is an equivalence relation with n classes of size s, where $1 \leq n, s \leq \omega$, the computational problem is to decide whether there exists an equivalence relation with n classes of size s that meets certain constraints.

1.3 Results

Our first result is the complexity classification of the CSPs of all reducts of Henson graphs, showing in particular that a uniform approach to infinitely many "base structures" (namely, the n-th Henson graph for each $n \geq 3$) is possible.

▶ **Theorem 1.** *Let $n \geq 3$, and let Γ be a finite signature reduct of the n-th Henson graph (H_n, E). Then* $\mathrm{CSP}(\Gamma)$ *is either in* P *or* NP*-complete.*

We then obtain a similar complexity dichotomy for reducts of homogeneous equivalence relations, expanding earlier results for special cases [16, 6].

▶ **Theorem 2.** *Let (C_n^s, E) be an infinite graph whose reflexive closure Eq is an equivalence relation with n classes of size s, where $1 \leq n, s \leq \omega$. Then for any finite signature reduct Γ of (C_n^s, E), the problem* $\mathrm{CSP}(\Gamma)$ *is either in* P *or* NP*-complete.*

Together with the classification of countable homogeneous graphs, and the fact that the complexity of the CSPs of the reducts of the Rado graph have been classified [13], this completes the CSP classification of reducts of all countably infinite homogeneous graphs, confirming further instances of the open conjecture that CSPs of reducts of finitely bounded homogeneous structures are either in P or NP-complete [15, 2].

▶ **Corollary 3.** *Let Γ be a finite signature reduct of a countably infinite homogeneous graph. Then* $\mathrm{CSP}(\Gamma)$ *is either in* P *or* NP*-complete.*

1.4 The strategy

The method we employ follows to a large extent the method invented in [13] for the corresponding classification problem where the 'base structure' is the random graph. The key component of this method is the usage of Ramsey theory (in our case, a result of Nešetřil and Rödl [24]) and the concept of *canonical functions* introduced in [12]. There are, however, some interesting differences and novelties that appear in the present proof, as we now shortly outline.

1.4.1 Henson graphs

When studying the proofs in [13], one might get the impression that the complexity of the method grows with the model-theoretic complexity of the base structure, and that for the random graph we have really reached the limits of bearableness for applying the Ramsey method.

However, quite surprisingly, when we step from the random graph to the graphs (H_n, E), which are in a sense more complicated structures from a model-theoretic point of view[1], the classification and its proof become easier again. It is one of the contributions of the present article to explain the reasons behind this effect. Essentially, certain *behaviours* of canonical functions existing on the random graph can not be realised in (H_n, E). For example the canonical polymorphisms of behaviour "max" (cf. preliminaries) play no role for the present classification, but account over the random graph for the tractability of, inter alia, the 4-ary relation defined by the formula $E(x, y) \vee E(u, v)$.

[1] For example, the random graph has a *simple* theory [27], whereas the Henson graphs are the most basic examples of structures whose theory is *not* simple.

Interestingly, we are able to reuse results about canonical functions over the random graph, since the calculus for composing behaviours of canonical functions is the same for any other structure with the same type space, and in particular the Henson graphs. Via this meta-argument we can, on numerous occasions, make statements about canonical functions over the Henson graphs which were proven earlier for the Rado graph, ignoring completely the actual underlying structure; even more comfortably, we can *a posteriori* rule out some possibilities in those statements because of the K_n-freeness of the Henson graphs. Examples of this phenomenon appear in Lemmas 14 and 15.

On the other hand, along with these simplifications, there are also new additional difficulties that appear when investigating reducts of (H_n, E) and that were not present in the classification of reducts of the random graph, which basically stem from the lower degree of symmetry of (H_n, E) compared to the Rado graph. For example, in expansions of Henson graphs by finitely many constants, not all orbits induce copies of Henson graphs; the fact that the analogous statement does hold for the Rado graph was used extensively in [13].

1.4.2 Equivalence relations

Similarly to the situation for the equivalence relation with infinitely many infinite classes studied in [16], there are two interesting sources of NP-hardness for the reducts Γ of other homogeneous equivalence relations: namely, if the equivalence relation is invariant under the polymorphisms of Γ, then the structure obtained from Γ by factoring by the equivalence relation might have a NP-hard CSP, implying NP-hardness for the CSP of Γ itself; or, roughly, for a fixed equivalence class the restriction of Γ to that class might have a NP-hard CSP, again implying NP-hardness of the CSP of Γ (assuming that Γ is a *model-complete core*, see Sections 3 and 6). But whereas for the equivalence relation with infinitely many infinite classes both the factor structure and the restriction to a class are again infinite structures, for the other homogeneous equivalence relations one of the two is a finite structure, obliging us to combine results about CSPs of finite structures with those of infinite structures. As it turns out, the two-element case is, not surprisingly, different from the other finite cases and, quite surprisingly, significantly more involved than the other cases.

2 Preliminaries

The following lemma has been first stated in [22] for finite domain structures Γ only, but the proof there also works for arbitrary infinite structures.

▶ **Lemma 4.** *Let $\Gamma = (D, R_1, \ldots, R_\ell)$ be a relational structure, and let R be a relation that has a primitive positive definition in Γ. Then* $\mathrm{CSP}(\Gamma)$ *and* $\mathrm{CSP}(D, R, R_1, \ldots, R_\ell)$ *are polynomial-time equivalent.*

▶ **Theorem 5** (from [10])**.** *Let Γ be a countable ω-categorical structure. Then the relations preserved by the polymorphisms of Γ are precisely those having a primitive positive definition in Γ.*

These facts make it possible to apply a universal algebraic approach, and classify the complexity of reducts of an ω-categorical structure through understanding the polymorphism clones of these reducts. In fact, we can state our results in terms of the polymorphism clones, see Theorems 22 and 38. Roughly speaking, we will conclude that if Γ is a reduct of a homogeneous graph with a finite relational language, then $\mathrm{CSP}(\Gamma)$ is NP-complete iff for some finite tuple c in Γ, the clone $\mathrm{Pol}(\Gamma, c)$ maps to the clone of projections via a continuous homomorphism.

If such a polymorphism does not exist, it indicates the existence of certain kind of functions in $\mathrm{Pol}(\Gamma)$, which satisfy an equation that prevents them from being mapped to projections with a homomorphism. The idea is to find patterns in the behaviour of these interesting functions, and show that they must generate one out of a given finite number of well-behaved functions; those appearing in Theorems 22 and 38, and whose incidence in $\mathrm{Pol}(\Gamma)$ automatically make $\mathrm{CSP}(\Gamma)$ be solvable in polynomial time. In order to find these well-behaved functions in $\mathrm{Pol}(\Gamma)$, we apply the method mentioned in Section 1.4 by using canonical functions.

▶ **Definition 6.** Let Δ be a structure. The *type* $\mathrm{tp}(a)$ of an n-tuple a in Δ is the set of first-order formulas with free variables $x_1, \ldots, x_n$ that hold for a in Δ. For structures $\Delta_1, \ldots, \Delta_k$ and tuples $a^1, \ldots, a^n \in \Delta_1 \times \cdots \times \Delta_k$, the type $\mathrm{tp}(a^1, \ldots, a^n)$ of $(a^1, \ldots, a^n)$ in $\Delta_1 \times \cdots \times \Delta_k$ is the k-tuple containing the types of $(a_i^1, \ldots, a_i^n)$ in Δ_i for each $1 \leq i \leq k$.

It is well-known that in homogeneous structures such as (H_n, E) and (C_n^k, E), two n-tuples have the same type if and only if they are in the same orbit of the automorphism group.

▶ **Definition 7.** Let $\Delta_1, \ldots, \Delta_k$ and Λ be structures. A *behaviour* B between $\Delta_1, \ldots, \Delta_k$ and Λ is a partial function from the types over $\Delta_1, \ldots, \Delta_k$ to the types over Λ. Pairs (s, t) with $B(s) = t$ are also called *type conditions*. We say that a function $f\colon \Delta_1 \times \cdots \times \Delta_k \to \Lambda$ *satisfies the behaviour* B if whenever $B(s) = t$ and $(a^1, \ldots, a^n)$ has type s in $\Delta_1, \ldots, \Delta_k$, then the n-tuple $(f(a_1^1, \ldots, a_k^1), \ldots, f(a_1^n, \ldots, a_k^n))$ has type t in Λ. A function $f\colon \Delta_1 \times \cdots \times \Delta_k \to \Lambda$ is *canonical* if it satisfies a behaviour which is a total function from the types over $\Delta_1, \ldots, \Delta_k$ to the types over Λ.

To provide immediate examples for these notions, we now define some behaviours that will appear in our proof as well as in the precise CSP classification. For m-ary relations $R_1, \ldots, R_k$ over a set D, we will in the following write $R_1 \cdots R_k$ for the m-ary relation on D^k that holds between k-tuples $x^1, \ldots, x^m \in D^k$ iff $R_i(x_i^1, \ldots, x_i^m)$ holds for all $1 \leq i \leq k$.

▶ **Definition 8.** Given a homogeneous graph G we say that a binary injective operation $f\colon G^2 \to G$ is

- *balanced in the first argument* if for all $u, v \in G^2$ we have that $\mathrm{E}{=}(u, v)$ implies $E(f(u), f(v))$ and $\mathrm{N}{=}(u, v)$ implies $N(f(u), f(v))$;
- *E-dominated (N-dominated) in the first argument* if for all $u, v \in G^2$ with $\neq{=}(u, v)$ we have that $E(f(u), f(v))$ ($N(f(u), f(v))$);
- *balanced/E-dominated/N-dominated in the second argument* if $(x, y) \mapsto f(y, x)$ is balanced/E-dominated/N-dominated in the first argument;
- *balanced/E-dominated/N-dominated* if f is balanced/E-dominated/N-dominated in both arguments, and *unbalanced* if f is not balanced;
- *of behaviour p_1* if for all $u, v \in G^2$ with $\neq{\neq}(u, v)$ we have $E(f(u), f(v))$ iff $E(u_1, v_1)$;
- *of behaviour p_2* if $(x, y) \mapsto f(y, x)$ is of behaviour p_1;
- *of behaviour projection* if it is of behaviour p_1 or p_2;
- *of behaviour* min if for all $u, v \in G^2$ with $\neq{\neq}(u, v)$ we have $E(f(u), f(v))$ iff $\mathrm{EE}(u, v)$.

A ternary canonical injection $f\colon G^3 \to G$ is

- *hyperplanely of behaviour projection* iff the functions $(u, v) \mapsto f(c, u, v)$, $(u, v) \mapsto f(u, c, v)$, and $(u, v) \mapsto f(u, v, c)$ are of behaviour projection for all $c \in G$. Similarly other hyperplane behaviours, such as hyperplanely E-dominated, are defined.
- of behaviour *minority* if for all $u, v \in G^3$ with $\neq{\neq}{\neq}(u, v)$ we have $E(f(u), f(v))$ if and only if $\mathrm{EEE}(u, v)$, $\mathrm{NNE}(u, v)$, $\mathrm{NEN}(u, v)$, or $\mathrm{ENN}(u, v)$.

2.1 Overview

This article is organised as follows. Basic notions and definitions, as well as the fundamental facts of the method we are going to use, are deferred for reasons of space to the appendix. Our notation and definitions may also be found in [13] unless they were already represented in the introduction.

Sections 3 to 5 deal with the Henson graphs: Section 3 is complexity-free and investigates the structure of reducts of Henson graphs via polymorphisms and Ramsey theory. In Section 4, we provide hardness results for different classes of reducts. In Section 5 we rephrase Theorem 1, and we discuss the complexity classification in more detail, formulating in particular a tractability criterion for CSPs of reducts of Henson graphs.

Section 6 investigates the structure of reducts of homogeneous equivalence relations via polymorphisms and Ramsey theory and describes the polynomial-time cases.

3 Polymorphisms over Henson graphs

We investigate polymorphisms of reducts of (H_n, E). We start with unary polymorphisms in Section 3.1, obtaining that we can assume that the relations E and N are pp-definable in our reducts. We then turn to binary polymorphisms in Section 3.2, obtaining Proposition 16 telling us that we may further assume the existence of a binary injective polymorphism. Building on the results of those sections, we show in Section 3.3 via an analysis of ternary polymorphisms that for any reduct which pp-defines the relations E and N, either the polymorphisms preserve a certain relation H, or there is a polymorphism of behaviour min (Proposition 18).

3.1 The unary case: model-complete cores

A countable ω-categorical structure Δ is called a *model-complete core* if $\mathrm{Aut}(\Delta)$ is dense in $\mathrm{End}(\Delta)$, or equivalently, every endomorphism of Δ is an elementary self-embedding, i.e., preserves all first-order formulas over Δ. Every countable ω-categorical structure Γ is *homomorphically equivalent* to an up to isomorphism unique ω-categorical model-complete core Δ, that is, there exists homomorphisms from Γ into Δ and vice-versa [3]. Since the CSPs of homomorphically equivalent structures are equal, it has proven fruitful in classification projects to always work with model-complete cores. The following proposition essentially calculates the model-complete cores of the reducts of Henson graphs.

▶ **Proposition 9.** *Let Γ be a reduct of (H_n, E). Then either* $\mathrm{End}(\Gamma)$ *contains a function whose image induces an independent set, or* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(\Gamma)} = \overline{\mathrm{Aut}(H_n, E)}$.

In the first case of Proposition 9, the model-complete core of the reduct is in fact a reduct of equality. Since the CSPs of reducts of equality have been classified [6], we do not have to consider any further reducts with an endomorphism whose image induces an independent set.

▶ **Lemma 10.** *Let Γ be a reduct of (H_n, E), and assume that* $\mathrm{End}(\Gamma)$ *contains a function whose image is an independent set. Then Γ is homomorphically equivalent to a reduct of $(H_n, =)$.*

In the second case of Proposition 9, it turns out that all polymorphisms preserve the relations E, N, and $\neq$, by the following lemma and Theorem 5.

▶ **Lemma 11.** *Let Γ be such that* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(H_n, E)}$. *Then E, N, and $\neq$ have primitive positive definitions in Γ.*

Before moving on to binary polymorphisms, we observe the following corollary of Proposition 9, first mentioned in [28].

▶ **Corollary 12.** *For every $n \geq 3$, the permutation group $\mathrm{Aut}(H_n, E)$ is a maximal closed subgroup of the full symmetric group on H_n, i.e., every closed subgroup of the full symmetric group containing $\mathrm{Aut}(H_n, E)$ either equals $\mathrm{Aut}(H_n, E)$ or the full symmetric group.*

3.2 Binary polymorphisms

We investigate binary functions preserving E, N, and $\neq$. A finitary operation $f(x_1, \ldots, x_n)$ on a set is *essential* if it does not depend on only one of its arguments x_i.

▶ **Lemma 13.** *Every essential function $f\colon H_n^k \to H_n$ that preserves E, N, and $\neq$ generates a binary injection.*

▶ **Lemma 14.** *Let $f\colon H_n^2 \to H_n$ be a function of behaviour* min *that preserves E and N. Then f generates a binary function of behaviour* min *that is N-dominated.*

By Proposition 9, Lemma 11 and Lemma 13, we may assume that $\mathrm{Pol}(\Gamma)$ contains a binary injection f, as otherwise the complexity of $\mathrm{CSP}(\Gamma)$ is known: see the explanation in the end of this subsection. After an analysis of the possible behaviours of f, we can make further assumptions on the binary injection in $\mathrm{Pol}(\Gamma)$.

▶ **Lemma 15.** *Let $f\colon H_n^k \to H_n$ be an essential function that preserves E, N, and $\neq$. Then f generates one of the following binary canonical injections: of behaviour* min *and N-dominated; or of behaviour p_1, balanced in the first, and N-dominated in the second argument.*

We conclude this section by summarising the results we have so far.

▶ **Proposition 16.** *Let Γ be a reduct of (H_n, E), where $n \geq 3$. Then either*
(1) *Γ is homomorphically equivalent to a reduct of $(H_n, =)$, or*
(2) *Γ pp-defines E, N, and $\neq$.*
In the latter case we have that either
(2a) *every function in* $\mathrm{Pol}(\Gamma)$ *is essentially unary, or*
(2b) $\mathrm{Pol}(\Gamma)$ *contains one of the two binary canonical injections of Lemma 15.*

Note that if item (1) holds then $\mathrm{CSP}(\Gamma)$ is either in P or NP-complete [6], and if item (2a) holds then $\mathrm{CSP}(\Gamma)$ is NP-complete (Theorem 10 in [5]). In case (2b), when $\mathrm{Pol}(\Gamma)$ contains a binary canonical injection of behaviour min which is N-dominated then $\mathrm{CSP}(\Gamma)$ is in P, as we will discuss later. It thus remains to further consider the second case of Lemma 15, which we do in the next subsection.

3.3 The relation H

We investigate Case (2b) of Proposition 16. The following relation characterises the NP-complete cases in this situation.

▶ **Definition 17.** We define a 6-ary relation $H(x_1, y_1, x_2, y_2, x_3, y_3)$ on H_n by

$$\begin{aligned}
&\bigwedge_{i,j\in\{1,2,3\},i\neq j,u\in\{x_i,y_i\},v\in\{x_j,y_j\}} N(u,v) \\
&\wedge \big((E(x_1,y_1) \wedge N(x_2,y_2) \wedge N(x_3,y_3)) \\
&\quad \vee\ (N(x_1,y_1) \wedge E(x_2,y_2) \wedge N(x_3,y_3)) \\
&\quad \vee\ (N(x_1,y_1) \wedge N(x_2,y_2) \wedge E(x_3,y_3))\big)\ .
\end{aligned}$$

The importance of the relation H is reflected in the following proposition, which states that if Γ is a reduct of (H_n, E) with E and N primitive positive definable in Γ, then either H has a primitive positive definition in Γ, in which case CSP(Γ) is NP-complete, or Pol(Γ) has a certain canonical polymorphism which will imply tractability of the CSP. NP-completeness and tractability for those cases will be discussed in Sections 4 and 5.

▶ **Proposition 18.** *Let Γ be a reduct of (H_n, E) with E and N primitive positive definable in Γ. Then at least one of the following holds:*
(a) *There is a primitive positive definition of H in Γ.*
(b) Pol(Γ) *contains a canonical binary injection of behaviour* min.

4 CSPs over Henson graphs

We now explain why any reduct of (H_n, E) which has H among its relations, and hence by Lemma 4 every reduct which pp-defines H, has an NP-hard CSP. While it would be possible to show NP-hardness of CSP(H_n, H) directly by reduction of, say, the NP-hard problem positive 1-in-3-SAT, we will use results from [14], and in fact a recent strengthening thereof from [2], to prove hardness more elegantly via a structural property of Pol(H_n, H).

▶ **Definition 19.** Let Γ be a structure. A *projective clone homomorphism* of Γ is a mapping from Pol(Γ) onto its projections which: preserves arities; fixes each projection; and preserves composition.

A *projective strong h1 clone homomorphism* of Γ is a mapping as above, where the third condition is weakened to preservation of composition with projections.

▶ **Theorem 20** (from [2])**.** *Let Γ be a countable ω-categorical structure in a finite relational language which has a uniformly continuous strong h1 clone homomorphism. Then* CSP(Γ) *is NP-hard.*

▶ **Proposition 21.** *The structure (H_n, H) has a uniformly continuous strong h1 clone homomorphism. Consequently,* CSP(H_n, H) *is NP-hard.*

5 Summary for the Henson graphs

We can restate Theorem 1 in a more detailed fashion as follows.

▶ **Theorem 22.** *Let Γ be a reduct of a Henson graph (H_n, E). Then one of the following holds.*
(1) *Γ has an endomorphism whose image induces an independent set, and is homomorphically equivalent to a reduct of $(H_n, =)$.*
(2) Pol(Γ) *has a uniformly continuous projective clone homomorphism.*
(3) Pol(Γ) *contains a binary canonical injection which is of behaviour* min *and N-dominated.*
Items (2) *and* (3) *cannot simultaneously hold, and when Γ has a finite relational signature, then* (2) *implies NP-completeness and* (3) *implies tractability of its CSP.*

The first statement follows directly from the proof of Theorem 1, with the additional observation that the strong h1 clone homomorphism defined in Proposition 21 is in fact a clone homomorphism. When (3) holds for a reduct, then (2) cannot hold, because (3) implies the existence of $f(x, y) \in$ Pol(Γ) and $\alpha \in \overline{\mathrm{Aut}(\Gamma)}$ such that $f(x, y) = \alpha f(y, x)$ holds, and equation impossible to satisfy by projections. In fact, by further analysing case (1), one can easily show that it also implies either (2) or (3), so that we have the following.

▶ **Corollary 23.** *For every reduct* Γ *of a Henson graph* (H_n, E)*, precisely one of the following holds:* $\mathrm{Pol}(\Gamma)$ *has a uniformly continuous projective clone homomorphism; or* $\mathrm{Pol}(\Gamma)$ *contains* $f(x,y) \in \mathrm{Pol}(\Gamma)$ *and* $\alpha \in \overline{\mathrm{Aut}(\Gamma)}$ *such that* $f(x,y) = \alpha f(y,x)$*.*

When Γ *has a finite relational signature, then the first case possesses NP-completeness and the second case the tractability of its CSP.*

6 Reducts of homogeneous equivalence relations

We now investigate polymorphisms of reducts of the graphs (C_n^s, E), for $2 \leq n, s \leq \omega$, with precisely one of n, s equal to ω. Recall from the preliminaries that we write Eq for the reflexive closure of E.

Similarly to the case of the Henson graphs, we start with unary polymorphisms in Section 6.1, reducing the problem to model-complete cores.

We then turn to higher-arity polymorphisms; here, the organisation somewhat differs from the case of the Henson graphs. The role of the NP-hard relation H from the Henson graphs is now taken by the two sources of NP-hardness mentioned in the introduction: the first source being that factoring by the equivalence relation Eq yields a structure with an NP-hard problem, and the second source being that restriction to some equivalence class yields a structure with an NP-hard problem. In Section 6.2, we show that in fact, one of the two sources always applies for model-complete cores when $2 < n < \omega$ or $2 < s < \omega$. Consequently, only the higher-arity polymorphisms of the reducts of (C_2^ω, E) and (C_ω^2, E) require deeper investigation using Ramsey theory; this will be dealt with in Sections 6.3 and 6.4, respectively.

6.1 The unary case: model-complete cores

▶ **Proposition 24.** *Let* Γ *be a reduct of* (C_n^s, E)*, where* $1 \leq n, s \leq \omega$*, and at least one of* n, s *equals* ω*. Then* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(\Gamma)} = \overline{\mathrm{Aut}(C_n^s, E)}$*, or* $\mathrm{End}(\Gamma)$ *contains an endomorphism onto a clique or an independent set.*

In the following sections, we investigate essential polymorphisms of reducts Γ of (C_n^s, E) which are model-complete cores, i.e., $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(C_n^s, E)}$. The following proposition implies that in that situation, the equivalence relation Eq is invariant under $\mathrm{Pol}(\Gamma)$.

▶ **Proposition 25.** *Let* Γ *be a reduct of* (C_n^s, E)*, where* $1 \leq n, s \leq \omega$*. If* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(C_n^s, E)}$*, then* E*,* N *and* Eq *are preserved by the polymorphisms of* Γ*.*

Therefore, in the above situation Eq is an equivalence relation which is invariant under $\mathrm{Pol}(\Gamma)$, and so $\mathrm{Pol}(\Gamma)$ acts naturally on the equivalence classes of Eq. Moreover, if we fix any $c \in C_n^s$ and expand the structure Γ by the constant c, then the equivalence class C of c has a primitive positive definition in that expansion (Γ, c), since Eq and c do. Hence, C is invariant under $\mathrm{Pol}(\Gamma, c)$, and so $\mathrm{Pol}(\Gamma, c)$ acts naturally on C via restriction. In the following sections, we analyse these actions.

6.2 The case $2 < n < \omega$ or $2 < s < \omega$

It turns out that in these cases, one of the sources of hardness always applies. We will use the following fact about function clones on a finite domain.

▶ **Proposition 26** (from [20])**.** *Every function clone on a finite domain of at least three elements which contains all permutations as well as an essential function contains a unary constant function.*

▶ **Proposition 27.** *Let* Γ *be a reduct of* (C_n^ω, E)*, where* $2 < n < \omega$*, such that* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(C_n^\omega, E)}$*. Then the action of* $\mathrm{Pol}(\Gamma)$ *on the equivalence classes of Eq has no essential and no constant operation.*

▶ **Proposition 28.** *Let* Γ *be a reduct of* (C_ω^s, E)*, where* $2 < s < \omega$*, such that* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(C_\omega^s, E)}$*. Then for any* $c \in C_\omega^s$*, the action of* $\mathrm{Pol}(\Gamma, c)$ *on the equivalence class of* c *has no essential and no constant operation.*

6.3 The case of two infinite classes: $n = 2$ and $s = \omega$

The following proposition states that either one of the two sources of hardness applies, or $\mathrm{Pol}(\Gamma)$ contains a ternary canonical function with a certain behaviour.

▶ **Proposition 29.** *Let* Γ *be a reduct of* (C_2^ω, E) *such that* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(C_2^\omega, E)}$*. Then one of the following holds:*

- *the action of* $\mathrm{Pol}(\Gamma)$ *on the classes of Eq has no essential function;*
- *the action of* $\mathrm{Pol}(\Gamma, c)$ *on the equivalence class of* c *has no essential function, for some* $c \in C_2^\omega$*;*
- $\mathrm{Pol}(\Gamma)$ *contains a canonical ternary injection of behaviour minority which is hyperplanely of behaviour E-dominated projection.*

To prove the proposition, we need to recall a special case of Post's classical result about function clones acting on a two-element set, as well as a result on function clones on a countable set which contain all permutations. Comparing this statement with Proposition 26 sheds light on why the case of this section is more involved than the cases of the preceding section.

▶ **Proposition 30** (Post [25])**.** *Every function clone with domain* $\{0, 1\}$ *containing both permutations of* $\{0, 1\}$ *as well as an essential function contains a unary constant operation or the ternary addition modulo 2.*

▶ **Proposition 31** (from [6])**.** *Every closed function clone on a countably infinite set which contains all permutations as well as an essential operation contains a binary injection.*

▶ **Proposition 32.** *Let* Γ *be preserved by a ternary injection* h *of behaviour minority which is hyperplanely an E-dominated projection. Then* $\mathrm{CSP}(\Gamma)$ *can be solved in polynomial time.*

6.4 The case of infinitely many classes of size two: $n = \omega$ and $s = 2$

As in the preceding section, we show that either one of the two sources of hardness applies, or $\mathrm{Pol}(\Gamma)$ contains a ternary canonical function of a certain behaviour.

▶ **Proposition 33.** *Let* Γ *be a reduct of* (C_ω^2, E) *such that* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(C_\omega^2, E)}$*. Then one of the following holds:*

- *the action of* $\mathrm{Pol}(\Gamma)$ *on the classes of Eq has no essential function;*
- *the action of* $\mathrm{Pol}(\Gamma, c)$ *on the equivalence class of* c *has no essential function, for some* $c \in C_\omega^2$*;*
- $\mathrm{Pol}(\Gamma)$ *contains a ternary canonical function* h *with* $h(N, \cdot, \cdot) = h(\cdot, N, \cdot) = h(\cdot, \cdot, N) = N$ *and which behaves like a minority on* $\{E, =\}$*.*

To prove the proposition, we are again going to make use of Propositions 30 and 31, and the following lemma.

▶ **Lemma 34.** *Let* Γ *be a reduct of* (C^2_ω, E) *such that* $\mathrm{End}(\Gamma) = \overline{\mathrm{Aut}(C^2_\omega, E)}$. *If* $\mathrm{Pol}(\Gamma)$ *contains a ternary function which behaves like* $x + y + z$ *modulo 2 on some equivalence class, then it contains a ternary function which behaves like* $x + y + z$ *modulo 2 on all equivalence classes.*

Let Γ be a reduct of (C^2_ω, Eq) where Eq is an equivalence relation with infinitely many classes of size two such that $\mathrm{Pol}(\Gamma)$ contains a ternary canonical function h as in item 3 of Proposition 33.

▶ **Proposition 35.** *A relation with a first-order definition in* (C^2_ω, Eq) *is preserved by* h *if and only if it can be defined by a conjunction of formulas of the form*

$$N(x_1, y_1) \vee \cdots \vee N(x_k, y_k) \vee Eq(z_1, z_2) \tag{1}$$

for $k \geq 0$, *or of the form*

$$N(x_1, y_1) \vee \cdots \vee N(x_k, y_k) \vee (|\{i \in S : x_i \neq y_i\}| \equiv_2 p) \tag{2}$$

where $p \in \{0, 1\}$ *and* $S \subseteq \{1, \ldots, k\}$.

▶ **Proposition 36.** *There is a polynomial-time algorithm that decides whether a given set* Φ *of formulas as in the statement of Proposition 35 is satisfiable.*

▶ **Corollary 37.** *Let* Γ *be a reduct of* (C^2_ω, Eq) *with finite signature and such that* $\mathrm{Pol}(\Gamma)$ *contains the operation* h. *Then* $\mathrm{CSP}(\Gamma)$ *is in P.*

We close the section with a more detailed variant of Theorem 2.

▶ **Theorem 38.** *Let* (C^s_n, E) *be an infinite graph whose reflexive closure* Eq *is an equivalence relation with* n *classes of size* s, *where* $1 \leq n, s \leq \omega$. *Let* Γ *be a reduct of* (C^s_n, E). *Then one of the following holds.*

(1) Γ *has an endomorphism whose image induces a clique or an independent set, and is homomorphically equivalent to a reduct of* $(C^s_n, =)$.

(2) Γ *is a model complete core and* $\mathrm{Pol}(\Gamma, c)$ *has a uniformly continuous projective clone homomorphism for some* $c \in (C^s_n, E)$.

(3) $n = 2, s = \omega$, Γ *is a model complete core, and* $\mathrm{Pol}(\Gamma)$ *contains a canonical ternary injection of behaviour minority which is hyperplanely of behaviour E-dominated projection.*

(4) $n = \omega, s = 2$, Γ *is a model complete core, and* $\mathrm{Pol}(\Gamma)$ *contains a ternary canonical function* h *with* $h(N, \cdot, \cdot) = h(\cdot, N, \cdot) = h(\cdot, \cdot, N) = N$ *and which behaves like a minority on* $\{E, =\}$.

Neither items (2) *and* (3), *nor items* (2) *and* (4) *can simultaneously hold, and when* Γ *has a finite relational signature, then* (2) *implies NP-completeness and both* (3) *and* (4) *imply tractability of its CSP.*

7 Outlook

We have classified the computational complexity of CSPs for reducts of the infinite homogeneous graphs. Our proof shows that the scope of the classification method from [13] is much larger than one might expect at first sight. The general research goal here is to identify larger and larger classes of infinite-domain CSPs where systematic complexity classification is possible; a general dichotomy conjecture is open for CSPs of reducts of finitely bounded homogeneous structures [15, 2]. The next step in this direction might be to show a general complexity dichotomy for reducts of homogeneous structures whose age is finitely bounded and has the *free amalgamation property* (the Henson graphs provide natural examples for such structures). The present paper indicates that this problem might be within reach.

Abstract

In the context of statistical databases, the release of accurate statistical information about the collected data often puts at risk the privacy of the individual contributors. The goal of differential privacy is to maximise the utility of a query while protecting the individual records in the database. A natural way to achieve differential privacy is to add statistical noise to the result of the query. In this context, a mechanism for releasing statistical information is thus a trade-off between utility and privacy. In order to balance these two "conflicting" requirements, privacy preserving mechanisms calibrate the added noise to the so-called *sensitivity* of the query, and thus a precise estimate of the sensitivity of the query is necessary to determine the amplitude of the noise to be added.

In this paper, we initiate a systematic study of sensitivity of counting queries over relational databases. We first observe that the sensitivity of a Relational Algebra query with counting is not computable in general, and that while the sensitivity of Conjunctive Queries with counting is computable, it becomes unbounded as soon as the query includes a join. We then consider restricted classes of databases (databases with constraints), and study the problem of computing the sensitivity of a query given such constraints. We are able to establish bounds on the sensitivity of counting conjunctive queries over constrained databases. The kind of constraints studied here are: functional dependencies and cardinality dependencies. The latter is a natural generalisation of functional dependencies that allows us to provide tight bounds on the sensitivity of counting conjunctive queries.

1 Introduction

With the emergence of new systems and services such as eHealth, electronic tickets (*e.g.*, London Oyster card), mobile phones, or social networks, important amounts of information concerning our everyday activities are collected in various databases. Statistical analysis of such datasets could be very useful for improving services, or enabling research and market studies for example. But at the same time, the collection and storage of all this data puts at risk our individual privacy. A solution to address this problem is not to release the *exact*

result of any query on a sensitive dataset, but rather to perturb the released results by adding some noise. Differential privacy [3, 6] precisely characterises the level of privacy provided by such randomized mechanisms. It offers a worst-case statistical guarantee on the increase in harm that an individual can be exposed to, if deciding to contribute her data to the dataset.

The concept of differential privacy is rooted in the notion of *neighboring databases*, that is, databases that differ in the presence or not of the information regarding one participant. More precisely, a mechanism $\mathcal{M}$ is ε-differentially private, for $\varepsilon \geq 0$ if for any two neighboring databases D and D' and for any subset $S \subseteq \mathcal{R}$ of possible outputs we have:

$$\Pr[\mathcal{M}(D) \in S] \quad \leq \quad \mathbf{e}^{\varepsilon} \cdot \Pr[\mathcal{M}(D') \in S].$$

That is, the probability that $\mathcal{M}$ releases an element of S on D is almost the same as the probability that $\mathcal{M}$ releases an element of S on D'. In the definition of differential privacy the parameter ε plays a central role. It gives the concrete bound on the increase in *harm* that an individual I can be exposed to, by contributing her data to the database.

Several mechanisms have been proposed to turn a deterministic query into a differentially private one, like the Laplace mechanism, the exponential mechanism, the Gaussian mechanism, etc. An extended introduction to these and other mechanisms (and more generally to differential privacy) is the recent monograph by Dwork and Roth [7]. In order to provide a good balance between privacy and utility, such ε-differential private mechanisms calibrate the added noise to the so-called *sensitivity* of the query. The sensitivity of a query Q captures the influence that an individual's data can have on the output of the query. More precisely, let us denote by $D \sim D'$ the fact that two databases D and D' are *neighbors*. The sensitivity of a numeric query Q is then

$$\max_{D \sim D'} |Q(D) - Q(D')|.$$

This measure is generally referred to as the *global sensitivity* of the query to distinguish it from other notions of local or smooth sensitivity [13].

To avoid adding too much noise and thus sacrificing too much utility to achieve the intended level of differential privacy, the sensitivity of the query needs to be computed as accurately as possible. However, this problem is undecidable in general as we shall see. In this paper we propose algorithms for computing upper bounds on the sensitivity of queries. Our results hold in a rather general setting: we consider counting conjunctive queries over multi-table databases. Further, our results are not tied to any particular neighboring relation, but hold for any relation of *bounded order*. This work is a first step towards understanding the class of queries and neighboring relations that are amenable to differential privacy.

Relational databases. Most of the works on differential privacy assume the simplified situation where the database is a monolithic table [7]. However, real life databases consist of not one, but many tables containing the information scattered. Of course, one could build a unique table from all these tables, by simply producing the cartesian product of all the tables in the database. Nevertheless, this immediately raises two problems. First, materialising the cartesian product of many—possibly big—tables is impractical, and often plain impossible due to space and time requirements. Second, the notion of neighboring databases now becomes *unbounded* which makes queries have unbounded sensitivity, and thus not amenable to differential privacy mechanisms. For example, given two tables (T_1, T_2) and a neighbor $T_1' = T_1 \setminus \{\bar{t}\}$ of T_1 for some record $\bar{t} \in T_1$, we have that, whereas (T_1', T_2) is the neighbor of (T_1, T_2) resulting from removing *one* record, $T_1 \times T_2$ differs from $T_1' \times T_2$ in a number of records equal to $|T_2|$. This in general makes it impossible for non-trivial queries to have bounded sensitivity, unless further restrictions on the databases are assumed.

Neighboring relation. Most works on differential privacy define neighboring databases as those that differ in exactly one record. This corresponds to assuming that each individual contributes at most one record in the database. However, as pointed out in [10] this assumption does not hold for many applications such as social networks or tabular data. So the definition of neighboring databases needs to be tailored to the application at hand with privacy in mind. Indeed, neighboring databases should, strictly speaking, differ in the complete set of information pertaining to one individual, which could mean more than one record. Alternative definitions of neighboring have been proposed [10, 5]. In particular, our results are not tied to any particular definition of the neighboring relation.

SQL. SQL is arguably the prevalent query language for relational databases. It is equivalent to first order logic (FO) over relational structures and to Relational Algebra (RA). Here, we focus on SQL with aggregation, and study the static analysis problem of computing the sensitivity of SQL queries. As a first step in the larger programme of studying aggregate queries, we study the *counting* operator. We concentrate our investigation on one of the most prominent fragments of SQL, namely the Conjunctive Queries, corresponding to positive "select-from-where" queries [1].

Contributions. We first establish, in Section 2, that finding the sensitivity of a SQL query with counting is not computable in general. In the remaining sections we restrict our study to counting Conjunctive Queries. Section 3 shows that the sensitivity for this fragment is computable, although the characterisation shows that sensitivity becomes unbounded as soon as we have a 'non-trivial' join.

Now, in most scenarios the class of databases of interest for the application at hand are restricted (or constrained), and oftentimes the sensitivity of a query Q restricted to a constrained class of databases can become bounded. Following this idea, we then study the problem of computing global sensitivity restricted to databases from a constrained class. In Section 4, we focus on *Functional Dependencies* (FD), that allow constraining databases by rules of the form "in the table T, the i-th column determines the j-th column", in other words, "there are no 2 rows of T with the same datum in the i-th column but distinct data in their j-th columns". Further, in Section 5 we study *Cardinality Dependencies*, which are a generalisation of FDs, with rules of the form "there are no more than k rows of T with the same datum in the i-th column but pairwise distinct data in their j-th columns". Finally, Section 6 concludes and discusses future work.

Related work. Several works have studied methods for computing the sensitivity of a given query or program. The work most related to ours is the one of Palamidessi and Stronati [14]. They study the problem of computing the sensitivity of queries in relational algebra. Their approach is based on the use of constraints on attributes: every attribute comes with a bounded range, e.g. $0 \leq \text{age} \leq 100$. They are able to provide tight bounds on the sensitivity of the query Q. This approach can be applied to general SQL queries but it has the drawback that it requires to constrain the ranges for all the attributes. In this paper, instead, we focus on counting queries and on more lax semantic restrictions, namely functional dependencies and cardinality dependencies.

Pierce and Reed [15] and Gaboardi et al. [8] use relational algebra operations with a fixed, predetermined sensitivity, and a linear type system to track the use of the data in programs. This combination permits to have sensitivity analyses that extend, beyond SQL, to a full functional programming language. Their approach can provide "bad" estimates on

the sensitivity of given queries due to the use of fixed sensitivity for relational operations. Our approach could provide a kernel query language providing more precise estimates that could be then combined with their type systems.

Chaudhuri et al. in [4] study automatic program analyses that provide bounds on the sensitivity of numerical imperative programs. Their approach is not directly related to specific query languages but our work could, in principle, be combined with their techniques to design a general purpose programming language for differential privacy.

Several works have pointed out and studied the problem of providing a bound to the sensitivity of queries in disconnected structures. McSherry [12], in the setting of tabular data, considers a restricted form of join where the data of the two tables are grouped by their join keys, and then groups are joined using their group keys. The same solution has been used also in [15, 8]. A similar approach, with different restrictions, has also been used by Palamidessi and Stronati in [14]. This approach limits the situations where differential privacy can be used with a good utility. To overcome this problem, several approaches considered alternative notions of sensitivity such as *local sensitivity* [13] or *empirical sensitivity* [5].

2 Preliminaries

Let $\mathbb{N} = \{0, 1, 2, \dots\}$ and let $\underline{n} = \{1, \dots n\}$ for every $n \in \mathbb{N}$. We write $\bar{a}$ to denote a vector of elements, whose i-th element is denoted by $\bar{a}[i]$. We write A^* [resp. A^+, A^n] for the set of strings [resp. non-empty strings, length-n strings] over A, and ε for the empty string.

2.1 Relational structures

A **relational vocabulary** $\sigma = (\mathcal{K}, \mathcal{R})$ consists of a collection $\mathcal{K}$ of **constants** (usually denoted by $c_1, c_2, \dots$), and a collection $\mathcal{R}$ of **relation symbols**, each with a specified **arity**. By σ_n we denote a vocabulary $\sigma_n = (\mathcal{K}, \mathcal{R})$ where $\mathcal{K} = \{c_1, \dots, c_n\}$. For a relation R we write $\mathit{arity}(R) \in \mathbb{N}$ to denote its arity; and we sometimes write $R^{(r)}$ to specify that R has arity r. A **σ-structure** $\mathbb{A}$ consists of a universe A containing $\mathcal{K}$, or **domain**, and an **interpretation** which associates to each relation symbol $R \in \mathcal{R}$, a relation $R^{\mathbb{A}} \subseteq A^{\mathit{arity}(R)}$, and for each constant $c \in \mathcal{K}$, $c^{\mathbb{A}} = c$. An **isolated element** of $\mathbb{A}$ is an element $a \in A$ which does not appear in any interpretation. Let STR be the set of all finite structures (we write $\mathit{STR}[\sigma]$ to make explicit the vocabulary). We use $\mathbb{A}, \mathbb{B}, \mathbb{C}, \mathbb{A}', \mathbb{B}', \dots$ to denote relational structures from STR, and $A, B, C, A', B', \dots$ to denote their respective domains.

▶ **Example 1.** As our running example, we will consider a database of patients, doctors and hospitals, with tables

- *Hos(id, loc)*, containing the hospitals with their location,
- *Pat(id, sex, hos)*, listing the patients with an identifier, gender and the hospital where they are being treated,
- *Doc(id, specialty, hos)*, listing the doctors with their identifier, their specialty and the hospital where they practice,
- *PatDoc(pat, doc)*, containing the patients and their current attending doctor.

Such a database can be described over the vocabulary $\sigma = (\mathcal{K}, \mathcal{R})$ containing relations $\mathcal{R} = \{\mathit{Hos}^{(2)}, \mathit{Pat}^{(3)}, \mathit{Doc}^{(3)}, \mathit{PatDoc}^{(2)}\}$ and some constants such as $\mathcal{K} = \{c_{\mathrm{F}}, c_{\mathrm{O}}\}$.

A **graph** is a structure $G = (V, E)$, where E is a binary relation that is symmetric and irreflexive. Thus, our graphs are undirected, loopless, and without parallel edges. The **Gaifman graph** of a σ-structure $\mathbb{A}$, denoted by $\mathcal{G}(\mathbb{A})$, is the (undirected) graph whose set of nodes is the universe of $\mathbb{A}$, and whose set of edges consists of all pairs (a, a') of distinct

elements of A such that a and a' appear together in some tuple of a relation in $\mathbb{A}$. Recall that the **distance** between two vertices u, v of a graph is the length of the shortest path from u to v. We define the distance between two elements a, b of a structure $\mathbb{A}$ as their distance in $\mathcal{G}(\mathbb{A})$, which we denote by $dist_{\mathbb{A}}(a, b)$. We write $A \sqcup B$ for the disjoint union of A and B.

A **homomorphism** from a $(\mathcal{K}, \mathcal{R})$-structure $\mathbb{A}$ to a $(\mathcal{K}', \mathcal{R}')$-structure $\mathbb{B}$ such that $\mathcal{K} \subseteq \mathcal{K}'$ and $\mathcal{R} \subseteq \mathcal{R}'$ is a mapping $h : A \to B$ so that for each relation symbol $R \in \mathcal{R}$, if $(a_1, \ldots, a_r) \in R^{\mathbb{A}}$, then $(h(a_1), \ldots, h(a_r)) \in R^{\mathbb{B}}$, and for every constant $c \in \mathcal{K}$, $h(c) = c$. We will sometimes write $h(a_1, \ldots, a_r)$ as short for $(h(a_1), \ldots, h(a_r))$. We write $\mathbb{A} \to \mathbb{B}$ to denote that there is a homomorphism from $\mathbb{A}$ to $\mathbb{B}$, and we write $h : \mathbb{A} \to \mathbb{B}$ to denote that h is a homomorphism from $\mathbb{A}$ to $\mathbb{B}$. If $\mathbb{A} \to \mathbb{B}$ and $\mathbb{B} \to \mathbb{A}$ we say that $\mathbb{A}$ and $\mathbb{B}$ are **hom-equivalent**. We use $\cong$ for the isomorphism relation. Given a σ-structure $\mathbb{A}$ and a set $B \subseteq A$ there is (up to isomorphism) a unique structure $\mathbb{A}'$ so that

- it is hom-equivalent to $\mathbb{A}$, that is, there are $h : \mathbb{A} \to \mathbb{A}'$ and $h' : \mathbb{A}' \to \mathbb{A}$,
- $h(a) = h'(a) = a$ for all $a \in B$,
- it has the minimal number of elements.

Such a structure $\mathbb{A}'$ is called the **core preserving** B (or simply **core** if $B = \emptyset$). We write $core(\mathbb{A}, B)$ [resp. $core(\mathbb{A})$] to denote the core of $\mathbb{A}$ preserving B [resp. the core of $\mathbb{A}$].

2.2 Logic

Let $\mathcal{V}$ be a collection of first-order variables equipped with a linear order $<$. Let σ be a relational vocabulary. A **term** is either a first order variable $x \in \mathcal{V}$ or a constant from σ. The **atomic formulas** of σ are those of the form $R(t_1, \ldots, t_n)$, where $R \in \sigma$ is a relation symbol of arity r, and $t_1, \ldots, t_r$ are terms. Formulas of the form $t = t'$ are also atomic formulas, and we refer to them as **equalities**. The collection of **first-order formulas** (FO formulas) is obtained by closing the atomic formulas under negation, conjunction, disjunction, universal and existential first-order quantification. The semantics of first-order logic is standard. The set of variables of φ is denoted by $var(\varphi)$, and the set of free variables by $free(\varphi)$. We often write $\varphi(x_1, \ldots, x_n)$ where $\{x_1, \ldots, x_n\} = free(\varphi)$ and $x_1 < \cdots < x_n$, to stress the free variables. If $\mathbb{A}$ is a σ-structure and $\varphi(\bar{x})$ is a first-order formula, we use the notation $\mathbb{A} \models \varphi[\bar{a}]$ to denote the fact that φ is true in $\mathbb{A}$ when its free variables $\bar{x}$ are interpreted by the tuple of elements $\bar{a}$. When φ contains no free variables, we say that it is a **sentence**, and in this case we simply write $\mathbb{A} \models \varphi$. For any formula $\varphi(x_1, \ldots, x_n)$ and structure $\mathbb{A}$, we write $\varphi(\mathbb{A})$ to denote $\{(a_1, \ldots, a_n) \in A^n \mid \mathbb{A} \models \varphi[a_1, \ldots, a_n]\}$. We use '()' to denote the 0-ary tuple of elements. Hence, if φ has no free variables we interpret $\varphi(\mathbb{A})$ as $\{()\}$ if $\mathbb{A} \models \varphi$ or $\emptyset$ otherwise. Note that, in this case, $|\varphi(\mathbb{A})| = 1$ iff $\mathbb{A} \models \varphi$. We use $\equiv$ for the logical equivalence relation and $\equiv_{\mathcal{C}}$ for the equivalence relation restricted to a class of structures $\mathcal{C}$.

Given a class of FO formulas $\mathcal{L}$, by $\mathcal{L}^{\#}$ we denote the class of **counting queries** $\{\#\varphi \mid \varphi \in \mathcal{L}\}$. The evaluation of $\#\varphi$ in $\mathbb{A}$, denoted $\#\varphi(\mathbb{A})$, is defined as $|\varphi(\mathbb{A})|$, that is, as the number of distinct tuples making φ true in $\mathbb{A}$.

▶ **Example 2.** Continuing our running example, we consider the query that counts the number of oncology doctors that are treating female patients in the same hospital as they practice:

```
SELECT count distinct Doc.id
FROM Pat, Doc, PatDoc
WHERE Doc.specialty = 'O' and
      Pat.sex = 'F' and
      Pat.hos = Doc.hos and
      PatDoc.pat = Pat.id and
      PatDoc.doc = Doc.id
```

This can be equivalently expressed with the formula $\#\varphi$, where

$$\varphi(x_{doc}) = \exists x_{pat}, x_{hos} \; . \; Doc(x_{doc}, c_{\mathrm{O}}, x_{hos}) \wedge Pat(x_{pat}, c_{\mathrm{F}}, x_{hos}) \wedge PatDoc(x_{pat}, x_{doc}) \, .$$

2.3 Global sensitivity

In its standard formulation, Differential Privacy requires the privacy bound to be valid for every pair of structures that differ in one record. However, it is possible that an individual contributes more than a single record to the database. Further it may be that the database contains tables with public information. For this reason we do not set for our study a particular neighboring relation. Our results hold for any **neighboring relation** $\mathcal{N} \subseteq STR[\sigma] \times STR[\sigma]$.

Having said that, a specific neighboring relation, called **1-neighboring**, will be particularly useful for our proofs. Given two σ-structures $\mathbb{A}, \mathbb{B}$ with $\sigma = (\mathcal{K}, \mathcal{R})$, we say that $\mathbb{A}$ is a **substructure** of $\mathbb{B}$ (noted $\mathbb{A} \subseteq \mathbb{B}$) if $A \subseteq B$, and $R^{\mathbb{A}} \subseteq R^{\mathbb{B}}$ for all $R \in \sigma$. We write $\mathbb{A} \prec \mathbb{A}'$ if $\mathbb{A} \subsetneq \mathbb{A}'$ and there is no $\mathbb{B}$ so that $\mathbb{A} \subsetneq \mathbb{B} \subsetneq \mathbb{A}'$. We say that $\mathbb{A}, \mathbb{B}$ are 1-neighboring structures, noted $\mathbb{A} \sim_1 \mathbb{B}$, if $\mathbb{A} \prec \mathbb{B}$ or $\mathbb{B} \prec \mathbb{A}$. In other words, $\mathbb{A} \sim_1 \mathbb{B}$ if $\mathbb{A}$ can be obtained from $\mathbb{B}$ (and B from A) by removing/adding a tuple or an isolated node.

We say that the neighboring relation $\mathcal{N}$ is **of order** $k \in \mathbb{N}$, if any two neighboring relational structures differ in at most k elements. More formally, $\mathcal{N}$ is of order k if for any $(\mathbb{A}, \mathbb{B}) \in \mathcal{N}$, there exist $\mathbb{A}_0, \ldots, \mathbb{A}_\ell$ such that $\ell \leq k$, $\mathbb{A} = \mathbb{A}_0$, $\mathbb{B} = \mathbb{A}_\ell$ and $\mathbb{A}_{i-1} \sim_1 \mathbb{A}_i$ for all $i \in \underline{\ell}$. We say that the neighboring relation is unbounded if no such k exists.

The **global sensitivity** of a function $f : STR \to \mathbb{N}$ over a class of models $\mathcal{C} \subseteq STR$ with respect to a neighboring relation $\mathcal{N} \subseteq \mathcal{C} \times \mathcal{C}$ is:

$$\mathrm{GS}^{\mathcal{N}}_{\mathcal{C}}(f) \stackrel{def}{=} \max_{(\mathbb{A},\mathbb{A}') \in \mathcal{N}} |f(\mathbb{A}) - f(\mathbb{A}')|.$$

▶ **Example 3.** Suppose now that we want to find out the number of oncological patients in the state of New York with the query

$$\varphi(x_{pat}) = \exists x_{hos}, x_{doc}, x_{sex} \; . \\ Doc(x_{doc}, c_{\mathrm{O}}, x_{hos}) \wedge Pat(x_{pat}, x_{sex}, x_{hos}) \wedge PatDoc(x_{pat}, x_{doc}) \wedge Hos(x_{hos}, x_{loc})$$

It is not hard to see that this query has unbounded global sensitivity when all relations are considered sensitive, and thus all databases that differ in any one element are neighbors. Indeed changing the location of a hospital from Indiana to New-York can increase the number of ontological patients in the state of New York by any number.

▶ **Observation 1.** *For any neighboring relation $\mathcal{N}$ of order k and any class of databases $\mathcal{C}$, the global sensitivity of a query Q is bounded with respect to $\mathcal{N}$ over $\mathcal{C}$ iff it is bounded with respect to $\sim_1$ over $\mathcal{C}$. Further, the global sensitivity with respect to $\mathcal{N}$ and relative to the class $\mathcal{C}$ is bounded by $k \cdot GS^{\sim_1}_{\mathcal{C}}(Q)$. So in the remaining of the paper we focus on 1-neighboring.*

We will study the following problem, given a query language $\mathcal{L}$, and a class of relational structures $\mathcal{C}$

Problem:	GlobalSensitivity($\mathcal{L}$, $\mathcal{C}$)
Input:	$Q \in \mathcal{L}$
Output:	$\mathrm{GS}^{\sim_1}_{\mathcal{C}}(Q)$

Unfortunately, this problem is undecidable already for counting first-order logic (and therefore for counting Relational Algebra [1]).

▶ **Theorem 4.** GlobalSensitivity*(FO$^{\#}$, STR) is non-computable.*

The fact that the global sensitivity problem for FO is undecidable is not really surprising since most static analysis problems for FO on unrestricted structures are undecidable. This is why in the next sections we will focus on Conjunctive Queries.

3 Conjunctive queries

One of the most studied fragments of FO in relation to database queries is the fragment of *Conjunctive Queries* (CQ). We now, and for the rest of the paper, restrict our study to counting conjunctive queries, and show that sensitivity for this fragment is computable.

The class of Conjunctive Queries (also known as Primitive Positive Logic, or Existential Positive FO) is the fragment of FO corresponding to positive '*select-project-join*' queries of the Relational Algebra or to positive '*select-from-where*' queries of SQL, where by 'positive' we mean that there are no inequalities in the *select* [resp. *where*] conditions (we refer the reader to [1, §4] for more details). These are formulae of the form

$$\varphi(x_1,\dots,x_n) = \exists y_1,\dots,y_m\, \theta, \tag{$\dagger$}$$

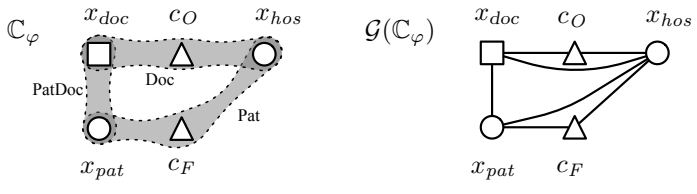
where θ is a conjunction of atomic formulae. Since we deal with constants, and, in future sections, with constrained databases, a conjunctive query can also be *false* (noted $\bot$). However, all the results that we show will assume that the input formula is not equivalent to $\bot$ (*i.e.*, that it is satisfiable, which can be checked in polynomial time)—for the particular case where formulae are unsatisfiable all the results are trivial, and this will avoid lengthy statements. For simplicity, we assume that the formulae do not contain equalities.

Every conjunctive query of the form (†) over a relational vocabulary σ_k gives rise to a **canonical structure** (sometimes called *tableau*) $\mathbb{C}_\varphi$ with $n+m+k$ elements, where the elements of $\mathbb{C}_\varphi$ are the variables $x_1,\dots,x_n,y_1,\dots,y_m$ plus the constants $c_1,\dots,c_k$, the relations of $\mathbb{C}_\varphi$ consist of the tuples of terms in the conjuncts of θ. Given a CQ φ, we write $\mathbb{C}_\varphi$ for the canonical structure of φ, and C_φ for its domain (*i.e.*, the variables $x_1,\dots,x_n,y_1,\dots,y_m$ and constants $c_1,\dots,c_k$). We also define $\mathbb{C}_\varphi^-$ as the result of removing all isolated constants from $\mathbb{C}_\varphi$ (note that $\mathbb{C}_\varphi^-$ may not necessarily be a structure over the same vocabulary of φ due to the absence of some constants). Likewise, any σ_k-structure $\mathbb{A}$ with domain $A = \{x_1,\dots,x_n\} \cup \{c_1,\dots,c_k\}$ gives rise to a canonical CQ $\varphi(x_1,\dots,x_n)$ where $\mathit{var}(\varphi) = \mathit{free}(\varphi) = \{x_1,\dots,x_n\}$, and φ has a conjunct $R(\bar t)$ iff $\bar t \in R^{\mathbb{A}}$. Note that for every σ_k-structure $\mathbb{A}$ there is $\mathbb{A}' \cong \mathbb{A}$ and φ so that φ is the canonical query of $\mathbb{A}'$.

A CQ φ is **acyclic** if $\mathcal{G}(\mathbb{C}_\varphi)$ is acyclic. We say that a CQ φ is **connected** if $\mathcal{G}(\mathbb{C}_\varphi^-)$ is connected, otherwise it is **disconnected**. Note that every disconnected CQ φ so that $\mathcal{G}(\mathbb{C}_\varphi)$ has n connected components can be equivalently written in the form $\varphi = \bigwedge_{i\in\underline{n}} \psi_i(\bar x_i)$ so that $\psi_i(\bar x_i)$ is a connected CQ for every i, and for all $i \neq j$, $\bar x_i$ and $\bar x_j$ have no variables in common. We say that ψ_i is a **connected conjunct** of φ, and we say that ψ_i is a **sentential connected conjunct** if it is a sentence (*i.e.*, $\bar x_i = ()$). Given $\varphi = \bigwedge_{i\in\underline{n}} \psi_i(\bar x_i)$ a disconnected CQ with each ψ_i being a connected conjunct, we further define $\overline{\varphi}^j$ as the conjunction of all the ψ_s's but ψ_j.

▶ **Example 5** (Cont. from Ex. 2)**.** The canonical σ-structure $\mathbb{C}_\varphi$ has universe $\{x_{pat}, x_{hos}, x_{doc}, c_{\mathrm{O}}, c_{\mathrm{F}}\}$ and relations (shown in Figure 1):

$$\mathit{Doc}^{\mathbb{C}_\varphi} = \{(x_{doc}, c_{\mathrm{O}}, x_{hos})\}, \quad \mathit{Pat}^{\mathbb{C}_\varphi} = \{(x_{pat}, c_{\mathrm{F}}, x_{hos})\}, \quad \mathit{PatDoc}^{\mathbb{C}_\varphi} = \{(x_{pat}, x_{doc})\}.$$



]t]

Figure 1 Depiction of the canonical structure of φ as defined in Example 2 as well as its Gaifman graph. Square vertices denote free variables and triangle vertices denote constants.

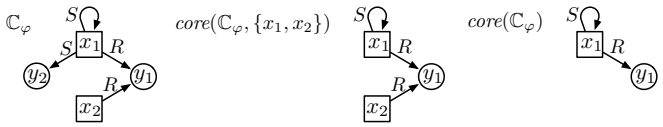


Figure 2 Core of CQ's.

Core of CQ's. For a CQ query $\varphi(\bar{x}) = \exists \bar{y}.\theta$ over σ_k we define $core(\varphi)$ as the CQ query $\varphi'(\bar{x}) = \exists \bar{y}'.\theta'$ where θ' is the canonical query of $core(\mathbb{C}_\varphi, \bar{x})$ and $\bar{y}'$ is the set of all non-constant elements of $core(\mathbb{C}_\varphi, \bar{x})$ that are not in $\bar{x}$. Note that $\mathbb{C}_{core(\varphi)} \cong core(\mathbb{C}_\varphi, \bar{x})$. We say that $\varphi(\bar{x})$ is a **core-CQ** if $\mathbb{C}_{core(\varphi)} \cong core(\mathbb{C}_\varphi)$, and we write CQ_{core} for the class of all core-CQ's. We define $core(\#\varphi)$ as $\#core(\varphi)$ for every CQ φ.

▶ **Example 6.** Given $\varphi(x_1, x_2) = \exists y_1, y_2.S(x_1, x_1) \wedge S(x_1, y_2) \wedge R(x_1, y_1) \wedge R(x_2, y_1)$, whose canonical structure is depicted in Figure 2, we have that $core(\varphi) \equiv \exists y_1.S(x_1, x_1) \wedge R(x_1, y_1) \wedge R(x_2, y_1)$, and that φ is not a core-CQ since $core(\mathbb{C}_\varphi, \{x_1, x_2\})$ is not isomorphic to $core(\mathbb{C}_\varphi)$, as shown in Figure 2.

Given a connected CQ φ, let us define

$$\Delta_{STR}(\#\varphi) = \begin{cases} \infty & \text{if } \exists x \in free(\varphi).\ \exists R \in \mathcal{R}.\ \exists \bar{a} \in R^{core(\varphi)}.\ x \notin \bar{a} \\ 1 & \text{otherwise} \end{cases}$$

▶ **Proposition 7.** *For every connected CQ$^\#$ Q, we have $GS^{\sim_1}_{STR}(Q) = \Delta_{STR}(Q)$.*

▶ **Example 8** (Cont. from Ex. 5)**.** Note that we have $\Delta_{STR}(\#\varphi) = \infty$ since $core(\varphi) = \varphi$ and x_{doc} is not in the tuple (x_{pat}, c_F, x_{hos}) of the relation $Pat^{\mathbb{C}_\varphi}$, and thus that $\mathrm{GS}^{\sim_1}_{STR}(Q) = \infty$.

We extend the definition of Δ_{STR} to disconnected CQ$^\#$ as follows. For any $\varphi = \bigwedge_{i \in \underline{n}} \varphi_i$ disconnected CQ so that each φ_i is a connected conjunct, we define

$$\Delta_{STR}(\#\varphi) = \begin{cases} \Delta_{STR}(\#\varphi_k) & \text{if } \exists k \in \underline{n}.\ free(\varphi) = free(\varphi_k) \ \wedge\ \mathbb{C}_{\overline{\varphi}^k} \to \mathbb{C}_{\varphi_k} \\ \infty & \text{otherwise} \end{cases}$$

▶ **Theorem 9.** *For every CQ$^\#$ Q, we have $GS^{\sim_1}_{STR}(Q) = \Delta_{STR}(Q)$.*

The above characterization shows that, even when we deal with *connected* CQ's (arguably the most common), we obtain unbounded sensitivity very easily. Indeed, as soon as one has a 'join' with a free variable which is not the joining attribute, such as $\#\varphi(x) = \#\,\exists y, z\,.\,R(x, y) \wedge S(y, z)$ the global sensitivity is unbounded. Although this means that for every $N \in \mathbb{N}$ there are structures $\mathbb{A} \sim_1 \mathbb{A}'$ so that $\#\varphi(\mathbb{A}) - \#\varphi(\mathbb{A}') > N$, it may be that $\mathbb{A}, \mathbb{A}'$ do not correspond to databases that could arise in the domain of application at hand. However, when restricting the set of considered structures to ones satisfying some constraints, it may well be that the sensitivity becomes bounded. The next two sections will focus on evaluating sensitivity of queries over constrained structures.

4 Functional Dependencies

In this section we show bounds for the sensitivity of queries in the presence of what are called *functional dependencies*. In databases, it is often the case that a set of attributes determines another attribute. Such constraints are called functional dependencies. In this section functional dependencies where one attribute determine another are considered.

▶ **Example 10** (Cont. from Ex. 2)**.** Note that, the global sensitivity of $\#\varphi$ is unbounded. Indeed, this is a consequence of the possibility of having patients with unbounded number of attending doctors and doctors working in any number of hospitals. However, this does not correspond to databases that could occur in practice, since patients have normally one attending doctor and doctors work in at most one hospital. This is why the use of database constraints becomes useful, to restrict the collection of databases we are interested in, and thus to improve the bounds of the sensitivity of queries.

We write $R[i \to j]$ to denote a **functional dependency of a relation** R **of arity** n **between components** $i \in \underline{n}$ **and** $j \in \underline{n}$. A structure $\mathbb{A}$ satisfies a functional dependency (henceforth "FD") $R[i \to j]$ if $\max_{a \in A}(|\{\bar{b}[j] \mid \bar{b} \in R^{\mathbb{A}}, \bar{b}[i] = a\}|) \leq 1$. We use the symbol Σ to denote a set of FDs, and we write $\#_\Sigma R[i \to j]$ to denote 1 if $R[i \to j] \in \Sigma$, or ∞ otherwise. We write $\mathcal{C}_\Sigma$ for the class of all relational structures satisfying all FDs in Σ.

Given a CQ query φ and a set of FDs Σ we define the **Σ-chase** [11, 2] of φ, noted $chase_\Sigma(\varphi)$, as the closure of the application of the following rule:

- For every $R[i \to j] \in \Sigma$ and every pair of conjuncts $R(\bar{t})$ and $R(\bar{s})$ of φ so that $\bar{t}[i] = \bar{s}[i]$ and $\bar{t}[j] \neq \bar{s}[j]$,
  - if $\bar{s}[j]$ is a variable, replace every occurrence of $\bar{s}[j]$ with $\bar{t}[j]$;
  - if $\bar{s}[j]$ and $\bar{t}[j]$ are constants, output $\bot$.

It can be seen that the application of these rules is terminating and Church-Rosser confluent, up to renaming of variables [1].

The following result shows that, as soon as we have a disconnected query, the sensitivity is likely to be unbounded.

▶ **Proposition 11.** *For every disconnected CQ query φ containing a conjunct without constants and at least one free variable, and for every set Σ of FD's, we have $GS^{\sim_1}_{\mathcal{C}_\Sigma}(\#\varphi) = \infty$.*

Paths. A **path** of a $(\mathcal{K}, \mathcal{R})$-structure $\mathbb{A}$ between an element $a \in A$ and $b \in A$, is a string

$$p = (R_1, i_1, a_1, j_1, b_1) \cdots (R_n, i_n, a_n, j_n, b_n) \in (\mathcal{R} \times \mathbb{N} \times A \times \mathbb{N} \times A)^* \qquad (\star)$$

so that either $p = \varepsilon$ and $a = b$ (*i.e.*, the empty path); or $a_1 = a$, $b_n = b$, $a_i = b_{i-1}$ for all $1 < i \leq n$, and for every $\ell \in \underline{n}$ we have $i_\ell, j_\ell \in \underline{arity(R_i)}$ and there is $\bar{a} \in R^{\mathbb{A}}_\ell$ so that $\bar{a}[i_\ell] = a_\ell$ and $\bar{a}[j_\ell] = b_\ell$. A path of the form $(\star)$ is **simple** if $a_i \neq b_i \neq b_j$ for all $1 \leq i < j \leq n$. Note that in particular the empty path ε is simple. We write $p : A_1 \rightsquigarrow_{\mathbb{A}} A_2$ to denote that p is a simple path of $\mathbb{A}$ from an element of $A_1 \subseteq A$ to an element of $A_2 \subseteq A$. We write $a \rightsquigarrow_{\mathbb{A}} b$, $A_1 \rightsquigarrow_{\mathbb{A}} b$, $a \rightsquigarrow_{\mathbb{A}} A_2$ as short for $\{a\} \rightsquigarrow_{\mathbb{A}} \{b\}$, $A_1 \rightsquigarrow_{\mathbb{A}} \{b\}$, $\{a\} \rightsquigarrow_{\mathbb{A}} A_2$ respectively.

▶ **Example 12.** For a structure $\mathbb{A}$ with relations $R^{\mathbb{A}} = \{(a_1, a_2, a_3), (a_1, a_4, a_6)\}$, $S^{\mathbb{A}} = \{(a_5, a_6)\}$, and $T^{\mathbb{A}} = \{(a_3, a_5, a_4)\}$, we have that $p : a_1 \rightsquigarrow_{\mathbb{A}} a_4$ for $p = (R, 1, a_1, 3, a_3)$ $(T, 1, a_3, 2, a_5)$ $(S, 1, a_5, 2, a_6)$ $(R, 3, a_6, 2, a_4)$, as depicted in Figure 3

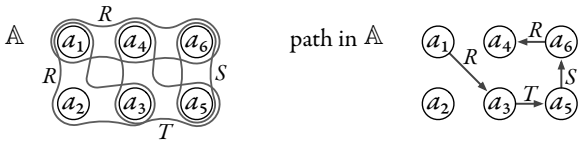

Figure 3 A path in a structure.

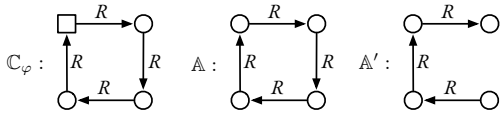

Figure 4 Structures of Example 14. Square vertices denote free variables.

Given a vocabulary $\sigma = (\mathcal{K}, \mathcal{R})$ and a path p of the form $(\star)$, let $m \in \underline{n}$ be the greatest index m so that $b_m \in \mathcal{K}$, or 0 otherwise. We define the **cardinality of path** p as

$$\#_\Sigma(p) \stackrel{def}{=} \prod_{m<\ell\leq n} \#_\Sigma R_\ell[i_\ell \to j_\ell] \tag{1}$$

where as usual the product of the empty sequence is 1, and ∞ is absorbing wrt the product ($\infty \cdot N = N \cdot \infty = \infty$). Note that $\#_\Sigma(\varepsilon) = 1$. The intuition is that $\#_\Sigma(p)$ gives a bound on how many different elements b can be reached from a through p on any structure $\mathbb{A} \in \mathcal{C}_\Sigma$ (*i.e.*, so that $p : a \rightsquigarrow_{\mathbb{A}} b$).

Let $Q = \#\psi(x_1, \ldots, x_n)$ be a connected CQ$^\#$ over a vocabulary $\sigma = (\mathcal{K}, \mathcal{R})$, and let $\varphi = \mathit{core}(\mathit{chase}_\Sigma(\psi))$. We define

$$\Delta^+_\Sigma(Q) \stackrel{def}{=} \max_{R\in\mathcal{R}} \sum_{\bar{a}\in R^{\mathbb{C}_\varphi}} \max_{i\in\underline{n}} \left(\min_{p_i : \bar{a} \rightsquigarrow_{\mathbb{C}_\varphi} x_i} \#_\Sigma(p_i) \right)$$

$$\Delta^-_\Sigma(Q) \stackrel{def}{=} \max_{R\in\mathcal{R}} \max_{\bar{a}\in R^{\mathbb{C}_\varphi}} \max_{i\in\underline{n}} \left(\min_{p_i : \bar{a} \rightsquigarrow_{\mathbb{C}_\varphi} x_i} \#_\Sigma(p_i) \right).$$

▶ **Observation 2.** *Note that $\Delta^-_\Sigma(Q)$ is either 1 or ∞ and that $\Delta^-_\Sigma(Q) = \infty$ iff $\Delta^+_\Sigma(Q) = \infty$. Further, observe that $\Delta^+_\Sigma(Q) - \Delta^-_\Sigma(Q) \leq n_Q - 1$, where n_Q is the maximum number of elements in a relation of the canonical structure of $\mathit{core}(\mathit{chase}_\Sigma(\psi))$, assuming $Q = \#\psi$.*

▶ **Theorem 13.** *Given a set Σ of functional dependencies and a connected CQ$^\#$ query Q, we have that $GS^{\sim_1}_{\mathcal{C}_\Sigma}(Q) \leq \Delta^+_\Sigma(Q)$. Further, if $Q \in \mathrm{CQ}^\#_{core}$, we have $GS^{\sim_1}_{\mathcal{C}_\Sigma}(Q) \geq \Delta^-_\Sigma(Q)$.*

▶ **Observation 3.** *When computing lower and upper bounds for global sensitivity of query $Q = \#\psi(x_1, \ldots, x_n)$ in the presence of functional dependencies, we consider $\mathit{core}(\mathit{chase}_\Sigma(\psi))$ (rather than $\mathit{core}(\psi)$) as it gives a corresponding* canonical minimal *query. This allows us to obtain tighter bounds than if we hadn't taken the chase of ψ.*

▶ **Example 14.** Take for instance the CQ with one free variable of Figure 4. Observe that, for $\Sigma = \{R[1 \to 2],\ R[2 \to 1]\}$, we have that $\mathrm{GS}^{\sim_1}_{\mathcal{C}_\Sigma}(\#\varphi) \leq \Delta^+_\Sigma(\#\varphi) = 4$, which is tight since $\#\varphi(\mathbb{A}) = 4$, and $\#\varphi(\mathbb{A}') = 0$. Further, this example can be easily generalized, obtaining that for every $n \in \mathbb{N}$ there is a CQ Q so that $\mathrm{GS}^{\sim_1}_{\mathcal{C}_\Sigma}(Q) = n = \Delta^+_\Sigma(Q)$.

▶ **Example 15** (Cont. from Ex. 2)**.** As noted in Example 10, $\#\varphi$ has unbounded global sensitivity. However, if every patient has no more than one attending doctor, the sensitivity

of $\#\varphi$ becomes bounded. Indeed, if $\Sigma = \{PatDoc[1 \to 2]\}$, then

$$\Delta^{-}_{\Sigma}(\#\varphi) \leq \mathrm{GS}^{\sim_1}_{\mathcal{C}_\Sigma}(\#\varphi) \leq \Delta^{+}_{\Sigma}(\#\varphi)$$

by Theorem 13—observe that $\varphi \in \mathrm{CQ}_{core}$ since it is unary. Since $\Delta^{-}_{\Sigma}(\#\varphi) = \Delta^{+}_{\Sigma}(\#\varphi) = 1$, it thus follows that $\mathrm{GS}^{\sim_1}_{\mathcal{C}_\Sigma}(\#\varphi) = 1$.

As we have shown, adding functional dependencies immediately improves the global sensitivity of queries. However, functional dependencies are often very restrictive, and it may not always be possible to impose such restrictions. This leads to a more general notion of dependencies, that we call *cardinality dependencies*. These dependencies bound the number of elements associated with component i of a relation R for each fixed element of a component j. This will be the object of study of our next section.

5 Cardinality Dependencies

While functionality constraints are a very natural restriction of databases, there are many scenarios in which, although we don't have an attribute i functionally determining an attribute j in a relation, we have a **cardinality dependency** nonetheless. This is a dependency of the form "there are at most n different attributes j sharing the same attribute i in the relation R"—functional dependencies being the special case when $n = 1$.

These dependencies arise naturally when modelling relations between entities (such as in ER modelling [9]). For example, the business rules underlying a company database may allow that an employee has more than one manager, but no more than 2. Another example is for bounded domain attributes: whereas the name of a person does not determine the gender, there cannot be more than two possibilities of gender for any given name. As we will see next, cardinality dependencies provide further means to give tighter bounds for the global sensitivity of CQ's.

▶ **Example 16** (Cont. from Ex. 15)**.** We already noticed that constraining each patient to have at most one attending doctor, brings the sensitivity of $\#\varphi$ down to 1. However, it may be that a patient can have more than one attending doctor, although it can't have an *unbounded* number of attending doctors. For example, a scenario in which a patient has *at most* 3 attending doctors.

More formally, we write $R[i \xrightarrow{k} j]$ to denote a **k-cardinality dependency of a relation R of arity n between components $i \in \underline{n}$ and $j \in \underline{n}$**. A structure $\mathbb{A}$ satisfies a cardinality dependency (henceforth "CD") $R[i \xrightarrow{k} j]$ if $\max_{a \in A}(|\{\bar{b}[j] \mid \bar{b} \in R^{\mathbb{A}}, \bar{b}[i] = a\}|) \leq k$. For the particular case where $k = 1$, note that $R[i \xrightarrow{k} j]$ is a *functional* dependency. We use the symbol Σ to denote a set of CD's, and we write $\#_\Sigma R[i \to j]$ to denote the minimum k so that $R[i \xrightarrow{k} j] \in \Sigma$, or ∞ otherwise. As before, we write $\mathcal{C}_\Sigma$ for the class of all relational structures satisfying all CDs in Σ. We define the cardinality of a path $\#_\Sigma(p)$ as in (1), where now Σ is a set of CD's, and in the definition $\#_\Sigma R[i \to j]$ is interpreted as defined above, over CD's.

Upper bound. Given a connected $\mathrm{CQ}^{\#}$ query Q over a vocabulary $\sigma = (\mathcal{R}, \mathcal{K})$ so that $core(Q) = \#\varphi(x_1, \ldots, x_n)$, let us define

$$\Delta^{+}_{\Sigma}(Q) \stackrel{def}{=} \max_{R \in \mathcal{R}} \left(\sum_{\bar{a} \in R^{\mathbb{C}_\varphi}} \left(\min_{\substack{p_1,\ldots,p_n \text{ s.t.} \\ p_i : \bar{a} \rightsquigarrow_{\mathbb{C}_\varphi} x_i \text{ for } i \in \underline{n}}} \left(\prod_i \#_\Sigma(p_i) \right) \right) \right).$$

▶ **Observation 4.** *Note that in the presence of cardinality dependencies, when computing upper bounds for global sensitivity of a query $Q = \#\psi(x_1, \ldots, x_n)$, we now consider $core(\psi)$ (rather than $core(chase_\Sigma(\psi))$). This is because $core(chase_\Sigma(\psi))$ is not necessarily a conjunctive query, but rather a union of conjunctive queries which we do not handle.*

▶ **Theorem 17.** *Given a set of cardinality dependencies Σ, for all connected $CQ^\#$ queries Q we have $GS^{\sim_1}_{\mathcal{C}_\Sigma}(Q) \leq \Delta^+_\Sigma(Q)$.*

▶ **Example 18** (Cont. from Ex. 16)**.** If every patient has at most 3 attending doctors, the sensitivity of $\#\varphi$ becomes bounded. Indeed, if $\Sigma = \{PatDoc[1 \xrightarrow{3} 2]\}$, then $\mathrm{GS}^{\mathcal{R}}_{\mathcal{C}_\Sigma}(\#\varphi) \leq \Delta^+_{\mathcal{R},\Sigma}(\#\varphi) = 3$ by Theorem 17.

6 Conclusion

We have given bounds for the global sensitivity of counting Conjunctive Queries under the functionality or cardinality constraints. These bounds can be used to turn those queries in differentially private ones by using mechanisms like the Laplacian or the Gaussian mechanisms without adding too much noise. The proposed algorithms for computing these bounds have exponential complexity, but since effectively many interesting queries are often small, our results are still practical.

There are several interesting directions that we will pursue in future work. We will study other aggregation operations already present in SQL such as *average* or *sum*. We will also investigate sensitivity of queries with negation, where one can ask for example for the number of patients that are *not* treated by a given doctor. Further, we have focused here on global sensitivity but there are other notions of sensitivity that have been proposed. In particular, the so-called *local sensitivity* is studied in [13]. The local sensitivity is defined by quantifying not over all possible databases but only over the ones in the neighborhood of the particular database under analysis. The local sensitivity is often lower than the global sensitivity, but adding noise proportional to the local sensitivity does not ensure differential privacy. Nevertheless, adding the noise proportional to a smooth approximation of the local sensitivity permits to recover differential privacy.

Abstract

We study the computational complexity of the cooperative and non-cooperative rational synthesis problems, as introduced by Kupferman, Vardi and co-authors. We provide tight results for most of the classical omega-regular objectives, and show how to solve those problems optimally.

1 Introduction

Rational synthesis [14, 19] asks to synthesize a system that is executed in an environment made of several components that are assumed to be rational, and not fully antagonistic as in the classical two player zero-sum setting [23]. Rationality of the environment is modeled by assuming that the components behave according to a Nash equilibrium (NE). Rational synthesis has been introduced in [14, 19] in two different settings.

In the first setting, called *cooperative rational synthesis* [14], the environment cooperates with the system: components of the environment agree to play a NE that is winning for Player 0 (if it exists). In the second setting, called *non-cooperative rational synthesis* [19], the components of the environment may follow any strategy, provided that it is a NE. In this setting, one has to output (if it exists) a strategy σ_0 for the system which has to be winning against all the possible strategy profiles that include σ_0 for Player 0 and which are NE.

The main contribution of the original papers is to propose and to motivate the definitions above. The only computational complexity results given in those papers are as follows: the cooperative and non-cooperative rational synthesis problems are 2ExpTime-c for specifications expressed in linear temporal logic (LTL), thus matching exactly the complexity of

LTL	2ExpTime-c[14]	2ExpTime-c[14]	2ExpTime-c[19]	2ExpTime-c[19]

classical zero-sum two-player LTL synthesis [21]. The upper bound is obtained by reductions to the satisfiability problem of formulas in Strategy Logic (SL) [20]. The reduction to SL and the use of LTL specifications does not allow one to understand finely the computational complexity aspects of solving the underlying n player non-zero sum games.

Contributions. To better understand the computational complexity of the rational synthesis problems and how to solve their underlying games algorithmically, we consider variants of those problems for games played on turn-based graph structures for reachability, safety, Büchi, coBüchi, parity, Rabin, Streett and Muller objectives for unfixed and fixed number of players. The fixed number of players case is interesting as the number of components forming the environment may be limited to a few in practical applications. Our results are summarized in Table 1.

On the positive side, our results show that for a *fixed* number of players, and for objectives that admit a polynomial time solution in the two-player zero-sum case (reachability, safety, Büchi and coBüchi), cooperative and non-cooperative rational synthesis can be solved in PTime. On the negative side, for rich omega regular objectives defined by parity, Rabin, or Streett objective, the complexity increases. First, games with parity objectives cannot be solved in polynomial time unless PTime equals NP while it is conjectured that this result does not hold for two-player zero sum parity games. Second, games with Rabin or Streett objectives are PSpace-c for the non-cooperative setting while they have solution in nondeterministic polynomial time for their zero-sum two player versions. When the number of players is not fixed, the complexity is usually substantially higher than for the two-player zero-sum case. For example, non-cooperative rational synthesis is PSpace-H for all objectives, so even for safety objectives.

Cooperative rational synthesis is a special case of constrained NE (Player 0 has to be winning). The complexity of constrained NE has been studied in [25] for some classes of objectives: this gives us upper-bounds for cooperative synthesis and Büchi, coBüchi, parity and Streett objectives. For the other objectives, we show how to extend the approach proposed in [25]. Solutions to the *non-cooperative* case are much more involved and based on a fine tuned application of tree automata techniques. This is a central contribution of our paper. In particular, our tree automata have exponential size but we show how to test their emptiness in PSpace to obtain optimal algorithms for Streett, Rabin and Muller objectives and fixed number of players.

The tree automata that we construct not only allow us to test the existence of solution to the non-cooperative rational synthesis problem but also to symbolically represent all the strategies for the system that are solutions. This set is thus regular and can be manipulated

with automata-based techniques. Also, it should be clear that our algorithms are amenable to symbolic implementations when the game structure is given with binary decision diagrams. This is important as it shows that our techniques pave the way to implementations that have proven useful and efficient by the CAV community (see e.g. tools like nuSMV [11]).

To obtain lower-bounds, we design original and informative reductions.

Related work. Non-zero sum games for synthesis are gaining attention recently, see e.g. [4] for a survey. *Secure equilibria* were introduced in [9] and their potential for synthesis was demonstrated in [8]. Secure equilibria is a refinement of NE [24]. *Doomsday equilibria* extend secure equilibria to the n player case [7]. Subgame perfect equilibria, that also refines NE, were first studied in [24, 25]. To model rationality of players, the notion of *admissible strategy* is used in [3, 13] instead of the notion of NE, and computational aspects are studied in [6], potential for synthesis is studied in [5]. All those works consider games played on a game structure with classical ω-regular objectives and provide tight complexity results for almost all the relevant synthesis problems. This is not the case for *cooperative* and *non-cooperative rational synthesis* for which only the complexity for specifications given in LTL was known [14, 19]. This paper provides algorithms and precise computational complexity results.

Structure of the paper. In Sect. 2, we recall the definition of the cooperative and non-cooperative synthesis problem as introduced in [14, 19], together with the game structure variant and objectives that we study here. Sect. 3 provides lower and upper complexity bounds for the cooperative rational synthesis problem. Sect. 4 provides results for the non-cooperative variant. Sect. 5 summarizes complexity results when the number of players is fixed. Due to the lack of space, we provide sketches of proof of our results in this paper and all the detailed proofs can be downloaded at the following address: [12].

2 Multiplayer Games and Rational Synthesis

Multiplayer Games. Let $k \in \mathbb{N}$. A *multiplayer arena* $(k+1)$-players arena is a tuple $\mathcal{A} = \langle \Omega, V, (V_i)_{i\in\Omega}, E, v_0 \rangle$, where $\Omega = \{0, 1, ..., k\}$ is a finite set of players, (V, E) is a finite directed graph whose vertices are called *states*, $v_0 \in V$ is the initial state and $(V_i)_{i\in\Omega}$ is a partition of V where V_i is the set of states controlled by Player $i \in \Omega$. A *play* in $\mathcal{A}$ starts in the initial state v_0 and proceeds in rounds. At each round, the player controlling the current state chooses the next position according to $E \subseteq \bigcup_{i\in\Omega} V_i \times V_{i+1 \bmod k}$.[1]. Formally, a play $\pi = v_0 v_1 \dots$ is an infinite path in V^ω such that v_0 is the initial state and $(v_i, v_{i+1}) \in E$ for each $i \geqslant 0$. The prefix (or history) of π up to v_n is written $\pi[:n]$ and its last state $\pi(n)$. We denote by $\sqsubset$ the prefix relation, by $\mathsf{Plays}(\mathcal{A})$ the set of plays, and by $\mathsf{Prefs}(\mathcal{A})$ for its set of finite prefixes. For $\pi \in V^\omega$, $\inf(\pi)$ is the set of states occurring infinitely many times in π.

A *strategy* of Player $i \in \Omega$ in $\mathcal{A}$ is a total function $\sigma_i : V^*V_i \mapsto V$ s.t. for all $x \in V^*$, for all $v \in V_i$, $(v, \sigma_i(xv)) \in E$. Note that as rounds are ordered, σ_i has type $V^*V_i \mapsto V_{i+1 \bmod k}$. A play π is *consistent* with σ_i if $\pi(n+1) = \sigma_i(\pi[:n])$ for all $n \geqslant 0$ s.t. $\pi(n) \in V_i$. The *outcome* of σ_i is the set of plays $out(\sigma_i) \subseteq \mathsf{Plays}(\mathcal{A})$ that are consistent with σ_i. Given $h \in V^*$, we define $\sigma_i|_h$ as $\sigma_i|_h(h') = \sigma_i(hh')$ for all $h' \in V^*V_i$. A *winning objective* (or just objective) is

[1] Wlog. we assume that each vertex has a successor by E and that player's rounds are ordered according to their index. Otherwise we just add a polynomial number of extra intermediate states and the winning objectives considered in this paper can be modified accordingly.

a set $\mathcal{O} \subseteq V^\omega$. It is *tail* if it is closed under removing prefixes. A Player i's strategy σ_i is *winning*[2] for $\mathcal{O}$ if $out(\sigma_i) \subseteq \mathcal{O}$. We consider the classical classes of objectives [17]:

- *Safety/Reachability*: Given a set $S \subseteq V$ of safe states, $\mathsf{Safe}(S) = \{\pi \in V^\omega \mid \forall n \geqslant 0 : \pi(n) \in S\}$ and given a set T of target states, $\mathsf{Reach}(T) = \{\pi \in V^\omega \mid \exists n \geqslant 0 : \pi(n) \in T\} = \overline{\mathsf{Safe}(\overline{T})}$.
- *Büchi/coBüchi*: Given a set $F \subseteq V$, $\mathsf{Buchi}(F) = \{\pi \in V^\omega \mid \inf(\pi) \cap F \neq \varnothing\}$ and $\mathsf{coBuchi}(F) = \{\pi \in V^\omega \mid \inf(\pi) \cap F = \varnothing\} = \overline{\mathsf{Buchi}(F)}$.
- *Streett/Rabin*: Given a set $\Psi \subseteq 2^V \times 2^V$, $\mathsf{Streett}(\Psi) = \bigcap_{(L,R)\in\Psi}(\mathsf{coBuchi}(L) \cup \mathsf{Buchi}(R))$ and $\mathsf{Rabin}(\Psi) = \bigcup_{(L,R)\in\Psi}(\mathsf{Buchi}(L) \cap \mathsf{coBuchi}(R)) = \overline{\mathsf{Streett}(\Psi)}$.
- *Parity*: For a priority mapping $p{:}V \to \mathbb{N}$, $\mathsf{Parity}(p) = \{\pi \in V^\omega \mid \min\{p(v) | v \in \inf(\pi)\} \text{ is even}\}$.
- *Muller*: Given a Boolean formula μ over V, $\mathsf{Muller}(\mu) = \{\pi \in V^\omega \mid \inf(\pi) \models \mu\}$.

A *multiplayer game* is a pair $\mathcal{G} = \langle \mathcal{A}, (\mathcal{O}_i)_{i\in\Omega} \rangle$ where $(\mathcal{O}_i)_{i\in\Omega}$ is the tuple of objectives for each Player $i \in \Omega$. For all class of objectives X, we say that $\mathcal{G}$ is a multiplayer X-game if all objectives $\mathcal{O}_i$ are in X. The notations Plays and Prefs carries over naturally to $\mathcal{G}$ by considering its underlying arena. For $v \in V$, one denotes by $\mathcal{G}[v]$ the game $\mathcal{G}$ whose initial state is replaced by v (winning objectives are unchanged). A state $v \in V$ is *winning* for Player i if he has a winning strategy in $\mathcal{G}[v]$, and one denotes by $W_i^{\mathcal{G}}$ (or just W_i) the set of *winning states* of Player i, also called the *winning set* of Player i.

Nash Equilibria. A *strategy profile* $\bar{\sigma}$ in a multiplayer game $\mathcal{G} = \langle \mathcal{A}, (\mathcal{O}_i)_{i\in\Omega} \rangle$ is a tuple $\bar{\sigma} = (\sigma_i)_{i\in\Omega}$ of strategies, one for each player. The *outcome* $out(\bar{\sigma})$ of $\bar{\sigma}$ is the only play consistent with all strategies σ_i (it always exists and is unique). Given a strategy τ for Player i, we write $(\bar{\sigma}_{-i}, \tau)$ for the strategy profile obtained by replacing σ_i with τ in $\bar{\sigma}$. For winning objectives $(\mathcal{O}_i)_{i\in\Omega}$ for each player, the *payoff* of a strategy profile $\bar{\sigma}$ is the vector $pay(\bar{\sigma}) \in \{0,1\}^{\{k+1\}}$ defined by $pay(\bar{\sigma})[i] = 1$ iff $out(\bar{\sigma}) \in \mathcal{O}_i$. We write $pay_i(\bar{\sigma})$ for Player i's payoff in $pay(\bar{\sigma})$. Payoffs are compared by the pairwise natural order on their bits, denoted by $\leqslant$, i.e. $pay(\bar{\sigma}) \leqslant pay(\bar{\beta})$ if $pay_i(\bar{\sigma}) \leqslant pay_i(\bar{\beta})$ for all $i \in \Omega$.

A strategy profile $\bar{\sigma} = (\sigma_i)_{i\in\Omega}$ is called a *Nash equilibrium* (NE) if no player can improve his payoff by (unilaterally) switching to a different strategy, i.e. for all players $i \in \Omega$ and all strategies τ of Player i, $pay(\bar{\sigma}_{-i}, \tau) \leqslant pay(\bar{\sigma})$. We say that $\bar{\sigma}$ is a 0-*fixed* Nash equilibrium (0NE) if $pay(\bar{\sigma}_{-i}, \tau) \leqslant pay(\bar{\sigma})$ for all players $i \in \Omega \backslash \{0\}$ and all strategies τ of i. In other words, it is a Nash equilibrium in which Player 0 is not allowed to deviate. Any NE is 0-fixed, but the converse may not hold.

Cooperative and non-cooperative rational synthesis. Rational synthesis aims at finding a winning strategy for the system (Player 0) against an environment composed of several components (Players 1 to k) that are assumed to play rationally. Rationality of the environment is modeled by NE, and following [14, 19], we consider two settings, depending on whether the environment cooperates or not: The cooperative and non-cooperative rational synthesis problems (CRSP and NCRSP resp.) ask, given as input a $(k+1)$-player game $\mathcal{G}$ with winning objectives $(\mathcal{O}_i)_{i\in\Omega}$, the following questions according to the two settings:

cooperative: Is there a 0-fixed Nash equilibrium $\bar{\sigma}$ such that $pay_0(\bar{\sigma}) = 1$?

non-cooperative: Is there a strategy σ_0 for Player 0 such that for every 0-fixed Nash equilibrium $\bar{\sigma} = \langle \sigma_0, \ldots, \sigma_k \rangle$, we have $pay_0(\bar{\sigma}) = 1$?

[2] Here we implicitly consider a two-player zero-sum game in which Player i has objective $\mathcal{O}$ and plays against all the other players in $\Omega \backslash \{i\}$ who have objective $\overline{\mathcal{O}}$.

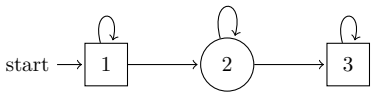

Figure 1 Example for rational synthesis.

▶ **Example 1.** Consider Figure 1 in which Player 0 owns round states and Player 1 square states, with the reachability objectives $R_0 = \{2\}$ and $R_1 = \{3\}$. Consider the Player 0's strategies σ_0 which loops forever in state 2, and σ_0' which eventually moves to state 3.

Let Player 1 cooperate with σ_1 that moves to state 2 (making Player 0 win). Both strategy profiles $\langle \sigma_0, \sigma_1 \rangle$ and $\langle \sigma_0', \sigma_1 \rangle$ are solutions to the cooperative setting: for the first strategy profile Player 1 loses but cannot get better payoff by deviating, and for the later one Player 1 wins. Strategy σ_0 is not a solution to the non-cooperative setting: Player 1 could stay forever in state 1 (according to a strategy σ_1'). The profile $\langle \sigma_0, \sigma_1' \rangle$ is a 0-fixed NE because even by deviating and going to state 2 Player 1 would still lose, and it is losing for Player 0. However, σ_0' is a solution to the non-cooperative setting: The only 0-fixed NE in that case are when Player 1 eventually move to state 2, making him and Player 0 win.

In [14, 19], both CRSP and NCRSP are shown 2EXPTIME-COMPLETE when the winning objectives are defined by LTL formulas, through a reduction to strategy logic. In this paper, we refine this complexity result for particular kinds of winning objectives. In general, the synthesis problem also asks to *synthesise* (i.e. construct) a solution when it exists: Our algorithms also solve the synthesis problem.

3 Cooperative Rational Synthesis Problem (CRSP)

We establish here complexity bounds for CRSP for unfixed number of players. First, some results are obtained as special cases of constrained NE problems [25]. The constrained NE problem asks to decide, given a $k+1$-player game $\mathcal{G} = \langle \mathcal{A}, (\mathcal{O}_i)_{i \in \Omega} \rangle$, and for each player i, a lower bound $l_i \in \{0,1\}$ and an upper bound $u_i \in \{0,1\}$ such that $l_i \leqslant u_i$, whether there exists a NE $\overline{\sigma}$ s.t. $l_i \leqslant pay_i(\overline{\sigma}) \leqslant u_i$ for all $i \in \Omega$. CSRP is a special case of this problem, by setting $l_0 = u_0 = 1$, $l_i = 0$ and $u_i = 1$ for all $i \in \Omega \backslash \{0\}$. The constrained NE problem is known to be in PTIME for Büchi objectives, and in NP for co-Büchi, Streett and parity objectives [25]. So one immediately gets the upper bounds of Table 1 for these measures (and unfixed k).

To establish the remaining upper bounds, we characterize NE by means of LTL formulas. We extend the technique used in [25] for tail objectives to safety and reachability.

Generic solution to cooperative rational synthesis. Syntax and semantics of LTL can be found in [2]. Let V be the set of vertices of $\mathcal{G}$. We use LTL formulas to express properties of infinite paths of $\mathcal{G}$, where we take V as set of atomic propositions. In particular, $s \in V$ is true in s, and false otherwise. For $S \subseteq V$, the formula S is a shortcut for $\bigvee_{s \in S} s$, and LTL($\mathcal{G}$) denotes the set of LTL formulas over V. Let $(W_i^{\mathcal{G}})_{0 \leqslant i \leqslant k}$ be the winning sets of each player and $b \in \{0,1\}$. We define an LTL[$\mathcal{G}$]-formula $\phi_{b\text{Nash}}^{\mathcal{G}}$ that will characterize NE ($b = 1$) and 0-NE ($b = 0$):

$$\phi_{b\text{Nash}}^{\mathcal{G}} = \begin{cases} \bigwedge_{i=1-b}^{k} ((\neg W_i^{\mathcal{G}} \,\mathcal{U}\, \neg S_i) \vee \Box S_i) & \text{if } \mathcal{O}_i \text{ are safety objectives of the form} \\ & \mathcal{O}_i = \mathsf{Safe}(S_i) \text{ for } S_i \subseteq V \\ \bigwedge_{i=1-b}^{k} \neg \varphi_i \rightarrow \Box \neg W_i^{\mathcal{G}} & \text{if } \mathcal{O}_i \text{ are either all reachability or all tail} \\ & \text{objectives definable by a LTL}[\mathcal{G}] \text{ formula } \varphi_i \end{cases}$$

Assume that $b = 1$, and consider the formula for safety objectives. Intuitively, it says that for all players $i \in \{0, \dots, k\}$, either Player i always stays safe, or if eventually he visits an unsafe position, then he should never visit a winning position until he meets an unsafe position for the first time. This is because otherwise he could apply a winning strategy and satisfy his own objective, and therefore has some incentive to deviate. As announced:

▶ **Proposition 2** (Characterization of 0-fixed NE and NE ([25] for tail objectives)). *Let $\mathcal{G}$ be a multiplayer game with either all safety, all reachability, or all tail objectives, definable in LTL[$\mathcal{G}$]. Then, the following hold:*

1. *For all $\pi \in \mathit{Plays}(\mathcal{G})$, if $\pi \models \phi^{\mathcal{G}}_{0Nash}$ (resp. $\pi \models \phi^{\mathcal{G}}_{1Nash}$), then there exists a 0-fixed NE (resp. NE) $\bar{\sigma}$ in $\mathcal{G}$ such that $out(\bar{\sigma}) = \pi$,*
2. *For all 0-fixed NE (resp. NE) $\bar{\sigma}$ in $\mathcal{G}$, $out(\bar{\sigma}) \models \phi^{\mathcal{G}}_{0Nash}$ (resp. $out(\bar{\sigma}) \models \phi^{\mathcal{G}}_{1Nash}$).*

Based on the latter proposition, it is not difficult to design a procedure to decide CRSP: first, compute the winning sets W_i, and then check whether the game $\mathcal{G}$ contains a path which satisfies the formula $\phi^{\mathcal{G}}_{0\text{Nash}} \wedge \phi_0$, where ϕ_0 is the objective of Player 0, expressed in LTL[$\mathcal{G}$]. To establish precise upper bounds, one needs to consider the complexity of computing the winning sets, and then the complexity of model-checking these particular LTL formulas. Due to lack of space, we cannot cover all the cases, but let us briefly expose the case of safety conditions. For safety, it is well-known that computing the sets W_i can be done in PTime. Then, we prove a short witness property: if there exists a path satisfying the formula $\phi^{\mathcal{G}}_{0\text{Nash}} \wedge \phi_0$, then there exists a lasso path uv^ω such that u and v have polynomial length. Therefore, it suffices to guess such a lasso path, and to check that it satisfies the formula $\phi^{\mathcal{G}}_{0\text{Nash}} \wedge \phi_0$, which again can be done in PTime. This yields an NP algorithm for safety CRSP. Similar arguments apply for reachability.

Lower bounds. In [25] was shown the NP-hardness of the threshold NE problem for coBüchi objectives and thresholds $l_0 = u_0 = 1$, $l_i = 0$ and $u_i = 1$, $\forall i \in \{1, \dots, k\}$. Therefore, one immediately gets the NP lower bounds of Table 1 for coBüchi objectives, Streett, Rabin and parity objectives, which can (polynomially) express coBüchi objectives. For the other cases, we provide lower bounds with genuine reductions. For Muller objectives, we show that it is already PSpace-hard even for two players and the precise complexity results for a fixed number of players are discussed in the last section of the paper. We finish the section by showing the NP-hardness proof for the safety case (which was not considered in [25]).

▶ **Lemma 3.** *CRSP for multiplayer safety objectives is NP-hard.*

Proof. By reduction from $3SAT$. Given a set of clauses $S = \{C_1, \dots, C_k\}$, one constructs the $(k+1)$-player safety game of Fig. 2. Up to vertex C_1, the previous states are controlled by Player 0, and each state C_i is controlled by Player i. All states but U_s are safe for Player 0. For all $i \in \{1, \dots, k\}$, U_e is unsafe for Player i, as well as the state 0_x if $\neg x$ appears in C_j, and the state 1_x if x appears in C_j. If S is satisfiable by some valuation ν, then Player 0 chooses, in state x, the successor $\nu(x)_x$. That way, Player 1 to k have visited an unsafe state before reaching C_1, and have no incentive to deviate if their strategy is to go to U_e. Conversely, if there is a solution to CRSP, necessarily the game end up in U_e, as Player 0 must be winning. It means that before reaching the states C_i all safety conditions for Players 1 to k have been violated, otherwise going to U_s could be a profitable deviation. In other words, for all clauses i, there exists a literal ℓ in C_i such that 1_x (resp. 0_x) has been visited if $\ell = x$ (resp. if $\ell = \neg x$). So the truth values chosen by Player 0 satisfies S.

◀

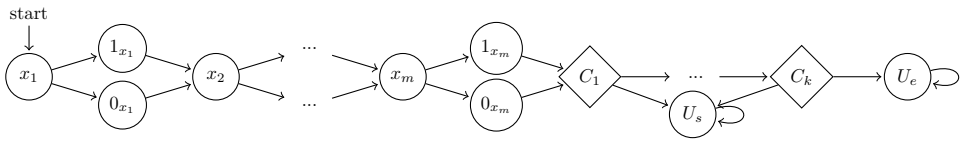

Figure 2 Cooperative Safety: Reduction from 3-SAT.

4 Non-Cooperative Rational Synthesis Problem (NCRSP)

We study here the complexity of NCRSP for unfixed number of players. In this setting, cooperation of the environment is not assumed, and so the system has to win against all 0-fixed NE. In Prop. 2, we have characterised 0-fixed NE by means of an LTL formula $\phi^{\mathcal{G}}_{0\text{Nash}}$. This allowed us to solve CRSP via a reduction to model-checking. It is tempting to think that NCRSP reduces to a two-player zero-sum game between Player 0, whose objective is $\phi^{\mathcal{G}}_{0\text{Nash}} \rightarrow \varphi_0$, and the coalition of the other players. However, Example 1 shows that this is not true in general. Indeed, in this example there is a solution to NCRSP, but no solution to the two-player game with objective $(\Box\bar{R}_1 \rightarrow \Box\bar{W}_1) \rightarrow \Diamond R_0$. Since $W_1 = \{3\}$, whatever the strategy of Player 0 is, if Player 1 stays in state 1 forever, the path $\pi = (1)^\omega$ satisfies $(\Box\bar{R}_1 \rightarrow \Box\bar{W}_1)$ but not $\Diamond R_0$ and therefore Player 0 loses. The intrinsic reason why the reduction to two-player games is incorrect lies in the definition of NCRSP: once a Player 0's strategy σ_0 is fixed, only 0-fixed NE with respect to σ_0 are considered, while the formula $\phi_{0\text{Nash}}$ can be satisfied by paths which are outcomes of other 0-fixed NE, i.e. for a different strategy of Player 0.

The non-cooperative case is more involved and requires tree automata based techniques: we see strategies σ_0 as trees t_{σ_0}, and use *tree automata* to define the set of solutions to NCRSP. Testing existence of a solution then reduces to tree automata non-emptiness.

Strategy trees and good deviations. Let Λ be a finite set of directions and Σ be an alphabet. A Σ-labeled Λ-tree is a mapping $t : \Lambda^* \rightarrow \Sigma$. Its set of nodes is Λ^*. Let $\mathcal{A}$ be a $k+1$-player arena with set of states V, and let $\sigma_0 : V^*V_0 \rightarrow V$ be a strategy of Player 0 in $\mathcal{A}$. We explain how σ_0 is encoded as a tree. The labels are in the set $\Sigma = V \cup \{*_i \mid 1 \leqslant i \leqslant k\} \cup \{\#\}$, and the set of directions is $\Lambda = V$. Therefore, any node of the tree is a history h. Then, if $h = \epsilon$ (root node), we set its label to $\#$. Otherwise, it is of the form $h = h'v$, then there are two cases: (i) if $v \in V_0$, then $t_{\sigma_0}(h) = \sigma_0(h)$, (ii) if $v \in V_i$ for $i \neq 0$, then $t_{\sigma_0}(h) = *_i$ (only the turn i is encoded). We denote by T_0 the set of strategy trees t_{σ_0}. Note that each Σ-labeled V-tree represents a partial function from V^* to Σ, which may not be a strategy, because it is not total and may not be consistent with the edge relation E of the arena. A *branch* in t_{σ_0} is an infinite sequence of directions $\pi \in V^\omega$. It is *compatible* with σ_0 if for all finite prefixes h of π whose last state is in V_0, $h.t_{\sigma_0}(h)$ is a prefix of π.

We now want to characterize the strategy trees t_{σ_0} s.t. σ_0 is a solution to NCRSP in a game $\mathcal{G} = \langle \mathcal{A}, (\mathcal{O}_i)_{i\in\Omega} \rangle$ with either all safety, all reachability, or all tail objectives. Consider a branch π of t_{σ_0} compatible with σ_0: It is not the outcome of a σ_0-fixed NE iff some player loses ($\pi \notin \mathcal{O}_i$ for some $i \neq 0$) and there is a prefix h from which Player i has a winning strategy against all other players (and the strategy σ_0). We call the history h a good deviation point. Formally, h is a *good deviation point* if there exists $i \in \{1, \dots, k\} = \Omega\backslash\{0\}$ s.t. $\pi \notin \mathcal{O}_i$ and there is a strategy σ_i for Player i s.t. for all strategies $(\sigma_j)_{i\in\{1,\dots,k\}\backslash\{i\}}$, $h.out(\sigma_0|_h, ..., \sigma_{i-1}|_h, \sigma_i|_h, \sigma_{i+1}|_h, ..., \sigma_k|_h) \in \mathcal{O}_i$. A branch $\pi \in V^\omega$ has a *good deviation* if some of its prefix h is a good deviation point. Let us denote by $\mathsf{NCRSP}(\mathcal{G})$ the set of strategy trees t_{σ_0} such that σ_0 is a solution to the NCRSP in $\mathcal{G}$. Then:

▶ **Lemma 4.** *For all strategies σ_0 of Player 0, $t_{\sigma_0} \in \mathsf{NCRSP}(\mathcal{G})$ iff for all branches π of t_{σ_0} compatible with σ_0, either $\pi \in \mathcal{O}_0$ or π has a good deviation.*

Reduction to tree-automata emptiness. Based on Lemma 4, we construct a non-deterministic automaton defining $\mathsf{NCRSP}(\mathcal{G})$. A *non-deterministic tree automaton* $\mathcal{T}$ over Σ-labeled Λ-trees is a tuple (Q, Q_0, δ) where Q is a finite set of states, $Q_0 \subseteq Q$ is a finite set of initial states, and δ is a transition relation of the form $\delta : Q \times \Sigma \to 2^{\Lambda \to Q}$, i.e., it maps any pair of states and labels to a set of mappings from directions to states (states sent the children of the current node). A *run* of $\mathcal{T}$ on a tree t is Q-labeled Λ-tree $r : \Lambda^* \to Q$ such that $r(\epsilon) \in Q_0$ and for all $h \in \Lambda^*$, all $d \in \Lambda$, the mapping $d \in \Lambda \mapsto r(hd) \in Q$ is in $\delta(r(h), t(h))$. The image of a branch $\pi = \lambda_1\lambda_2 \cdots \in \Lambda^\omega$ by r is the word in Q^ω defined by $r(\epsilon)r(\lambda_1)r(\lambda_1\lambda_2)\ldots$. With respect to an accepting condition $\alpha \subseteq Q^\omega$, r is accepting if the images of all its branches are in α, and the *language* of $\mathcal{T}$ is the set $\mathcal{L}_\alpha(T)$ of trees for which there exists an accepting run.

▶ **Lemma 5.** *Let $\mathcal{G} = \langle \mathcal{A}, \mathcal{O} = (\mathcal{O}_i)_{i\in\Omega}\rangle$ be a $(k+1)$-player game with n vertices. One can construct a non-deterministic tree automaton $\mathcal{T}_\mathcal{A}$ (with an exponential number of states in k, and polynomial in $|V|$) with an accepting condition $\alpha_\mathcal{A}(\mathcal{O})$ such that $\mathcal{L}_{\alpha_\mathcal{A}(\mathcal{O})}(\mathcal{T}_\mathcal{A}) = \mathsf{NCRSP}(\mathcal{G})$. Moreover, for all runs r of $\mathcal{T}_\mathcal{A}$, for all branches π of r, the number of states appearing in π is polynomial in $|V|$ and k.*

Proof. We sketch the construction of $\mathcal{T}_\mathcal{A}$ and the definition of $\alpha_\mathcal{A}(\mathcal{O})$. First, it is not difficult to make sure that $\mathcal{T}_\mathcal{A}$ only accepts trees that are strategy trees: It has to remember the last direction v taken and make sure that if $v \in V_0$, the current node is labeled by some $v' \in V$ s.t. $(v, v') \in E$, and otherwise by the symbol $*_i$ if $v \in V_i$. This requires only a polynomial number of states. Therefore in the following, we assume that $\mathcal{T}_\mathcal{A}$ only runs on proper tree encodings t_{σ_0} of strategies σ_0.

The construction of $\mathcal{T}_\mathcal{A}$ is based on Lemma 4: For each branch of t_{σ_0}, it will check that either it is not compatible with σ_0, or it belongs to $\mathcal{O}_0$, or it will guess a prefix and check it is a good deviation. To guess good deviations, $\mathcal{T}_\mathcal{A}$ has to guess subtrees in which players have a winning strategy. This information is stored in a set $W \subseteq \Omega$, with the following semantics: if $\mathcal{T}_\mathcal{A}$ is in some state with set W at some node $h \in V^*$ and $i \in W$, then Player i has a winning strategy from h against σ_0 and any strategy of the players in $\Omega\backslash\{0, i\}$ for objective $\mathcal{O}_i$. The set of players for which a good deviation has been guessed is stored in a set $D \subseteq \Omega$, with the following semantics: if $\mathcal{T}_\mathcal{A}$ is in some state with set D and $i \in D$, at some node $h \in V^*$, then some prefix of h is a good deviation. The information on W is maintained as follows: at some node $hv \in V^*$, if $i \in W$ and $v \in V_i$, then $\mathcal{T}_\mathcal{A}$ non-deterministically send W to one of the successor of v (and $W\backslash\{i\}$ in the other ones) and if $v \notin V_i$, $\mathcal{T}_\mathcal{A}$ sends W in all successors of v. The information D is monotonic: either the current node h (owned by Player i) is not guessed to be a good deviation for any player and D is sent to all successors, or it is guessed to be a good deviation for Player i, $i \notin D$, and then $D \cup \{i\}$ (and W) is sent to all successors but one in which is sent D and $W \cup \{i\}$. This monotonic behavior is crucial for obtaining algorithms with optimal worst-case complexities.

Formally, $\mathcal{T}_\mathcal{A} = (Q, \{q_0\}, \delta)$ with $Q = \{q_0, \top\} \cup (2^\Omega \times 2^\Omega \times V)$. Then, we have $\delta(q_0, \#) = \{\rho_0\}$ where $\rho_0(v_0) = (\varnothing, \varnothing, v_0)$ and $\rho_0(v) = \bot$ for all $v \neq v_0$. For all $q = (W, D, v) \in Q$ such that $v \in V_0$ and all $v' \in V$, $\delta(q, v') = \{\rho_{v'}\}$ where $\rho_{v'}(v') = (W, D, v')$ and $\rho_{v'}(v'') = \bot$ for all $v'' \neq v'$ (the latter case correspond to directions v'' which are not compatible with the strategy). For all $v \neq \#$, $\delta(\top, v) = \{\rho_\top\}$ where $\rho_\top(v') = \top$ for all $v' \in V$. Then, for a state $q = (W, D, v)$ and a label $*_i$ ($i \neq 0$), we consider four cases:

1. $i \in D \cap W$: Such a state will never be reachable by construction.
2. $i \in D \cap \overline{W}$: In this case, we just propagate the information D and W. I.e. $\delta(q, *_i) = \{\rho\}$ s.t. $\rho(v') = (W, D, v')$ for all $(v, v') \in E$.
3. $i \in W \cap \overline{D}$: In this case, one has to check that Player i has a winning strategy in some successor of v', which is guessed non-deterministically, and to which the W information is sent. I.e. $\delta(q, *_i) = \{\rho_{v'} \mid (v, v') \in E\}$ where $\rho_{v'}(v') = (W, D, v')$ and $\rho_{v'}(v'') = (W \backslash \{i\}, D \cup \{i\}, v')$ for all $v'' \neq v'$.
4. $i \in \overline{W} \cap \overline{D}$: In this case, either we do not guess anything, or we guess that Player i has a good deviation, and update the sets W and D accordingly. I.e. $\delta(q, *_i) = \{\rho\} \cup \{\gamma_{v'} \mid (v, v') \in E\}$ where $\gamma_{v'}(v') = (W \cup \{i\}, D, v')$ and $\gamma_{v'}(v'') = (W, D \cup \{i\}, v')$ for all $v'' \neq v'$.

Along a path of a run of $\mathcal{T}_{\mathcal{A}}$, there are monotonicity properties for the W and D-components of the states. Indeed, by construction, $\mathcal{T}_{\mathcal{A}}$ never removes a player from D. For W, a player i can be removed (case 3) but then it is added to D and, once a player belongs to D, it can never be added to W again. It is correct since for a history h, if one guesses that Player i has a winning strategy from history hv, then i is added to D for all successors hv' ($v' \neq v$) and there is no need to guess again later on a good deviation for Player i in the subtrees rooted at the nodes hv', and therefore no need to add i in W again. Therefore along a path η of a run, there is only a polynomial number of different components D and W, and they necessarily stabilize eventually, to a set that we denote by $\lim_D(\eta)$ and $\lim_W(\eta)$.

Finally, the accepting condition $\alpha_{\mathcal{A}}(\mathcal{O})$ asks that on each path of the accepting run, either it is of the form $Q^*\{\bot\}^\omega$, or Player 0 wins, or there is a player that loses but belongs to some D eventually. For safety objectives, we also have to add the constraint that the losing player belongs to D before visiting an unsafe state. Additionally, the accepting condition also expresses constraints on the W components: each player $i \in \lim_W(\eta)$ wins. Formally, if we denote by $\mathrm{IRuns}(\mathcal{T}_{\mathcal{A}})$ the set of images of branches of runs of $\mathcal{T}_{\mathcal{A}}$, and by $\eta|_V$ the V-projection of any $\eta \in (Q\backslash\{\bot\})^\omega$, we have:

$$\alpha_{\mathcal{A}}(\mathcal{O}) = Q^*\{\top\}^\omega \cup (\{\eta \in \mathrm{IRuns}(\mathcal{T}_{\mathcal{A}}) \cap (Q\backslash\{\top\})^\omega \mid \eta|_V \in \mathcal{O}_0 \vee \bigvee_{i=1}^{k} \left(\eta|_V \notin \mathcal{O}_i \wedge \varphi_{\exists dev}(i, \eta)\right)\} \cap$$
$$\cap \{\eta \in \mathrm{IRuns}(\mathcal{T}_{\mathcal{A}}) \cap (Q\backslash\{\top\})^\omega \mid \bigwedge_{i \in \lim_W(\eta)} \eta|_V \in \mathcal{O}_i\})$$

where the formula $\varphi_{\exists dev}(i, \eta)$ says that there is a good deviation for Player i. That is, if $D_0 D_1 \ldots$ is the sequence of D-components in η, then $\varphi_{\exists dev}(i, \eta) = i \in \lim_D(\eta)$ for tail or reachability objectives, and $\varphi_{\exists dev}(i, \eta) = \exists p \geqslant 0, i \in D_p \wedge \forall p' \leqslant p, \eta|_V[p] \in S_i$ for safety conditions $\mathsf{Safe}(S_i)$. Details can be found in the technical report. ◀

Tree automata emptiness. We now study the complexity of testing non-emptiness of the languages $\mathcal{L}_{\alpha_{\mathcal{A}}(\mathcal{O})}(\mathcal{T}_{\mathcal{A}})$ for the objectives $\mathcal{O}$ of this paper. Classically, non-deterministic tree automata emptiness is reduced to solving a two-player zero sum game between Eve, who constructs a tree and a run on this tree, and Adam, whose goal is to prove that the run is non-accepting, by choosing directions in the tree and falsifying the acceptance condition. Formally, remind that the alphabet is $\Sigma = V \cup \{*_i \mid 1 \leqslant i \leqslant k\} \cup \{\bot\}$ and for a function $f : V \to Q$, we denote by $\mathsf{Range}(f)$ its range. We construct a zero-sum two-player game $\mathcal{G}' = \langle V_E, V_A, E', q_0 \rangle$ where $V_E = Q$, $V_A = \{\mathsf{Range}(f) \mid \exists q \in Q, \alpha \in \Sigma, f \in \delta(q, \alpha)\}$. Then, the transition relations is defined for all $q \in Q$, all $P \in V_A$, by $(q, P) \in E'$ if there exists $\alpha \in \Sigma$ and $f \in \delta(q, \alpha)$ s.t. $P = \mathsf{Range}(f)$, and $(P, q) \in E'$ if $q \in P$. That is, to go from q to P, Eve chooses a symbol α and a function $f : V \to Q$ in $\delta(q, \alpha)$. Then, Adam chooses a direction in V, but since he wants to construct a sequence of states not in $\alpha_{\mathcal{A}}(\mathcal{O})$, one only

needs to remember $\mathsf{Range}(f)$. Adam then picks a state in that set. Eve's objective is the set $\{q_1w_1q_2w_2\cdots \in (V_EV_A)^\omega \mid q_1q_2\cdots \in \alpha_{\mathcal{A}}(\mathcal{O})\}$. It can be shown that Eve has a winning strategy in $\mathcal{G}'$ iff $\mathcal{L}_{\alpha_{\mathcal{A}}(\mathcal{O})}(\mathcal{T}_{\mathcal{A}}) \neq \varnothing$. By a fine analysis of solving this game, we obtain:

▶ **Proposition 6.** *Let $\mathcal{G} = \langle \mathcal{A}, \mathcal{O} = (\mathcal{O}_i)_{i\in\Omega}\rangle$ be a multiplayer game. Non-emptiness of $\mathcal{L}_{\alpha_{\mathcal{A}}(\mathcal{O})}(\mathcal{T}_{\mathcal{A}})$ can be checked in* PSpace *for $\mathcal{O} \in \{\mathsf{Safety}, \mathsf{Reachability}, \mathsf{Büchi}, \mathsf{coBüchi}\}$, and in* ExpTime *for $\mathcal{O} \in \{\mathsf{Parity}, \mathsf{Streett}, \mathsf{Rabin}, \mathsf{Muller}\}$.*

Proof. It amounts to study the complexity of solving $\mathcal{G}'$ for the objectives of this paper. Note that the arena of $\mathcal{G}'$ has linear size in the size of $\mathcal{T}_{\mathcal{A}}$. For safety, reachability, Büchi and coBüchi winning objectives, we reduce the problem of solving $\mathcal{G}'$ to a finite duration reachability tree game of exponential size, whose duration is polynomial (in the size of the original arena of $\mathcal{G}$). This reduction exploits the monotonicity of the sets W and D, and the fact that the game can be stopped once a cycle has been formed. It is similar in spirit to the technique of *first-cycle game* from [1] but the winning condition of $\mathcal{G}'$ do not fall in the general hypothesis of [1] under which infinite duration games reduce to first-cycle games. Our finite duration tree game, though of exponential size, is not constructed explicitly but solved on-the-fly by a PTime alternating algorithm. This gives a PSpace upper-bound for NCRSP.

We now study the complexity of solving $\mathcal{G}'$ when the original game $\mathcal{G}$ has Muller conditions $\mathsf{Muller}(\mu_i)$ for the $k+1$ players. We transform $\mathcal{G}'$ into a two-player zero-sum parity game with an exponential number of states but a polynomial number of priorities, which can be solved in ExpTime (in the size of $\mathcal{G}$). This reduction is based on the *Last Appearance Record (LAR)* [15, 26], which allows us to identify states in V appearing infinitely often. Formally, V is assumed to be linearly ordered, i.e. $V = \{v_1, \ldots, v_n\}$. We let $P(V)$ the set of permutations of V, which we represent by words of length n over V with pairwise different letters. We define a deterministic finite automaton $LAR_V = (P(V) \times \{0, \ldots, |V|-1\}, (m_0, h_0), \to)$, $m_0 = v_1 \ldots v_n$ and $h_0 = 1$, and $(m, h) \xrightarrow{v} (x_1x_2v, |x_1|)$ where $m = x_1vx_2 \in P(V)$ for some $x_1, x_2 \in V^*$ and $v \in V$. Positions h are called *hits*. LAR_V has the following property: take a sequence $\pi \in V^\omega$ and the associated sequence of LAR_V's states $\ell = (m_0, h_0)(m_1, h_1)\ldots$, let h^π_{min} be the smallest hit appearing infinitely often in ℓ, then the sequence of subsets $(\{m_i[r] \mid r \geqslant h^\pi_{min}\})_{i\geqslant 0}$ eventually equals $\inf(\pi)$.

Remind that $Q = \{q_0, \top\} \cup (2^\Omega \times 2^\Omega \times V)$, therefore each sequence of states not in $Q^*\{\top\}^\omega$ also gives the sequence of visited vertices of $\mathcal{G}$. We take the product of $\mathcal{G}'$ with LAR_V to add LAR information to the game $\mathcal{G}'$, and transform Eve's winning condition in $\mathcal{G}'$ into a parity condition pr in this product as follows: one uses $2|V|+2$ priorities and, for product states with q_0 or $\top$ as first component, the priority is 0, otherwise for states of the form $((W, D, v), (m, h))$, we let:

$$pr((W,D,v),(m,h)) = \begin{cases} 2h & \text{if } \forall i \in W, \{m[r] \mid r \geqslant h\} \models \mu_i \text{ and} \\ & \quad (\{m[r] \mid r \geqslant h\} \models \mu_0 \text{ or } \exists i \in D \text{ s.t. } \{m[r] \mid r \geqslant h\} \models \neg\mu_i) \\ 2h+1 & \text{otherwise} \end{cases}$$

For states whose first component belongs to Adam, we just put priority $2|V|+2$, so that they have no influence. That way we obtain a parity game $\mathcal{G}_{par}$ with an exponential number of states (in $\mathcal{G}$) but a polynomial number of priorities, in which Eve has a winning strategy iff she has a winning strategy in $\mathcal{G}'$. Finally, parity games can be solved in PTime in the number of states and exponential in the number of priorities [18, 22]. ◀

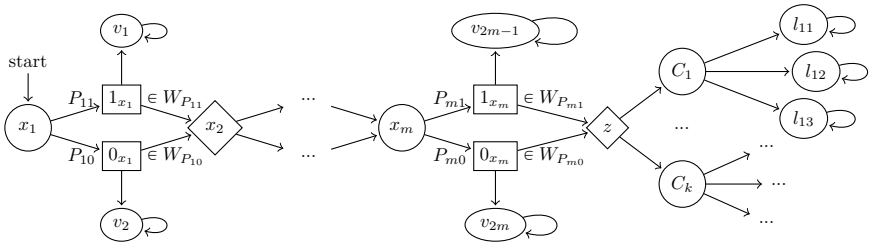

Figure 3 The arena $\mathcal{A}_\psi$ used to show that NCRSP is PSPACE-h.

▶ **Theorem 7.** *For multiplayer games, NCRSP is in* ExpTime *for objectives of type* $X \in \{\mathsf{Parity}, \mathsf{Streett}, \mathsf{Rabin}, \mathsf{Muller}\}$ *and in* PSpace *if* $X \in \{\mathsf{Safety}, \mathsf{Reachability}, \mathsf{Büchi}, \mathsf{coBüchi}\}$. *It is* PSpace-hard *for all objectives.*

Proof. The upper-bounds are consequence of Lemma 4, Lemma 5, and Proposition 6. Let us establish the lower bounds. Our proof is a reduction from QBF which uniformly works for all the types of objective. Let $\psi = \exists x_1 \forall x_2 ... \exists x_m \gamma(x_1, x_2, ..., x_m)$ be a QBF in 3CNF with k clauses $C_1, C_2, ..., C_k$. We build a $2m + 2$ players game $\mathcal{G}_\psi$, with players $\Omega = \{A, B, P_{10}, P_{11}, P_{20}, P_{21}, \ldots, P_{m0}, P_{m1}\}$, the system being played by player A, such that ψ is true if and only if $\mathcal{G}_\psi$ admits a solution to the NCRSP. The arena $\mathcal{A}_\psi$ of the game is depicted in Figure 3.

For each existential (resp. universal) variable x_i in ψ, the arena $\mathcal{A}_\psi$ contains a rounded (resp. diamond) state x_i controlled by Player A (resp. player B). For each node $x_i, 1 \leqslant i < m$, $\mathcal{A}_\psi$ contains the edges $(x_i, 0_{x_i}), (x_i, 1_{x_i})$, as well as the edges $(0_{x_i}, x_{i+1}), (1_{x_i}, x_{i+1})$, choices of edges in those states naturally encode valuations of the variables of the QBF formula.

For each $1 \leqslant i \leqslant m$, the rectangle state 1_{x_i} (resp. 0_{x_i}) is controlled by player P_{i1} (resp. P_{i0}) and has an additional edge leading to the self-loop over the state v_{2i-1} (resp. v_{2i}). The value nodes $1_{x_m}, 0_{x_m}$ (for the last variable x_m) are then connected to a vertex z controlled by Player B. From there Player B can choose a clause, i.e. an edge $(z, C_i), 1 \leqslant i \leqslant k$. Finally, each state associated to a clause C_i is controlled by Player A and has three outgoing edges toward the terminal nodes (with self-loops) l_{i1}, l_{i2}, l_{i3}, one for each literal in C_i.

Given the arena described above for the X-game $\mathcal{G}_\psi$, it is easy to phrase with the different types of objectives, the following winning conditions:

1. All paths that end in a state labeled with v_i $(1 \leqslant i \leqslant 2m)$ are winning for all the players.
2. All paths that end in a state labeled with l_{ij} $(1 \leqslant i \leqslant k, 1 \leqslant i \leqslant 3)$ are winning for all the players but Player A and Player P_{hb} such that $(l_{ij} = x_h \wedge b = 1) \vee (l_{ij} = \neg x_h \wedge b = 0)$.

Let us establish the correctness of our reduction. Assume that ψ is true. Then, the existential player has a winning strategy in the QBF game associated to ψ, i.e. he can choose the value of existentially quantified variables x_i as a function of the values given by the universal player to the universally quantified variables x_j, with $j \leqslant i$, so that ψ evaluates to true. We claim that, if Player A plays in the game arena according to such a winning strategy of the existential player, then Player A wins his objective whenever the other players play a NE. Indeed, there are two possibilities: either the game ends in a looping state labeled with v_i, and all players win (including Player A) or the game reaches z where Player B chooses a clause. As the strategy played by Player B encodes a winning strategy of the existential player in the QBF game, we know that each clause is satisfied, so Player A can choose a literal that evaluates to true in the clause. With such a choice, he makes sure that the player associated to this literal is losing while the play has visited a state in which this player has

decided to continue the game instead of going to a looping state labeled with v_i. This means that this player has a profitable deviation in the profile associated to the outcome of the game and so this outcome of the game is not a NE.

Otherwise, ψ is false. Then the universal player has a winning strategy in the QBF game associated to ψ. Consider a strategy profile where Player B plays according to this strategy and each Player P_{ib}, $1 \leqslant i \leqslant m, b \in \{0,1\}$, plays to continue the game and avoid looping states labelled by v_i. Then the game reaches state z, and Player B can choose a clause C_i that is false according to the instantiation of variables along the path followed so far. Therefore, for any choice of Player A from C_i, the play will be winning for all the players with the exception of Player A, and the player associated to the literal that has been chosen by Player A in the clause. This outcome is part of a NE as the later player cannot improve on his payoff by deviating as in the current profile, the play does not visit the rectangle state associated to the literal that evaluates to false, and so he has no available deviation at all. ◀

5 Fixed number of players

Several instances of the rational synthesis problems become tractable for fixed number of players. The number of players is a natural parameter to study: in practical applications, the number of components composing the environment may be limited to a few.

Cooperative Setting. We provide a generic reduction for the lower bounds of Table 1.

▶ **Lemma 8.** *Let $X \in \{\mathsf{Safety}, \mathsf{Reachability}, \mathsf{Büchi}, \mathsf{coBüchi}, \mathsf{Parity}, \mathsf{Streett}, \mathsf{Rabin}, \mathsf{Muller}\}$. Given a two-player zero-sum game between players A and B with an objective of type X for Player A, we can construct a multiplayer game with objective of type X with two players $\Omega = \{0,1\}$ such that Player A does not have a winning strategy in the zero-sum game if and only if the multiplayer game is a positive instance of the CRSP problem.*

Proof. Let $\mathcal{G}$ be a two-players zero-sum game where the protagonist (player A) has the objective ψ, and so Player B has objective $\neg\psi$. We construct the two-players CRSP $\mathcal{G}'$ by considering a copy of $\mathcal{G}$ and two fresh states v and w. The state v is the initial state of $\mathcal{G}'$ and has a transition to the initial state of $\mathcal{G}$ and a transition to w, which is equipped with a self-loop. The environment (Player 1) controls v, w and the states belonging to Player A in $\mathcal{G}$, while the system (Player 0) controls the states belonging to Player B in $\mathcal{G}$. For the winning conditions, Player 0 wins only if the play gets into w (and stays there forever), while the objective of the environment is ψ (i.e. the objective of Player A in $\mathcal{G}$).

$\mathcal{G}'$ is a positive instance of the CRSP problem iff Player 1 playing edge $v \to w$ is a NE. But clearly Player 1 does not have an incentive to deviate iff Player A does not have a winning strategy in $\mathcal{G}$ for forcing ψ. ◀

As an example, we get NP-hardness for the CRSP problem with Streett objectives because two-player zero-sum Streett games are coNP-hard.

The upper bounds on k-fixed CRSP for $X \in \{\mathsf{Reach}, \mathsf{Safe}, \mathsf{Büchi}, \mathsf{coBüchi}, \mathsf{Parity}, \mathsf{Rabin}\}$ listed in Table 1 can be obtained with the following procedure. First, compute the winning sets W_i for each of the $k+1$ players using the classical algorithms to solve two-player zero-sum games (w.r.t. the corresponding objective) and label the arena with the information $(W_i)_{i\in\Omega}$ (seen as atomic propositions). Then, check whether there is a path π such that $\pi \models \varphi_0 \wedge \phi^{\mathcal{G}}_{0\text{Nash}}$ (witnessing a solution to CRSP, by Proposition 2). The first step can be done in polynomial time for $X \in \{\mathsf{Reach}, \mathsf{Safe}, \mathsf{Büchi}, \mathsf{coBüchi}\}$, in UP$\cap$coUP for parity

conditions and in P^{NP} for Rabin conditions (as checking whether a state belongs to W_i is in NP). Due to the assumption that k is a fixed constant, the second step can be done in PTime for $X \in \{\mathsf{Reach}, \mathsf{Safe}, \mathsf{Büchi}, \mathsf{coBüchi}, \mathsf{Parity}\}$ and in NP for Rabin conditions. For Streett k-fixed CRSP, an NP upper bound was given in [25]. For Muller objectives, by Lemma 8, the problem is PSpace-hard and the PSpace upper bound follows from the unfixed case.

Non-Cooperative Setting. Results are summarized in the last column of Table 1. We start by the justification of the lower bounds. First, it should be clear that deciding the winner in a zero-sum two-player game with objective of type X is a special case of the NCRSP problem. Indeed, assume Player A has objective ψ in a game $\mathcal{G}$. Then, if we give objective ψ to Player 0 on the same game arena and declare all plays winning for Player 1, it is easy to see that this is a positive instance to the NCRSP problem iff Player A has a winning strategy in $\mathcal{G}$ for ψ. So this explains all the lower bounds but for $X \in \{\mathsf{Parity}, \mathsf{Streett}, \mathsf{Rabin}\}$. In the long version of this work [12], we provide a PSpace lower bound also to Streett and Rabin k-fixed NCRSP. This is done in two steps: first a reduction from QBF to zero-sum two-player Muller games is provided, similar to the one given in [16]. Then, the latter is reduced to a Street (resp. Rabin) NCRSP with two players. Finally, the lower bounds for parity k-fixed NCRSP reported in Table 1 have been obtained by reduction from the generalized parity games considered in [10], where the objective is a disjunction (dually, a conjunction) of parity conditions. In particular, we have proven that NCRSP on 3-players (resp. 4-players) parity game is NP (resp. coNP)-hard.

For $X \in \{\mathsf{Safety}, \mathsf{Reachability}, \mathsf{Büchi}, \mathsf{coBüchi}\}$, if the number of players in the given NCRSP is a fixed constant k, then the two-player game construction to test tree automata emptiness in Section 4 yields a polynomial size two-player zero-sum game $\mathcal{G}'$, where the formula characterizing the winning condition has constant size. The latter can be converted into an equivalent deterministic Büchi tree automaton of polynomial size, whose product with $\mathcal{G}'$ gives a Büchi game, solvable in PTime. Finally, if $X \in \{\mathsf{Parity}, \mathsf{Streett}, \mathsf{Rabin}, \mathsf{Muller}\}$, the corresponding k-fixed NCRSP can be reduced to a polynomial-size two-player game, with a 0-sum Muller acceptance condition defined by a boolean formula of polynomial size. Hence, the PSpace upper bound listed in Table 1 applies to k-fixed NCRSP with the above objectives.

Abstract

It is shown that the shortest-grammar problem remains NP-complete if the alphabet is fixed and has a size of at least 24 (which settles an open question). On the other hand, this problem can be solved in polynomial-time, if the number of nonterminals is bounded, which is shown by encoding the problem as a problem on graphs with interval structure. Furthermore, we present an $\mathcal{O}(3^n)$ exact exponential-time algorithm, based on dynamic programming. Similar results are also given for 1-level grammars, i. e., grammars for which only the start rule contains nonterminals on the right side (thus, investigating the impact of the "hierarchical depth" on the complexity of the shortest-grammar problem).

the compressed data without prior decompression forms a vibrant research area, usually subsumed under the term *algorithmics on compressed strings*.

Compressing a word by a context-free grammar, so-called *grammar-based compression*, is particularly well suited for this purpose.[1] Nevill-Manning and Witten [17, 16], and Kieffer et al. [10, 9, 23] are stated as the origins of this concept, but a closer look into the older literature reveals that the *external pointer macro* (*without overlapping and with pointer size* 1) defined by Storer and Szymanski [22, 21] is also equivalent to grammar-based compression.

The success of grammars with respect to algorithmics on compressed strings is due to the fact that they cover many compression schemes from practice (most notably, the family of Lempel-Ziv encodings) and that they are mathematically easy to handle (see Lohrey [11] for a survey on the role of grammar-based compression for algorithmics on compressed strings). Many basic problems on strings, e. g., comparison, pattern matching, membership in a regular language, retrieving subwords, etc. can all be solved in polynomial-time directly on the grammars [11]. In addition, grammar-based compression has been successfully applied in combinatorial group theory and to prove problems in computational topology to be polynomial-time solvable [11]. Grammars as compressions have also been extended to more complicated objects, e. g., trees (see [1, 12, 13, 14]) and two-dimensional words (see [3]).

On the other hand, work on the *shortest-grammar problem*, i. e., computing a minimal grammar for a given word w, is somewhat scarce; its NP-completeness, the major downside of grammar-based compression, has been used as a justification to focus on approximation algorithms. In this regard, the best achieved approximation ratio is $\mathcal{O}(\log(\frac{|w|}{m^*}))$ (see [18, 4]), where m^* is the size of a smallest grammar, and an approximation ratio better than $\frac{8569}{8568} \approx 1.0001$ is not possible (see [4]), assuming $\mathsf{P} \neq \mathsf{NP}$ (the research seems to have stagnated at this gap between lower and upper bound). However, the existing hardness reductions (also for the inapproximability result) have a serious deficiency: they assume the terminal alphabet to be unbounded. In [2], it is claimed that the hardness for alphabets of size 3 follows from [21], but a closer look into [21] does not confirm this. For string problems, where we typically deal with not only constant, but also very small alphabets, e. g., of size 2 or 4, this is rather unsatisfying. Another neglected aspect is the parameterised point of view, i. e., can minimal grammars be efficiently computed, if certain parameters (e. g., alphabet size, levels of the derivation tree, number of rules) are bounded? Furthermore, the fact that for grammar compressions basic problems can be solved without decompression motivates scenarios, where an extensive running time is invested only once, in order to obtain an optimal compression, which is then stored and worked with. This assumption naturally leads to exact exponential-time algorithms, which are not yet considered in the literature.

We investigate these aspects of the shortest-grammar problem. First, we close the gap with respect to fixed alphabets left open in the literature, by showing the NP-completeness for alphabets of size 24 in Section 3, which provides a more solid foundation for approximations (or heuristics), but leaves the cases of small alphabets open.[2] After this negative result, in Section 4, we show that minimal grammars can be computed in polynomial-time, provided that the size of the nonterminal alphabet is bounded. This is achieved by a reduction to a graph problem, which, since the graphs are structurally simple, can be efficiently solved (note that especially for string problems successful applications of this common algorithmic technique are rare). Additionally, we show that an FPT-algorithm with respect to this

[1] Such context-free grammars are also called *straight-line programs* in the literature.
[2] Note that this negative result also transfers to the shortest-grammar problem for trees.

parameter is unlikely (under complexity theoretical assumptions). Finally, we turn our attention to exact exponential-time algorithms in Section 5 and first observe that brute-force algorithms with running time $\mathcal{O}(c^{|w|})$, for a constant c, can be easily found, but we also present an $\mathcal{O}(3^{|w|})$ dynamic programming algorithm.

Moreover, these questions are also investigated for 1-*level grammars*, i. e., only the start rule contains nonterminals; thus, measuring the impact of the "hierarchical depth" of the grammars. Considering that the exploitation of hierarchical structure is one of the main features of grammars (allowing exponential compression rates, in contrast to 1-level grammars, where quadratic is the best), it is surprising that our results suggest that computing general grammars is, if at all, only insignificantly more difficult than computing 1-level grammars.

Due to space restriction, we only give proof sketches for the main results.

2 Preliminaries

Let $\mathbb{N} = \{1, 2, 3, \ldots\}$. By $|A|$, we denote the cardinality of a set A. Let Σ be a finite alphabet of *symbols*. A *word* or *string* (over Σ) is a sequence of symbols from Σ. For any word w over Σ, $|w|$ denotes the length of w and ε denotes the *empty word*, i. e., $|\varepsilon| = 0$. The symbol Σ^+ denotes the set of all non-empty words over Σ and $\Sigma^* = \Sigma^+ \cup \{\varepsilon\}$. For the *concatenation* of two words w_1, w_2 we write $w_1 \cdot w_2$ or simply $w_1 w_2$. For every symbol $a \in \Sigma$, by $|w|_a$ we denote the number of occurrences of symbol a in w. We say that a word $v \in \Sigma^*$ is a *factor* of a word $w \in \Sigma^*$ if there are $u_1, u_2 \in \Sigma^*$ such that $w = u_1 v u_2$. If $u_1 = \varepsilon$ or $u_2 = \varepsilon$, then v is a *prefix* (or a *suffix*, respectively) of w. Furthermore, $\mathsf{F}(w) = \{u \colon u \text{ is a factor of } w\}$ and $\mathsf{F}_{\geq 2}(w) = \{u \colon u \in \mathsf{F}(w), |u| \geq 2\}$. For a position j, $1 \leq j \leq |w|$, we refer to the symbol at position j of w by the expression $w[j]$ and $w[j..j'] = w[j]w[j+1] \ldots w[j']$, $j \leq j' \leq |w|$. By w^R, we denote the *reversal* of w, i. e., $w^R = w[n]w[n-1] \ldots w[1]$, where $|w| = n$.

A *factorisation* of a word w is a tuple $(u_1, u_2, \ldots, u_k)$ with $u_i \neq \varepsilon$, $1 \leq i \leq k$ such that $w = u_1 u_2 \ldots u_k$. A factorisation $p = (u_1, u_2, \ldots, u_k)$ is a *refinement* of a factorisation $q = (v_1, v_2, \ldots, v_m)$, denoted by $p \preceq q$, if $(u_{j_{i-1}+1}, u_{j_{i-1}+2}, \ldots, u_{j_i})$ is a factorisation of v_i, $1 \leq i \leq m$ for some $\{j_i\}_{0 \leq i \leq m}$, with $0 = j_0 < j_1 < \ldots < j_m = k$.

Grammars: A *context-free grammar* is a tuple $G = (N, \Sigma, R, S)$, where N is the set of *nonterminals*, Σ is the *terminal alphabet*, $S \in N$ is the *start symbol* and $R \subseteq N \times (N \cup \Sigma)^+$ is the set of *rules* (as a convention, we write rules $(A, w) \in R$ also in the form $A \to w$). A context-free grammar $G = (N, \Sigma, R, S)$ is a *singleton grammar* if R is a total function $N \to (N \cup \Sigma)^+$ and the relation $\{(A, B) \colon (A, w) \in R, |\alpha|_B \geq 1\}$ is acyclic.

For a singleton grammar $G = (N, \Sigma, R, S)$, let $\mathsf{D}_G : (N \cup \Sigma) \to (N \cup \Sigma)^+$ be defined by $\mathsf{D}_G(A) = R(A)$, $A \in N$, and $\mathsf{D}_G(a) = a$, $a \in \Sigma$. We extend D_G to a morphism $(N \cup \Sigma)^+ \to (N \cup \Sigma)^+$ by setting $\mathsf{D}_G(\alpha_1 \alpha_2 \ldots \alpha_n) = \mathsf{D}_G(\alpha_1)\,\mathsf{D}_G(\alpha_2) \ldots \mathsf{D}_G(\alpha_n)$, for $\alpha_i \in (N \cup \Sigma)$, $1 \leq i \leq n$. Furthermore, for every $\alpha \in (N \cup \Sigma)^+$, we set $\mathsf{D}^1_G(\alpha) = \mathsf{D}_G(\alpha)$, $\mathsf{D}^k_G(\alpha) = \mathsf{D}(\mathsf{D}^{k-1}_G(\alpha))$, for every $k \geq 2$, and $\mathfrak{D}_G(\alpha) = \lim_{k \to \infty} \mathsf{D}^k_G(\alpha)$ is the *derivative* of α. By definition, $\mathfrak{D}_G(\alpha)$ exists for every $\alpha \in (N \cup \Sigma)^+$ and is an element from Σ^+. The size of the singleton grammar G is defined by $|G| = \sum_{A \in N} |\,\mathsf{D}_G(A)|$ and its number of *levels* is $\min\{k \colon \mathsf{D}^k_G(S) = \mathfrak{D}_G(S)\}$. In particular, a grammar with d levels is a *d-level grammar*.

From now on, we simply use the term *grammar* instead of singleton grammar and if the grammar under consideration is clear from the context, we also drop the subscript G. We set $\mathfrak{D}(G) = \mathfrak{D}(S)$ and say that G *is a grammar for* $\mathfrak{D}(G)$. In the tuple (N, Σ, R, S), we sometimes replace S directly by $\mathsf{D}(S)$, which we then call the *compressed string* (*of* G) and which we denote by cs.

Let $G = (N, \Sigma, R, cs)$ be a 1-level grammar. The *profit* of a rule $(A, \alpha) \in R$ is defined by $\mathsf{p}(A) = |cs|_A(|\alpha| - 1) - |\alpha|$. Intuitively speaking, if all occurrences of A in cs are replaced by α and the rule $A \to \alpha$ is deleted, then the size of the grammar increases by exactly $\mathsf{p}(A)$. Consequently, $|G| = |\mathfrak{D}(G)| - \sum_{A \in N} \mathsf{p}(A)$.

A grammar G is *minimal* if $|G| = \min\{|G'| \colon G' \text{ is a grammar for } \mathfrak{D}(G)\}$ and the problem of computing small grammars is defined as follows:

Shortest Grammar Problem (SGP)
Instance: A word w and a $k \in \mathbb{N}$.
Question: Does there exist a grammar G with $\mathfrak{D}(G) = w$ and $|G| \leq k$?

The Shortest 1-Level Grammar Problem (1-SGP) is defined analogously, with the only difference that we ask for a 1-level grammar of size at most k.

Examples: Even for small – say binary – alphabets and a fixed word with a simple structure, finding minimal grammars can be surprisingly difficult. In order to substantiate this claim, let $w = \prod_{i=1}^{n} 10^i$ be a word over $\Sigma = \{0, 1\}$, where $n = 2^k$, $k \in \mathbb{N}$. One way of compressing w that comes to mind is by the use of rules $A_1 \to 10$, $A_i \to A_{i-1}0$, $2 \leq i \leq n-1$, and a compressed string $A_1 A_2 \dots A_{n-1} A_{n-1} 0$, which leads to a grammar G_1 of size $3n-1$. However, it is also possible to construct the factors 0^i, $1 \leq i \leq n$, "from the middle" by rules $A_1 \to 010$, $A_i \to 0A_{i-1}0$, $2 \leq i \leq \frac{n}{2} - 1$, and a compressed string $1(A_1)^2(A_2)^2 \dots$. By using these ideas, we can construct a smaller grammar G_2 of size $\frac{5n}{2} + 2k - 3$. Both of these grammars achieve a compression rate of order $\mathcal{O}(\sqrt{|w|})$, but, generally, grammars are capable of exponential compression rates (see [4]). Aiming for such exponential compression, it seems worthwhile to represent every unary factor 0^{2^ℓ}, $1 \leq \ell \leq k$, by a nonterminal B_ℓ (obviously, this requires only k rules of size 2) and then represent all unary factors by sums of these powers (e. g., 0^{74} is compressed by $B_1 B_3 B_6$). However, this yields a grammar G_3 of size $\frac{k(n+3)}{2} - 2$, which, if k is sufficiently large, is worse than the previous grammars.

A smaller grammar can be obtained by combining the idea of G_2 with that of representing factors 0^{2^ℓ} by nonterminals B_ℓ. More precisely, for every ℓ, $1 \leq i \leq k-2$, we represent 0^{2^ℓ} by an individual nonterminal B_ℓ and, in addition, we use rules $A_1 \to 010$, $A_i \to 0A_{i-1}0$, $2 \leq i \leq \frac{n}{4}$. Then the left and right half of w can be compressed in the way of G_2, with the only difference that in the right part, for every unary factor, we also need an occurrence of B_{k-1}, i. e., the compressed string is $1(A_1)^2 \dots (A_{\frac{n}{4}})^2 B_{k-2} (A_1 B_{k-1})^2 \dots (A_{\frac{n}{4}-1} B_{k-1})^2 A_{\frac{n}{4}} (B_{k-2})^3$. The size of this grammar G_4 is only $\frac{9n}{4} + 2k - 2$.

3 NP-Hardness of Computing Minimal Grammars for Fixed Alphabets

In [4], Charikar et al. prove the shortest-grammar problem to be NP-complete by a reduction from the vertex cover problem (which is based on ideas used by Storer and Szymanski in [22]). A simple modification of this reduction yields the following.

▶ **Theorem 1.** 1-SGP *is* NP*-complete.*

In these reductions, we encode the different vertices of a graph by single symbols and also use individual separator symbols (i. e., symbols with only one occurrence in the word to be compressed). This makes it particularly easy to devise suitable gadgets, but, on the other hand, it assumes that we have an arbitrarily large alphabet at our disposal, which, for practical situations, is not justified. In the remainder of this section, we shall extend these hardness results to the more realistic case of fixed alphabets. The general structure of

our reductions is similar to the ones of [4, 21], but, due to the constraint of having a fixed alphabet, they substantially differ on a more detailed level.

Since fixed alphabets make it impossible to use single symbols (or even words of constant size) as separators or as representing vertices, we need to use special encodings for which we are able to determine how a smallest grammar will compress them (in this regard, recall our examples from page 4 demonstrating how difficult it can be to determine a smallest grammar even for a single simply structured word). This constitutes a substantial technical challenge, which complicates our reductions considerably.

3.1 The 1-Level Case

As a tool for proving the hardness of 1-SGP, but also as a result in its own right, we first show that the compression of any 1-level grammar is at best quadratic (in contrast to general grammars, which can achieve exponential compression (see [4])).[3]

▶ **Lemma 2.** *Let G be a 1-level grammar. Then $|G| \geq 2\left\lfloor\sqrt{|\mathfrak{D}(G)|}\right\rfloor$.*

In order to prove the NP-hardness of 1-SGP for constant alphabets, we devise a reduction from the vertex cover problem. To this end, let $\mathcal{G} = (V, E)$ be a graph with $V = \{v_1, \ldots, v_n\}$ and $E = \{(v_{j_{2i-1}}, v_{j_{2i}}) \colon 1 \leq i \leq m\}$. Without loss of generality, we assume $n \geq 40$. We define $\Sigma = \{\mathtt{a}, \mathtt{b}, \diamond, \star, \#\}$ and $[\diamond] = \diamond^{n^3}$. For each i, $1 \leq i \leq n$, we encode v_i by a word $\overline{v_i} \in \{\mathtt{a}, \mathtt{b}\}^{\lceil\log(n)\rceil}$ such that $\overline{v_i} \neq \overline{v_j}$ if and only if $i \neq j$ (e. g., by taking $\overline{v_i}$ to be the binary representation of i over symbols $\mathtt{a}$ and $\mathtt{b}$ with $\lceil\log(n)\rceil$ many digits). We now define the following word over Σ:

$$w = \prod_{i=1}^{n} (\#\overline{v_i}[\diamond]\overline{v_i}\#[\diamond])^{2\lceil\log(n)\rceil+3} \prod_{i=1}^{n} (\#\overline{v_i}\#[\diamond])^{\lceil\log(n)\rceil+1} \prod_{i=1}^{m} (\#\overline{v_{j_{2i-1}}}\#\overline{v_{j_{2i}}}\#[\diamond])^2 \star [\diamond]^{n^3}.$$

▶ **Theorem 3.** 1-SGP *is* NP*-hard, even for* $|\Sigma| = 5$.

Proof Sketch. A smallest grammar for w produces the two parts to the left and right of $\star$ independently, since $|w|_\star = 1$. According to Lemma 2, the right side $[\diamond]^{n^3}$ is best compressed by n^3 occurrences of a nonterminal D with derivative $[\diamond]$ and, by a slightly more involved argument, it can be shown that also for the whole word w, it is still best to compress all occurrences of $[\diamond]$ by D. Having established this basic property, it is then possible to show that the remaining rules have derivative $\#\overline{v_i}$, $\overline{v_i}\#$ or $\#\overline{v_j}\#$. The grammar is smallest, if every edge $\#\overline{v_{j_{2i-1}}}\#\overline{v_{j_{2i}}}\#$ is compressed by using a rule of the last type; thus, those rules translate into a vertex cover. Analogously, a vertex cover translates into a grammar. ◀

3.2 The Multi-Level Case

In the above reduction, the main difficulty is the use of unary factors as separators. However, once those separators are in place, we know the factors of w that are produced by nonterminals and, for a minimal 1-level grammar, this already fully determines the compressed string and, thus, the grammar itself. For the multi-level case, the situation is much more complicated. Even if we manage to force the compressed string to factorise w into parts that are either separators or codewords of vertices, this only determines the top-most level of the grammar and we do not necessarily know how these single factors are further hierarchically compressed

[3] The bound of Lemma 2 is tight, e. g., consider $\mathtt{a}^{n^2}$ and a grammar with rules $S \to A^n$ and $A \to \mathtt{a}^n$.

and, more importantly, the dependencies between these compressions (i. e., how they share the same rules).

To deal with these issues, we rely on a larger alphabet Σ and we use palindromic codewords $u \star u^R$, where $\star \in \Sigma$ and u is a word over an alphabet of size 7 representing a 7-ary number. The purpose of the palindromic structure is twofold. Firstly, it implies that codewords always start and end with the same symbol, which, in the construction of w, makes it easier to avoid the situation that an overlapping between neighbouring codewords is repeated elsewhere in w (see Lemma 4). Secondly, if all codewords are produced by individual nonterminals, then we can show that they are produced best "from the middle", similar as the rules of the example grammar G_2 from page 4. In addition to this, we also need a vertex colouring and an edge colouring of certain variants of the graph to be encoded.

In order to formally define the reduction, we first give some preparatory definitions. Let $\Sigma = \{x_1, \ldots, x_7, d_1, \ldots, d_7, \star, \#, \mathfrak{c}_1, \mathfrak{c}_2, \$_1, \ldots, \$_6\}$ be an alphabet of size 24. The function $M\colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ is defined by $M(q,k) := \min\{r > 0\colon \exists t \in \mathbb{N}\colon q = tk + r\}$.[4] Let the functions $f\colon \mathbb{N} \to \{x_1, \ldots, x_7\}^+$ and $g\colon \mathbb{N} \to \{d_1, \ldots, d_7\}^+$ be defined by $f(q) := x_{a_0} x_{a_1} \ldots x_{a_k}$ and $g(q) := d_{a_0} d_{a_1} \ldots d_{a_k}$, for every $q \in \mathbb{N}$, where $k \in \mathbb{N} \cup \{0\}$ and $a_i \in \{1, 2, \ldots, 7\}$, $0 \leq i \leq k$, are such that $q = \sum_{i=0}^{k} a_i 7^i$ is satisfied.[5] For every $i \in \mathbb{N}$, let $\langle i \rangle_v := f(i) \star f(i)^R$ and $\langle i \rangle_\diamond := g(i) \star g(i)^R$. The factors $\langle i \rangle_v$ and $\langle i \rangle_\diamond$ are called *codewords*; $\langle i \rangle_v$ represents a vertex v_i, while the $\langle i \rangle_\diamond$ are used as separators. The functions f and g are bijections and they are 7-ary representations of the integers $n > 0$ (least significant digit first). Thus, for every $n, n' \in \mathbb{N}$ with $M(n,7) \neq M(n',7)$, the words $\langle n \rangle_v$ and $\langle n' \rangle_v$ do not share any prefixes or suffixes (and the same holds for the words $\langle n \rangle_\diamond$).

Let $\mathcal{G} = (V, E)$ be a subcubic graph (i. e., a graph with maximum degree 3) with $V = \{v_1, \ldots, v_n\}$ and $E = \{\{v_{j_{2i-1}}, v_{j_{2i}}\}\colon 1 \leq i \leq m\}$ (note that the vertex cover problem remains NP-hard if restricted to subcubic graphs (see [7])). Let $\mathcal{G}' = (V, E')$ be the multi-graph defined by $E' := \big\{\{v_{j_{2i}}, v_{j_{2i+1}}\}\colon 1 \leq i \leq m-1\big\}$. By [19], it is possible to compute in polynomial-time a proper edge-colouring (meaning a colouring such that no two edges which share one or two vertices have the same colour) for a multi-graph with at most $\lfloor \frac{3}{2} m \rfloor$ colours, where m is the maximum degree of the multi-graph. Since $\mathcal{G}$ is subcubic, the maximum degree of $\mathcal{G}'$ is three and we can compute a proper edge-colouring $C_e\colon E' \to \{1,2,3,4\}$ for $\mathcal{G}'$ with colours {1,2,3,4}. Let $\mathcal{G}^2 = (V, E'')$ be the graph defined by $E'' = \{\{u,v\}\colon \{u,w\}, \{w,v\} \in E \text{ for some } w \in V \setminus \{u,v\}, u \neq v\}$. Since $\mathcal{G}$ is subcubic, $\mathcal{G}^2$ has maximum degree at most six. Let $C_v\colon \{1, \ldots, n\} \to \{1,2,3,4,5,6,7\}$ be a proper vertex-colouring (defined over the vertex-indices of $V = \{v_1, \ldots, v_n\}$) for $\mathcal{G}^2$ with colours $\{1,2,3,4,5,6,7\}$. Such a colouring can be computed by an algorithmic version of Brook's theorem [20].

Let $w_\mathcal{G} = uvw$ be the word representing $\mathcal{G}$, where $u, v, w \in \Sigma^+$ are defined as follows.[6]

$$u = \prod_{j=0}^{6} \left(\prod_{i=1}^{14n} (\langle i \rangle_\diamond \ \langle M(i+j, 14n) \rangle_v) \right) \ \$_1$$

$$v = \prod_{i=1}^{n} (\# \ \langle 7i + C_v(i) \rangle_v \ \mathfrak{c}_1 \ \langle 7i - 1 \rangle_\diamond) \ \$_2 \prod_{i=1}^{n} (\# \ \langle 7i + C_v(i) \rangle_v \ \mathfrak{c}_2 \ \langle 7i - 2 \rangle_\diamond) \ \$_3$$

[4] M is the positive modulo-function, i. e., $M(q,k) = q \% k$, if $q \% k \neq 0$ and $M(q,k) = k$, otherwise.

[5] Since, for every $q \in \mathbb{N}$, there are unique $k \in \mathbb{N}$ and $a_i \in \{1, 2, \ldots, 7\}$, $1 \leq i \leq k$, such that $q = \sum_{i \geq 0}^{k} a_i 7^i$, the functions f and g are well-defined.

[6] Note that $m \leq \frac{3n}{2}$, so $7m < 14n$ in the word w.

$$\prod_{i=1}^{n}(\langle 7i+C_v(i)\rangle_v \ \#\ \langle 7i-2\rangle_\diamond\ \mathfrak{c}_1)\ \ \$_4 \prod_{i=1}^{n}(\langle 7i+C_v(i)\rangle_v \ \#\ \langle 7i-1\rangle_\diamond\ \mathfrak{c}_2)\ \ \$_5$$
$$\prod_{i=1}^{n}(\#\ \langle 7i+C_v(i)\rangle_v \ \#\ \langle 7i\rangle_\diamond)\ \ \$_6$$
$$w = \prod_{i=1}^{m-1}(\#\ \langle 7j_{2i-1}+C_v(j_{2i-1})\rangle_v \ \#\ \langle 7j_{2i}+C_v(j_{2i})\rangle_v \ \#\ \langle 7i+C_e(v_{j_{2i}},v_{j_{2i+1}})\rangle_\diamond)$$
$$\#\ \langle 7j_{2m-1}+C_v(j_{2m-1})\rangle_v \ \#\ \langle 7j_{2m}+C_v(j_{2m})\rangle_v \#$$

The next lemma states that any factor of $w_\mathcal{G}$ is not repeated, if it spans over the $\star$ of some codeword $\langle i\rangle_v$ or $\langle i\rangle_\diamond$ and also reaches over the boundaries of this codeword into some other factor. This property, which can be proven by a straightforward, but rather cumbersome analysis, is crucial for the correctness of the reduction and also responsible for the complicated structure of $w_\mathcal{G}$. Here, we only wish to point out that it follows from the fact that all occurrences of the same codeword are delimited by distinct symbols. This is ensured by the symbols $\#, \mathfrak{c}_1, \mathfrak{c}_2, \$_1, \ldots, \$_6$, by the fact that codewords $\langle i\rangle_v$ and $\langle i\rangle_\diamond$ start and end with $x_{M(i,7)}$ and $d_{M(i,7)}$, respectively, and, for the part w, by the colourings C_e and C_v.

▶ **Lemma 4.** *There is a minimal grammar $G = (N, \Sigma, R, S)$ for $w_\mathcal{G}$ such that, for every $A \in N$, $|\mathfrak{D}(A)|_\star \geq 1$ implies that $\mathfrak{D}(A)$ is a factor of some $\#\,\langle 7i+C_v(i)\rangle_v\,\#$, $1 \leq i \leq n$, or a factor of some $\langle j\rangle_\diamond$, $1 \leq j \leq 14n$.*

▶ **Lemma 5.** *There is a minimal grammar G for $w_\mathcal{G}$ such that, for every i, $1 \leq i \leq 14n$, there is a nonterminal with derivative $\langle i\rangle_\diamond$ and a nonterminal with derivative $\langle i\rangle_v$, and, for every i, $1 \leq i \leq n$, there is a nonterminal with derivative $\#\,\langle 7i+C_v(i)\rangle_v$ and a nonterminal with derivative $\langle 7i+C_v(i)\rangle_v\#$.*

Proof Sketch. Let G be a minimal grammar. Since $|u|_\star = 196n$, Lemma 4 implies that $|\beta| \geq 196n$, where β is the prefix of the compressed string producing u. Also by Lemma 4, every $\langle i\rangle_\diamond$ or $\langle i\rangle_v$ that is not a derivative of some rule, is produced by at least two nonterminals (we assume that there are k many such *bad* codewords). This implies that β contains at least $7\lceil\frac{k}{2}\rceil$ additional nonterminals (each codeword has 7 occurrences in u and the nonterminal not producing $\star$ can be used in the production of at most 2 bad codewords). Hence, $|\beta| \geq 196n + 7\lceil\frac{k}{2}\rceil$. For every bad codeword $x \in \{\langle i\rangle_\diamond, \langle i\rangle_v\}$, we can add a new rule $A_x \to \alpha_x$ with $|\alpha_x| = 3$ and $\mathfrak{D}(A_x) = x$ (this can be done by right sides of the form $d_j A d_j$, where A derives another codeword). This increases the size of the grammar by $3k$, but we can now produce every codeword of u by one nonterminal, which shortens β by $7\lceil\frac{k}{2}\rceil > 3k$.

We now add rules $\overleftarrow{V_i} \to \#V_{7i+C_v(i)}$, $\overrightarrow{V_i} \to V_{7i+C_v(i)}\#$, where $\mathfrak{D}(V_{7i+C_v(i)}) = \langle 7i+C_v(i)\rangle_v$, and use them, in addition to the rules for the codewords $\langle i\rangle_\diamond$, to obtain a new compressed string from $w_\mathcal{G}$ (where also every factor $\#\langle 7i+C_v(i)\rangle_v\#$ that has been produced before by a single nonterminal is compressed by a rule $\overleftrightarrow{V_i} \to \overleftarrow{V_i}\#$). Then, we erase all old rules with derivatives $\#f(7i+C_v(i))\star r_i$, $r_i \star f(7i+C_v(i))^R\#$. The deletion of these rules and the size of the new compressed string compensates the size increase of adding the new rules. ◀

▶ **Lemma 6.** *There is a minimal grammar G for $w_\mathcal{G}$ with the rules $\{r_{\diamond,i}, r_{v,i} \colon 1 \leq i \leq 14n\}$, where $r_{\diamond,i} = D_i \to d_i \star d_i$ and $r_{v,i} = V_i \to x_i \star x_i$, $1 \leq i \leq 7$, $r_{\diamond,i} = D_i \to g(i)[1]D_{h(i)}g(i)[1]$ and $r_{v,i} = V_i \to f(i)[1]V_{h(i)}f(i)[1]$, $8 \leq i \leq 14n$ with $h(i) = \frac{1}{7}(i - M(i,7))$, $\{\overleftarrow{V_i} \to \#V_{7i+C_v(i)}, \overrightarrow{V_i} \to V_{7i+C_v(i)}\# \colon 1 \leq i \leq n\}$, $\{\overleftrightarrow{V_i} \to \#\overrightarrow{V_i} \colon i \in \mathfrak{I}\}$, for an $\mathfrak{I} \subseteq \{1, \ldots, n\}$, and with the compressed string*

$\prod_{j=0}^{6}\left(\prod_{i=1}^{14n}(D_i\, V_{M(i+j,14n)})\right)\prod_{i=1}^{n}\left(\overleftarrow{V_i}\ \mathfrak{c}_1\ D_{7i-1}\right)\prod_{i=1}^{n}\left(\overleftarrow{V_i}\ \mathfrak{c}_2\ D_{7i-2}\right)\prod_{i=1}^{n}\left(\vec{V_i}\ D_{7i-2}\ \mathfrak{c}_1\right)$
$\prod_{i=1}^{n}\left(\vec{V_i}\ D_{7i-1}\ \mathfrak{c}_2\right)\prod_{i=1}^{n}(y_i\ D_{7i})\prod_{i=1}^{m-1}(z_i D_{7i+C_e(v_{j_{2i}},v_{j_{2i+1}})})z_m$,
where for every i, $1\le i\le n$, $y_i=\overleftrightarrow{V_i}$, *if* $i\in\mathfrak{I}$ *and* $y_i=\overleftarrow{V_i}\#$, *otherwise, and, for every* k, $1\le k\le m$, $z_k\in\{\overleftrightarrow{V}_{j_{2k-1}}\vec{V}_{j_{2k}},\overleftarrow{V}_{j_{2k-1}}\overleftrightarrow{V}_{j_{2k}}\}$ *if* $\{j_{2k-1},j_{2k}\}\cap\mathfrak{I}\neq\emptyset$, $z_k=\overleftarrow{V}_{j_{2k-1}}\overleftarrow{V}_{j_{2k}}\#$, *otherwise.*

Proof Sketch. Lemma 5 ensures nonterminals $V_i\to\alpha_i$ with $\mathfrak{D}(\alpha_i)=\langle i\rangle_v$. We now replace it by a rule $V_i\to x_i\star x_i$ or $V_i\to f(i)[1]V_{h(i)}f(i)[1]$, as described in the statement of the lemma. If $|\alpha_i|\ge 3$, this is fine, but if $|\alpha_i|=2$, we have to argue more carefully: we remove $V_i\to AB$ for which i is maximal and observe that this implies that either A or B cannot occur on any right side of a rule; thus, can be removed. Repeating this argument turns all rules with derivative $\langle i\rangle_v$ in the right form and a similar argument applies to the rules with derivatives $\langle i\rangle_\diamond$. Now it only remains to prove that the compressed string can be assumed to have the desired form. If we replace all $\langle i\rangle_v$, $\langle i\rangle_\diamond$, $\#\langle i\rangle_v$ and $\langle i\rangle_v\#$ in $w_{\mathcal{G}}$ by the respective nonterminals, then this produces a compressed string whose size may increase compared to the original one, but only by the number of factors $\#\langle i\rangle_v\#$ that have been compressed by a single nonterminal and are now compressed by $\overleftarrow{V_i}\#$. This can be repaired by simply adding a rule $\overleftrightarrow{V_i}\to\#\vec{V_i}$, resulting in the set $\mathfrak{I}$ mentioned in the statement of the lemma. ◀

Lemma 6 allows us to argue similarly as for the reduction from [4]: $\Gamma=\{v_i\colon i\in\mathfrak{I}\}$ is a vertex cover (if $\{v_i,v_j\}\in E$ is not covered, then adding $\overleftrightarrow{V_i}\to\#\vec{V_i}$ does not increase the size of the grammar) and $|G|=f(m,n)+|\Gamma|$, where f is a polynomial. Furthermore, a vertex cover Γ translates into a grammar of size $f(m,n)+|\Gamma|$, by setting $\mathfrak{I}=\{i\colon v_i\in\Gamma\}$. Thus, $\mathcal{G}$ has a vertex cover Γ iff there is a grammar G for $w_{\mathcal{G}}$ with $|G|\le f(m,n)+|\Gamma|$.

▶ **Theorem 7.** SGP *is* NP*-complete, even for alphabets of size* 24.

4 Minimal Grammars with a Bounded Number of Nonterminals

A natural follow-up question to the hardness for fixed alphabets is whether polynomial-time solvability is possible if instead the cardinality of the nonterminal alphabet N is bounded. In this section, we answer this question in the affirmative by representing words $w\in\Sigma^*$ as graphs $\Phi_{\mathrm{m}}(w)$ and $\Phi_1(w)$, such that smallest independent dominating sets of these graphs correspond to a smallest grammar and a smallest 1-level grammar, respectively, for w.

We first define $\Phi_1(w)$ and then derive $\Phi_{\mathrm{m}}(w)$ from $\Phi_1(w)$. Let $\Phi_1(w)=(V,E)$ be defined by $V=V_1\cup V_2\cup V_3$ and $E=E_1\cup E_2\cup E_3$, where

$$V_1=\{(i,j)\colon 1\le i\le j\le|w|\},\qquad E_1=\{\{(i_1,j_1),(i_2,j_2)\}\colon i_1\le i_2\le j_1\},$$
$$V_2=\mathsf{F}_{\ge 2}(w),\qquad E_2=\{\{w[i..j],(i,j)\}\colon 1\le i<j\le|w|\},$$
$$V_3=\{(u,i)\colon u\in V_2,0\le i\le|u|\},\qquad E_3=\{\{u,(u,i)\}\colon u\in V_2,0\le i\le|u|\}.$$

Intuitively speaking, the vertices of V_1 represent every factor by its start and end position, whereas V_2 contains exactly one vertex per factor of length at least 2. Every $u\in V_2$ is connected to (i,j), if and only if $w[i..j]=u$. Vertices (i,j), (i',j') are connected if they refer to overlapping factors. For every $u\in V_2$, there are $|u|+1$ special vertices in V_3 that are only connected with u. Consequently, $\Phi_1(w)$ consists of $|w|$ layers, where the i^{th} layer contains the vertices $(j,j+(i-1))\in V_1$, $1\le j\le|w|-(i-1)$, the vertices $\{u\in V_2\colon|u|=i\}$ and the vertices $\{(u,j)\in V_3\colon|u|=i,0\le j\le|u|\}$ (see Figure 1 for an illustration).

▶ **Lemma 8.** *Let* $w\in\Sigma^*$, $k\ge 1$. *There is an independent dominating set* D *of cardinality* k *for* $\Phi_1(w)$ *if and only if there is a* 1*-level grammar* G *for* w *with* $|G|=k-|\,\mathsf{F}_{\ge 2}(w)|$.

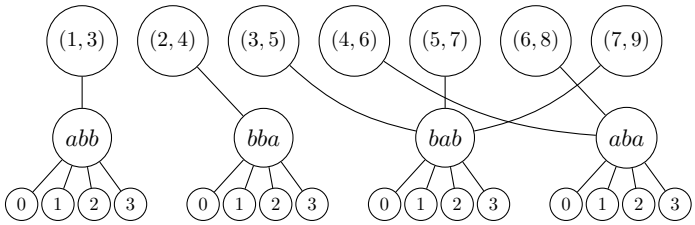

Figure 1 The third layer of $\Phi_1(abbababab)$ (edges E_1 omitted).

Proof Sketch. For an independent dominating set D of $\Phi_1(w)$, $V_1 \cap D$ induces a factorisation of w. For every $(i,j) \in D$, $w[i..j] \notin D$, which implies that all $|w[i..j]|+1$ many V_3-neighbours of $w[i..j]$ are in D. Now a 1-level grammar can be obtained by constructing rules for all $V_2 \setminus D$. Analogously, a 1-level grammar translates into an independent dominating set. ◀

In order to extend this idea to the multi-level case, what comes to mind is to somehow represent the vertices $u \in V_2$ again by graph structures of the type $\Phi_1(u)$ and repeating this step, which considerably increases the size of the graph. Fortunately, it turns out that a surprisingly simple modification of $\Phi_1(w)$ is sufficient. For a word $w \in \Sigma^*$, let $\Phi_{\mathrm{m}}(w) = (V, E)$ be defined as follows. Let $V = V_1 \cup V_2 \cup V_3 \cup V_4$, where V_1 and V_2 are defined as for $\Phi_1(w)$, $V_3 = \{(u,0) \colon u \in V_2\}$ and $V_4 = \bigcup_{u \in V_2} V_{4,u}$ with $V_{4,u} = \{(u,i,j) \colon 1 \le i \le j \le |u|, u[i..j] \neq u\}$ for every $u \in V_2$. Moreover, $E = E_1 \cup E_2 \cup E_3 \cup E_4 \cup E_5$, where E_1 and E_2 are defined as for $\Phi_1(w)$, $E_3 = \{\{u,(u,0)\} \colon u \in V_2\} \cup \{\{u,(u,i,j)\} \colon u \in V_2, (u,i,j) \in V_{4,u}\}$, $E_4 = \bigcup_{u \in V_2} E_{4,u}$, where, for every $u \in V_2$, $E_{4,u} = \{\{(u,i_1,j_1),(u,i_2,j_2)\} \subseteq V_{4,u} \colon i_1 \le i_2 \le j_1\}$ and $E_5 = \{\{u,(v,i,j)\} \colon u,v \in V_2, v[i..j] = u, u \neq v\}$.

Intuitively speaking, $\Phi_{\mathrm{m}}(w)$ differs from $\Phi_1(w)$ in the following way. We add to every vertex $u \in V_2$ a subgraph $(V_{4,u}, E_{4,u})$, which is completely connected to u and which represents u in the same way as the subgraph (V_1, E_1) of $\Phi_1(w)$ represents w, i. e., factors $u[i..j]$ are represented by (u,i,j) and edges represent overlappings. Moreover, if a $u \in V_2$ is a factor of some $v \in V_2$, then there is an edge from u to all the vertices $(v,i,j) \in V_{4,v}$ that satisfy $v[i..j] = u$. Finally, every $u \in V_2$ is also connected with an otherwise isolated vertex $(u,0) \in V_3$. See Figure 2 for a partial illustration of a $\Phi_{\mathrm{m}}(w)$.

▶ **Lemma 9.** *Let $w \in \Sigma^*$, $k \ge 1$. There is an independent dominating set D of cardinality k for $\Phi_{\mathrm{m}}(w)$ if and only if there is a grammar G for w with $|G| = k - |\,\mathsf{F}_{\ge 2}(w)|$.*

Proof Sketch. The correspondence of independent dominating sets D for $\Phi_{\mathrm{m}}(w)$ and grammars for w is similar as in the 1-level case. Again, $D \cap V_1$ induces a factorisation of w, and, in the same way, for every $u \in V_2 \setminus D$ (i. e., the factors for which rules will be constructed), $D \cap V_{4,u}$ induces a factorisation of u. Each $(v,i,j) \in D \cap V_{4,u}$ with $|v| \ge 2$ is connected to $v \in V_2$, which implies that $v \notin D$; thus, v will also be represented by a rule and so on. ◀

The proofs of Lemmas 8 and 9 also show how an independent dominating set D of $\Phi(w) \in \{\Phi_1(w), \Phi_{\mathrm{m}}(w)\}$ translates into a grammar for w, which, in the following, we will denote by $\mathsf{G}(D)$. Consequently, we can solve the smallest grammar problem by computing minimal independent dominating sets. Unfortunately, this is a hard problem, even for quite restricted graph classes [15, Theorem 13]. However, $\Phi(w)$ may have structural features that could be exploited in this regard, e. g., it is a 2-interval graph (see [8]).

Our algorithmic application is based on the following observation. If we are looking for a grammar $G = (N, \Sigma, R, cs)$ with $\{\mathfrak{D}(A) \colon A \in N\} = F$, for some set $F \subseteq \mathsf{F}_{\ge 2}(w)$, then we need an independent dominating set D with $(\mathsf{F}_{\ge 2}(w) \setminus F) \subseteq D$ and $F \cap D = \emptyset$. Obviously,

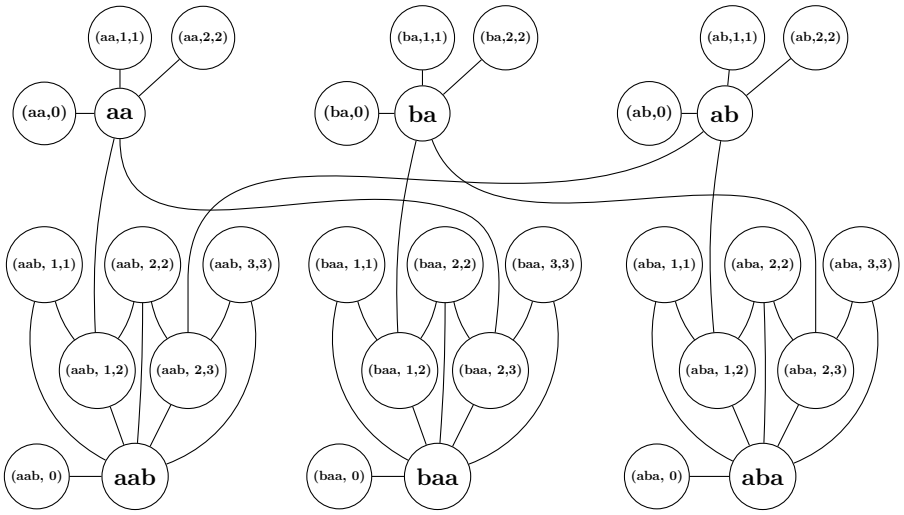

Figure 2 Second and third layer of $\Phi_{\mathrm{m}}(abaabaa)$ (vertices V_1 and edges $E_1 \cup E_2$ omitted).

D is the disjoint union of $(\mathsf{F}_{\geq 2}(w) \setminus F)$ and an independent dominating set D' for the graph $\mathcal{H} = \Phi(w) \setminus (N[\mathsf{F}_{\geq 2}(w) \setminus F] \cup F)$,[7] which is necessarily an interval graph; thus, a smallest independent dominating set for it can be efficiently computed (see [6]). For a word w and a set $F \subseteq \mathsf{F}_{\geq 2}(w)$, we define $\mathsf{MinIDS}(w, F) = D_{\mathcal{H}} \cup (\mathsf{F}_{\geq 2}(w) \setminus F)$, where $D_{\mathcal{H}}$ is a smallest independent dominating set for $\mathcal{H} = \Phi_{\mathrm{m}}(w) \setminus (N[\mathsf{F}_{\geq 2}(w) \setminus F] \cup F)$, and $\mathsf{1L\text{-}MinIDS}(w, F)$ is defined analogously by using $\Phi_1(w)$ instead of $\Phi_{\mathrm{m}}(w)$. In this way, for any set $F \subseteq \mathsf{F}_{\geq 2}$, we can compute a grammar that is minimal among all grammars that have rules for exactly the factors in F (this is also an interesting problem in its own right, e. g., if a compressed word is extended by a new part that should be compressed by already existing rules).

▶ **Lemma 10.** *Let $w \in \Sigma^+$ and $F \subseteq \mathsf{F}_{\geq 2}(w)$. $\mathsf{MinIDS}(w, F)$ and $\mathsf{1L\text{-}MinIDS}(w, F)$ can be computed in time $\mathcal{O}(|w|^6)$ and $\mathcal{O}(|w|^4)$, respectively. Furthermore, $\mathsf{G}(\mathsf{MinIDS}(w, F))$ is a minimal grammar for w and $\mathsf{G}(\mathsf{1L\text{-}MinIDS}(w, F))$ is a minimal 1-level grammar for w.*

If instead of a set F of factors, we are only given an upper bound k on $|N|$, then we can compute a minimal grammar by enumerating all $F \subseteq \mathsf{F}_{\geq 2}(w)$ with $|F| \leq k$ and computing $\mathsf{G}(\mathsf{MinIDS}(w, F))$. This shows that minimal grammars can be computed in polynomial time if the number of nonterminals is bounded.

▶ **Theorem 11.** *Let $w \in \Sigma^*$ and $k \in \mathbb{N}$. A grammar (1-level grammar, resp.) for w with at most k rules that is minimal among all grammars (1-level grammars, resp.) for w with at most k rules can be computed in time $\mathcal{O}(|w|^{2k+6})$ ($\mathcal{O}(|w|^{2k+4})$, resp.).*

The next question is whether these problems are also fixed-parameter tractable with respect to the number of nonterminals.[8] Unfortunately, this seems unlikely, since, as stated by the next result, these parameterisations of 1-SGP and SGP are $\mathsf{W}[1]$-hard.

▶ **Theorem 12.** 1-SGP *and* SGP *parameterised by $|N|$ are $\mathsf{W}[1]$-hard.*

[7] $N[v]$ is the closed neighbourhood of vertex v and for $C \subseteq V$, $N[C] = \bigcup_{v \in C} N[v]$.

[8] For unexplained concepts of parameterised complexity, we refer to Downey and Fellows [5].

This can be proven by reducing from independent set, i. e., a graph $\mathcal{G} = (\{v_1, v_2, \ldots, v_n\}, E)$ and $k \in \mathbb{N}$ is transformed into the word $w = \prod_{\{v_i,v_j\}\in E}(\#v_i\#v_j\#\diamond) \prod_{i=1}^{n}(\#v_i\#\diamond)^{n-|N(v_i)|}$, where $N(v_i)$ is the neighbourhood of v_i and every occurrence of $\diamond$ stands for a distinct symbol. To see the the correctness of this reduction, it is sufficient to observe that the vertices v_i of an independent set for G correspond to the rules of a grammar of form $A_i \to \#v_i\#$.

5 Exact Exponential Time Algorithms

Computing $\mathsf{G}(\mathsf{MinIDS}(w, F))$, for all $F \subseteq \mathsf{F}_{\geq 2}(w)$, yields a simple brute-force algorithm with a running time in $\mathcal{O}(2^{|w|^2})$. Another obvious approach is to enumerate all ordered trees with $|w|$ leaves (for each such tree T, an optimal grammar whose derivation tree has the structure T can be easily computed), which can be done in time $\mathcal{O}(8^{|w|})$.[9] In the following, we shall give more sophisticated exact exponential-time algorithms with running times in $\mathcal{O}^*(1.8392^{|w|})$, for the 1-level case, and $\mathcal{O}^*(3^{|w|})$, for the multi-level case.

Let $G = (N, \Sigma, R, cs)$ be a grammar for w and let $\alpha = A_1 \ldots A_k$, $A_i \in (\Sigma \cup N)$, $1 \leq i \leq k$. The *factorisation of* $\mathfrak{D}(\alpha)$ *induced by* α is the tuple $(\mathfrak{D}_G(A_1), \ldots, \mathfrak{D}_G(A_k))$. Furthermore, the factorisation of w induced by cs is called the *factorisation of* w *induced by* G.

5.1 The 1-Level Case

Let $q = (u_1, u_2, \ldots, u_k)$ be a factorisation for a word w and let $\Gamma_q = \{u_i \colon 1 \leq i \leq k, |u_i| \geq 2\}$ and let the 1-level grammar $G_q = (N_q, \Sigma, R_q, cs_q)$ be defined by $R_q = \{(A_u, u) \colon u \in \Gamma_q\}$, $N_q = \{A_u \colon u \in \Gamma_q\}$ and $cs_q = B_1 \ldots B_k$ with $B_j = A_{u_j}$, if $u_j \in \Gamma_q$ and $B_j = u_j$, otherwise.

▶ **Lemma 13.** *For any factorisation $q = (u_1, u_2, \ldots, u_k)$ for w, G_q is minimal among all 1-level grammars for w that induce the factorisation q.*

Choosing the smallest among all grammars $\{G_q \colon q \text{ is a factorisation of } w\}$ yields an $\mathcal{O}^*(2^n)$ algorithm for 1-SGP. However, it is not necessary to enumerate factorisations that contain at least two consecutive factors of length 1, which improves this result as follows.

▶ **Theorem 14.** 1-SGP *can be solved exactly in polynomial space and in time $\mathcal{O}^*(1.8392^{|w|})$.*

5.2 The Multi-Level Case

The obvious idea for a dynamic programming algorithm is to extend a smallest i-level grammar by a new level in order to obtain a smallest $(i+1)$-level grammar. However, this approach does not seem to work if we take the levels of a grammar to be $cs, \mathsf{D}(cs), \mathsf{D}(\mathsf{D}(cs)), \ldots, w$ (note that these are also the levels of the derivation tree). Intuitively speaking, the problem is that if we try to either add a new level on top (i. e., a new compressed string) of the grammar or at the bottom (by further compressing the terminal right sides of the last rules applied), then this decision is not local, since it is possible that rules to be added are already used somewhere else in the grammar. So we need to define levels in such a way that all occurrences of a nonterminal are on the same level.

For a d-level grammar $G = (N, \Sigma, R, cs)$, let $N_1, \ldots, N_d$ be the partition of N into $N_i = \{A \in N \colon (\mathsf{D}_G^i(A) \in \Sigma^+) \wedge (\mathsf{D}_G^{i-1}(A) \notin \Sigma^+)\}$ and let $\mathsf{L}_i \colon (N \cup \Sigma)^* \to (N \cup \Sigma)^*$, $1 \leq i \leq d$, be component-wise defined by $\mathsf{L}_i(x) = \mathsf{D}(x)$, if $x \in N_i$ and $\mathsf{L}_i(x) = x$, otherwise.

[9] There are $C_{|w|-1} \leq 4^{|w|-1}$ ordered binary trees with $|w|$ leaves, where $C_{|w|-1}$ is the $(|w|-1)^{\text{th}}$ Catalan number, and every ordered tree can be obtained from a binary one by contracting some of its edges.

Taking the strings $(\mathsf{L}_{i+1} \circ \mathsf{L}_{i+2} \circ \cdots \circ \mathsf{L}_d)(cs)$, which contain all occurrences of nonterminals N_i, as the levels of the grammar, we are able to define a dynamic programming algorithm.[10]

▶ **Theorem 15.** SGP *can be solved exactly in time and space* $\mathcal{O}^*(3^{|w|})$.

Proof Sketch. With the help of the mappings L_i, we can define the term *profit* for rules from a d-level grammar $G = (N, \Sigma, R, cs)$ as follows. The profit for a rule $A \to \alpha$ with $A \in N_d$ can be defined like in the 1-level case, i. e., $\mathsf{p}(A) = |cs|_A(|\alpha| - 1) - |\alpha|$, considering that removing this rule and replacing each occurrence of A in cs by α increases the size of the grammar by $|cs|_A(|\alpha| - 1) - |\alpha|$. Inductive use of this argument allows us to define the profit of any rule $A \to \alpha$ with $A \in N_i$ by $\mathsf{p}(A) := |(\mathsf{L}_{i+1} \circ \mathsf{L}_{i+2} \circ \cdots \circ \mathsf{L}_d)(cs)|_A(|\alpha| - 1) - |\alpha|$. This allows us to compute the size of a G by $|w| - \sum_{A \in N} \mathsf{p}(A)$. The dynamic programming algorithm runs trough steps $i = 1, 2, \ldots, \frac{w}{2}$ and in step i, it considers all possibilities for two factorisations q_{i-1} and q_i of w induced by $(\mathsf{L}_i \circ \mathsf{L}_{i+1} \circ \cdots \circ \mathsf{L}_d(cs)$ and $(\mathsf{L}_{i+1} \circ \cdots \circ \mathsf{L}_d)(cs)$, respectively (note that this implies $q_{i-1} \preceq q_i$). The differences between q_{i-1} and q_i implicitly define N_i. Let $q_i = (v_1, v_2, \ldots, v_k)$ and let $q_{i-1} = (u_1, u_2, \ldots, u_\ell)$, i. e., for some j_i, $0 \leq i \leq k$, with $1 = j_0 < j_1 < \ldots < j_k = \ell + 1$, $(u_{j_{i-1}}, u_{j_{i-1}+1}, \ldots, u_{j_i-1})$ is a factorisation of v_i, $1 \leq i \leq k$. If $j_s - j_{s-1} > 1$ for some $1 \leq s \leq k$, N_i contains a nonterminal A with $|\,\mathsf{D}(A)| = j_s - j_{s-1}$ and $\mathfrak{D}(A) = v_s$. The term $|\,\mathsf{L}_i \circ \mathsf{L}_{i+1} \circ \cdots \circ \mathsf{L}_d)(cs)|_A$ is also implicitly given by counting how often the sequence of factors $(u_{j_{s-1}+1}, \ldots, u_{j_s})$ independently occurs in q_{i-1} and is combined into one single factor in q_i, i.e.: $|\{t\colon (u_{j_{t-1}+1}, \ldots, u_{j_t}) = (u_{j_{s-1}+1}, \ldots, u_{j_s})\}|$. This allows to calculate the profit of the rule for A without knowing the exact structure of the rules for nonterminals in N_j with $j \neq i$. By Lemma 13, this choice of nonterminals for N_i is optimal for the fixed induced factorisations, which means that a search among all choices for q_{i-1} and q_i yields a minimal i-level grammar for w. The running time of this algorithm is dominated by enumerating all pairs q_{i-1} and q_i of factorisations of w. However, due to $q_{i-1} \preceq q_i$, these pairs can be compressed as vectors $\{0, 1, 2\}^{|w|-1}$ (the entries denote whether the corresponding position in w is factorised by both, only one or none of the factorisations). Hence, enumerating these pairs of vectors can be done in time $\mathcal{O}(3^{|w|})$. ◀

6 Conclusions

We conclude this work by deriving some parameterised complexity results.[11] The shortest-grammar problem (1-level and multi-level) is Para-NP-hard with respect to $|\Sigma|$, it is in XP with respect to $|N|$, but also W[1]-hard, so most likely not in FPT. Furthermore, the hardness of 1-SGP shows that bounding or parameterising by the number of levels does not help either. However, if we parameterise by both $|\Sigma|$ and $\ell = \max\{|\,\mathfrak{D}(A)|\colon A \in N\}$, then it is sufficient to compute $\mathsf{G}(\mathsf{MinIDS}(w, F))$ for every set $F \subseteq \{u\colon u \in \Sigma^+, |u| \leq \ell\}$, which, since the number of such sets is bounded by the parameters, yields an fpt-algorithm. A probably more interesting combination of parameters, for which the existence of an fpt-algorithm is still open, would be $|\Sigma|$ and $|N|$.

The most interesting question (also from a practical point of view) left open is whether it is possible to compute minimal grammars for small (especially binary) alphabets in polynomial-time. The substantial effort that was necessary to prove Theorem 7 suggests that answering this question in the negative might be difficult. On the other hand, it is not apparent how a small alphabet could help in order to efficiently compute smallest grammars and, if

[10] The composition $(f \circ g)$ of mapping $f : A \to A$, $g : A \to A$ is defined by $(f \circ g)(a) = f(g(a))$.
[11] For unexplained concepts of parameterised complexity, we refer to Downey and Fellows [5].

this is possible, it seems that deeper combinatorial insights with respect to grammar-based compression are necessary.

The Complexity of Downward Closure Comparisons

Georg Zetzsche*

LSV, CNRS & ENS Cachan, Université Paris-Saclay, France
zetzsche@lsv.fr

Abstract

The downward closure of a language is the set of all (not necessarily contiguous) subwords of its members. It is well-known that the downward closure of every language is regular. Moreover, recent results show that downward closures are computable for quite powerful system models.

One advantage of abstracting a language by its downward closure is that then equivalence and inclusion become decidable. In this work, we study the complexity of these two problems. More precisely, we consider the following decision problems: Given languages K and L from classes $\mathcal{C}$ and $\mathcal{D}$, respectively, does the downward closure of K include (equal) that of L?

These problems are investigated for finite automata, one-counter automata, context-free grammars, and reversal-bounded counter automata. For each combination, we prove a completeness result either for fixed or for arbitrary alphabets. Moreover, for Petri net languages, we show that both problems are Ackermann-hard and for higher-order pushdown automata of order k, we prove hardness for complements of nondeterministic k-fold exponential time.

1 Introduction

The downward closure of a language is the set of (not necessarily contiguous) subwords of its members. It is a well-known result of Haines [17] that the downward closure of *every* language is regular. Of course, it is not always possible to compute the downward closure of a given language, but oftentimes it is. For example, it has been shown to be computable for such powerful models as *Petri net languages* by Habermehl, Meyer, and Wimmel [14] and *higher-order pushdown automata* by Hague, Kochems, and Ong [15]. A sufficient condition for computability can be found in [34].

Moreover, not only are downward closures often computable, they are also a meaningful abstraction of infinite-state systems. In a complex system, one can abstract a component by the downward closure of the messages it sends to its environment. This corresponds to the assumption that messages can be dropped on the way. Furthermore, recent work of La Torre, Muscholl, and Walukiewicz [32] shows that among other mild conditions, computing downward closures is sufficient for verifying safety conditions of parametrized asynchronous shared-memory systems.

The advantage of having an abstraction of an infinite-state systems as regular languages is that the latter offer an abundance of methods for analysis. An important example is deciding

behavioral equivalence or inclusion. This is notoriously hard to do and for nondeterministic infinite-state systems, language equivalence and inclusion are usually undecidable. Using downward closures, such behavioral comparisons can be made in an approximative manner.

Despite these facts, results about the complexity of deciding whether the downward closure of one language includes or equals that of another mainly considered regular languages. Bachmeier, Luttenberger, and Schlund [4] have shown that the equivalence problem for downward closures of two given NFAs is coNP-complete. Karandikar, Niewerth, and Schnoebelen [22] strengthened coNP-hardness to the case of DFAs over binary alphabets and proved coNP-completeness for the inclusion variant. They also obtained NL-completeness of inclusion in the case of NFAs over a unary alphabet. Together with exponential-time downward closure constructions [4, 7, 11, 33, 27], these results imply that equivalence and inclusion are in coNEXP for context-free grammars. Rampersad, Shallit, and Xu [31] proved that one can decide in linear time whether the downward closure of a given NFA contains all words. Subsequently, Karandikar, Niewerth, and Schnoebelen [22] showed that this problem is NL-complete. Similar questions have been studied for upward closures [4, 22].

Previous work on downward closures of infinite-state systems has mainly focused on mere computability [1, 2, 7, 14, 15, 33, 34, 35] or on descriptional complexity [3, 10, 11, 27, 22]. This work studies the complexity of the inclusion and the equivalence problem of downward closures between some prominent types of system models—finite automata, one-counter automata, reversal-bounded counter automata [19], and context-free grammars. More precisely, we are interested in the following questions: For two system models $\mathcal{M}$ and $\mathcal{N}$ and languages L and K generated by some device in $\mathcal{M}$ and $\mathcal{N}$, respectively, what is the complexity of (i) deciding whether $K{\downarrow} \subseteq L{\downarrow}$ (*downward closure inclusion problem*) or (ii) deciding whether $K{\downarrow} = L{\downarrow}$ (*downward closure equivalence problem*)?

Contribution. We determine the complexity of the downward closure inclusion problem and the downward closure equivalence problem among finite automata, one-counter automata, reversal-bounded counter automata (either with a fixed number of counters and reversals or without), and context-free grammars.

For the inclusion problem, we prove completeness results in all cases except for two. The complexities range from coNP over Π_2^{P} to coNEXP (see Table 1). The two cases for which we provide no completeness compare context-free grammars or general reversal-bounded counter automata on the one side with reversal-bounded counter automata with a fixed number of counters and reversals on the other side. However, we prove that both of these problems are coNP-complete for each fixed input alphabet. For the equivalence problem, the situation is similar. We prove completeness for each of the cases except for the combination above. Again, fixing the alphabet leads to coNP-completeness.

The tools developed to achieve these results fall into three categories. First, there are several generic results guaranteeing small witnesses to yield upper bounds. Second, we prove model-specific results about downward closures that yield the upper bounds in each case. Third, we have a general method to prove lower bounds for downward closure comparisons. In fact, it applies to more models than the above: We prove that for Petri net languages, the two comparison problems are Ackermann-hard. For higher-order pushdown automata of order k, we show co-k-NEXP-hardness.

Related work. Another abstraction of formal languages is the well-known Parikh image [28]. The Parikh image of a language $L \subseteq X^*$ contains for each word $w \in L$ a vector in $\mathbb{N}^{|X|}$ that counts the number of occurrences of each letter. For some language classes, it is known that

Table 1 Complexity of the inclusion problem. The entry in row $\mathcal{M}$ and column $\mathcal{N}$ is the complexity of $\mathcal{M} \subseteq_{\downarrow} \mathcal{N}$. Except in the case Ideal $\subseteq_{\downarrow}$ Ideal, all entries indicate completeness. A † means that the entry refers to the fixed alphabet case (for at least two letters).

their Parikh image is effectively semilinear, which implies decidability of the inclusion and equivalence problem for Parikh images. The investigation of these problems' complexity has been initiated by Huynh [18] in 1985, who showed that this problem is Π_2^{P}-hard and in coNEXP for regular and context-free languages. Kopczyński and To [23, 24] have then shown that these problems are Π_2^{P}-complete for fixed alphabets. Only very recently, Haase and Hofman [13] have shown that the case of general alphabets is coNEXP-complete.

Due to space restrictions, most proofs can only be found in the full version of this work [36].

2 Concepts and Results

If X is an alphabet, X^* ($X^{\leq n}$) denotes the set of all words (of length $\leq n$) over X. The empty word is denoted by $\varepsilon \in X^*$. For words $u, v \in X^*$, we write $u \preceq v$ if $u = u_1 \cdots u_n$ and $v = v_0 u_1 v_1 \cdots u_n v_n$ for some $u_1, \ldots, u_n, v_0, \ldots, v_n \in X^*$. It is well-known that $\preceq$ is a well-quasi-order on X^* and that therefore the *downward closure* $L{\downarrow} = \{u \in X^* \mid \exists v \in L \colon u \preceq v\}$ is regular for every $L \subseteq X^*$ [17]. An *ideal* is a set of the form $Y_0^* \{x_1, \varepsilon\} Y_1^* \cdots \{x_n, \varepsilon\} Y_n^*$, where $Y_0, \ldots, Y_n$ are alphabets and $x_1, \ldots, x_n$ are letters. We will make heavy use of the fact that every downward closed language can be written as a finite union of ideals, which was first discovered by Jullien [21]. By $\mathbb{P}(S)$, we denote the powerset of the set S.

A *finite automaton* is a tuple $\mathcal{A} = (Q, X, \Delta, q_0, Q_f)$, where Q is a finite set of *states*, X is its input alphabet, $\Delta \subseteq Q \times X^* \times Q$ is a finite set of *edges*, $q_0 \in Q$ is its *initial state*, and $Q_f \subseteq Q$ is the set of its *final states*. The language accepted by $\mathcal{A}$ is denoted $L(\mathcal{A})$. Sometimes, we write $|\mathcal{A}|$ for the number of states of $\mathcal{A}$.

A *context-free grammar* is a tuple $\mathcal{G} = (N, T, P, S)$ where N and T are pairwise disjoint alphabets, whose members are called the *nonterminals* and *terminals*, respectively. $S \in N$ is the *start symbol* and P is the finite set of *productions* of the form $A \to w$ with $A \in N$ and $w \in T^*$. The language generated by $\mathcal{G}$ is defined as usual.

One-counter Automata. A *one-counter automaton (OCA)* is a nondeterministic finite automaton that has access to one counter that assumes natural numbers as values. The possible operations are *increment*, *decrement*, and *test for zero*. We will not require a formal definition, since in fact, all we need is the well-known fact that membership and emptiness are NL-complete and the recent result that given an OCA $\mathcal{A}$, one can compute in polynomial time an NFA $\mathcal{B}$ with $L(\mathcal{B}) = L(\mathcal{A}){\downarrow}$ [3].

Reversal-bounded counter automata. Intuitively, an *r-reversal-bounded k-counter automaton* [19] (short (k,r)-RBCA) is a nondeterministic finite automaton with k counters that can store natural numbers. For each counter, it has operations *increment*, *decrement*, and *zero test*. Moreover, a computation is only valid if each counter *reverses* at most r times. Here, a computation *reverses* a counter c if on c, it first executes a sequence of increments and then a decrement command or vice versa. See [19] for details.

Instead of working directly with RBCA, we will work here with the model of *blind counter automata* [9]. It is not as well-known as RBCA, but simpler and directly amenable to linear algebraic methods. A *blind k-counter automaton* is a tuple $\mathcal{A} = (Q, X, q_0, \Delta, Q_f)$, where Q, X, q_0, and Q_f are defined as in NFAs, but Δ is a finite subset of $Q \times (X \cup \{\varepsilon\}) \times \{-1,0,1\}^k \times Q$. A *walk* is a word $\delta_1 \cdots \delta_m \in \Delta^*$ where $\delta_i = (p_i, x_i, d_i, p'_i)$ for $i \in [1,m]$ and $p'_j = p_{j+1}$ for $j \in [1, m-1]$. The *effect* of the walk is $d_1 + \cdots + d_m$. Its *input* is $x_1 \cdots x_m \in X^*$. If the walk has effect 0 and $p_0 = q_0$ and $p_m \in Q_f$, then the walk is *accepting*. The *language accepted by* $\mathcal{A}$ is the set of all inputs of accepting walks.

Using blind counter automata is justified because to each (k,r)-RBCA, one can construct in logarithmic space a language-equivalent $(kr,1)$-RBCA [5], which is essentially a blind kr-counter automaton. On the other hand, every blind k-counter automaton can be turned in logarithmic space into a $(k+1,1)$-RBCA [20]. Hence, decision problems about (k,r)-RBCA for fixed k and r correspond to problems about blind k-counter automata for fixed k.

In the following, by a *model*, we mean a way of specifying a language. In order to succinctly refer to the different decision problems, we use symbols for the models above. By Ideal, NFA, OCA, $\mathsf{RBC}_{k,r}$, RBC, CFG, we mean ideals, finite automata, OCA, RBCA with a fixed number of counters and reversals, general RBCA, and context-free grammars, respectively. Then, for $\mathcal{M}, \mathcal{N} \in \{\mathsf{Ideal}, \mathsf{NFA}, \mathsf{OCA}, \mathsf{RBC}_{k,r}, \mathsf{RBC}, \mathsf{CFG}\}$, we consider the following problems. In the *downward closure inclusion problem* $\mathcal{M} \subseteq_\downarrow \mathcal{N}$, we are given a language K in $\mathcal{M}$ and a language L in $\mathcal{N}$ and are asked whether $K{\downarrow} \subseteq L{\downarrow}$. For the *downward closure equivalence problem* $\mathcal{M} =_\downarrow \mathcal{N}$, the input is the same, but we are asked whether $K{\downarrow} = L{\downarrow}$.

Results. The complexity results for the inclusion problem are summarized in Table 1. For the equivalence problem, we will see that every hardness result for $\mathcal{M} \subseteq_\downarrow \mathcal{N}$ also holds for $\mathcal{M} =_\downarrow \mathcal{N}$. Since for non-ideal models, the appearing complexity classes are pairwise comparable, this implies that the complexity for $\mathcal{M} =_\downarrow \mathcal{N}$ is then the harder of the two classes for $\mathcal{M} \subseteq_\downarrow \mathcal{N}$ and $\mathcal{N} \subseteq_\downarrow \mathcal{M}$. For example, the problem $\mathsf{NFA} =_\downarrow \mathsf{RBC}$ is Π_2^P-complete and for fixed alphabets, $\mathsf{RBC}_{k,r} =_\downarrow \mathsf{CFG}$ is coNP-complete.

3 Ideals and Witnesses

Our algorithms for inclusion use three types of witnesses. The first type is a slight variation of a result of [4]. The latter authors were interested in equivalence problems, which caused their bound to depend on both input languages. The proof is essentially the same.

▶ **Proposition 1** (Short witness). *If $\mathcal{A}$ is an NFA and $K{\downarrow} \not\subseteq L(\mathcal{A}){\downarrow}$, then there exists a $w \in K{\downarrow} \setminus L(\mathcal{A}){\downarrow}$ with $|w| \leq |\mathcal{A}| + 1$.*

The other types of witnesses strongly rely on ideals, which requires some notation. An ideal is a product $I = Y_0^*\{x_1, \varepsilon\}Y_1^* \cdots \{x_n, \varepsilon\}Y_n^*$ where the Y_i are alphabets and the x_i are letters. Its *length* $|I|_\mathsf{I}$ is the smallest n such that I can be written in this form. Since every downward closed language can be written as a finite union of ideals, we can extend this definition to languages: $|L|_\mathsf{I}$ is the smallest n such that $L{\downarrow}$ is a union of ideals of length $\leq n$.

Sometimes, it will be convenient to work with a different length measure of ideals. An *ideal expression (of length n)* is a product $L_1 \cdots L_n$, where each L_i is of the form Y^* or $\{x, \varepsilon\}$, where Y is an alphabet and x is a letter. Note that $Y^* = Y^*\{x, \varepsilon\}$ if $x \in Y$ and $\{x, \varepsilon\} = \emptyset^*\{x, \varepsilon\}$. Therefore, an ideal expression of length n defines an ideal of length $\leq n$. In analogy to $|\cdot|_{\mathsf{I}}$, for a language L, we define its *expression length* $|L|_{\mathsf{E}}$ to be the smallest n such that $L{\downarrow}$ can be written as a finite union of ideal expressions of length $\leq n$. The expression length has the advantage of being subadditive: For languages K, L we have $|KL|_{\mathsf{E}} \leq |K|_{\mathsf{E}} + |L|_{\mathsf{E}}$. Moreover, we have $|L|_{\mathsf{I}} \leq |L|_{\mathsf{E}} \leq 2|L|_{\mathsf{I}} + 1$.

The measure $|\cdot|_{\mathsf{I}}$ turns out to be instrumental for the inclusion problem. Note that $K{\downarrow} \not\subseteq L{\downarrow}$ if and only if there is an ideal $I \subseteq K{\downarrow}$ of length $\leq |K|_{\mathsf{I}}$ with $I \not\subseteq L{\downarrow}$. We can therefore guess ideals and check inclusion for them. From now on, we assume alphabets to come linearly ordered. This means for every alphabet Y, there is a canonical word w_Y in which every letter from Y occurs exactly once.

▶ **Proposition 2** (Ideal witness). *Let $I = Y_0^*\{x_1, \varepsilon\}Y_1^* \cdots \{x_n, \varepsilon\}Y_n^*$. Then the following are equivalent:* (i) *$I \subseteq L{\downarrow}$.* (ii) *$w_{Y_0}^m x_1 w_{Y_1}^m \cdots x_n w_{Y_n}^m \in L{\downarrow}$ for every $m \geq |L|_{\mathsf{I}} + 1$.* (iii) *$w_{Y_0}^m x_1 w_{Y_1}^m \cdots x_n w_{Y_n}^m \in L{\downarrow}$ for some $m \geq |L|_{\mathsf{I}} + 1$.*

A word of the form $w_{Y_0}^m x_1 w_{Y_1}^m \cdots x_n w_{Y_n}^m \in L{\downarrow}$ with $m \geq |L|_{\mathsf{I}} + 1$ is therefore called an *ideal witness for I and L*. The proof of Proposition 2 is a simple pumping argument based on the fact that an ideal of length $\leq m$ admits an NFA with $\leq m + 1$ states. Ideal witnesses are useful when we have a small bound on $|K|_{\mathsf{I}}$ and $|L|_{\mathsf{I}}$ but only a large bound on the NFA size of $L{\downarrow}$. Observe that putting a bound on $|L|_{\mathsf{I}}$ amounts to proving a pumping lemma: We have $|L|_{\mathsf{I}} \leq n$ if and only if for every $w \in L$, there is an ideal I with $|I|_{\mathsf{I}} \leq n$ and $x \in I \subseteq L{\downarrow}$.

However even if, say, $|K|_{\mathsf{I}}$ is polynomial and $|L|_{\mathsf{I}}$ is exponential, ideal witnesses can be stored succinctly in polynomial space, by keeping a binary representation of the power m. For instance, this will be used in the case $\mathsf{NFA} \subseteq_{\downarrow} \mathsf{RBC}$.

Sometimes, we have a small bound on $|L|_{\mathsf{I}}$, but $|K|_{\mathsf{I}}$ may be large. Then, ideal witnesses are too large to achieve an optimal algorithm. In these situations, we can guarantee smaller witnesses if we fix the alphabet.

▶ **Proposition 3** (Small alphabet witness). *Let $K, L \subseteq X^*$. If $K{\downarrow} \not\subseteq L{\downarrow}$, then there exists a $w \in K{\downarrow} \setminus L{\downarrow}$ with $|w| \leq |X| \cdot (|L|_{\mathsf{I}} + 1)^{|X|}$.*

The proof of Proposition 3 is more involved than Propositions 2 and 1. Note that a naive bound can be obtained by intersecting exponentially (in $|L|_{\mathsf{I}}$) many automata for the ideals of $L{\downarrow}$ and complementing the result. This would yield a doubly exponential (in $|L|_{\mathsf{I}}$) bound, even considering the fact that ideals have linear-size DFAs. We can, however, use the latter fact in a different way.

A DFA is *ordered* if its states can be partially ordered so that for every transition $p \xrightarrow{x} q$, we have $p \leq q$. In other words, the automaton is acyclic except for loop transitions. The following lemma is easy to see: In order to check membership in an ideal, one just has to keep a pointer into the expression that never moves left.

▶ **Lemma 4.** *Given an ideal representation of length n, one can construct in logarithmic space an equivalent ordered DFA with $n + 2$ states.*

An ordered DFA *cycles* at a position of an input word if that position is read using a loop. The following lemma is the key idea behind Proposition 3. Together with Lemma 4, it clearly implies Proposition 3. For unary alphabets, it is easy to see. We use induction on $|X|$ and show, roughly speaking, that without such a position, no strict subalphabet can be

used for too long. Then, all letters have to appear often, meaning a state has to repeat after seeing the whole alphabet. Hence, the automaton stays in this state until the end.

▶ **Lemma 5.** *If $w \in X^*$ with $|w| > |X| \cdot (n-1)^{|X|}$, then w has a position at which every ordered n-state DFA cycles.*

4 Insertion trees

In Section 5, we will show upper bounds for the size of downward closure NFAs and for ideal lengths for counter automata. These results employ certain decompositions of NFA runs into trees, which we discuss here. Let $\mathcal{A} = (Q, X, \Delta, q_0, Q_f)$ be a finite automaton. A *walk* is a word $w = \delta_1 \cdots \delta_m \in \Delta^*$ where $\delta_i = (p_i, x_i, p'_i)$ for $i \in [1, m]$ and $p'_j = p_{j+1}$ for $j \in [1, m-1]$. The walk is a *(p_1-)cycle* if $p_1 = p'_m$. In this case, we define $\sigma(w) := p_1$. A cycle is *prime* if $p_i = p_1$ implies $i = 1$. A cycle is *simple* if $p_i = p_j$ implies $i = j$. A state q *occurs* on the cycle if $p_i = q$ for some i. If $i \neq 1$, then q occurs *properly*.

A common operation in automata theory is to take a run and delete cycles until the run has length at most $|Q|$. The idea behind an insertion tree is to record where we deleted which cycles. This naturally leads to a tree.

For our purposes, trees are finite, unranked and ordered. An *insertion tree* is a tree $t = (V, E)$ together with a map $\gamma\colon V \to \Delta^*$ that assigns to each vertex $v \in V$ a simple cycle $\gamma(v)$ such that if u is the parent of v, then $\sigma(\gamma(v))$ properly occurs in $\gamma(u)$. Note that we allow multiple children for a state that occurs in $\gamma(u)$.

Since t is ordered and in every simple cycle there is at most one proper occurrence of each state, an insertion tree defines a unique (typically not simple) cycle $\alpha(t)$. Formally, if t is a single vertex v, then $\alpha(t) := \gamma(v)$. If t consists of a root r and subtrees $t_1, \ldots, t_s$, then $\alpha(t)$ is obtained by inserting each $\alpha(t_i)$ in $\gamma(r)$ at the (unique) occurrence of $\sigma(\alpha(t_i))$. The *height* of an insertion tree is the height of its tree.

▶ **Lemma 6.** *Every prime cycle of $\mathcal{A}$ admits an insertion tree of height at most $|Q|$.*

The idea is to pick a cycle c strictly contained in the prime cycle, but of maximal length. Then, after removing c, no state occurs both before and after the old position of c. This forces any insertion tree t of the remainder to place this position in the root. We then apply induction to the subtrees of t and to c. The resulting trees can then all be attached to the root, increasing the height by at most one.

One application of Lemma 6 is to construct short ideals in a pumping lemma for counter automata. Part of this construction is independent from counters, so we stay with NFAs for a moment. Suppose we have an insertion tree $t = (V, E)$ with map $\gamma\colon V \to \Delta^*$ and a subset $F \subseteq V$, whose members we call *fixed vertices* or *fixed cycles*. Those in $V \setminus F$ are called *pumpable vertices/cycles*.

We use fixed and pumpable vertices to guide a pumping process as follows. A sequence $s = t_1 \cdots t_m$ of insertion trees is called *compatible* if $\sigma(\alpha(t_1)) = \cdots = \sigma(\alpha(t_m))$. We assume that we have a global set F of vertices that designates the fixed vertices for all these trees. Suppose v is a pumpable vertex. We obtain new compatible sequences in two ways:

- Let $v_1, \ldots, v_\ell$ be the children of v. We choose $i \in [0, \ell]$ and split up v at i, meaning that we create a new vertex v' with $\gamma(v') = \gamma(v)$ to the right of v and move $v_{i+1}, \ldots, v_\ell$ (and, of course, their subtrees) to v'.
- If the whole subtree under v is pumpable (we call such subtrees *pumpable*), then we can duplicate this subtree and attach its root somewhere as a sibling of v.

If v is a root, these operations mean that we introduce a new tree in the sequence. If a compatible sequence s' is obtained from s by repeatedly performing these operations, we say that s' is obtained by *pumping* s. This allows us to define the following language:

$$P(t_1 \cdots t_m, F) = \{\iota(\alpha(t'_1) \cdots \alpha(t'_k)) \mid t'_1 \cdots t'_k \text{ results from pumping } t_1 \cdots t_m\}.$$

Here, for a walk w, $\iota(w)$ denotes the input word read by w. The following lemma will yield the desired short ideals.

▶ **Lemma 7.** *Let $s = t_1 \cdots t_m$ be a compatible sequence of insertion trees of height $\leq h$ and let F be a set of fixed vertices. Then, the language $P(s, F)\downarrow$ is an ideal that satisfies $|P(s, F)\downarrow|_{\mathsf{E}} \leq h|F|(2|Q| + |F|)^2$.*

Roughly speaking, the pumping process is designed so that pumpable subtrees only cause alphabets Y in factors Y^* of the ideal to grow and thus do not affect the ideal length. Hence, the only vertices that contribute to the length are those that are ancestors of vertices in F. Since the trees have height $\leq h$, there are at most $h|F|$ such ancestors.

5 Counter Automata

In this section, we construct downward closure NFAs for counter automata and prove upper bounds for ideal lengths. Mere computability of downward closures of blind counter automata can be deduced from computability for Petri net languages [14]. However, that necessarily results in non-primitive recursive automata (see Section 8). As a special case of stacked counter automata, blind counter automata were provided with a new construction method in [35]. That algorithm, however, yields automata of non-elementary size. Here, we prove an exponential bound.

▶ **Theorem 8.** *For each n-state blind k-counter automaton $\mathcal{A}$, there is an NFA $\mathcal{B}$ with $L(\mathcal{B}) = L(\mathcal{A})\downarrow$ and $|\mathcal{B}| \leq (3n)^{5nk+7k^3}$. Moreover, $\mathcal{B}$ can be computed in exponential time.*

Linear Diophantine equations. In order to show correctness of our construction, we employ a result of Pottier [29], which bounds the norm of minimal non-negative solutions to a linear Diophantine equation. Let $A \in \mathbb{Z}^{k\times m}$ be an integer matrix. We write $\|A\|_{1,\infty}$ for $\sup_{i\in[1,k]}(\sum_{j\in[1,m]} |a_{ij}|)$, where a_{ij} is the entry of A at row i and column j. A solution $x \in \mathbb{N}^m$ to the equation $Ax = 0$ is *minimal* if there is no $y \in \mathbb{N}^m$ with $Ay = 0$ and $y \leq x$, $y \neq x$. The set of all solutions clearly forms a submonoid of $\mathbb{N}^m$, which is denoted M. The set of minimal solutions is denoted $\mathcal{H}(M)$ and called the *Hilbert basis* of M. Let r be the rank of A. Pottier showed the following.

▶ **Theorem 9** (Pottier [29])**.** *For each $x \in \mathcal{H}(M)$, $\|x\|_1 \leq (1 + \|A\|_{1,\infty})^r$.*

By applying Theorem 9 to the matrix $(A| - b)$, it is easy to deduce that for each $x \in \mathbb{N}^m$ with $Ax = b$, there is a $y \in \mathbb{N}^m$ with $Ay = b$, $y \leq x$, and $\|y\|_1 \leq (1 + \|(A| - b)\|_{1,\infty})^{r+1}$.

Automata for the downward closure. Let $\mathcal{A}$ be a blind k-counter automaton with n states. The idea of the construction of $\mathcal{B}$ is to traverse insertion trees of prime cycles of $\mathcal{A}$. Although insertion trees were introduced for finite automata, they also apply to blind counter automata if we regard the counter updates as input symbols. $\mathcal{B}$ keeps track of where it is in the tree using a stack of bounded height. The stack alphabet will be $\Gamma = Q \times [-n, n]^k$. We define $B = n + n \cdot (3n)^{(k+1)^2}$. The state set of our automaton $\mathcal{B}_1$ is the following:

$$Q_1 = Q \times \Gamma^{\leq n} \times [-B, B]^k \times \mathbb{P}([-n, n]^k) \times \mathbb{P}([-n, n]^k).$$

Here, the number of states is clearly doubly exponential, but we shall make the automaton smaller in two later steps. The idea behind $\mathcal{B}_1$ is that counter values in the interval $[-B, B]$ are simulated precisely (in the factor $[-B, B]^k$). Roughly speaking, whenever we encounter a cycle, we can decide whether to (i) add its effect to this precise counter or to (ii) remember the effect as "must be added at least once". We call the former *precise cycles*; the latter are dubbed *obligation cycles* and are stored in the first factor $\mathbb{P}([-n, n]^k)$. In either case, the effect of a cycle is kept as "repeatable" in the second factor $\mathbb{P}([-n, n]^k)$.

In order to be able to guess for each cycle whether it should be a precise cycle or an obligation cycle, we traverse an insertion tree of (the prime cycles on) a walk of $\mathcal{A}$. On the stack (the factor $\Gamma^{\leq n}$), we keep the cycles that we have started to traverse. Suppose we are executing a cycle in a vertex v and the path from the root to v consists of the vertices $v_1, \ldots, v_m$. Let $\gamma(v_i)$ be a q_i-cycle for $i \in [1, m]$. Then, the stack content is $(q_1, u_1) \cdots (q_m, u_m)$, where u_i is the effect of the part of $\gamma(v_i)$ that has already been traversed.

In the end, we verify that (i) the precise counter is zero and (ii) one can add up obligation cycles (each of them at least once) and repeatable cycles to zero. The latter condition is captured in the following notion. Let $S, T \subseteq \mathbb{Z}^k$ be finite sets with $S = \{u_1, \ldots, u_s\}$, $T = \{v_1, \ldots, v_t\}$. We call the pair (S, T) *cancellable* if there are $x_1, \ldots, x_s \in \mathbb{N} \setminus \{0\}$ and $y_1, \ldots, y_t \in \mathbb{N}$ with $\sum_{i=1}^{s} x_i u_i + \sum_{i=1}^{t} y_i v_i = 0$. In particular, $(\emptyset, T)$ is cancellable for any finite $T \subseteq \mathbb{Z}^k$. Together, (i) and (ii) guarantee that the accepted word is in the downward closure: They imply that we could have executed all of the obligation cycles and some others (again) to fulfill our obligation. Hence, there is a run of $\mathcal{A}$ accepting a superword.

The number of cycles we can use as precise cycles is limited by the capacity B of our precise counter. We shall apply Theorem 9 to show that there is always a choice of cycles to use as precise cycles so as to reach zero in the end and not exceed the capacity.

The first type of transition in $\mathcal{B}_1$ is the following. For each transition $(p, a, d, q) \in \Delta$ and state $(p, \varepsilon, v, S, T) \in Q_1$ such that $v + d \in [-B, B]^k$, we have a transition

$$(p, \varepsilon, v, S, T) \xrightarrow{a} (q, \varepsilon, v + d, S, T). \tag{1}$$

These allow us to simulate transitions in a walk of $\mathcal{A}$ that are not part of a cycle. We can guess that a cycle is starting. If we are in state p, then we push $(p, 0)$ onto the stack:

$$(p, w, v, S, T) \xrightarrow{\varepsilon} (p, w(p, 0), v, S, T). \tag{2}$$

While we are traversing a cycle, new counter effects are stored in the topmost stack entry. For each $(p, a, d, q) \in \Delta$ and $(p, w(r, u), v, S, T) \in Q_1$ with $u + d \in [-n, n]^k$, we have:

$$(p, w(r, u), v, S, T) \xrightarrow{a} (q, w(r, u + d), v, S, T). \tag{3}$$

When we are at the end of a cycle, we have to decide whether it should be a precise cycle or an obligation cycle. The following transition means it should be precise: The counter effect u of the cycle is added to the counter v, the stack is popped, and u is added to the set of repeatable effects T. For each $(p, w(p, u), v, S, T) \in Q_1$ with $v + u \in [-B, B]^k$, we have:

$$(p, w(p, u), v, S, T) \xrightarrow{\varepsilon} (p, w, v + u, S, T \cup \{u\}). \tag{4}$$

In order to designate the cycle as an obligation cycle, we have the following transition: The stack is popped and u is added to both S and T. For each state $(p, w(p, u), v, S, T) \in Q_1$, we include the transition

$$(p, w(p, u), v, S, T) \xrightarrow{\varepsilon} (p, w, v, S \cup \{u\}, T \cup \{u\}) \tag{5}$$

The initial state is $(q_0, \varepsilon, 0, \emptyset, \emptyset)$ and the final states are all those of the form $(q, \varepsilon, 0, S, T)$ where q is final in $\mathcal{A}$ and (S, T) is cancellable. Employing Lemma 6 and Theorem 9, one can now show that $L(\mathcal{A}) \subseteq L(\mathcal{B}_1) \subseteq L(\mathcal{A})\downarrow$.

State space reduction I. We have thus shown that $L(\mathcal{B}_1)\downarrow = L(\mathcal{A})\downarrow$. However, $\mathcal{B}_1$ has a doubly exponential number of states. Therefore, we now reduce the number of states in two steps. First, instead of remembering the set S of obligation effects, we only maintain a linearly independent set of vectors generating the same vector space. For a set $R \subseteq \mathbb{Q}^k$, let $\mathrm{span}(R)$ denote the $\mathbb{Q}$-vector space generated by R. Moreover, $\mathbb{I}(R)$ denotes the set of linearly independent subsets of R. Our new automaton $\mathcal{B}_2$ has states

$$Q_2 = Q \times \Gamma^{\leq n} \times [-B, B]^k \times \mathbb{I}([-n, n]^k) \times \mathbb{P}([-n, n]^k)$$

and a state in $\mathcal{B}_2$ is final if it is final in $\mathcal{B}_1$. $\mathcal{B}_2$ has the same transitions as $\mathcal{B}_1$, except that aside from those of type (5), it has

$$(p, w(p, u), v, S, T) \xrightarrow{\varepsilon} (p, w, v, S', T \cup \{u\}) \tag{6}$$

for each linearly independent subset $S' \subseteq S \cup \{u\}$ such that $\mathrm{span}(S') = \mathrm{span}(S \cup \{u\})$. Of course, such an S' exists for any S and u. This means, by induction on the length, for any walk of $\mathcal{B}_1$ from (p, w, v, S, T) to (q, w', v', S', T'), we can find a walk with the same input in $\mathcal{B}_2$ from (p, w, v, S, T) to (q, w', v', S'', T') with $S'' \subseteq S'$ and $\mathrm{span}(S'') = \mathrm{span}(S')$. Since (S', T') is cancellable and $S' \subseteq T'$, the pair (S'', T') is cancellable as well. This means, our walk in $\mathcal{B}_2$ is accepting and hence $L(\mathcal{B}_1) \subseteq L(\mathcal{B}_2)$. It remains to verify that $L(\mathcal{B}_2) \subseteq L(\mathcal{B}_1)$.

Observe that for any walk arriving in (q, w, v, S, T) in $\mathcal{B}_2$, there is a corresponding walk in $\mathcal{B}_1$ arriving in (q, w, v, S', T) for some $S' \supseteq S$ with $\mathrm{span}(S') = \mathrm{span}(S)$. The next lemma tells us that if (q, w, v, S, T) is a final state in $\mathcal{B}_2$, then (q, w, v, S', T) is final in $\mathcal{B}_1$. This implies that $L(\mathcal{B}_2) \subseteq L(\mathcal{B}_1)$ and hence $L(\mathcal{B}_2) = L(\mathcal{B}_1)$.

▶ **Lemma 10.** *Let $T \subseteq \mathbb{Z}^k$ and $S_1 \subseteq S_2 \subseteq \mathbb{Z}^k$ such that $\mathrm{span}(S_1) = \mathrm{span}(S_2)$. If (S_1, T) is cancellable, then so is (S_2, T).*

State space reduction II. We apply a similar transformation to the last factor of the state space. In $\mathcal{B}_3$, we have the state space

$$Q_3 = Q \times \Gamma^{\leq n} \times [-B, B]^k \times \mathbb{I}([-n, n]^k) \times \mathbb{I}([-n, n]^k).$$

and a state is final in $\mathcal{B}_3$ if and only if it is final in $\mathcal{B}_2$. Analogous to $\mathcal{B}_2$, we change the transitions so that instead of adding $u \in [-n, n]^k$ to T, we store an arbitrary $T' \in \mathbb{I}(T \cup \{u\})$.

This time, it is clear that $L(\mathcal{B}_3) \subseteq L(\mathcal{B}_2)$: For every walk in $\mathcal{B}_3$ arriving at (q, w, v, S, T), there is a corresponding walk in $\mathcal{B}_2$ arriving at (q, w, v, S, T') such that $T \subseteq T'$. Clearly, if (S, T) is cancellable, then (S, T') must be cancellable as well. The following lemma implies $L(\mathcal{B}_2) \subseteq L(\mathcal{B}_3)$: It says that for each walk in $\mathcal{B}_2$ arriving at (q, w, v, S, T), there is a corresponding walk in $\mathcal{B}_3$ arriving at (q, w, v, S, T') for some linearly independent $T' \subseteq T$ such that (S, T') is cancellable and hence (q, w, v, S, T') is final.

▶ **Lemma 11.** *Let $S, T \subseteq \mathbb{Z}^k$ such that (S, T) is cancellable. Then there is a linearly independent subset $T' \subseteq T$ such that (S, T') is cancellable.*

We have thus shown that $L(\mathcal{B}_3)\downarrow = L(\mathcal{A})\downarrow$. An estimation of the size of Q_3 now completes the proof of Theorem 8. We apply Theorem 8 to derive an algorithm for $\mathsf{Ideal} \subseteq_\downarrow \mathsf{RBC}$.

▶ **Corollary 12.** *The problem* Ideal $\subseteq_\downarrow$ RBC *is in* NP.

Since Theorem 8 provides an exponential bound on $|L(\mathcal{A})|_{\mathsf{I}}$, we can use an ideal witness $w = w_{Y_0}^m x_1 w_{Y_1}^m \cdots x_\ell w_{Y_\ell}^m$ (Proposition 2) for which we have to check membership in $L(\mathcal{A})$. Since ℓ is polynomial and m exponential, we can compute a compressed representation of w in form of a *straight-line program*, a context-free grammar that generates one word [25]. It follows easily from work of Hague and Lin [16] that membership of such compressed words in languages of blind (or reversal-bounded) counter automata is decidable in NP.

Fixed number of counters. Unfortunately, the size bound for the NFAs provided by Theorem 8 has the number of states in the exponent, meaning that if we fix the number k of counters, we still have an exponential bound. In fact, we leave open whether one can construct polynomial-size NFAs for fixed k. However, in many cases it suffices to have a polynomial bound on the length of ideals.

▶ **Theorem 13.** *If $\mathcal{A}$ is an n-state blind k-counter automaton, then $|L(\mathcal{A})|_{\mathsf{I}} \leq (5n)^{7(k+1)^2}$.*

Recall that an upper bound on $|L|_{\mathsf{I}}$ is essentially a pumping lemma (see Section 3). Here, the idea is to take a walk of $\mathcal{A}$ and delete cycles until the remaining walk u is at most n steps. For the deleted cycles, we take an insertion tree of height at most n (Lemma 6). Then, using Theorem 9, we pick a subset F (whose size is polynomial when fixing k) of cycles that can balance out the effect of u. We then employ Lemma 7 to the insertion trees to construct an ideal whose length is polynomial in $|F|$.

6 Context-Free Grammars

We turn to context-free grammars. First, we mention that given a context-free grammar $\mathcal{G}$, one can construct in exponential time an (exponential-size) NFA accepting $L(\mathcal{A})\downarrow$ [4, 7, 11, 33, 27]. Second, we provide an algorithm for the problem Ideal $\subseteq_\downarrow$ CFG.

▶ **Theorem 14.** *The problem* Ideal $\subseteq_\downarrow$ CFG *is in* P.

In [34], this problem has been reduced to the *simultaneous unboundedness problem (SUP)* for context-free languages. The latter asks, given a language $L \subseteq a_1^* \cdots a_n^*$, whether we have $L\downarrow = a_1^* \cdots a_n^*$. Moreover, this reduction is clearly polynomial. Hence, we assume that $L(\mathcal{G}) \subseteq a_1^* \cdots a_n^*$ and that the grammar $\mathcal{G} = (N, T, P, S)$ is productive and in Chomsky normal form, meaning that productions are of the form $A \to BC$, $A \to a_i$, or $A \to \varepsilon$ for $A, B, C \in N$. First, we add productions $A \to \varepsilon$ for all $A \in N$, so that the resulting grammar $\mathcal{G}'$ satisfies $L(\mathcal{G}') = L(\mathcal{G})\downarrow$. For each $A \in N$, we can in polynomial time construct a CFG for $\{w \in (N \cup T)^* \mid A \Rightarrow_{\mathcal{G}'}^* w\}$, so we can compute the sets $L_i = \{A \in N \mid A \Rightarrow_{\mathcal{G}'}^* a_i A\}$ and $R_i = \{A \in N \mid A \Rightarrow_{\mathcal{G}'}^* A a_i\}$ using membership queries. We can thus compute the grammar $\mathcal{G}^\omega$, which results from $\mathcal{G}'$ by (i) removing all productions $A \to a_i$, (ii) adding $A \to a_i^\omega A$ for each $A \in L_i$ and (iii) adding $A \to A a_i^\omega$ for each $A \in R_i$. Clearly, an occurrence of a_i^ω certifies the ability to generate an unbounded number of a_i's. Thus, if $a_1^\omega \cdots a_n^\omega \in L(\mathcal{G}^\omega)$, then $a_1^* \cdots a_n^* \subseteq L(\mathcal{G}') = L(\mathcal{G})\downarrow$. It is not hard to see that the converse is true as well. We have thus reduced the SUP to the membership problem.

7 Algorithms

Algorithms for $\mathcal{M} \subseteq_\downarrow$ Ideal. Suppose $\mathcal{M} =$ Ideal and we want to decide whether $I \subseteq J$ for ideals $I, J \subseteq X^*$. In logspace, we construct an ideal witness w for I and J (Proposition 2)

and a DFA $\mathcal{A}$ for $X^* \setminus J$ (Proposition 4) and check whether $w \in L(\mathcal{A})$. In all other cases, to decide $L{\downarrow} \subseteq I$, we construct a DFA $\mathcal{A}$ for $X^* \setminus I$ and check whether $L{\downarrow} \cap L(\mathcal{A}) = \emptyset$.

Algorithms for $\mathcal{M} \subseteq_{\downarrow}$ NFA. Suppose $\mathcal{M} = \mathsf{Ideal}$ and we want to decide whether $I \subseteq L(\mathcal{A}){\downarrow}$ for an NFA $\mathcal{A}$. Since $|L(\mathcal{A})|_{\mathsf{I}} \leq |\mathcal{A}|$, we can construct in logspace an ideal witness w for I and $L(\mathcal{A}){\downarrow}$ and verify $w \in L(\mathcal{A}){\downarrow}$. In all other cases, we use a short witness for coNP-membership.

Algorithms for $\mathcal{M} \subseteq_{\downarrow}$ OCA. Suppose $\mathcal{M} = \mathsf{Ideal}$ and we want to decide whether $I \subseteq L(\mathcal{A}){\downarrow}$ for an OCA $\mathcal{A}$. We have a polynomial bound on $|L(\mathcal{A})|_{\mathsf{I}}$ (see Section 2). Hence, we construct in logspace an ideal witness w for I and $L(\mathcal{A}){\downarrow}$. We can also construct in logspace an OCA $\mathcal{A}'$ with $L(\mathcal{A}') = L(\mathcal{A}){\downarrow}$. Membership for OCA is in $\mathsf{NL} = \mathsf{coNL}$, so we can verify $w \in I$ and $w \notin L(\mathcal{A}') = L(\mathcal{A}){\downarrow}$. In all other cases, we convert the OCA to an NFA (see Section 2).

Algorithms for $\mathcal{M} \subseteq_{\downarrow} \mathsf{RBC}_{k,r}$. Let $\mathcal{A}$ be drawn from $\mathsf{RBC}_{k,r}$. First, suppose $\mathcal{M} = \mathsf{Ideal}$ and we want to decide whether $I \subseteq L(\mathcal{A})$. By Theorem 13, we have a polynomial bound on $|L(\mathcal{A})|_{\mathsf{I}}$ and can construct in logspace an ideal witness w for I and $L(\mathcal{A})$. We can also construct in logspace an RBCA $\mathcal{A}'$ with $L(\mathcal{A}') = L(\mathcal{A}){\downarrow}$. Since membership for $\mathsf{RBC}_{k,r}$ is in NL [12], we can check whether $w \in L(\mathcal{A}')$. Now let $\mathcal{M} \in \{\mathsf{NFA}, \mathsf{OCA}, \mathsf{RBC}_{k,r}\}$ and we are given L in $\mathcal{M}$ and an automaton $\mathcal{A}$ from $\mathsf{RBC}_{k,r}$. For NFA, OCA, and $\mathsf{RBC}_{k,r}$, we have a polynomial bound on $|L|_{\mathsf{I}}$ (see Section 2 and Theorem 13). Thus, we guess an ideal I of polynomial length and then verify that $I \subseteq L{\downarrow}$ but $I \not\subseteq L(\mathcal{A}){\downarrow}$. Since $\mathsf{Ideal} \subseteq_{\downarrow} \mathcal{M}$ and $\mathsf{Ideal} \subseteq_{\downarrow} \mathsf{RBC}_{k,r}$ are in NL, the verification is done in NL. Hence, non-inclusion is in NP. For $\mathcal{M} \in \{\mathsf{CFG}, \mathsf{RBC}\}$, we assume a fixed alphabet. Let L be in $\mathcal{M}$. Then Proposition 3 and Theorem 13 provide us with a witness of polynomial length. Since (non-)membership in $L{\downarrow}$ and in $L(\mathcal{A}){\downarrow}$ can be decided in NP, non-inclusion is in NP.

Algorithms for $\mathcal{M} \subseteq_{\downarrow}$ CFG. The case $\mathsf{Ideal} \subseteq_{\downarrow} \mathsf{CFG}$ is shown in Theorem 14. Suppose $\mathcal{M} \in \{\mathsf{NFA}, \mathsf{OCA}, \mathsf{RBC}_{k,r}\}$ and we are given L in $\mathcal{M}$ and a CFG $\mathcal{G}$. We have a polynomial bound on $|L|_{\mathsf{I}}$ (see Section 2 and Theorem 13), so that we can guess a polynomial-length ideal I. Since $\mathsf{Ideal} \subseteq_{\downarrow} \mathcal{M}$ is in NL in every case and $\mathsf{Ideal} \subseteq_{\downarrow} \mathsf{CFG}$ is in P, we can verify in polynomial time that $I \subseteq L{\downarrow}$ and $I \not\subseteq L(\mathcal{G}){\downarrow}$. Thus, non-inclusion is in NP. In the case $\mathcal{M} \in \{\mathsf{RBC}, \mathsf{CFG}\}$, we construct exponential-size downward closure NFAs and check inclusion for them (and the latter problem is in coNP). This yields a coNEXP algorithm.

Algorithms for $\mathcal{M} \subseteq_{\downarrow}$ RBC. Let $\mathcal{A}$ be from RBC. The ideal case is treated in Corollary 12. When given L in $\mathcal{M} \in \{\mathsf{NFA}, \mathsf{OCA}, \mathsf{RBC}_{k,r}\}$, we guess a polynomial length ideal I and verify that $I \subseteq L{\downarrow}$ in NL. Since $\mathsf{Ideal} \subseteq_{\downarrow} \mathsf{RBC}$ is in NP, we can also check in coNP that $I \not\subseteq L(\mathcal{A}){\downarrow}$. Hence, non-inclusion is in Σ_2^{P}. For $\mathcal{M} \in \{\mathsf{CFG}, \mathsf{RBC}\}$, we proceed as for $\mathcal{M} \subseteq_{\downarrow} \mathsf{CFG}$.

8 Hardness

In this section, we prove hardness results. Most of them are deduced from a generic hardness theorem that, under mild assumptions, derives hardness from the ability to generate finite sets with long words. We will work with bounds that exhibit the following useful property. A monotone function $f\colon \mathbb{N} \to \mathbb{N}$ will be called *amplifying* if $f(n) \geq n$ for $n \geq 0$ and there is a polynomial p such that $f(p(n)) \geq f(n)^2$ for large enough $n \in \mathbb{N}$. We say that a model *has property* $\Delta(f)$ (or short: *is* $\Delta(f)$) if for each given $n \in \mathbb{N}$, one can construct in polynomial time a description of a finite language whose longest word has length $f(n)$. For the sake of simplicity, we will abuse notation slightly and write $\Delta(f(n))$ instead of $\Delta(f)$. For a function $t\colon \mathbb{N} \to \mathbb{N}$, we use $\mathsf{coNTIME}(t)$ to denote the complements of languages accepted by nondeterministic Turing machines that are time bounded by $O(t(n^c))$ for some constant c.

We also need two mild language theoretic properties. A *transducer* is a finite automaton where every edge reads input and produces output. For a transducer $\mathcal{T}$ and a language L, the language $\mathcal{T}L$ consists of all words output by the transducer while reading a word from L. We call a model $\mathcal{M}$ a *full trio model* if given a transducer $\mathcal{T}$ and a language L described with $\mathcal{M}$, one can compute in polynomial time a description of $\mathcal{T}L$. A *substitution* is a map $\sigma\colon X \to \mathbb{P}(Y^*)$ that replaces each letter by a language. For languages L, we define $\sigma(L)$ in the obvious way. We call σ *simple* if $X \subseteq Y$ and there is some $x \in X$ such that for all $x' \in X \setminus \{x\}$, we have $\sigma(x') = \{x'\}$ and x occurs in each word from L at most once. We say that $\mathcal{M}$ has *closure under simple substitutions* if given a description of L and of $\sigma(x)$ in $\mathcal{M}$, we can compute in polynomial time a description of $\sigma(L)$.

▶ **Theorem 15.** *Let $t\colon \mathbb{N} \to \mathbb{N}$ be amplifying and let $\mathcal{M}$ and $\mathcal{N}$ be full trio models that are $\Delta(t)$ and have closure under simple substitutions. Then both $\mathcal{M} \subseteq_\downarrow \mathcal{N}$ and $\mathcal{M} =_\downarrow \mathcal{N}$ are hard for* coNTIME(t)*. Moreover, this hardness already holds for binary alphabets.*

Since NFAs are $\Delta(n)$, Theorem 15 yields coNP-hardness for inclusion and equivalence. In [4], hardness of equivalence was shown directly. RBCA and CFG clearly exhibit closure under simple substitutions and can generate exponentially long words. This yields:

▶ **Corollary 16.** *For $\mathcal{M}, \mathcal{N} \in \{CFG, RBC\}$, $\mathcal{M} \subseteq_\downarrow \mathcal{N}$ and $\mathcal{M} =_\downarrow \mathcal{N}$ are* coNEXP*-hard.*

From Theorem 15, we can also deduce hardness for other models. It was shown by Habermehl, Meyer, and Wimmel [14] that downward closures or Petri net languages are computable, which implies decidability of our problems. We use Theorem 15 to prove an Ackermann lower bound. Let $A_n\colon \mathbb{N} \to \mathbb{N}$ be defined as $A_0(x) = x + 1$, $A_{n+1}(0) = A_n(1)$, and $A_{n+1}(x+1) = A_n(A_{n+1}(x))$. Then, the function $A\colon \mathbb{N} \to \mathbb{N}$ with $A(n) = A_n(n)$ is the *Ackermann function*. Of course, for large enough n, we have $A_n(x) \geq x^2$. For such n, we have $A(n+1) = A_n(A_{n+1}(n)) \geq A_{n+1}(n)^2 \geq A(n)^2$, so A is amplifying. A result of Mayr and Meyer [26] (see also [30]) states that given $n \in \mathbb{N}$, one can construct in polynomial time a Petri net that, from its initial marking, can produce up to $A(n)$ tokens in an output place. Hence, Petri nets are $\Delta(A)$ and they clearly satisfy the language-theoretic conditions.

▶ **Corollary 17.** *For Petri net languages, inclusion and equivalence of downward closures is Ackermann-hard.*

Building on the sufficient condition of [34], Hague, Kochems, and Ong [15] have shown that downward closures are computable for higher-order pushdown automata. However, the method of [34] does not yield any information about the complexity of this computation. For $k \in \mathbb{N}$, we denote by $\exp_k$ the function with $\exp_0(n) = n$ and $\exp_{k+1}(n) = 2^{\exp_k(n)}$. It is easy to see that order-k pushdown automata are $\Delta(\exp_k)$ (for instance, one can adapt Example 2.5 of [8]). By co-k-NEXP, we denote the complements of languages accepted by nondeterministic Turing machines in time $O(\exp_k(n^c))$ for some constant c.

▶ **Corollary 18.** *For higher-order pushdown automata of order k, inclusion and equivalence of downward closures is hard for* co-k-NEXP*.*

Our last hardness result could also be shown using the method of Theorem 15. However, it is simpler to reduce a variant of the subset sum problem [6].

▶ **Proposition 19.** NFA $\subseteq_\downarrow$ RBC *and* NFA $=_\downarrow$ RBC *are Π_2^{P}-hard, even for binary alphabets.*

We have thus shown hardness for all inclusion problems that do not involve ideals. The remaining cases inherit hardness from the emptiness problem (for $\mathcal{M} \subseteq_\downarrow$ Ideal) or the non-emptiness problem (Ideal $\subseteq_\downarrow \mathcal{M}$).

Abstract

In combinatorics of words, a concatenation of k consecutive equal blocks is called a power of order k. In this paper we take a different point of view and define an anti-power of order k as a concatenation of k consecutive pairwise distinct blocks of the same length. As a main result, we show that every infinite word contains powers of any order or anti-powers of any order. That is, the existence of powers or anti-powers is an unavoidable regularity. Indeed, we prove a stronger result, which relates the density of anti-powers to the existence of a factor that occurs with arbitrary exponent. From these results, we derive that at every position of an aperiodic uniformly recurrent word start anti-powers of any order. We further show that any infinite word avoiding anti-powers of order 3 is ultimately periodic, and that there exist aperiodic words avoiding anti-powers of order 4. We also show that there exist aperiodic recurrent words avoiding anti-powers of order 6, and leave open the question whether there exist aperiodic recurrent words avoiding anti-powers of order k for $k = 4, 5$.

1 Introduction

Suppose you are in a room with a hundred people and somebody tells you that by an incredible coincidence the people in the room have *all different* birthdays. Of course this is much less surprising than if all the people had *the same* birthday; still you remember from your first course in combinatorics (or even before) that already in a class of fifty people the probability that no two people have the same birthday is less than 3%. So actually you are in a very *special* situation![1]

For a number of instances of objects taken from a fixed class using some rule, being all distinct can be viewed as a kind of regularity. This has been already considered extensively

[1] To be more precise, the probability that at least two people have the same birthday in a room of 100 people is about 0.9999996928.

in computer science. For example, the probability of collisions must be properly quantified when designing hashing functions. In the context of string processing, one usually deals with factors (substrings) of a word, and it is sometimes useful to factorize a word in blocks that are all distinct — a widely known example is the Lempel-Ziv factorization, at the basis of the eponymous compression algorithm. The problem of factoring a string in blocks that are all distinct (sometimes called equality-free factorization [7]) has practical applications also in bio-informatics, since it appears to be connected with gene synthesis [2]. Equality-free factorizations have been further considered by Fernau et al. [4], motivated by injective pattern matching with variables, which is identical to the special case of solving word equations where the left side of the equation does not contain variables, and different variables must be replaced by different words. In particular, in [4] it is proved that given a finite word w and a number k, the problem whether it is possible to factorize w into at least k distinct factors is $\mathcal{NP}$-complete.

In the context of infinite words, the complexity of sequences is often described by means of parameters that capture some kind of repetitiveness. To this end, one often considers as a degree of repetitiveness the maximal number of consecutive all-equal blocks occurring in the sequence, regardless of the length of the single blocks. A concatenation of k consecutive equal blocks is called *a power of order k*, or simply *a k-power*. E.g., *aabaabaabaab* is a 4-power. A first classification of infinite words consists in identifying those that are *k-power-free* for some $k \geq 2$, meaning that they do not contain any factor that is a k-power. Words avoiding k-powers have been the object of study of combinatorics on words since the very beginning of the theory [8] (cf. also [5]).

In this paper we adopt a different point of view based on the difference rather than on the equality. We consider the problem of finding in infinite words consecutive blocks of the same length that are all distinct. Of course, in the context of infinite words it is the requirement that the blocks all have the same length that makes the problem non-trivial, since otherwise one can always take arbitrarily long concatenations of blocks of increasing length to guarantee that they are all distinct.

We define an *anti-power of order k*, or simply a *k-anti-power*, as a concatenation of k consecutive pairwise distinct blocks of the same length. E.g., *aabaaabbbaba* is a 4-anti-power. A simple computation shows that there are in general much more anti-powers than powers for a fixed length and a fixed order; yet there are much less anti-powers than possible factors of the same given length.

Let us focus on an example. The Thue-Morse word

$$t = 01101001100101101001011001101001100101100110 \cdots$$

is perhaps the most prominent example in combinatorics of words [1]. It is defined as the word whose n-th digit is the parity of the number of 1s in the binary expansion of $n-1$ (so the first digit is the parity of 1s in 0, the second digit is the parity of 1s in 1, the third digit is the parity of 1s in 10, etc.). The Thue-Morse word does not contain *overlaps*, i.e., factors of the form $awawa$ for a letter a and a word w. In particular, the Thue-Morse word does not contain 3-powers (note that, on the other hand, every infinite binary word must contain 2-powers).

The shortest prefix of the Thue-Morse word that is a 2-antipower is 01. The shortest prefix that is a 3-anti-power is $01101 \cdot 00110 \cdot 01011$, of length 15. One can verify that the shortest 4-anti-power prefix has length 20. The first few lengths of the shortest prefixes of t that are k-anti-powers for different values of k are displayed in Table 1. A natural question is therefore the following: Given an integer $k > 1$, is it always possible to find a prefix of t

Table 1 The first few values of the sequence of lengths of the shortest prefixes of the Thue-Morse word that are k-anti-powers.

k	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	30	50	100
length	15	20	25	30	77	88	99	110	121	132	143	154	195	208	221	234	247	260	870	2450	9700
ratio	5	5	5	5	11	11	11	11	11	11	11	11	13	13	13	13	13	13	29	49	97

that is a k-anti-power? In this paper we answer this question in the affirmative. Actually, we prove a much stronger result. Indeed, we prove that the existence of powers of any order or anti-powers of any order is an unavoidable regularity:

▶ **Theorem 1.** *Every infinite word contains powers of any order or anti-powers of any order.*

Formally, an *unavoidable regularity* is a property P such that it is not possible to construct arbitrarily long words not satisfying P (cf. [3]). Some important theorems in combinatorics on words concern unavoidable regularities. Most of them follow from results originally stated in other areas of combinatorics, e.g., the Ramsey's, van der Waerden's and Shirshov's theorems (see [3, 5, 6] for further details).

Actually, we prove a stronger result, from which Theorem 1 follows. Given an infinite word x, we prove that if for some integer k the lower density of the set of lengths n for which the prefix of x of length kn is a k-anti-power is smaller than one, then there exists a word (whose length depends on k) that occurs in x with arbitrary exponent (Theorem 4). This implies that if an infinite word x has the property that each of its factors appears with bounded exponent (in the terminology of combinatorics on words we say that x is *ω-power-free*), then in x must start anti-powers of any order at every position. In particular, since a uniformly recurrent word is either purely periodic or ω-power-free, this property holds for every aperiodic uniformly recurrent word, as for example the Thue-Morse word or any Sturmian word[2].

In the second part of the paper, we focus on the avoidability of anti-powers. We show that any infinite word avoiding 3-anti-powers is ultimately periodic, and that there exist aperiodic words avoiding 4-anti-powers. We also show that there exist aperiodic *recurrent* words avoiding 6-anti-powers. We leave it as an open question to determine whether there exist aperiodic recurrent words avoiding 4-anti-powers or 5-anti-powers.

We conclude with final considerations and discuss open problems and further possible directions of investigation.

2 Preliminaries

Let $\mathbb{N} = \{1, 2, 3, \ldots\}$. Let $\mathbb{A}$ be a (possibly infinite) non-empty set, called the *alphabet*, whose elements are called *letters*. A *word* over $\mathbb{A}$ is a finite or infinite sequence of letters from $\mathbb{A}$. The *length* $|u|$ of a finite word u is the number of its letters. We let $\mathbb{A}^+$ denote the set of all finite words of positive length over $\mathbb{A}$, and $\mathbb{A}^{\mathbb{N}}$ the set of all infinite words over $\mathbb{A}$, that is, the

[2] Sturmian words are aperiodic words of minimal factor complexity. They are very well studied objects in combinatorics on words (see for instance [6]).

set of all maps from $\mathbb{N}$ to $\mathbb{A}$. Given a finite word u, we write u^ω the infinite word $uuu\cdots$ obtained by concatenating an infinite number of copies of u.

Given a finite or infinite word x, we say that a word u is a *factor* of x if $x = vuy$ for some words v and y. We say that u is a *prefix* (resp. *suffix*) of x if $x = uy$ (resp. $x = yu$) for some word y. We say that a word $u \neq x$ is a *border* of x if u is both a prefix and a suffix of x.

An infinite word x is *purely periodic* if there exists a positive integer p such that the letters occurring at positions i and j coincide whenever $i = j \mod p$. Equivalently, x is purely periodic if and only if $x = u^\omega$ for some word u of length p. An infinite word x is *ultimately periodic* if $x = uy$ for a finite word u and a purely periodic word y. An infinite word is *aperiodic* if it is not ultimately periodic.

An infinite word x is said to be *recurrent* if every finite factor of x occurs in x infinitely often. Equivalently, x is recurrent if and only if every finite prefix of x has a second occurrence as a factor. An infinite word x is said to be *uniformly recurrent* if every finite factor of x occurs syndetically (that is, it occurs infinitely often and with bounded gaps). Equivalently, x is uniformly recurrent if and only if for every finite factor u of x there exits an integer m such that u occurs in every factor of x of length m.

An infinite word x is said to be *k-power-free* for some integer $k > 1$ if for every finite factor u of x, one has that u^k is not a factor of x. An infinite word x is said to be *ω-power-free* if for every finite factor u of x there exists a positive integer l such that u^l is not a factor of x. Of course, if a word is k-power-free for some integer k, then it is ω-power-free, but the converse is not always true.

An important relationship between uniformly recurrent and ω-power-free words is the following (see for instance [3]):

▶ **Theorem 2.** *Every uniformly recurrent word is either purely periodic or ω-power-free.*

3 Unavoidability of powers or anti-powers

In order to state our main result, we need to introduce some definitions.

Let x be an infinite word and $k \in \mathbb{N}$. We set

$$P(x,k) = \{m \in \mathbb{N} \mid \text{ the prefix of } x \text{ of length } km \text{ is a } k\text{-power}\}.$$

Analogously, we set

$$AP(x,k) = \{m \in \mathbb{N} \mid \text{ the prefix of } x \text{ of length } km \text{ is a } k\text{-anti-power}\}.$$

Note that $P(x,1) = AP(x,1) = \mathbb{N}$ and that $P(x,k) \cap AP(x,k) = \emptyset$ for every $k \geq 2$. For example, if $x = 01^\omega$, we have $P(x,k) = AP(x,k) = \emptyset$ for every $k \geq 3$.

Recall that for any subset $X \subseteq \mathbb{N}$, the *lower density* of X is defined by

$$\underline{d}(X) = \liminf_{n\to\infty} \frac{|X \cap \{1,2,\ldots,n\}|}{n}.$$

Note that if X is finite, then $\underline{d}(X) = 0$. Moreover, if $\underline{d}(X) =< 1/t$ for some integer $t > 0$, then that there exist infinitely many integers m such that $\{m, m+1, \ldots, m+t-1\} \subset \mathbb{N} \setminus X$.

We are now going to prove our main result (Theorem 4). We premise a technical lemma.

▶ **Lemma 3.** *Let v be a border of a word w and u the word such that $w = uv$. If l is an integer such that $|w| > l|u|$, then u^l is a prefix of w.*

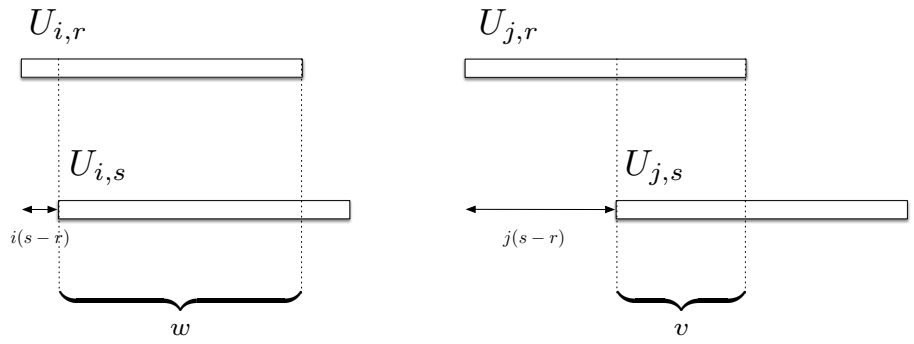

Figure 1 The proof of Theorem 4.

Proof. By induction on l. For $l = 1$ the statement trivially holds. Suppose $l > 1$. Since u is shorter than v and both are prefixes of w, we have that u is a prefix of v. Let us write $v = uv'$. Then $w = uuv'$ and v' is a border of v. Since $|v| = |w| - |u| > (l-1)|u|$, we can apply the induction hypothesis and derive that u^{l-1} is a prefix of v, whence u^l is a prefix of w. ◀

▶ **Theorem 4.** *Let x be an infinite word. Suppose that*

$$\underline{d}(AP(x,k)) < \left(1 + \binom{k}{2}\right)^{-1} = \frac{2}{2 + k(k-1)}$$

for some $k \in \mathbb{N}$. Then there exists $u \in \mathbb{A}^+$ with $|u| \leq (k-1)\binom{k}{2}$ such that u^l is a factor of x for every $l \geq 1$.

Proof. Fix k such that $\underline{d}(AP(x,k)) < (1+\binom{k}{2})^{-1}$. Since $AP(x,1) = \mathbb{N}$, and the lower density of $\mathbb{N}$ is 1, we have $k \geq 2$. We set $M = (k-1)\binom{k}{2}$. We have to show there exists $u \in \mathbb{A}^+$ with $|u| \leq M$ such that u^l is a factor of x for every $l \geq 1$. By the pigeonhole principle, it suffices to show that for every $l \in \mathbb{N}$ there exists $u \in \mathbb{A}^+$ with $|u| \leq M$ such that u^l is a factor of x.

So, let us fix $l \in \mathbb{N}$, and set $N = (l+1)M$. Since $\underline{d}(AP(x,k)) < (1 + \binom{k}{2})^{-1}$, there exists an integer $m > N$ such that $\{m, m+1, \ldots, m + \binom{k}{2}\} \subset \mathbb{N} \setminus AP(x,k)$.

For every j and r such that $0 \leq j \leq k-1$ and $m \leq r \leq m + \binom{k}{2}$, set

$$U_{j,r} = x_{jr+1}x_{jr+2}\cdots x_{(j+1)r},$$

so that $|U_{j,r}| = r$ and $U_{0,r}, U_{1,r}, \ldots, U_{k-1,r}$ are the first k consecutive blocks of x of length r. Thus for each $m \leq r \leq m + \binom{k}{2}$ there exist i and j, with $0 \leq i < j \leq k-1$, such that $U_{i,r} = U_{j,r}$. By the pigeonhole principle, there exist r and s, with $m \leq r < s \leq m + \binom{k}{2}$, and i and j, with $0 \leq i < j \leq k-1$, such that $U_{i,r} = U_{j,r}$ and $U_{i,s} = U_{j,s}$.

Notice that $(i+1)r > is + 1$ and $(j+1)r > js + 1$.

Let us now set $w = x_{is+1}x_{is+2}\cdots x_{(i+1)r}$ and $v = x_{js+1}x_{js+2}\cdots x_{(j+1)r}$ (see Figure 1). We have

$$|v| = (j+1)r - js < (i+1)r - is = |w|,$$

whence v is a border of w. Writing $w = uv$, we have

$$1 \leq |u| = |w| - |v| = (j-i)(s-r) \leq (k-1)\binom{k}{2} = M,$$

and

$$|w| > |v| = r - j(s-r) \geq m - (k-1)\binom{k}{2} = m - M > N - M = lM.$$

Thus, $|w| > l|u|$ and, by Lemma 3, u^l is a prefix of w, and therefore u^l is a factor of x. ◀

A more precise consequence of Theorem 4 is the following.

▶ **Corollary 5.** *Let x be a uniformly recurrent word. Then either*

$$\underline{d}(AP(x,k)) \geq \frac{2}{2+k(k-1)} \tag{1}$$

for every $k \in \mathbb{N}$ or there exists $r > 0$, such that

$$\underline{d}(P(x,k)) \geq r \tag{2}$$

for every $k \in \mathbb{N}$.

Proof. According to Theorem 4, if (1) does not hold for some $k' \in \mathbb{N}$, then $x = u^\omega$ for some u with $1 \leq |u| \leq (k'-1)\binom{k'}{2}$. Whence $n|u| \in P(x,k)$ for each $n, k \in \mathbb{N}$. The result now follows by setting $r = 1/|u|$. ◀

Note that the $\underline{d}(P(x,k)) \geq r$ for every k is stronger than just $\underline{d}(P(x,k)) > 0$. Conversely, if $\underline{d}(P(x,k)) > 0$ for some $k \geq 2$, then $\underline{d}(P(x,2)) > 0$, and from this it is immediate to see that x is periodic. In fact, something stronger is true: following the notation in the proof of Theorem 4, if there exists $j \geq 1$ such that $\underline{d}\{r \mid U_{0,r} = U_{j,r}\} > 0$, then x is periodic. And $\underline{d}(P(x,2)) > 0$ is a special case of this assumption (when $j = 1$).

▶ **Corollary 6.** *Let x be a uniformly recurrent word. If*

$$\underline{d}(AP(x,k)) < \frac{2}{2+k(k-1)}$$

for some $k \in \mathbb{N}$, then x is purely periodic.

Another direct consequence of Theorem 4 is the following.

▶ **Theorem 7.** *Let x be an infinite word. If x is ω-power-free, then at every position of x start anti-powers of any order.*

Proof. Suppose that there exists a positive integer k and a suffix x' of x such that no prefix of x' is a k-anti-power. Then $AP(x',k) = \emptyset$, whence $\underline{d}(AP(x',k)) = 0$. By Theorem 4, there exists a factor u of x' such that u^l is a factor of x' for every $l \geq 1$, hence x is not ω-power-free. ◀

From Theorems 2 and 7, we derive the following corollary.

▶ **Corollary 8.** *Let x be a uniformly recurrent aperiodic word. Then at every position of x start anti-powers of any order.*

4 Avoiding anti-powers

In this section we deal with avoidability of anti-powers.

▶ **Definition 9.** Given $k > 1$, we say that an infinite word x avoids k-anti-powers if no factor of x is a k-anti-power. That is, among any k consecutive blocks of the same length in x, at least two of them are equal. We say that an infinite word x avoids anti-powers if x avoids k-anti-powers for some k.

Periodic words avoid anti-powers, the period length being an upper bound for the maximal number of distinct consecutive blocks of the same length. In the following, we discuss the avoidability of anti-powers for aperiodic words. By Corollary 8, if an aperiodic word avoids anti-powers, then it cannot be uniformly recurrent.

Of course, any word containing at least two different letters cannot avoid 2-anti-powers. For 3-anti-powers, we have the following result.

▶ **Lemma 10.** *Let x be an infinite word. If x avoids 3-anti-powers, then x is a binary word.*

Proof. Suppose x avoids 3-anti-powers and contains three different letters. Then there is a factor of x of the form $u = ab^nc$ with $n \geq 1$ and a, b, c distinct letters. We will extend this factor to the right and force a 3-anti-power for every n. For $n = 1$, the word abc is already an anti-power. Take now $n = 2$. To avoid 3-anti-powers, $abbc$ can only be extended to $abbcb$. In the next step, the only option is $abbcbc$, and after that $abbcbcb$. But now, the word $abbcbcbyy'$ contains a 3-anti-power for every letters y, y'. Suppose now $u = ab^nc$ with $n \geq 3$. If n is odd, let $m = (n-1)/2$ and note that u can be factored as $ab^m \cdot b^{m+1} \cdot c$, so that u will be extended to the right to a 3-anti-power of length $3(m+1)$. If n is even, u can be factored as $u = ab^m \cdot b^{m+1} \cdot bc$, so that again u will be extended to the right to a 3-anti-power of length $3(m+1)$. ◀

Hence, in what follows we will suppose that x is an infinite word over the binary alphabet $\mathbb{A} = \{0, 1\}$.

▶ **Proposition 11.** *Let x be an infinite word. If x avoids 3-anti-powers, then it cannot contain a factor of the form 10^n1 or 01^n0 with $n > 1$.*

Proof. Suppose that x contains a factor of the form $u = 10^n1$ with $n > 1$ (the other situation is symmetric). The cases $n = 2, 3, 4, 5$ can be checked by computer, so let us suppose $n \geq 6$.

Suppose first n even, and write $n = 2m$. Since $u = 10^{m-1} \cdot 0^m \cdot 01$, any extension of u to the right will produce a 3-anti-power of length $3m$. If n is odd, $n = 2m + 1$, then we can write $u = 10^{m-1} \cdot 0^m \cdot 001$, so that any extension of u to the right will produce a 3-anti-power of length $3m$. ◀

▶ **Corollary 12.** *Let x be an infinite word avoiding 3-anti-powers. Then x is ultimately periodic.*

Actually, from Proposition 11, we have that an infinite word avoiding 3-anti-powers can only be of the form $x = (01)^\omega$, $x = 01^\omega$, or $x = 0^n10^\omega$ for some $n > 0$, up to exchanging letters.

▶ **Proposition 13.** *There exist aperiodic words avoiding 4-anti-powers.*

Proof. We exhibit an example of an aperiodic word avoiding 4-anti-powers. Let $(\alpha_i)_{i\geq 1}$ be an increasing sequence of positive integers with $\alpha_{i+1} \geq 5\alpha_i$ for each $i \geq 1$. Let $x \in \{0, 1\}^{\mathbb{N}}$

be defined by $x_n = 1$ if $n = \alpha_i$ for some $i \geq 1$, and $x_n = 0$ otherwise. Clearly x is aperiodic. Moreover, given $m \geq 0$ and $n \in \mathbb{N}$, if $|x_{m+1}x_{m+2}\cdots x_{m+n}|_1 \geq 2$, then for some $i \geq 1$

$$m + 1 \leq \alpha_i < 5\alpha_i \leq \alpha_{i+1} \leq m + n$$

and hence $n > 4\alpha_i \geq 4(m + 1)$ whence $m + 1 < n/4$. We claim that x avoids 4-anti-powers. In fact, suppose to the contrary that for some $m \geq 0$ and $n \in \mathbb{N}$ we have $x_{m+1}\cdots x_{m+n}$, $x_{m+n+1}\cdots x_{m+2n}$, $x_{m+2n+1}\cdots x_{m+3n}$, and $x_{m+3n+1}\cdots x_{m+4n}$ are pairwise distinct. Then at least three of the four blocks must contain an occurrence of 1. Thus $|x_{m+n+1}\cdots x_{m+4n}|_1 \geq 2$ from which it follows that $m + n + 1 < 3n/4$ and hence $m + 1 < 0$, a contradiction. ◀

The word in the previous proposition is not recurrent. It is natural to ask whether there exist recurrent words avoiding 4-anti-powers. We do not know the answer. However, we can state the following result.

▶ **Proposition 14.** *There exist aperiodic recurrent words avoiding* 6*-anti-powers.*

Proof. We exhibit an example of an aperiodic recurrent word avoiding 6-anti-powers. Let $w_0 = 0$ and $w_n = w_{n-1}1^{3|w_{n-1}|}w_{n-1}$ for every $n > 0$. Let w be the infinite word obtained as the limit of the sequence of words $(w_n)_{n\geq 1}$. Then clearly w is recurrent. Without loss of generality, we can assume that each occurrence of w_n in w is preceded and followed by $1^{3|w_n|}$, since w avoids 6-anti-powers if $1^\infty w$ does.

Let $v = v_1v_2\cdots v_6$ be a non-empty factor of w of length $6k$. Let n be the largest integer such that $|w_n| = 5^n < 2k$. By the hypothesis on n, no v_i can intersect two occurrences of w_n.

Suppose first that for some i, v_i is contained as a factor in w_n. By the hypothesis on n, neither $v_{i-1}v_i$ nor v_iv_{i+1} is contained in w_n. Since w_n is preceded and followed by $1^{3|w_n|}$, either v_{i-3} and v_{i-2} (if $i \geq 4$) or v_{i+2} and v_{i+3} (if $i < 4$) are both equal to 1^k, so that v cannot be an anti-power.

If instead no v_i is contained as a factor in w_n, then one of the following cases must hold:

(i) There is an occurrence of w_n intersecting v_i and the next occurrence of w_n intersects v_{i+1}. In this case, either v_{i-3} and v_{i-2} or v_{i+3} and v_{i+4} are both equal to 1^k.

(ii) There is an occurrence of w_n intersecting v_i and the next occurrence of w_n intersects v_{i+2}, so that $v_{i+1} = 1^k$. In this case, either v_{i-2} or v_{i+4} must be equal to 1^k.

(iii) There are two consecutive blocks v_i, v_{i+1} both equal to 1^k.

In all cases, v cannot be an anti-power. ◀

5 Conclusions and open problems

We proved that every infinite word contains powers of any order or anti-powers of any order, that is, the existence of powers or anti-powers is an unavoidable regularity. This result can also be stated in the following finite version.

▶ **Theorem 15.** *For every integers $k > 1$ and $r > 1$ there exists $N = N(k, r)$ such that every word of length N contains a k-power or an r-anti-power. Furthermore, for $k > 2$, one has $k^2 - 2 \leq N(k, k) \leq k^5 + k^3$.*

The upper bound follows from the proof of Theorem 4. For the lower bound, it is easy to prove that the word $(0^{k-1}1)^{k-2}0^{k-2}10^{k-2}$ of length $k^2 - 3$ avoids both k-powers and k-anti-powers, for any $k > 2$.

In the case of binary alphabet, it can be verified that $N(2, 2) = 2$, $N(3, 2) = 3$, $N(2, 3) = 4$, $N(3, 3) = 9$, $N(4, 3) = 12$, $N(3, 4) > 16$, $N(4, 4) > 16$. We do not know how these numbers
