$\deg_H(v)/b_v$. In DB-SF we are given graph G, degree bounds, and k connectivity demands. Let σ_i denote the i-th demand. The i-th demand is a pair of vertices $\sigma_i = (s_i, t_i)$, where $s_i, t_i \in V$. In DB-SF the goal is to find a subgraph $H \subseteq G$ such that for each demand σ_i, s_i is connected to t_i in H, for every vertex $v \in V$, $l_H(v) \leq 1$, and $w(H)$ is minimized. In this paper without loss of generality we assume the demand endpoints are distinct vertices with degree one in G and degree bound infinity.

In the online variant of the problem, we are given graph G and degree bounds in advance. However the sequence of demands are given one by one. At arrival of demand σ_i, we are asked to provide a subgraph H_i, such that $H_{i-1} \subseteq H_i$ and s_i is connected to t_i in H_i.

The following integer program is a natural mixed packing and covering integer program for EW-DB-SF. Let $\mathcal{S}$ denote the collection of subsets of vertices that separate the endpoints of at least one demand. For a set of vertices S, let $\delta(S)$ denote the set of edges with exactly one endpoint in S. In $\mathbb{SF}\_\mathbb{IP}$, for an edge e, $x_e = 1$ indicates that we include e in the solution while $x_e = 0$ indicates otherwise. The variable α indicates an upper bound on the violation of the load of every vertex and an upper bound on the violation of the weight. The first set of constraints ensures that the load of a vertex is upper bounded by α. The second constraint ensures that the violation for the weight is upper bounded by α. The third set of constraints ensures that the endpoints of every demand are connected. Here we assume w_{opt} is known to the algorithm, although this can be waived by standard doubling techniques.

$$\text{minimize} \quad \alpha \ . \tag{$\mathbb{SF}\_\mathbb{IP}$}$$

$$\forall v \in V \quad \frac{1}{b_v} \sum_{e \in \delta(\{v\})} x_e \leq \alpha \ . \tag{1}$$

$$\frac{1}{w_{\text{opt}}} \sum_{e \in E} w(e) x_e \leq \alpha \ . \tag{2}$$

$$\forall S \subseteq \mathcal{S} \quad \sum_{e \in \delta(S)} x_e \geq 1 \ . \tag{3}$$

$$x_e \in \{0,1\}, \alpha \in \mathbb{Z}_{>0} \ .$$

1.3 Overview of the Paper

We begin Section 2 by providing a bounded frequency IP for EW-DB-SF. The IP is not a proper formulation of the problem, however, we can show that one can map feasible solutions of EW-DB-SF to feasible solutions of the IP without increasing the cost too much. In Section 3 we provide a deterministic algorithm for online bounded frequency mixed packing/covering IPs. In the full version of the paper, we also provide a matching lower bound for the competitive ratio of any randomized algorithm. Finally, in Section 4 we merge our techniques to obtain online polylogarithmic-competitive algorithms for EW-DB-SF.

2 Finding the Right Integer Program

In this section we design an online mixed packing and covering integer program for EW-DB-SF. We show this formulation is near optimal, i.e. any $f-$approximation for this formulation, implies an $O(f \log^2 n)$-approximation for EW-DB-SF. In Section 4 we show there exists an online algorithm that finds an $O(\log n)$-approximation solution for this IP and violates degree bounds by $O(\log^3 n \log w_{\text{opt}})$, where w_{opt} denotes the optimal weight.

First we define some notations. For a sequence of demands $\sigma = \langle (s_1, t_1), \ldots, (s_k, t_k) \rangle$, we define $R_\sigma(i)$ to be a set of i edges, connecting the endpoints of the first i demands.

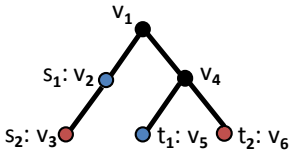

Figure 1 An example where every vertex has degree-bound 3 and every edge has weight 1. The first demand is (v_2, v_5) and the second demand is (v_3, v_6). The optimal solution for $\mathbb{SF}\_\mathbb{IP}$ is a subgraph, say H, with the set of all edges and vertices, i.e. $H = G$. However an optimal solution for $\mathbb{PC}\_\mathbb{IP}$ is: Two subgraphs H_1 for the first request which has edges $\{e(v_1, v_2), e(v_1, v_4), e(v_4, v_5)\}$ and H_2 for the second request which has edges $\{e(v_2, v_3), e(v_4, v_5), e(v_4, v_6)\}$. Note that $w(H) = 5$ and $w(H_1) + w(H_2) = 6$, since we have edge $e(v_4, v_5)$ in both H_1 and H_2. Moreover the number of edges incident with v_4 in the solution of $\mathbb{PC}\_\mathbb{IP}$ is 4, i.e. $\deg_{H_1}(v_4) + \deg_{H_2}(v_4) = 4$.

In particular $R_\sigma(i) := \bigcup_{j=1}^{i} e(s_j, t_j)$, where $e(s_j, t_j)$ denotes a direct edge from s_j to t_j. Moreover, we say subgraph H_i satisfies the connectivity of demand $\sigma_i = (s_i, t_i)$, if s_i and t_i are connected in graph $H_i \cup R_\sigma(i-1)$. Let $\mathcal{H}_i$ denote the set of all subgraphs that satisfy the connectivity of demand σ_i. In $\mathbb{PC}\_\mathbb{IP}$ variable α denotes the violation in the packing constraints. Furthermore for every subgraph $H \subseteq G$ and demand σ_i, there exists a variable $x^i_H \in \{0, 1\}$. $x^i_H = 1$ indicates we add the edges of H to the existing solution, at arrival of demand σ_i. The first set of constraints ensure the degree-bounds are not violated more than α. The second constraint ensures the weight is not violated by more than α. The third set of constraints ensure the endpoints of every demand are connected.

$$\text{minimize} \quad \alpha \ . \tag{$\mathbb{PC}\_\mathbb{IP}$}$$

$$\forall v \in V \qquad \frac{1}{b_v} \sum_{i=1}^{k} \sum_{H \subseteq G} \deg_H(v) x^i_H \leq \alpha \ . \tag{4}$$

$$\frac{1}{w_{\text{opt}}} \sum_{i=1}^{k} \sum_{H \subseteq G} w(H) x^i_H \leq \alpha \ . \tag{5}$$

$$\forall \sigma_i \qquad \sum_{H \in \mathcal{H}_i} x^i_H \geq 1 \ . \tag{6}$$

$$\forall H \subseteq G, 1 \leq i \leq k \qquad \mathbf{x}^i_H \in \{0, 1\} \ .$$

$$\alpha > 0 \ .$$

We are considering the online variant of the mixed packing and covering program. We are given the packing Constraints (4) and (5) in advance. At arrival of demand σ_i, the corresponding covering Constraint (6) is added to the program. We are looking for an online solution which is feasible at every online stage. Moreover the variables x_H should be monotonic, i.e. once an algorithm sets $x_H = 1$ for some H, the value of x_H is 1 during the rest of the algorithm. Figure 1 illustrates an example which indicates the difference between the solutions of $\mathbb{PC}\_\mathbb{IP}$ and $\mathbb{SF}\_\mathbb{IP}$.

Let popt and lopt denote the optimal solutions for $\mathbb{PC}\_\mathbb{IP}$ and $\mathbb{SF}\_\mathbb{IP}$, respectively. Lemma 4 shows that given an online solution for $\mathbb{PC}\_\mathbb{IP}$ we can provide a feasible online solution for $\mathbb{SF}\_\mathbb{IP}$ of cost popt.

▶ **Lemma 4.** *Given a feasible solution $\{\mathbf{x}, \alpha\}$ for $\mathbb{PC}\_\mathbb{IP}$, there exists a feasible solution $\{\mathbf{x}', \alpha\}$ for $\mathbb{SF}\_\mathbb{IP}$.*

In the rest of this section, we show that we do not lose much by changing $\mathbb{SF}\_\mathbb{IP}$ to $\mathbb{PC}\_\mathbb{IP}$. In particular we show $\mathsf{popt} \leq O(\log^2 n)\mathsf{lopt}$.

To this end, we first define the *connective* list of subgraphs for a graph G, a forest F, and a list of demands σ. We then prove an existential lemma for such a list of subgraphs with a desirable property for any $\langle G, F, \sigma\rangle$. With that in hand, we prove $\mathsf{popt} \leq O(\log^2 n)\mathsf{lopt}$. In what follows, we refer the reader to the full version of the paper for detailed proofs.

Given G, a list of demands $\sigma = \langle (s_1, t_1), \ldots, (s_k, t_k)\rangle$, and a forest $F \subseteq G$:

▶ **Definition 5.** Let $Q = \langle Q_1, Q_2, Q_3, \ldots, Q_k\rangle$ be a list of k subgraphs of F. We say Q is a *connective list* of subgraphs for $\langle G, F, \sigma\rangle$ iff for every $1 \leq i \leq k$ there exists no cut disjoint from Q_i that separates s_i from t_i, but does not separate any s_j from t_j for $j < i$.

The intuition behind the definition of connective subgraphs is the following: If Q is a connective list of subgraphs for an instance $\langle G, F, \sigma\rangle$ then for every i we are guaranteed that the union of all subgraphs $\cup_{j=1}^{i} Q_i$ connects s_i to t_i. In Lemma 6 we show for every $\langle G, F, \sigma\rangle$, there exists a connective list of subgraphs for $\langle G, F, \sigma\rangle$, such that each edge of F appears in at most $O(\log^2 n)$ subgraphs of Q.

▶ **Lemma 6.** *Let G be a graph and F be a forest in G. If σ is a collection of k demands $\langle (s_1, t_1), \ldots, (s_k, t_k)\rangle$, then there exists a connective list of subgraphs $Q = \langle Q_1, Q_2, \ldots, Q_k\rangle$ for $\langle G, F, \sigma\rangle$ such that every edge of F appears in at most $3\log^2 |V(F)|$ number of Q_i's.*

Proof. Here we give a sketch of the proof of lemma; we refer the reader to the full version for detailed proofs. We first prove a cost-minimization variant of the lemma. Consider an arbitrary weight vector $\hat{w} : F \to \mathbb{R}^{\geq 0}$. We argue that there is a connective list Q, such that $\sum_i \hat{w}(Q_i) \leq O(\log^2 n)\hat{w}(F)$. Let $\hat{H}_i = (V, F \cup R_\sigma(i), \hat{w}_i)$ denote a weighted graph for which $\hat{w}_i(e) = \hat{w}(e)$ for $e \in F$, and $\hat{w}_i(e) = 0$ for $e \in R_\sigma(i)$. Now we note that there is no cost-sharing among Q_i's in the goal $\sum_i \hat{w}(Q_i)$. Therefore the optimal choice for Q_i corresponds to the minimum-weight (s_i, t_i)-path in $\hat{H}_{i-1}$. Hence, we need to analyze the cost of these greedy choices.

Awerbuch et al. [4] showed that the greedy algorithm is indeed $O(\log^2 n)$-competitive for the edge-weighted Steiner forest problem. The standard greedy algorithm is slightly different from the greedy process we discussed above. In the greedy algorithm of Awerbuch et al., at time step i we choose a minimum-cost (s_i, t_i)-path in a graph in which there is a zero-cost edge between *any* pair of vertices in the same connected component of the current solution; not just the (s_j, t_j) pairs of the previous demands. However, in their analysis they only use the zero-cost edges among the terminals of a previous demand. This is indeed not surprising since we hardly have any control on the greedy choices other than the fact that they satisfy the demands. Therefore the following claim follows from the result of Awebuch et al.[2]:

▶ **Claim 7** (implicitly proven in Theorem 2.1 of [4]). *For any weight function $\hat{w}$ defined over F, there exists a connective list Q for which*

$$\sum_i \hat{w}(Q_i) \leq O(\log^2 n)\hat{w}(F).$$

However, Claim 7 is not enough for us. We need a solution in which every edge is used at most $O(\log^2 n)$ times, not just in an amortized sense. Indeed we can show that since

[2] There is also a lower bound of $\Omega(\log n)$ for the competitive ratio of the greedy algorithm. Closing the gap between this lower bound and the upper bound of $O(\log^2 n)$ for EW Steiner forest is an important open problem.

there is a solution for *every* weight function, we can have a *fractional* connective list Q in which every edge is used (fractionally) at most $O(\log^2 n)$ times. This implies that we have a fractional connective list. Finally, we provide a rounding argument which obtains an integral connective list by losing only a constant factor; which completes the proof of lemma. ◀

Finally, we can leverage Lemma 6 to show $\mathsf{popt} \leq O(\log^2 n)\mathsf{lopt}$. This shows we can use $\mathbb{PC}\_\mathbb{IP}$ as an online mixed packing/covering IP to obtain an online solution for ONLINE EDGE-WEIGHTED DEGREE-BOUNDED STEINER FOREST losing a factor of $O(\log^2 n)$. In Section 4 we show this formulation is an online bounded frequency mixed packing/covering IP, thus we leverage our technique for such IPs to obtain a polylogarithmic-competitive algorithm for online EW-DB-SF.

3 Online Bounded Frequency Mixed Packing/Covering IPs

In this section we consider bounded frequency online mixed packing and covering integer programs. For every online mixed packing and covering IP with covering frequency k, we provide an online algorithm that violates each packing constraint by at most a factor of $O(k \log m)$, where m is the number of packing constraints. We note that this bound is independent of the number of variables, the number of covering constraints, and the coefficients of the mixed packing and covering program. Moreover the algorithm is for integer programs, which implies obtaining an integer solution does not rely on (online) rounding.

In particular we prove there exists an online $O(k \log m)$-competitive algorithm for any mixed packing and covering IP such that every variable has covering frequency at most k, where the covering frequency of a variable x_r is the number of covering constraints with a non-zero coefficient for x_r.

We assume that all variables are binary. One can see this is without loss of generality as long as we know every variable $x_r \in \{1, 2, 3, \ldots, 2^l\}$. Since we can replace x_r by l variables $y_r^1, \ldots, y_r^l$ denoting the digits of x_r and adjust coefficients accordingly. Furthermore, for now we assume that the optimal solution for the given mixed packing and covering program is 1. In Theorem 10 we prove that we can use a doubling technique to provide an $O(k \log m)$-competitive solution for online bounded frequency mixed packing and covering programs with any optimal solution. The algorithm is as follows. We maintain a family of subsets $\mathcal{S}$. Initially $\mathcal{S} = \emptyset$. Let $\mathcal{S}(j)$ denote $\mathcal{S}$ at arrival of C_{j+1}. For each covering constraint C_{j+1}, we find a subset of variables S_{j+1} and add S_{j+1} to $\mathcal{S}$. We find S_{j+1} in the following way. For each set of variables S, we define a cost function $\tau_S(\mathcal{S}(j))$ according to our current $\mathcal{S}$ at arrival of C_{j+1}. We find a set S_{j+1} that satisfies C_{j+1} and minimizes $\tau_S(\mathcal{S}(j))$. More precisely we say a set of variables S satisfies C_{j+1} if

- $\sum_{x_r \in S} C_{j+1,r} x_r \geq 1$, where $C_{j+1,r}$ denotes the coefficient of C_{j+1} for x_r.
- For each packing constraint P_i, $\sum_{x_r \in S} \frac{1}{k} P_{ir} \leq 1$.

Now we add S_{j+1} to $\mathcal{S}$ and for every $x_r \in S_{j+1}$, we set $x_r = 1$. We note that there always exists a set S that satisfies C_{j+1}, since we assume there exists an optimal solution with value 1. Setting S to be the set of all variables with value one in an optimal solution which have non-zero coefficient in C_{j+1}, satisfies C_{j+1}. It only remains to define $\tau_S(\mathcal{S}(j))$. But before that we need to define $\Delta_i(S)$ and $F_i(\mathcal{S}(j))$. For packing constraint P_i and subset of variables S, we define $\Delta_i(S)$ as $\Delta_i(S) := \sum_{x_r \in S} \frac{1}{k} P_{ir}$. For packing constraint P_i and $\mathcal{S}(j)$, let

$$F_i(\mathcal{S}(j)) := \sum_{S \in \mathcal{S}(j)} \Delta_i(S) \ . \tag{7}$$

Now let $\tau_S(\mathcal{S}(j)) = \sum_{i=1}^{m} \rho^{F_i(\mathcal{S}(j))+\Delta_i(S)} - \rho^{F_i(\mathcal{S}(j))}$, where $\rho > 1$ is a constant to be defined later.

Algorithm 1

Input: Packing constraints P, and an online stream of covering constraints $C_1, C_2, \ldots$.
Output: A feasible solution for online bounded frequency mixed packing/covering.
Offline Process:

1: Initialize $\mathcal{S} \leftarrow \emptyset$.

Online Scheme; assuming a covering constraint C_{j+1} is arrived:

1: $S_{j+1} \leftarrow \arg\min_S\{\tau_S(\mathcal{S}(j)) \mid S \text{ satisfies } C_{j+1}\}$.
2: **for all** $x_r \in S_{j+1}$ **do**
3: $\quad x_r \leftarrow 1$.

Let $\mathbf{x}^*$ be an optimal solution, and $\mathbf{x}^*(j)$ denote its values at online stage j. We define $G_i(j)$ as

$$G_i(j) := \sum_{l=1}^{j} \sum_{r:C_{lr}>0} \frac{1}{k} x_r^* P_{ir} \ . \tag{8}$$

Now we define a potential function Φ_j for online stage j.

$$\Phi_j = \sum_{i=1}^{m} \rho^{F_i(\mathcal{S}(j))}(\gamma - G_i(j)) \ , \tag{9}$$

where $\rho, \gamma > 1$ are constants to be defined later.

▶ **Lemma 8.** *There exist constants ρ and γ, such that Φ_j is non-increasing.*

Proof. We find ρ and γ such that $\Phi_{j+1} - \Phi_j \leq 0$. By the definition of Φ_j,

$$\Phi_{j+1} - \Phi_j = \sum_{i=1}^{m} \rho^{F_i(\mathcal{S}(j+1))}(\gamma - G_i(j+1)) - \rho^{F_i(\mathcal{S}(j))}(\gamma - G_i(j)) \ . \tag{10}$$

By Equation (7), $\rho^{F_i(\mathcal{S}(j+1))} - \rho^{F_i(\mathcal{S}(j))} = \rho^{F_i(\mathcal{S}(j))+\Delta_i(S)} - \rho^{F_i(\mathcal{S}(j))}$. Moreover by Equation (8), $(\gamma - G_i(j+1)) - (\gamma - G_i(j)) = -\sum_{r:C_{j+1,r}>0} \frac{1}{k} x_r^* P_{ir}$. For simplicity of notation we define $B_i(j+1) := \sum_{r:C_{j+1,r}>0} \frac{1}{k} x_r^* P_{ir}$. Thus we can write Equation (10) as:

$$\Phi_{j+1} - \Phi_j = \sum_{i=1}^{m} \rho^{F_i(\mathcal{S}(j+1))}(\gamma - G_i(j) - B_i(j+1)) - \rho^{F_i(\mathcal{S}(j))}(\gamma - G_i(j)) \tag{11}$$

$$= \sum_{i=1}^{m} (\gamma - G_i(j))(\rho^{F_i(\mathcal{S}(j))+\Delta_i(S)} - \rho^{F_i(\mathcal{S}(j))}) - \rho^{F_i(\mathcal{S}(j+1))} B_i(j+1) \quad \text{Since } G_i(j) \geq 0$$

$$\leq \sum_{i=1}^{m} \gamma(\rho^{F_i(\mathcal{S}(j))+\Delta_i(S)} - \rho^{F_i(\mathcal{S}(j))}) - \rho^{F_i(\mathcal{S}(j+1))} B_i(j+1) \qquad F_i(\mathcal{S}(j+1)) \geq F_i(\mathcal{S}(j))$$

$$\leq \sum_{i=1}^{m} \gamma(\rho^{F_i(\mathcal{S}(j))+\Delta_i(S)} - \rho^{F_i(\mathcal{S}(j))}) - \rho^{F_i(\mathcal{S}(j))} B_i(j+1) \ .$$

Now according to the algorithm for each subset of variables S' such that $\sum_{x_r \in S'} C_{j+1}(x_r) \geq 1$, either $\tau_S(\mathcal{S}(j)) \leq \tau_{S'}(\mathcal{S}(j))$ or there exists a packing constraint P_i such that $\Delta_i(S') > 1$. In

$B_i(j+1)$, we are considering variables x_r such that $x^*_e = 1$, thus for every P_i, $B_i(j+1) \leq 1$. Therefore setting S' to be the set of variables x_r such that $x^*_r = 1$ and $C_{j+1,r} > 0$, we have $\tau_S(\mathcal{S}(j)) \leq \tau_{S'}(\mathcal{S}(j))$. Thus $\sum_{i=1}^m \rho^{F_i(\mathcal{S}(j))+\Delta_i(S)} - \rho^{F_i(\mathcal{S}(j))} \leq \sum_{i=1}^m \rho^{F_i(\mathcal{S}(j))+B_i(j+1)} - \rho^{F_i(\mathcal{S}(j))}$. Therefore we can rewrite Inequality (11) as

$$\begin{aligned}\Phi_{j+1} - \Phi_j &\leq \sum_{i=1}^m \gamma(\rho^{F_i(\mathcal{S}(j))+B_i(j+1)} - \rho^{F_i(\mathcal{S}(j))}) - \rho^{F_i(\mathcal{S}(j))} B_i(j+1) \qquad (12)\\ &= \sum_{i=1}^m \rho^{F_i(\mathcal{S}(j))}(\gamma\rho^{B_i(j+1)} - \gamma - B_i(j+1)) \ .\end{aligned}$$

We would like to find ρ and γ such that Φ_j is non-increasing. We find ρ and γ such that for each packing constraint P_i, $\gamma\rho^{B_i(j+1)} - \gamma - B_i(j+1) \leq 0$. Thus

$$\gamma\rho^{B_i(j+1)} - \gamma \leq B_i(j+1) \qquad \text{Since } 0 \leq B_i(j+1) \leq 1 \qquad (13)$$

$$\gamma\rho B_i(j+1) - \gamma \leq B_i(j+1) \qquad \text{By simplifying} \qquad (14)$$

$$\rho \leq 1 + 1/\gamma \ . \qquad (15)$$

Thus if we set $\rho \leq 1 + 1/\gamma$, Φ_j is non-increasing, as desired. ◀

Now we prove Algorithm 1 obtains a solution of at most $O(k \log m)$.

▶ **Lemma 9.** *Given an online bounded frequency mixed packing covering IP with optimal value 1, there exists a deterministic integral algorithm with competitive ratio $O(k \log m)$, where m is the number of packing constraints and k is the covering frequency of the IP.*

Proof. By Lemma 8 for each stage j, $\Phi_{j+1} \leq \Phi_j$. Therefore $\Phi_j \leq \Phi_0 = \gamma m$. Thus for each packing constraint P_i,

$$\rho^{F_i(\mathcal{S}(j))}(\gamma - G_i(j)) \leq \gamma m \ . \qquad (16)$$

Thus,

$$\rho^{F_i(\mathcal{S}(j))} \leq \frac{\gamma m}{(\gamma - G_i(j))} \leq \frac{\gamma m}{\gamma - 1} \ . \qquad \text{Since } G_i(j) \leq 1 \qquad (17)$$

Thus we can conclude

$$F_i(\mathcal{S}(j)) \in O(\log m) \ . \qquad (18)$$

By definition of $F_i(\mathcal{S}(j))$, $F_i(\mathcal{S}(j)) = \sum_{S\in\mathcal{S}(j)} \Delta_i(S) = \sum_{S\in\mathcal{S}(j)} \sum_{x_r\in S} \frac{1}{k} P_{ir}$. Since each variable x_r is present in at most k sets, $\frac{1}{k} P_i \cdot \mathbf{x}(j) \leq F_i(\mathcal{S}(j))$. Thus by Inequality (18) $P_i\mathbf{x}(j) \in O(k \log m)$, which completes the proof. ◀

Finally we prove there exists an online $O(k \log m)$-competitive algorithm for bounded frequency online mixed packing and covering integer programs with any optimal value.

▶ **Theorem 10.** *Given an instance of the online mixed packing/covering IP, there exists a deterministic integral algorithm with competitive ratio $O(k \log m)$, where m is the number of packing constraints and k is the covering frequency of the IP.*

4 Putting Everything Together

In this section we consider the online mixed packing/covering formulation discussed in Section 2 for ONLINE EDGE-WEIGHTED DEGREE-BOUNDED STEINER FOREST $\mathbb{PC}\_\mathbb{IP}$. In this section we show this formulation is an online bounded frequency mixed packing/covering IP. Therefore we our techniques discussed in Section 3 to obtain a polylogarithmic-competitive algorithm for ONLINE EDGE-WEIGHTED DEGREE-BOUNDED STEINER FOREST.

First we assume we are given the optimal weight w_{opt} as well as degree bounds. We can obtain the following theorem.

▶ **Theorem 11.** *Given the optimal weight w_{opt}, there exists an online deterministic algorithm which finds a subgraph with total weight at most $O(\log^3 n)w_{opt}$ while the degree bound of a vertex is violated by at most a factor of $O(\log^3 n)$.*

Proof. By Lemma 4, given a feasible online solution for $\mathbb{PC}\_\mathbb{IP}$ with violation α, we can provide an online solution for $\mathbb{SF}\_\mathbb{IP}$ with violation α. Moreover, in Section 2 we show that $\mathsf{popt} \leq O(\log^2 n)\mathsf{lopt}$. Thus given an online solution for $\mathbb{PC}\_\mathbb{IP}$ with competitive ratio f, there exists an $O(f \log n)$-competitive algorithm for ONLINE DEGREE-BOUNDED STEINER FOREST. We note that in $\mathbb{PC}\_\mathbb{IP}$ we know the packing constraints in advance. In addition every variable x_H^i has non-zero coefficient only in the covering constraint corresponding to connectivity of the i-th demand endpoints, i.e. the covering frequency of every variable is 1. Therefore by Theorem 10 there exists an online $O(\log m)$-competitive solution for $\mathbb{PC}\_\mathbb{IP}$, where m is the number of packing constraints, which is $n + 1$. Thus there exists an online $O(\log^3 n)$-competitive algorithm for ONLINE DEGREE-BOUNDED STEINER FOREST. This means the violation for both degree bounds and weight is of $O(\log^3 n)$. ◀

Finally if w_{opt} is not given, we show in the full version of the paper that by applying standard doubling techniques one can prove Theorem 1 using the result shown above.

Abstract

We consider the online carpool fairness problem of [Fagin and Williams, 1983] in which an online algorithm is presented with a sequence of pairs drawn from a group of n potential drivers. The online algorithm must select one driver from each pair, with the objective of partitioning the driving burden as fairly as possible for all drivers. The *unfairness* of an online algorithm is a measure of the worst-case deviation between the number of times a person has driven and the number of times they would have driven if life was completely fair.

We introduce a version of the problem in which drivers only carpool with their neighbors in a given social network graph; this is a generalization of the original problem, which corresponds to the social network of the complete graph. We show that for graphs of degree d, the unfairness of deterministic algorithms against adversarial sequences is exactly $d/2$.

For random sequences of edges from planar graph social networks we give a [deterministic] algorithm with logarithmic unfairness (holds more generally for any bounded-genus graph). This does not follow from previous random sequence results in the original model, as we show that restricting the random sequences to sparse social network graphs may increase the unfairness.

A very natural class of randomized online algorithms are so-called static algorithms that preserve the same state distribution over time. Surprisingly, we show that any such algorithm has unfairness $\tilde{\Theta}(\sqrt{d})$ against oblivious adversaries. This shows that the *local random greedy* algorithm of [Ajtai et al, 1996] is close to optimal amongst the class of static algorithms. A natural (non-static) algorithm is global random greedy (which acts greedily and breaks ties at random). We improve the lower bound on the competitive ratio from $\Omega(\log^{1/3}(d))$ to $\Omega(\log d)$. We also show that the competitive ratio of global random greedy against adaptive adversaries is $\Omega(d)$.

1 Introduction

In multiple experimental studies involving hundreds of graduate students, Loewenstein, Thompson, and Bazerman [8] give evidence that individuals are strongly averse to outcomes where they are at a disadvantage relative to others. Moreover, albeit significantly less so, the grad students were also averse to outcomes where they have a relative advantage in payoff. Fehr and Schmidt [6] coined the phrase *inequity aversion* to describe this phenomena. Festinger [7] had much earlier introduced the concept of cognitive dissonance, and inequity aversion is modeled as a special case thereof. Supposedly, inequity aversion may lead individuals to make significant changes, including stopping interpersonal relationships where inequities arise.

The *carpool* problem, introduced by Fagin and Williams [5], is a stylized mathematical model in which one can study questions related to minimizing inequity. As described in [5], *"suppose that n people, tired of spending their time and money in gasoline lines, decide to form a carpool. We present a scheduling algorithm for determining which person should drive on any given day. We want a scheduling algorithm that will be perceived as fair by all the members."* A priori, it seems that fairness should not be hard to achieve, but – unfortunately – precise answers as to what extent one can avoid inequity have been sought over two decades with seemingly little progress.

Formally, each day t, a set of people $S_t \subseteq \{1, \ldots, n\}$ form a carpool. The goal is to choose who drives, so that on all days t, the overall driving burden to date has been partitioned fairly: Let $f_i(t)$ be driver i's fair share of the driving on day t, which is $1/|S_t|$ for each $i \in S_t$ and 0 otherwise. Define $F_i(t)$ to be driver i's fair share of the driving on all days up to day t, that is $F_i(t) = \sum_{\tau \le t} f_i(\tau)$, and let $D_i(t)$ be the number of times i has actually driven out of the first t days. For a particular sequence $\{S_t\}_{t=1}^{T}$, and algorithm for deciding who drives, we define

$$\text{the unfairness on day } t \;=\; \max_{\text{driver } i} |D_i(t) - F_i(t)|. \tag{1}$$

A carpool algorithm decides which person in S_t drives on day t; the *maximum unfairness* of the algorithm is

$$\max_{T \ge 1} \max_{\{S_t\}_{t=1}^{T}} [\text{unfairness on day } T]\,.$$

Notice that the definition of unfairness takes into account **all** trips i took, regardless of who i's companions were on that trip, that is, it is a global notion of fairness.

The offline version of the problem, when $\{S_t\}_{t=1}^{T}$ is known in advance, is easy: there is an algorithm that guarantees maximum unfairness of 1 and this is optimal (see, e.g. [10].)

Ajtai, Aspnes, Naor, Rabani, Schulman, and Waarts [1] studied the online version of problem, in which the algorithm must select a driver on day t, based only on the history up to time t. They obtained a number of extremely interesting results. First, they showed that, up to losing a factor of 2, one may assume that all the sets S_t consist of two persons. Thus, one can think of the process as a sequence of edge additions (*requests*), say $S_t = (i, j)$ at time t, to a multigraph on $\{1, \ldots, n\}$ (the people), with the algorithmic decision being one of choosing the orientation of the edge (towards the driver for that carpool). The goal then is to minimize

$$\max_{\text{vertex } i} |\,\text{indegree}(i) - \text{outdegree}(i)\,|\,.$$

Ajtai et al. obtained results for two different online settings: when the requests (carpools) are selected uniformly at random, and when the request sequence is selected by an oblivious

adversary that knows the algorithm, but not the outcome of any random choices the algorithm makes.

The first algorithm they considered was *Global Greedy*: on request (i, j), the driver among i and j with minimum unfairness (as defined in equation (1)) drives,; in case of a tie, the choice is arbitrary. For a uniformly random request sequence, they showed that for each t, *Global Greedy* has expected unfairness on that day of $O(\log \log n)$.

For the adversarial case, Ajtai et al showed that every deterministic algorithm has unfairness $\lfloor n/2 \rfloor$. They also showed that this is tight: *Global Greedy* has unfairness at most $n/2$ for every request sequence. They were able to obtain a better upper bound using *Randomized Local Greedy*: This algorithm considers each pair of drivers separately, and alternates which one drives each time they form a carpool. The only randomness is in the uniformly random choice of which of the two drives the very first time they carpool. They showed that *Randomized Local Greedy* has maximum unfairness equal to $\Theta(\sqrt{n \log n})$.

They conjectured that *Randomized Global Greedy*, the variant of *Global Greedy* in which ties are broken at random is much better, perhaps even polylog(n).

Finally, they proved that every randomized algorithm has maximum unfairness of at least $\Omega\left((\log n)^{1/3}\right)$.

Our Results

We study the carpool problem in the setting where the people involved belong to a social network G, and every request (carpool) is a pair of people that are connected in the social network, *i.e.* an edge of G. In this context, the work of [5, 1] can be seen as studying the special case where the social network is a clique.

We prove the following results for request sequences restricted to edges of a social network G with n vertices, and of maximum degree d.

Deterministic algorithms, adversarial requests

We show that for every deterministic algorithm there exists a request sequence on G resulting in unfairness of at least $\lfloor d/2 \rfloor$. This is tight: we give a deterministic algorithm that never generates unfairness greater than $d/2$ (Theorem 1).

What is most interesting about this result is that, in contrast to the case where the graph is complete, the optimal deterministic algorithm is *not* the *Global Greedy* algorithm. In fact, we show that for every connected G (irrespective of its maximum degree), there is a request sequence on which *Global Greedy* has worst-case unfairness $\geq \lfloor n/2 \rfloor$ (Theorem 2). Thus, *Global Greedy* can be a factor $\Omega(n)$ worse than the optimal deterministic algorithm (e.g., when the graph has constant degree).

Random requests

Our second set of results concerns random requests: We show that if the sequence of requests is generated by choosing edges of G uniformly at random, then the removal of edges from the graph can increase the unfairness for the *Global Greedy* algorithm: When G is a path, *Global Greedy* has expected unfairness at least $\Omega((\log n / \log \log n)^{1/3})$ (Theorem 5). This stands in contrast to the $O(\log \log n)$ upper bound of Ajtai et al when the graph G is a clique.

For a social network G of bounded genus (e.g., planar graphs, the torus, etc.) – we introduce the "star algorithm" - an algorithm with expected maximum unfairness $O(\log n)$ (Corollary 4).

Randomized algorithms, adversarial requests

Oblivious Adversaries: Oblivious adversaries determine the event sequence in advance, the algorithm may toss coins, and one considers the expected cost to the algorithm.

The results of Ajtai et al. show that *Randomized Local Greedy* gives maximum expected unfairness of $O(\sqrt{d \log d})$, since each vertex has degree at most d and the unfairness at each node is the expected value of the sum of at most d random variables that are equally likely to be 1 or -1. One can view this algorithm as maintaining an invariant probability distribution over unfairness configurations: for each t, regardless of the history of requests, each edge is oriented uniformly at random. In this sense, it is a *static algorithm*. Static algorithms form a very natural class of randomized online algorithms. Intuitively, they render an adversary powerless to construct a bad request sequence: every request sequence will perform the same against such an algorithm. We show that unfortunately, this intuition is incorrect and that the competitive ratio of *every* static algorithm is at least $\Omega(\sqrt{d})$.

As mentioned above, the *Randomized Global Greedy* algorithm has been conjectured to give a good competitive ratio against oblivious adversaries. We prove that *Randomized Global Greedy* has unfairness $\Omega(\log n)$ (on a clique of size n), improving upon the previous lower bound of $\Omega\left((\log n)^{1/3}\right)$ from [1]. This involves a rather complex proof, for which we only give a high level sketch here, the full details are available online.

Adaptive Adversaries: Adaptive adversaries determine the next event in the event sequence as a function of the previous responses of the online algorithm. *I.e.*, as a function of how the previous car pooling events were addressed.

We show that *no* randomized algorithm (static or not) has unfairness better than $d/4$ against an adaptive adversary [11].

Other Related Work

Another problem that can model fairness issues is Tijdeman's *chairman assignment problem* [10] where a chairman has to be appointed by a community of unequal groups. An axiomatic approach to the problem and its relationship to the Shapley value of a game was given in [9]. Generalizations of the carpool problem appear in [4, 3, 2].

Notation

In what follows, we often suppress the dependence on t in our notation for the unfairness of driver i at time t. Specifically, we use x_i to denote the unfairness of driver i at time t (i.e. $x_i := 2\big(D_i(t) - F_i(t)\big) = \text{indegree}(i) - \text{outdegree}(i)$), where t is understood. Note that $\sum_i x_i = \sum_i [\text{indegree}(i) - \text{outdegree}(i)] = 0$ at all times, and that we are assuming that all carpools are of size 2.

2 Deterministic algorithms

▶ **Theorem 1.** *Let G be a graph of maximum degree d. Then for every deterministic algorithm A, there exists a request sequence σ such that after A processes σ the unfairness is $\lceil d/2 \rceil$. This is tight: there is a deterministic algorithm such that after it processes every request sequence the unfairness is at most $\lceil d/2 \rceil$.*

Proof. For the first part, we restrict our sequences to the subgraph of G consisting of a maximum degree vertex and all of its neighbors, *i.e.,* a star with d leaves. For each

deterministic algorithm, we will prove that either the unfairness is unbounded or there is a sequence of requests for which the root of the star has unfairness $\pm\lceil d/2\rceil$.

Fix a deterministic algorithm. We will say that it is in state $\vec{x} = (x_1, \ldots, x_d)$ when the unfairness of leaf i is x_i (any ordering of the children is fine) and therefore the unfairness of the root is $-\sum_1^d x_i$. Let S be the set of states that can be reached by some request sequence. We can assume that for all i, $|x_i| \leq \lceil d/2\rceil$; if not, we are done. Therefore, S is bounded.

Select $\vec{x} \in S$ which minimizes $\varphi(\vec{x}) = x_1 + 2x_2 + \cdots + 2^{d-1}x_d$. Let r be a request sequence that reaches $\vec{x}$. If we extend r with request $(root, 1)$, then by the minimality of $\varphi(\vec{x})$, the online algorithm is not allowed to move to $(x_1 - 1, \vec{x}_{-1})$, so it will move to state $(x_1 + 1, \vec{x}_{-1})$. More generally, for $k \in [1, d]$, suppose that we extend r by requests (root plus leaves) $1, 2, \ldots, k$. Then since $\varphi(x_1 + 1, \ldots, x_{k-1} + 1, x_k - 1, x_{k+1}, \ldots, x_d) > \varphi(\vec{x})$, the online algorithm will end up at state $(x_1 + 1, \ldots, x_{k-1} + 1, x_k + 1, x_{k+1}, \ldots, x_d)$. If we then extend r by the sequence $1, 2, \ldots, d$, the online algorithm will move to state $\vec{x} + \vec{1}$. The first state has root unfairness $-\sum_1^d x_i$ and the second state has root unfairness $d - \sum_1^d x_i$, so one of those two numbers is greater than or equal to $\lceil d/2\rceil$ in absolute value.

For the second part, we show that any G can be oriented so that the indegree and outdegree of every vertex differ by at most 1. We then run the online algorithm that serves requests for the edge $\{i, j\}$ by alternatingly having i as a driver and j as a driver, starting with i iff the edge is directed from j to i. ◀

▶ **Theorem 2.** *Consider the Greedy algorithm and assume that ties are broken by an adversary. Then for any connected request graph, there exists a request sequence for which Greedy has unfairness at least* $\lfloor n/2\rfloor$.

Proof Sketch. The proof is by induction, restricting requests to a subgraph that is a tree. The idea is to increase the spread of the values by taking an edge $\{i, j\}$ between a subtree with low average unfairness and a subtree with high average unfairness. Then perform requests in the first subtree to maximize x_i, in the second subtree to minimize x_j. Then, if $x_i > x_j$, requesting edge $\{i, j\}$ will result in an even greater unbalance between the two subtrees. ◀

3 Random requests

3.1 Random requests on bounded genus graphs

We first prove the result for a star.

▶ **Theorem 3.** *Let G be a star with d leaves, root r and suppose that the requests are uniformly random. Then there is an algorithm such that for any time t, the unfairness at each leaf is at most one and the root has expected unfairness $O(1)$, with an exponential tail:* $\Pr(|Unfairness(r)| > k) \leq c\lambda^k$ *for some (c, λ) with $c > 0$ and $0 < \lambda < 1$.*

Sketch of Proof of Theorem 3. The "star algorithm" is the following:

1. Every leaf $1 \leq i \leq d$ has a counter $x_i \in \{-1, 0, 1\}$. Initially, set $x_i = 0$ for all $i \in S_0 = \{1, \ldots, d/2\}$.[1] Set $x_i = 1$ for all $i \in S_1 = \{d/2 + 1, \ldots, 3d/4\}$, and set $x_i = -1$ for all $i \in S_{-1} = \{3d/4 + 1, \ldots, d\}$. The root r maintains a counter $x_0 = -\sum_1^n x_i$, which is initially equal to zero.

[1] For simplicity, we will assume that d is a multiple of four; this is not necessary.

2. When a random request (r, i) arrives, if $x_i \neq 0$ then the algorithm orients the edge so that $x_i = 0$. If $x_i = 0$ and $x_0 \neq 0$ then the algorithm orients the edge so that $|x_0|$ decreases. If $x_i = x_0 = 0$ then the choice is random.

To analyze this, observe that, in expectation, half of the leaves have value 0. If the root has unfairness x, then a request to an edge connecting the root to a non-zero leaf might increase $|x|$, but any request to an edge connecting the root to a 0 leaf reduces $|x|$. Hence, with some work, we obtain a proof that $|x|$ is bounded on average and that its distribution has an exponential tail. ◀

▶ **Corollary 4.** *Let G be a bounded genus graph on n vertices and suppose that the requests are random. Then there is a deterministic algorithm with average maximum unfairness $O(\log n)$.*

Proof. We partition the edges of G into stars so as to ensure that each vertex is a leaf of at most a constant number of stars, and the center of exactly one star. To handle a sequence of requests, for each star, handle the subsequence of the requests that are edges of that star using the algorithm from Theorem 3. ◀

3.2 Poor performance of *Global Greedy* for random requests on the line

Ajtai et al. [1] prove that a uniformly random sequence of requests in the complete graph induces a unfairness of $O(\log \log n)$ for *Global Greedy* with any tie breaking rule. We show that this is not necessarily true when the possible requests are restricted to edges in the social network.

▶ **Theorem 5.** *Consider a sequence of independent requests drawn uniformly at random when the graph is a line. Then the* Global Greedy *algorithm, with ties broken at random, has expected unfairness $\Omega\left((\log n/\log\log n)^{1/3}\right)$.*

To prove this theorem, we will need the following lemma.

▶ **Lemma 6.** *When the graph G is a line with n vertices, there exists a sequence of length $f(n) = \Theta(n^3)$ that creates maximum unfairness of $n/2$ for the* Global Greedy *algorithm with adversarial tie-breaking. After $f(n)/2$ steps of that sequence the maximum unfairness is already at least $n/8$.*

Proof of Theorem 5. The idea is to consider multiple short segments of the line. The segments are of length k (to be determined below, about $\log^{1/3} n$), every segment has 2 extra vertices on the right, so there are about n/k different segments. We refer to the two extra vertices on the right of each segment as the "buffer zone" of the segment.

Consider a sequence of L random requests on the line, and focus on those, among those L requests, that fall into a particular segment and its buffer zone. A segment received Lk/n requests on average. Let L be such that $Lk/n = (3/4)f(k)$ and restrict attention to *good* segments, i.e. those segments that receive a number of requests in $[f(k)/2, f(k)]$.

With probability about $(1/k)^{k^3}$ the leftmost and rightmost buffer edges are never requested, and the requests to the segment follow the exact pattern of (a prefix of) the $f(k)$ requests required for the lower bound of Lemma 6. Conditioned upon this happening, the probability that the decisions made for tie breaking are as in Lemma 6 is at least $(1/2)^{f(k)}$, thus the probability that an unfairness of at least $k/8$ is reached in a particular good segment is $\geq (1/(2k))^{f(k)}$.

With probability at least $1/2$, the number of good segments is $\Omega(n/k)$, and by independence of the request sequence inside each segment, the probability that no segment gets

unfairness $k/8$ is at most $\left(1-\frac{1}{(2k)^{f(k)}}\right)^{\Omega(n/k)}$. This is at most $1/e$ for $\Omega(n/k) > (2k)^{\Theta(k^3)}$. Taking the logarithm gives $\log n = \Theta(k^3)\log(k)$, hence $k = \Theta\left((\log n/\log\log n)^{1/3}\right)$. ◀

4 Lower bounds against Adaptive Adversaries

In this section we show an adaptive adversary which achieves an $\Omega(d)$ lower bound for any randomized algorithm, on a star with d leaves.

Let $V = \{i_1, i_2, \ldots, i_d\}$ be the leaves of the star and let r be the root. Define the subsets:

$$\begin{aligned} V^+ &= \left\{i_j \in V | x_{i_j} > 0\right\}, \\ V^- &= \left\{i_j \in V | x_{i_j} < 0\right\}, \\ V^0 &= \left\{i_j \in V | x_{i_j} = 0\right\}. \end{aligned}$$

▶ Remark. For simplicity, we assume that d is divisible by 4, but this is not necessary.

Our adversary generates a sequence, until either $|x_r| \geq d/4$ or there is a leaf i_j such that $|x_{i_j}| \geq d/4$. The sequence is generated as follows:

1. If there is a leaf i_j such that $v \in V^0$ then issue the request (r, i_j).
2. If $V^0 = \emptyset$ and $|V^+| \geq d/2$ then let $V^+ = \{i_1, \ldots, i_k\}$ such that $x_{i_j} \leq x_{i_{j+1}}$ and issue the requests (r, i_j) in order of increasing j. Stop after processing a request increases x_{i_j}.
3. If $V^0 = \emptyset$ and $|V^-| > d/2$ then let $V^- = \{i_1, \ldots, i_k\}$ such that $x_{i_j} \geq x_{i_{j+1}}$ and issue the requests (r, i_j) in order of increasing j. Stop after processing a request decreases x_{i_j}.

The following lemma is proved in [11].

▶ **Lemma 7.** *The request sequence generated by the adaptive adversary described above is well defined,* i.e.*,*

1. *Exactly one of the three cases happens at each iteration.*
2. *In case 2 either the unfairness of a leaf increases or $x_r > d/4$.*
3. *In case 3 either the unfairness of a leaf decreases or $x_r < -d/4$.*

For our analysis we define the potential function

$$\Phi(V) = \sum_{i \in V} d^{|x_i|}.$$

Note that this potential function does *not* take into account x_r.

▶ **Lemma 8.** *After each iteration of the adversary's decision loop the potential $\Phi(V)$ increases by at least $d-1$ or $|x_r| \geq d/4$.*

Proof Sketch. We prove this by case analysis:

1. If there exists a leaf i_j such that $i_j \in V^0$ then the potential increases by exactly $d-1$.
2. If $|V^+| \geq d/2$ then from Lemma 7 the unfairness of one leaf was increased and at most the unfairness of $d-1$ leaves was decreased.
3. If $|V^-| > d/2$ then from Lemma 7 the unfairness of one leaf was decreased and at most the unfairness of $d-1$ leaves was increased.

In all three cases, the increase in potential caused by just one leaf is greater by more than $d-1$ than the decrease caused by the other leaves. ◀

▶ **Theorem 9.** *Assume that the social network is a star with d leaves. For any randomized algorithm, the adaptive adversary presented achieves unfairness $\Omega(d)$.*

Proof. From Lemma 7 the request sequence generated by the adversary is well defined and from Lemma 8, after each iteration of the adversary's decision loop either the potential $\Phi(V)$ increases by at least $d-1$ or $|x_r| \geq d/4$.

The initial potential is $\Phi(V) = d$. If after $(d \cdot d^{d/4-1})/(d-1) - 1$ iterations of the loop the inequality $|x_r| < d/4$ always holds then

$$\Phi(V) \geq d \cdot d^{d/4-1} - (d-1) + d \geq d \cdot d^{d/4-1} + 1.$$

So there must be at least one leaf with unfairness $\geq d/4$. ◀

5 Lower bounds against Oblivious Adversaries

5.1 Static Algorithms

Next, we consider *static algorithms* and bound the optimal unfairness that can be achieved by an algorithm in this class.

▶ **Definition 10.** A *state* is a vector $(x_i)_i$ where $x_i \in \mathbb{Z}$ represents the unfairness of vertex i. A randomized online algorithm is called *static* if there exists a probability distribution π over the set of states such that if the algorithm starts in π (*i.e.*, it starts at a state drawn according to π) then it remains in π after every possible request sequence.

Let $U(\vec{x})$ denote the maximum unfairness of state x. Then[2] the *expected maximum unfairness* of a static algorithm is

$$\sum_{\vec{x}} \pi(\vec{x}) \cdot U(\vec{x}).$$

As discussed in the introduction, *Randomized Local Greedy* preserves the distribution π in which each edge is oriented uniformly at random, and so *Randomized Local Greedy* is a static algorithm. The expected unfairness of every vertex i is $\Theta(\sqrt{d_i})$, where d_i is the degree of i, and the maximum unfairness is at most $O(\sqrt{n \log n})$ [1]. In particular, for the star with d leaves the unfairness of each leaf is at most 1, and the unfairness of the root is $\Theta(\sqrt{d})$.

▶ **Theorem 11.** *Assume G is the star with d leaves.*
1. *A slight variant of Local Greedy (Balanced Local Greedy) has optimal unfairness.*
2. *This value is $\Theta(\sqrt{d})$.*

Since states $\vec{x}$ that correspond to unfairness always satisfy $\sum_{i \in V} x_i = 0$, one of the coordinates can be inferred from the others. For compactness, we will drop the coordinate associated to the root and represent the state as a vector indexed by the leaves only.

To prove Theorem 11, we first state a property satisfied by the static distributions of static algorithms for the star with d leaves.

▶ **Lemma 12.** *Fix a static algorithm and let $\pi(\vec{x})$ be the corresponding static distribution. Fix a leaf j and $\vec{x}_{-j}$. Then the probability of states with even x_j must be equal to the probability of states with odd x_j:*

$$\sum_{k \in \mathbb{Z}} \pi(k, \vec{x}_{-i})(-1)^k = 0. \tag{2}$$

[2] There is a subtlety here in that the algorithm does not actually move initially to a state drawn from this distribution. Rather, it "pretends" to, and hence this definition of expected unfairness can be off by a factor of 2.

Proof. Suppose that the next request is the edge from root to leaf j. Conditioning on being on one of the states with given $\vec{x}_{-j}$, the state moves from even x_j to odd x_j and vice versa. Since the distribution before and after the request is the same, the two events must be equiprobable. ◀

Proof of Theorem 11. We define an infinite linear programming relaxation P with one variable $\pi(\vec{x})$ for each $\vec{x} \in \mathbb{Z}^d$. By Lemma 12, the expected unfairness of any static algorithm is at least

$$\min \sum_x \pi(\vec{x})U(\vec{x}) \text{ s.t. } \quad \begin{cases} \sum_{\vec{x}} \pi(\vec{x}) & = 1 \\ \sum_k \pi(k, \vec{x}_{-i})(-1)^k & = 0 \quad \forall i \forall \vec{x}_{-i} \end{cases}$$

Consider a vector $\vec{x}$ such that $x_i = 0$. Then, by elimination, the second constraint determines $\pi(\vec{x})$ in terms of the variables $\pi(k, \vec{x}_{-i})$ for $k \neq 0$, and the vectors $(k, \vec{x}_{-i})$ have one fewer zero coordinate than $\vec{x}$. Extending this by induction on the number of non-zero coordinates of $\vec{x}$, we show in Claim 13 below that each variable $\pi(\vec{x})$ with at least one zero coordinate in $\vec{x}$ can be expressed as a linear combination of the variables $\pi(\vec{y})$ with $\vec{y} \in (\mathbb{Z}_{\neq 0})^d$.

▶ **Claim 13.** *Let $Q(\vec{x}) = \{\vec{y} : x_i(y_i - x_i) = 0$ and $y_i \neq 0$, for all $i\}$. Then for all $\vec{x}$*

$$\pi(\vec{x}) = (-1)^{\#0(\vec{x})} \sum_{\vec{y} \in Q(\vec{x})} \pi(\vec{y})(-1)^{\sum_i y_i - x_i}. \tag{3}$$

Moreover, the set of Equations (3) *for all $\vec{x} \notin (\mathbb{Z}_{\neq 0})^d$ are equivalent to the set of Equations* (2) *in the linear program P.*

Proof. We transform Equations (2) to the form of Equations (3), inductively by the number of zero entries of $\vec{x}$.

The base case, in which $\vec{x}$ has no 0's is vacuous. For the induction step, assume that Equation (3) holds for all $\vec{x}$ that have at most k 0's. Consider some $\vec{x}$ that has $k+1$ 0's: $\vec{x} = (0, \vec{x}_{-i})$ for some x_{-i} that has k 0's. Solving (2) for $\pi(\vec{x})$ we get

$$\begin{aligned} \pi(0, \vec{x}_{-i}) &= -\sum_{y_i \neq 0} \pi(y_i, \vec{x}_{-i})(-1)^{y_i} \\ &= -\sum_{y_i \neq 0} (-1)^{\#0(\vec{x}_{-i})} \sum_{\vec{y}_{-i} \in Q(\vec{x}_{-i})} \pi(y_i, \vec{y}_{-i})(-1)^{\sum_{k \neq i} y_k - x_k}(-1)^{y_i} \\ &= (-1)^{\#0(\vec{x})} \sum_{\vec{y} \in Q(\vec{x})} \pi(\vec{y})(-1)^{\sum_i y_i - x_i}. \end{aligned}$$

Notice that there are $k+1$ different equations in the set of Equations (2), one for each 0 in $\vec{x}$, that are transformed into the same equation. ◀

To simplify the linear program P, substitute the right hand side of every equality of the form given in Equation (3) for $\pi(\vec{x})$ (for all $\vec{x} \notin (\mathbb{Z}_{\neq 0})^d$) into the constraint $\sum_{\vec{x}} \pi(\vec{x}) = 1$. This yields

$$\sum_{\vec{y} \notin (\mathbb{Z}_{\neq 0})^d} \alpha_{\vec{y}} \pi(\vec{y}) = 1, \tag{4}$$

for some constants $\{\alpha_{\vec{y}}\}$.

By construction, any solution to this equation can be extended to a solution to the set of Equations (2). This allows us to reduce the linear programing relaxation to one with a single constraint. Therefore it has an optimal solution with only one non-zero variable. Let $\pi(\vec{y}^*)$ denote this variable. By substituting back to (3), we get that $\pi(\vec{x})$ is zero unless

$$\vec{x} \in H := \{\vec{z} \quad \text{s.t. for all } i \quad z_i \in \{0, y_i^*\}\}.$$

Moreover, since for $\vec{x} \in H$, there is only one non-zero term on the right hand side of (3), we can conclude that $\forall \vec{x} \in H$, either $\pi(\vec{x}) = \pi(\vec{y}^*)$ or $\pi(\vec{x}) = -\pi(\vec{y}^*)$.

Next, observe that all coordinates of $\vec{y}^*$ must be odd. Indeed, if some y_i^* is even, then (3) implies that for every vector $\vec{x} \in H$ we have $\pi(y_i^*, \vec{x}_{-i}) = -\pi(0, \vec{x}_{-i})$, which implies that the sum of π on the vectors in H is 0, a contradiction. Thus, all coordinates of $\vec{y}^*$ are odd, and so $\pi(\vec{x}) = \pi(\vec{y}^*)$ for all $\vec{x} \in H$. Since these probabilities sum to 1, they must all be equal to $1/2^d$.

Let $|\vec{x}| = |\sum_i x_i|$. The expected unfairness of the root is

$$\sum_{\vec{x}} \pi(\vec{x})|\vec{x}| = \sum_{x \in H} \pi(\vec{x})|\vec{x}| = \sum_{x \in \{0, y_i^*\}^d} \frac{1}{2^d}|\vec{x}| = \mathrm{E}[|\sum_i y_i^* X_i|],$$

where X_i are 0-1 unbiased Bernoulli random variables. The following claim shows that this quantity is minimized when exactly half ($\lfloor d/2 \rfloor$, to be precise) of the y_i^*'s are 1 and the rest are -1, exactly as in the case of *Balanced Local Greedy*.

▶ **Claim 14.** *Let $y_1^*, \ldots, y_d^*$ be odd integers and $X_1, \ldots, X_n$ be independent unbiased Bernoulli variables. The expectation*

$$E[|\sum_i y_i^* X_i|]$$

is minimized when half ($\lfloor d/2 \rfloor$, to be precise) of the y_i^*'s are -1 and the remaining are +1. This minimum value is $\Theta(\sqrt{d})$.

It follows from the theorem that the optimal unfairness among static algorithms is at least equal to the unfairness at the root of the *Balanced Local Greedy*. Since its unfairness on the leaves is at most one, *Balanced Local Greedy* has almost optimal unfairness among the static algorithms, within an additive term of 1. In fact, the additive term can be reduced to $O(1/\sqrt{d})$.

The main result of this section dashes any hopes to find a static algorithm with small unfairness. However, many natural algorithms – among them the *Global Greedy* algorithm – are not static and we hope that they will be shown to have small unfairness (substantially less than $O(\sqrt{d})$).

5.2 Bounds on *Randomized Global Greedy*

A very natural algorithm, *Randomized Global Greedy* is a candidate algorithm to give small competitive ratios against an oblivious algorithm. This algorithm is greedy, choosing the driver with the lower number of times to her credit, and breaking ties at random. The difference between *Randomized Global Greedy* and *Randomized Local Greedy* is that *Randomized Local Greedy* only uses randomization initially to determine the initial state and then alternates drivers whenever the same pair reappear.

Previously, the lower bound on the competitive ratio of *Randomized Global Greedy* was $\Omega(\log^{1/3} n)$ (on a clique) whereas the upper bound was $O(n)$. We improve the lower bound

to $\Omega(\log n)$. To do this we make use of a potential function, the sum over drivers of the differences between the number of trips minus the number of times that the driver drove.

The key idea is to repeatedly generate unfairness and "push" it to some target set of drivers. This process works essentially as follows:

1. Apply a sequence of requests to generate potential in some set of drivers.
2. "Push" the potential to a target set of drivers.
3. Repeat.
4. Eventually, the target set will have high potential, which implies high unfairness.

We present here a sketch of the lower bound proof, full details of this process can be seen online at [11]. In this MSc thesis (of one of the authors) one can also see similar techniques applied to other settings.

First, we begin with a definition of the potential function.

▶ **Definition 15.** Let $i_1, i_2, \ldots, i_n$ be n vertices where x_{i_j} is the unfairness of vertex i_j. Assume that there is a value $u \in \mathbb{Z}$ such that for all $1 \leq j \leq n$ it holds that $x_{i_j} \in \{u-1, u, u+1\}$. Define the potential with respect to base unfairness u as

$$\Phi_u(\{x_{i_1}, x_{i_2}, \ldots, x_{i_n}\}) = \sum_{1 \leq j \leq n} (x_{i_j} - u).$$

Now that we have defined the potential function, we define "pushing".

▶ **Definition 16.** Let $v', v'', r \in V$ be distinct vertices and let $S = \{i_1, i_2, i_3, \ldots, i_n\}$ be a set of n vertices such that $v', v'', r \notin S$.

Let $\alpha \in \mathbb{N}$ be a large number, as a function of n. The sequence $\text{push}_u(\{v', v''\}, S, r)$ is composed of three subsequences:

$$\begin{aligned}
&\text{push}^{s1}_u(\{v', v''\}, S, r) = (r, v'), (r, v''),\\
&\text{push}^{d}_u(\{v', v''\}, S, r) = (r, i_n), (r, i_n), (r, i_{n-1}), (r, i_{n-1}), \ldots, (r, i_1), (r, i_1),\\
&\text{push}^{s2}_u(\{v', v''\}, S, r) = (r, v''), (r, v').
\end{aligned}$$

And,

$$\begin{aligned}
\text{push}_u(\{v', v''\}, S, r) = \ &\big(\text{push}^{s1}_u(\{v', v''\}, S, r) \| \\
&\text{push}^{d}_u(\{v', v''\}, S, r) \| \text{push}^{s2}_u(\{v', v''\}, S, r)\big)^{\alpha}.
\end{aligned}$$

▶ Remark. Notation: (v, w) is a shorthand for requesting that v and w carpool together.

We use the following property thats holds after the *Randomized Global Greedy* algorithm processes $\text{push}_u(\{v', v''\}, S, r)$:

Define $\Phi_{\text{init}}(S) = \Phi(S)$ and $\Phi_{\text{init}}(\{v', v''\}) = \Phi(\{v', v''\})$ as the potentials before processing the sequence $\text{push}_u(\{v', v''\}, S, r)$. Define $\Phi_{\text{end}}(S) = \Phi(S)$ and $\Phi_{\text{end}}(\{v', v''\}) = \Phi(\{v', v''\})$ as the potentials after processing the sequence.

▶ **Lemma 17.** *Assume that: (a) For some $u \in \mathbb{Z}$, $x_r = u$, (b) That $x'_v, x''_v \in \{u-1, u+1\}$, and (c) For all $i \in S$, $x_i \in \{u-1, u+1\}$.*

If $|(x_{v'} - u) + (x_{v''} - u) + \Phi_{\text{init}}(S)| \leq |S|$ then, with high probability, after the Randomized Global Greedy *algorithm processes the sequence $\text{push}_u(\{v', v''\}, S, r)$ the equality $\Phi_{\text{end}}(S) = \Phi_{\text{init}}(S) + \Phi_{\text{init}}(\{v', v''\})$ holds.*

Proof Sketch. Observe that if $x_{v'} = u+1$, $x_{v''} = u+1$ and $x_r = u$ then after processing the subsequence $(r, v'), (r, v'')$, with probability $1/2$, $x_r = u+2$. Now observe that if $x_r = u+2$ and for some j, $x_{i_j} = u-1$ then after processing the two requests $(r, i_j), (r, i_j)$ it holds that $x_{i_j} = u+1$ and $x_r = u$. Thus the potential of $\{v', v''\}$ was "pushed" into i_j.

A similar thing happens if $x_{v'} = u-1$, $x_{v''} = u-1$ and $x_{i_j} = u+1$. The constant α is chosen to be large such this occurs with high probability.

The full proof is available online in [11]. ◀

Now, using this push sequence we "accumulate" a large potential (in respect to base unfairness u) in a specific set A such that $|A| = O(n)$. *I.e.*, we define a sequence such that after *Randomized Global Greedy* processes it $Pr(|\Phi_u(A)| > |A/2|) > 1/2$. In essence, this is done by repeatedly using a sequence that creates unfairness in a small set G and "pushing" this unfairness into A. This is called "accumulation".

Another useful subsequence is that of "distillation", which takes the potential of a set and, with high probability, pushes it into a subset. Let r be a vertex and $S = \{i_1, i_2, i_3, \ldots, i_m\}$ be a set of m vertices such that m is even and $r \notin S$. The $\text{distill}_u(S, r)$ event sequence is

$$\text{distill}_u(S, r) = \text{push}_u(\{i_1, i_2\}, \{i_3, \ldots, i_m\}, r) \| \text{push}_u(\{i_3, i_4\}, \{i_5, \ldots, i_m\}, r) \| \cdots \| \text{push}_u(\{i_{m-3}, i_{m-2}\}, \{i_{m-1}, i_m\}, r).$$

Define the tail of S, S_ℓ, as $S_\ell = \{i_k \in S | k \geq \ell\}$.

▶ **Lemma 18.** *With high probability, after the* Randomized Global Greedy *algorithm processes the sequence* $\text{distill}_u(S)$

$$\Phi_u(S_{|S|-|\Phi_u(S)|+1}) = \Phi_u(S).$$

Proof Sketch. This stems from repeatedly applying Lemma 17 to increasingly smaller sets. The full proof is available online in [11]. ◀

Now using the sequences "accumulation" and "distillation" we are able to create (with probability greater than $1/2$) a set A such that $|A| = O(n)$ and $|\Phi_u(A) = |A|$. The latter is equivalent to all the unfairnesses of vertices in A being equal to either $u-1$ or $u+1$.

Now split A into three different sets, A_1, A_2, and A_3 and do "accumulation" and "distillation" to each set individually. Now, with some probability, one of these subsets has unfairnesses which are all equal to either $u-2$ or $u+2$. Repeat this process. In [11] we prove that this can be repeated $\Omega(\log n)$ times with constant probability. And thus the following theorem is proved:

▶ **Theorem 19.** *The sequence above achieves an expected unfairness of* $\Omega(\log n)$ *for the* Randomized Global Greedy *algorithm when run on a clique.*

6 Open Questions

The outstanding open questions that follow immediately from this work are:

- Is there any randomized algorithm with unfairness $o(\sqrt{d})$ on the star with d leaves?
- Does *Randomized Global Greedy* have $o(n)$ unfairness on the star or on the line?

At this point we have no non-trivial upper bound on the star. The best algorithm we know is *Randomized Local Greedy*, which achieves $\sqrt{n}$ unfairness.

Acknowledgments. We are grateful to Nimrod Fiat and Clemens von Stengel for their help during the early stages of this work.

An Improved Analysis of the ER-SpUD Dictionary Learning Algorithm*

Jarosław Błasiok[†1] **and Jelani Nelson**[‡2]

1 **Harvard University, Cambridge, MA, USA**
jblasiok@g.harvard.edu
2 **Harvard University, Cambridge, MA, USA**
minilek@g.harvard.edu

Abstract

In *dictionary learning* we observe $Y = AX + E$ for some $Y \in \mathbb{R}^{n\times p}$, $A \in \mathbb{R}^{m\times n}$, and $X \in \mathbb{R}^{m\times p}$, where $p \geq \max\{n, m\}$, and typically $m \geq n$. The matrix Y is observed, and A, X, E are unknown. Here E is a "noise" matrix of small norm, and X is column-wise sparse. The matrix A is referred to as a *dictionary*, and its columns as *atoms*. Then, given some small number p of samples, i.e. columns of Y, the goal is to learn the dictionary A up to small error, as well as the coefficient matrix X. In applications one could for example think of each column of Y as a distinct image in a database. The motivation is that in many applications data is expected to sparse when represented by atoms in the "right" dictionary A (e.g. images in the Haar wavelet basis), and the goal is to learn A from the data to then use it for other applications.

Recently, the work of [24] proposed the dictionary learning algorithm **ER-SpUD** with provable guarantees when $E = 0$ and $m = n$. That work showed that if X has independent entries with an expected θn non-zeroes per column for $1/n \lesssim \theta \lesssim 1/\sqrt{n}$, and with non-zero entries being subgaussian, then for $p \gtrsim n^2 \log^2 n$ with high probability **ER-SpUD** outputs matrices A', X' which equal A, X up to permuting and scaling columns (resp. rows) of A (resp. X). They conjectured that $p \gtrsim n \log n$ suffices, which they showed was information theoretically necessary for *any* algorithm to succeed when $\theta \simeq 1/n$. Significant progress toward showing that $p \gtrsim n \log^4 n$ might suffice was later obtained in [17].

In this work, we show that for a slight variant of **ER-SpUD**, $p \gtrsim n \log(n/\delta)$ samples suffice for successful recovery with probability $1 - \delta$. We also show that without our slight variation made to **ER-SpUD**, $p \gtrsim n^{1.99}$ samples are required even to learn A, X with a small success probability of $1/\mathit{poly}(n)$. This resolves the main conjecture of [24], and contradicts a result of [17], which claimed that $p \gtrsim n \log^4 n$ guarantees high probability of success for the original **ER-SpUD** algorithm.

1 Introduction

The *dictionary learning* or *sparse coding* problem is defined as follows. There is a hidden set of vectors $a_1, a_2, \ldots a_m \in \mathbb{R}^n$ (called a "dictionary"), with $\mathit{span}\{a_1, \ldots a_m\} = \mathbb{R}^n$. We

are given a sequence of samples $y_i = Ax_i + \epsilon_i$, where each x_i is a sparse vector and ϵ_i is noise. In other words each y_i is close to a linear combination of few vectors a_k. The goal is to recover both matrix A and the sparse representations x_i. We can write it as a matrix equation, $Y = AX + E$, where the vectors y_i are the columns of Y, and x_i are columns of X. Let $A \in \mathbb{R}^{n \times m}$ and $X \in \mathbb{R}^{m \times p}$. Traditionally, and as motivated by applications, the interesting regime of parameters is when A is of full row rank (in particular $n \leq m$) [2].

The dictionary learning problem is motivated by the intuition that the dictionary A is in some sense the "right" spanning set for representing vectors y_i since it allows sparse representation. In some domains this correct basis is known thanks to a deep understanding of the domain in question: for example the Fourier basis for audio processing, or Haar wavelets for images. Here we want to infer analogous "nice" representations of the data from the data itself. As it turns out, even in situations such as audio and image processing in which traditional transforms are useful, replacing them with dictionaries learned directly from data turned out to improve quality of the solution (see for example [12], which applied a dictionary learning algorithm for image denoising).

This problem has found a tremendous number of applications in various areas, such as image and video processing (e.g. [21, 10, 12]; see [19] for more references), image classification [23, 20] as well as neurobiology [16]. Given its huge practical importance, a number of effective heuristics for dictionary learning were proposed [3, 18] – those are based on iterative methods for solving the (non-convex) optimization problem of minimizing the sparsity of X' subject to Y being close to $A'X'$. Some of these algorithms work well in practice but without provable guarantees.

1.1 Prior work

Until recently there was little theoretical understanding of the dictionary learning problem. Spielman, Wang and Wright in [24] proposed the first algorithm that provably solves this problem in some regime of parameters. More concretely, they assumed no presence of noise (i.e. $E = 0$), and that A is a basis (that is $n = m$), potentially adversarially chosen. The vectors x_i are sampled independently at random from some distribution – specifically, each entry $x_{i,j}$ is nonzero with probability $1 - \theta$, and once it is nonzero, it is a symmetric subgaussian random variable (i.e. with tails decaying at least as fast as a gaussian), independent from every other entry. Henceforth we say that a matrix $X \in \mathbb{R}^{n \times p}$ follows the *Bernoulli-subgaussian model* with parameter θ, if the entries $X_{i,j}$ are i.i.d. with $X_{i,j} = \chi_{i,j} g_{i,j}$, where $\chi_{i,j} \in \{0, 1\}$ are Bernoulli random variables with $\mathbb{E}\, \chi_{i,j} = \theta$, and $g_{i,j}$ are symmetric subgaussian random variables. We also say that X follows the Bernoulli-Rademacher model if $g_{i,j}$ in the above definition are independent Rademachers (i.e. uniform ± 1).

Under the Bernoulli-subgaussian model for X, [24] proved that once the number of samples p is $\Omega(n \log n)$ and the sparsity $s = \theta n$ (i.e. expected number of nonzero entries in each column of X) is at least constant and at most $\mathcal{O}(n)$, the matrix Y with high probability has a unique decomposition as a product $Y = AX$, up to permuting and rescaling rows of X and columns of A. Moreover, the number of samples $p = \Omega(n \log n)$ was proven to be optimal in the constant sparsity regime $s = \Theta(1)$. In particular, it is possible in principle to find such a decomposition information-theoretically, but unfortunately not necessarily with an efficient algorithm.

[1] As written, their work has certain errors which we discuss later in detail. Nevertheless, using some of our approaches we believe it should be possible to salvage their sample complexity bound in the

Figure 1 Comparison of algorithms with proven guarantees for dictionary learning. Last column indicates whether the dictionary can be arbitrary, or if additional structure is assumed in order to guarantee recovery. Algorithms marked with star require quasi-polynomial running time. $\kappa(A)$ denotes condition number.

In addition to the above, they proposed an efficient algorithm **ER-SpUD** (*Efficient Recovery of Sparsely Used Dictionaries*) to find this unique decomposition, in a more restricted regime of parameters. Namely, they proposed an algorithm and proved that it finds correctly the unique decomposition $Y = AX$, with high probability over X, as long as the sparsity s is at least constant and at most $\mathcal{O}(\sqrt{n})$, and the number of samples p is at least $\Omega(n^2 \log^2 n)$. The low sparsity constraint was inherent to their solution: according to the proof in the same paper, if $s = \Omega(\sqrt{n \log n})$ the algorithm with high probability fails to find the correct decomposition. They conjectured however, that with the number of samples p as small as $\mathcal{O}(n \log n)$, **ER-SpUD** should return the correct decomposition with high probability, matching the sample lower bound for when $s = O(1)$.

Since then, much more theoretical work has been dedicated to the dictionary learning problem; see Figure 1. In the work of Agarwal et al. [2], and independently Arora et al. [5], an algorithm was proposed that works for overcomplete dictionaries A (i.e. when $m > n$), under additional structural assumptions on A – namely that A is *incoherent*, i.e. the projection of any standard basis vector onto the column space of A has small norm. The algorithm presented in [2] requires $p = \tilde{\mathcal{O}}(m^2)$ samples, where $\tilde{\mathcal{O}}(f) = \mathcal{O}(f \cdot \log^{O(1)}(f))$. A more detailed analysis of the dependence between sparsity and number of samples was provided in the work [5] for their algorithm – for $s = \mathcal{O}(\min(\frac{\sqrt{n}}{\log n}, m^{2/5}))$, they require $\tilde{\Omega}(m^2 s^{-2} + m s^2)$ samples; if s is larger than $m^{2/5}$, but smaller than $\mathcal{O}(\min(m^{1/2-\varepsilon}, \frac{\sqrt{n}}{\log n}))$ the algorithm requires $\mathcal{O}(m^C)$ samples, where C is a large constant depending on ε. In the lowest sparsity regime, i.e. $s = \mathcal{O}(\mathrm{polylog}(n))$, the sample complexity stated in their analysis simplifies to $\tilde{\Omega}(m^2)$. For comparison, in the most favorable sparsity regime $s = \Theta(m^{1/4})$, the number of samples necessary for correct recovery is $\Omega(m^{3/2})$. The work [5] also proves correct recovery by this algorithm in the presence of noise. Later Arora et al. [4] gave a quasipolynomial time algorithm working for sparsity up to $\mathcal{O}(n/\mathrm{polylog}(n))$, but under much stronger assumptions

Bernoulli-gaussian model for X, but not in the more general Bernoulli-subgaussian model (since in particular, $p \gtrsim n^{1.99}$ samples are required for that algorithm even to succeed with polynomially small *success* probability; see the full version for details.

on the structure of A. Those assumptions include in particular, that the dictionary A itself is assumed to be sparse, which is violated in many natural examples, e.g. the discrete Fourier basis. They prove that their algorithm correctly recovers the hidden dictionary given access to $p = \mathcal{O}(m^C)$ samples, for some unspecified constant C.

Barak et al. [7] proposed an algorithm fitting in the Sum-of-Squares framework, which works in polynomial time for sparsity $\mathcal{O}(n^{1-\epsilon})$ for any constant $\epsilon > 0$ and in quasipolynomial time for sparsity as large as $\mathcal{O}(n)$, again given access to $\mathcal{O}(m^C)$ samples for some unspecified constant C. Moreover, this algorithm works under the presence of noise and a more general model of X. In particular, coordinates within a single column are not required to be fully independent. Recently, Sun et al. [25] proposed a polynomial time algorithm for the case when $n = m$ and sparsity is as large as $\mathcal{O}(n)$. Their result works in a similar model as in [24], without any additional assumptions on the matrix A, and with matrix X having independent entries that are product of Bernoulli and gaussian random variables (as opposed to the weaker subgaussian assumption in [24]). The sample complexity depends polynomially on n and the condition number of the dictionary matrix A. In particular, in the low sparsity regime ($s = \Theta(\text{polylog}(n))$), this sample complexity is as large as $\tilde{\Omega}(n^9)$ even if the matrix A is well conditioned.

Work on Independent Component Analysis (ICA) [13, 22, 8, 6, 14, 27] is also relevant to the dictionary learning problem. In this problem, again one is given $Y = AX + E$ for square A, with the assumption that the entries of X are i.i.d. (and X need not necessarily be sparse). The works in ICA then say that A, X can be efficiently recovered using few samples, but where the sample complexity depends on the distribution of entries of X. For example in the case of Bernoulli-Rademacher entries with $\theta = 1/n$ (constant sparsity per column of X), these works require large polynomial sample complexity. For example, [27, Theorem 1] implies a sufficient sample complexity in this setting of $p \gg n^{12}$.

From Figure 1, one can see that the "holy grail" of dictionary learning is to achieve the following features simultaneously: (1) low sample complexity, i.e. nearly-linear in the dimension n and number of atoms m, (2) the ability to handle noise (the more noise handled the better), (3) handling overcomplete dictionaries (i.e. dictionaries for which m may be larger than n), (4) handling a larger range of sparsity, with $s = O(n)$ being the best, (5) making no assumptions on the dictionary A, (6) a fast algorithm to actually learn the dictionary from samples, and (7) making few assumptions on the matrix X.

Most of the aforementioned results focus on weakening the sparsity constraint under which it is possible to perform learning, or handling overcomplete dictionaries or noise. These all, however, come at an expense: the number of samples necessary for those algorithms to provably work is quite large, often of order n^C for large constant C. Some of the algorithms also make strong assumptions on A, and/or have quasi-polynomial running time.

Recently, Luh and Vu in [17] made significant progress toward showing that the **ER-SpUD** algorithm proposed in [24] actually solves the dictionary learning problem already with $p = \mathcal{O}(n \log^4 n)$ samples. They claimed to prove that this p in fact suffices for dictionary learning. In fact however, several probabilistic events were analyzed in [24], and if they all occurred then **ER-SpUD** performed correct recovery. The work [17] analyzed arguably the most complex of these events more efficiently, showing a certain crucial inequality held with good probability when $p \gtrsim n \log^4 n$ ($x \gtrsim y$ means that $x > Ky$ for some universal constant $K > 0$). Unfortunately there is a gap: [24] required this inequality to hold for exponentially many settings of variables, and thus one wants the inequality to hold for any fixed instantiation with very high probability to then union bound, and [17] does not provide such a probabilistic analysis. More seriously, there are other events defined in [24]

which *require* $p \gtrsim n^2$ to hold whp in the Bernoulli-subgaussian model (except in the case the subgaussians are actual gaussians), and [17] did not discuss these events at all. In fact, in the full version we prove that in the Bernoulli-Rademacher model the **ER-SpUD** algorithm of [24] actually *requires* $p \gtrsim n^{1.99}$ to succeed with probability even polynomially small in n, contradicting the main result of [17] which claimed $1 - o(1)$ successful learning for p nearly linear in n.

Our contribution: We very slightly modify the algorithm **ER-SpUD** to obtain another polynomial-time dictionary learning algorithm "**ER-SpUD(DCv2)**" for the noiseless case with $m = n$, which circumvents our $p \gtrsim n^{1.99}$ lower bound for **ER-SpUD** in the Bernoulli-subgaussian model. We then show that **ER-SpUD(DCv2)** provides correct dictionary learning with probability $1 - \delta$ with sparsity $s = \mathcal{O}(\sqrt{n})$ as long as $p \gtrsim n \log(n/\delta)$. In particular our result shows that a slight modification of **ER-SpUD** provides correct dictionary learning for complete dictionaries with no noise, which provably works with high probability using $p \gtrsim n \log n$ samples. This resolves the main open problem of [24].

Furthermore, the work of [17] observed that the method of their proof is connected to generic chaining, but that after a certain point the methods "become different in all aspects" [17, Section G]. They also advertised and proved a new "refined version of Bernstein's concentration inequality for a sum of independent variables". Unlike their work, our analysis has the benefit of using standard off-the-shelf concentration and chaining results, thus making the proof simpler and more easily accessible since it is less ad-hoc.

1.2 Approach overview

In Figure 2 we give the algorithm **ER-SpUD(DCv2)** analyzed in this work, a slight modification of **ER-SpUD(DC)** from [24]. The only difference between DCv2 and the original DC variant in [24] is that we try all $\binom{p}{2}$ pairings of columns, whereas DC tried a random pairing of the p columns into $p/2$ pairs. As we show in the full version, one of the several conditions in [24] necessary for their proof of successful recovery of (A, X) from Y actually requires $p = \Omega(n^2)$ if using the DC variant, and hence our switch to DCv2 allows p to be reduced to $\mathcal{O}(n \log n)$.

Henceforth when we refer to **ER-SpUD**, we are referring to **ER-SpUD(DCv2)** unless we state otherwise.

The main insight in the recovery analysis of [24] is that the last line of the **ER-SpUD** pseudocode in Figure 2 can be rewritten (only in the analysis, since A, X are unknown) as $\min_w \|w^T AX\|_1$ subject to $(A(Xe_{j_1} + Xe_{j_2}))^T w = 1$. Then writing $z = A^T w$, this linear program (LP) is equivalent to the secondary LP $\min_z \|z^T X\|_1$ subject to $b_j^T z = 1$, since we could recover $w = (A^T)^{-1} z$ since A is invertible. Here b_j denotes $Xe_{j_1} + Xe_{j_2}$. The ideal case then is that the only optimal solution to the second LP will be a vector z_* that is 1-sparse. In this case, the solution to the LP that we *actually* solve is equal to $w_* = (A^T)^{-1} z_* = (z_*^T A^{-1})^T$ and thus a scaled row of A^{-1}, implying $w_*^T Y$ is a scaled row of X. Thus, if z_* is 1-sparse in the second LP, then the solution to the first LP allows us to recover a scaled row of X.

The work [24] then outlines certain conditions for X that, if they hold, guarantee correct recovery of (A, X). We now state these deterministic conditions, as per [24], which imply correct recovery of (A, X) via **ER-SpUD** when they all simultaneously hold.

(P0) Every row of X has positive support size at most $(10/9)\theta p$. Furthermore, every linear combination of rows of X in which at least two of the coefficients in the linear combination are non-zero has support size at least $(11/9)\theta p$.

3. Set $\boldsymbol{X} = [\boldsymbol{x}_1, \dots, \boldsymbol{x}_n]^T$, and $\boldsymbol{A} = \boldsymbol{Y}\boldsymbol{Y}^T(\boldsymbol{X}\boldsymbol{Y}^T)^{-1}$.

Figure 2 ER-SpUD recovery algorithm.

(P1) For every b satisfying $\|b\|_0 \le 1/(8\theta)$, any solution z_* to the optimization problem

$$\min \|z^T X\|_1 \text{ subject to } b^T z = 1 \tag{1}$$

has support$(z_*) \subseteq$ support(b).

(P2) Let q be $\frac{1}{8\theta}$. For every $J \in \binom{[n]}{q}$ and every $b \in \mathbb{R}^n$ satisfying $|b|_{(2)}/|b|_{(1)} \le 1/2$, the solution to the restricted problem

$$\|z^T X_{J,*}\|_1 \text{ subject to } b^T z = 1 \tag{2}$$

is unique, 1-sparse, and is supported on the index of the largest entry of b. Here $|b|$ is the vector whose ith entry is $|b_i|$, and $|b|_{(j)}$ is the jth largest entry of $|b|$. Also, $X_{J,*}$ denotes the submatrix of X with rows in J.

(P3) For every $i \in [n]$ there exist a pair of columns Xe_{j_1} and Xe_{j_2} in X such that for $b = Xe_{j_1} + Xe_{j_2}$ with support J, we have that $0 < |J| \le 1/(8\theta)$, $|b|_{(2)}/|b|_{(1)} \le 1/2$, and the unique largest entry of $|b|$ has index i.

The main result of [24] is then obtained by proving the following theorem, and then by showing that **(P0)**–**(P3)** all hold whp for $p \gtrsim n^2 \log^2 n$.

▶ **Theorem 1** ([24]). *Suppose conditions* **(P0)**–**(P3)** *all hold. Then* ***ER-SpUD*** *and* ***Greedy*** *from Figure 2 recover* (A', X') *such that* $X' = \Pi D X$ *and* $A = AD^{-1}\Pi^{-1}$ *for some diagonal scaling matrix* D *and permutation matrix* Π. *That is, the recovered* (A', X') *are correct up to scaling and permuting rows (resp. columns) of* X *(resp.* A*).*

It was implicit in [24], and made explicit in [17], that to analyze the probability **(P1)** holding as a function of p, it suffices to prove some upper bound on some stochastic process. Namely, [17] proves that for Π a Bernoulli-subgaussian matrix with p rows, for $p = \Omega(n \log^4 n)$

$$\mathbb{P}\left(\sup_{\|v\|_1 = 1} |\|\Pi v\|_1 - \mathbb{E}\,\|\Pi v\|_1| < c_0 \mu_{min} \right) > 1 - o(1) \tag{3}$$

for some constant $c_0 < 1$, and $\mu_{min} := \inf_{\|v\|_1=1} \mathbb{E}\,\|X^T v\|_1$. Both [24, 17] though required the stochastic process of Eq. (3) to be bounded for roughly $\binom{n}{1/(8\theta)}$ choices of Π, formed by taking various submatrices of X^T. The naive approach is to then argue that the inequality holds with failure probability $\ll 1/\binom{n}{1/(8\theta)}$ for a fixed Π so then union bound over all such submatrices. Unfortunately the failure probability in [17] was not made explicit and was only given as $o(1)$, so it does not clearly allow for this union bound.

We show that, first of all, **(P1)** can be relaxed to some **(P1')** such that it suffices to only show Eq. (3) holds for polynomially many submatrices of X; showing **(P1')** suffices requires only a very minor change in the previous analysis of [24]. Next, more importantly, we show that $p \gtrsim n \log(n/\delta)$ suffices for Eq. (3) to hold with probability $1 - \delta$. This is one of our main technical contributions, and is established using a generic chaining argument [26]. It is worth pointing out that simpler chaining inequalities, such as Dudley's inequality, would yield suboptimal results in our setting by logarithmic factors.

Next, we also show that **(P2)** can be weakened to some other event **(P2')** that holds whp as long as $p \gtrsim \theta^{-1} \log(n/\delta)$ – this requires only a minor change in the analysis of [24].

Finally, in Lemma 4 we show that event **(P3)** holds whp for $p \gtrsim n \log(n/\delta)$. This is the part where the modification of the algorithm was necessary, so that pairs of columns Xe_{j_1} and Xe_{j_2} mentioned in this condition refers to all $\binom{p}{2}$ pairs of columns, as opposed to a fixed pairing (with $\lfloor \frac{p}{2} \rfloor$ pairs). Note that this condition actually fails to hold for the unmodified version of the algorithm with $p \ll n^2$, for example when the matrix X is drawn from the Bernoulli-Rademacher model, which is the main reason the unmodified algorithm fails to perform recovery (see the full version).

1.3 Recent and independent work

In a recent and independent work, Adamczak showed a main result similar to ours [1]. In particular, he showed that by making the same modification to **ER-SpUD** that we have made (**ER-SpUD(DCv2)**), $p \gtrsim n \log n$ suffices for successful dictionary learning with probability $1 - 1/p$. Unlike our analysis which is based on Bernstein's inequality and generic chaining, the proof in [1] combines Bernstein's inequality with Talagrand's contraction principle, which leads to an overall simpler proof than ours. The main differences in the results themselves are that attention in [1] was not given to dependence of p on the failure probability δ, and the analysis in our full version that **ER-SpUD(DC)** fails for $p \ll n^2$ also does not appear there, so that our stated results are slightly stronger in these regards.

2 Sufficient conditions for successful recovery

We first define **(P1')**, **(P2')** as follows.

(P1') For every b that can be expressed as the sum of two columns of X, $|S| < p/4$ and

$$\forall v \in \mathbb{R}^{|\bar{J}|},\ \|v^T X_{\bar{J},*}\|_1 - 2\|v^T X_{\bar{J},S}\|_1 > Cp\sqrt{\frac{\theta}{|\bar{J}|}}\|v\|_1 \tag{4}$$

where $C > 0$ is some fixed constant, $J = \mathrm{support}(b)$, $\bar{J} = [n] \backslash J$, and $S \subseteq [p]$ is the set of columns of X with support intersecting J.

(P2') Let q be $\frac{1}{8\theta}$. For every b equaling the sum of two columns of X and with $J \subset [n]$ its support, let $b' \in \mathbb{R}^{|J|}$ be the projection of b onto its support. If $0 < |J| \leq q = 1/(8\theta)$ and $|b|_{(2)}/|b|_{(1)} \leq 1/2$, then the solution to the restricted problem

$$\|z^T X_{J,*}\|_1 \text{ subject to } (b')^T z = 1 \tag{5}$$

is unique, 1-sparse, and is supported on the index of the largest entry of b'. Here $|b'|$ is the vector whose ith entry is $|b'_i|$, and $|b'|_{(j)}$ is the jth largest entry of $|b'|$. Also, $X_{J,*}$ denotes the submatrix of X with rows in J.

In the full version, we show that it suffices that **(P1')** and **(P2')** hold instead of **(P1)** and **(P2)** to guarantee correctness of **ER-SpUD(DCv2)**. In particular, we show the following lemma.

▶ **Lemma 2.** *Suppose conditions* **(P0)**, **(P1')**, **(P2')**, *and* **(P3)** *all hold. Then* ***ER-SpUD*** *and* ***Greedy*** *from Figure 2 recover* (A', X') *such that* $X' = \Pi DX$ *and* $A = AD^{-1}\Pi^{-1}$ *for some diagonal scaling matrix* D *and permutation matrix* Π. *That is, the recovered* (A', X') *are correct up to scaling and permuting rows (resp. columns) of* X *(resp.* A*).*

In the full version, we then show **(P0)**, **(P1')**, **(P2')**, and **(P3)** all simultaneously hold with probability $1 - \delta$ as long as $p \gtrsim n \log(n/\delta)$ and $1/n \lesssim \theta \lesssim 1/\sqrt{n}$, which when combined with Lemma 2 implies that **ER-SpUD** has the desired correctness guarantee under this same regime for p, θ.

▶ **Theorem 3.** *For* $p \gtrsim n \log(n/\delta)$ *and* $1/n \lesssim \theta \lesssim 1/\sqrt{n}$,

$$\mathbb{P}(\neg(\mathbf{P0}) \vee \neg(\mathbf{P1'}) \vee \neg(\mathbf{P2'}) \vee \neg(\mathbf{P3})) < \delta \tag{6}$$

▶ Remark. Here we sketch just how **(P1')** is analyzed in Theorem 3, similarly to the discussion in [24, 17]. This reveals why our chaining result, Theorem 12, is relevant.

For **(P1')**, the analysis is almost identical to the proofs of [24, Lemma 11] and [17, Lemma V.2] regarding **(P1)**. We repeat the slightly modified argument here for **(P1')**. Let b be a particular sum of two columns of X. We will show that the condition of **(P1')** fails to hold for b with probability at most δ/p^2, which implies $\mathbb{P}(\neg\textbf{(P1')}) \le \delta$ by a union bound over all $\binom{p}{2}$ such b. Let J, S be as in the definition of **(P1')** above. Define the event $\mathcal{E}_S$ as the event that $|S| < p/4$. Since $\theta n \le c\sqrt{n}$ for some small $c > 0$, if $b = X_{*,j_1} + X_{*,j_2}$, it follows that any column index $j \notin \{j_1, j_2\}$ has support intersecting J with probability at most $1/10$ (by making c sufficiently small). Thus $\mathbb{E}\,|S| < p/10$, implying $\mathbb{P}(\neg\mathcal{E}_S) = \mathbb{P}(|S| \ge p/4)$ is at most $\exp(-\Omega(p)) \le \delta/p^2$ by the Chernoff bound and fact that $p \gtrsim \log(p^2/\delta)$.

The definition of $\mathcal{E}_N$ is the following event:

$$\forall v \in \mathbb{R}^{|\bar{J}|},\ \|v^T X_{\bar{J},*}\|_1 - 2\|v^T X_{\bar{J},S}\|_1 > Cp\sqrt{\frac{\theta}{|\bar{J}|}}\|v\|_1 \tag{7}$$

for some constant C, where $\bar{J}$ denotes $[n]\backslash J$. Note though that $X_{\bar{J},*}$ is itself a matrix of i.i.d. Bernoulli-subgaussian entries (except for the two columns j_1, j_2, which are both zero). Thus setting $\Pi = X^T_{\bar{J},*}$ and applying Theorem 12 with our choice of p, with probability at least $1 - \delta/p^2$, for all $v \in B_1$,

$$\|v^T X_{\bar{J},*}\|_1 \ge \frac{7}{8}\,\mathbb{E}\,\|v^T X_{\bar{J},*}\|_1 = \frac{7p}{8}\,\mathbb{E}\,|v^T (X_{\bar{J},*})_{*,1}| \stackrel{\text{def}}{=} \frac{7p}{8}\alpha(v), \tag{8}$$

where $(X_{\bar{J},*})_{*,1}$ clumsily denotes the first column of the matrix $X_{\bar{J},*}$. The last inequality follows from [24, Lemma 16]. Also, conditioned on $\mathcal{E}_S$, $|S| < p/4$. Let X' be the matrix $X_{\bar{J},S}$ padded with $p/4 - |S|$ additional columns, each independent of but identically distributed to the columns of X. Then, even conditioned on $\mathcal{E}_S$, X' is a $|\bar{J}| \times p/4$ matrix of i.i.d. Bernoulli-gaussian entries (except for two columns which are both identically zero, corresponding to j_1, j_2). Thus applying Theorem 12 to $\Pi = (X')^T$, with probability at least $1 - \delta/p^2$,

$$\forall v \in B_1,\ \|v^T X'\|_1 \le \frac{3}{2}\,\mathbb{E}\,\|v^T X'\|_1 = \frac{3p}{8}\,\mathbb{E}\,|v^T X'_{*,1}| = \frac{3p}{8}\alpha(v). \tag{9}$$

Then by combining (8), (9) and scaling by $\|v\|_1$, we see that the left hand side of (7) is at least $\frac{p}{8}\alpha(v) \gtrsim p\sqrt{\frac{\theta}{|J|}}\|v\|_1$, with the inequality following from [24, Lemma 16].

We are now going to sketch how to show that with probability $1-\delta$ condition **(P3)** holds. The full proof is in the full version.

Consider the special case that $X_{ij} = b_{ij}g_{ij}$ with Bernoulli random variable b_{ij} and independent *continuous* subgaussian random variable g_{ij}. In such a case there would exist some fixed threshold t_0, such that $\mathbb{P}(|X_{ij}| > t_0) = \frac{1}{n}$ – it would mean that a constant fraction of columns would have *unique* entry larger than this threshold. For a single index $i \in [n]$ we would expect that at least $C\frac{p}{n} > \log\frac{n}{\delta}$ columns have a unique entry larger than t_0 and such that this entry has index i. Let us focus on this set of columns. If supports of any two such columns had common intersection exactly equal to $\{i\}$ – and if the sign on this i-th coordinate were matching, then in fact sum of those two columns would exhibit a factor two gap between the largest and the second largest entry, with largest entry being on the i-th position – indeed, entry on position i would have magnitude larger than $2t_0$, whereas all other entries are at most t_0 in absolute value. We can expect to find such a pair with probability $1-\frac{\delta}{n}$, as all columns are expected to be $\mathcal{O}(\sqrt{n})$ sparse – therefore for a fixed pair containing $\{i\}$, their supports would intersect on exactly $\{i\}$ with constant probability. We then prove that there exist such a pair with probability at least $\frac{\delta}{n}$ for every fixed i, and hence by union bound property **(P3)** holds with probability δ.

In the actual proof we do not assume that g_{ij} is continuous, and hence a threshold t_0 for which $\mathbb{P}(|X_{ij}| > t_0) = \frac{1}{n}$ might not exist, and the proof is slightly more complicated, but it follows the same general intuition. We prove the following in the full version.

▶ **Lemma 4.** *Let $X \in \mathbb{R}^{n\times p}$ be a Bernoulli-Subgaussian matrix with $\theta = \mathcal{O}(\frac{1}{\sqrt{n}})$. If $p = \Omega(n\log\frac{n}{\delta})$, then with probability at least $1-\delta$ condition* **(P3)** *holds.*

3 Chaining background

We now provide some preliminary definitions and results we will need to prove Theorem 12. As per Lemma 2 and the proof of Theorem 3, Theorem 12 fits in to show that **ER-SpUD** achieves correct recovery with probability $1-\delta$ for $p \gtrsim n\log(n/\delta)$ and $1/n \lesssim \theta \lesssim 1/\sqrt{n}$.

In this subsection we provide relevant definitions for a technique called *generic chaining*, as well as statements of some of the results in the area. Those tools have been designed to provide answers about the supremum of the fluctuations from the mean for a large collection of random variables, when the reasonable bounds for covariances in terms of the geometry of the set of indices are at hand.

▶ **Definition 5** (Admissible sequence)**.** For an arbitrary set T, we say that a sequence of its subsets $(T_k)_{k=0}^{\infty}$ is admissible if for every number k it is true that $T_k \subset T_{k+1}$ and $|T_k| \le 2^{2^k}$ for $k \ge 1$ and $|T_0| = 1$.

▶ **Definition 6** (Gamma functionals)**.** For a metric space (T,d) we define

$$\gamma_\alpha(T,d) := \inf_{(T_k)} \sup_{x\in T} \sum_{k=0}^{\infty} 2^{k/\alpha} d(x,T_k) \tag{10}$$

where the infimum is taken over all admissible sequences T_k. In the above formula we define as usual $d(x,T_k) := \inf_{t\in T_k} d(x,t)$.

▶ **Fact 7.** *If d and d' are two metrics such that for $d(t_1,t_2) = Cd'(t_1,t_2)$ for every pair of points t_1,t_2, then $\gamma_\alpha(T,d) = C\gamma_\alpha(T,d')$*

▶ **Theorem 8** (Generic chaining [26], Theorem 2.2.23)**.** *Let T be an arbitrary set of indices, and $d_1, d_2 : T \times T \to \mathbb{R}_{\geq 0}$ two metrics on T. Suppose that with any point $t \in T$ we have associated random variable X_t, with $\mathbb{E}\, X_t = 0$. Suppose moreover, that for any two points $u, w \in T$ we have a tail bound: $\mathbb{P}\left(|X_u - X_v| > \lambda\right) \lesssim \exp\left(-\frac{\lambda^2}{d_1(u,v)^2}\right) + \exp\left(-\frac{\lambda}{d_2(u,v)}\right)$. Then $\mathbb{E} \sup_{u\in T} |X_u| \lesssim \gamma_2(T, d_1) + \gamma_1(T, d_2)$.*

▶ **Theorem 9** (Dirksen, [11])**.** *Let T be an arbitrary set of indices and $d_1, d_2 : T \times T \to \mathbb{R}_{\geq 0}$ two metrics on T. Suppose that with any point $t \in T$ we have associated random variable X_t, such that $\mathbb{E}\, X_t = 0$. Suppose moreover that for any two points $u, w \in T$, we have a tail bound*

$$\mathbb{P}(|X_u - X_v| > \lambda) \lesssim \exp\left(-\frac{\lambda^2}{d_1(u,v)^2}\right) + \exp\left(-\frac{\lambda}{d_2(u,v)}\right)$$

Then for there exists an universal constant C, such that for any $u > 0$

$$\mathbb{P}\left(\sup_{u\in T} |X_u| > C(\gamma_2(T, d_1) + \gamma_1(T, d_2) + \sqrt{u}\Delta(T, d_1) + u\Delta(T, d_2))\right) < e^{-u}$$

where $\Delta(T, d) := \sup_{u,v\in T} d(u, v)$.

▶ **Theorem 10** (Majorizing measures [26], Theorem 2.4.1)**.** *Let $T \subset \mathbb{R}^n$, and assume that $g = (g_1, \dots g_n)$ is a vector of i.i.d. standard normal random variables. Then $\mathbb{E} \sup_{t\in T} \langle g, t\rangle \simeq \gamma_2(T, d_2)$, where d_p is the metric induced by the ℓ_p norm.*

▶ **Theorem 11** ([26], Theorem 10.2.8)**.** *Let $T \subset \mathbb{R}^n$, and assume that $x = (x_1, \dots, x_n)$ is a vector of i.i.d. standard exponential random variables. Then $\mathbb{E} \sup_{t\in T} \langle t, x\rangle \simeq \gamma_2(T, d_2) + \gamma_1(T, d_\infty)$*

4 Proof of the stochastic process bound

In this section we will prove the following theorem, which provides a stronger form of Eq. (3).

▶ **Theorem 12.** *Let $\Pi \in \mathbb{R}^{m\times n}$ be a random matrix with i.i.d. random entries $\pi_{ij} = \chi_{ij} g_{ij}$, where $\chi_{ij} \in \{0, 1\}$ is a Bernoulli random variable with $\mathbb{E}\, \chi_{ij} = \theta$, and g_{ij} symmetric subgaussian random variable. Moreover, assume that $\frac{1}{n} \leq \theta$. When $m = \Omega(\varepsilon^{-2} n \log \frac{n}{\delta})$,*

$$\mathop{\mathbb{P}}_{\Pi}\left(\sup_{v\in B_1} |\|\Pi v\|_1 - \mathbb{E}\, \|\Pi v\|_1| > \varepsilon \cdot \mathbb{E}\, \|\Pi v\|_1\right) < \delta \tag{11}$$

We now prove the theorem. Define $B_1 := \{t \in \mathbb{R}^n : \|t\|_1 \leq 1\}$. For each $v \in B_1$, consider $\tilde{X}_v := \|\Pi v\|_1 - \mathbb{E}\, \|\Pi v\|_1$. We wish to prove that with high probability over Π we have $\sup_{v\in B_1} |\tilde{X}_v| \leq \varepsilon\mu_{min}$, where $\mu_{min} := m\sqrt{\frac{\theta}{n}}$ is such that for every $v \in B_1$ we have $\mathbb{E}\, \|\Pi v\|_1 \geq \mu_{min}$ (see [24, Lemma 16] for a proof). Let $\pi_1, \dots \pi_m$ be the rows of matrix Π. With each $v \in B_1$ we associate another random variable $X_v := \sum_{i=1}^m \sigma_i |\langle \pi_i, v\rangle|$, with the σ_i being independent Rademachers.

▶ **Lemma 13.** *For every integer p we have*

$$\| \sup_{v\in B_1} |\tilde{X}_v| \|_p \lesssim \| \sup_{v\in B_1} |X_u| \|_p . \tag{12}$$

Proof. Without loss of generality consider even integer p, so that $|X_u|^p = X_u^p$. Let $\tilde{\Pi}$ be a random matrix, independent and identically distributed as Π. By Jensen's inequality we

have

$$\begin{aligned}\|\sup_{v\in B_1}|\tilde{X}_v|\|_p &= \left\|\sup_{v\in B_1}\|\Pi v\|_1 - \mathop{\mathbb{E}}_{\tilde{\Pi}}\|\tilde{\Pi}v\|_1\right\|_p \\ &\le \left\|\sup_{v\in B_1}\|\Pi v\|_1 - \|\tilde{\Pi}v\|_1\right\|_p \\ &= \left\|\sup_{v\in B_1}\sum_{i=1}^m |\langle\pi_i,v\rangle| - |\langle\tilde{\pi}_i,v\rangle|\right\|_p\end{aligned}$$

Now each summand $|\langle\pi_i,v\rangle| - |\langle\pi_i,v\rangle|$ is symmetric random variable, and they are independent. We can thus introduce independent random signs σ_i without altering the distribution:

$$\begin{aligned}\|\sup_{v\in B_1}|\tilde{X}_v|\|_p &\lesssim \left\|\sup_{v\in B_1}\sum_{i=1}^m \sigma_i(|\langle\pi_i,v\rangle| - |\langle\tilde{\pi}_i,v\rangle|)\right\|_p \\ &\le \left\|\sup_{v\in B_1}\sum_{i=1}^m \sigma_i|\langle\pi_i,v\rangle|\right\|_p + \left\|\sup_{v\in B_1}\sum_{i=1}^p(-\sigma_i)|\langle\tilde{\pi}_i,v\rangle|\right\|_p \\ &= 2\left\|\sup_{v\in B_1}\sum_{i=1}^m \sigma_i|\langle\pi_i,v\rangle|\right\|_p \lesssim \left\|\sup_{v\in B_1}|X_v|\right\|_p\end{aligned}$$

◀

We will first analyze tail behavior of the random variable $\sup_{v\in B_1}|X_v|$, and then use Lemma 13 together with [15, Lemma 4.10] to obtain tail bounds for the random variable of original interest $\sup_{v\in B_1}|\tilde{X}_v|$.

In order to use Theorem 9 to obtain tail bounds for supremum of X_u, we need to bound tails of random variables $X_u - X_v$ for $u, v \in B_1$.

▶ **Lemma 14.** *For every pair of points $u, v \in B_1$, we have*

$$\mathbb{P}(|X_u - X_v| > \lambda) \lesssim \exp\left(-\frac{\lambda^2}{2m\theta\|u-v\|_2^2}\right) + \exp\left(-\frac{\lambda}{\|u-v\|_\infty}\right) \tag{13}$$

Proof. We can write

$$X_u - X_v = \sum_{i=1}^m \sigma_i(|\langle\pi_i,u\rangle| - |\langle\pi_i,v\rangle|) \tag{14}$$

Define $Q_i := \sigma_i(|\langle\pi_i,u\rangle| - |\langle\pi_i,v\rangle|)$. We have $X_u - X_v = \sum_{i=1}^m Q_i$, where all Q_i are symmetric and identically distributed.

Moreover, we have $|Q_i| = ||\langle\pi_i,u\rangle| - |\langle\pi_i,v\rangle|| \le |\langle\pi_i,u-v\rangle|$. Observe that each π_{ij} is $(\sqrt{2\theta},1)$-subgamma. Here we say a random variable Z is (σ,B)-subgamma if $\mathbb{E}\,Z = 0$ and $\psi_Z(\lambda) \le \lambda^2\sigma^2/(2(1-B\lambda))$ for all $|\lambda| < 1/|B|$, where $\psi_Z(\lambda) = \ln \mathbb{E}\,e^{\lambda Z}$. By basic properties of subgamma random variables (see [9, Section 2.4]), we know that $\langle\pi_i, u-v\rangle$ is $(\sqrt{2\theta}\|u-v\|_2, \|u-v\|_\infty)$-subgamma.

Now, as both Q_i and $\langle\pi_i,u-v\rangle$ are symmetric, and $|Q_i| \le |\langle\pi_i,u-v\rangle|$ always, we deduce that each Q_i is also $(\sqrt{2\theta}\|u-v\|_2, \|u-v\|_\infty)$-subgamma.

Finally, $X_u - X_v$, as a sum of independent subgamma random variables is $(\sqrt{2m\theta}\|u-v\|_2^2, \|u-v\|_\infty)$-subgamma. This, together with [9, Section 2.4] implies the tail bound

$$\mathbb{P}\left(\left|\sum_{i=1}^m Q_i\right| > \lambda\right) \lesssim \exp\left(\frac{\lambda^2}{2m\theta\|u-v\|_2^2}\right) + \exp\left(\frac{\lambda}{\|u-v\|_\infty}\right) \tag{15}$$

◀

With this lemma in hand, we can use Theorem 9, to deduce the tail bound for supremum of $|X_v|$.

$$\mathbb{P}\left(\sup_{v\in B_1}|X_u| > M + \sqrt{u}D_1 + uD_2\right) < e^{-u} \tag{16}$$

Where $M := C_1(\gamma_2(B_1, \sqrt{2m\theta}d_2) + \gamma_1(B_1, d_\infty))$, $D_1 := C_2\Delta(B_1, \sqrt{2m\theta}d_2)$, and $D_2 := C_3\Delta(B_1, d_\infty)$, with d_2, d_∞ being metrics on $\mathbb{R}^n$ induced by norms ℓ_2, ℓ_∞ respectively, and C_1, C_2, C_3 are universal constants.

We claim that, we can deduce similar tail bounds for $\sup_{v\in B_1}|\tilde{X}_u|$. Namely

$$\mathbb{P}\left(\sup_{v\in B_1}|\tilde{X}_u| > L(M + \sqrt{u}D_1 + uD_2)\right) < e^{-u} \tag{17}$$

for some universal constant L.

Indeed it is known (see [15, Lemma 4.10]) that tail bounds of the form Eq. (16) imply moment bounds of the form $\|\sup_{v\in B_1}|X_v|\|_p \lesssim M + \sqrt{p}D_1 + pD_2$. By Lemma 13, the same (up to a constant) p-norm bounds are true for $\sup_{v\in B_1}|\tilde{X}_v|$. Finally, [15, Lemma 4.10] also implies similar tail behavior of the random variable $\sup_{v\in B_1}\tilde{X}_v$, as in Eq. (17).

If we set $u := \log\frac{1}{\delta}$ in Eq. (17), we will get an upper bound for $\sup_{v\in B_1}\tilde{X}_v$ which is satisfied with probability at least $1-\delta$. We need to understand the values of M, $\sqrt{u}D_1$ and uD_2, for this setting of u, and we will show how to pick m such that sum of those values is smaller than $\varepsilon\mu_{min}$.

Let us focus now on bounding M. We have $\gamma_2(B_1, \sqrt{2m\theta}d_2) = \sqrt{2m\theta}\gamma_2(B_1, d_2)$. We need an upper bound for $\gamma_2(B_1, d_2)$ and $\gamma_1(B_1, d_\infty)$. We prove the following in the full version, using Theorem 10 and Theorem 11.

▶ **Fact 15.** *$\gamma_2(B_1, d_2) \lesssim \sqrt{\log n}$ and $\gamma_1(B_1, d_\infty) \lesssim \log n$.*

Fact 15 together with previous discussion yield an upper bound $M \lesssim \sqrt{m\theta\log n} + \log n$.

Moreover, as $d_2(u, v) \le d_1(u, v)$ for any $u, v \in \mathbb{R}^n$, where d_1 is the metric induced by the ℓ_1 norm, we can easily upper bound diameter of B_1 in d_2 by diameter of B_1 and d_1 and therefore obtain an upper bound for D_1

$$D_1 = C_1\Delta(B_1, \sqrt{em\theta}d_2) = C_1\sqrt{em\theta}\Delta(B_1, d_2) \le C_1 2\sqrt{em\theta}$$

and similarly $\Delta(B_1, d_\infty) = 2$. Altogether, we have following inequalities: $M \lesssim \sqrt{m\theta\log n} + \log n$, $D_1 \lesssim \sqrt{m\theta}$, and $D_2 \lesssim 1$. Plugging this back to Eq. (17), we have

$$\mathbb{P}\left(sup_{v\in B_1}|\tilde{X}_v| < L_2\left(\sqrt{m\theta(\log n + \log\frac{1}{\delta})} + \log n + \log\frac{1}{\delta}\right)\right) < \delta \tag{18}$$

where again L_2 is some constant.

The following inequalities are equivalent: $L_2\sqrt{m\theta\log\frac{n}{\delta}} \le \frac{1}{2}\varepsilon\mu_{min}$, $L_2\sqrt{m\theta\log\frac{n}{\delta}} \le \frac{1}{2}\varepsilon\sqrt{\frac{\theta}{n}}m$, and $\frac{4L_2^2}{\varepsilon^2}n\log\frac{n}{\delta} \le m$. Similarly, the assumption $\theta \ge \frac{1}{n}$ implies that if $m > \frac{2L_2}{\varepsilon}n\log\frac{n}{\delta}$, then also $L_2\log\frac{n}{\delta} \le \frac{1}{2}\varepsilon\mu_{min}$, so once m is larger than both those values, Eq. (18) implies $\mathbb{P}\left(\sup_{v\in B_1}|\tilde{X}_v| > \varepsilon\mu_{min}\right) < \delta$, as desired.

Acknowledgments. We thank John Wright for pointing out to us the recent independent work [1].

Abstract

Approximate counting via correlation decay is the core algorithmic technique used in the sharp delineation of the computational phase transition that arises in the approximation of the partition function of anti-ferromagnetic two-spin models.

Previous analyses of correlation-decay algorithms implicitly depended on the occurrence of *strong spatial mixing*. This, roughly, means that one uses worst-case analysis of the recursive procedure that creates the sub-instances. In this paper, we develop a new analysis method that is more refined than the worst-case analysis. We take the shape of instances in the computation tree into consideration and we amortise against certain "bad" instances that are created as the recursion proceeds. This enables us to show correlation decay and to obtain an FPTAS even when strong spatial mixing fails.

We apply our technique to the problem of approximately counting independent sets in hypergraphs with degree upper-bound Δ and with a lower bound k on the arity of hyperedges. Liu and Lin gave an FPTAS for $k \geq 2$ and $\Delta \leq 5$ (lack of strong spatial mixing was the obstacle preventing this algorithm from being generalised to $\Delta = 6$). Our technique gives a tight result for $\Delta = 6$, showing that there is an FPTAS for $k \geq 3$ and $\Delta \leq 6$. The best previously-known approximation scheme for $\Delta = 6$ is the Markov-chain simulation based FPRAS of Bordewich, Dyer and Karpinski, which only works for $k \geq 8$.

Our technique also applies for larger values of k, giving an FPTAS for $k \geq 1.66\Delta$. This bound is not as strong as existing randomised results, for technical reasons that are discussed in the paper. Nevertheless, it gives the first deterministic approximation schemes in this regime. We further demonstrate that in the hypergraph independent set model, approximating the partition function is NP-hard even within the uniqueness regime.

1 Introduction

We develop a new method for analysing correlation decays in spin systems. In particular, we take the shape of instances in the computation tree into consideration and we amortise against certain "bad" instances that are created as the recursion proceeds. This enables us to show correlation decay and to obtain an FPTAS even when strong spatial mixing fails. To the best of our knowledge, strong spatial mixing is a requirement for all previous correlation-decay based algorithms. To illustrate our technique, we focus on the computational complexity of approximately counting independent sets in *hypergraphs*, or equivalently on counting the satisfying assignments of monotone CNF formulas.

The problem of counting independent sets in *graphs* (denoted #IS) is extensively studied. A beautiful connection has been established, showing that approximately counting independent sets in graphs of maximum degree Δ undergoes a computational transition which coincides with the uniqueness phase transition from statistical physics on the infinite Δ-regular tree. The computational transition can be described as follows. Weitz [17] designed an FPTAS for counting independent sets on graphs with maximum degree at most $\Delta = 5$. On the other hand, Sly [15] proved that there is no FPRAS for approximately counting independent sets on graphs with maximum degree at most $\Delta = 6$ (unless NP = RP). The same connection has been established in the more general context of approximating the partition function of the hard-core model [17, 12, 15, 4, 5, 16] and in the even broader context of approximating the partition functions of generic antiferromagnetic 2-spin models [14, 5, 16, 8] (which includes, for example, the antiferromagnetic Ising model). As a consequence, the boundary for the existence of efficient approximation algorithms for these models has been mapped out.

Approximate counting via correlation decay is the core technique in the algorithmic developments which enabled the sharp delineation of the computational phase transition. Another standard approach for approximate counting, namely Markov Chains Monte Carlo (MCMC) simulation, is also conjectured to work up to the uniqueness threshold, but the current analysis tools that we have do not seem to be powerful enough to show that. For example, sampling independent sets via MCMC simulation is known to have fast mixing only for graphs with degree at most 4 [11, 3], rather than obtaining the true threshold of 5.

In this work, we consider counting independent sets in hypergraphs with upper-bounded vertex degree, and lower-bounded hyperedge size. A hypergraph $H = (V, \mathcal{F})$ consists of a vertex set V and a set $\mathcal{F}$ of hyperedges, each of which is a subset of V. A hypergraph is said to be *k-uniform* if every hyperedge contains exactly k vertices. Thus, a 2-uniform hypergraph is the same as a graph. We will consider the more general case where each hyperedge has arity at least k, rather than exactly k.

An independent set in a hypergraph H is a subset of vertices that does not contain a hyperedge as a subset. We will be interested in computing Z_H, which is the total number of independent sets in H (also referred to as the partition function of H). Formally, the problem of counting independent sets has two parameters – a degree upper bound Δ and a lower bound k on the arity of hyperedges. The problem is defined as follows (see also Section 2 for an equivalent formulation in terms of monotone CNF formulas).

Name #HyperIndSet(k, Δ).
Instance A hypergraph H with maximum degree at most Δ where each hyperedge has cardinality (arity) at least k.
Output The number Z_H of independent sets in H.

Previously, #HyperIndSet(k, Δ) has been studied using the MCMC technique by Borderwich, Dyer, and Karpinski [1, 2] (see also [3]). They give an FPRAS for all $k \geq \Delta + 2 \geq 5$

and for $k \geq 2$ and $\Delta = 3$. Despite equipping path coupling with optimized metrics obtained using linear programming, these bounds are not tight for small k. Liu and Lu [9] showed that there exists an FPTAS for all $k \geq 2$ and $\Delta \leq 5$ using the correlation decay technique.

Thus, the situation seems to be similar to the graph case – given the analysis tools that we have, correlation-decay brings us closer to the truth than the best-tuned analysis of MCMC simulation algorithms. On the other hand, the technique of Liu and Lu [9] does not extend beyond $\Delta = 5$. To explain why, we need to briefly describe the correlation-decay-based algorithm framework introduced by Weitz [17]. The main idea is to build a recursive procedure for computing the marginal probability that any given vertex is in the independent set. The recursion works by examining sub-instances with "boundary conditions" which require certain vertices to be in, or out, of the independent set. The recursion structure is called a "computation tree". Nodes of the tree correspond to intermediate instances, and boundary conditions are different in different branches. The computation tree allows one to compute the marginal probability exactly but the time needed to do so may be exponentially large since, in general, the tree is exponentially large. Typically, an approximate marginal probability is obtained by truncating the computation tree to logarithmic depth so that the (approximation) algorithm runs in polynomial time. If the correlation between boundary conditions at the leaves of the (truncated) computation tree and the marginal probability at the root decays exponentially with respect to the depth, then the error incurred from the truncation is small and the algorithm succeeds in obtaining a close approximation.

All previous instantiations under this framework require a property called *strong spatial mixing* (SSM), which roughly states that, conditioned on *any* boundary condition on intermediate nodes, the correlation decays (see Section 2.1 in the full version). SSM thus guards against the worst-case boundary conditions that might be created by the recursive procedure.

Let the $(\Delta - 1)$-ary k-uniform hypertree $\mathbb{T}_{k,\Delta}$ be the recursively-defined hypergraph in which each vertex has $\Delta - 1$ "descending" hyperedges, each containing $k - 1$ new vertices.

▶ **Observation 1.** Let $k \geq 2$. For $\Delta \geq 6$, strong spatial mixing *does not hold* on $\mathbb{T}_{k,\Delta}$.

Observation 1 follows from the fact that the infinite $(\Delta - 1)$-ary tree $\mathbb{T}_{2,\Delta}$ can be embedded in the hypertree $\mathbb{T}_{k,\Delta}$, and from well-known facts about the phase transition on $\mathbb{T}_{2,\Delta}$.

Observation 1 prevents the generalisation of Liu and Lu's algorithm [9] so that it applies for $\Delta \geq 6$, even with an edge-size lower bound k. The problem is that the construction of the computation tree involves constructing intermediate instances in which the arity of a hyperedge can be as small as 2. So, even if we start with a k-uniform hypergraph, the computation tree will contain instances with small hyperedges. Without strong spatial mixing, these small hyperedges cause problems in the analysis. Lu, Yang and Zhang [10] discuss this problem and say "How to avoid this effect is a major open question whose solution may have applications in many other problems." This question motivates our work.

To overcome this difficulty, we introduce a new amortisation technique in the analysis. Since lack of correlation decay is caused primarily by the presence of small-arity hyperedges within the intermediate instances, we keep track of such hyperedges. Thus, we track not only the correlation, but also combinatorial properties of the intermediate instances in the computation tree. Using this idea, we obtain the following result.

▶ **Theorem 2.** *There is an FPTAS for* $\#\mathsf{HyperIndSet}(3, 6)$.

Note that $\#\mathsf{HyperIndSet}(2, 6)$ is NP-hard to approximate due to [15], so our result is tight for $\Delta = 6$. This also shows that $\Delta = 6$ is the first case where the complexity of approximately counting independent sets differs on hypergraphs and graphs, as for $\Delta \leq 5$ both admit an

FPTAS [9]. Moreover, Theorem 2 is stronger than the best MCMC algorithm [2] when $\Delta = 6$ as [2] only works for $k \geq 8$.

We also apply our technique to large k.

▶ **Theorem 3.** *There exists a constant k_0 such that for all positive integers $k \geq k_0$ and Δ satisfying $k \geq 1.66\Delta$ there is an FPTAS for the problem* $\#\mathsf{HyperIndSet}(k, \Delta)$.

In the large k case, our result is worse than that obtained by analysis of the MCMC algorithm [2] ($k \geq 1.66\Delta$ rather than $k \geq \Delta + 2$) but it is incomparable since our algorithm is deterministic rather than randomised. The reason that our bound is worse is mainly due to technical difficulty in the analysis that we will explain shortly. In fact, we believe that, in the long run, analysis of the correlation-decay based algorithm is more likely to reveal the exact critical threshold than analysis of MCMC simulation, although other new ideas will probably be required in order to achieve sufficiently precise analysis.

The main technical difficulty in correlation-decay analysis is bounding a function that we call the "decay rate". This boils down to solving an optimization problem with $(k-1)(\Delta-1)$ variables. In previous work (e.g. [13]), this optimization has been solved using a so-called "symmetrization" argument, which reduces the problem to a univariate optimization via convexity. However, the many variables represent different branches in the computation tree. Since our analysis takes the shape of intermediate instances in the tree into consideration, the symmetrization argument does not work for us, and different branches take different values at the maximum. This problem is compounded by the fact that the shape of the sub-tree consisting of "bad" intermediate instances is heavily lopsided, and the assignment of variables achieving the maximum is far from uniform. Given these problems, there does not seem to be a clean solution to the optimization in our analysis. Instead of optimizing, we give an upper bound on the maximum decay rate. In Theorem 2, as k and Δ are small, the number of variables is manageable, and our bounds are much sharper than those in Theorem 3. On the other hand, because of this, the proof of Theorem 3 is much more accessible, and we will use Theorem 3 as a running example to demonstrate our technique.

We also provide some insight on the hardness side. Recall that for graphs it is NP-hard to approximate $\#\mathsf{IS}$ beyond the uniqueness threshold ($\Delta = 6$) [15]. We prove that it is NP-hard to approximate $\#\mathsf{HyperIndSet}(6, 22)$ (Corollary 29). In contrast, we show in the full version that uniqueness holds on the 6-uniform Δ-regular hypertree iff $\Delta \leq 28$ (Corollary 36). Thus, efficient approximation schemes cease to exist well below the uniqueness threshold on the hypertree. In fact, we show that this discrepancy grows exponentially in k: for large k, it is NP-hard to approximate $\#\mathsf{HyperIndSet}(k, \Delta)$ when $\Delta \geq 5 \cdot 2^{k/2}$ (Theorem 28 and Corollary 30), despite the fact that uniqueness holds on the hypertree for all $\Delta \leq 2^k/(2k)$ (Lemma 37 in the full version). Theorem 28 follows from a rather standard reduction to the hard-core model on graphs. Nevertheless, it demonstrates that the computational-threshold phenomena in the hypergraph case ($k > 2$) are different from those in the graph case ($k = 2$).

As mentioned earlier, there are models where efficient (randomised) approximation schemes exist (based on MCMC simulation) even though SSM does not hold. In fact, this can happen even when uniqueness does not hold. A striking example is the ferromagnetic Ising model (with external field). As [14] shows, there are parameter regimes where uniqueness holds but strong spatial mixing fails. It is easy to modify the parameters so that even uniqueness fails. Nevertheless, Jerrum and Sinclair [6] gave an MCMC-based FPRAS that applies for all parameters and for general graphs (with no degree bounds). It is still an open question to give a correlation decay based FPTAS for the ferromagnetic Ising model.

We conclude this section by giving an outline of the rest of the paper. In Section 2, we give some preliminaries. We reformulate $\#\mathsf{HyperIndSet}(k, \Delta)$ as the problem of counting

satisfying assignments in monotone CNF formulas, which will allow us to use the computation tree of Liu and Lu [9]. In Section 3, we give an overview of our proof approach, describing the main idea behind our new amortisation technique. In Section 4, we give the main ingredients which we use to prove Theorem 3 (large k). Section 5 describes the main lemma which yields Theorem 2 ($k = 3$). Section 6 gives the formal statements and proofs of the hardness results.

2 Preliminaries: monotone CNF formulas & the computation tree

The problem of counting the independent sets of a hypergraph has an equivalent formulation in terms of monotone CNF formulas. Given a hypergraph $H = (V, \mathcal{F})$, let C be a Boolean formula with variable set V. For each hyperedge, construct a clause which is the disjunction of all variables corresponding to vertices in the hyperedge. Let C be the conjunction of all such clauses. Note that C is a monotone formula – no variable is negated. Also, independent sets of H are in one-to-one correspondence with satisfying assignments of C – a variable is assigned value "true" in an assignment if and only if it is out of the corresponding independent set. Going the other direction, any monotone CNF formula can be viewed as a hypergraph. In the technical sections of this paper, we use the monotone CNF formulation and, in particular, the computation tree of Liu and Lu [9]. Below we give the relevant definitions and notation; our notation aligns as much as possible with that of [9].

Let C be an instance of a monotone CNF formula. We will denote the set of variables in C by V and set $n := |V|$. Variables in V will be denoted by $x_1, x_2, \ldots$ and clauses in C by $c_1, c_2, \ldots$. The arity of a clause c will be denoted by $|c|$, i.e., $|c|$ is the number of variables appearing in the clause c. We assume throughout that no variable appears twice in the same clause. For a variable $x \in V$, we denote by $d_x(C)$ the number of clauses where x appears. When x and C are clear from context, we will simply use d to denote $d_x(C)$. When C is clear from context, we will use Δ to denote $\max_{x \in V} d_x(C)$ and we will say that C is a formula with max degree Δ. Let $\mathcal{C}_{k,\Delta}$ be the set of all monotone CNF formulas which have max degree Δ and whose clauses have arity at least k. Note that some formulas in $\mathcal{C}_{k,\Delta}$ may have some clauses with arbitrarily large arities.

Our goal is to approximately count the number of satisfying assignments of a formula $C \in \mathcal{C}_{k,\Delta}$, which we denote by $Z(C)$. Since C is monotone, an assignment $\sigma : V \to \{0, 1\}$ is satisfying if, for every clause in C, there is at least one variable $x \in c$ with $\sigma(x) = 1$. Note that $Z(C) > 0$ since the all-1 assignment satisfies every monotone CNF formula. For convenience, we will use the simplified notation "$x = 1$" to denote (the set of) satisfying assignments of C in which x is set to 1, and we similarly use "$x = 0$". We associate the formula C with a probability distribution in which each satisfying assignment has probability mass $1/Z(C)$. We will denote probabilities with respect to this distribution by $\Pr_C(\cdot)$.

Let x be a variable in V. Define $R(C, x) := \frac{\Pr_C(x=0)}{\Pr_C(x=1)}$, this is well-defined since $\Pr_C(x = 1) > 0$ by the monotonicity of C. In fact, the monotonicity of C also implies that $0 \leq R(C, x) \leq 1$, where the upper bound follows from the fact that, for every satisfying assignment with $x = 0$, flipping the assignment of x to 1 does not affect satisfiability. Our interest in the quantity $R(C, x)$ stems from the following simple lemma (the proof follows the argument in [9, Appendix A] and is given for completeness in the full version).

▶ **Lemma 5.** *Let k and Δ be positive integers. Suppose that there is a polynomial-time algorithm (in n and $1/\varepsilon$) that takes an n-variable formula $C \in \mathcal{C}_{k,\Delta}$, a variable x of C, and an $\varepsilon > 0$ and computes a quantity $\widehat{R}(C, x)$ satisfying $|\widehat{R}(C, x) - R(C, x)| \leq \varepsilon$. Then, there exists an FPTAS which approximates $Z(C)$ for every $C \in \mathcal{C}_{k,\Delta}$.*

Liu and Lu [9] established that a computation tree approach gives a recursive procedure for *exactly* calculating $R(C, x)$ for any monotone CNF formula C and any variable $x \in C$. We next give the details of this recursive procedure (see [9, Lemma 5]). First, we introduce the following definitions (see Definitions 6 and 7 in the full version).

We call the variable x *forced* in C if x appears in a clause of arity 1 in C. We call the variable x *free* if x does not appear in any clause of C. We call the clause c *redundant* in C if there is a clause c' in C such that c is a (strict) superset of c' (note that removing c from C does not affect the set of satisfying assignments of C). We next give the details of the computation tree. The nodes in the computation tree will be pairs (C, x) such that

$$C \text{ is a monotone CNF formula and } x \text{ is a variable which is not forced in } C. \tag{1}$$

Let C, x satisfy (1). We first perform a pre-processing step on C which involves (i) initially removing all of the redundant clauses, (ii) then, removing all clauses of arity 1. Note that part (ii) of the preprocessing step removes all forced variables that were present in C; at the time of the removal, forced variables appear only in clauses of arity 1 since part (i) of the preprocessing step has already removed all redundant clauses in C (and hence all clauses of arity greater than 1 that contain forced variables). Denote the formula after the completion of the preprocessing step by $\widetilde{C}$. Note that every clause in $\widetilde{C}$ is also a clause in the initial formula C, so x is not forced in $\widetilde{C}$. Further, since removing redundant clauses does not change the set of satisfying assignments of C, and x is not forced in C, we have that $R(\widetilde{C}, x) = R(C, x)$.

If x is free in $\widetilde{C}$ (the formula after the pre-processing step), then the start node (C, x) is (declared) a leaf of the computation tree (note that in this case $R(C, x) = 1$). In the sequel, we assume that x is not free in $\widetilde{C}$. Denote by $\{c_i\}_{i\in[d]}$ the clauses where x occurs in $\widetilde{C}$ and let $w_i = |c_i| - 1$ (note that $d \geq 1$). We will use $\mathbf{w}$ to denote the vector $(w_1, \ldots, w_d)$. The variables in clause c_i other than x will be denoted by $x_{i,1}, \ldots, x_{i,w_i}$. For the pair (C, x), we next construct pairs $(C_{i,j}, x_{i,j})$ for $i \in [d]$ and $j \in [w_i]$, where $C_{i,j}$ is an appropriate subformula obtained from $\widetilde{C}$, roughly, by hard-coding (some of) the occurrences of the variables in $\widetilde{C}$ to either 1 or 0 (this will be explained below and will henceforth be referred to as pinning)[1].

Precisely, for $i \in [d]$, let C_i be the formula obtained from $\widetilde{C}$ by removing clauses $c_1, \ldots, c_{i-1}$ (note that this has the same effect as pinning the occurrences of x in these clauses to 1) and pinning the occurrences of x in $c_{i+1}, \ldots, c_d$ to 0. For $j \in [w_i]$, the formula $C_{i,j}$ is obtained from C_i by further removing clause c_i and pinning all the occurrences of $x_{i,1}, \ldots, x_{i,j-1}$ to 0.

In the full version, we prove that the pairs $(C_{i,j}, x_{i,j})$ satisfy (1) for all $i \in [d]$, $j \in [w_i]$. We next state the relation between $R(C, x)$ and the $R(C_{i,j}, x_{i,j})$'s. It is proved in [9, Lemma 5], using a Weitz-type telescopic expansion (see also the full version for the argument), that

$$R(C, x) = \prod_{i=1}^{d} \left(1 - \prod_{j=1}^{w_i} \frac{R(C_{i,j}, x_{i,j})}{1 + R(C_{i,j}, x_{i,j})}\right). \tag{2}$$

By applying (2) recursively, it is not hard to see that one can compute the quantity $R(C, x)$ *exactly*. Of course, exact computation using this scheme will typically require exponential time, so as in [9] we will stop the recursion at some (small) depth L to keep the computations feasible within polynomial time. This will yield a quantity $R(C, x, L)$ and the hope is that, by choosing L appropriately, the error $|R(C, x, L) - R(C, x)|$ will be sufficiently small.

[1] Note that our notation for i, j is different from the one in [9]; there, the roles of i, j are interchanged.

In light of (2), and analogously to [9], we define $R(C, x, L)$ for integer $L \geq 0$ as follows. Namely, for integer L we set

$$R(C,x,L) = \begin{cases} 1, & \text{if } x \text{ is free in } \widetilde{C} \text{ or } L \leq 0, \\ \prod_{i=1}^{d} \left(1 - \prod_{j=1}^{w_i} \frac{R(C_{i,j}, x_{i,j}, L-l_{w_i})}{1+R(C_{i,j}, x_{i,j}, L-l_{w_i})}\right), & \text{otherwise,} \end{cases} \tag{4}$$

where $l_{w_i} := \lceil \log_6(w_i + 1) \rceil$ (note that $l_1 = \ldots = l_5 = 1$). The choice of l_{w_i} is such that the size of the computation tree is polynomial for $L = O(\log n)$; the particular choice of the logarithm base in the definition of l_{w_i} is not important as long as it is a big enough constant.

Using correlation decay techniques together with a new method to account for the shape of the computation tree, we will show the following key lemma (proved in Section 5).

▶ **Lemma 10.** *Let $\Delta = 6$. There exist constants α, τ with $0 < \alpha < 1$ and $\tau > 0$ such that the following holds for all integers L. Let C be a monotone CNF formula whose clauses all have arity greater than or equal to 3 and, further, each variable occurs in at most Δ clauses. Then, for the quantity $R(C, x, L)$ defined recursively from (4), it holds that*

$$|R(C,x,L) - R(C,x,\infty)| \leq \tau\alpha^L.$$

In the following section, we give an overview of our approach to proving Lemma 10. We also prove an analogous lemma in the case where k, Δ are large, see Lemma 11 in Section 4.

Proof of Theorems 2 and 3 assuming Lemmas 10 and 11. Invoke Lemmas 5, 10 and 11 and the reformulation of $\#\mathsf{HyperIndSet}(k, \Delta)$ in terms of the monotone CNF problem. ◀

3 Proof Approach

To prove Lemma 10, the standard approach so far in the literature has been to show that, for a node (C, x) in the computation tree, the quantity $|R(C, x, L) - R(C, x, \infty)|$ is bounded by $\alpha \max_{i,j} |R(C_{i,j}, x_{i,j}, L-1) - R(C_{i,j}, x_{i,j}, \infty)|$ for some constant $0 < \alpha < 1$ and then, inductively, to deduce that $|R(C, x, L) - R(C, x, \infty)|$ decays exponentially in L. This approach has been extremely successful when strong spatial mixing holds [14, 8, 9, 13, 18, 10].

In our setting, this inductive approach is problematic since, inside the computation tree, we are faced with the possibility that the formula at the root of a subtree has many arity-2 clauses. For $\Delta \geq 6$, these subtrees prohibit the application of the above proof scheme since they are in non-uniqueness and hence the desired step-by-step decay is no longer present.

While arity-2 clauses are problematic, clauses with larger arity do at least lead to good decay of correlation in a single step. Thus, our approach is to do an amortised analysis. In a single step, we track both the one-step decay of correlation and the immediate creation of arity-2 clauses, which will later lead to worse decay. More formally, instead of tracking the quantity $R(C, x, L)$, we track the quantity $m(C, x, L) = \delta^{b(C)} R(C, x, L)$ where $b(C)$ denotes the number of arity-2 clauses in the formula C (the "bad" clauses) and $\delta \in (0, 1)$ is an appropriate constant. (In fact, in Section 5, we define $m(C, x, L)$ as $\delta^{b(C)}\Phi(R(C, x, L))$ for an appropriate function Φ, see (28).)

Crucially, note that the root formula C satisfies $|m(C, x, L) - m(C, x, \infty)| = |R(C, x, L) - R(C, x, \infty)|$, since by the assumption in Lemma 10 we have that $b(C) = 0$. Thus, the key step in the proof of Lemma 10 is to show that the quantity $|m(C, x, L) - m(C, x, \infty)|$ decays exponentially with L; we will show that, for some constant $\alpha \in (0, 1)$, for an arbitrary node (C, x) in the computation tree, it holds that

$$|m(C,x,L) - m(C,x,\infty)| \leq \alpha \max_{i,j} |m(C_{i,j}, x_{i,j}, L-1) - m(C_{i,j}, x_{i,j}, \infty)|. \tag{5}$$

Since arity-2 clauses are the source of problems it is important not to create too many of them. Therefore, we also have to be careful in the construction of the computational tree. We achieve this by carefully ordering the clauses that we process at each step to avoid creating arity-2 clauses as much as possible.

Unfortunately, the quantity $m(C, x, L)$ is more complicated than the plain message $R(C, x, L)$ which has been studied before since it incorporates combinatorial information about the formula C and thus it does not satisfy a simple recursion (unlike $R(C, x, L)$). Nevertheless, we are able to define a multi-variable quantity κ (see (32)) and to show that when $\kappa \leq 1$, inequality (5) holds.

The technical details of applying the approach are quite intricate in the context of Lemma 10. In Section 4, we first apply the approach to the case of large k, where the proof is (significantly) shorter. There, instead of tracking the number of clauses of arity 2, we track (roughly) the aggregate arities of the clauses in C. Other than that, the high-level proof approach is similar to what is described above. In Section 5, we give an outline of the more difficult proof of Lemma 10.

4 The case of large k

In this section, we show the following lemma. Let $c := 0.565$ and $\beta \sim 1.65115$ be the solution to $2^{0.0001}c^\beta = 2 \times 0.9997(1 - c^\beta)c^2$.

▶ **Lemma 11.** *Let $\beta \sim 1.65$ be defined as above. Let k be a sufficiently large positive integer and let Δ be a positive integer satisfying $k \geq \beta\Delta + 3$. There are real numbers α and τ satisfying $0 < \alpha < 1$ and $\tau > 0$ such that for every $C \in \mathcal{C}_{k,\Delta}$ and every integer L,*

$$|R(C, x, L) - R(C, x, \infty)| \leq \tau\alpha^L, \tag{6}$$

where the quantity $R(C, x, L)$ is defined recursively from (4)*.*

To estimate the error $|R(C, x, L) - R(C, x, \infty)|$, we will track a specific quantity $m(C, x, L)$ which is assigned to each node in the computation tree. Let C be the original monotone CNF formula and let (N, x) be a node in the computation tree. As explained earlier, each clause c' of N is obtained from a clause c of C by pinning a certain number of variables to 0 (possibly none), which effectively is the same as removing those variables. We call these 0-pinnings *deficits* and let $\max\{0, k - |c'|\}$ be number of deficits of c'. Note that a clause of arity larger than k is considered to have no deficit, although some variables of it may have been pinned to 0. Let $D(N) = \sum_{c' \in N} \max\{0, k - |c'|\}$ denote the total deficits of N. Also observe that if a clause c of C does not show up in N, it does not contribute any deficits. For any node (N, x) in the computation tree, let $m(N, x, L) := \delta^{D(N)} R(N, x, L)$ where $\delta \in (0, 1)$ is a constant that we will choose later.

Now let us calculate how the number of deficits changes in one step of the recursion. Let (N, x) be a node in the computation tree. Note that pinning any variable to 1 will remove all clauses containing it, and will therefore eliminate all deficits of these clauses. Moreover, for a clause of arity 2, pinning any of its variables to either 0 or 1 will eliminate the whole clause due to the preprocessing step. Let $b_2(N, x)$ (or simply b_2 when N and x are clear from the context) denote the number of arity-2 clauses containing x in N. In the recursion, we will always order the clauses so that arity-2 clauses come last. Thus, clauses $c_1, \ldots, c_{d-b_2}$ each have arity at least 3 and clauses $c_{d-b_2+1}, \ldots, c_d$ each have arity 2. Due to these arity-2 clauses, the deficits in every branch below (N, x) will decrease by at least $b_2(k - 2)$.

Now consider an integer i in the range $1 \leq i \leq d - b_2$. Recall that in N_i, we pin appearances of x prior to i to 1, thus eliminating deficits in clauses $c_1, \ldots, c_{i-1}$. Together with the removal

of clause c_i, these removals decrease the total deficits by $\sum_{t=1}^{i} \max\{0, k-1-w_t\}$, where $w_t = |c_t| - 1$. Let $s_i = \sum_{t=1}^{i} \max\{0, k-1-w_t\}$. We also pin all appearances of x after i to 0, increasing the total number of deficits by at most $d - i - b_2$. Here we have a "$-b_2$" because pinning a variable to 0 in a arity-2 clause does not increase the deficits. Moreover, in $N_{i,j}$, we pin all appearances of $j-1$ other variables to 0. Each of these pinnings may contribute at most $\Delta - 1$ deficits, giving a total increase of at most $(\Delta-1)(j-1)$. Next consider $i \geq d - b_2 + 1$. For such an i, clause c_i has arity 2, and it is easy to see that deficits do not increase in the branch corresponding to $N_{i,j}$. Also note that the preprocessing steps do not increase deficits. Hence we have the following upper bounds on $D(N_{i,j})$ for $i \in [d]$:

$$D(N_{i,j}) \leq \begin{cases} D(N) - b_2(k-2) - s_i + d - i - b_2 + (\Delta-1)(j-1) & \text{if } 1 \leq i \leq d - b_2, \\ D(N) - b_2(k-2) - s_{d-b_2} & \text{if } d - b_2 + 1 \leq i. \end{cases} \tag{7}$$

The key to our analysis is to bound the correlation decay of $m(C, x, L)$. We will analyse the recursion for $m(C, x, L)$ based on that of $R(C, x, L)$. Recall that the recursion for $R(C, x, L)$ depends on the function $F^{d,\mathbf{w}}(\mathbf{r})$ implicitly defined by (4), i.e.,

$$F^{d,\mathbf{w}}(\mathbf{r}) := \prod_{i=1}^{d} \left(1 - \prod_{j=1}^{w_i} \frac{r_{i,j}}{1 + r_{i,j}}\right), \tag{8}$$

where $r_{i,j} \in [0,1]$ for all $i \in [d]$, $j \in [w_i]$ (so $R(C, x, L) = F^{d,\mathbf{w}}(\{R(C_{i,j}, x_{i,j}, L - l_{w_i})\})$).

For $i \in [d]$, the following quantity $\rho_{\delta,\alpha}^{\mathbf{w},i}$ will roughly upper bound the sensitivity of $|m(C, x, L) - m(C, x, \infty)|$ to the i-th clause in which x appears in C, or more precisely, to the quantities $|m(C_{i,j}, x_{i,j}, L - l_{w_i}) - m(C_{i,j}, x_{i,j}, \infty)|$ for $j \in [w_i]$:

$$\rho_{\delta,\alpha}^{\mathbf{w},i}(\mathbf{r}) := \begin{cases} \alpha^{-l_{w_i}} \delta^{s_i + i - d + b_2} \sum_{j=1}^{w_i} \delta^{-(j-1)(\Delta-1)} \left|\frac{\partial F^{d,\mathbf{w}}}{\partial r_{i,j}}\right| & \text{if } 1 \leq i \leq d - b_2, \\ \alpha^{-l_{w_i}} \delta^{s_{d-b_2}} \left|\frac{\partial F^{d,\mathbf{w}}}{\partial r_{i,1}}\right| & \text{if } d - b_2 + 1 \leq i \leq d. \end{cases} \tag{10}$$

Note that $\rho_{\delta,\alpha}^{\mathbf{w},i}(\mathbf{r})$ depends also on $r_{i',j}$ with $i' \neq i$. The decay rate of $|m(C, x, L) - m(C, x, \infty)|$ in terms of L, for all formulas C with max degree Δ, will be captured by the aggregation of $\rho_{\delta,\alpha}^{\mathbf{w},i}(\mathbf{r})$'s, namely, $\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r}) := \delta^{b_2(k-2)} \sum_{i=1}^{d} \rho_{\delta,\alpha}^{\mathbf{w},i}(\mathbf{r})$. The main technical lemma of the section is the following.

▶ **Lemma 12.** *For all sufficiently large Δ, for any $k \geq \beta\Delta + 3$ where $\beta \sim 1.65115$ is defined earlier, there exists constants $0 < \delta < 1$, $0 < \alpha < 1$, and $U > 0$ such that, for all $\mathbf{0} \leq \mathbf{r} \leq \mathbf{1}$, $\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r})$ is at most 1 when $d \leq \Delta - 1$ and at most U when $d = \Delta$.*

Before sketching the proof of Lemma 12, let's show that it is sufficient to imply Lemma 11.

Proof of Lemma 11 (Sketch). Let δ, α be as in Lemma 12. For $C \in \mathcal{C}_{k,\Delta}$, we have $D(C) = 0$, so $|m(C, x, L) - m(C, x, \infty)| = |R(C, x, L) - R(C, x, \infty)|$.

The lemma will thus follow by showing that for every node (N, x) of the computation tree the quantity $|m(N, x, L) - m(N, x, \infty)|$ decays roughly as α^L. The proof is by induction on L; the base cases $L \leq 0$ are easy to show since $\delta \in (0, 1)$. For the induction step, one needs the following key inequality (obtained by considering the gradient of $F^{d,\mathbf{w}}$):

$$|m(N, x, L) - m(N, x, \infty)| \leq \max_{\mathbf{r}} \left\{ \left(\sum_{i=1}^{d} \sum_{j=1}^{w_i} \delta^{D(N) - D(N_{i,j})} \alpha^{-l_{w_i}} \left| \frac{\partial F^{d,\mathbf{w}}(\mathbf{r})}{\partial r_{i,j}} \right| \right) \right\} \times \max_{i,j} \left\{ \alpha^{l_{w_i}} \left| m(N_{i,j}, x_{i,j}, L - l_{w_i}) - m(N_{i,j}, x_{i,j}, \infty) \right| \right\}. \tag{16}$$

Our bounds (7) on $D(N)-D(N_{i,j})$ for $i\in[d]$, $j\in[w_i]$ imply that the $\max_{\mathbf{r}}\{\cdot\}$ expression in (16) is upper bounded by $\max_{\mathbf{r}}\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r})$ (since $\delta\in(0,1)$). Thus, by Lemma 12, one obtains step-wise decay of $m(N,x,L)$. (The case $d=\Delta$ arises only at the root formula.) ◀

Proof of Lemma 12 (Sketch). Let $\alpha=0.9999$ and δ be such that $\delta^{\Delta}=c$ (recall, $c=0.565$).

The proof has two main steps. In the first step, one obtains a bound on $\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r})$ that does not depend on $\mathbf{r}$ (i.e., we bound the terms which depend on the "messages" $R(C,x,L)$). We do this for each clause c_i; the bound we obtain depends only on the arity of the clause, or, for the purposes of this proof, on w_i. The second step is then to maximize over the possible values of the w_i's.

For $w_i\geq 2$, let $\mu(w_i):=\max\{2,w_i\left(2-2^{1-w_i}\right)^{-1}\}$. The result of the first step is the following bound on $\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r})$ (note that $\mathbf{r}$ is completely eliminated).

$$\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r})\leq\delta^{b_2(k-2)}\left(\sum_{i=1}^{d-b_2}\alpha^{-l_{w_i}}\delta^{s_i+i-d+b_2-(w_i-1)(\Delta-1)}2^{-w_i}\mu(w_i)+\alpha^{-1}b_2\right),\tag{21}$$

Using the fact that $\alpha^{-l_{w_i}}\leq\alpha^{-1}w_i^{0.0001}$ for any $w_i\geq 2$, we obtain that, if $w_i>k-1$, then the right hand side of (21) increases if we replace w_i with $k-1$. Henceforth we may assume that $w_i\leq k-1$, which allows us to rewrite $s_i=s_{i-1}+k-1-w_i$. Using the fact that $\delta^{\Delta}=c$, we then obtain

$$\alpha\,\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r})\leq\delta^{k+b_2(k-1)}\eta_d(\mathbf{w})+b_2\delta^{b_2(k-2)},\quad\eta_d(\mathbf{w}):=\sum_{i=1}^{d-b_2}\delta^{s_{i-1}}w_i^{0.0001}(2c)^{-w_i}\mu(w_i).\tag{22}$$

Convexity arguments show that the maximum of $\eta_d(\mathbf{w})$ is achieved at $\mathbf{w}=\mathbf{w}'$, where $w_i'=k-1$ for $1\leq i\leq t$ and $w_i'=2$ for $t+1\leq i\leq d-b_2$ for some $0\leq t\leq d-b_2-1$. We thus obtain

$$\eta_d(\mathbf{w})\leq\eta_d(\mathbf{w}')\leq\Delta(k-1)^{1.0001}(2c)^{-(k-1)}\left(2-2^{2-k}\right)^{-1}+\frac{2^{0.0001}}{2c^2(1-\delta^{k-3})}\leq 0.9998c^{-\beta},\tag{26}$$

where the last inequality follows from $\frac{2^{0.0001}}{2c^2(1-\delta^{k-3})}\leq\frac{2^{0.0001}}{2c^2}\cdot\frac{1}{1-c^{\beta}}=0.9997c^{-\beta}$ (using the definition of c,δ) and that for large Δ and k, we have $\Delta(k-1)^{1.0001}(2c)^{-(k-1)}\left(2-2^{2-k}\right)^{-1}<0.0001$ (using that $2c>1$ and $k\geq\beta\Delta+3$). Now, plug (26) into (22):

$$\alpha\,\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r})\leq\delta^{b_2(k-2)}\left(0.9998\,\delta^k c^{-\beta}+b_2\right)\leq c^{\beta b_2}\left(0.9998+b_2\right)\leq\alpha,\tag{27}$$

where the last inequality follows from $c^{\beta}<1/2$. (27) yields $\kappa_{\delta,\alpha}^{d,b_2,\mathbf{w}}(\mathbf{r})\leq 1$, as claimed. ◀

5 A finer analysis to treat $k\geq 3$, $\Delta=6$

In this section, we describe the main technical ingredient to prove Lemma 10 (which in turn was critical in deducing Theorem 2 in Section 2).

Let (C,x) be a non-leaf node in the computation tree, where the root node is a monotone CNF formula with max degree $\Delta=6$ all of whose clauses have arity at least $k=3$. Denote by $b(C)$ the total number of clauses of arity 2 in C. Recall that $\widetilde{C}$ is the formula obtained from C after the preprocessing step. Also, $c_1,\ldots,c_d$ are the clauses in which x appears in $\widetilde{C}$ and $w_i=|c_i|-1$. We have $d\geq 1$ since (C,x) is a non-leaf node and $w_i\geq 1$ for all i because of property (1). Let b_3 denote the number of clauses such that $|c_i|=3$ and let b_2 denote the number of clauses such that $|c_i|=2$.

When processing the node (C, x), we will order the clauses in which x appears in $\widetilde{C}$ so that clauses with $|c_i| = 3$ are processed first. We thus have that $d, b_2, b_3 \in \mathbb{Z}$ and $\mathbf{w} = (w_1, \ldots, w_d) \in \mathbb{Z}^d$ satisfy

$$\begin{aligned} &1 \le d, \quad 0 \le b_2, b_3 \le d, \quad b_2 + b_3 \le d \\ &w_i = 2 \text{ for } i = 1, \ldots, b_3, \quad w_i \ge 3 \text{ or } w_i = 1 \text{ for } i = b_3 + 1, \ldots, d. \end{aligned} \tag{30}$$

As already described in Section 3, to prove Lemma 10, we will track a quantity $m(C, x, L)$ which is assigned to each node in the computation tree. Let $\eta := \eta(\Delta) = (1/2)^\Delta$. Define $m(C, x, L)$ by

$$m(C, x, L) := \delta^{b(C)}\, \Phi(R(C, x, L)) \tag{28}$$

where $\delta \in (0, 1]$, and $\Phi : [\eta, 1] \to \mathbb{R}$ satisfies:

$$\Phi \text{ is continuously differentiable on } [\eta, 1], \text{ and } \varphi := \Phi' \text{ satisfies } \varphi(z) > 0 \text{ for } z \in [\eta, 1]. \tag{29}$$

For $\Delta = 6$, the value of δ will be later chosen to be $\delta = 9789/10000$ and Φ will be specified in the upcoming equation (46). Also, note that for all nodes (C, x) in the computation tree the quantity $m(C, x, L)$ is well-defined; this is because of the property (1) and the lower bound $R(C, x, L) \ge \eta$ (follows from (4), see Remark 8 in the full version).

We will show Lemma 10 with $\alpha := 1 - 10^{-4}$. In particular, we aim to show that α upper bounds the decay rate of $|m(C, x, L) - m(C, x, \infty)|$, i.e., $|m(C, x, L) - m(C, x, \infty)|$ decays roughly as α^L (modulo a multiplicative constant). As in the proof of Lemma 11, this yields Lemma 10 when applied to the root formula of the tree (since it has no arity-2 clauses).

Ler $\mathbf{r}$ be a real vector with components $r_{i,j}$ for $i \in [d]$ and $j \in [w_i]$, $\mathbf{0} \le \mathbf{r} \le \mathbf{1}$. For $i \in [d]$, we will use the following analogue of the quantity $\rho^{\mathbf{w},i}_{\delta,\alpha}(\mathbf{r})$ defined in Section 4 (see (10)):

$$\rho^{\mathbf{w},i}_{\delta,\Phi,\alpha}(\mathbf{r}) := \alpha^{-l_{w_i}} \sum_{j=1}^{w_i} \left(\frac{1}{\delta}\right)^{(j-1)(\Delta-1)} \frac{1}{\varphi(r_{i,j})} \left|\frac{\partial F^{d,\mathbf{w}}}{\partial r_{i,j}}\right|, \tag{31}$$

where recall that the function $F^{d,\mathbf{w}}(\mathbf{r})$ gives the recursion (4) that $R(\cdot,\cdot,\cdot)$ satisfies (cf. (8)). Once again, the quantity $\rho^{\mathbf{w},i}_{\delta,\Phi,\alpha}(\mathbf{r})$ will roughly upper bound the sensitivity of $|m(C, x, L) - m(C, x, \infty)|$ to the quantities $|m(C_{i,j}, x_{i,j}, L) - m(C_{i,j}, x_{i,j}, \infty)|$ for $j \in [w_i]$. The decay rate of $|m(C, x, L) - m(C, x, \infty)|$ will be captured by the following quantity:

$$\kappa^{d,b_2,b_3,\mathbf{w}}_{\delta,\Phi,\alpha}(\mathbf{r}) := \varphi(F^{d,\mathbf{w}}(\mathbf{r}))\, \delta^{b_2} \left(\sum_{i=1}^{b_3} \left(\frac{1}{\delta}\right)^{b_3 - i} \rho^{\mathbf{w},i}_{\delta,\Phi,\alpha}(\mathbf{r}) + \sum_{i=b_3+1}^{d} \rho^{\mathbf{w},i}_{\delta,\Phi,\alpha}(\mathbf{r}) \right). \tag{32}$$

Finally, we specify the function Φ. For $z \in (0, 1]$, let

$$\Phi(z) := \frac{1}{\chi\psi} \log\left(\frac{z^\chi}{\psi - z^\chi}\right) \text{ with } \chi = 1/2,\ \psi = 13/10, \text{ so } \varphi(z) = \Phi'(z) = \frac{1}{z(\psi - z^\chi)}. \tag{46}$$

Our main technical lemma is the following (proved in Section 6 of the full version).

▶ **Lemma 14.** *Let $\Delta = 6$, $\chi = 1/2$, $\psi = 13/10$, $\delta = 9789/10000$, $\alpha = 1 - 10^{-4}$ and Φ be defined from (46). There exists a constant $U > 0$ such that, for all $d, b, \mathbf{w}$ satisfying (30), for all $(1/2)^{\Delta-1}\mathbf{1} \le \mathbf{r} \le \mathbf{1}$, it holds that $\kappa^{d,b_2,b_3,\mathbf{w}}_{\delta,\Phi,\alpha}(\mathbf{r})$ is at most 1 when $d \le \Delta - 1$ and at most U when $d = \Delta$.*

Lemma 10 can be derived from Lemma 14 using an argument analogous to the one used to derive Lemma 11 from Lemma 12, see Section 5 in the full version for the details.

The proof of Lemma 14 is significantly harder however than the proof of Lemma 12. For one thing, the analysis has to account for the (irrational) function φ (without which the step-wise contraction is simply not true) present in the expression for $\kappa^{d,b_2,b_3,\mathbf{w}}_{\delta,\Phi,\alpha}(\mathbf{r})$. Further, the two-step procedure that we followed in the proof of Lemma 12, that is, maximising first over $\mathbf{r}$ and then maximising over $\mathbf{w}$, is far too crude. Instead, we need to slowly reduce the number of the variables akin to the approach in [9]. In our case, however, to bound tightly the contribution of δ, we need to prove asymmetric inequalities in several variables with irrational expressions (see the key Lemmas 15, 19 and 20 in the full version). To keep the length of the paper reasonable and easier to read through, we rigorously verify certain two-variable inequalities using a computer; as the reader will notice, in some cases, even reducing to such two-variable inequalities requires a significant analytical effort (see the proofs of the aforementioned lemmas, for example).

6 Hardness Results

We prove the hardness results stated in the Introduction. We will work with the problem $\#\mathsf{HyperIndSet}(k,\Delta)$ (instead of the monotone CNF formulation). The proof is via a reduction to the independent set model on graphs which was used by Bordewich *et al.* [2]. The precise inapproximability results for the hard-core model had not yet been proved at the time [2] was written, so we carry out the details explicitly to obtain the bound that their reduction gives.

We use the inapproximability result of Sly and Sun [16] for the hard-core model. Recall, for a graph $G=(V,E)$, the partition function of G in the hard-core model with parameter $\lambda>0$ is given by $Z_G(\lambda):=\sum_I \lambda^{|I|}$ where the sum ranges over all independent sets I of G.

▶ **Theorem 27** ([16]). *For $\Delta\geq 3$, let $\lambda_c(\Delta):=(\Delta-1)^{\Delta-1}/(\Delta-2)^{\Delta}$. For all $\lambda>\lambda_c(\Delta)$, it is* NP*-hard to approximate $Z_G(\lambda)$ on Δ-regular graphs G, even within an exponential factor.*

▶ **Theorem 28.** *Let $k\geq 2$, $\Delta\geq 3$ be integers. Suppose that $2^{\lceil k/2\rceil}-1<\frac{(\Delta-2)^{\Delta}}{(\Delta-1)^{\Delta-1}}$. Then, it is* NP*-hard to approximate $\#\mathsf{HyperIndSet}(k,\Delta)$, even within an exponential factor.*

Proof (Sketch). Let $\lambda:=1/(2^{\lceil k/2\rceil}-1)$. Let G be a Δ-regular n-vertex graph. Construct a hypergraph H by replacing every vertex of G by a (distinct) set of $\lceil k/2\rceil$ vertices and place a hyperedge among the corresponding sets of vertices for each edge of G. Then $Z_H=(2^{\lceil k/2\rceil}-1)^n\,Z_G(\lambda)$, from which the theorem easily follows (see full version for details). ◀

▶ **Corollary 29.** *Let $k=6$, $\Delta=22$. It is* NP*-hard to approximate $\#\mathsf{HyperIndSet}(k,\Delta)$.*

▶ **Corollary 30.** *Let $k\geq 2$. For $\Delta\geq 5\cdot 2^{k/2}$, it is* NP*-hard to approximate $\#\mathsf{HyperIndSet}(k,\Delta)$.*

A Complexity Trichotomy for Approximately Counting List H-Colourings*†‡§

Abstract

We examine the computational complexity of approximately counting the list H-colourings of a graph. We discover a natural graph-theoretic trichotomy based on the structure of the graph H. If H is an irreflexive bipartite graph or a reflexive complete graph then counting list H-colourings is trivially in polynomial time. Otherwise, if H is an irreflexive bipartite permutation graph or a reflexive proper interval graph then approximately counting list H-colourings is equivalent to #BIS, the problem of approximately counting independent sets in a bipartite graph. This is a well-studied problem which is believed to be of intermediate complexity – it is believed that it does not have an FPRAS, but that it is not as difficult as approximating the most difficult counting problems in #P. For every other graph H, approximately counting list H-colourings is complete for #P with respect to approximation-preserving reductions (so there is no FPRAS unless NP = RP). Two pleasing features of the trichotomy are (i) it has a natural formulation in terms of hereditary graph classes, and (ii) the proof is largely self-contained and does not require any universal algebra (unlike similar dichotomies in the weighted case). We are able to extend the hardness results to the bounded-degree setting, showing that all hardness results apply to input graphs with maximum degree at most 6.

1 Overview

We study the complexity of approximately counting the list H-colourings of a graph. List H-colourings generalise H-colourings in the same way that list colourings generalise proper vertex colourings. Fix an undirected graph H, which may have loops but not parallel edges. Given a graph G, an *H-colouring of G* is a homomorphism from G to H – that is, a mapping $\sigma : V(G) \to V(H)$ such that, for all $u, v \in V(G)$, $\{u, v\} \in E(G)$ implies $\{\sigma(u), \sigma(v)\} \in E(H)$. If we identify the vertex set $V(H)$ with a set $Q = \{1, 2, \ldots, q\}$ of "colours", then we can

think of the mapping σ as specifying a colouring of the vertices G, and we can interpret the graph H as specifying the allowed colour adjacencies: adjacent vertices in G can be assigned colours i and j, if and only if vertices i and j are adjacent in H.

Now consider the graph G together with a collection of sets $\mathbf{S} = \{S_v \subseteq Q : v \in V(G)\}$ specifying allowed colours at each of the vertices. A *list H-colouring of* $(G, \mathbf{S})$ is an H-colouring σ of G satisfying $\sigma(v) \in S_v$, for all $v \in V$. In the literature, the set S_v is referred to as the "list" of allowed colours at vertex v, but there is no implied ordering on the elements of S_v – S_v is just a set of allowed colours.

Suppose that H is a *reflexive* graph (i.e., a graph in which each vertex has a loop). Feder and Hell [4] considered the complexity of determining whether a list H-colouring exists, given an input $(G, \mathbf{S})$. They showed that the problem is in FP if H is an interval graph, and that it is NP-complete, otherwise. Feder, Hell and Huang [5] studied the same problem in the case where H is *irreflexive* (i.e., H has no loops). They showed that the problem is in FP if H is a circular arc graph of clique covering number two (which is the same as being the complement of an interval bigraph [12]), and that it is NP-hard, otherwise. Finally, Feder, Hell and Huang [6] generalised this result to obtain a dichotomy for all H. They introduced a new class of graphs, called bi-arc graphs, and showed that the problem is in FP if H is a bi-arc graph, and NP-complete, otherwise.

We are concerned with the computational complexity of counting list H-colourings. Specifically we are interested in how the complexity of the following computational problem depends on H.

Name #List-H-Col.
Instance A graph G and a collection of colour sets $\mathbf{S} = \{S_v \subseteq Q : v \in V(G)\}$, where $Q = V(H)$.
Output The number of list H-colourings of $(G, \mathbf{S})$.

Note that it is of no importance whether we allow or disallow loops in G – a loop at vertex $v \in V(G)$ can be encoded within the set S_v – so we adopt the convention that G is loop-free. As in the case of the decision problem, H is a parameter of the problem – it does not form part of the problem instance. Sometimes we obtain sharper results by introducing an additional parameter Δ, which is an upper bound on the degrees of the vertices of G. Thus #List-H-Col(Δ) is the special case of #List-H-Col in which the graph G has degree at most Δ. Although #List-H-Col and #List-H-Col(Δ) are the main objects of study in this paper, we occasionally need to discuss the more basic versions of these problems without lists.

Name #H-Col.
Instance A graph G.
Output The number of H-colourings of G.

Once again, #H-Col(Δ) is the special case of #H-Col in which the degree of G is at most Δ. To illustrate the definitions, let K_2' be the first graph illustrated in Figure 1, consisting of two connected vertices with a loop on vertex 2. #K_2'-Col is the problem of counting independent sets in a graph since the vertices mapped to colour 1 by any homomorphism form an independent set. Let K_3 be the complete irreflexive graph on three vertices. Then #K_3-Col is the problem of counting the proper 3-colourings of a graph.

The computational complexity of computing exact solutions to #H-Col and #H-Col(Δ) was determined by Dyer and Greenhill [3]. Dyer and Greenhill showed that #H-Col is in FP if H is a complete reflexive graph or a complete bipartite irreflexive graph, and #H-Col

is #P-complete otherwise. Their dichotomy also extends to the bounded-degree setting. In particular, they showed that if H is not a complete reflexive graph or a complete bipartite irreflexive graph then there is an integer Δ_H such that, for all $\Delta \geq \Delta_H$, #H-Col(Δ) is #P-complete.

Since the polynomial-time cases in Dyer and Greenhill's dichotomy clearly remain solvable in polynomial-time in the presence of lists, their dichotomy for #H-Col carries over to #List-H-Col without change. In other words, there is no difference between the complexity of #H-Col and #List-H-Col as far as exact computation is concerned. However, this situation changes if we consider approximate counting, and this is the phenomenon that we explore in this paper.

With a view to reaching the statement of the main results as quickly as possible, we defer precise definitions of the relevant concepts to Section 2, and provide only indications here. From graph theory we import a couple of well studied hereditary graph classes, namely bipartite permutation graphs and proper interval graphs. These classes each have several equivalent characterisations, and we give two of these, namely, excluded subgraph and matrix characterisations, in Section 2. It is sometimes useful to restrict the definition of proper interval graphs to simple graphs. However, in this paper, as in [4], we consider reflexive proper interval graphs.

From complexity theory we need the definitions of a Fully Polynomial Randomised Approximation Scheme (FPRAS), of approximation-preserving (AP-) reducibility, and of the counting problems #SAT and #BIS. An FPRAS is a randomised algorithm that produces approximate solutions within specified relative error with high probability in polynomial time. An AP-reduction from problem Π to problem Π' is a randomised Turing reduction that yields close approximations to Π when provided with close approximations to Π'. It meshes with the definition of an FPRAS in the sense that the existence of an FPRAS for Π' implies the existence of an FPRAS for Π. The problem of counting satisfying assignments of a Boolean formula is denoted by #SAT. Every counting problem in #P is AP-reducible to #SAT, so #SAT is said to be complete for #P with respect to AP-reductions. It is known that there is no FPRAS for #SAT unless RP = NP. The problem of counting independent sets in a bipartite graph is denoted by #BIS. The problem #BIS appears to be of intermediate complexity: there is no known FPRAS for #BIS (and it is generally believed that none exists) but there is no known AP-reduction from #SAT to #BIS. Indeed, #BIS is complete with respect to AP-reductions for a complexity class #RHII$_1$ which is discussed further in the full version.

We say that a problem Π is #SAT-hard if there is an AP-reduction from #SAT to Π, that it is #SAT-easy if there is an AP-reduction from Π to #SAT, and that it is #SAT-equivalent if both are true. Note that all of these labels are about the difficulty of *approximately* solving Π, not about the difficulty of exactly solving it. Similarly, Π is said to be #BIS-hard if there is an AP-reduction from #BIS to Π, #BIS-easy if there is an AP-reduction from Π to #BIS, and #BIS-equivalent if there are both.

Our main result is a trichotomy for the complexity of approximating #List-H-Col.

▶ **Theorem 1.** *Suppose that H is a connected undirected graph (possibly with loops).*

(i) *If H is an irreflexive complete bipartite graph or a reflexive complete graph then* #List-H-Col *is in* FP*.*

(ii) *Otherwise, if H is an irreflexive bipartite permutation graph or a reflexive proper interval graph then* #List-H-Col *is* #BIS*-equivalent.*

(iii) *Otherwise,* #List-H-Col *is* #SAT*-equivalent.*

▶ Remarks. **1.** The assumption that H is connected is made without loss of generality,

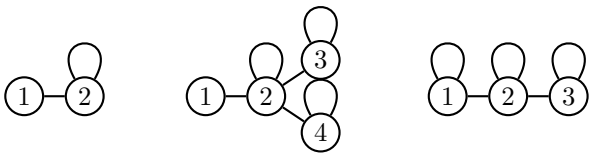

Figure 1 K_2', 2-wrench and P_3^*.

since the complexity of #List-H-Col is determined by the maximum complexity of #List-H'-Col over all connected components H' of H.

2. Part (ii) of Theorem 2 can be strengthened. For the graphs H covered by this part of the theorem, #List-H-Col is actually complete for the complexity class $\#\mathrm{RH}\Pi_1$. See the full version for a definition of $\#\mathrm{RH}\Pi_1$ and a proof of membership of #List-H-Col in $\#\mathrm{RH}\Pi_1$.

Theorem 1 also extends to the bounded-degree case.

▶ **Theorem 2.** *Suppose that H is a connected undirected graph (possibly with loops).*

(i) *If H is an irreflexive complete bipartite graph or a reflexive complete graph then, for all Δ, #List-H-Col(Δ) is in* FP.

(ii) *Otherwise, if H is an irreflexive bipartite permutation graph or a reflexive proper interval graph then, for all $\Delta \geq 6$, #List-H-Col(Δ) is* #BIS*-equivalent.*

(iii) *Otherwise, for all $\Delta \geq 6$, #List-H-Col(Δ) is* #SAT*-equivalent. Further, if H is reflexive or irreflexive, #List-H-Col(Δ) is* #SAT*-equivalent for $\Delta \geq 3$.*

▶ Remarks.

1. The condition $\Delta \geq 6$ is necessary for any hardness result that holds for all graphs H. In particular, there is a graph H that is not an irreflexive complete bipartite graph or a reflexive complete graph but for which #List-H-Col(Δ) has an FPTAS. An example is the graph $H = K_2'$ for which Weitz's self-avoiding walk algorithm [22] gives an FPTAS for #List-H-Col(Δ) for $\Delta \leq 5$.
2. In general, the lowest value of the degree bound Δ such that #List-H-Col(Δ) is computationally hard depends on the particular graph H.

Proof of Theorems 1 and 2. Part (i) is trivial. Part (ii) follows from Lemmas 13 and 14. Part (iii) follows from Lemmas 7, 9, and 11. ◀

The most obvious issue raised by our theorems is the computational complexity of approximately counting H-colourings (in the absence of lists). This question was extensively studied by Kelk [14] and others, and appears much harder to resolve, even when there are no degree bounds. It is known [7] that #H-Col is #BIS-hard for every connected undirected graph H that is neither an irreflexive bipartite permutation graph nor a reflexive proper interval graph. It is not known for which connected H the problem is #BIS-easy and for which it is #SAT-equivalent, and whether one or the other always holds. In fact, there are specific graphs H, two of them with as few as four vertices, for which the complexity of #H-Col is unresolved. It is far from clear that a trichotomy should be expected, and in fact there may exist an infinite sequences (H_t) of graphs for which #H_t-Col is reducible to #H_{t+1}-Col but not vice versa. Some partial results and speculations can be found in [14].

As we noted, #H-Col and #List-H-Col have the same complexity as regards exact computation. However, for approximate computation they are different, assuming (as is widely believed) that there is no AP-reduction from #SAT to #BIS. An example is provided

by the 2-wrench (see Figure 1). It is known [2, Theorem 21] that #2-WRENCH-COL is #BIS-equivalent, but we know from Theorem 1 that the list version #LIST-2-WRENCH-COL is #SAT-equivalent since the 2-wrench is neither irreflexive nor reflexive. One way to see that #LIST-2-WRENCH-COL is #SAT-equivalent is to note that the 2-wrench contains K_2' as an induced subgraph, and that this induced subgraph can be "extracted" using the list constraints $S_v = \{1, 2\}$, for all $v \in V(G)$. But #LIST-K_2'-COL is already known to be #SAT-equivalent [2, Theorem 1]. Indeed, systematic techniques for extracting hard induced subgraphs form the main theme of the paper. It is for this reason that the theory of hereditary graph classes comes into play, just as in [6].

Another recent research direction, at least in the unbounded-degree case, is towards weighted versions of list colouring. Here, the graph H is augmented by edge-weights, specifying for each pair of colours i, j, the cost of assigning i and j to adjacent vertices in G. The computational complexity of obtaining approximate solutions was studied by Chen, Dyer, Goldberg, Jerrum, Lu, McQuillan and Richerby [1], and by Goldberg and Jerrum [11]. There is a trichotomy for the case in which the input has no degree bound, but this is obtained in a context where *individual* spins at vertices are weighted and not just the interactions between *pairs* of adjacent spins. In this paper we have restricted the class of problems under consideration to ones having 0,1-weights on interactions, but at the same time we have restricted the problem instances to ones having 0,1-weights on individual spins. So we have a different tradeoff and the results from the references that we have just discussed do not carry across, even in the unbounded-degree setting. Indeed, towards the end of the paper, in Section 5, we give an example to show that Theorem 1 is not simply the restriction of earlier results to 0,1-interactions (not merely because the proofs differ, but, in a stronger sense, because the results themselves are different).

Two things are appealing about our theorems. First, unlike the weighted classification theorems [1], here the truth is pleasingly simple. The trichotomies for #LIST-H-COL and #LIST-H-COL(Δ) have a simple, natural formulation in terms of hereditary graph classes. Second, the proofs of the theorems are largely self-contained. The proofs do not rely on earlier works such as [1], which require multimorphisms and other deep results from universal algebra. The proof of Theorem 1 is self-contained apart from some very elementary and well-known starting points, which are collected together in Lemma 6. The proof of Theorem 2 is similarly self-contained, though it additionally relies on recent results [18, 8] about approximating the partition function of the anti-ferromagnetic Ising model on bounded degree graphs (these are also contained in Lemma 6).

2 Complexity- and graph-theoretic preliminaries

As the complexity of computing exact solutions of #LIST-H-COL is well understood, we focus on the complexity of computing approximations. The framework for this has already been explained in many papers, so we provide an informal description only here and direct the reader to Dyer, Goldberg, Greenhill and Jerrum [2] for precise definitions.

The standard notion of efficient approximation algorithm is that of a *Fully Polynomial Randomised Approximation Scheme* (or FPRAS). This is a randomised algorithm that is required to produce a solution within relative error specified by a tolerance $\varepsilon > 0$, in time polynomial in the instance size and ε^{-1}. Evidence for the non-existence of an FPRAS for a problem Π can be obtained through *Approximation-Preserving* (or AP-) *reductions*. These are randomised polynomial-time Turing reductions that preserve (closely enough) the error tolerance. The set of problems that have an FPRAS is closed under AP-reducibility.

Every problem in #P is AP-reducible to #SAT, so #SAT is complete for #P with respect to AP-reductions. The same is true of the counting version of any NP-complete decision problem. It is known that these problems do not have an FPRAS unless RP = NP. On the other hand, using the bisection technique of Valiant and Vazirani [20, Corollary 3.6], we know that #SAT can be approximated (in the FPRAS sense) by a polynomial-time probabilistic Turing machine equipped with an oracle for the decision problem SAT.

In the statement and proofs of our theorems we refer to two hereditary graph classes. A class of undirected graphs is said to be *hereditary* if it is closed under taking induced subgraphs. The classes of bipartite permutation graphs and proper interval graphs have been widely studied and many equivalent characterisations of them are known. We are concerned with the excluded subgraph and matrix characterisations.

A graph is a *bipartite permutation graph* if and only if it contains none of the following as an induced subgraph: X_3, X_2, T_2 or a cycle C_ℓ of length ℓ not equal to four. (Refer to Figure 2 for specifications of X_3, X_2 and T_2.) This characterisation was noted by Köhler [15], who observed that it follows from an excluded subgraph characterisation of Gallai [9, 10]. The argument is given by Hell and Huang [12], in the proof of their Theorem 3.4, in particular parts (iv) and (vi).

A graph is a *proper interval graph* if and only if it contains none of the following as an induced subgraph: the claw, the net, S_3 or a cycle C_ℓ of length ℓ at least four. (Refer to Figure 3 for specifications of the claw, the net and S_3.) This characterisation is due to Wegner [21] and Roberts [17], and is stated is by Jackowski [13] as his Theorem 1.4, specifically the equivalence of (i) and (iii). In this context, note that a *chordal* graph is one that contains no induced cycles of length other than three.

The two graph classes also have matrix characterisations. Say that a 0,1-matrix $A = (A_{i,j} : 1 \leq i \leq n, 1 \leq j \leq m)$ has *staircase form* if the 1s in each row are contiguous and the following condition is satisfied: letting $\alpha_i = \min\{j : A_{i,j} = 1\}$ and $\beta_i = \max\{j : A_{i,j} = 1\}$, we require that the sequences (α_i) and (β_i) are non-decreasing. It is automatic that the columns share the contiguity and monotonicity properties, so the property of having staircase form is in fact invariant under matrix transposition.

A graph is a bipartite permutation graph if the rows and columns of its biadjacency matrix can be (independently) permuted so that the resulting biadjacency matrix has staircase form. This characterisation is presented by Spinrad, Brandstädt and Stewart [19], specifically the equivalence of (i) and (ii) in their Theorem 1.

A graph is a proper interval graph if the rows and columns of its adjacency matrix can be (simultaneously) permuted so that the resulting adjacency matrix has staircase form. This fact comes directly from the characterisation of proper interval graphs that gives the class its name, namely, that they are graphs which have an interval intersection model in which no interval is a proper subset of another. The ordering of intervals by left endpoint (which is the same as the ordering by right endpoint) gives the required permutation of rows and columns.

As we mentioned in Section 1, an appealing feature of our theorems is that our proofs are largely self-contained. The only pre-requisites for the proof are complexity results classifying some very well-known approximation problems. These are collected in Lemma 6, which is proved in the full version. For this, we will use the graph K_2' defined in Section 1 (see Figure 1), the path P_4 of length three (with four vertices) and the problem #1P1NSAT of counting the satisfying assignments of a CNF formula in which each clause has at most one negated literal and at most one unnegated literal. We will also use the following definition.

▶ **Definition 4.** Let $0 < \lambda < 1$ be a rational number and let Δ be a positive integer. Define
Name AntiFerroIsing$_\lambda(\Delta)$.
Instance *A graph G of maximum degree at most Δ.*
Output *The partition function of the antiferromagnetic Ising model with parameter λ evaluated on instance G, i.e., $Z_\lambda(G) = \sum_{\sigma:V\to\{\pm1\}} \prod_{\{u,v\}\in E(G)} \lambda^{\delta(\sigma(u),\sigma(v))}$, where $\delta(i,j)$ is 1 if $i = j$ and 0 otherwise.*

▶ **Lemma 6.** *The following problems are* #SAT*-equivalent: #K_2'-Col(Δ) for any $\Delta \geq 6$, and* AntiFerroIsing$_\lambda(\Delta)$ *for any $\Delta \geq 3$ and $0 < \lambda < (\Delta-2)/\Delta$. The following problems are* #BIS*-equivalent: #P_4-Col(Δ) for $\Delta \geq 6$ and* #1p1nSat.

3 #SAT-equivalence

The aim of this section is to establish the #SAT-equivalence parts of Theorems 1 and 2.

▶ **Lemma 7.** *Suppose that H is a connected undirected graph. If H is neither reflexive nor irreflexive then, for all $\Delta \geq 6$,* #List-H-Col(Δ) *is* #SAT*-equivalent. Hence,* #List-H-Col *is* #SAT*-equivalent.*

Proof. Let $\Delta \geq 6$. Since H is connected, it must contain K_2' as an induced subgraph. So #K_2'-Col(Δ) is AP-reducible to #List-H-Col(Δ). By Lemma 6, #K_2'-Col(Δ) is #SAT-equivalent. ◀

The gadgets that we use in our reductions in the upcoming lemmas are of a particularly simple kind, namely paths.[1] Let the vertex set of the L-vertex path be $\{1, 2, \ldots, L\}$, where the vertices are numbered according to their position on the path. The end vertices 1 and L are *terminals*, which make connections with the rest of the construction. For each vertex $1 \leq k \leq L$ there is a set of allowed colours S_k. We can describe a gadget by specifying L and specifying the sets $(S_1, S_2, \ldots, S_L)$. In our application, each set S_i has cardinality 2, and $S_1 = S_L$.

Fix a connected graph H (note that H may have loops). Our strategy for proving that #List-H-Col(Δ) is #SAT-equivalent is to find a gadget $(\{i_1, j_1\}, \{i_2, j_2\}, \ldots, \{i_L, j_L\})$ such that

(i) the sequence $(i_1, \ldots, i_L)$ is a path in H, and likewise $(j_1, \ldots, j_L)$;
(ii) it is never the case that both $\{i_k, j_{k+1}\} \in E(H)$ and $\{j_k, i_{k+1}\} \in E(H)$; and
(iii) $i_1 = j_L$ and $j_1 = i_L$.

If we achieve these conditions then, as we shall see, the colours at the terminals will be negatively correlated, and from there we will be able to encode instances of AntiFerroIsing$_\lambda(\Delta)$ for some integer $\Delta \geq 3$ and $\lambda \in (0, \frac{\Delta-2}{\Delta})$, and this is #SAT-equivalent (Lemma 6). Note that although the ordering of elements within the sets S_i is irrelevant to the workings of the gadget, we write the pairs in a specific order to bring out the path structure that we have just described.

Fix H and let $A = A_H$ be the adjacency matrix of H. Denote by $A_{(i,j),(i',j')}$ the 2×2 submatrix of A indexed by rows i and j and columns i' and j'. We regard the indices in the notation $A_{(i,j),(i',j')}$ as ordered; thus the first row of this 2×2 matrix comes from row i of A and the second from row j.

[1] We were also able to make use of path gadgets in [11], though, as noted (see Section 1) the results unfortunately do not carry over to our setting. Here the use of structural graph theory makes the discovery of such gadgets pleasingly straightforward.

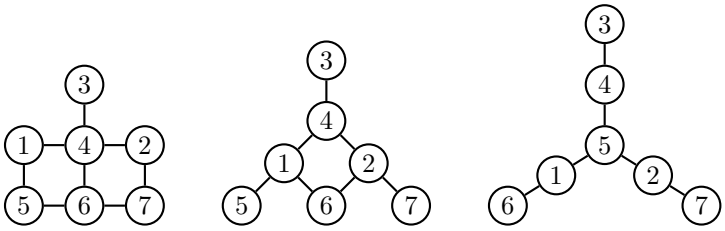

Figure 2 X_3, X_2 and T_2.

Given a gadget, i.e., sequence $(\{i_1, j_1\}, \{i_2, j_2\}, \ldots, \{i_L, j_L\})$, consider the product of 2×2 submatrices of A:

$$D' = A_{(i_1,j_1),(i_2,j_2)} A_{(i_2,j_2),(i_3,j_3)} \cdots A_{(i_{L-1},j_{L-1}),(i_L,j_L)}. \tag{1}$$

If conditions (i)–(iii) for gadget construction are satisfied then each of the 2×2 matrices in the product has 1s on the diagonal; also, all of them have at least one off-diagonal entry that is 0. Thus, each matrix has determinant 1, from which it follows that $\det D' = 1$.

Now consider the matrix D that is obtained by swapping the two columns of D'. This swap rectifies the "twist" that occurs in the passage from (i_1, j_1) to $(i_L, j_L) = (j_1, i_1)$, but it also flips the sign of the determinant, leaving $\det D = -1$. Let $r = i_1 = j_L$ and $s = j_1 = i_L$. The matrix D can be interpreted as giving the number of list H-colourings of the gadget when the k'th vertex of the gadget (for $k \in \{1, \ldots, L\}$ is assigned the list $\{i_k, j_k\}$, so the terminals are restricted to colours in $\{r, s\}$. Thus the entry in the first row and column of D is the number of colourings with both terminals receiving colour r, the entry in the first row and second column is the number of colourings with terminal 1 receiving colour r and terminal L receiving colour s, the entry in the second row and first column is the number of colourings with terminal 1 receiving colour s and terminal L receiving colour r and finally the entry in the second row and second column is the number of colourings with both terminals receiving colour s. We call $D = D(\Gamma)$ the *interaction matrix* associated with the gadget Γ. Since $\det D < 0$ the gadget provides a negative correlation between the colours at the terminals, which, as we will see, will allow a reduction from $\text{AntiFerroIsing}_\lambda(\Delta)$.

In the full version, Lemma 8 first applies the technique to get the #SAT-equivalences in the unbounded-degree case. For these arguments, we intentionally keep the construction of the gadgets as simple as possible. While this would also lead to a value of Δ such that #List-H-Col(Δ) is #SAT-equivalent, the value of Δ would be much larger than 6. Nevertheless, we are able to refine the constructions to obtain the bounded-degree results of Theorem 2. Lemma 9 here combines Lemmas 8 and 9 of the full version and illustrates the key ideas.

▶ **Lemma 9.** *Suppose that H is a connected undirected graph. If H is irreflexive but it is not a bipartite permutation graph, then for all $\Delta \geq 3$, #List-H-Col(Δ) is #SAT-equivalent (so #List-H-Col is also #SAT-equivalent).*

Proof (One Case). Graphs that are not bipartite permutation graphs contain one of the following as an induced subgraph: X_3, X_2, T_2, or a cycle of length other than 4. (Refer to Figure 2.) Here we present the case X_3. The remaining cases are similar and can be found in the full version.

We first show that the unbounded problem #List-X_3-Col is #SAT-equivalent. The gadget in this case is $\Gamma = \big(\{1, 2\}, \{4, 7\}, \{3, 6\}, \{4, 5\}, \{2, 1\}\big)$. The conditions (i)–(iii) for

gadget construction are easy to check. Explicit calculation using (1) yields

$$D' = A_{(1,2),(4,7)}A_{(4,7),(3,6)}A_{(3,6),(4,5)}A_{(4,5),(2,1)} = \left(\begin{smallmatrix}1&0\\1&1\end{smallmatrix}\right)\left(\begin{smallmatrix}1&1\\0&1\end{smallmatrix}\right)\left(\begin{smallmatrix}1&0\\1&1\end{smallmatrix}\right)\left(\begin{smallmatrix}1&1\\0&1\end{smallmatrix}\right) = \left(\begin{smallmatrix}2&3\\3&5\end{smallmatrix}\right).$$

Swapping the columns of D' yields the interaction matrix $D = \left(\begin{smallmatrix}3&2\\5&3\end{smallmatrix}\right)$. As we explained earlier, $\det D = -1$. Obtaining a matrix D with negative determinant is moving in the right direction, but in order to encode antiferromagnetic Ising we ideally want the matrix $D = (D_{i,j})$ to also satisfy $D_{1,1} = D_{2,2}$ and $D_{1,2} = D_{2,1}$. Observe that the graph X_3 has an automorphism of order two, $\pi = (1,2)(5,7)$, that transposes vertices 1 and 2, which are the terminals of the gadget Γ. Consider the gadget obtained from Γ by letting π act on the colour sets, namely

$$\begin{aligned}\Gamma^\pi &= \big(\{\pi(1),\pi(2)\},\{\pi(4),\pi(7)\},\{\pi(3),\pi(6)\},\{\pi(4),\pi(5)\},\{\pi(2),\pi(1)\}\big)\\ &= \big(\{2,1\},\{4,5\},\{3,6\},\{4,7\},\{1,2\}\big),\end{aligned}$$

The interaction matrix $D^\pi = \left(\begin{smallmatrix}3&5\\2&3\end{smallmatrix}\right)$ corresponding to Γ^π is the same as D, except that the rows and columns are swapped. Placing Γ and Γ^π in parallel, identifying the terminals, yields a composite gadget Γ^* whose interaction matrix is $D^* = \left(\begin{smallmatrix}D_{1,1}D_{2,2} & D_{1,2}D_{2,1}\\ D_{2,1}D_{1,2} & D_{2,2}D_{1,1}\end{smallmatrix}\right) = \left(\begin{smallmatrix}9&10\\10&9\end{smallmatrix}\right)$. Note that the gadget Γ^* has maximum degree 2 (this observation will be important for the bounded-degree case). Also, $\det D^* = D_{1,1}^2D_{2,2}^2 - D_{1,2}^2D_{2,1}^2 = (D_{1,1}D_{2,2}+D_{1,2}D_{2,1})\det D < 0$. So we have an AP-reduction from AntiFerroIsing$_\lambda$ with $\lambda = D_{1,1}D_{2,2}/(D_{1,2}D_{2,1})$ to #List-H-Col: given an instance G of AntiFerroIsing$_\lambda$, simply replace each edge $\{u,v\}$ of G with a copy of the gadget Γ^*, identifying the two terminals of Γ^* with the vertices u and v, respectively. (Since Γ^* is symmetric, it does not matter which is u and which is v.) The problem AntiFerroIsing$_\lambda$ is #SAT-equivalent by Lemma 6. So for this case ($H = X_3$), we have $\lambda = \frac{9}{10}$.

We next show that, for $\Delta \geq 3$, #List-X_3-Col(Δ) is #SAT-equivalent. The smallest Δ such that AntiFerroIsing$_{\frac{9}{10}}(\Delta)$ is #SAT-equivalent is $\Delta = 21$, so the argument above would only give that #List-X_3-Col(Δ) is #SAT-equivalent for $\Delta \geq 21$ (in fact, $\Delta \geq 2\cdot 21 = 42$, since the terminals of Γ^* have degree 2). To improve this, we will implement thickenings of the gadget Γ^* using carefully chosen list colourings to keep the degree of the gadget small. More precisely, for integer $t \geq 0$, we will construct inductively gadgets Γ_t^* such that:

- **(i)** The allowed colours of the terminals of Γ_t^* will be $\{1,2\}$ for odd t and $\{5,7\}$ for even t.
- **(ii)** The two terminals of Γ_t^* will each have degree 1, and all other vertices of Γ_t^* will have degree at most 3.
- **(iii)** The interaction matrix of Γ_t^* will be $D_t^* = \left(\begin{smallmatrix}9^{2^t} & 10^{2^t}\\ 10^{2^t} & 9^{2^t}\end{smallmatrix}\right)$.

By taking t sufficiently large, the reduction above, using Γ_t^* as gadget instead of Γ^*, yields that #List-X_3-Col(Δ) is #SAT-equivalent for $\Delta \geq 3$. It remains to build the gadgets Γ_t^*.

Γ_0^* is obtained from Γ^* by connecting each terminal of Γ^* to a new vertex whose allowed set of colours is $\{5,7\}$ (recall that the allowed colours of the terminals of Γ^* are in $\{1,2\}$). The terminals of Γ_0^* are the two new vertices. Γ_0^* clearly satisfies properties (i) and (ii) for $t = 0$. To find the interaction matrix of Γ_0^*, note that colour 1 is adjacent to colour 5 in X_3 but not to colour 7. Similarly, colour 2 is adjacent to colour 7 in X_3 but not to colour 5. Thus, $D(\Gamma_0^*) = \left(\begin{smallmatrix}1&0\\0&1\end{smallmatrix}\right)\left(\begin{smallmatrix}9&10\\10&9\end{smallmatrix}\right)\left(\begin{smallmatrix}1&0\\0&1\end{smallmatrix}\right) = D_0^*$, proving that Γ_0^* satisfies all properties (i)–(iii), as desired.

To construct Γ_{t+1}^* from Γ_t^*, take two copies of Γ_t^*, place them in parallel, identifying their terminals in the natural way. Now, analogously to the construction of Γ_0^*, connect each (doubled-up) terminal of Γ_t^* to a new vertex whose allowed set of colours is $\{1,2\}$ if t is even and $\{5,7\}$ if t is odd. The final graph is the gadget Γ_{t+1}^* and the new vertices

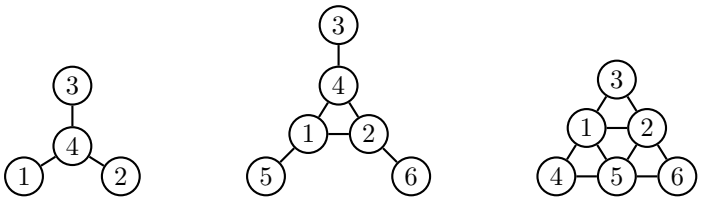

Figure 3 The claw, the net and S_3.

introduced in the second step of the construction are its terminals. It is clear that Γ^*_{t+1} satisfies property (i) and, using the fact that Γ^*_t satisfies property (ii), we have that Γ^*_{t+1} satisfies property (ii) as well. Arguing analogously as for Γ^*_0, the interaction matrix of Γ^*_{t+1} is given by $D(\Gamma^*_{t+1}) = \left(\begin{smallmatrix}1&0\\0&1\end{smallmatrix}\right)\begin{pmatrix}(9^{2^t})^2 & (10^{2^t})^2\\ (10^{2^t})^2 & (9^{2^t})^2\end{pmatrix}\left(\begin{smallmatrix}1&0\\0&1\end{smallmatrix}\right) = D^*_{t+1}$, where the squared entries account for the 2-thickening of the gadget Γ^*_t. This proves that Γ^*_{t+1} has property (iii), concluding the proof for $H = X_3$. The other cases are similar, and are given in the full version (where more of the general principles are explained). ◀

The remaining cases of parts (iii) of Theorems 1 and 2 are covered by Lemmas 10 and 11 of the full version, which we combine here.

▶ **Lemma 11.** *Suppose that H is a connected undirected graph. If H is a reflexive graph that is not a proper interval graph, then, for $\Delta \geq 3$, #List-H-Col(Δ) is #SAT-equivalent (so #List-H-Col is #SAT-equivalent).*

Proof Sketch. The line of argument is similar to those used in Lemma 9. Graphs that are not proper interval graphs contain one of the following as an induced subgraph: the claw, the net, S_3, or a cycle of length at least four. (Refer to Figure 3 but note that loops are omitted.) We show that #List-H-Col is #SAT-equivalent when H is any of these (and the bounded-degree analogue). The details can be found in the full version. ◀

4 #BIS-equivalence

We now deal with the #BIS-equivalent cases in Theorems 1 and 2.

▶ **Lemma 13.** *Suppose that H is a connected undirected graph. If H is not a reflexive complete graph or an irreflexive complete bipartite graph then, for all $\Delta \geq 6$, #List-H-Col(Δ) is #BIS-hard. Hence, #List-H-Col is #BIS-hard.*

Proof Sketch. In the full version, we show that any graph covered by the lemma contains one of the following as an induced subgraph: K'_2, P^*_3, P_4 or an odd cycle. These are (at least) #BIS-hard: by Lemma 6 for K'_2 and P_4, by Lemma 12 of the full version for P^*_3, and by Lemma 9 for an odd cycle. ◀

▶ **Lemma 14.** *Suppose that H is a connected undirected graph. If H is an irreflexive bipartite permutation graph or a reflexive proper interval graph, then #List-H-Col is #BIS-easy.*

Proof Sketch. The reduction is done in a more general weighted setting by Chen, Dyer, Goldberg, Jerrum, Lu, McQuillan and Richerby [1]: see the proofs of Lemmas 45 and 46 of that article. However, in the current context, we can simplify the reduction significantly (eliminating the need for multimorphisms and other concepts from universal algebra), and we can also extract (see the full paper) the slightly stronger statement that #List-H-Col

is in #RHΠ$_1$. The target problem for our reduction is #1P1NSAT which is #BIS-equivalent by Lemma 6.

We will treat the case where H is an irreflexive bipartite permutation graph. The other case is similar (as explained in the full version). Without loss of generality, suppose that H is connected and that its biadjacency matrix B has q_1 rows and q_2 columns and is in staircase form. Let A be the adjacency matrix $\left(\begin{smallmatrix} B & 0 \\ 0 & B^T \end{smallmatrix}\right)$, which is formally defined as follows.

$$A_{i,j} = \begin{cases} B_{i,j}, & \text{if } 1 \le i \le q_1,\ 1 \le j \le q_2 \\ B_{j-q_2,i-q_1}, & \text{if } q_1+1 \le i \le q_1+q_2,\ q_2+1 \le j \le q_2+q_1 \\ 0, & \text{otherwise.} \end{cases}$$

Let $q = q_1 + q_2$. For each $i \in \{1,\dots,q\}$, let $\alpha_i = \min\{j : A_{i,j} = 1\}$ and let $\beta_i = \max\{j : A_{i,j} = 1\}$. Since B is in staircase form, so is A, so the sequences (α_i) and (β_i) are non-decreasing. Let $r_1,\dots,r_q$ be the colours associated with the rows of A and $c_1,\dots,c_q$ be the colours associated with the columns of A, in order. Note that $\{r_1,\dots,r_q\}$ and $\{c_1,\dots,c_q\}$ are different permutations of the vertices of H,

Suppose that $(G,\mathbf{S})$ is an instance of #LIST-H-COL. Assume without loss of generality that G is bipartite. Otherwise, it has no H-colourings. Let $V_1(G) \cup V_2(G)$ be the bipartition of $V(G)$. We will construct an instance Ψ of #1P1NSAT such that the number of satisfying assignments to Ψ is equal to the number of list H-colourings of $(G,\mathbf{S})$.

The variable set of Ψ is $\mathbf{x} = \{x_i^u : u \in V(G) \text{ and } 0 \le i \le q\}$. For each vertex $u \in V(G)$ we introduce the clauses (x_0^u) and $(\neg x_q^u)$. Also, for each $j \in \{1,\dots,q\}$ we introduce the clause $\mathrm{IMP}(x_j^u, x_{j-1}^u)$. Denote by $\Psi_V(\mathbf{x})$ the formula obtained by taking the conjunction of all these clauses.

We will interpret the assignment to the variables in $\mathbf{x}$ as an assignment σ of colours to the vertices of G according to the following rule. If $u \in V_1(G)$ then $x_i^u = 1$ if and only if $\sigma(u) = r_j$ for some $j > i$. If $u \in V_2(G)$ then $x_i^u = 1$ if and only if $\sigma(u) = c_j$ for some $j > i$. Note that there is a one-to-one correspondence between assignments to $\mathbf{x}$ that satisfy the clauses in $\Psi_V(\mathbf{x})$ and assignments σ of colours to the vertices of G.

We now introduce further clauses to enforce the constraint on colours received by adjacent vertices. For each edge $\{u,v\} \in E(G)$ with $u \in V_1(G)$ and $v \in V_2(G)$, and for each $i \in \{1,\dots,q\}$, we add the clauses $\mathrm{IMP}(x_{i-1}^u, x_{\alpha_i-1}^v)$ and $\mathrm{IMP}(x_{\beta_i}^v, x_i^u)$. Denote by $\Psi_E(\mathbf{x})$ the formula obtained by taking the conjunction of all of these clauses.

We next argue that there is a bijection between H-colourings of G and satisfying assignments to $\Psi_V(\mathbf{x}) \wedge \Psi_E(\mathbf{x})$. In one direction, suppose σ is an H-colouring of G. We wish to show that all clauses in $\Psi_E(\mathbf{x})$ are satisfied. Consider an edge $\{u,v\} \in E(G)$ with $u \in V_1(G)$ and $v \in V_2(G)$ and the corresponding clause $\mathrm{IMP}(x_{i-1}^u, x_{\alpha_i-1}^v)$. The clause is satisfied unless $x_{i-1}^u = 1$, so suppose $x_{i-1}^u = 1$. Then by the interpretation of assignments, $\sigma(u) = r_j$ for some $j \ge i$. Since σ is an H-colouring, this implies that $\sigma(v) = c_k$ for some $k \ge \alpha_i$. But by the interpretation of assignments, this means that $x_{\alpha_i-1}^v = 1$, so the clause is satisfied. The argument for the other clause $\mathrm{IMP}(x_{\beta_i}^v, x_i^u)$ coresponding to the edge $\{u,v\}$ is similar – see the full version.

In the other direction, suppose $\Psi_V(\mathbf{x}) \wedge \Psi_E(\mathbf{x})$ is satisfied. Consider an edge $\{u,v\} \in E(G)$ with $u \in V_1(G)$ and $v \in V_2(G)$ and suppose that $\sigma(u) = r_i$. In the corresponding assignment $x_{i-1}^u = 1$ so by the clause $\mathrm{IMP}(x_{i-1}^u, x_{\alpha_i-1}^v)$ we have $x_{\alpha_i-1}^v = 1$ so $\sigma(v) = c_k$ for some $k \ge \alpha_i$. In the corresponding assignment $x_i^u = 0$ so by the clause $\mathrm{IMP}(x_{\beta_i}^v, x_i^u)$, $x_{\beta_i}^v = 0$, so $\sigma(v) = c_k$ for some $k \le \beta_i$. We conclude that the colours $\sigma(u)$ and $\sigma(v)$ are adjacent in H. This holds for every edge, so σ is an H-colouring of G.

Finally, we add clauses to deal with lists. A colour assignment $\sigma(u) = r_i$ with $u \in V_1(G)$ is uniquely characterised by $x^u_{i-1} = 1$ and $x^u_i = 0$. So we can eliminate the possibility of $\sigma(u) = r_i$ by introducing the clause $\mathrm{IMP}(x^u_{i-1}, x^u_i)$. A similar clause will forbid a vertex $v \in V_2(G)$ to receive colour c_j. Let $\Psi_L(\mathbf{x})$ be the conjunction of all such clauses, arising from the lists in $\mathbf{S}$. Let $\Psi(\mathbf{x}) = \Psi_V(\mathbf{x}) \wedge \Psi_E(\mathbf{x}) \wedge \Psi_L(\mathbf{x})$. Then the list H-colourings of $(G, \mathbf{S})$ are in bijection with the satisfying assignments to $\Psi(\mathbf{x})$, as required ◀

5 A counterexample

The situation that we have studied in this paper is characterised by having hard interactions between pairs of adjacent spins (a pair is either allowed or it is disallowed) and hard constraints on individual spins (again, a spin is either allowed at a particular vertex or it is disallowed). Our results apply both in the degree-bounded case and in the unbounded-degree case. In the unbounded case, earlier work treated the situation with weighted interactions and weighted spins. The characterisations derived in these weighted scenarios (see, e.g. [11, Thm 1]) have a similar feel to the trichotomy that we have presented in Theorem 1. We may wonder whether, in the unbounded case, at least, there is a common generalisation. That is, in the unbounded case, does the trichotomy of [11] survive if weights on spins are replaced by lists? The answer is no. There are examples of weighted spin systems with just $q = 2$ spins whose partition function is #SAT-hard to approximate with vertex weights but efficiently approximable (in the sense that there is an FPRAS) with lists instead of weights.

Here is one such example. Following Li, Lu and Yin [16], define the interaction matrix $A = (a_{ij} : 0 \le i, j \le 1)$ by $A = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, and the partition function associated with an instance G by $Z_A(G) = \sum_{\sigma : V(G) \to \{0,1\}} \prod_{\{u,v\} \in E(G)} a_{\sigma(u),\sigma(v)}$. This is the partition function of a variant of the independent set model, which instead of defining the interaction between spin 1 and itself (two vertices that are out of the independent set) to be 1, defines this interaction weight to be 2.

Li, Lu and Yin [16, Theorem 21] show that Weitz's self-avoiding walk algorithm [22] gives an FPTAS for $Z_A(G)$. Also, Weitz's correlation decay algorithm [22] can accommodate lists. Indeed, the construction of the self-avoiding walk tree relies on being able to "pin" colours at individual vertices. So the partition function remains easy to approximate (in the sense that there is an FPTAS) even in the presence of lists. In contrast, the approximation problem becomes #SAT-hard if arbitrary weights are allowed. Indeed, by weighting spin 0 at each vertex $u \in V(G)$ by $2^{d(u)}$, where $d(u)$ is the degree of u, we recover the usual independent set partition function, which is #SAT-equivalent (Lemma 6). (The same fact can be read off from general results in many papers, including [11, Thm 1].) Thus, even in the unbounded case, the dichotomies presented in [11, Thm 1] and [1, Thm 6] do not hold with lists in place of weights. So even in the unbounded-degree case, it was necessary to explicitly analyse list homomorphisms in order to derive precise characterisations quantifying the problem of approximately counting these.

Abstract

Given an edge-weighted graph G, let PerfMatch(G) denote the weighted sum over all perfect matchings M in G, weighting each matching M by the product of weights of edges in M. If G is unweighted, this plainly counts the perfect matchings of G.

In this paper, we introduce parity separation, a new method for reducing PerfMatch to unweighted instances: For graphs G with edge-weights 1 and -1, we construct two unweighted graphs G1 and G2 such that PerfMatch(G) = PerfMatch(G1) − PerfMatch(G2). This yields a novel weight removal technique for counting perfect matchings, in addition to those known from classical #P-hardness proofs. Our technique is based upon the Holant framework and matchgates. We derive the following applications:

Firstly, an alternative #P-completeness proof for counting unweighted perfect matchings.

Secondly, C=P-completeness for deciding whether two given unweighted graphs have the same number of perfect matchings. To the best of our knowledge, this is the first C=P-completeness result for the "equality-testing version" of any natural counting problem that is not already #P-hard under parsimonious reductions.

Thirdly, an alternative tight lower bound for counting unweighted perfect matchings under the counting exponential-time hypothesis #ETH.

1 Introduction

The problem of counting perfect matchings has played a central role in counting complexity since Valiant [27] introduced the class #P and established #P-completeness of counting perfect matchings in unweighted bipartite graphs. This problem was previously already considered in statistical physics [26, 21, 22] and Valiant's computational hardness result explains the lack of progress encountered in this area for finding efficient algorithms for counting perfect matchings.

As complexity theorists, we can appreciate this seminal #P-completeness result from another perspective: The problem of counting perfect matchings in *unweighted* graphs presented the first example of a natural hard counting problem with an easy decision version, since Edmond's classical algorithm [14] allows to decide in polynomial time whether a graph

contains *at least one* perfect matching. This showed exemplarily that the complexity-theoretic study of counting problems amounts to more than merely checking whether NP-hardness proofs for decision problems carry over to their counting versions.

For instance, a fundamental peculiarity of counting problems that is not shared by decision problems are *cancellations*: In (weighted) counting problems, witness structures may cancel each other out, and this can have strong effects on the complexity of the problem. The most prominent example of this phenomenon might be the situation of the *determinant* and the *permanent*, both summing over the same permutations, however with different weights. This results in the permanent being #P-complete by Valiant's result, whereas the determinant can be computed in polynomial time. The *accidental* and *holographic* algorithms introduced by Valiant [28, 29] provide examples for further and more unexpected cancellations that render counting problems easy.

However, cancellations are also crucial for negative results: In many #P-hardness proofs, such as [4, 2, 3], we first define an intermediate variant of the target problem on weights ± 1. Examples for this strategy include the original reduction from #SAT to counting unweighted perfect matchings [27]: In this setting, let G be a graph with edge-weights $w : E(G) \to \{-1, 1\}$, let $\mathcal{PM}[G]$ denote its set of perfect matchings, and define

$$\text{PerfMatch}(G) := \sum_{M \in \mathcal{PM}[G]} \prod_{e \in M} w(e). \tag{1}$$

Given an instance to this weighted problem, that is, a graph G derived from a 3-CNF formula, its space of witness structures $\mathcal{PM}[G]$ can then be partitioned into "good" structures that correspond to satisfying assignments, and "bad" structures that could be called combinatorial noise. By careful construction of such a graph G on edge-weights ± 1, we can ensure that bad structures come in pairs of weight $+1$ and -1, thus canceling out, whereas good structures all have weight $+1$.

To conclude #P-completeness of counting unweighted perfect matchings, it remains to simulate the weight -1 from the intermediate problem. This can be achieved by several techniques, which we survey in the next part of the introduction. Let us however first point out that the main contribution of this paper is a novel technique for precisely this part of the reduction: Using a method we call *parity separation*, we reduce the computation of $\text{PerfMatch}(G)$ for a ± 1-weighted graph G to the difference of PerfMatch for two unweighted graphs, that is, to the difference of two numbers of perfect matchings.

▶ **Lemma 1** (Parity Separation). *Let G be a graph on n vertices and m edges that is weighted by a function $w : E(G) \to \{-1, 1\}$. Then we can construct in time $\mathcal{O}(n + m)$ two unweighted graphs G_1 and G_2, each on $\mathcal{O}(n + m)$ vertices and edges, such that*

$$\text{PerfMatch}(G) = \text{PerfMatch}(G_1) - \text{PerfMatch}(G_2). \tag{2}$$

Intuitively speaking, this allows us to "collect" positive and negative terms of $\text{PerfMatch}(G)$ for ± 1-weighted graphs. This way, we can reduce the effect of cancellations incurred *within* PerfMatch to a mere difference *outside* of PerfMatch.

In the remainder of this introduction, we present parity separation in more detail and demonstrate three applications that can be derived from it: Firstly, and not surprisingly, we obtain a new #P-completeness proof for counting perfect matchings. Secondly, we can show $\mathsf{C}_{=}\mathsf{P}$-completeness of deciding whether two graphs have the same number of perfect matchings. Thirdly, we also obtain tight lower bounds under the exponential-time hypothesis.

1.1 #P-completeness via parity separation

To put parity separation into context, we first recapitulate Valiant's #P-hardness result for counting perfect matchings in more detail. Let us denote the problem of evaluating PerfMatch on graphs with edge-weights from $A \subseteq \mathbb{Q}$ by PerfMatch^A. For consistency with [13], we write PerfMatch^{0,1} for the problem of counting perfect matchings in unweighted graphs. That is, we explicitly include $0 \in A$ for PerfMatch^A, although zero-weight edges could be simply deleted.

First step: From #SAT to PerfMatch$^{-1,0,1}$

It is shown in [27, Lemma 3.1] that PerfMatch^W is #P-hard for $W := \{-1, 0, 1, 2, 3\}$. More precisely, from a 3-CNF formula φ, a number $t(\varphi) \in \mathbb{N}$ and a bipartite graph $G = G(\varphi)$ on weights W are constructed in polynomial time, such that

$$\#\mathsf{SAT}(\varphi) = \frac{\mathrm{PerfMatch}(G)}{4^{t(\varphi)}}, \tag{3}$$

This however only yields hardness for a weighted generalization of counting perfect matchings. To obtain a useful reduction source for further problems, it is crucial to reduce PerfMatch^W to PerfMatch^{0,1}, as reductions from PerfMatch to other problems would otherwise need to take care of the weights in W, which is particularly problematic for the edge-weight -1 in the case of unweighted reduction targets.

In fact, the weight -1 is the only problem we encounter: Edges e of positive integer edge-weight w can be simulated easily by replacing e with w parallel edges of unit weight, possibly subdividing edges twice to obtain simple graphs. This trick however clearly does not apply for the weight -1, so we need a different strategy.

Second step: From PerfMatch$^{-1,0,1}$ to PerfMatch^{0,1}

By now, two different strategies are known for removing the weight -1, which we briefly survey in the following. Let G be a graph with n vertices and $m > 0$ edges, all on weights -1 and 1.

- **Modular arithmetic**: Variations of the following approach were originally used by Valiant [27] and later by Zanko [32] and Ben-Dor and Halevi [1]: Write $M = 2^m + 1$ and observe that $\mathrm{PerfMatch}(G) < M$. We can hence replace the weight -1 by the positive integer $M - 1$ to obtain a graph G' satisfying $\mathrm{PerfMatch}(G) \equiv \mathrm{PerfMatch}(G')$ modulo M. The weight $M - 1$ can be simulated by a gadget as in the previous paragraph, and using a more involved construction [32], it can be seen that a gadget on $\mathcal{O}(m)$ vertices and edges suffices, yielding a total number of $\mathcal{O}(nm)$ vertices and $\mathcal{O}(m^2)$ edges in G'. Then we compute $\mathrm{PerfMatch}(G')$ modulo M and obtain $\mathrm{PerfMatch}(G)$, as we may assume from (3) that $\mathrm{PerfMatch}(G) \geq 0$. In total, we obtain one reduction image for PerfMatch^{0,1} on $\mathcal{O}(nm)$ vertices and $\mathcal{O}(m^2)$ edges.
- **Polynomial interpolation:** An alternative technique for removing the edge-weight -1 from G is to replace it by an indeterminate x. This gives rise to a graph G_x on edge-weights $\{1, x\}$ for which $\mathrm{PerfMatch}(G_x)$ is a polynomial $p(x) \in \mathbb{Z}[x]$ of degree at most $n/2$. We can evaluate $p(i)$ for $i \in \{0, \ldots, n/2\}$ by substituting $x \leftarrow i$ in G_x and simulating this positive weight by a gadget as discussed before. This allows us to recover $p(-1) = \mathrm{PerfMatch}(G)$ via Lagrangian interpolation. In total, using gadgets as in [32, 13], we obtain $\mathcal{O}(n)$ reduction images for PerfMatch^{0,1} on $\mathcal{O}(m \log n)$ vertices and $\mathcal{O}(m \log n + m)$ edges each.

Both weight removal techniques allow to reduce PerfMatch$^{-1,0,1}$ to PerfMatch^{0,1} and thus complete the #P-completeness proof of the latter problem. Note however that both approaches map weighted graphs G with m edges to unweighted graphs with a super-linear number of edges. Using parity separation, we obtain a third way of performing the weight removal step, which differs substantially from both approaches mentioned before and features only constant blowup:

- **Parity separation:** Using Lemma 1, compute two unweighted graphs G_1 and G_2 from G such that PerfMatch(G) is the mere difference of PerfMatch(G_1) and PerfMatch(G_2). In total, we obtain 2 reduction images for PerfMatch^{0,1} on $\mathcal{O}(n+m)$ vertices and edges.

Together with the first step, this implies an alternative #P-completeness proof for the problem PerfMatch^{0,1} of counting perfect matchings in unweighted graphs. For the sake of completeness, we also include a self-contained reduction from #SAT to PerfMatch$^{-1,0,1}$.

▶ **Theorem 2.** PerfMatch^{0,1} *is* #P*-complete under polynomial-time Turing reductions.*

1.2 $\mathsf{C}_=\mathsf{P}$-completeness via parity separation

Apart from an alternative #P-completeness proof, Lemma 1 also yields implications for the structural complexity of PerfMatch: We show that deciding whether two unweighted graphs have the same number of perfect matchings is complete for the complexity class $\mathsf{C}_=\mathsf{P}$, which was introduced in [25, 31] and further elaborated in [16, 15].

To define $\mathsf{C}_=\mathsf{P}$, let us associate the following language $\mathsf{A}_=$ with each counting problem $\mathsf{A} \in \#\mathsf{P}$: The inputs to $\mathsf{A}_=$ are pairs (x, y) of instances to A, and we are asked to determine whether $\mathsf{A}(x) = \mathsf{A}(y)$ holds. We can then define[1] the class $\mathsf{C}_=\mathsf{P} := \{\mathsf{A}_= \mid \mathsf{A} \in \#\mathsf{P}\}$.

For instance, it is clear that $\#\mathsf{SAT}_=$, the problem that asks whether two 3-CNF formulas have the same number of satisfying assignments, is $\mathsf{C}_=\mathsf{P}$-complete under polynomial-time many-one reductions. In fact, $\mathsf{C}_=\mathsf{P}$-completeness holds for every problem $\mathsf{A}_=$ whose counting version #A is #P-complete under parsimonious reductions. We recall the notion of parsimonious (and other) reductions in Definition 5.

The relationship between $\mathsf{C}_=\mathsf{P}$ and other complexity classes has been studied in structural complexity theory, and several results are surveyed in [15]. For instance, we clearly have $\mathsf{coNP} \subseteq \mathsf{C}_=\mathsf{P}$, and using the witness isolation technique [30], we see that NP is contained in $\mathsf{C}_=\mathsf{P}$ under randomized reductions. Let us also observe that $\mathsf{NP}^{\#\mathsf{P}} \subseteq \mathsf{NP}^{\mathsf{C}_=\mathsf{P}}$: Whenever we issue an oracle call to #P, we may instead guess the output number, and then check whether we guessed correctly by using the $\mathsf{C}_=\mathsf{P}$ oracle.

To the best of the author's knowledge, no *natural* $\mathsf{C}_=\mathsf{P}$-complete problem $\mathsf{A}_=$ is known whose counting version A is *not* #P-complete under parsimonious reductions.[2] It is clear that the problem PerfMatch^{0,1} of counting unweighted perfect matchings cannot be #P-complete under parsimonious reductions, unless $\mathsf{P} = \mathsf{NP}$. Therefore, the following completeness

[1] We deviate here from the standard definition of $\mathsf{C}_=\mathsf{P}$, according to which we have $L \in \mathsf{C}_=\mathsf{P}$ iff the following holds: There is a polynomial-time nondeterministic Turing machine M such that $x \in L$ iff the numbers of accepting and rejecting computation paths of $M(x)$ are equal. It can be verified easily that this is equivalent to our definition.

[2] Here, we stressed *natural*, because we can easily construct artificial $\mathsf{C}_=\mathsf{P}$-complete problems $\mathsf{A}_=$ whose counting version #A admits no parsimonious reduction from #SAT: Consider as an example the counting problem $\#\mathsf{SAT}'$ that asks to count satisfying assignments, incremented by 1. If $\#\mathsf{SAT}'$ had a parsimonious reduction from #SAT, then every CNF-formula would be satisfiable. On the other hand, the reduction from $\#\mathsf{SAT}_=$ to $\#\mathsf{SAT}'_=$ is trivial.

result for $\text{PerfMatch}^{0,1}_{=}$ seems relevant for structural complexity theory, as it establishes a $\mathsf{C}_{=}\mathsf{P}$-variant of Valiant's result.

▶ **Theorem 3.** $\text{PerfMatch}^{0,1}_{=}$ *(deciding whether two unweighted graphs have the same number of perfect matchings) is* $\mathsf{C}_{=}\mathsf{P}$*-complete under polynomial-time many-one reductions.*

To prove this theorem, we first reduce instances (φ, φ') for $\#\mathsf{SAT}_{=}$ to ± 1-weighted graphs G that satisfy $\text{PerfMatch}(G) = 0$ iff $\#\mathsf{SAT}(\varphi) = \#\mathsf{SAT}(\varphi')$. This requires a modification of the first step in the $\#\mathsf{P}$-hardness reduction, which is however supported easily by our alternative proof. Then we apply Lemma 1 on the graph G to obtain unweighted graphs G_1 and G_2 satisfying (2). In particular, their numbers of perfect matchings agree iff $\text{PerfMatch}(G)$ vanishes, that is, iff (φ, φ') is a yes-instance for $\#\mathsf{SAT}_{=}$.

To conclude this subsection, we note that the complexity of a similar problem was posed as an open question in [8]: Given two directed acyclic graphs, decide whether their numbers of topological orderings agree. It was shown in [5] that counting topological orderings is $\#\mathsf{P}$-complete under Turing reductions, but the decision version is trivial for DAGs. Our result for $\text{PerfMatch}^{0,1}_{=}$ might be useful to prove $\mathsf{C}_{=}\mathsf{P}$-completeness for this and other problems. For instance, a reduction was recently found [24] from $\text{PerfMatch}^{0,1}_{=}$ to deciding whether two formulas in 2-CNF are satisfied by the same number of assignments.

1.3 Tight lower bounds via parity separation

We turn our attention to conditional *quantitative* lower bounds: A relatively new subfield in computational complexity makes use of assumptions stronger than $\mathsf{P} \neq \mathsf{NP}$ or $\mathsf{FP} \neq \#\mathsf{P}$ to prove tight (exponential) lower bounds on the running times needed to solve computational problems. A popular such assumption is the exponential-time hypothesis ETH, introduced by Impagliazzo et al. [19, 20], which states that the satisfiability of n-variable formulas φ in 3-CNF cannot be decided in time $2^{o(n)}$. For counting problems, an analogous variant $\#\mathsf{ETH}$ was introduced by Dell et al. [13], and it postulates the same for the problem of *counting* satisfying assignments to φ.

Assuming ETH, it was shown for a vast body of popular decision problems that the known exponential-time exact algorithms are somewhat optimal: For instance, there is a trivial $2^{\mathcal{O}(m)}$ time algorithm for finding a Hamiltonian cycle (or various other structures) in an m-edge graph, but $2^{o(m)}$ time algorithms would refute ETH. See [23] for a nice survey.

Similar lower bounds were shown for counting problems under $\#\mathsf{ETH}$, see [17, 18, 13], and a very recent paper [9] introduced *block interpolation*, an approach to make the technique of polynomial interpolation (as seen in the second step of Section 1.1) compatible with tight lower bounds under $\#\mathsf{ETH}$. For several problems, that of counting perfect matchings being among them, block interpolation gave the first tight $2^{\Omega(m)}$ lower bounds under $\#\mathsf{ETH}$.

When applying this framework to $\text{PerfMatch}^{0,1}$, we would first reduce $\#\mathsf{SAT}$ on n-variable 3-CNFs φ to instances $G = G(\varphi)$ for $\text{PerfMatch}^{-1,0,1}$ with $\mathcal{O}(n)$ edges as in the first step of the $\#\mathsf{P}$-hardness proof. Then we apply the block interpolation technique to reduce G to $2^{o(n)}$ unweighted instances G' for $\text{PerfMatch}^{0,1}$ with $\mathcal{O}(n)$ edges. While this sub-exponential number of instances is compatible with the goal of proving tight lower bounds, it leaves open the natural question whether the same reduction could be achieved with only polynomially many oracle calls on graphs with $\mathcal{O}(n)$ edges.

Using Lemma 1, we obtain a strong positive answer to this question: Replacing the application of block interpolation by one of parity separation, we obtain a reduction to merely *two* instances of $\text{PerfMatch}^{0,1}$. And as a synthesis of structural and quantitative complexity, we also obtain a tight lower bound for the equality-testing problem $\text{PerfMatch}^{0,1}_{=}$.

▶ **Theorem 4.** *Unless* #ETH *fails, the problem* $\text{PerfMatch}^{0,1}$ *admits no algorithm with running time* $2^{o(m)}$ *on simple graphs with* m *edges. Furthermore, the same applies to* $\text{PerfMatch}^{0,1}_{=}$ *under the decision version* ETH*.*

Organization of this paper

The remainder of this paper is structured as follows: In Section 2, we introduce the Holant framework and matchgates, concepts that are crucial to our constructions. These are put to use in Section 3, where we prove Lemma 1, our main result. Its applications, as discussed above, are shown in Section 4.

2 Preliminaries

Graphs in this paper may be edge- or vertex-weighted. Given a graph G and $v \in V(G)$, denote the edges incident with v by $I(v)$. If the context of an argument unambiguously determines a graph G, we write $n = |V(G)|$ and $m = |E(G)|$.

We denote the Hamming weight of strings $x \in \{0,1\}^*$ by $\text{hw}(x)$. Given a statement φ, we let $[\varphi] = 1$ if φ is true, and $[\varphi] = 0$ otherwise. For convenience, we recall that several reduction notions are distinguished in the study of counting complexity: The most restrictive notion is that of *parsimonious* (many-one) reductions, which can be slightly relaxed to *weakly* parsimonious reductions. The most permissive notion is that of *Turing* reductions.

▶ **Definition 5.** Let A and B be counting problems. Let $f : \{0,1\}^* \to \{0,1\}^*$ and $g : \{0,1\}^* \to \mathbb{Q}$ be polynomial-time computable functions. If $\mathsf{A}(x) = g(x) \cdot \mathsf{B}(f(x))$ holds for all $x \in \{0,1\}^*$, then we call (f, g) a *weakly parsimonious (polynomial-time) reduction* from A to B and write $\mathsf{A} \leq_p \mathsf{B}$. If additionally $g(x) = 1$ holds for all $x \in \{0,1\}^*$, then we call f *parsimonious* and write $\mathsf{A} \leq_p^{pars} \mathsf{B}$.

If $\mathbb{T}$ is a deterministic polynomial-time algorithm that solves A with an oracle for B, then we call $\mathbb{T}$ a *Turing reduction* from A to B and write $\mathsf{A} \leq_p^T \mathsf{B}$.

2.1 Weighted sums of (perfect) matchings

The quantity PerfMatch on edge-weighted graphs, as defined in (1) and [29], will be the central object of investigation in this paper. For intermediate steps, we also consider the quantity MatchSum introduced in [29].

▶ **Definition 6.** For vertex-weighted graphs G with $w : V(G) \to \mathbb{Q}$, let $\mathcal{M}[G]$ denote the set of (not necessarily perfect) matchings in G. Recall that $\mathcal{PM}[G] \subseteq \mathcal{M}[G]$ denotes the perfect matchings in G. For $M \in \mathcal{M}[G]$, let $\text{usat}(M)$ denote the set of unmatched vertices in M. Then we define

$$\text{MatchSum}(G) = \sum_{M \in \mathcal{M}[G]} \prod_{v \in \text{usat}(M)} w(v).$$

Given $W \subseteq \mathbb{Q}$, we write PerfMatch^W for the problem of evaluating $\text{PerfMatch}(G)$ on graphs G with weights $w : E(G) \to W$. Likewise, write MatchSum^W on graphs with weights $w : V(G) \to W$. Please note that an edge of weight 0 in PerfMatch can be treated as if it were not present, whereas weight 0 at a vertex v in MatchSum signifies that v must be matched. We can easily reduce PerfMatch^W for finite $W \subseteq \mathbb{Q}$ to $\text{PerfMatch}^{-1,0,1}$:

▶ **Lemma 7** (folklore). *Let G be edge-weighted by $w : E(G) \to \mathbb{Q}$. Let $q \in \mathbb{N}$ denote the least common denominator of the weights in G, and let $T = \max_{e \in E(G)} q \cdot w(e)$. Then we can compute a number $B \in \mathbb{N}$ and an edge-weighted graph G' on $\mathcal{O}(n + Tm)$ vertices and edges, all of weight ± 1, such that* $\text{PerfMatch}(G) = q^{-B} \cdot \text{PerfMatch}(G')$.

2.2 Holant problems

We give an introduction to the *Holant framework*, summarizing ideas from [29, 6, 7]. A more detailed introduction to our notation can be found in [11].

▶ **Definition 8** (adapted from [29]). A *signature graph* is an edge-weighted graph Ω, which may feature parallel edges, with a *vertex function* $f_v : \{0,1\}^{I(v)} \to \mathbb{Q}$ at each $v \in V(\Omega)$.

The *Holant* of Ω is a particular sum over edge assignments $x \in \{0,1\}^{E(\Omega)}$. We sometimes identify x with the set $x^{-1}(1)$ of indices that have value 1 under x. Given $S \subseteq E(\Omega)$, we write $x|_S$ for the restriction of x to S, which is the unique assignment in $\{0,1\}^S$ that agrees with x on S. Then we define

$$\text{Holant}(\Omega) := \sum_{x \in \{0,1\}^{E(\Omega)}} \left(\prod_{e \in x} w(e) \right) \left(\prod_{v \in V(\Omega)} f_v(x|_{I(v)}) \right). \tag{4}$$

As a first example, we can reformulate $\text{PerfMatch}(G)$ easily as the Holant of a signature graph $\Omega = \Omega(G)$ by declaring $f_v : \{0,1\}^{I(v)} \to \{0,1\}$ for $v \in V(G)$ to be the vertex function that maps $x \in \{0,1\}^*$ to 1 iff $\text{hw}(x) = 1$ and to 0 else.

When considering signature graphs Ω in the following, we will always assume that $I(v)$ for each $v \in V(\Omega)$ is ordered in a fixed (usually implicit) way. This way, if v is a vertex of degree $d \in \mathbb{N}$, we can simply view f_v as a function $f_v : \{0,1\}^d \to \mathbb{Q}$, and we call this representation a *signature*.

▶ **Example 9.** The following are signatures of arity $k \in \mathbb{N}$ on inputs $x \in \{0,1\}^{[k]}$ with $x = (x_1, \ldots, x_k)$.

$$\begin{aligned}
\texttt{EQ} &: x \mapsto [x_1 = \ldots = x_k] \\
\texttt{HW}_{=1} &: x \mapsto [\text{hw}(x) = 1] \\
\texttt{HW}_{\leq 1} &: x \mapsto [\text{hw}(x) \leq 1] \\
\texttt{ODD} &: x \mapsto x_1 \oplus \ldots \oplus x_k \\
\texttt{EVEN} &: x \mapsto 1 \oplus x_1 \oplus \ldots \oplus x_k.
\end{aligned}$$

We may write, say, $\texttt{EQ}_4$ to denote the arity-4 signature $\texttt{EQ}$. Note that these signatures are symmetric, as they depend only upon the Hamming weight on the input.

Similarly as for PerfMatch, we can also express MatchSum as a Holant problem.

▶ **Lemma 10.** *Let G be a graph with vertex-weights $w : V(G) \to \mathbb{Q}$. Then* $\text{MatchSum}(G) = \text{Holant}(\Omega)$ *holds with the signature graph Ω that is derived from G by placing $\texttt{VTX}_{w(v)}$ at $v \in V(G)$ and assigning weight 1 to all edges. Here, $\texttt{VTX}_w$ for $w \in \mathbb{Q}$ is defined as*

$$\texttt{VTX}_w : \quad x \mapsto \begin{cases} w & \text{if } \text{hw}(x) = 0, \\ 1 & \text{if } \text{hw}(x) = 1, \\ 0 & \text{otherwise.} \end{cases}$$

We can easily reduce edge-weighted Holant problems to unweighted versions as follows.

▶ **Lemma 11.** *Let Ω' be defined as follows from Ω: Subdivide each edge $e \in E(\Omega)$ into two edges, assign weight 1 to the obtained subdivision edges, and equip the obtained subdivision vertices with the signature $\texttt{EDGE}_{w(e)}$, where*

$$\texttt{EDGE}_w : \quad x \mapsto \begin{cases} w & \text{if } x = 11, \\ 0 & \text{if } x \in \{01, 10\}, \\ 1 & \text{if } x = 00. \end{cases}$$

Then Ω' features only the edge-weight 1, and we have $\mathrm{Holant}(\Omega) = \mathrm{Holant}(\Omega')$.

Finally, a signature is called *even* if its support contains only bitstrings of even Hamming weight. The problem #SAT can be rephrased as a Holant problem with even signatures:

▶ **Lemma 12.** *For $n, m, d \in \mathbb{N}$, let φ be a d-CNF formula on variables $x_1, \ldots, x_n$ and clauses $c_1, \ldots, c_m$. We construct a signature graph Ω as follows:*

- *For each $i \in [n]$, let $r(i)$ denote the number of occurrences of x_i (as a positive or negative literal) in φ. Create a* variable vertex *v_i in Ω, with signature $\texttt{EQ}_{2r(i)}$.*
- *For each $j \in [m]$, let $x_{i_1}, \ldots, x_{i_d}$ be the variables that clause c_j depends upon. We create a* clause vertex *w_j in Ω, and for $\kappa \in [d]$, we add two parallel edges of weight 1 between w_j and v_{i_κ} as the $2\kappa - 1$-th and 2κ-th edges in the ordering of $I(w_j)$.*
- *For each $j \in [m]$, consider clause c_j as a Boolean function on variables $z_1, \ldots, z_d$, where z_i for $i \in [d]$ represents the i-th variable in c_j. Define a function c'_j on variables $y_1, \ldots, y_{2d}$ that outputs $c_j(y_1, y_3, \ldots, y_{2d-1})$ if $y_{2i} = y_{2i-1}$ for all $i \in [d]$. On all other inputs, the value of c'_j is defined to be zero. Assign such a signature c'_j to the vertex w_j.*

Then we have $\#\mathsf{SAT}(\varphi) = \mathrm{Holant}(\Omega)$. Note that Ω is a signature graph with $n + m$ vertices and $2dm$ edges that features only even signatures and the edge-weight 1.

▶ Remark. The degree of clause vertices above is $2d$ rather than d to ensure that their signatures are even. The need for this will become clear in the next subsection.

2.3 Gates and matchgates

Given a signature graph Ω, we can sometimes simulate vertex functions by gadgets or *gates*, which are signature graphs with so-called *dangling edges* that feature only one endpoint. These notions are borrowed from the $\mathcal{F}$-gates in [7]. Matchgates were first considered in [29].

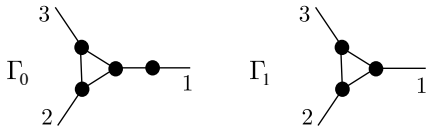
▶ **Definition 13** (adapted from [7])**.** For disjoint sets A, B, and for assignments $x \in \{0,1\}^A$ and $y \in \{0,1\}^B$, we write $xy \in \{0,1\}^{A \cup B}$ for the assignment that agrees with x on A, and with y on B. We also say that the assignment xy *extends* x. A *gate* is a signature graph Γ containing a set $D \subseteq E(\Gamma)$ of dangling edges, all of which have edge-weight 1. The *signature realized by* Γ is the function $\mathrm{Sig}(\Gamma) : \{0,1\}^D \to \mathbb{Q}$ that maps x to

$$\mathrm{Sig}(\Gamma, x) = \sum_{y \in \{0,1\}^{E(\Gamma) \setminus D}} \left(\prod_{e \in xy} w(e) \right) \left(\prod_{v \in V(\Gamma)} f_v(xy|_{I(v)}) \right). \tag{5}$$

A gate Γ is a *matchgate* if it features only the signature $\texttt{HW}_{=1}$.

In the following, we consider the dangling edges D of gates Γ to be labelled as $1, \ldots, |D|$. This way, we can view $\mathrm{Sig}(\Gamma)$ as a function of type $\{0,1\}^{|D|} \to \mathbb{Q}$ instead of $\{0,1\}^D \to \mathbb{Q}$. We will use gates to realize required signatures as "gadgets" consisting of other (usually simpler) signatures. Consider the following example, which appeared in [29].

▶ **Example 14.** It can be verified that $\texttt{EVEN}_3$ and $\texttt{ODD}_3$ are realized by the matchgates Γ_0 and Γ_1 below, where all vertices are assigned $\texttt{HW}_{=1}$ and all edges have weight 1.



Using this, we can realize the signatures $\texttt{ODD}_k$ and $\texttt{EVEN}_k$ for any arity $k \geq 3$ as matchgates, noted also in [29, Theorem 3.3]. This will be required in Section 3.

▶ **Example 15.** For all $k \geq 3$, there exists a gate $\Gamma_{\texttt{EVEN}}$ with $\text{Sig}(\Gamma_{\texttt{EVEN}}) = \texttt{EVEN}_k$. It consists of vertices $v_1, \ldots, v_{k-2}$ equipped with $\texttt{EVEN}_3$, edges $e_1, \ldots, e_{k-3}$ of weight 1, and dangling edges $[k]$.

We can likewise realize $\texttt{ODD}_k$ by a gate $\Gamma_{\texttt{ODD}}$ that is constructed as above, but with $\texttt{ODD}_3$ rather than $\texttt{EVEN}_3$ at v_{k-2}.

In the following, we formalize the operation of *inserting* a gate Γ into a signature graph so as to simulate a desired signature. A more detailed version of this operation can be found in Definition 2.10 and Lemma 2.11 of [11].

▶ **Lemma 16.** *Let Ω be a signature graph, let $v \in V(\Omega)$ with $D = I(v)$ and let Γ be a gate with dangling edges D. We can* insert Γ at v *by deleting v and keeping D as dangling edges, and then placing Γ into Ω and identifying each dangling edge $e \in D$ across Γ and Ω. If Ω' is derived from Ω by inserting a gate Γ with $\text{Sig}(\Gamma) = f_v$ at v, then $\text{Holant}(\Omega) = \text{Holant}(\Omega')$.*

By an argument presented in the author's PhD thesis [11], also used in [12], we can realize every even signature f by some matchgate $\Gamma = \Gamma(f)$. If the image of f is W, then Γ contains $W \cup \{\pm 1, 1/2\}$ as edge-weights. For sake of completeness, we include a self-contained proof in the full version.

▶ **Lemma 17** ([11, 12])**.** *Let Ω be a signature graph on n vertices and m edges, with even vertex functions $\{f_v\}_{v \in V(\Omega)}$ that map into $W \subseteq \mathbb{Q}$. Let $s = \max_{v \in V(\Omega)} |\text{supp}(f_v)|$. Then we can construct, in linear time, a graph G on $\mathcal{O}(n + sm)$ vertices and edges such that $\text{Holant}(\Omega) = \text{PerfMatch}(G)$. The edge-weights of G are $W \cup \{\pm 1, 1/2\}$.*

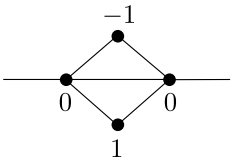
3 The parity separation technique

We are ready to prove Lemma 1, our main result. The proof proceeds by establishing, with several intermediate steps, the reduction chain

$$\text{PerfMatch}^{-1,0,1} \leq_p \text{MatchSum}^{-1,0,1} \leq_p^T \text{PerfMatch}^{0,1}. \tag{6}$$

For the first reduction in (6), we apply a gadget Γ realizing the signature $\texttt{EDGE}_{-1}$ from Lemma 11 to all edges of weight -1.

▶ **Lemma 18.** *We have $\texttt{EDGE}_{-1} = \text{Sig}(\Gamma)$, where Γ is the gate below. In Γ, each vertex features the signature $\texttt{VTX}_w$ for the number $w \in \{-1, 0, 1\}$ it is annotated with in the drawing.*



This allows us to transform an instance for PerfMatch$^{-1,0,1}$ to one for MatchSum$^{-1,0,1}$.

▶ **Lemma 19.** *Let G be a graph with n vertices and m edges, all of weight ± 1. Then we can compute a graph G' on $\mathcal{O}(n+m)$ edges, with vertices of weight $\{-1,0,1\}$, such that* PerfMatch(G) = MatchSum(G').

Proof. We assume that $|V(G)|$ is even, as otherwise PerfMatch$(G) = 0$. First, let Ω be the signature graph constructed by assigning $\texttt{HW}_{=1}$ to all vertices of G, and then applying the signature $\texttt{EDGE}_{-1}$ as in Lemma 11. We obtain PerfMatch(G) = Holant(Ω).

Then realize each occurrence of $\texttt{EDGE}_{-1}$ by the gate Γ from Lemma 18. Note that Γ features no edge-weights, and only $\texttt{VTX}_w$ for $w \in \{-1,0,1\}$. We obtain a signature graph Ω' whose signatures are all of the type $\texttt{VTX}_w$ for $w \in \{-1,0,1\}$, and which satisfies Holant(Ω) = Holant(Ω'). Note that $\texttt{HW}_{=1} = \texttt{VTX}_0$, so this indeed covers all vertices of Ω'.

By Lemma 10, we may equivalently consider Holant(Ω') = MatchSum(G'), where G' is a vertex-weighted graph obtained from Ω' as follows: Keep all vertices and edges of Ω' intact, and if $v \in V(\Omega')$ features the signature $\texttt{VTX}_w$, for $w \in \{-1,0,1\}$, then assign the vertex weight w to v in G'. ◀

For the second reduction in (6), we perform the actual act of parity separation: We will split the vertex-weighted graph G' into an even part G_0 and an odd part G_1, both unweighted, such that the *perfect* matchings of the even (resp. odd) part correspond bijectively to the matchings of G' with an even (resp. odd) number of unmatched vertices of weight -1.[3] Since $(-1)^{even} = 1$ and $(-1)^{odd} = -1$, this clearly implies that MatchSum(G) is the difference of PerfMatch(G_0) and PerfMatch(G_1).

To proceed, we first use the signatures EVEN and ODD from Example 9 to obtain an alternative reformulation of MatchSum$^{-1,0,1}$ as the difference of two Holants.

▶ **Lemma 20.** *Let G' be a graph with vertex-weights $\{-1,0,1\}$. For $a,b \in \{0,1\}$, let $\Phi_{ab} = \Phi_{ab}(G')$ be the signature graph obtained as follows:*

1. *Assign the signature $\texttt{HW}_{=1}$ to all vertices of G'.*
2. *For $x \in \{-1,0,1\}$, let $V_x \subseteq V(G')$ denote the set of vertices of weight x in G'. For $x \in \{-1,1\}$, add a vertex u_x connected to V_x.*
   - *Assign to u_{-1} the signature EVEN if $a = 0$, and assign ODD if $a = 1$.*
   - *Assign to u_1 the signature EVEN if $b = 0$, and assign ODD if $b = 1$.*

   Then we have MatchSum(G') = Holant(Φ_{00}) − Holant(Φ_{11}).

The second reduction in (6) follows by realizing the signatures ODD and EVEN appearing in Φ_{00} and Φ_{11} via matchgates that feature neither edge- nor vertex-weights. Note that the only other appearing signature $\texttt{HW}_{=1}$ is trivially realized by such a matchgate.

Proof of Lemma 1. Follows from Lemma 19 (to reduce PerfMatch$^{-1,0,1}$ to MatchSum$^{-1,0,1}$) with Lemma 20 (to reformulate MatchSum$^{-1,0,1}$ as a Holant problem) and Example 15 (to realize the ODD and EVEN signatures in the Holant problem by unweighted matchgates). ◀

[3] This step is inspired by a reduction [29, Theorem 3.3] from certain instances of MatchSum on planar graphs to PerfMatch on planar graphs.

4 Parity separation in action

In the final section of this paper, we cover the three applications of parity separation that we discussed in the introduction.

4.1 Completeness for #P

We can easily show the #P-completeness of $\text{PerfMatch}^{0,1}$ via parity separation. To this end, we first express #SAT as a Holant problem on even signature graphs, as seen in Lemma 12. Together with Lemma 17, this yields $\#\mathsf{SAT} \leq_p \text{PerfMatch}^B$ with $B = \{-1, 0, 1/2, 1\}$. We use Lemma 7 to remove the edge-weight $1/2$, and finally remove the weight -1 by parity separation as in Lemma 1. Altogether, we obtain the following lemma.

▶ **Lemma 21.** *Let φ be a 3-CNF formula with n variables and m clauses. Then we can compute a number $T \in \mathbb{N}$ and construct two unweighted graphs G_1 and G_2 on $\mathcal{O}(n+m)$ vertices and edges, all in time $\mathcal{O}(n+m)$, such that $2^T \cdot \#\mathsf{SAT}(\varphi) = \text{PerfMatch}(G_1) - \text{PerfMatch}(G_2)$.*

This readily implies Theorem 2, the desired #P-completeness result.

4.2 Completeness for $\mathsf{C}_=\mathsf{P}$

For our next application, we apply the parity separation technique to prove Theorem 3. That is, we prove $\mathsf{C}_=\mathsf{P}$-completeness of the problem $\text{PerfMatch}^{0,1}_=$ that asks, given two unweighted graphs G_1 and G_2, whether their numbers of perfect matchings agree. We call graphs satisfying this property *equipollent graphs* and will likewise speak of *equipollent formulas* if their numbers of satisfying assignments agree.

Proof of Theorem 3. The problem $\text{PerfMatch}^{0,1}_=$ is clearly contained in $\mathsf{C}_=\mathsf{P}$. For the hardness part, we reduce from the $\mathsf{C}_=\mathsf{P}$-complete problem $\#\mathsf{SAT}_=$ that asks, given 3-CNF formulas φ and φ', to determine whether they are equipollent. To this end, we construct unweighted graphs G and G' that are equipollent if and only if φ and φ' are.

Assume that φ and φ' are defined on the same set of variables $x_1, \ldots, x_n$ and feature the same number m of clauses. This can be achieved by renaming variables, and by adding dummy variables and clauses. If, say, φ has less variables than φ', then we can add dummy variables to φ', together with clauses that ensure that every dummy variable has the same assignment as x_1. We can also duplicate clauses.

Let $C_1, \ldots, C_m$ and $C'_1, \ldots, C'_m$ denote the clauses in φ and φ', respectively. We introduce a *selector* variable x^* and define a formula ψ on the variable set $\mathcal{X} = \{x^*, x_1, \ldots, x_n\}$, which has clauses $D_1, \ldots, D_m$ and $D'_1, \ldots, D'_m$, where $D_i := (x^* \vee C_i)$ and $D'_i := (\neg x^* \vee C'_i)$ for $i \in [m]$. If $a(x^*) = 0$ holds in an assignment $a \in \{0,1\}^{\mathcal{X}}$, then all clauses $D'_1, \ldots, D'_m$ are satisfied by $\neg x^*$, but in order for a to satisfy ψ, the clauses $D_1, \ldots, D_m$ have to be satisfied by $x_1, \ldots, x_n$. In other words, if a satisfies ψ and $a(x^*) = 0$, then the restriction of a to $x_1, \ldots, x_n$ satisfies φ. Likewise, if a satisfies ψ and $a(x^*) = 1$, then the restriction of a to $x_1, \ldots, x_n$ satisfies φ'. Hence, we can define the following quantity

$$S := \sum_{a \in \{0,1\}^{\mathcal{X}}} (-1)^{a(x^*)} \cdot [\psi \text{ satisfied by } a]$$

and we observe that $S = \#\mathsf{SAT}(\varphi) - \#\mathsf{SAT}(\varphi')$. It is clear that $S = 0$ if and only if φ and φ' are equipollent. As in Lemma 12, we then express $S = \text{Holant}(\Omega)$ for a signature graph

$\Omega = \Omega(\psi)$, with one modification: At the vertex v^* corresponding to the variable x^*, we do not use the signature $\texttt{EQ}$, but rather a modified signature

$$\texttt{EQ}_{-} : \quad y \mapsto \begin{cases} -1 & \text{if } y = 1 \dots 1, \\ 1 & \text{if } y = 0 \dots 0, \\ 0 & \text{otherwise.} \end{cases}$$

We realize Ω via Lemma 17 to obtain a graph G on edge-weights $1/2, \pm 1$, simulate the edge-weight $1/2$ via Lemma 7, and obtain an edge-weighted graph H with weights ± 1 together with a number $T \in \mathbb{N}$ such that

$$S = \text{Holant}(\Omega) = 2^{-T} \cdot \text{PerfMatch}(H). \tag{7}$$

Using Lemma 1, we then obtain unweighted graphs G and G' such that

$$\text{PerfMatch}(H) = \text{PerfMatch}(G) - \text{PerfMatch}(G'). \tag{8}$$

Then G and G' are equipollent iff $S = 0$, which in turn holds iff φ and φ' are equipollent. ◀

4.3 Tight lower bounds under #ETH

By the exponential-time hypothesis #ETH, there is no $2^{o(n)}$ time algorithm for counting satisfying assignments to 3-CNF formulas φ with n variables. Applying the counting version of the so-called sparsification lemma, shown in [13], we may additionally assume that φ features $m = \mathcal{O}(n)$ clauses. Then Lemma 21 clearly implies the lower bound for $\text{PerfMatch}^{0,1}$ claimed in Theorem 4.

Concerning $\text{PerfMatch}^{0,1}_{=}$, it is even easier to prove lower bounds under ETH than to prove its $\mathsf{C}_{=}\mathsf{P}$-completeness, as we may (i) reduce from SAT rather than $\mathsf{SAT}_{=}$, and (ii) use the more permissive notion of Turing (rather than many-one) reductions: With Lemma 21, we can construct unweighted graphs G_1 and G_2 on $\mathcal{O}(m)$ vertices and edges that are equipollent iff φ is *unsatisfiable*, thus a $2^{o(m)}$ time algorithm would contradict ETH. This proves Theorem 4.

5 Conclusion and future work

We have added a new method to the known techniques (modular arithmetic and polynomial interpolation) for removing the edge-weight -1 from $\text{PerfMatch}^{-1,0,1}$. This method is based on matchgates and the simple observation that $(-1)^{even} = 1$ and $(-1)^{odd} = -1$. We obtained non-trivial applications that could not be obtained via the previously known techniques.

Our work leaves some interesting questions open for further investigations. For instance, we could not find a way to show #P-completeness of $\text{PerfMatch}^{0,1}$ on *bipartite* graphs by parity separation. Is there a complexity-theoretic explanation for this? On another note, can we prove $\mathsf{C}_{=}\mathsf{P}$-completeness for other "equality-testing" versions of counting problems?

Acknowledgments. The author wishes to thank Markus Bläser, Mingji Xia, Meena Mahajan and Jin-Yi Cai for interesting discussions. Furthermore, thanks to Patrick Scharpfenecker for pointing out [24].

On the Hardness of Partially Dynamic Graph Problems and Connections to Diameter

Søren Dahlgaard*

University of Copenhagen, Denmark

Abstract

Conditional lower bounds for dynamic graph problems has received a great deal of attention in recent years. While many results are now known for the fully-dynamic case and such bounds often imply worst-case bounds for the partially dynamic setting, it seems much more difficult to prove amortized bounds for incremental and decremental algorithms. In this paper we consider partially dynamic versions of three classic problems in graph theory. Based on popular conjectures we show that:

- No algorithm with amortized update time $O(n^{1-\varepsilon})$ exists for incremental or decremental maximum cardinality bipartite matching. This significantly improves on the $O(m^{1/2-\varepsilon})$ bound for sparse graphs of Henzinger et al. [STOC'15] and $O(n^{1/3-\varepsilon})$ bound of Kopelowitz, Pettie and Porat[1]. Our linear bound also appears more natural. In addition, the result we present separates the node-addition model from the edge insertion model, as an algorithm with total update time $O(m\sqrt{n})$ exists for the former by Bosek et al. [FOCS'14].
- No algorithm with amortized update time $O(m^{1-\varepsilon})$ exists for incremental or decremental maximum flow in directed and weighted sparse graphs. No such lower bound was known for partially dynamic maximum flow previously. Furthermore no algorithm with amortized update time $O(n^{1-\varepsilon})$ exists for directed and unweighted graphs or undirected and weighted graphs.
- No algorithm with amortized update time $O(n^{1/2-\varepsilon})$ exists for incremental or decremental $(4/3-\varepsilon')$-approximating the diameter of an unweighted graph. We also show a slightly stronger bound if node additions are allowed. The result is then extended to the static case, where we show that no $O((n\sqrt{m})^{1-\varepsilon})$ algorithm exists. We also extend the result to the case when an additive error is allowed in the approximation. While our bounds are weaker than the already known bounds of Roditty and Vassilevska Williams [STOC'13], it is based on a weaker conjecture of Abboud et al. [STOC'15] and is the first known reduction from the 3SUM and APSP problems to diameter. Showing an equivalence between APSP and diameter is a major open problem in this area (Abboud et al. [SODA'15]), and thus showing even a weak connection in this direction is of interest.

1 Introduction

Arguably one of the most important goals of computer science is to understand the complexity of natural computational problems. For many such problems we know of polynomial time algorithms, but getting matching unconditional lower bounds seem far beyond the scope of our current techniques. Therefore a recent and very active line of research at top-level conferences concerns itself with hardness results in the class **P** [26, 6, 8, 17, 21, 3, 14, 4, 13, 12, 10, 2, 1]. Such results are obtained by reducing from classic problems like 3SUM, APSP and CNF-SAT, for which there exist very popular conjectures about the running time. We call such a hardness result a *conditional lower bound (CLB)* as it is based (conditioned) on the truthfulness of some popular conjecture. The main goal of CLBs is to explain barriers in algorithm development and provide "warning signs" that improving an algorithm for some problem has major and surprising consequences for a classic problem like the ones mentioned above, which researchers have worked on for decades, and trying to do so may be ill-advised.

One particular area that has received a lot of attention from this perspective is dynamic graph problems [29, 26, 6, 8, 17, 21]. In dynamic graph problems we are asked to maintain some property about a graph such as reachability or shortest paths distances as the graph undergoes changes (typically edge insertions and deletions). One may also consider the partially dynamic cases where only edge insertions are allowed (incremental) or edge deletions (decremental) or cases where node insertion and deletion is allowed. Several conditional lower bounds are known for both partially and fully dynamic problems such as shortest paths [29, 17], maximum bipartite matching [6, 17, 21], maximum flow [8], reachability [26, 6, 17], and many more.

1.1 Difficulties of partially dynamic

Most of the research on CLBs for dynamic graph problems has been focused on the fully dynamic case, however such results do not translate well into CLBs for incremental or decremental algorithms. A typical reduction works by 1) building a structured base graph, 2) for each element in some subset of the input perform a series of insertions and queries to decide whether this element is in a possible solution, 3) perform a series of deletions returning the graph to its base state. From a partially dynamic perspective we may use the above procedure to get similar *worst-case* bounds, by keeping track of the data structure state and simulating step 3 by *rolling back* the insertions, however this kills any hope of good amortized bounds. As noted in [6, 17, 21] it seems more difficult to obtain good bounds in this case, and specialized reductions are often needed.

1.2 Bounds under weaker assumptions

While proving higher lower bounds is the main goal of CLBs, a simultaneous goal is to prove similar CLBs under weaker assumptions, thus lending more credibility to the belief that a problem is difficult or even impossible. Several recent papers concerns themselves with this be either replacing a conjecture with a weaker version as done by Abboud et al. in [4] or by showing similar reductions under several conjectures [32, 5, 7, 8, 17]. As an example Abboud, Vassilevska Williams, and Yu [8] showed that 3SUM, APSP and CNF-SAT can all be reduced to the same problem of finding triangles in a node-colored graph and showed several interesting results based on the following conjecture:

▶ **Conjecture 1** ([8]). *At least one of the following is true:*

1. *There is no algorithm for the 3-SUM problem running in $O(n^{2-\varepsilon})$ for any $\varepsilon > 0$.*

2. *There is no algorithm for the APSP problem on weighted graphs running in* $O(n^{3-\varepsilon})$ *for any* $\varepsilon > 0$.
3. *For every* $\delta > 0$ *there is an integer* $k \geq 3$ *such that* k*-SAT on* n *variables and* $O(n)$ *clauses cannot be solved in* $2^{(1-\delta)n}\operatorname{poly}(n)$ *time.*

The third item in Conjecture 1 is what is known as the strong exponential time hypothesis (SETH) [18] and the $O(n)$ bound on the number of clauses follows from the sparsification lemma of Impagliazzo, Paturi, and Zane [19].

1.3 Our results

In this paper we consider three of the perhaps most classic problems in graph theory, namely maximum flow, maximum bipartite matching and diameter in the partially dynamic setting. For maximum flow and maximum bipartite matching we show new, stronger, and more natural conditional lower bounds. For diameter we show a new reduction from Conjecture 1 to both the partially dynamic version of diameter and, perhaps more interestingly, the static case. This is the first known connection from APSP and 3SUM to diameter in graphs and addresses one of the main open problems in the area as stated in [3].

Maximum bipartite matching. In dynamic maximum cardinality bipartite matching we wish to maintain the size of a maximum matching in a dynamic graph G. One can trivially do this in $O(m)$ time by finding an augmenting path. Sankowski [30] gave a fully dynamic algorithm with update time $O(n^{1.495})$ by using fast matrix multiplication. In the incremental setting, one may consider a node-addition version in which the right-hand side of the bipartite graph is given and the left-hand side arrives one node at a time with all its incident edges. In this model Bosek et al. [11] gave an algorithm with total running time of $O(m\sqrt{n})$. From a hardness perspective, Abboud and Vassilevska Williams [6] gave reductions from 3SUM, triangle detection and boolean matrix multiplication to fully-dynamic maximum cardinality bipartite matching. In particular, they showed that a $O(n^{2-\varepsilon})$ algorithm would imply a faster *combinatorial* boolean matrix multiplication algorithm. Their reductions, however, only imply worst-case bounds in the case of partially dynamic algorithms. This was addressed by Kopelowitz, Pettie and Porat [21] who revisited Pătraşcu's reductions from [26] and showed that any $O(n^{1/3-\varepsilon})$ algorithm for incremental MCM would imply a truly subquadratic algorithm for 3SUM. They also showed the same result for $O(n^{0.39-\varepsilon})$ algorithms when node insertions are allowed. Subsequently, in an online version of [17], it was shown how to obtain a CLB of $O(m^{1/2-\varepsilon})$ in sparse graphs by reducing from the online matrix-vector multiplication (OMv) problem.

In this paper we show the following theorem:

▶ **Theorem 2.** *There is no algorithm for solving incremental (or decremental) maximum cardinality bipartite matching with amortized time* $O(n^{1-\varepsilon})$ *per insertion (or deletion) and* $O(n^{2-\varepsilon})$ *time per query unless the OMv conjecture of [17] is false.*

One thing to note about Theorem 2 is that it separates the node-addition model from the edge-insertion model as it implies a total running time of $O(mn^{1-o(1)})$ in contrast to the $O(m\sqrt{n})$ running time of the algorithm from [11]. Furthermore, the reduction used to prove Theorem 2 also rules out any efficient incremental (or decremental) approximation algorithm that works by ruling out the existence of short augmenting paths. Ruling out such paths is a popular way of ensuring a good approximation ratio [25].

Maximum flow. Single-source single-sink maximum flow (*st* Max-Flow) is one of the most classic problems in graph theory. In recent years there have been several breakthrough results for *st* maximum flow using the powerful tools of Laplacian system solvers and interior point methods [24, 31, 20, 22]. These algorithms seem to take near-line time in practice, and the limits of our current analysis might be the bottleneck in proving such upper bounds. Proving super-linear conditional lower bounds for this problem may thus be difficult if not impossible. Therefore, Abboud et al. [8] considered different variants of the problem such as single-source maximum flow and *ST* maximum flow. They also showed that any algorithm solving the fully-dynamic version of *st* maximum flow with amortized update and query time $O(n^{1-\varepsilon})$ for any $\varepsilon > 0$ would refute Conjecture 1. Finally, we note that it is possible to modify the $m^{1-o(1)}$ CLB for fully dynamic #SSR of Abboud and Vassilevska Williams [6] to obtain a $m^{1-o(1)}$ CLB for fully-dynamic *st* max-flow in sparse graphs.

In this paper we show that even in the incremental and decremental case *st* maximum flow exhibit the same kind of CLB, but based solely on SETH. This is summarized in the following theorem:

▶ **Theorem 3.** *There is no algorithm for solving incremental (or decremental) max st flow on a weighted and directed graph with n nodes and $\tilde{O}(n)$ edges with amortized time $O(m^{1-\varepsilon})$ per operation for any $\varepsilon > 0$ unless SETH is false.*

Our bound shows that we cannot hope to get incremental maximum flow in offline time as is the case for other problems. We note that the above result only holds for directed and weighted graphs. We show similar results for other types of graphs:

▶ **Theorem 4.** *There is no algorithm for solving incremental (or decremental) max st flow on unweighted directed graphs or weighted undirected graphs on n nodes with amortized time $O(n^{1-\varepsilon})$ per operation for any $\varepsilon > 0$ unless the OMv conjecture is false.*

This result follows directly from Theorem 2 by using textbook reductions from maximum bipartite matching to directed flow (see e.g. [15]) and from directed flow to undirected flow (see e.g. [23]).

Diameter. The diameter problem asks us to compute the longest shortest-path distance in a graph G. Efficiently computing or approximating the diameter is a basic problem in graphs [3, 9, 14, 16, 28]. One can trivially compute the diameter in the same time as computing APSP, however in general no better algorithm is known. It remains a major open problem whether a reduction exists in the other direction [3] – that is, can we compute all distances in the same time as the longest? One can, however, approximate the diameter faster. Roditty and Vassilevska Williams [28] showed how to compute a 3/2-approximation in time $\tilde{O}(m\sqrt{n})$ randomized, and Chechik et al. [14] showed how to obtain the same guarantee deterministically in time $\tilde{O}(\min(m^{3/2}, mn^{2/3}))$. More recently, it was shown by Cairo, Grossi and Rizzi [13] how to obtain a $(2 - \frac{1}{2^k})$-approximation in time $\tilde{O}(mn^{\frac{1}{k+1}})$. From a hardness perspective it is known that any algorithm able to distinguish between diameter 3 and 2 in time $O(m^{2-\varepsilon})$ for sparse graphs would refute SETH [28]. Chechik et al. [14] showed that approximating within a $4/3 - \varepsilon$ factor with additive error $\beta = O(m^{\delta})$ in time $O(m^{2-2\delta-\varepsilon'})$ for sparse graphs would also refute SETH, and this bound was improved in [13] to rule out any $3/2 - \varepsilon$ approximation with the same additive error and time bounds based on SETH (also for sparse graphs). From the perspective of dynamic algorithms Abboud and Vassilevska Williams [6] showed that any algorithm for $4/3 - \varepsilon$-approximating the diameter in a fully dynamic graph with amortized update time $O(m^{2-\varepsilon'})$ would refute SETH. We also

note, that the above static reductions rules out any $O(m^{1-\varepsilon'})$ amortized update time for incremental algorithms.

We note that all the reductions mentioned above are based on SETH. Similar to the work of [8, 4] we seek to replace this assumption by a weaker one. In this paper we show the first reduction from 3SUM and APSP to the diameter problem. That is, we show that a fast algorithm for approximating the diameter implies a faster algorithm for the APSP and 3SUM problems. The bounds we achieve are not as strong as the known bounds based on SETH [28, 14, 13], however they are based on a weaker conjecture and hold even if SETH turns out to be false, thus giving more credibility to the difficulty of the problem. For the partially dynamic case we show the following theorem:

▶ **Theorem 5.** *There exists no incremental (or decremental) algorithm that approximates the diameter of an unweighted graph within a factor of $4/3-\varepsilon$ running in amortized time $O(n^{1/2-\varepsilon'})$ for any $\varepsilon,\varepsilon'>0$ unless Conjecture 1 is false. Furthermore, if we allow node insertions in the incremental case the bound is $O(n^{0.618-\varepsilon'})$.*

In order to achieve the result for node insertions, we use the technique of Kopelowitz et al. [21] leveraging rollback with our standard incremental bound. By doing this we obtain a graph with fewer nodes and thus a better bound. More interestingly, we are able to generalize our results from the incremental case to the following result for static graphs:

▶ **Theorem 6.** *There exists no static $4/3-\varepsilon$ approximation to the diameter on unweighted graphs running in $O((n\sqrt{m})^{1-\varepsilon'})$ time for any $\varepsilon,\varepsilon'>0$ and any number of edges m unless Conjecture 1 is false.*

As mentioned, this is the first known reduction from APSP to diameter and shows at least some weak connection in this direction. An interesting property of Theorem 6 is that it holds *for any* m as a function of n and thus an algorithm need not exist *for all* m. As a corollary of Theorem 6 we see that no algorithm can $(4/3-\varepsilon)$-approximate the diameter of static unweighted graph in time $O(n^{2-\varepsilon'})$ for any ε,ε' unless Conjecture 1 is false. This is reminiscent of the bounds from [28, 14, 13], however not quite as strong as it does not hold for sparse graphs, for which we get a bound of $O(m^{3/2-\varepsilon'})$.

Similar to [14, 13] we also extend the above bound to the case of $(4/3-\varepsilon)$-approximations with additive error $O(m^\delta)$. We show the following

▶ **Corollary 7.** *There exists no static $4/3-\varepsilon$ approximation with additive error $O(m^\delta)$ with running time $O(m^{\frac{3}{2}(1-\delta)-\varepsilon'})$ or incremental/decremental algorithm with amortized time $O(m^{\frac{1}{2}-\frac{3\delta}{2}-\varepsilon'})$ for any $\varepsilon,\varepsilon'>0$ unless Conjecture 1 is false.*

1.4 A note on the decremental results and preprocessing

We will in general only describe the reductions in the incremental case and note that the decremental results are obtained by removing the edges in the reverse order of insertions. This requires an assumption on the beginning graph, and we will thus assume any suitable graph on $\tilde{O}(n)$ edges in the sparse case and the complete graph in the dense case.

Furthermore, we do not assume that any of the algorithms are allowed to preprocess the graph. It is often an assumption in the design of amortized partially dynamic algorithms that one starts with the empty (or complete) graph in order for the analysis to work. Thus, our results hold for this case.

2 Preliminaries

Notation. Throughout the paper we assume that matrices are boolean. Thus the output of a vector-matrix-vector multiplication will always be a single bit. We use $[n]$ to denote the set $\{0, \ldots, n-1\}$.

Online vector-matrix-vector multiplication. We will consider the online vector-matrix-vector multiplication problem of [17]:

▶ **Definition 8** (OuMv problem [17]). Let M be a binary $n \times n$ matrix than can be preprocessed. After preprocessing n vector pairs $(u^1, v^1), \ldots, (u^n, v^n)$ arrive one at a time and the task is to compute $(u^i)^T M v^i$ before being presented with the $i+1$th vector pair for every i.

In [17] they showed that the OMv problem can be reduced to the OuMv problem. They also came up with the following conjecture:

▶ **Conjecture 9** ([17]). *There is no algorithm for the OMv problem (and thus the OuMv problem) running in time $O(n^{3-\varepsilon})$ for any $\varepsilon > 0$.*

Triangle collection. We will also consider the triangle collection problem of [8]:

▶ **Definition 10** (Triangle collection [8]). Given a node-colored graph G, is it true that for every triplet of colors a, b, c there exists a triangle (u, v, w) in G where u has color a, v has color b and w has color c?

In fact, we will consider the more structured triangle collection* (TC*) problem which they also used in [8]

▶ **Definition 11** (Triangle collection* [8]). Let n, Δ, p be parameters and let G be an undirected node-colored tripartite graph with partitions A, B, C. Let G be any graph with the following structure:

- Each partition has its own n colors and we denote these by the numbers of $[n]$ for each partition.
- A contains nodes of the form a^i_j, where $i \in [n]$ is the color of the node and $j \in [\Delta]$.
- B and C contains nodes of the form $b^i_{j,x}$ and $c^i_{j,x}$ where $i \in [n]$ is the color of the node and $j \in [\Delta], x \in [p]$.

And the edges of G are as follows:

- For each $i, i' \in [n]$ and $j \in [\Delta]$ there is an edge from a^i_j to $b^{i'}_{j,x}$ for *exactly one* x. Similarly there is an edge from a^i_j to $c^{i'}_{j,y}$ for exactly one y (note that y and x need not be the same for the same j and i').
- There may be an edge between nodes $b^i_{j,x}$ and $c^{i'}_{j',y}$ *only if* $j = j'$.

We ask the following question: Does there exist a triple of colors (one color per partition) such that G does not contain a triangle with these colors?

In [8] it was shown that this problem does not have a truly subcubic algorithm unless Conjecture 1 is false.

It will be important that the reductions from these problems to TC* hold even when Δ and p are bounded by polylog(n).

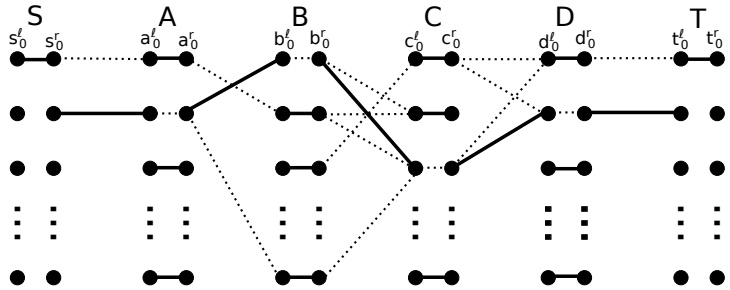

Figure 1 Reduction to incremental maximum matching.

3 Incremental maximum matching

We will reduce from the OuMv problem of Definition 8. Observe that the OuMv problem is equivalent to the following statement: For each vector pair u^i, v^i determine whether indices j, k exist, such that $u^i_j = v^i_k = M_{jk} = 1$. In order to model this as an incremental maximum matching problem we construct the following graph: Create 6 copies of $2n$ nodes and name these S, A, B, C, D, T. Partition A into n pairs of nodes $a^\ell_1, a^r_1, \ldots, a^\ell_n, a^r_n$. Do the same for S, B, C, D, T. Add the edges (a^ℓ_i, a^r_i) for each i and do the same for B, C, D. Now for each i, j add the edge (b^r_i, c^ℓ_j) if $M_{ij} = 1$. Observe that this graph has a unique maximum matching each (ℓ, r) pair. Observe also that the graph is bipartite. Now we do the following n phases – one for each u^i, v^i vector pair.

1. For each j such that $u^i_j = 1$ add the edge (a^r_i, b^ℓ_j).
2. For each j such that $v^i_j = 1$ add the edge (c^r_j, d^ℓ_i).
3. Add the edges (s^r_i, a^ℓ_i) and (d^r_i, t^ℓ_i).
4. Query the size of a maximum matching.
5. Add the edges (s^ℓ_i, s^r_i) and (t^ℓ_i, t^r_i).

This is illustrated in Figure 1.

▶ **Lemma 12.** *Let the setting be as above and let the phases be numbered* $0, 1, \ldots, n-1$. *Then the size of the maximum matching during the* i*th phase is exactly* $4n + 2i + 1$ *if the resulting vector-matrix-vector product is* 1 *and* $4n + 2i$ *otherwise.*

Proof. Note that prior to any of the i phases the size of the maximum matching is exactly $4n + 2i$, which is also a perfect matching of the graph induced by the edges. To see this observe that each $s^\ell_0, \ldots, s^\ell_{i-1}$ must be matched to its corresponding $s^r_0, \ldots, s^r_{i-1}$, and this is the only edge incident to the ℓ-nodes. As a consequence of this, each a^ℓ_j must be matched with a^r_j, and so on.

Now consider the ith phase. Adding any edge (a^r_i, b^ℓ_j) or (c^r_j, d^ℓ_i) cannot increase the size of the maximum matching, as the size of the subgraph induced by the edges of the graph does not increase – i.e. all nodes with edges incident to them are already matched.

Assume that adding the edges (s^r_i, a^ℓ_i) and (t^ℓ_i, d^r_i) increases the matching. The matching can increase by at most 1, as only two more nodes can be matched. Furthermore the matching must now contain edges as follows

$$(s^r_i, a^\ell_i), (a^r_i, b^\ell_j), (b^r_j, c^\ell_k), (c^r_k, d^\ell_x), (d^r_x, t^\ell_y) \ .$$

Now observe that each t^ℓ_y for $y < i$ *must* be matched to t^r_y, as the right nodes have no other incident edges and all nodes have to be matched for the size of the matching to increase.

Thus we must have $y = i$ in the list above, but this means that we have exactly found a pair j, k such that $u_j^i = v_k^i = M_{jk} = 1$ and the vector-matrix-vector product is thus 1.

Conversely, assume that the vector-matrix-vector product is 1, then such an index pair j, k must exist and we can find the following matching of size $4n + 2i + 1$: Match the edges

$$(s_i^r, a_i^\ell), (a_i^r, b_j^\ell), (b_j^r, c_k^\ell), (c_k^r, d_i^\ell), (d_i^r, t_i^\ell) \ .$$

For all $x < i$ add the edges (s_x^ℓ, s_x^r) and (t_x^ℓ, t_x^r) to the matching. For all $x \neq i$ add the edges (a_x^ℓ, a_x^r) and (d_x^ℓ, d_x^r) to the matching. And for all $x \neq j$ and $y \neq k$ add the edges (b_x^ℓ, b_x^r) and (c_y^ℓ, c_y^r) to the matching. This matches all nodes incident to an edge and has size $4n + 2i + 1$. This is also exactly the matching illustrated in Figure 1 for $i = 1$. ◀

It follows from Lemma 12 that we can solve the OuMv problem correctly via this reduction. The reduction creates a graph with $O(n)$ nodes and $O(n^2)$ edges. We perform $O(n^2)$ insertions and $O(n)$ queries giving the result in Theorem 2

4 Maximum flow

In order to show Theorem 3 we will use a similar graph construction as have been used numerous times before [27, 28, 14, 6]: First partition the variables of the SAT problem into two groups A and B of $n/2$ variables each. For each possible assignment to the variables in A we create a node in our graph G (and likewise for B). Furthermore, for each clause of the SAT formula, we create a node as well. We denote the corresponding sets of nodes by A, B, C. Set $N = 2^{n/2} = |A| = |B|$. For each pair of nodes $a \in A, c \in C$ we add the directed edge (a, c) with capacity N if the partial assignment a *does not* satisfy the clause c. Similarly, for each pair of nodes $b \in B, c \in C$ we add the directed edge (c, b) with capacity 1 if b does not satisfy c. Finally we add two nodes s, t and add edges (b, t) with capacity 1 for each $b \in B$.

We now continue in phases with a phase for each $a \in A$. Denote these nodes by $a_1, a_2, \ldots, a_N$:

1. Add the edge (s, a_i) with capacity N.
2. Query the maximum flow between s and t.
3. Add the edge ("shortcut") (a_i, t) with capacity N.

▶ **Lemma 13.** *Let the setup be as described above. If the st flow returned during any of the i phases is $< i \cdot N$, then the SAT formula is satisfiable. Otherwise the formula is not satisfiable.*

Proof. Observe, that prior to the ith phase, the flow is exactly $(i-1) \cdot N$, as we can use the paths $(s, a_j), (a_j, t)$ for each $j < i$, which has capacity N and exactly $(i-1) \cdot N$ flow leaves s.

Now assume that the partial formula corresponding to a_i can be completed to a satisfying assignment. In this case, there must be some node $b \in B$, for which there is no path from a_i to b. This follows because such a path has to go through a node $c \in C$, but then both a_i and b do not satisfy the clause c, which is a contradiction. However, the only way to send flow from a_i to t is through the nodes $b \in B$ and thus it is not possible to send all N units of flow from a_i to t.

Now assume that the flow is $< i \cdot N$, then there must be some $b \in B$ such that there is no path from a_i to b. Otherwise, we could route N units of flow from a_i to t via the nodes of B and the remaining $(i-1) \cdot N$ units through the "shortcuts". It now follows that a_i and b together satisfy all clauses (otherwise there would be a path) and thus the CNF formula is satisfiable.

Since this is true for all of the i phases, the statement of the lemma follows. ◀

As a consequence of Lemma 13 we may use the above procedure to solve the given SAT problem. By the sparsification lemma of [19] it follows that we can assume the graph has $O(N)$ nodes and $\tilde{O}(N)$ edges and we perform a total of $\tilde{O}(N)$ insertions and queries. The result of Theorem 3 thus follows directly.

5 Diameter

In this section we show how to obtain conditional lower bounds for the problem of approximating the diameter of an unweighted graph within a factor of $4/3 - \varepsilon$.

5.1 A graph construction

We will first describe the graph structure we use.

▶ **Definition 14.** Let G be an instance of the TC* problem as defined above. We will define the graph $H_{\gamma,k}(G)$. The idea is that $H_{\gamma,k}(G)$ "corresponds" to the colors $\{kn^\gamma, \dots, (k+1)n^\gamma - 1\}$ of A. Thus k is a number in $[n^{1-\gamma}]$. The nodes of this graph are as follows:

- The nodes B and C of G.
- For each color $i \in \{kn^\gamma, (k+1)n^\gamma - 1\}$ of A we add the nodes $a^i_0, \dots, a^i_{n-1}$ and $t^i_0, \dots, t^i_{n-1}$.
- We also add several special nodes: A "master node" u, n^γ "skip nodes" v_i and three "connector nodes" w_1, w_2, w_3.

For a color $i \in \{kn^\gamma, (k+1)n^\gamma - 1\}$ we denote the nodes $a^i_0, \dots a^i_{n-1}$ by A_i and the collection of all A_is by A. We do the same for T_i and T.

The edges of $H_{\gamma,k}(G)$ are as follows:

- Add the edges between B and C in G.
- Connect the node w_1 to each node of A and w_2.
- Connect w_2 to each node of B and C as well as w_3 and the master node u.
- Connect w_3 to each node of T.
- Connect u to all nodes v_i.
- For each $i \in \{kn^\gamma, (k+1)n^\gamma - 1\}$ do as follows:
  - Connect v_i to all nodes of $T \setminus T_i$ and to all nodes of A_i.
  - For each $i' \in [n]$ and each edge $(a^i_j, b^{i'}_{j,x}) \in G$ add the edge $(a^i_{i'}, b^{i'}_{j,x})$.
  - For each $i' \in [n]$ and each edge $(a^i_j, c^{i'}_{j,x}) \in G$ add the edge $(c^{i'}_{j,x}, t^i_{i'})$.

An overview of the graph $H_{\gamma,k}(G)$ is illustrated in Figure 2 and a more detailed view in Figure 3.

The idea is that length three paths between A_i and T_i correspond to triangles in G containing the color i of A. Each of the n nodes in A_i thus correspond to picking a color from B and each of the n nodes in T_i correspond to picking a color from C. If two such nodes don't have a length three path there is no triangle in G of the corresponding triplet of colors. In this case the connector nodes ensure that there is a length four path between the nodes. The master and skip nodes ensure that all other nodes have distance at most 3. This is captured by the following lemma:

▶ **Lemma 15.** *Let G be an instance to the TC* problem and let $H_{\gamma,k}(G)$ be as defined above. Let $i \in \{kn^\gamma, (k+1)n^\gamma - 1\}$ be a color of A and let $\alpha, \beta \in [n]$ be colors of B and C respectively. Then the distance from a^i_α to t^i_β in $H_{\gamma,k}(G)$ is 3 if the colors i, α, β have a triangle in G and 4 otherwise.*

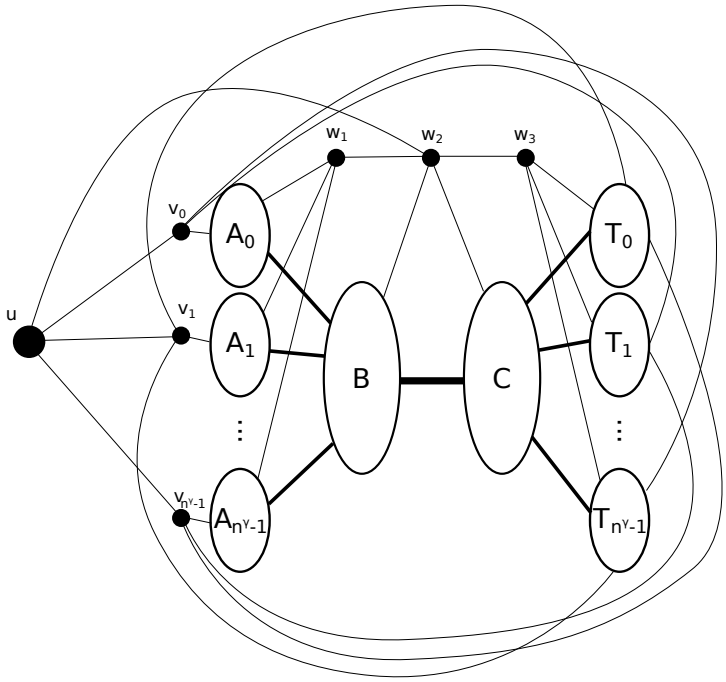

Figure 2 Diameter structure.

Proof. Assume first that there is a triangle $a^i_j, b^\alpha_{j,x}, c^\beta_{j,y}$ for some j in G (note that such a triangle can only occur if j is the same for all the three nodes). In this case there is a path $a^i_\alpha, b^\alpha_{j,x}, c^\beta_{j,y}, t^i_\beta$ in $H_{\gamma,k}(G)$ and thus the distance is at most 3. Observe also, that no node is connected to both A_i and T_i and thus the distance is strictly greater than 2.

Now assume that the distance from a^i_α to t^i_β is 3. Such a path has to go from A_i to B to C to T_i as any node w_ℓ, v_ℓ or u either has distance 3 to one of a^i_α or t^i_β or it has distance 2 to both of them. Now consider a shortest path $a^i_\alpha, b, c, t^i_\beta$, where b and c are the nodes of B and C on this path. Clearly the node b must have color α in G as it would not have an edge to a^i_α otherwise, and similarly c must have color β in G. Thus the path consists of nodes $a^i_\alpha, b^\alpha_{j,x}, c^\beta_{j',y}, t^i_\beta$. Since no edge in G goes between nodes with different j-values we must have $j' = j$. It is now clear that the edge $(a^i_\alpha, b^\alpha_{j,x})$ corresponds to the edge $(a^i_j, b^\alpha_{j,x})$ in G and the edge $(c^\beta_{j,y}, t^i_\beta)$ corresponds to the edge $(a^i_j, c^\beta_{j,y})$ in G. Thus, these three nodes form a triangle of the correct color triple in G. ◀

Furthermore it is easy to see that the longest distance in $H_{\gamma,k}(G)$ is at most 4, thus the diameter is 4 exactly when one of the corresponding color triplets do not have a triangle in G and 3 otherwise.

5.2 Dynamic

We will first consider the problem without node additions. For simplicity we only consider the incremental case and note that the decremental case follows by deleting edges until we obtain the same graph[2].

[2] Under the assumption that the algorithm starts with some suitable graph

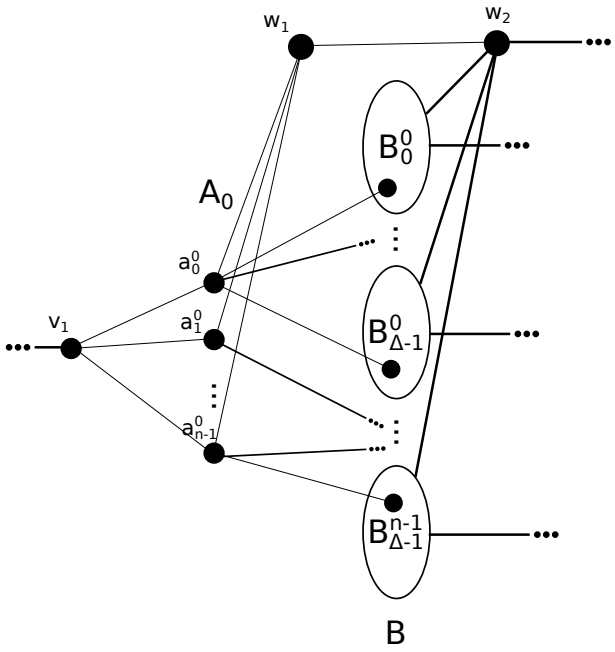

Figure 3 Diameter structure.

Given an instance to the TC* problem we create the graph $H_{1,0}(G)$ (that is, the graph representing all colors of A). This graph is created by adding edges incrementally and has $\tilde{O}(n^2)$ nodes and edges. It follows that an edge insertion must take $n^{1/2-o(1)}$ time unless Conjecture 1 is false.

Next, we consider the problem with node additions. It was shown in [21] that if we allow node additions in the problem of incremental maximum matching, it is possible to show stronger lower bounds by leveraging the amortized running time with the widely used rollback technique. We here apply the same argument to the problem of incremental diameter approximation.

The goal is again to construct (a subgraph of) $H_{1,0}(G)$ but we do not start with all nodes in the graph. We will assume that the amortized running time of an insert operation is n^α for some α. The goal is to get a bound on α by expressing the total running time in terms of α and using the assumption on running time for TC*. We let $\hat{n}$ denote the current number of nodes in the graph G. We continue as follows:

1. Insert all nodes of B and C into the dynamic graph. Also insert the nodes w_1, w_2, w_3 and u. We also insert all the edges induced by these nodes in $H_{1,0}(G)$ into the graph.
2. For each color $i \in [n]$ of A we do a phase:
   - We insert the nodes of A_i, T_i, v_i into the dynamic graph and all the edges induced by these nodes and the current state of the dynamic graph in $H_{1,0}(G)$.
   - Query the diameter of the graph.
   - Assume we inserted k edges+nodes in this phase. If the total running time of all these insertions was greater than $2k\hat{n}^\alpha$ we keep the nodes in the graph. Otherwise we rollback all operations of this phase.

We answer the question of the TC* problem according to whether the diameter was 3 all the time or not similar to the proof of the case without node additions.

The goal is now to bound α by using the method of [21]. We will do this by carefully

counting the number of "amortized credit units" the data structure has and using this to bound the total number of nodes added to the graph (i.e. not rolled back).

Observe that after the first step, we have added $\tilde{O}(n^2)$ edges to the graph and $\tilde{O}(n)$ nodes. Thus the data structure has at most $\tilde{O}(n^{2+\alpha})$ credit at this point (this happens if almost all operations were $O(1)$). Now consider the total time spent by the algorithm. This can be bounded by $\tilde{O}(n^2 \cdot N^\alpha)$ where N is the number of nodes at the end of all phases. This is the case since $N \geq N_0$, where $N_0 = \tilde{O}(n)$ is the number of nodes after the first step and there are at most $\tilde{O}(n^2)$ total operations. Note that this would not be the case if we did not have a bound on the cost of the rolled back operations, but we only rollback the cheap operations, so this is okay. We wish to express N in terms of n and α in order to express the total running time in terms of these.

Observe, that every time we keep the added nodes in the graph, the data structure spent at least twice the amortized cost. Since we started out with $\tilde{O}(n^{2+\alpha})$ credit it must be true that

$$\sum_{i=N_0}^{N} i^\alpha \leq \text{cost of non-rollbacked operations} = \tilde{O}(n^{2+\alpha}) \ .$$

The worst case is if N is polynomially larger than N_0, and thus $\sum_{i=N_0}^{N} i^\alpha = \Omega(N^{1+\alpha})$. It follows that $N = \tilde{O}(n^{\frac{2+\alpha}{1+\alpha}})$. Thus the total running time is $\tilde{O}(n^2 \cdot n^{\frac{2+\alpha}{1+\alpha}\alpha})$. Now, by Conjecture 1 we must have $\frac{2+\alpha}{1+\alpha}\alpha = 1 - o(1)$. Solving this for α gives $\alpha = \frac{\sqrt{5}-1}{2} < 0.618$.

5.3 Static

Proof of Theorem 6. Let G be an instance of the TC* problem with parameters n, Δ, p with Δ and p bounded by $\tilde{O}(1)$ and $m = \tilde{O}(n^2)$ as in [8].

For a parameter $0 < \gamma \leq 1$ we create the graphs $H_{\gamma,0}(G), \ldots, H_{\gamma,n^{1-\gamma}-1}(G)$ and solve the diameter problem on these graphs up to a $4/3 - \varepsilon$ approximation. This is sufficient to distinguish between diameters 4 and 3 in all of the graphs. Now, if the diameter is 4 in just one of the graph we answer that there exists a triplet of colors such that there is no triangle in G. This follows from Lemma 15.

We note that the graphs $H_{\gamma,k}(G)$ each have $N = \tilde{O}(n^{1+\gamma})$ nodes and $M = \tilde{O}(n^2)$ edges. Assume now that that any algorithm approximating the diameter within a factor of $4/3 - \varepsilon$ in time $O(N\sqrt{M}^{1-\varepsilon'}) = O(n^{2+\gamma-\varepsilon'})$ for any $\varepsilon, \varepsilon' > 0$ exists. Since we create $n^{1-\gamma}$ instances of the problem this would imply an $O(n^{3-\varepsilon''})$ algorithm for the TC* problem for some $\varepsilon'' > 0$. ◀

5.4 Additive error

To see Corollary 7 we fix m^α and consider TC* on a graph G with N nodes and $M = \tilde{O}(N^2)$ edges such that $M = m^{1-\alpha}$. We then create $H_{1,0}(G)$ and subdivide each edge into m^α nodes. This graph now has m nodes and edges and any algorithm solving $4/3 - \varepsilon$ diameter with additive error $O(m^\alpha)$ in time $M^{3/2-\varepsilon'} = m^{\frac{3}{2}(1-\alpha)-\varepsilon''}$ time thus violates Conjecture 1.

Abstract

We present an algorithm that can update the 2-edge-connected blocks of a directed graph with n vertices through a sequence of m edge insertions in a total of $O(mn)$ time. After each insertion, we can answer the following queries in asymptotically optimal time:

- Test in constant time if two query vertices v and w are 2-edge-connected. Moreover, if v and w are not 2-edge-connected, we can produce in constant time a "witness" of this property, by exhibiting an edge that is contained in all paths from v to w or in all paths from w to v.
- Report in $O(n)$ time all the 2-edge-connected blocks of G.

This is the first dynamic algorithm for 2-connectivity problems on directed graphs, and it matches the best known bounds for simpler problems, such as incremental transitive closure.

1 Introduction

A dynamic graph algorithm aims at updating efficiently the solution of a problem after an update, such as an edge insertion or an edge deletion, faster than recomputing it from scratch. A problem is said to be *fully dynamic* if the update operations include both insertions and deletions of edges, and it is said to be *partially dynamic* if only one type of update, either insertions or deletions, is allowed. More specifically, a problem is said to be *incremental* (resp., *decremental*) if only insertions (resp., deletions) are allowed. In this paper, we present new incremental algorithms for 2-edge connectivity problems on directed graphs (digraphs). Before defining the problem, we first review some definitions. Let $G = (V, E)$ be a digraph. G is *strongly connected* if there is a directed path from each vertex to every other vertex. The *strongly connected components* (in short *SCC's*) of G are its maximal strongly connected subgraphs. Vertices $u, v \in V$ are *strongly connected* if they are in the same SCC of G. An edge of G is a *strong bridge* if its removal increases the number of SCC's. Let G be strongly connected: G is 2-*edge-connected* if it has no strong bridges. The 2-*edge-connected components* of G are its maximal 2-edge-connected subgraphs. Vertices $u, v \in V$ are said to

be 2-*edge-connected*, denoted by $u \leftrightarrow_{2e} v$, if there are two edge-disjoint directed paths from u to v and two edge-disjoint directed paths from v to u. A 2-*edge-connected block* of a digraph $G = (V, E)$ is a maximal subset $B \subseteq V$ such that $u \leftrightarrow_{2e} v$ for all $u, v \in B$ (see Figure 1).

We remark that in digraphs 2-connectivity has a much richer and more complicated structure than in undirected graphs. To see this, observe that, while in undirected graphs blocks are exactly the same as components, in digraphs there is a substantial difference between those two notions. In particular, two vertices that are 2-edge-connected (i.e., in the same 2-edge-connected block) may lie in different 2-edge-connected components (e.g., vertices i and j in Figure 1, each of them being in a 2-edge-connected component by itself). As a result, 2-connectivity problems on digraphs appear to be much harder than on undirected graphs. For undirected graphs it has been known for over 40 years how to compute 2-edge- and 2-vertex- connected components in linear time [33]. For digraphs, however, only $O(mn)$ algorithms were known (see e.g., [25, 26, 28, 30]). It was shown only recently how to compute the 2-edge- and 2-vertex- connected blocks in linear time [13, 14], and the best current bound for computing the 2-edge- and the 2-vertex- connected components is $O(n^2)$ [18].

Our Results. We initiate the study of the dynamic maintenance of 2-edge-connectivity relationships in directed graphs. We present an algorithm that can update the 2-edge-connected blocks of a digraph G with n vertices through a sequence of m edge insertions in a total of $O(mn)$ time. After each insertion, we can answer the following queries in asymptotically optimal time:

- Test in constant time if two query vertices v and w are 2-edge-connected. Moreover, if v and w are not 2-edge-connected, we can produce in constant time a "witness" of this property, by exhibiting an edge that is contained in all paths from v to w or in all paths from w to v.
- Report in $O(n)$ time all the 2-edge-connected blocks of G.

Ours is the first dynamic algorithm for 2-connectivity problems on digraphs, and it matches the best known bounds for simpler problems, such as incremental transitive closure [23]. This is a substantial improvement over the $O(m^2)$ simple-minded algorithm, which recomputes the 2-edge-connected blocks from scratch after each edge insertion.

Related Work. Many efficient algorithms for several dynamic graph problems have been proposed in the literature, including dynamic connectivity [20, 22, 31, 37], minimum spanning trees [8, 11, 21, 22], edge/vertex connectivity [8, 22] on undirected graphs, and transitive closure [7, 19, 27] and shortest paths [6, 27, 38] on digraphs. Once again, dynamic problems on digraphs appear to be harder than on undirected graphs. Indeed, most of the dynamic algorithms on undirected graphs have polylog update bounds, while dynamic algorithms on digraphs have higher polynomial update bounds. The hardness of dynamic algorithms on digraphs has been recently supported also by conditional lower bounds [1].

Our Techniques. Known algorithms for computing the 2-edge-connected blocks of a digraph G [13, 16] hinge on properties that seem very difficult to dynamize. The algorithm in [13] uses very complicated data structures based on 2-level auxiliary graphs. The loop nesting forests used in [16] depends heavily on an underlying dfs tree of the digraph, and the incremental maintenance of dfs trees on general digraphs is still an open problem (incremental algorithms are known only for the special case of DAGs [10]). Despite those inherent difficulties, we find a way to bypass loop nesting forests by suitably combining the approaches in [13, 16] in a novel framework, which is amenable to dynamic implementations. Another complication is that, although our problem is incremental, strong bridges may not only be deleted but also added (when a new SCC is formed). As a result, our data structures undergo a fully dynamic repertoire of updates, which is known to be harder. By organizing carefully those updates, we are still able to obtain the desired bounds. For lack of space, some technical details and proofs are omitted from this extended abstract and will be given in the full paper.

2 Dominator trees and 2-edge-connected blocks

Given a rooted tree, we denote by $T(v)$ the subtree of T rooted at v (we also view $T(v)$ as the set of descendants of v). Given a digraph $G = (V, E)$, and a set of vertices $S \subseteq V$, we denote by $G[S]$ the subgraph induced by S. We introduce next some of the building blocks of our new incremental algorithm.

Flow graphs, dominators, and bridges. A *flow graph* is a digraph with a distinguished *start vertex* s such that every vertex is reachable from s. Let $G = (V, E)$ be a strongly connected graph. The *reverse digraph* of G, denoted by $G^R = (V, E^R)$, is obtained by reversing the direction of all edges. Let s be a fixed but arbitrary start vertex of a strongly connected digraph G. Since G is strongly connected, all vertices are reachable from s and reach s, so we can view both G and G^R as flow graphs with start vertex s. To avoid ambiguities, throughout the paper we will denote those flow graphs respectively by G_s and G_s^R. Vertex u is a *dominator* of vertex v (u *dominates* v) in G_s if every path from s to v in G_s contains u. The dominator relation can be represented by a tree D rooted at s, the *dominator tree* of G_s: u dominates v if and only if u is an ancestor of v in D. For any $v \neq s$, we denote by $d(v)$ the parent of v in D. Similarly, we can define the dominator relation in the flow graph G_s^R, and let D^R denote the dominator tree of G_s^R, and $d^R(v)$ the parent of v in D^R. Dominators and dominator trees can be computed in linear time [2, 5, 9, 12]. An edge (u, v) is a *bridge* of a flow graph G_s if all paths from s to v include (u, v).[1] Let s be an arbitrary start vertex of G.

[1] Throughout the paper, to avoid confusion we use consistently the term *bridge* to refer to a bridge of a flow graph and the term *strong bridge* to refer to a strong bridge in the original graph.

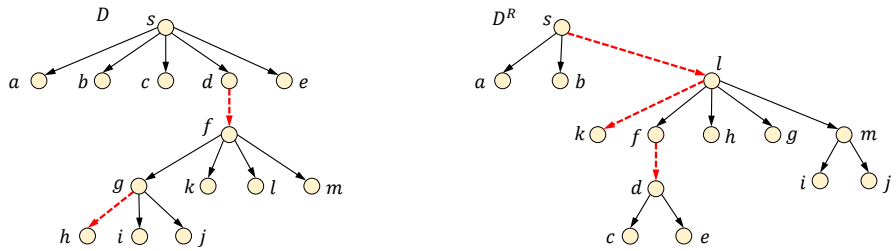

Figure 2 The dominator trees of flow graphs G_s and G_s^R. Strong bridges of G are shown red and dashed. (Better viewed in color.)

As shown in [24], an edge $e = (u, v)$ is strong bridge of G if and only if it is either a bridge of G_s or a bridge of G_s^R.

As a consequence, all the strong bridges of G can be obtained from the bridges of the flow graphs G_s and G_s^R, and thus there can be at most $2(n-1)$ strong bridges overall. Figure 2 illustrates the dominator trees D and D^R of the flow graphs G_s and G_s^R that correspond to the strongly connected digraph G of Figure 1. After deleting from the dominator trees D and D^R respectively the bridges of G_s and G_s^R, we obtain the *bridge decomposition* of D and D^R into forests $\mathcal{D}$ and $\mathcal{D}^R$. Throughout the paper, we denote by D_u (resp., D_u^R) the tree in $\mathcal{D}$ (resp., $\mathcal{D}^R$) containing vertex u, and by r_u (resp., r_u^R) the root of D_u (resp., D_u^R). The following lemma from [13] holds for a flow graph G_s of a strongly connected digraph G (and hence also for the flow graph G_s^R of G^R).

▶ **Lemma 1** ([13]). *Let G be a strongly connected digraph and let (u, v) be a strong bridge of G. Also, let D be the dominator tree of the flow graph G_s, for an arbitrary start vertex s. Suppose $u = d(v)$. Let w be any vertex that is not a descendant of v in D. Then there is path from w to v in G that does not contain any proper descendant of v in D. Moreover, all simple paths in G from w to any descendant of v in D must contain the edge $(d(v), v)$.*

Lemma 1 gives an initial partition of the vertices of G into subsets that contain the 2-edge-connected blocks of G. That is, for any two vertices u and v, we have $u \leftrightarrow_{2e} v$ only if u and v are in the same trees in the forests $\mathcal{D}$ and $\mathcal{D}^R$ (i.e., $r_u = r_v$ and $r_u^R = r_v^R$).

Loop nesting forests and bridge-dominated components. Let G be a digraph. A *loop nesting forest* represents a hierarchy of strongly connected subgraphs of G [35], defined with respect to a dfs tree T of G, as follows. For any vertex u, $loop(u)$ is the set of all descendants x of u in T such that there is a path from x to u in G containing only descendants of u in T. Any two vertices in $loop(u)$ reach each other. Therefore, $loop(u)$ induces a strongly connected subgraph of G; it is the unique maximal set of descendants of u in T (that includes u) that does so. The $loop(u)$ sets form a laminar family of subsets of V: for any two vertices u and v, $loop(u)$ and $loop(v)$ are either disjoint or nested. The *loop nesting forest* H of G, with respect to T, is the forest in which the parent of any vertex v, denoted by $h(v)$, is the nearest proper ancestor u of v in T such that $v \in loop(u)$ if there is such a vertex u, and null otherwise. Then $loop(u)$ is the set of all descendants of vertex u in H, which we will also denote as $H(u)$ (the subtree of H rooted at vertex u). A loop nesting forest can be computed in linear time [5, 35]. Since we deal with strongly connected digraphs, each vertex is contained in a loop, so H is a tree. Therefore, we will refer to H as the *loop nesting tree* of G. Let $e = (u, v)$ be a bridge of the flow graph G_s, and let $G[D(v)]$ denote the

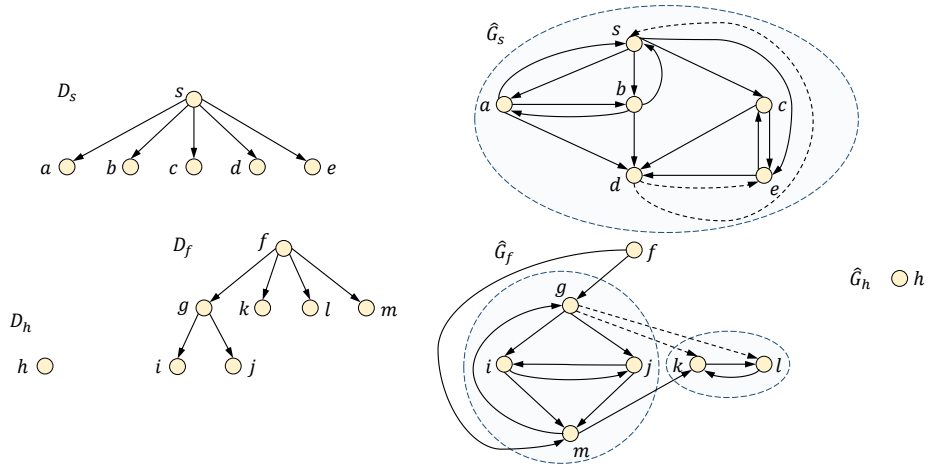

Figure 3 The bridge decomposition of the dominator tree D of Figure 2, the corresponding auxiliary graphs $\widehat{G}_r$ (the auxiliary edges are shown dashed) and their SCC's shown encircled.

subgraph induced by the vertices in $D(v)$. Let C be an SCC of $G[D(v)]$: we say that C is an *e-dominated component* of G. We also say that $C \subseteq V$ is a *bridge-dominated component* if it is an e-dominated component for some bridge e: it can be shown that bridge-dominated components form a laminar family. Let $e = (u, v)$ be a bridge of G_s, and let w be a vertex in $D(v)$ such that $h(w) \notin D(v)$. As shown in [16], $H(w)$ induces an SCC in $G[D(v)]$, and thus it is an e-dominated component.

Bridge decomposition and auxiliary graphs. Now we define a notion of *auxiliary graphs* that play a key role in our approach. Auxiliary graphs were defined in [13] to decompose the input digraph G into smaller digraphs (not necessarily subgraphs of G) that maintain the original 2-edge-connected blocks of G. Unfortunately, the auxiliary graphs of [13] are not suitable for our purposes, and we need a slightly different definition. For each root r of a tree in the bridge decomposition $\mathcal{D}$ we define the *auxiliary graph* $\widehat{G}_r = (V_r, E_r)$ *of* r as follows. The vertex set V_r of $\widehat{G}_r$ consists of all the vertices in D_r. The edge set E_r contains all the edges of G among the vertices of V_r, referred to as *ordinary* edges, and a set of *auxiliary* edges, which are obtained by contracting vertices in $V \setminus V_r$, as follows. Let v be a vertex in V_r that has a child w in $V \setminus V_r$. Note that (v, w) is a bridge and w is a root in the bridge decomposition $\mathcal{D}$ of D. For each such child w of v, we contract w and all its descendants in D into v. Figure 3 shows the bridge decomposition of the dominator tree D and the corresponding auxiliary graphs. Differently from [13], our auxiliary graphs do not preserve the 2-edge-connected blocks of G. Note that each vertex appears exactly in one auxiliary graph. Furthermore, each original edge corresponds to at most one auxiliary edge. Therefore, the total number of vertices in all auxiliary graphs is n, and the total number of edges is at most m. We use the term *auxiliary components* to refer to the SCC's of the auxiliary graphs.

▶ **Lemma 2.** *All the auxiliary graphs of a flow graph G_s can be computed in linear time.*

A new algorithm for 2-edge-connected blocks. We next sketch a new linear-time algorithm to compute the 2-edge-connected blocks that combines ideas from [13] and [16] and that will be useful for our incremental algorithm. We refer to this algorithm as the 2ECB labeling algorithm. Similarly to [16], our algorithm assigns a label to each vertex, so that two vertices

are 2-edge-connected if and only if they have the same label. The labels are defined by the bridge decomposition of the dominator trees and by the auxiliary components, as follows. Let $\widehat{G}_r$ be an auxiliary graph of G_s. We pick a *canonical vertex* for each SCC C of $\widehat{G}_r$, and denote by c_x the canonical vertex of the SCC that contains x. We define c_x^R for the SCC's of the auxiliary graphs of G_s^R analogously. We define the label of x as $label(x) = \langle r_x, c_x, r_x^R, c_x^R \rangle$.

▶ **Lemma 3.** *Let x and y be any vertices of G. Then, x and y are 2-edge-connected if and only if $label(x) = label(y)$.*

▶ **Theorem 4.** *The 2ECB labeling algorithm computes the 2-edge-connected blocks of a strongly connected digraph in linear time.*

Incremental dominators and incremental SCC's. We will use two other building blocks for our new algorithm, namely incremental algorithms for maintaining dominator trees and SCC's. As shown in [15], the dominator tree of a flow graph with n vertices can be maintained in $O(m \min\{n, k\} + kn)$ time during a sequence of k edge insertions, where m is the total number of edges after all insertions. For maintaining the SCC's of a digraph incrementally, Bender et al. [4] presented an algorithm that can handle the insertion of m edges in a digraph with n vertices in $O(m \min\{m^{1/2}, n^{2/3}\})$ time. Since we aim at an $O(mn)$ bound, we maintain the SCC's with a simpler data structure based on topological sorting [29], augmented so as to handle cycle contractions, as suggested by [17]. We refer to this data structure as IncSCC, and we will use it both for maintaing the SCC's of the input graph, and the auxiliary components (i.e., the SCC's of the auxiliary graphs). We maintain the SCC's and a topological order for them. Each SCC is represented by a canonical vertex, and the partition of the vertices into SCC's is maintained through a set union data structure [34, 36]. The data structure supports $unite(p, q)$, which, given canonical vertices p and q, merges the SCC's containing p and q into one new SCC and makes p the canonical vertex of the new SCC. It also supports $find(v)$, which returns the canonical vertex of the SCC containing v. Here we use the abbreviation $f(v)$ to stand for $find(v)$. The topological order is represented by a simple numbering scheme, where each canonical vertex is numbered with an integer in the range $[1, n]$, so that if (u, v) is an edge of G, then either $f(u) = f(v)$ (u and v are in the same SCC) or $f(u)$ is numbered less than $f(v)$ (when u and v are in different SCC's). With each canonical vertex p we store a list $out(p)$ of edges leaving vertices that are in the same SCC as p, i.e., edges (u, v) with $f(u) = p$. Note that $out(p)$ may contain multiple vertices in the same SCC (i.e., vertices u and v with $f(u) = f(v)$), due to the SCC contractions (and shortcut edges, in case of the auxiliary components) during edge insertions. Also, $out(p)$ may contain loops, that is, vertices v with $f(v) = p$. Each out list is stored as a doubly linked circular list, so that we can merge two lists and delete a vertex from a list in $O(1)$. When the incremental SCC data structure detects that a new SCC is formed, it locates the SCC's that are merged and chooses a canonical vertex for the new SCC. The IncSCC data structure can handle m edge insertions in a total of $O(mn)$ time.

3 Incremental 2-edge-connectivity in strongly connected digraphs

To maintain the 2-edge-connected blocks of a strongly connected digraph during edge insertions, we design an incremental version of the labeling algorithm of Section 2. In order to respond to the insertion of an edge, we have to update the vertex labels, so we need to update both the bridge decomposition of D and D^R, and the strongly connected components of the resulting auxiliary graphs. Note, in particular, that the second task involves moving

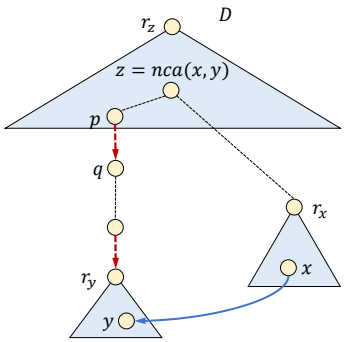

Figure 4 The bridge decomposition of D before the insertion of a new edge (x, y).

and merging vertices from one auxiliary graph to another. If labels are maintained explicitly, one can answer in $O(1)$ time queries on whether two vertices are 2-edge-connected, and report in $O(n)$ time all the 2-edge-connected blocks. Let (x, y) be the edge to be inserted. We say that vertex v is *affected* by the update if $d(v)$ (its parent in D) changes. Let $Dom(v)$ denote the set of all vertices that dominate v: note that $Dom(v)$ may change even if v is not affected. Similarly, an auxiliary component (resp., auxiliary graph) is affected if it contains an affected vertex.

We let $nca(x, y)$ denote the nearest common ancestor of x and y in the dominator tree D. We also denote by $D[u, v]$ the path from u to v in D. If $nca(x, y)$ and y are in different subtrees in the bridge decomposition of D before the insertion of the edge (x, y), we let (p, q) be the first bridge encountered on the path $D[nca(x, y), y]$ (Figure 4). We denote by $depth(v)$ the depth of vertex v in D. Most of the proofs in this section will be given in the full paper.

Affected vertices and canceled bridges. There are affected vertices after the insertion of (x, y) if and only if $nca(x, y)$ is not a descendant of $d(y)$ [32]. A characterization of the affected vertices is provided by the following lemma, which is a refinement of a result in [3].

▶ **Lemma 5.** ([15]) *A vertex v is affected after the insertion of edge (x, y) if and only if $depth(nca(x, y)) < depth(d(v))$ and there is a path π in G from y to v such that $depth(d(v)) < depth(w)$ for all $w \in \pi$. If v is affected, then it becomes a child of $nca(x, y)$ in D.*

The algorithm in [15] applies Lemma 5 to identify affected vertices by starting a search from y (if y is not affected, then no other vertex is). We assume that the outgoing and incoming edges of each vertex are maintained as linked lists, so that a new edge can be inserted in $O(1)$, and that the dominator tree D is represented by the parent function d. We also maintain the depth of vertices in D. We say that a vertex v is *scanned*, if the edges leaving v are examined during the search for affected vertices, and that it is *visited* if there is a scanned vertex u such that (u, v) is an edge in G. Every scanned vertex is either affected or a descendant of an affected vertex in D. By Lemma 5, a visited vertex v is scanned if $depth(nca(x, y)) < depth(d(v))$. Let (u, v) be a bridge of G_s. We say that (u, v) is *canceled* by the insertion of edge (x, y) if it is no longer a bridge after the insertion. We say that (u, v) is *locally canceled* if (u, v) is a canceled bridge and v is not affected. We need to treat the case of locally canceled bridges separately because in such an event the bridge decomposition of D changes, even if D remains the same. Note that if (u, v) is locally canceled, then $u = nca(x, y)$. In the next lemmata, we consider the effect of the insertion of edge (x, y) on

the bridges of G_s, and relate the affected and scanned vertices with the auxiliary components. Recall that (p, q) is the first bridge encountered on the path $D[nca(x, y), y]$ (Figure 4), $D(v)$ denotes the descendants of v in D, and $G[C]$ is the subgraph induced by the vertices in C.

▶ **Lemma 6.** *Suppose that bridge (p, q) is not locally canceled after the insertion of (x, y). Let $z = nca(x, y)$ and let v be an affected vertex such that $r_v \neq r_z$. All vertices reachable from v in $G[D(q)]$ are either affected or scanned.*

▶ **Lemma 7.** *Let $e = (u, v)$ be a bridge of G_s that is canceled by the insertion of edge (x, y). Then (i) y is a descendant of v in D, and (ii) y is in the same e-dominated component as v.*

▶ **Corollary 8.** *A bridge $e = (u, v)$ of G_s is canceled by the insertion of edge (x, y) if and only if $depth(nca(x, y)) \leq depth(u)$ and there is a path π in G from y to v such that $depth(u) < depth(w)$ for all $w \in \pi$.*

By Corollary 8, we can use the incremental algorithm of [15] to detect canceled bridges, without affecting the $O(mn)$ bound. Indeed, suppose $e = (u, v)$ is a canceled bridge. By Lemma 7, y is a descendant of v in D and in the same e-dominated component as v. Hence, v will be visited by the search from y. If a bridge (u, v) is locally canceled, there can be vertices in D_v that are not scanned, and that after the insertion will be located in D_u, without having their depth changed. This is a difficult case for our analysis: fortunately, the following lemma shows that this case can happen only $O(n)$ times overall.

▶ **Lemma 9.** *Suppose (u, v) is a bridge of G_s that is locally canceled by the insertion of edge (x, y). Then (u, v) is no longer a strong bridge in G after the insertion.*

Note that a canceled bridge that is not locally canceled may still appear as a bridge in G_s^R after the insertion of edge (x, y). The next lemmata allow us to identify the necessary changes in the auxiliary components of the affected subgraphs and $\widehat{G}_{r_z}$. All lemmata assume that bridge (p, q) is not locally canceled after the insertion of (x, y) and that $z = nca(x, y)$.

▶ **Lemma 10.** *Let C be an affected auxiliary component of an auxiliary graph $\widehat{G}_r$ with $r \neq r_z$. Then C consists of a set of affected siblings in D and possibly some of their affected or scanned descendants in D.*

An auxiliary component is *scanned* if it contains a scanned vertex. As with vertices, affected auxiliary components are also scanned (the converse is not necessarily true).

▶ **Lemma 11.** *Let C be a scanned auxiliary component of an auxiliary graph $\widehat{G}_r$ with $r \neq r_z$. Then all vertices in C are scanned.*

We say that a vertex v is *moved* if it is located in an auxiliary graph $\widehat{G}_r$ with $r \neq r_z$ before the insertion of (x, y), and in $\widehat{G}_{r_z}$ after the insertion. Lemmata 10 and 11 imply that if an auxiliary component C contains a moved vertex, then all vertices in the component are also moved. We call such an auxiliary component *moved*. Now we describe how to find the moved auxiliary components that need to be merged. Let H be the subgraph of G induced by the scanned vertices in $D(q)$. We refer to H as the *scanned subgraph*.

▶ **Lemma 12.** *Let ζ and ξ be two distinct roots in the bridge decomposition of D, such that $\zeta, \xi \neq r_z$, and D_ζ and D_ξ are contained in $D(q)$. Let C_ζ and C_ξ be scanned components in $\widehat{G}_\zeta$ and $\widehat{G}_\xi$, respectively. Then C_ζ and C_ξ are strongly connected in $G[D(q)]$ if and only if they are strongly connected in H.*

Now we introduce a dummy root r^* in H, together with an edge (v, r^*) for each scanned vertex v that has a leaving edge (v, w) such that $w \in D_z$ and w is in the auxiliary component of p in $\widehat{G}_{r_z}$. We denote this graph by H^*.

▶ **Lemma 13.** *A scanned vertex $v \notin D_z$ is strongly connected in $G[D(r_z)]$ to a vertex $w \in D_z$ if and only if r^* is reachable from v in H^*. In this case, v and p are also strongly connected in $G[D(r_z)]$.*

The Algorithm. We describe next our incremental algorithm for maintaining the 2-edge-connected blocks of a strongly connected digraph G. We refer to this algorithm as SCInc2ECB(G). We initialize the algorithm and the associated data structures by executing the labeling algorithm of Section 2. Algorithm Initialize(G, s), shown below, computes the dominator tree D, the set of bridges Br of flow graph G_s, the bridge decomposition $\mathcal{D}$ of D, and the corresponding auxiliary graphs $\widehat{G}_r$. Finally, for each auxiliary graph $\widehat{G}_r$, it finds its auxiliary components, computes the labels r_w and c_w for each vertex $w \in V_r$, and initializes an IncSCC data structure. The execution of Initialize(G^R, s) performs analogous steps in the reverse flow graph G_s^R.

Algorithm 1: Initialize(G, s)

```
1  Set s to be the designated start vertex of G.
2  Compute the dominator tree D and the set of bridges Br of the corresponding flow
     graph G_s.
3  Compute the bridge decomposition 𝒟 of D.
4  foreach root r in 𝒟 do
5  |  Compute the auxiliary graph Ĝ_r of r.
6  |  Compute the strongly connected components in Ĝ_r.
7  |  foreach strongly connected component C in Ĝ_r do
8  |  |  Choose a vertex v ∈ C as the canonical vertex of the auxiliary component C.
9  |  |  foreach vertex w ∈ C do
10 |  |  |  Set r_w = r and c_w = v.
11 |  |  end
12 |  end
13 |  Initialize a IncSCC data structure for Ĝ_r.
14 end
```

Algorithm 2: SCInsertEdge(G, e)

```
1  Let s be the designated start vertex of G, and let e = (x, y).
2  Compute the nearest common ancestor z and z^R of x and y in D and D^R respectively.
3  Update the dominator trees D and D^R, and return the lists S and S^R of the vertices
     that were scanned in D and D^R respectively.
4  if a bridge is locally canceled in G_s or in G_s^R then
5  |  Execute Initialize(G, s) and Initialize(G^R, s).
6  else
7  |  Execute UpdateAC(𝒟, z, x, y, S) and UpdateAC(𝒟^R, z^R, y, x, S^R).
8  end
```

Algorithm 3: UpdateAC$(\mathcal{D}, z, x, y, L)$

Let r_z be root of the tree D_z in $\mathcal{D}$ that contains z.
Let $c_{x'}$ be the canonical vertex of the nearest ancestor x' of x in D such that $x' \in D_z$.
Let (p, q) be the first bridge on the path $D[z, y]$, and let c_p be the canonical vertex of p.
Form the scanned graph H^* that contains the scanned vertices $S \setminus D_z$ and the edges among them.
Compute the strongly connected components $\mathcal{C}$ of $H^* \setminus r^*$ and order them topologically.
Compute the components $\mathcal{C}^*$ of $\mathcal{C}$ that reach r^* in H^*.
foreach *strongly connected component C in $\mathcal{C}^*$ that is moved* **do**
    Merge C with the component of c_p.
end
forall *strongly connected components in $\mathcal{C} \setminus \mathcal{C}^*$ that are moved* **do**
    Insert the components in the topological order of $\widehat{G}_{r_z}$ just after the component of c_p.
end
foreach *vertex $w \in S$* **do**
    if *w is moved to $\widehat{G}_{r_z}$* **then** set $r_w = r_z$.
end
Update the lists of out edges in the IncSCC data structures of $\widehat{G}_{r_z}$ and of the affected auxiliary graphs.
Insert edge $(c_{x'}, y)$ in the list of outgoing edges of $c_{x'}$ and update the IncSCC data structure of $\widehat{G}_{r_z}$.

When a new edge $e = (x, y)$ is inserted, algorithm SCInc2ECB executes procedure SCInsertEdge(G, e), which updates dominator trees D and D^R, together with the corresponding bridge decompositions. It also finds the set of scanned vertices in G_s and G_s^R. If a bridge of D or D^R is locally cancelled, then we restart the algorithm by executing Initialize. Otherwise, we need to update the auxiliary components in G_s and G_s^R. These updates are handled by procedure UpdateAC. Before describing UpdateAC, we provide some details on the implementation of the IncSCC data structures, which maintain the auxiliary components of each auxiliary graph $\widehat{G}_r$ using the "one-way search" structure of [17, Sections 2 and 6]. Since we need to insert and delete canonical vertices, we augment this data structure as follows. We maintain the canonical vertices of each auxiliary component in a linked list L_r, arranged according to the given topological order of $\widehat{G}_r$. For each vertex v in L_r, we also maintain a rank in L_r which is an integer in $[1, n]$ such that for any two canonical vertices u and v in L_r, $rank(u) < rank(v)$ if and only if u precedes v in L_r. The ranks of all vertices can be stored in a single array of size n. Also, with each canonical vertex w, we store a pointer to the location of w in L. We represent L_r with a doubly linked list so that we can insert and delete a canonical vertex in constant time. When we remove vertices from a list L_r we do not need to update the ranks of the remaining vertices in L_r. The insertion of an edge (x, y) may remove vertices from various lists L_r, but may insert vertices only in L_{r_z}. After these insertions, we recompute the ranks of all vertices in L_{r_z} just by traversing the list and assigning rank i to the i-th vertex in the list. We maintain links between an original edge e, stored in the adjacency lists of G, and at most one copy of e in a *out* list of IncSCC. This enables us to keep for each shortcut edge $e' = (v', w)$ a one-to-one correspondence with the original edge $e = (v, w)$ that created e'. We do that because if an ancestor of v is moved

to the auxiliary graph $\widehat{G}_{r_z}$ that contains v' ($v' = p$ in Figure 5), then e may correspond to a different shortcut edge or it may even become an ordinary edge of $\widehat{G}_{r_z}$. Using this mapping we can update the *out* lists of IncSCC. To initialize the IncSCC structure of an auxiliary graph, we compute a topological order of the auxiliary components in $\widehat{G}_r$, and create the list of outgoing edges $out(v)$ for each canonical vertex v.

If inserting edge (x, y) does not locally cancel a bridge in G_s and G_s^R, then we update the auxiliary components of G_s using procedure UpdateAC($\mathcal{D}, z, x, y, S$), where $\mathcal{D}$ is the updated bridge decomposition of D, $z = nca(x, y)$, and S is a list of the vertices scanned during the update of D. We do the same to update the auxiliary components of G_s^R. Procedure UpdateAC first computes the auxiliary components that are moved to $\widehat{G}_{r_z}$, possibly merging some of them, and then inserts the edge (x, y) as an original or a shortcut edge of $\widehat{G}_{r_z}$, depending on whether $x \in D_{r_z}$ or not. Note that the insertion of (x, y) may cause the creation of a new auxiliary component in $\widehat{G}_{r_z}$. Now we specify some further details in the implementation of UpdateAC. The vertices that are moved to $\widehat{G}_{r_z}$ are the scanned vertices in S that are not descendants of a strong bridge. Hence, we can mark the vertices that are moved to $\widehat{G}_{r_z}$ during the search for affected vertices. The next task is to update the *out* lists of the canonical vertices in $\widehat{G}_{r_z}$ and the affected auxiliary graphs. We process the list of scanned vertices S as follows. Let v be such a vertex. If v is not marked, i.e., is not moved to $\widehat{G}_{r_z}$, then we process the edges leaving v; otherwise, we process both the edges leaving v and the edges entering v. Suppose v is marked. Let (v, w) be an edge leaving v in G. If w is also in $\widehat{G}_{r_z}$ after the insertion, then we add the edge (v, w) in $out(f(v))$. Moreover, if w is not in S, then it was already located in $\widehat{G}_{r_z}$ before the insertion, so we delete the shortcut edge stored in $out(f(p))$. If w is not in $\widehat{G}_{r_z}$ after the insertion, then (v, w) is a bridge in D and we do nothing. Now consider an edge (w, v) entering v in G. If w is scanned, then we will process (w, v) while processing the edges leaving w. Otherwise, w remains a descendant of p, so we insert the edge (w, v) in $out(f(p))$. Now we consider the unmarked scanned vertices v. Let (v, w) an edge leaving v in G. If $w \in D_z$, we insert the edge (v, w) into $out(f(v'))$, where v' is the nearest marked ancestor of v in D. Otherwise, if $w \notin D(r_z)$, the edge (v'', w), where v'' is the nearest ancestor of v in D_w, already exists since v was a descendant of v'' before the insertion of (x, y). Next, we consider the updates in the L_r lists and the vertex ranks. While we process S, if we encounter a moved canonical vertex $v \in S$ that was located in an auxiliary graph $\widehat{G}_r$ with $r_z \neq r$, then we delete v from L_r. Note that we do not need to update the ranks of the remaining vertices in lists L_r with $r \neq r_z$. To update L_{r_z}, we insert the moved canonical vertices of the SCC's in $\mathcal{C} \setminus \mathcal{C}^*$, in a topological order of $H = H^* \setminus r^*$, just after $f(p)$. Then we traverse L_{r_z} and update the ranks of the canonical vertices. The final step is to actually insert edge (x, y) in the IncSCC data structure of $\widehat{G}_{r_z}$. We do that by adding (x, y) in $out(f(x'))$, where x' is the nearest ancestor of x in D_z. If $rank(f(x')) > rank(f(y))$, then we execute the forward-search procedure of IncSCC.

The proof of correctness of Algorithm SCInc2ECB will be given in the full paper.

Running time of SCInc2ECB. We analyze the running time of Algorithm SCInc2ECB. Recall that G is a strongly connected digraph with n vertices that undergoes a sequence of edge insertions. We let m be the total number of edges in G after all insertions ($m \geq n$). First, we bound the time spent by Initialize. This procedure is called twice in the beginning of the SCInc2ECB, and twice after each time a bridge in G_s or in G_s^R is locally canceled. Then, Lemma 9 implies that such an event can happen at most $2(n-1)$ times. Hence, there are at most $4n$ calls to Initialize, and since each execution takes $O(m)$ time, the total time spent on Initialize is $O(mn)$. Similarly, the dominator trees of G_s and G_s^R can be updated

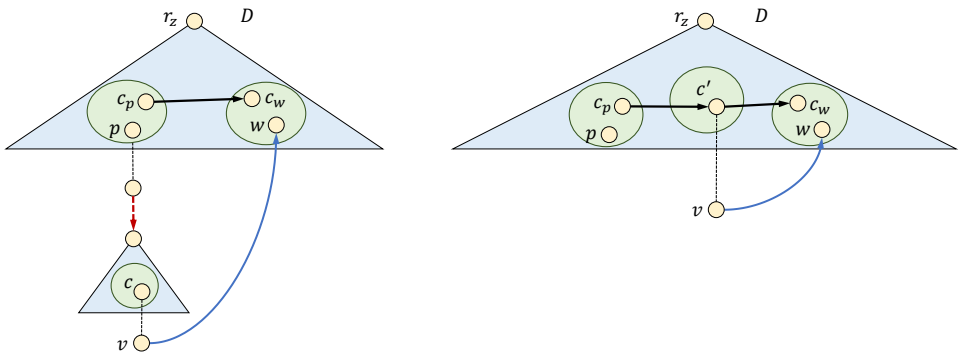

Figure 5 Before the insertion of (x, y), edge (v, w) corresponds to the shortcut edge (p, w) of $\widehat{G}_{r_z}$, and is stored in $out(c_p)$. An auxiliary component with canonical vertex c is affected by the insertion of (x, y) and is merged into a component with canonical vertex c' ($c' = c$ if the component is moved without merging with another component). Now c' becomes the canonical vertex of the nearest ancestor of v in D_z, and edge (v, w) is stored as a shortcut edge in $out(c')$.

in total $O(mn)$ time [15]. We next bound the total time required to update the auxiliary components. Consider an execution of UpdateAC. Let ν and μ, respectively, be the number of scanned vertices, after the insertion of edge (x, y), and their adjacent edges. The time to compute the affected subgraph H^*, compute the SCC's of $H^* \setminus r^*$, and the vertices that reach r^* is $O(\nu + \mu)$. In the same time, we can update the auxiliary components of $\widehat{G}_{r_z}$ and of the affected auxiliary graphs, their corresponding topological orders, and the *out* lists of the corresponding IncSCC data structures. Since each scanned vertex w is a descendant of an affected vertex, the depth of w decreases by at least one. Hence, the total time spent by UpdateAC for all insertions, excluding the execution of line 17, is $O(mn)$. It remains to bound the time required by the IncSCC data structures to handle the edge insertions in line 17 of UpdateAC. To do this, we extend the analysis from [17]. Note that we cannot immediately apply the analysis in [17], since here we have the complication that vertices and edges can be inserted to and removed from the IncSCC structures. We say that a vertex v and an edge e are *related* if there is a path that contains both v and e (in any order). Then, there are $O(mn)$ pairs of vertices and edges that can be related in all IncSCC structures for every auxiliary graph. We argue that each time the IncSCC structure traverses an edge (after the insertion in line 17 of UpdateAC), the cost of this action can be charged to a newly-related vertex-edge pair. Consider a vertex v and an edge $e = (u, w)$. Call the pair $\langle v, e\rangle$ *active* if v and e are in the same auxiliary graph $\widehat{G}_r$, and *inactive* otherwise. Note that since we identify shortcut edges with their corresponding original edge, e may actually appear in $\widehat{G}_r$ as an edge (u', w), where u' is the nearest ancestor of u in D_r. This fact, however, does not affect our analysis.

▶ **Lemma 14.** *The total number of edge traversals made during the forward searches in all IncSCC data structures is $O(mn)$.*

Proof. To prove the bound, it suffices to show that in all IncSCC data structures the total number of unrelated $\langle v, e\rangle$ pairs that are ever created is $O(mn)$. Consider an active pair $\langle v, e\rangle$ that becomes related in $\widehat{G}_r$. Then there is some path π in $G[D(r)]$ that contains both v and e. Suppose that the pair $\langle v, e\rangle$ later becomes active but unrelated in an auxiliary graph $\widehat{G}_{r'}$, where r' may be vertex r. Then π does not exist in $G[D(r')]$, which implies that some vertices of π are not descendants of r'. Then, by Lemma 1, π must contain the

bridge $(d(r'), r')$. Since π exists in $G[D(r)]$, the bridge $(d(r'), r')$ was a descendant of r before some insertion, and then became an ancestor of v. But this is impossible, since after an edge insertion, the new parent $d'(v)$ of v is on the path $D[s, d(v)]$. Hence, once a $\langle v, e\rangle$ pair becomes related, it can never become unrelated. The bound follows. ◀

▶ **Lemma 15.** *The total time to update all the IncSCC data structures is $O(mn)$.*

Proof. Updating the lists of out edges in the IncSCC data structures, and inserting or deleting canonical vertices can be charged to the cost of updating the dominator tree, and is thus $O(mn)$. By Lemma 14, all edge insertions that do not trigger merges of auxiliary components can be handled in $O(mn)$ time. The number of edge insertions that trigger merges of auxiliary components is at most $n - 1$, and each such insertion can be handled in $O(m + n)$ time, excluding unite operations. Taking into account also the total time for all unite operations yields the lemma. ◀

▶ **Theorem 16.** *The total running time of Algorithm SCInc2ECB for a sequence of edge insertions in a strongly connected digraph with n vertices is $O(mn)$, where m is the total number of edges in G after all insertions.*

Extension to general digraphs. Our approach can be extended to general (not strongly connected) digraphs, as shown in the following theorem. Details will be given in the full paper.

▶ **Theorem 17.** *We can maintain the 2-edge-connected blocks of a digraph with n vertices through a sequence of edge insertions in $O(mn)$ time, where m is the total number of edges in G after all insertions.*

Abstract

In a series of recent breakthroughs, Allen-Zhu and Orecchia [2, 1] leveraged insights from the linear coupling method [15], which is a first-order optimization scheme, to provide improved algorithms for packing and covering linear programs. The result in [1] is particularly interesting, as the algorithm for packing LP achieves both width-independence and Nesterov-like acceleration, which was not known to be possible before. Somewhat surprisingly, however, while the dependence of the convergence rate on the error parameter ϵ for packing problems was improved to $O(1/\epsilon)$, which corresponds to what accelerated gradient methods are designed to achieve, the dependence for covering problems was only improved to $O(1/\epsilon^{1.5})$, and even that required a different more complicated algorithm, rather than from Nesterov-like acceleration. Given the primal-dual connection between packing and covering problems and since previous algorithms for these very related problems have led to the same ϵ dependence, this discrepancy is surprising, and it leaves open the question of the exact role that the linear coupling is playing in coordinating the complementary gradient and mirror descent step of the algorithm. In this paper, we clarify these issues, illustrating that the linear coupling method can lead to improved $O(1/\epsilon)$ dependence for both packing and covering problems in a unified manner, i.e., with the same algorithm and almost identical analysis. Our main technical result is a novel dimension lifting method that reduces the coordinate-wise diameters of the feasible region for covering LPs, which is the key structural property to enable the same Nesterov-like acceleration as in the case of packing LPs. The technique is of independent interest and that may be useful in applying the accelerated linear coupling method to other combinatorial problems.

1 Introduction

A fractional covering problem, in its generic form, can be written as the following linear program (LP): $\min_{x\geq 0}\{c^T x : Ax \geq b\}$, where $c \in \mathbb{R}^n_{\geq 0}, b \in \mathbb{R}^m_{\geq 0}$, and $A \in \mathbb{R}^{m\times n}_{\geq 0}$.

Without loss of generality, one can scale the coefficients, in which case one can write this LP in the standard form:

$$\min_{x\geq 0}\{\vec{1}^T x : Ax \geq \vec{1}\}, \text{ where } A \in \mathbb{R}^{m\times n}_{\geq 0} \tag{1}$$

The fractional packing problem, which is the dual of fractional covering, can be written in the standard form as:

$$\max_{y\geq 0}\{\vec{1}^T y : Ay \leq \vec{1}\}, \text{ where } A \in \mathbb{R}^{m'\times n'}_{\geq 0} \tag{2}$$

We denote by OPT the optimal value of a LP. In this case, we say that x is a $(1+\epsilon)$-*approximation* for the covering LP if $Ax \geq \vec{1}$ and $\vec{1}^T x \leq (1+\epsilon)\,\text{OPT}$, and we say that y is a $(1-\epsilon)$-*approximation* for the packing LP if $Ay \leq \vec{1}$ and $\vec{1}^T y \geq (1-\epsilon)\,\text{OPT}$.

Packing and covering problems are important classes of LPs with wide applications, including most resource allocation problems, and they have long drawn interest in theoretical computer science. Although one can use general LP solvers such as the interior point method to solve packing and covering with convergence rate of $\log(1/\epsilon)$, such algorithms usually have very high per-iteration cost, as methods such as the computation of the Hessian and matrix inversion are involved. In the setting of large-scale problems, low precision iterative solvers are often more popular choices. Such solvers usually run in time with a nearly-linear dependence on the problem size, and they have $\text{poly}(1/\epsilon)$ dependence on the approximation parameter. Most such work falls into one of two categories. The first category follows the approach of transforming LPs to convex optimization problems, then applying efficient first-order optimization algorithms. Examples of work in this category include [8, 3, 9, 12, 2, 1], and all except [2, 1] apply to more general classes of LPs. The second category is based on the Lagrangian relaxation framework, and some examples of work in this category include [11, 5, 7, 13, 14, 6, 4]. For a more detailed comparison of this prior work, see Table 1 in [1]. Also, based on whether the running time depends on the width ρ, a parameter which typically depends on the dimension and the largest entry of A, these algorithms can also be divided into width-dependent solvers and width-independent solvers. Width-dependent solvers are usually pseudo-polynomial, as the running time depends at least linearly on $\rho\,\text{OPT}$, which itself can be large, while width-independent solvers are independent or logarithmically dependent on the width.

In this paper, we describe a solver for covering LPs of the form (1). The solver is width-independent, and it is a first-order method with a linear rate of convergence. That is, if we let N be the number of non-zeros in A, then the running time of our algorithm is $O\left(N\frac{\log^2(N/\epsilon)\log(1/\epsilon)}{\epsilon}\right)$. To simplify the following discussion, we will follow the standard practice of using $\tilde{O}$ to hide poly-log factors, in which case the running time of our algorithm for the covering problem is $\tilde{O}\left(N/\epsilon\right)$. Among other things, our result is an improvement over the recent bound of $\tilde{O}(N/\epsilon^{1.5})$ provided by Allen-Zhu and Orecchia for the covering problem in [1], and our result corresponds to the linear rate of convergence that accelerated gradient methods are designed to achieve [9].

At least as interesting as the $\tilde{O}(1/\epsilon^{0.5})$ improvement for covering LPs, however, is the context of this problem and the main technical contribution that we developed and exploited to achieve our improvement.

- The context for our results has to do with the linear coupling method that was introduced recently by Allen-Zhu and Orecchia [15]. This is a first order method for solving convex optimization problems, and it provides a conceptually simple way to integrate a gradient descent step and mirror descent step in each iteration. In the setting of standard smooth convex optimization, the method achieves the same convergence rate as that of the accelerated gradient descent method of Nesterov [9], and indeed the former can be viewed as an insightful reinterpretation of the latter. The high-level view of the method as a coupling of gradient descent steps and mirror descent steps offers more flexibility to the framework, as the combination allows the two steps to complement each other in ways beyond simply Nesterov-like acceleration. Indeed, it has shown initial promise by providing improved algorithms for packing and covering LPs [2, 1]. The packing algorithm of Allen-Zhu and Orecchia in [1] is particularly surprising, as it exploits the linear coupling framework to achieve both width-independence and Nesterov-like acceleration, which is widely believed to be very difficult, and is the first success in a long line of works in this area.

  The particular motivation for our work is a striking discrepancy between bounds provided for packing and covering LPs in [1]. In particular, they provide a $(1-\epsilon)$-approximation solver for the packing problem in $\tilde{O}(N/\epsilon)$, but they are only able to obtain $\tilde{O}(N/\epsilon^{1.5})$ for the covering problem. In the case of covering, they are unable to use the linear coupling method to achieve Nesterov-like acceleration, and even to get width-independence the authors need to integrate some ad-hoc and complicated techniques. This discrepancy between results for packing and covering LPs is rare, due to the duality between them. Filling this gap is of particular interests, as not being able to do so would suggest some fundamental structural differences between the two problems.

- Our main technical contribution is a novel diameter reduction method for fractional covering LPs that helps resolve this discrepancy. Recall that the smoothness parameter, e.g., Lipschitz constant, and the diameter of the feasible region are the two most natural limiting factors for most gradient based optimization algorithms. Indeed, many applications of general first-order optimization techniques can be attributed to the existence of norms or proximal setups for the specific problems that gives both good smoothness and diameter properties. In the particular case of coordinate descent algorithms based on the linear coupling idea, we additionally need good coordinate-wise diameter properties to achieve accelerated convergence.

  This is easy to accomplish for packing problems, but it is not easy to do for covering problems, and this is the difference that leads to the $\tilde{O}(1/\epsilon^{0.5})$ discrepancy between packing and covering algorithms in previous work [1]. Our diameter reduction method for general covering problems is based on dimension lifting, which transforms the covering problem space to a higher dimensional space, and the feasible region in the lifted space has both good global diameter bounds with respect to the canonical norm for accelerated stochastic coordinate descent (as is needed generally [10, 1]) as well as good coordinate-wise diameter bounds (as is needed for linear coupling [1]). Thus, it is likely of interest more generally for combinatorial optimization problems.

Once the diameter reduction is achieved, covering LP shares all the essential properties necessary to achieve both width-independence and Nesterov-like acceleration as in the case of packing problems, and fits elegantly into the scheme and analysis from [1] that was developed for packing LPs. We obtain improved $\tilde{O}(N/\epsilon)$ results for covering LPs, and this provides a unified acceleration method (unified in the sense that it is with the same algorithm and almost identical analysis) for both packing and covering LPs.

We will start in Section 2 with a discussion of some selected technical ideas and challenges from previous work. Then, in Section 3 we will present our main technical contribution, a novel diameter reduction method for any covering LP of the form given in (1). Finally, in Section 4 we describe how to combine this with previous work to obtain a unified acceleration method for packing and covering problems.

2 High-level Description of Challenges

At a high level, we (as well as Allen-Zhu and Orecchia [2, 1]) use the same two-step approach of Nesterov [9]. The first step involves smoothing, which transforms the constrained problem into a *smooth* objective function with trivial or no constraints. By smooth, we mean that the gradient of the objective function has some property in the flavor of Lipschitz continuity. Once smoothing is accomplished, the second step uses one of several first order methods for convex optimization in order to obtain an approximate solution to the smoothed objective. Standard applications of this approach usually lead to width-dependent algorithms, where the width enters the performance analysis as the magnitude of the gradients.

The first width-independent result following the optimization approach in [2] achieves width-independence by truncating the gradient, thus effectively reducing the width to 1. The algorithm uses, in a white-box way, the coupling of mirror descent and gradient descent from [15], where the progress from gradient descent covers the loss incurred by the truncation of the gradient (see Eqn. (7) below for the precise formulation of this loss), thus achieving width-independence. However, the role of gradient descent in the coupling is limited to width-independence, but not acceleration.

To improve the sequential packing solver in [2] with convergence $\tilde{O}(1/\epsilon^3)$ to $\tilde{O}(1/\epsilon)$, the same authors in [1] apply a stochastic coordinate descent method based on the linear coupling idea. Barring the difference between Lipschitz and local Lipschitz continuity, the results in [1] can be viewed as a variant of accelerated coordinate descent method [10]. There are two places where the algorithm achieves an improvement over prior packing-covering results.

- One factor of improvement is due to the better coordinate-wise Lipschitz constant over the full dimensional Lipschitz constant. Intuitively, in the case of packing or covering, the gradient of variable x_i depends on the penalties of constraints involving x_i, which further depend on all the variables in those constraints. As a result, if we move all the variables simultaneously, we can only take a small step before changing the gradient of x_i drastically. Sometimes coordinate descent comes with a downside, since if we update one variable each iteration, computing n partial derivatives in n iterations can be much more expensive than computing all the n partial derivatives in the same iteration. However, it can be shown in the case of packing and covering LPs, there is no such computation overhead.
- The other factor of improvement comes from Nesterov-like acceleration. In addition to giving width-independence as in [2], the gradient descent also covers the regret term incurred by the mirror descent step (see Eqn. (7) below for the precise formulation of this regret), which is the key insight from the original linear coupling result [15] to reproduce Nesterov's accelerated convergence. It turns out that nice diameter properties are necessary for the latter to be possible. On a high level, the regret incurred by mirror descent is proportional to its step size, which has an upper-bound proportional to the coordinate-wise diameter of the feasible region. On the other hand, the progress made by the gradient descent step is also proportional to its step size, which is inversely proportional to the Lipschitz parameter. For both packing and covering problems, the

coordinate-wise Lipschitz parameter of x_i is proportional to $1/\|A_{:i}\|_\infty$, as $\|A_{:i}\|_\infty$ captures the impact of x_i on the values of the constraints, which determine the gradient of x_i. This works out particularly well for packing problems, since the packing constraints $Ax \le \vec{1}$ impose a natural coordinate-wise diameter of $x_i^* \le 1/\|A_{:i}\|_\infty$ on the feasible region, which aligns the gradient descent step size and mirror descent step size, making the coupling possible to accelerate. The same small coordinate-wise diameter is also crucial to get good global diameter for the proximal setup used in mirror descent, which is necessary for mirror descent to achieve good convergence.

The combination of gradient truncation, stochastic coordinate descent, and acceleration due to the nice diameter properties lead to the $\tilde{O}(N/\epsilon)$ solver for the packing LP [1].

Shifting to solvers for the covering LP, one obvious obstacle to reproducing the packing result is we no longer have the small diameters. Indeed, a naive coordinate-wise upper bound from the covering constraints only gives $x_i^* \le 1/\min_j\{A_{ji} : A_{ji} > 0\}$, which is far from sufficient to give acceleration as the packing solver in [1]. The authors instead go back to the setup in their earlier work [2], where linear coupling only gives width-independence. The authors use a negative-width technique as in [3] (Theorem 3.3 with $l = \sqrt{\epsilon}$), that leads to the (improved, but still worse than for packing) $\tilde{O}(1/\epsilon^{1.5})$ convergence rate.

To get an $\tilde{O}(1/\epsilon)$ solver for the covering LP, it seems crucial to relate the gradient descent step and mirror descent step the same way as in the packing solver in [1]. Thus, we will work directly to reduce the coordinate-wise diameter. Our main result (presented next in Section 3) is a general diameter reduction method to achieve the same diameter property as in the packing solver, and this enables us (in Section 4) to extend all the crucial ideas of the packing solver in [1], as outlined in this section, to get a covering solver with running time $\tilde{O}(N/\epsilon)$.

3 Diameter Reduction Method for General Covering Problems

Given any covering LP of the form in (1), characterized by a matrix A, we formulate an equivalent covering LP with good diameter properties. This will involve lifting the instance to higher dimensional space by adding variables and redundant constraints. On a high level, as we discussed in last section, the obstacle for covering problems lies in the discrepency between the large coordinate-wise diameter of the feasible region and the small gradient descent step size. Our answer is essentially for each variable to create multiple copies with different resolutions. Certain copies will be in charge of searching over larger regions, but for them we modify their coefficients in the lifted space to allow larger gradient descent steps. We use $i \in [n]$ to denote the indices of the variables (i.e., columns of A) and $j \in [m]$ to denote the indices of constraints (i.e., rows of A). For ease of comparison with [1], and since our unified approach for both packing and covering uses their packing solver and a similar analysis, we use the same notation whenever possible.

For any $i \in [n]$, let

$$r_i \stackrel{\text{def}}{=} \frac{\max_j\{A_{ji} : A_{ji} > 0\}}{\min_j\{A_{ji} : A_{ji} > 0\}},$$

be the ratio between the largest non-zero coefficient and the smallest non-zero coefficient of variable x_i in all constraints, and let $n_i \stackrel{\text{def}}{=} \lceil \log r_i \rceil$. We first duplicate each original variable n_i times to obtain $\bar{x}_{(i,l)}, i \in [n], l \in [n_i]$ as the new variables. In terms of the coefficient matrix, we now have a new matrix, call it $\bar{A} \in \mathbb{R}_{\ge 0}^{m \times (\sum_i n_i)}$, which contains n_i copies of the i-th column $A_{:i}$. We denote a column of $\bar{A}$ by the tuple (i, l) with $l \in [n_i]$. Obviously,

the covering LP given by $\bar{A}$ is equivalent to the original covering LP given by A. Adding additional copies of variables, however, will allow us to improve the diameter. To reduce the diameter of this new covering LP, we further decrease some of the coefficients in $\bar{A}$, and we put upper bounds on the variables. In particular, for j, i, l, we have

$$\bar{A}_{j,(i,l)} = \min\{A_{j,i}, 2^l \min_j\{A_{ji} : A_{ji} > 0\}\}, \tag{3}$$

and for variable $\bar{x}_{(i,l)}$, we add the constraint

$$\bar{x}_{(i,l)} \leq \frac{2}{2^l \min_j\{A_{ji} : A_{ji} > 0\}}. \tag{4}$$

The next lemma shows that the covering LP given by $\bar{A}$ and the covering LP given by A are equivalent.

▶ **Lemma 1.** *The covering LP of A and the covering LP of $\bar{A}$ have the same optimal value* OPT. *Furthermore, there exists an optimal solution of the covering LP of $\bar{A}$ inside the region specified by* (4).

Proof. Let $\overline{\text{OPT}}$ be the optimal of the LP given by the covering constraints of $\bar{A}$ and the coordinate-wise upper-bounds in (4). We need to show $\text{OPT} = \overline{\text{OPT}}$. Given any feasible solution $\bar{x}$, consider the solution x where $x_i = \sum_{l=1}^{n_i} \bar{x}_{(i,l)}$. It is obvious $\vec{1}^T x = \vec{1}^T \bar{x}$, and $Ax \geq \vec{1}$, as coefficients in $\bar{A}$ are no larger than coefficients in A. Thus $\text{OPT} \leq \overline{\text{OPT}}$.

For the other direction, consider any feasible x. For each i, we can assume without loss of generality that

$$x_i \leq \frac{1}{\min_j\{A_{ji} : A_{ji} > 0\}}.$$

Let l_i be the largest index such that

$$x_i \leq \frac{2}{2^{l_i} \min_j\{A_{ji} : A_{ji} > 0\}},$$

and then let

$$\bar{x}_{(i,l)} = \begin{cases} x_i & \text{if } l = l_i \\ 0 & \text{if } l \neq l_i \end{cases}.$$

By construction, $\bar{x}$ satisfies all the upper bounds described in (4). Furthermore, for constraint j, we must have $\bar{A}_{j:}\bar{x} \geq 1$. Since for any i, $\bar{A}_{j,(i,l_i)}$ differs from A_{ji} only when $A_{ji} > 2^{l_i} \min_j\{A_{ji} : A_{ji} > 0\}$, and we must have $l_i < n_i$ in this case by definition of n_i, which gives $\bar{x}_{(i,l_i)} = x_i \geq \frac{1}{2^{l_i} \min_j\{A_{ji} : A_{ji} > 0\}}$ by our choice of l_i being the largest possible. Then we know $\bar{A}_{j,(i,l_i)} = 2^{l_i} \min_j\{A_{ji} : A_{ji} > 0\}$, so the j-th constraint is satisfied. Thus $\text{OPT} \geq \overline{\text{OPT}}$, and we can conclude $\text{OPT} = \overline{\text{OPT}}$. ◀

Given the equivalence of the covering LP defined by $\bar{A}$ and that defined by A, we now point out that the seemingly-redundant constraints of (4) turn out to be crucial. The reason is that we can search over a feasible region with nice diameter properties necessary to tap the full power of the linear coupling method. In particular, we can rewrite the constraints (4) to be

$$\bar{x}_{(i,l)} \leq \frac{2}{\|\bar{A}_{:(i,l)}\|_\infty}.$$

For any i, this is the same upper bound on $\bar{x}_{(i,l)}$ for $l < n_i$ (consider the row $j^* = \text{argmax}_j\{A_{ji}, A_{ji} > 0\}$), and it is a relaxation on $\bar{x}_{(i,n_i)}$.

The price we pay for this diameter improvement is that the new LP defined by $\bar{A}$ is larger than that defined by A. Two comments on this are in order. First, by Observation 3, r_i is bounded by n^2m/ϵ^2, and so the diameter reduction step only increases the problem size by $O(\log(mn/\epsilon))$. Second, we have presented our diameter reduction as an explicit pre-processing step so we can use one unified optimization algorithm (Algorithm 1 below) for both packing and covering, but in practice the diameter reduction would not have to be carried out explicitly. It can equivalently be implemented implicitly within the algorithm (a trivially-modified version of Algorithm 1 below) by randomly choosing a scale after picking the coordinate i and then computing $\bar{A}_{j,(i,l)}$ in (3) by shifting bits on the fly.

Given this reduction, in the rest of the paper, when we refer to the covering LP, we will implicitly be referring to the diameter reduced version, and we have the additional guarantee that there exists an optimal solution x^* to (1) such that

$$0 \leq x_i^* \leq \frac{2}{\|A_{:i}\|_\infty} \quad \forall i \in [n]. \tag{5}$$

4 An Accelerated Solver for (Packing and) Covering LPs

In this section, we will show covering LPs fit neatly into the scheme and analysis developed for packing LPs in [1], thus establishing a unified acceleration method for packing and covering problems. To motivate this, recall that for packing problems of the form (2), bounds of the form (5) automatically follow from the packing constraints $Ax \leq \vec{1}$. For readers familiar with the packing LP solver in [1], it should be plausible that—once we have this diameter property—the same stochastic coordinate descent optimization scheme will lead to a $\tilde{O}(N/\epsilon)$ covering LP solver.

In Section 4.1, we'll present some preliminaries and describe how we perform smoothing on the original covering objective function; and then in Section 4.2, we'll present the main algorithm. This algorithm involves a mirror descent step, that will be described in Section 4.3, a gradient descent step, that will be described in Section 4.4, and a careful coupling between the two, that will be described in Section 4.5. Finally, in Section 4.6, we will describe how to ensure we start at a good starting point. Some of the following results are technically-tedious but conceptually-straightforward extensions of analogous results from [1], and some of the results are restated from [1]; we defer most of the proofs to the full version.

4.1 Preliminaries and Smoothing the Objective

To start, let's assume that $\min_{j\in[m]} \|A_{j:}\|_\infty = 1$. This assumption is without loss of generality: since we can simply scale A for this to hold without sacrificing approximation quality. With this assumption, the following lemma holds.

▶ **Lemma 2.** $\text{OPT} \in [1, m]$.

With OPT being at least 1, the error we introduce later in the smoothing step will be small enough that the smoothing function approximates the covering LP well enough with respect to ϵ around the optimum.

▶ **Observation 3.** *It can be shown that to obtain a $(1+O(\epsilon))$-approximation, we can eliminate entries smaller than $\frac{\epsilon}{mn}$ and entries larger than $\frac{n}{\epsilon}$ from matrix A.*

We will turn the covering LP objective into a smoothed objective function $f_\mu(x)$, as used in [4, 2, 1], and we are going to find a $(1+\epsilon)$-approximation of the covering LP by approximately minimizing $f_\mu(x)$ over the region

$$\Delta \stackrel{\text{def}}{=} \{x \in \mathbb{R}^n : 0 \le x_i \le \frac{3}{\|A_{:i}\|_\infty}\}.$$

The function $f_\mu(x)$ is

$$f_\mu(x) \stackrel{\text{def}}{=} \vec{1}^T x + \max_{y \ge 0}\{y^T(\vec{1} - Ax) + \mu H(y)\},$$

and it is a smoothed objective in the sense that it turns the covering constraints into soft penalties, with $H(y)$ being a regularization term. Here, we use the generalized entropy $H(y) = -\sum_j y_j \log y_j + y_j$, where μ is the smoothing parameter balancing the penalty and the regularization. It is straightforward to compute the optimal y, and write $f_\mu(x)$ explicitly, as stated in the following lemma.

▶ **Lemma 4.** *$f_\mu(x) = \vec{1}^T x + \mu \sum_{j=1}^m p_j(x)$, where $p_j(x) \stackrel{\text{def}}{=} \exp(\frac{1}{\mu}(1 - (Ax)_j))$.*

Optimizing $f_\mu(x)$ over Δ gives a good approximation to OPT, in the following sense. If we let x^* be an optimal solution satisfying (5), and $u^* \stackrel{\text{def}}{=} (1+\epsilon/2)x^* \in \Delta$, then we have the properties in the following lemma.

▶ **Lemma 5.** *Setting the smoothing parameter $\mu = \frac{\epsilon}{4\log(nm/\epsilon)}$, we have*

1. *$f_\mu(u^*) \le (1+\epsilon)\,\mathrm{OPT}$.*
2. *$f_\mu(x) \ge (1-\epsilon)\,\mathrm{OPT}$ for any $x \ge 0$.*
3. *For any $x \ge 0$ satisfying $f_\mu(x) \le 2\,\mathrm{OPT}$, we must have $Ax \ge (1-\epsilon)\vec{1}$.*
4. *If $x \ge 0$ satisfies $f_\mu(x) \le (1+O(\epsilon))\,\mathrm{OPT}$, then $\frac{1}{1-\epsilon}x$ is a $(1+O(\epsilon))$-approximation to the covering LP.*
5. *The gradient of $f_\mu(x)$ is*

$$\nabla f_\mu(x) = \vec{1} - A^T p(\vec{x}) \quad \text{where} \quad p_j(x) \stackrel{\text{def}}{=} \exp(\frac{1}{\mu}(1 - (Ax)_j),$$

and $\nabla_i f_\mu(x) = 1 - \sum_j A_{ji} p_j(x) \in [-\infty, 1]$.

Although $f_\mu(x)$ gives a good approximation to the covering LP, $f_\mu(x)$ doesn't have the necessary Lipschitz-smoothness property due to the fast changing nature of exponential functions. However, $f_\mu(x)$ is *locally Lipschitz continuous*, in a sense quantified by the following lemma, and so we have a good improvement with a gradient step within certain range.

▶ **Lemma 6.** *Let $L \stackrel{\text{def}}{=} \frac{4}{\mu}$, for any $x \in \Delta$, and $i \in [n]$*

1. *If $\nabla_i f_\mu(x) \in (-1, 1)$, then for all $|\gamma| \le \frac{1}{L\|A_{:i}\|_\infty}$, we have*

$$|\nabla_i f_\mu(x) - \nabla_i f_\mu(x + \gamma\,\mathbf{e}_i)| \le L\|A_{:i}\|_\infty |\gamma|.$$

2. *If $\nabla_i f_\mu(x) \le -1$, then for all $\gamma \le \frac{1}{L\|A_{:i}\|_\infty}$, we have*

$$\nabla_i f_\mu(x + \gamma\,\mathbf{e}_i) \le (1 - \frac{L\|A_{:i}\|_\infty}{2}|\gamma|)\nabla_i f_\mu(x).$$

We call $L\|A_{:i}\|_\infty$ the *coordinate-wise local Lipschitz constant*. The significance of Lemma 6 is that for covering LPs the coordinate-wise local Lipschitz constant is inversely proportional to the coordinate-wise diameter. (This fact has been established previously for the case of packing LPs [1].)

4.2 An Accelerated Coordinate Descent Algorithm

Algorithm 1 Accelerated stochastic coordinate descent for both packing and covering

Input: $A \in \mathbb{R}^{m\times n}_{\geq 0}, x^{\text{start}} \in \Delta, f_\mu, \epsilon$ **Output**: $y_T \in \Delta$

$\mu \leftarrow \frac{\epsilon}{4\log(nm/\epsilon)}, L \leftarrow \frac{4}{\mu}, \tau \leftarrow \frac{1}{8nL}$

$T \leftarrow \lceil 8nL\log(1/\epsilon)\rceil = \tilde{O}(\frac{n}{\epsilon})$

$x_0, y_0, z_0 \leftarrow x^{\text{start}}, \alpha_0 \leftarrow \frac{1}{nL}$

for $k = 1$ to T **do**

  $\alpha_k \leftarrow \frac{1}{1-\tau}\alpha_{k-1}$

  $x_k \leftarrow \tau z_{k-1} + (1-\tau)y_{k-1}$

  Select $i \in [n]$ uniformly at random.

  ▷ Gradient truncation:

  Let $(\xi_k^{(i)})_i \leftarrow \begin{cases} -\mathbf{e}_i & \nabla_i f_\mu(x_k) < -1 \\ \nabla_i f_\mu(x_k)\cdot \mathbf{e}_i & \nabla_i f_\mu(x_k) \in [-1,1] \\ \mathbf{e}_i & \nabla_i f_\mu(x_k) > 1 \end{cases}$

  ▷ Mirror descent step:

  $z_k \leftarrow z_k^{(i)} \stackrel{\text{def}}{=} \text{argmin}_{z\in\Delta}\{V_{z_{k-1}}(z) + \langle z, n\alpha_k \xi_k^{(i)}\rangle\}$.

  ▷ Gradient descent step:

  $y_k \leftarrow y_k^{(i)} \stackrel{\text{def}}{=} x_k + \frac{1}{n\alpha_k L}(z_k^{(i)} - z_{k-1})$

end for

return y_T.

We will now show that the accelerated coordinate descent used in packing LP solver in [1] also works as a covering LP solver, with appropriately-chosen starting points and smoothed objective functions. Consider Algorithm 1, which is our main accelerated stochastic coordinate descent for both packing and covering. Note for both packing and covering LPs, we give $\Delta = \{x \in \mathbb{R}^n : 0 \leq x_i \leq \frac{3}{\|A_{:i}\|_\infty}\}$ as the input feasible region. The correctness of this algorithm and its running time guarantees for the packing problem have already been nicely presented in [1], and so here we will focus on the covering problem.

Our main result is summarized in the following theorems.

▶ **Theorem 7.** *With x^{start} computable in time $\tilde{O}(N)$ to be specified later, Algorithm 1 outputs y_T satisfying $\mathbb{E}[f_\mu(y_T)] \leq (1+6\epsilon)\,\text{OPT}$, and the running time is $\tilde{O}(N/\epsilon)$.*

A standard application of Markov bound gives the following corollary.

▶ **Corollary 8.** *There is a algorithm that, with probability at least $9/10$, computes a $(1+O(\epsilon))$-approximation to the fractional covering problem and has $\tilde{O}(N/\epsilon)$ expected running time.*

Before proceeding with our proof of these theorems, we discuss briefly the optimization scheme from [1] we will use. First, the A-norm is used as the proximal setup for mirror descent, where

$$\|x\|_A = \sqrt{\sum_i \|A_{:i}\|_\infty x_i^2}, \tag{6}$$

The corresponding distance generating function is $w(x) = \frac{1}{2}\|x\|_A^2$, and the Bregman divergence is $V_x(y) = \frac{1}{2}\|x-y\|_A^2$.[1]

[1] In particular, w is a 1-strongly convex function with respect to $\|\cdot\|_A$, and $V_x(y) \stackrel{\text{def}}{=} w(y) - \langle \nabla w(x), y - x\rangle - w(x)$. See [15] for a detailed discussion of mirror descent as well as and several interpretations.

Next, observe that Algorithm 1 works as follows. Each iteration integrates a mirror descent step and a gradient descent step. The standard analysis of mirror descent gives a convergence of $\frac{1}{\epsilon^2}$, and it depends on the width of the problem. Here is how the coupling of gradient descent and mirror descent achieves both width-independence and linear-rate acceleration.

- To eliminate the width from the convergence rate, the gradient $\nabla_i f_\mu(x_k)$ is split into the small component, $\xi_k^{(i)} = \max\{-1, \nabla_i f_\mu(x_k)\}\,\mathbf{e}_i$, and the large component, $\eta_k^{(i)} = \nabla_i f_\mu(x_k)\,\mathbf{e}_i - \xi_k^{(i)}$. Only the small component $\xi^{(i)}$ is given to the mirror descent step, and thus the width is effectively 1. However, the truncation incurs loss from the large component, as the mirror descent only acts on the small component. The progress from the gradient descent step is used to cover that loss.
- In order to get to $1/\epsilon$ convergence, recall that the $1/\epsilon^2$ in the convergence of mirror descent is largely due to the regret term accumulated along all iterations of mirror descent. The progress from the gradient step also covers the regret from the mirror descent step (see Eqn. (7) below for the precise formulation of this loss and regret). This enables the coupling to get Nesterov-like acceleration using the same approach in [15].

Before we moving to formalize the above discussion, here are some lemmas about the algorithm. The first lemma says that the gradient step we take is always valid (i.e., in Δ), which is crucial in the sense that we need the step length to be at least $\frac{1}{n\alpha_k L}$ of the mirror descent step length for the coupling to work.

▶ **Lemma 9.** *We have $x_k, y_k, z_k \in \Delta$ for all $k = 0, 1, \ldots, T$.*

The second lemma is clearly crucial to achieve the nearly linear time $\tilde{O}(N/\epsilon)$ algorithm.

▶ **Lemma 10.** *Each iteration can be implemented in expected $O(N/n)$ time.*

4.3 Mirror Descent Step

We now analyze the mirror descent step of Algorithm 1:

$$z_k \leftarrow z_k^{(i)} \stackrel{\text{def}}{=} \operatorname*{argmin}_{z\in\Delta}\{V_{z_{k-1}}(z) + \langle z, n\alpha_k \xi_k^{(i)}\rangle\}.$$

▶ **Lemma 11.** $\langle n\alpha_k \xi_k^{(i)}, z_{k-1} - u^*\rangle \le n^2\alpha_k^2 L\langle \xi_k^{(i)}, x_k - y_k^{(i)}\rangle + V_{z_{k-1}}(u^*) - V_{z_k}(u^*)\,.$

Also, we note that the mirror descent step, defined above in a variational way, can be explicitly written as

1. $z_k^{(i)} \leftarrow z_{k-1}$
2. $z_k^{(i)} \leftarrow z_k^{(i)} - n\alpha_k \xi_k^{(i)}/\|A_{:i}\|_\infty$
3. If $z_{k,i}^{(i)} < 0, z_{k,i}^{(i)} \leftarrow 0$; if $z_{k,i}^{(i)} > 3/\|A_{:i}\|_\infty, z_{k,i}^{(i)} \leftarrow 3/\|A_{:i}\|_\infty$.

4.4 Gradient Descent Step

We now analyze the gradient descent step of Algorithm 1. In particular, from the explicit formulation of the mirror descent step, we have that $|z_{k,i}^{(i)} - z_{k-1,i}| \le \frac{n\alpha_k|\xi_k^{(i)}|}{\|A_{:i}\|_\infty}$, which gives

$$|y_{k,i}^{(i)} - x_{k,i}| = \frac{1}{n\alpha_k L}|z_{k,i}^{(i)} - z_{k-1,i}| \le \frac{|\xi_k^{(i)}|}{L\|A_{:i}\|_\infty}.$$

The gradient step we take is within the local region, and so Lemma 6 applies. We bound the progress from the gradient descent step in the following lemma.

▶ **Lemma 12.** $f_\mu(x_k) - f_\mu(y_k^{(i)}) \ge \frac{1}{2}\langle \nabla f_\mu(x_k), x_k - y_k^{(i)}\rangle\,.$

4.5 Coupling of Gradient and Mirror Descent

Here, we will analyze the coupling between the gradient descent and mirror descent steps. This and the next section will give a proof of Theorem 7.

As we take steps on random coordinates, we will write the full gradient as

$$\nabla f_\mu(x_k) = \mathbb{E}_i[n\nabla_i f_\mu(x_k)] = \mathbb{E}_i[n\eta_k^{(i)} + n\xi_k^{(i)}].$$

As discussed earlier, we have the small component $\xi_k^{(i)} \in (-1, 1)\,\mathbf{e}_i$ and the large component $\eta_k^{(i)} = \nabla_i f_\mu(x_k) - \xi_k^{(i)} \in (-\infty, 0]\,\mathbf{e}_i$. We put the gradient and mirror descent steps together, and we bound the gap to optimality at iteration k:

$$\begin{aligned}
\alpha_k(f_\mu(x_k) - f_\mu(u^*)) \leq& \langle \alpha_k \nabla f_\mu(x_k), x_k - u^*\rangle \\
=& \langle \alpha_k \nabla f_\mu(x_k), x_k - z_{k-1}\rangle + \langle \alpha_k \nabla f_\mu(x_k), z_{k-1} - u^*\rangle \\
=& \langle \alpha_k \nabla f_\mu(x_k), x_k - z_{k-1}\rangle + \mathbb{E}_i[\langle n\alpha_k \eta_k^{(i)}, z_{k-1} - u^*\rangle] \\
&+ \mathbb{E}_i[\langle n\alpha_k \xi_k^{(i)}, z_{k-1} - u^*\rangle] \\
=& \frac{1-\tau}{\tau}\alpha_k \langle \nabla f_\mu(x_k), y_{k-1} - x_k\rangle + \mathbb{E}_i[\langle n\alpha_k \eta_k^{(i)}, z_{k-1} - u^*\rangle] \\
&+ \mathbb{E}_i[\langle n\alpha_k \xi_k^{(i)}, z_{k-1} - u^*\rangle] \\
\leq& \frac{1-\tau}{\tau}\alpha_k (f_\mu(y_{k-1}) - f_\mu(x_k)) + \mathbb{E}_i[\langle n\alpha_k \eta_k^{(i)}, z_{k-1} - u^*\rangle] \\
&+ \mathbb{E}_i[n^2\alpha_k^2 L\langle \xi_k^{(i)}, x_k - y_k^{(i)}\rangle + V_{z_{k-1}}(u^*) - V_{z_k^{(i)}}(u^*)].
\end{aligned}$$

The first line is due to convexity. The fourth line is due to $x_k = \tau z_{k-1} + (1-\tau)y_{k-1}$, so $\tau(x_k - z_{k-1}) = (1-\tau)(y_{k-1} - x_k)$. The last line is by Lemma 11.

We need to use the progress from the gradient step given in Lemma 12 to cover the loss from $\eta_k^{(i)}$, and the regret from the mirror descent step:

$$\underbrace{\mathbb{E}_i[\langle n\alpha_k \eta_k^{(i)}, z_{k-1} - u^*\rangle]}_{\text{loss from } \eta_k^{(i)}} + \underbrace{\mathbb{E}_i[n^2\alpha_k^2 L\langle \xi_k^{(i)}, x_k - y_k^{(i)}\rangle]}_{\text{regret from mirror descent}}, \tag{7}$$

The following lemma crucially relies on the nice coordinate-wise diameters of the feasible region Δ.

▶ **Lemma 13.** *The (scaled) progress from the gradient step covers both the loss from gradient truncation and the regret incurred by the mirror descent step*

$$\mathbb{E}_i[\langle n\alpha_k \eta_k^{(i)}, z_{k-1} - u^*\rangle] + \mathbb{E}_i[n^2\alpha_k^2 L\langle \xi_k^{(i)}, x_k - y_k^{(i)}\rangle] \leq \mathbb{E}_i[8n\alpha_k L(f_\mu(x_k) - f_\mu(y_k^{(i)}))].$$

Now we can show this gives Nesterov-like acceleration. We have

$$\begin{aligned}
\alpha_k(f_\mu(x_k) - f_\mu(u^*)) \leq& \frac{1-\tau}{\tau}\alpha_k (f_\mu(y_{k-1}) - f_\mu(x_k)) + \mathbb{E}_i[8n\alpha_k L(f_\mu(x_k) - f_\mu(y_k^{(i)})] \\
&+ \mathbb{E}_i[V_{z_{k-1}}(u^*) - V_{z_k^{(i)}}(u^*)].
\end{aligned}$$

With our choice of $\tau = \frac{1}{8nL}$, $\alpha_k = \frac{1}{1-\tau}\alpha_{k-1}$, we get

$$-\alpha_k f_\mu(u^*) \leq 8nL\alpha_{k-1} f_\mu(y_{k-1}) - \mathbb{E}_i[8nL\alpha_k f_\mu(y_k^{(i)})] + \mathbb{E}_i[V_{z_{k-1}}(u^*) - V_{z_k^{(i)}}(u^*)].$$

Telescoping the above inequality [2] along $k = 1, \ldots, T$, we get

$$\mathbb{E}[8nL\alpha_T f_\mu(y_T)] \leq \sum_{k=1}^{T} \alpha_k f_\mu(u^*) + 8nL\alpha_0 f_\mu(y_0) + V_{z_0}(u^*),$$

and thus

$$\mathbb{E}[f_\mu(y_T)] \leq \frac{\sum_{k=1}^{T} \alpha_k}{8nL\alpha_T} f_\mu(u^*) + \frac{\alpha_0}{\alpha_T} f_\mu(y_0) + \frac{1}{8nL\alpha_T} V_{z_0}(u^*).$$

We have $\sum_{k=1}^{T} \alpha_k = \alpha_T \sum_{k=0}^{T-1} (1 - \frac{1}{8nL})^k = 8nL\alpha_T(1 - (1 - \frac{1}{8nL})^T) \leq 8nL\alpha_T$, and by our choice of $T = \lceil 8nL \log(1/\epsilon) \rceil$, we also have

$$\frac{\alpha_0}{\alpha_T} = (1 - \frac{1}{8nL})^T \leq \epsilon, \frac{1}{8nL\alpha_T} \leq \frac{\epsilon}{8nL\alpha_0} = \frac{\epsilon}{8},$$

and thus

$$\mathbb{E}_i[f_\mu(y_T)] \leq f_\mu(u^*) + \epsilon f_\mu(y_0) + \frac{\epsilon}{8} V_{z_0}(u^*). \tag{8}$$

4.6 Finding a Good Starting Point

From (8), we see a good starting point $y_0 = x^{\text{start}}$ for Algorithm 1 is a point that is not too far away from the optimal in terms of the function value (i.e small $f_\mu(y_0)$), and not too far away from u^* in A-norm (i.e. small $V_{z_0}(u^*)$). For packing problems, starting with the all-0's vector will work, but this will not work for covering problems. Instead, for covering problems, we will show now a good enough x^{start} can be obtained in $\tilde{O}(N)$.

To do so, recall that we can get a 2-approximation $x^{\#}$ to the original covering LP in time $\tilde{O}(N)$ using various nearly linear time covering solvers, e.g., those of [7, 4, 6, 14]. Without loss of generality, we can assume $x_i^{\#} \in [0, \frac{2}{\|A_{:i}\|_\infty}]$, since we can use the diameter reduction process as specified in Lemma 1 to get a equivalent solution satisfying the conditions. Then, we have the following lemma.

▶ **Lemma 14.** *Let* $x^{\text{start}} = (1 + \epsilon/2)x^{\#}$*, we have* $x^{\text{start}} \in \Delta$*,* $f_\mu(x^{\text{start}}) \leq 4\,\text{OPT}$*, and* $V_{x^{\text{start}}}(u^*) \leq 6\,\text{OPT}$

It is now clear from (8) that we have

$$\mathbb{E}_i[f_\mu(y_T)] \leq f_\mu(u^*) + \epsilon f_\mu(y_0) + \frac{\epsilon}{8} V_{z_0}(u^*) \leq (1+\epsilon)\,\text{OPT} + 4\epsilon\,\text{OPT} + \epsilon\,\text{OPT} = (1+6\epsilon)\,\text{OPT}\,.$$

Thus, we have the approximation guarantee in Theorem 7. The running time follows directly from Lemma 10 and $T = \tilde{O}(n/\epsilon)$.

---

[2] More accurately, the telescoping works on

$$-\alpha_k f_\mu(u^*) \leq 8nL\alpha_{k-1}\mathbb{E}_{I_{k-1}}[f_\mu(y_{k-1})] - \mathbb{E}_{I_k}[8nL\alpha_k f_\mu(y_k^{(i)})] + \mathbb{E}_{I_{k-1}}[V_{z_{k-1}}(u^*)] - \mathbb{E}_{I_k}[V_{z_k^{(i)}}(u^*)].$$

where I_k is all the random coordinate choices made through the first iteration till k-th iteration. The final expectation on $f_\mu(y_T)$ is over all the T random choices.

Random-Edge Is Slower Than Random-Facet on Abstract Cubes

Abstract

Random-Edge and Random-Facet are two very natural randomized pivoting rules for the simplex algorithm. The behavior of Random-Facet is fairly well understood. It performs an expected *sub-exponential* number of pivoting steps on *any* linear program, or more generally, on any *Acyclic Unique Sink Orientation* (AUSO) of an arbitrary polytope, making it the fastest known pivoting rule for the simplex algorithm. The behavior of Random-Edge is much less understood. We show that in the AUSO setting, Random-Edge is *slower* than Random-Facet. To do that, we construct AUSOs of the n-dimensional hypercube on which Random-Edge performs an expected number of $2^{\Omega(\sqrt{n \log n})}$ steps. This improves on a $2^{\Omega(\sqrt[3]{n})}$ lower bound of Matoušek and Szabó. As Random-Facet performs an expected number of $2^{O(\sqrt{n})}$ steps on *any* n-dimensional AUSO, this established our result. Improving our $2^{\Omega(\sqrt{n \log n})}$ lower bound seems to require radically new techniques.

1 Introduction

Linear programming and the simplex algorithm. Linear programs (LPs) [3, 4, 28, 32] are among the most important mathematical optimization problems. The *simplex algorithm* (Dantzig [4]) is one of the most widely used methods for solving linear programs. It starts at a *vertex* of the polytope corresponding to the linear program. (We assume, for simplicity, that the LP is feasible, bounded, non-degenerate, that no two vertices have the same objective value, and that an initial vertex of the polytope is available.) If the current vertex is not optimal, then at least one of the *edges* incident to it leads to a neighboring vertex with a larger objective value. A *pivoting rule* determines which one of these vertices to move to. The simplex algorithm, with any pivoting rule, is guaranteed to find an optimal solution of an LP in a finite number of steps.

Unfortunately, with essentially all known *deterministic* pivoting rules, the simplex method requires an *exponential* number of steps on some LPs (see Klee and Minty [24] and [1, 2, 7,

15, 18]). While there are polynomial time algorithms for solving LP problems, most notably the *ellipsoid algorithm* (Khachian [23]) and *interior point methods* (Karmarkar [22]), these algorithms are not *strongly* polynomial, i.e., their running time, in the unit-cost model, depends on the number of *bits* in the representation of the coefficients of the LP, and not just on the combinatorial size of the problem, i.e., the number of variables and constraints. The question whether there exists a strongly polynomial time algorithm for solving linear programs is of great theoretical importance.

Randomized pivoting rules. Kalai [20] and Matoušek, Sharir and Welzl [29] devised a *randomized* pivoting rule, Random-Facet, that performs a *subexponential* number of pivoting steps, in expectation, on *any* LP. In particular, for an LP with n variables and $O(n)$ constraints, the expected number of pivoting steps performed by Random-Facet is at most $2^{O(\sqrt{n \log n})}$. A slightly improved version that performs an expected number of at most $2^{O(\sqrt{n})}$ pivoting steps on such LPs was recently obtained by the authors [17]. This improved version is currently the fastest known pivoting rule for the simplex algorithm.

Perhaps the most natural randomized pivoting rule is Random-Edge. When there are several improving edges from the current vertex, simply choose one of them uniformly at random. The best upper bound for Random-Edge on general LPs is exponential (Gärtner and Kaibel [13]). Whether this can be improved to a subexponential upper bound, similar to the one available for Random-Facet, is an intriguing open problem.

Friedmann et al. [8, 9, 11], building on results of Friedmann [6] and Fearnley [5], obtained a $2^{\tilde{\Omega}(n^{1/3})}$ lower bound on the expected number of pivoting steps performed by Random-Facet on LPs that correspond to *shortest paths* problems. [1] Friedmann et al. [9] also constructed LPs on which Random-Edge performs an expected number of $2^{\tilde{\Omega}(n^{1/4})}$ pivoting steps. We believe that this lower bound is not tight. However, as the $2^{\tilde{\Omega}(n^{1/4})}$ lower bound is already quite complicated, improving it seems to be a hard task. As a step in this direction we obtain a $2^{\Omega(\sqrt{n \log n})}$ lower bound for Random-Edge in the more general setting of *Acyclic Unique Sink Orientations* (AUSOs). In particular, this shows that in the AUSO setting, Random-Edge is slower than Random-Facet.

Acyclic Unique Sink Orientations (AUSOs). Each bounded LP has a polytope associated with it. The geometric vertices and edges of this polytope define a combinatorial graph. The objective function of the LP defines an *orientation* of the edges of this graph; An edge connecting vertices u and v is directed from u to v if and only if v has a better objective value. (We assume that no two vertices have the same objective value.) This orientation is clearly *acyclic*. It follows easily from the properties of LPs that every subgraph corresponding to a geometric *face* of the polytope has a *unique sink*, i.e., a unique vertex with no outgoing edges. The unique sink of the whole graph is then the optimal vertex of the LP.

This naturally motivates the definition of *Acyclic Unique Sink Orientations* (AUSOs). Let $G(P)$ be that graph that corresponds to a polytope P. An orientation of $G(P)$ is said to be an AUSO if and only if it is acyclic and any subgraph that corresponds to a face of P has a unique sink. The term AUSO was introduced by Szabó and Welzl [34]. The same notion was considered before, however, under several different names. Williamson Hoke [36] refers to them as *Completely Unimodal Numberings*, while Kalai [19, 20, 21] refers to them as *Abstract*

[1] In [9] we obtained a $2^{\tilde{\Omega}(\sqrt{n})}$ lower bound for a one-permutation variant of Random-Facet and erroneously claimed that the expected number of steps performed by this variant is equal to the expected number of steps performed by Random-Facet. Unfortunately, as we point out in [10], this is *not* the case.

Objective Functions. AUSOs provide an appealing abstraction of LPs. The subexponential upper bound on the behavior of Random-Facet only relies on the AUSOs properties and is thus valid also in the AUSO setting.

Of special interest are AUSOs of the n-dimensional *hypercube* whose properties we review in Section 2. In the sequel we restrict our attention to such AUSOs. Gärtner [12] proved a $2^{O(n^{1/2})}$ upper bound on the complexity of Random-Facet on AUSOs, and Matoušek [27] obtained an essentially tight $2^{\Omega(n^{1/2})}$ lower bound. (The improved version of Random-Facet of [17], which is not specialized to cubes, essentially matches Gärtner's bound. It is an interesting open problem whether a similar lower bound can be obtained for this algorithm.) Matoušek and Szabó [30, 31] obtained a lower bound of $2^{\Omega(n^{1/3})}$ on the complexity of Random-Edge on AUSOs. We improve their lower bound to $2^{\Omega(\sqrt{n \log n})}$, thus showing that Random-Edge is slower than Random-Facet on AUSOs. Hansen et al. [16] obtained a 1.8^n upper bound for Random-Edge on AUSOs. There is a large gap between the available upper and lower bounds. However, the $2^{\Omega(\sqrt{n \log n})}$ lower bound that we obtain is the best lower bound that can be obtained using current techniques. Improving it would require the use of *non-layered* AUSOs which are not yet known to exist.

Organization of paper. In the next section we review some basic properties of AUSOs of the Boolean hypercube. In Section 3 we describe a randomized product construction of AUSOs that plays a central role in the lower bound of Matoušek and Szabó [30, 31] as well as in our improved lower bound of $2^{\Omega(\sqrt{n})}$ which is described in Section 4. Section 5 contains an analysis of a random walk with *reshuffles* on a simple *path AUSO*. This analysis is needed to complete the proof of the lower bound presented in Section 4. In Section 6 we make the final push and improve the lower bound from $2^{\Omega(\sqrt{n})}$ to $2^{\Omega(\sqrt{n \log n})}$. In Section 7 we note that the AUSOs used to prove all known lower bounds for Random-Edge are *layered* and explain why it is unlikely that layered AUSOs could be used to obtain further improved lower bounds. A similar observation was made independently by Gärtner and Thomas [14]. We end in Section 8 with some concluding remarks and open problems.

2 Acyclic Unique Sink Orientations of the Hypercube

In this section we review the definition of AUSOs and describe some of their basic properties. We also introduce a simple *path* AUSO which plays a central role in our lower bound.

The n-cube is the undirected graph $C_n = (V_n, E_n)$, where $V_n = \{0,1\}^n$ and $E_n = \{\{\mathbf{x}, \mathbf{y}\} \mid \mathbf{x}, \mathbf{y} \in V_n, d_H(\mathbf{x}, \mathbf{y}) = 1\}$, where $d_H(\mathbf{x}, \mathbf{y})$ is the *Hamming distance* between $\mathbf{x}$ and $\mathbf{y}$. Every string $\mathbf{s} \in \{0,1,*\}^n$ defines a *subcube* of C_n induced by the vertex set $V_s = \{\mathbf{x} \in \{0,1\}^n \mid \mathbf{x}_i = \mathbf{s}_i \text{ or } \mathbf{s}_i = *\}$. The subcube defined by $\mathbf{s}$ is clearly isomorphic to a cube whose dimension is the number of $*$'s in $\mathbf{s}$.

An *orientation* of the n-cube is a directed graph obtained by orienting each edge $\{\mathbf{x}, \mathbf{y}\} \in E_n$ either from $\mathbf{x}$ to $\mathbf{y}$ or from $\mathbf{y}$ to $\mathbf{x}$. An orientation can be specified using a mapping $A : V_n \to \{0,1\}^n$ that satisfies the condition $A(\mathbf{x})_i \neq A(\mathbf{x} \oplus i)_i$, for every $\mathbf{x} \in V_n$. [2] The i-th edge of $\mathbf{x}$, i.e., $\{\mathbf{x}, \mathbf{x} \oplus i\}$ is directed *away* from $\mathbf{x}$ if and only if $A(\mathbf{x})_i = 1$. (Some authors refer to A as the *out-map* of the orientation. We consider it to be the orientation itself.) An orientation of a cube clearly induces orientations on all its subcubes. An orientation is

[2] Here, $A(\mathbf{x})_i$ denotes the i-th bit of $A(\mathbf{x}) \in \{0,1\}^n$, and $\mathbf{x} \oplus i$ is a shorthand for $\mathbf{x} \oplus \mathbf{e}_i$, where $\mathbf{e}_i = 0^{i-1}10^{n-i}$ is the i-th unit vector.

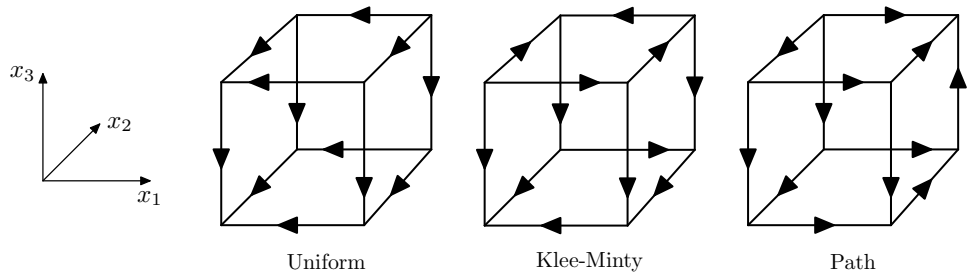

Figure 1 The uniform, Klee-Minty and the path AUSOs in dimension 3.

acyclic if there are no directed cycles. A *sink* of an orientation A of C_n is a vertex $\mathbf{x} \in V_n$ with no outgoing edges, i.e., $A(\mathbf{x}) = 0^n$. An acyclic orientation clearly has at least one sink, but it may have several.

▶ **Definition 1** (AUSOs)**.** An orientation A of the n-cube is an n-AUSO if and only if it is *acyclic* and if every subcube has a *unique sink* under A.

Perhaps the simplest AUSO is the *uniform* AUSO defined as follows $U(\mathbf{x}) = \mathbf{x}$. The sink of this AUSO is clearly 0^n. A more interesting and famous AUSO is the Klee-Minty cube [24] defined as follows $KM(\mathbf{x})_i = x_i \oplus x_{i+1} \oplus \cdots x_n$, for $i = 1, 2, \ldots, n$, where $\mathbf{x} = x_1 x_2 \ldots x_n$. The sink is again 0^n. (It is an instructive exercise to verify that the Klee-Minty cube is indeed an AUSO.) The Klee-Minty cube plays a prominent role in the lower bound of Matoušek and Szabó [30, 31]. One of the major steps in obtaining our improved lower bound is replacing the Klee-Minty cubes used in the lower bound of Matoušek and Szabó [30, 31] by the following much simpler AUSO.

▶ **Definition 2** (Path AUSO)**.** The *path* n-AUSO is defined as follows

$$P(\mathbf{x})_i = x_i \oplus (x_1 \wedge x_2 \wedge \cdots \wedge x_{i-1}) \ .$$

In other words, if $\mathbf{x} = x_1 x_2 \ldots x_n \in \{0,1\}^n$, then the i-th edge of $\mathbf{x}$ is directed away from $\mathbf{x}$ if and only if $x_1 x_2 \ldots x_i = 1^{i-1}0$ or $x_i = 1$ but $x_1 x_2 \ldots x_{i-1} \neq 1^{i-1}$. (Informally, a bit wants to become, or remain, a 1 if and only if all the bits preceding it are 1.) The sink of the path AUSO is clearly at 1^n. The uniform, Klee-Minty and the path AUSO for $n = 3$ are shown in Figure 1. The path AUSO is also used in a building block in [9, 11]. A realization of the path AUSO as a shortest paths problem in a weighted directed graph is given in Figure 2. Each n-bit string $\mathbf{x} = x_1 x_2 \ldots x_n$ corresponds to a *tree* of directed paths directed towards the target vertex 0. If $x_i = 0$, then $(i, 0)$ is included in the tree, otherwise $(i, i-1)$ is included in the tree. The i-th edge of $\mathbf{x}$ in the n-cube is directed away from $\mathbf{x}$ if and only if switching the outgoing edge of i in the tree reduces the distance to the target of at least one vertex. With this interpretation, it is clear that the path AUSO is an AUSO. (It is of course also easy to prove it directly.)

▶ **Lemma 3.** *The path AUSO is indeed an AUSO.*

Schurr and Szabó [33] describe two useful methods of constructing new AUSOs from existing ones. The first method takes an n-AUSO and *expands* each one of its 2^n vertices into an m-AUSO, resulting in an $(n+m)$-AUSO. (Each one of the 2^n vertices may be expanded into a different m-AUSO.) Schurr and Szabó [33] call it the *blowup* construction. We view it as a *product* of AUSOs.

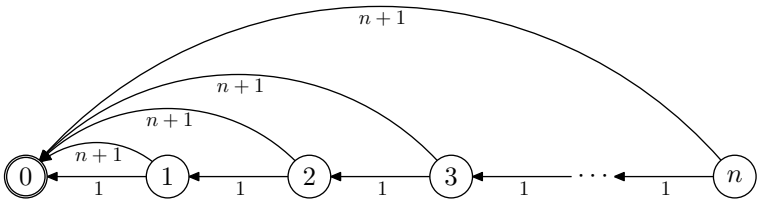

Figure 2 A realization of the path AUSO as a shortest paths problem in a weighted directed graph. Numbers attached to edges are edge weights.

▶ **Definition 4** (Product of AUSOs [33]). Let A be an n-AUSO, and let $m > 1$. For every $\mathbf{x} \in \{0,1\}^n$, let $B_{\mathbf{x}}$ be an m-AUSO. Define an $(n+m)$-AUSO $C = A \times \langle B_{\mathbf{x}} \rangle$ as follows:

$$C(\mathbf{x}, \mathbf{y}) \;=\; (A(\mathbf{x}), B_{\mathbf{x}}(\mathbf{y})) \;, \quad \text{for } \mathbf{x} \in \{0,1\}^n, \mathbf{y} \in \{0,1\}^m \;.$$

The proof that the product AUSO is indeed an AUSO is straightforward. (For the details, see [33].) Before describing the second method we need another definition.

▶ **Definition 5** (Hypersink [33]). A subcube of an AUSO is a *hypersink* if and only if all edges between vertices of the subcube and vertices outside the subcube are directed towards the subcube.

▶ **Lemma 6** (Hypersink replacement [33]). *Let A be an AUSO, let B be a subcube of A which is a hypersink, and let B' be an AUSO of the same dimension as B. Then, the AUSO A' obtained by modifying the orientation of the edges within B so that the resulting orientation is isomorphic to B' is again an AUSO.*

The proof of the lemma is again straightforward and can be found in [33]. Finally, the following well-known lemma will be used in Section 6.

▶ **Lemma 7** (Unique outmaps [34]). *Let A be an n-AUSO. Then, for every $\mathbf{x}_1 \neq \mathbf{x}_2 \in \{0,1\}^n$ we have $A(\mathbf{x}_1) \neq A(\mathbf{x}_2)$. In particular, the number of vertices of A of out-degree k is $\binom{n}{k}$.*

3 Random-Edge on Randomized Products

Matoušek and Szabó [30, 31] introduced the following simple and elegant *randomized product* construction. Let A be an n-AUSO and let B be an m-AUSO. Assume, for simplicity, that the sinks of A and B are at 1^n and 1^m, respectively. For every $\mathbf{x} \in \{0,1\}^n$, let $B_{\mathbf{x}}$ be a version of B in which the m coordinates are *randomly permuted*, each permutation being equally likely. (Note that the sink of $B_{\mathbf{x}}$ is still at 1^m.) Consider now the product $A \times \langle B_{\mathbf{x}} \rangle$. It is easy to check that the copy of A corresponding to $\mathbf{y} = 1^m$ is a hypersink of $A \times \langle B_{\mathbf{x}} \rangle$. We replace this copy of A by a *random translation* A' of A. A random translation of an n-AUSO A is obtained by choosing a random vertex $\mathbf{x}_0 \in \{0,1\}^n$ and making it the sink of an AUSO A' isomorphic to A. More precisely, we let $A'(\mathbf{x}) = A(\mathbf{x} \oplus \mathbf{x}_0)$. A formal definition of randomized products follows.

▶ **Definition 8** (Randomized product [30, 31]). Let A be an n-AUSO and let B be an m-AUSO whose sinks are at 1^n and 1^m, respectively. For every $\mathbf{x} \in \{0,1\}^n$, let $B_{\mathbf{x}}$ be a randomly permuted version of B, and let A' be a random translation of A. Then, the *randomized product* $C = A \times_R B$ is a distribution over AUSOs defined as follows:

$$C(\mathbf{x}, \mathbf{y}) \;=\; \begin{cases} (A(\mathbf{x}), B_{\mathbf{x}}(\mathbf{y})) & \text{, if } \mathbf{y} \neq 1^m \;, \\ (A'(\mathbf{x}), B_{\mathbf{x}}(\mathbf{y})) & \text{, otherwise .} \end{cases}$$

As $C = A \times_R B$ is obtained by performing a product of AUSOs followed by a hypersink replacement, it is clearly an AUSO, or rather a probability distribution over AUSOs.

Consider now the behavior of Random-Edge on $C = A \times_R B$, starting from some vertex $(\mathbf{x}, \mathbf{y})$, where $\mathbf{x} \in \{0,1\}^n$, $\mathbf{y} \in \{0,1\}^m$. Assume at first that $\mathbf{x} \neq 1^n$ and $\mathbf{y} \neq 1^m$. Each step of Random-Edge either changes a coordinate of $\mathbf{x}$ or of $\mathbf{y}$. If we only consider the steps in which $\mathbf{x}$ changes, and look only at $\mathbf{x}$, then as long as $\mathbf{y} \neq 1^m$, we get a standard Random-Edge walk on A.

The random walk on $\mathbf{y}$ induced by the Random-Edge walk on $C = A \times_R B$ is more interesting. When $\mathbf{x}$ is fixed, $\mathbf{y}$ performs a standard Random-Edge walk on $B_{\mathbf{x}}$. But, when a step from $\mathbf{x}$ to $\mathbf{x}'$ in A is made, the walk on $\mathbf{y}$ finds itself in a new AUSO $B_{\mathbf{x}'}$. Due to the acyclicity of A, $B_{\mathbf{x}'}$ was never visited before, and is thus completely random. The resulting random walk on $\mathbf{y}$ is what Matoušek and Szabó [30, 31] call a *random walk with reshuffles* on B. Such a random walk is likely to be much longer than a standard Random-Edge walk on B as the random reshuffles tend to destroy progress made since the last reshuffle.

When the random walk with reshuffles on B reaches its sink $\mathbf{y} = 1^m$, the hypersink A' is entered, and $\mathbf{y}$ remains fixed. Note that $\mathbf{y} = 1^m$ may be reached either before $\mathbf{x}$ reaches 1^n, or after it does. We prefer the second option, as then the Random-Edge walk on A ran to completion. Our construction will ensure that this happens with very high probability. As A' is a random translation of A, the ensuing random walk on A', even if it starts at $\mathbf{x} = 1^n$, is equivalent to a Random-Edge walk starting at a *random* vertex of A. Thus, under appropriate conditions, a Random-Edge walk on $C = A \times_R B$ is expected to be at least *twice* as long as a Random-Edge walk on A itself. This is the crux of the matter.

We next consider the probability of a reshuffle in a random walk with reshuffles on B. This probability must be high to make the random walk long. If the current vertex in $C = A \times_R B$ is $(\mathbf{x}, \mathbf{y})$ and there are s and t outgoing edges from $\mathbf{x}$ in A and $\mathbf{y}$ in B, respectively, then a reshuffle occurs with probability $s/(s+t)$, as Random-Edge on $C = A \times_R B$ chooses each outgoing edge with equal probability and each step in A causes a reshuffle of B. We let Random-Reshuffle$_k$ denote a random walk with reshuffles on B induced by a Random-Edge walk on $C = A \times_R B$, conditioned on all visited vertices of A having outdegree at least k. The probability of a reshuffle when $\mathbf{y}$ has outdegree t in B is then *at least* $k/(k+t)$.

To ensure that reshuffles occur with sufficiently high probability, we need a slight generalization of the randomized product construction.

▶ **Definition 9** (k-fold randomized product [30, 31])**.** Let A be an n-AUSO and let B be an m-AUSO whose sinks are at 1^n and 1^m, respectively, and let $k \geq 1$. For every $\mathbf{x} \in \{0,1\}^n$ and $1 \leq i \leq k$, let $B_{\mathbf{x},i}$ be a randomly permuted version of B, and let A' be a random translation of A. Then, the *k-fold randomized product* $C = A \times_R^k B$ is a distribution over AUSOs defined as follows:

$$C(\mathbf{x}, \mathbf{y}_1, \ldots, \mathbf{y}_k) \;=\; \begin{cases} (A(\mathbf{x}), B_{\mathbf{x},1}(\mathbf{y}_1), \ldots, B_{\mathbf{x},k}(\mathbf{y}_k)) & , \text{ if } \mathbf{y}_1 \neq 1^m \wedge \cdots \wedge \mathbf{y}_k \neq 1^m \;, \\ (A'(\mathbf{x}), B_{\mathbf{x},1}(\mathbf{y}_1), \ldots, B_{\mathbf{x},k}(\mathbf{y}_k)) & , \text{ otherwise} \;. \end{cases}$$

It is not difficult to check that for every random choice $C = A \times_R^k B$ is indeed an AUSO. Matoušek and Szabó [30, 31] need to apply the k-fold randomized product with $k = n^{1/3}$. We only need $k = 2$. As a result, the lower bound is improved from $2^{\Omega(\sqrt[3]{n})}$ to $2^{\Omega(\sqrt{n})}$. Using $k = 1$ is actually enough, but the probabilistic analysis is slightly more complicated. The details will appear in the full version of the paper.

▶ **Lemma 10** ([30, 31])**.** *Let A be an n-AUSO, let B be an m-AUSO and let $k > 1$. Suppose that the probability that the* Random-Edge *walk on A, starting at a random vertex, reaches*

a vertex with outdegree less than k in less than T steps is at most p. Suppose that the probability that a Random-Reshuffle$_k$ *walk on B, starting at a random vertex, reaches the sink in less than T steps is at most q. Then, the probability that the* Random-Edge *walk on $C = A \times_R^k B$, starting at a random vertex, reaches a vertex of outdegree less than k in less than $2T$ steps is at most $2p + kq$.*

Proof. Partition the Random-Edge walk on $C = A \times_R^k B$, starting at a random vertex, into two stages. The first stage ends when one of $B_1, \ldots, B_k$ reaches its sink, i.e., when a state of the form $(\mathbf{x}, \mathbf{y}_1, \ldots, \mathbf{y}_k)$, where $\mathbf{y}_i = 1^m$, for some $1 \leq i \leq k$, is reached. When the first stage ends, the orientation on the first n-coordinates changes to A', a random translation of A, and the second stage begins. The second stage lasts until the sink of $C = A \times_R^k B$ is reached.

The probability that the first stage lasts less than T steps is at most $p + kq$. Indeed, during the first T steps on C, at most T steps on A are performed. Thus, the probability that the Random-Edge walk on A reaches a vertex of outdegree less than k is at most p. As long as the walk on A visits vertices of outdegree at least k, the induced random walks on $B_1, \ldots, B_k$ are Random-Reshuffle$_k$ walks. Thus, the probability that a specific B_i reaches its sink during the first T steps on C is at most q, and the claim follows. During the first phase, there is at least one improving switch in every B_i, thus the outgedree of each visited vertex is at least k.

In the second stage, the orientation on the first n-coordinates changes to A'. As A' is a random translation of A, this is equivalent to starting a Random-Edge walk on A at a random starting vertex. The probability that this random walk reaches a vertex of outdegree less than k in less than T is steps is at most p.

Thus, the probability that the Random-Edge walk on $C = A \times_R^k B$, starting at a random vertex, reaches a vertex of outdegree less than k in less than $2T$ steps is at most $(p + kq) + p = 2p + kq$. ◀

4 The Lower Bound

A distribution of AUSOs on which Random-Edge makes $2^{\Omega(\sqrt{n})}$ steps, with high probability, is obtained by iterating the randomized product construction of the previous section. We follow the footsteps of Matoušek and Szabó [30, 31] making one crucial change; We use the *path* AUSO, defined in Section 2, instead of the Klee-Minty cube, as the main building block. Using the path AUSO allows us to simplify the proof and improve the lower bound. The following lemma, whose proof is given in the next section, is one of the main technical contributions of this paper.

▶ **Lemma 11.** *Let P_m be the path m-AUSO. There are constants $\alpha, \beta > 0$ such that the probability that* Random-Reshuffle$_2$ *on P_m, starting from a random vertex, performs less than $2^{\alpha m}$ steps before reaching the sink is at most $2^{-\beta m}$.*

Let m be an integer, and let $\ell = \gamma m$, where $\gamma < \min\{\alpha, \beta\}$, where α, β are the constants in Lemma 11. Let A_0 be an arbitrary m-AUSO. For concreteness, we let $A_0 = P_m$, the *path* AUSO of Section 2. We construct a sequence of $A_0, A_1, \ldots, A_\ell$ of AUSOs, where $A_i = A_{i-1} \times_R^2 P_m$ is an $(2i+1)m$-AUSO, for $0 \leq i \leq \ell$. Note that A_ℓ is of dimension $(2\ell+1)m = O(m^2)$. The following lemma, which easily implies a $2^{\Omega(\sqrt{n})}$ lower bound, claims that with high probability, Random-Edge performs at least $2^{\Omega(m)}$ steps when started at a random vertex of A_ℓ. We give an improved version of the lemma in Section 6.

▶ **Lemma 12.** *The probability that* Random-Edge *performs less than 2^ℓ steps when started at a random vertex of A_ℓ, where $\ell < \alpha m$, is at most $4 \cdot 2^{\ell - \beta m}$.*

Proof. Let p_i be the probability that RANDOM-EDGE, started at a random vertex of A_i, performs less than 2^i steps before reaching a vertex of outdegree less than 2. Note that $p_0 = (m+1)2^{-m}$ is just the probability that the random starting vertex of A_0 has outdegree at most 1, which by Lemma 7 is exactly $(m+1)2^{-m}$.

Let q_i be the probability that the RANDOM-RESHUFFLE$_2$ walk on P_m, in which the probability of reshuffle from a vertex of outdegree j is at least $2/(j+2)$, reaches the sink in less than 2^i steps, when started at a random vertex. Clearly, for every $1 \le i \le \ell$ we have $q_i \le q_\ell$. As $\ell \le \alpha m$, Lemma 11 implies that $q_\ell \le 2^{-\beta m}$.

By Lemma 10, we have $p_i \le 2(p_{i-1} + q_{i-1})$. It follows easily by induction that $p_i \le 2^i p_0 + 2(2^i - 1)q_i$, for $1 \le i \le \ell$. Thus, $p_\ell \le 2^\ell (m+1)2^{-m} + 2^{\ell+1}2^{-\beta m} \le 4 \cdot 2^{\ell - \beta m}$. ◀

As a corollary, we get:

▶ **Theorem 13.** *There exist n-AUSOs and appropriate starting points from which* RANDOM-EDGE *performs $2^{\Omega(n^{1/2})}$ steps with probability at least $1 - 2^{-\delta\sqrt{n}}$, for some $\delta > 0$.*

5 Random Walk with Reshuffles on the Path AUSO

In this section we provide a proof of Lemma 11, completing the proof of our first lower bound.

Let $\mathbf{y} \in \{0,1\}^m$ be a state of RANDOM-RESHUFFLE$_2$ on the path AUSO P_m. Let k be the *weight*, i.e., the number of 1's in $\mathbf{y}$ and let i be the number of leading 1's in $\mathbf{y}$. For example, if $m = 7$ and $\mathbf{y} = 1100101$, then $k = 4$ and $i = 2$. Also let $j = k - i$, the number of non-leading 1's. We say that $\mathbf{y}$ is of *type* (i, j). The outdegree of a state of type (i, j) is clearly $j + 1$.

From a state $\mathbf{y}$ of type (i, j) of RANDOM-RESHUFFLE$_2$ on P_m, there is a reshuffle with a probability of at *least* $2/(j+3)$, as all states of type (i, j) are of outdegree $j + 1$. Several reshuffles may occur in a row, but they have exactly the same effect as a single reshuffle.

If a state of weight k is reshuffled, the obtained state is of type $(k-j, j)$, where $0 \le j \le k$, with probability $a_{k,j} = \binom{m-(k-j+1)}{j} / \binom{m}{k}$. (Among the $\binom{m}{k}$ binary strings of length m and weight k, there are exactly $\binom{m-(k-j+1)}{j}$ strings that start with $1^{k-j}0$.) Clearly $\sum_{j=0}^{k} a_{k,j} = 1$.

When a reshuffle occurs, we initially consider only the type of the state obtained. We *delay* the decision as to which state exactly we are in. (All states belonging to the type are equally likely.) This simplifies the analysis, as we only need to consider $O(m^2)$ types ($\binom{m+1}{2} + 1$ to be exact) rather than 2^m possible states.

Suppose that we are now in a state of type (i, j), where $k = i + j$. One or more reshuffles are performed with a probability of at least $2/(j+3)$, and then a standard move is performed. Let (i', j'), where $k' = i' + j'$, be the type of the new state obtained. Note that $k' = k - 1$ or $k' = k + 1$, as a reshuffle does not change the weight and a single move either increases or decreases the weight by 1. We show that the probability of a weight increase, i.e., $k' = k + 1$ is bounded by some constant $c < \frac{1}{2}$. As the weight of a random starting vertex is close to $m/2$ and as the weight of the sink is m, it would follow that an exponential number of steps are needed, with high probability, to reach the sink.

Let $\bar{p}_k$ be the probability of a weight increase from a state of weight k given that a reshuffle occurs. We have $\bar{p}_k = \sum_{j=0}^{k} \frac{a_{k,j}}{j+1}$, as the reshuffle generates a state of type $(k-j, j)$ with probability $a_{k,j}$ and the probability of a weight increase from such a state is $1/(j+1)$.

Let $p_{k,j}(s)$ be the probability of a weight increase from a state of type $(k-j, j)$, when the corresponding state in A has s outgoing edges. The probability of a reshuffle from a state of type $(k-j, j)$ is $\frac{s}{j+s+1}$, and the probability of no reshuffle is $\frac{j+1}{j+s+1}$. If there is no reshuffle,

the probability of a weight increase is $\frac{1}{j+1}$. If there is a reshuffle, then the probability of a weight increase is $\bar{p}_k$. Hence,

$$p_{k,j}(s) \;=\; \frac{j+1}{j+s+1}\cdot\frac{1}{j+1} + \frac{s}{j+s+1}\cdot\bar{p}_k \;=\; \frac{1}{j+s+1} + \frac{s}{j+s+1}\cdot\bar{p}_k\;.$$

We next upper bound $\bar{p}_k$, the probability of a weight increase following a reshuffle from a state of weight k.

▶ **Lemma 14.** $\bar{p}_k \;<\; \dfrac{m-k}{(k+1)(m-k-1)}$.

Proof. A simple manipulation of binomial coefficients yields:

$$\frac{a_{k,j}}{j+1} \;=\; \frac{\binom{m-k+j-1}{j}}{\binom{m}{k}}\frac{1}{j+1} \;=\; \frac{\binom{m-k+j-1}{j+1}}{\binom{m}{k}}\frac{1}{m-k-1} \;=\; \frac{1}{m-k-1}\frac{\binom{m}{k+1}}{\binom{m}{k}}a_{k+1,j+1}\;.$$

Hence,

$$\bar{p}_k = \sum_{j=0}^{k}\frac{a_{k,j}}{j+1} = \frac{1}{m-k-1}\frac{\binom{m}{k+1}}{\binom{m}{k}}\sum_{j=0}^{k}a_{k+1,j+1} < \frac{1}{m-k-1}\frac{\binom{m}{k+1}}{\binom{m}{k}} = \frac{m-k}{(k+1)(m-k-1)}.$$

◀

▶ **Lemma 15.** *Let (i,j) be a type of* Random-Reshuffle$_2$ *walk on the path AUSO P_m of weight $k=i+j$ satisfying $8 \le k \le m-9$. Then, the probability that the type obtained after one step of a* Random-Reshuffle$_2$ *walk, i.e., a reshuffle with a probability of at least $2/(j+3)$ followed by a standard move, is of weight $k+1$ is at most $\frac{5}{12}$.*

Proof. We need to show that $p_{k,j}(s) \le \frac{5}{12}$, for every $8 \le k \le m-9$, $0 \le j \le k$, and $s \ge 2$. Recall that $p_{k,j}(s) = \frac{j+1}{j+s+1}\cdot\frac{1}{j+1} + \frac{s}{j+s+1}\cdot\bar{p}_k$. For $8 \le k \le m-9$ we have $\bar{p}_k \le \frac{1}{8}$, as $\frac{1}{k+1} \le \frac{1}{9}$ while $\frac{m-k}{m-k-1} \le \frac{9}{8}$. If $j \ge 2$, then $p_{k,j}(s) \le \frac{1}{3}$, for every $s \ge 1$, as $\frac{1}{j+1} \le \frac{1}{3}$ and $\bar{p}_k \le \frac{1}{3}$. If $j=1$, then $p_{k,1}(s) \le \frac{1}{2}\cdot\frac{1}{2} + \frac{1}{2}\cdot\frac{1}{8} = \frac{5}{16}$, again for every $s \ge 1$. Finally, if $j=0$, then $p_{k,0}(s) \le \frac{1}{3} + \frac{2}{3}\cdot\frac{1}{8} = \frac{5}{12}$, for every $s \ge 2$. ◀

Lemma 15 does not hold for Random-Reshuffle$_1$ as for $j=0$ we relied on the assumption $s \ge 2$. This is why we need to use 2-fold randomized products. Alternatively, we can look at *two* steps of Random-Reshuffle$_1$ on P_m. This yields a negative drift from all types, including $(i,0)$, but the proof is slightly more complicated. The details will appear in the full version of the paper.

▶ **Definition 16** (Biased random walk)**.** Let $0 \le c < \frac{1}{2}$. A random process on states $\{0,1,\ldots,n\}$ is *c-bounded* if and only if whenever the process is in state i, where $i > 0$, then it moves to state $i+1$ with probability at most c, and to state $i-1$ with the complementary probability of at least $1-c$. From state 0, the process moves to state 1 with probability 1.

In the above definition, the transition probabilities may depend on the history of the random process, as well as on external factors. The following claim is well known. For completeness, we include a proof that follows the presentation in Levin, Peres and Wilmer [25] (Section 17.3.1).

▶ **Lemma 17.** *Let $0 \le c < \frac{1}{2}$. The probability that a c-bounded random process on $\{0,1,\ldots,n\}$ that starts at state 0 reaches state n in less than K steps is at most $K\left(\frac{c}{1-c}\right)^{n-1}$. In particular, for any $\alpha < \frac{1-c}{c}$, the probability that the random walk reaches n in less than α^{n-1} steps is at most $\left(\frac{\alpha c}{1-c}\right)^{n-1}$.*

Proof. Let us assume that the probability of moving from i to $i+1$ is exactly c. It is not difficult to show that this implies the more general claim.

Let X_t be a c-bounded random walk on the integers starting at 1, i.e., $X_0 = 1$. Let $r = (1-c)/c$. It is easy to check that r^{X_t} is a *martingale*. Consider the *stopping time* τ defined as the smallest t for which $X_t = 0$ or $X_t = n$. By the *Optional Stopping Theorem* we get that $\mathbb{E}[r^{X_\tau}] = \mathbb{E}[r^{X_0}] = r$. Let a be the probability that the random walk reaches n before it reaches 0. Then $\mathbb{E}[r^{X_\tau}] = ar^n + (1-a)$. Thus $ar^n + (1-a) = r$ and $a = \frac{r-1}{r^n-1} < (1/r)^{n-1}$.

Returning to the c-bounded walk on $\{0, 1, \ldots, n\}$ starting at 0, we note that the expected number of times that this random walk returns to 0 before visiting n is a geometric random variable with parameter a. Thus the probability that the random walk reaches n in less than K steps, and in particular less than K returns to 0, is at most $1-(1-a)^K < Ka < K\left(\frac{c}{1-c}\right)^{n-1}$. ◀

Putting everything together, we get a proof of Lemma 11.

Proof of Lemma 11. A Random-Reshuffle$_2$ walk on the path AUSO P_m induces a random walk on *types* (i, j). The random walk on types induces a random walk on *weights*. Lemma 15 claims that when $8 \le k \le m-9$, the random walk on the weights is $\frac{5}{12}$-bounded. The weight of a random starting point of Random-Reshuffle$_2$ is binomially distributed. By Chernoff bound, the probability that the starting state of the bounded walk on the weights starts at a weight larger than $(\frac{1}{2}+\delta)m$, for some $\delta > 0$, is exponentially small. By Lemma 17 the probability that the random walk moves from the random starting point to $m-9$ in at most an exponential number of steps is exponentially small. The existence of appropriate constants α, β follows easily. ◀

6 An Improved Lower Bound

The improved lower bound of $2^{\Omega(\sqrt{n \log n})}$ is obtained using essentially the same construction but with a strengthened analysis. We again let $A_0 = P_m$ and $A_i = A_{i-1} \times^2_R P_m$, for $i = 1, ..., \ell$, but this time we choose $\ell = \gamma m \log m$, for some $\gamma > 0$. We can still show that with high probability Random-Edge performs at least 2^ℓ steps on A_ℓ. Thus A_ℓ is an n-AUSO, where $n = 2\gamma m^2 \log m$, on which Random-Edge performs with high probability at least 2^ℓ steps, where $\ell = \gamma m \log m = \Omega(\sqrt{n \log n})$. This establishes the following theorem, which is the main result of this paper.

▶ **Theorem 18.** *There exist n-AUSOs and appropriate starting points from which* Random-Edge *performs $2^{\Omega(\sqrt{n \log n})}$ steps with probability at least $1 - 2^{-\delta\sqrt{n}}$, for some $\delta > 0$.*

To prove this result, we need a strengthened version Lemma 11. Lemma 11 states that there are constants $\alpha, \beta > 0$ such that the probability that Random-Reshuffle$_2$ on P_m, starting from a random vertex, performs less than $2^{\alpha m}$ steps before reaching the sink is at most $2^{-\beta m}$. The proof of Lemma 11 relied on the fact that from a state of type (i, j), the probability of a reshuffle is at least $2/(j+3)$. If the reshuffle probabilities are always $2/(j+3)$, then Lemma 11 is essentially tight. However, the reshuffle probability is $2/(j+3)$ only if the vertex $\mathbf{x} \in A$ has only two outgoing edges. By Lemma 7 this can happen at most $\binom{n}{2}$ times. More generally, let $s = \sqrt{n}$. The number of vertices in A of outdegree less than s is at most $\sum_{i=0}^{s} \binom{n}{i} \le n^s$.

▶ **Definition 19** (Random-Reshuffle$_k^{(N,s)}$)**.** A Random-Reshuffle$_k^{(N,s)}$ walk on an m-AUSO B is a random walk with reshuffles on B in which the reshuffle probability from a

vertex $\mathbf{y} \in \{0,1\}^m$ of outdegree t is at least $s/(s+t)$, except for at most N times in which the reshuffle probability is only guaranteed to be at least $k/(k+t)$.

By the above discussion, the random process on B induced by a RANDOM-EDGE walk on $A \times_R^2 B$ is a RANDOM-RESHUFFLE$_k^{(N,s)}$ process, with $N \leq n^s$. The following lemma is a strengthening of Lemma 11. The proof will appear in the full version of the paper.

▶ **Lemma 20.** *Let P_m be the path m-AUSO. There are constants $\alpha, \beta > 0$ such that the probability that* RANDOM-RESHUFFLE$_2^{(N,s)}$ *on P_m, where $s = m^{1/2}$, $N \leq m^{3s}$, starting from a random vertex, performs less than $2^{\alpha m \log m}$ steps before reaching the sink is at most $2^{-\beta m}$.*

We note that Lemma 20 is essentially best possible, which is one of the reasons we believe that improving our $2^{\Omega(\sqrt{n \log n})}$ lower bound will require new techniques. (See also Section 7.)

▶ **Lemma 21.** *Let B be any m-AUSO. Then, with high probability* RANDOM-RESHUFFLE$_k$ *on B makes at most $O((km)^m) = 2^{O(m \log(km))}$ steps before reaching its sink.*

Proof. Each vertex of B is of distance at most m from the sink (see, e.g., [26, 16]). Thus, if there are m consecutive steps with no reshuffles and the right edge in B is followed, then the sink is reached. This happens with a probability of at least $((k+1)m)^{-m}$. ◀

The proof of Lemma 20 relies on the following strengthening of Lemma 17. The proof will appear in the full version of the paper.

▶ **Lemma 22.** *Let $0 \leq c_1 < c_2 < \frac{1}{2}$. Consider a random walk on $\{0, 1, \ldots, n\}$ in which in each step a controller is allowed to flip a coin with success probability at most c_1, or a coin with success probability at most c_2. The controller is allowed to make the second choice at most N times. According to the outcome of the coin, the process moves from i to either $i-1$ or $i+1$. (From 0 the move is always to 1.) Then, the probability that the walk reaches n in less than K steps is at most $K\left(\frac{c_1}{1-c_1}\right)^{n/2-1} + N\left(\frac{c_2}{1-c_2}\right)^{n/2-1}$.*

Relying on these strengthened lemmas, Theorem 18 follows using essentially the same arguments used to prove Theorem 13.

7 Decomposable and Layered AUSOs

The AUSOs used above to obtain the $2^{\Omega(\sqrt{n \log n})}$ lower bound, as well as the AUSOs used by Matoušek and Szabó [30, 31] and by Friedmann et al. [9] are *decomposable*.

▶ **Definition 23** ((k,ℓ)-decomposable AUSO)**.** A $(k\ell)$-AUSO is said to be (k,ℓ)-decomposable if its coordinates can be partitioned into k blocks $B_1, \ldots, B_k$ each of size ℓ such that if $\mathbf{x}$ is the sink of A and $\mathbf{y}$ agrees with $\mathbf{x}$ in $B_i, B_{i+1}, \ldots, B_k$, for some $1 \leq i \leq k$, then all the edges in these coordinates are directed towards $\mathbf{y}$.

Decomposable AUSOs belong to a much wider class of *layered AUSOs*. A layered AUSO is an AUSO whose vertices can be partitioned into a relatively small number of layers such that from each non-sink vertex there is a relatively short directed path to a vertex of a lower layer, and such that no directed path may lead from a vertex to a vertex of a higher layer. More formally:

▶ **Definition 24** ((k,ℓ)-Layered AUSOs)**.** An n-AUSO A is said to be (k,ℓ)-*layered* if its vertices can be partitioned into disjoint *layers* $L_0, L_1, \ldots, L_k$ such that: *(i)* L_0 only contains the sink. *(ii)* If $\mathbf{x} \in L_i$, where $i > 0$, then there is a directed path of length at most ℓ in A from $\mathbf{x}$ to some vertex $\mathbf{y} \in L_j$, for $j < i$. *(iii)* If $\mathbf{x} \in L_i$, then there is no directed path in A from $\mathbf{x}$ to any vertex $\mathbf{y} \in L_j$, for $j > i$.

▶ **Lemma 25.** *If A is a (k,ℓ)-decomposable AUSO then it is also (k,ℓ)-layered.*

Proof. Let $B_1, B_2, \ldots, B_k$ be the partition of the coordinates of A and let $\mathbf{x}$ be the sink of A. For $i = 0, 1, \ldots k$, let L_i be the set of vertices that agree with $\mathbf{x}$ in all the coordinates of $B_{i+1}, B_{i+2}, \ldots, B_k$ and differ from $\mathbf{x}$ in some coordinate of B_i. It is easy to check that all conditions are met by using the fact that every vertex in a subcube of dimension ℓ has a path of length at most ℓ to the sink of that subcube (see, e.g., [26, 16]). ◀

We next show that Random-Edge is fairly quick on layered AUSOs.

▶ **Lemma 26.** *The expected number of steps that* Random-Edge *performs on a (k,ℓ)-layered n-AUSO, from any starting vertex, is at most $k\ell n^\ell$.*

Proof. We show that the expected number of steps per layer is at most ℓn^ℓ, which proves the lemma. From every vertex in the current layer there is at least one path of length ℓ to a lower layer. Random-Edge follows this path with a probability of at least $1/n^\ell$. Therefore the expected number of trials before successfully following such a path is at most n^ℓ, and since each trial uses at most ℓ steps, the total expected number of steps is at most ℓn^ℓ. ◀

We note that the n-AUSOs used to obtain our $2^{\Omega(\sqrt{n \log n})}$ lower bound are (k,ℓ)-layered for $k = O(\sqrt{n \log n})$ and $\ell = O(\sqrt{n/\log n})$. Lemma 26 therefore shows that the expected number of steps performed by Random-Edge on our AUSOs is at most $2^{O(\sqrt{n \log n})}$, which means that our analysis of these AUSOs is tight up to a constant factor in the exponent. Moreover, to improve the lower bound it is necessary to construct n-AUSOs that are not $(2^{O(\sqrt{n \log n})}, O(\sqrt{n/\log n}))$-layered, or, more generally, not (k,ℓ)-layered for any choice of k and ℓ such that $k\ell n^\ell = 2^{O(\sqrt{n \log n})}$. No such AUSOs are currently known to exist. Similarly, to improve on the 1.8^n upper bound of Hansen et al. [16] it is enough to prove that every n-AUSO is $(2^{cn}, dn/\log n)$-layered, for $c + d < 0.847 < \log_2 1.8$.

The lower bound of Friedmann et al. [9] uses AUSOs that simulate a binary counter. A t-bit counter is simulated by $(t, n/t)$-decomposable n-AUSO. The lower bound obtained using such AUSOs is roughly 2^t. As $(t, n/t)$-decomposable n-AUSO are also $(t, n/t)$-layered, we get using Lemma 26 that the best lower bound that can be obtained using such AUSOs is $\min\{2^t, n^{n/t+1}\}$, which attains a maximum value of about $2^{\Theta(\sqrt{n \log n})}$ when $t = \sqrt{n \log n}$.

A notion of the *niceness* of AUSOs and USOs, which is related to the notions of decomposable and layered AUSOs was defined by Welzl [35]. Gärtner and Thomas [14] have independently observed that the AUSOs used to obtain our lower bound are $\sqrt{n \log n}$-nice and therefore cannot be used to obtain further improved lower bounds.

8 Concluding remarks and open problems

We proved a $2^{\Omega(\sqrt{n \log n})}$ lower bound on the number of steps performed by Random-Edge on some AUSOs. The two obvious open problems are proving a $2^{o(n)}$ upper bound and an improved lower bound of $2^{\omega(\sqrt{n \log n})}$. We believe that radically new techniques would be needed to prove a lower bound of $2^{\omega(\sqrt{n \log n})}$. Another interesting open problem is improving the $2^{\Omega(n^{1/4})}$ lower bound of [9] for AUSOs that correspond to actual linear programs.

Acknowledgments. We would like to thank Mikkel Thorup for encouraging us to improve our lower bound from $2^{\Omega(\sqrt{n})}$ to $2^{\Omega(\sqrt{n \log n})}$, to Yuval Peres for pointing us to [25] for a proof of Lemma 17, and to Bernd Gärtner and Antonis Thomas for bringing the concept of niceness of AUSOs to our attention.

Abstract

We study the problem of approximately solving positive linear programs (LPs). This class of LPs models a wide range of fundamental problems in combinatorial optimization and operations research, such as many resource allocation problems, solving non-negative linear systems, computing tomography, single/multi commodity flows on graphs, etc. For the special cases of pure packing or pure covering LPs, recent result by Allen-Zhu and Orecchia [2] gives $\tilde{O}(\frac{1}{\epsilon^3})$-time parallel algorithm, which breaks the longstanding $\tilde{O}(\frac{1}{\epsilon^4})$ running time bound by the seminal work of Luby and Nisan [10].

We present new parallel algorithm with running time $\tilde{O}(\frac{1}{\epsilon^3})$ for the more general mixed packing and covering LPs, which improves upon the $\tilde{O}(\frac{1}{\epsilon^4})$-time algorithm of Young [18, 19]. Our work leverages the ideas from both the optimization oriented approach [2, 17], as well as the more combinatorial approach with phases [18, 19]. In addition, our algorithm, when directly applied to pure packing or pure covering LPs, gives a improved running time of $\tilde{O}(\frac{1}{\epsilon^2})$.

1 Introduction

Mixed packing and covering linear programs (LPs) are LPs formulated with non-negative coefficients, non-negative constraints and non-negative variables. They model a wide range of fundamental problems in combinatorial optimization and operations research, thus have long drawn interest in theoretical computer science [10, 18, 2, 1]. Notable special cases include pure packing LPs and pure covering LPs, which apply to most resource allocation problems, and can be formulated respectively as $\max_{\boldsymbol{x}\geq 0}\{\boldsymbol{c}^T\boldsymbol{x} : \boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}\}$ and $\min_{\boldsymbol{x}\geq 0}\{\boldsymbol{c}^T x : \boldsymbol{A}x \geq \boldsymbol{b}\}$ where $\boldsymbol{c}, \boldsymbol{A}, \boldsymbol{b} \geq 0$. More general than the pure packing and covering LPs, the mixed packing and covering LPs further capture problems requiring both packing and covering constraints, including solving non-negative linear systems, computing tomography, and single/multi commodity flows on graphs.

Formally, the mixed packing and covering LP is the optimization problem

$$\min\{\lambda : \boldsymbol{P}\boldsymbol{x} \leq \lambda \boldsymbol{p}, \boldsymbol{C}\boldsymbol{x} \geq \boldsymbol{c}, \boldsymbol{x} \geq 0\} \tag{1}$$

where $\boldsymbol{P}, \boldsymbol{C}, \boldsymbol{p}, \boldsymbol{c}$ all have non-negative entries. A $(1+\epsilon)$-approximation is a feasible solution $\lambda, \boldsymbol{x}$ achieving $\lambda \leq (1+\epsilon)\lambda_{\text{OPT}}$.

Although one can use general LP solvers such as interior point method to solve packing and covering with convergence rate of $\log(\frac{1}{\epsilon})$ [8, 9, 5], such algorithms usually have very high per-iteration cost, as methods such as the computation of the Hessian and matrix inversion are involved. With the abundance of large-scale datasets, as well as the growing reliance on multiprocessors and cloud computing, low precision iterative solvers that can be highly parallelized are often more popular choices. Such parallel solvers compute approximate solutions usually in time with a poly-log dependence on the problem size, and nearly-linear total work, but they have $\text{poly}(\frac{1}{\epsilon})$ dependence on the approximation parameter ϵ.

Based on whether the running time depends on the width ρ, a parameter which typically depends on the dimension and the largest entry of $\boldsymbol{A}$, these algorithms can be divided into width-dependent solvers and width-independent solvers. Width-dependent solvers are usually pseudo-polynomial, as the running time depends at least linearly on $\rho\,\text{OPT}$, which itself can be large, while width-independent solvers are more efficient in the sense that they provide truly polynomial-time approximation solvers.

In this paper we focus on width-independent algorithms that produce $1+\epsilon$ approximations in $\text{poly}(\log n, \frac{1}{\epsilon})$ time and nearly-linear work. Time and work are standard notions from parallel algorithms that correspond to the longest chain of dependent operations and the total operations performed. In particular, time has a natural correspondence with iteration count, and these two measures have been used to study the performance of packing/covering LPs before [19]. Since the focus of this line of work is not on optimizing the log factors, we will follow the standard practice of using $\tilde{O}$ to hide poly-log factors (which are at most $\log^3 n$) in our discussion[1].

1.1 Previous work

Most of the works on mixed packing and covering LPs, as well as the works on the special cases of pure packing and pure covering LPs, take one of the two approaches. The first approach is based on turning the constrained LPs into convex and smooth objective functions with trivial or no constraints. Approximately solving the LP is then reduced to approximately optimizing the smoothed function (see [13]), and general-purpose optimization schemes are usually applied directly. This approach traditionally gives algorithms that work in more general settings, but are width-dependent in the case of packing and covering (e.g., [12, 3, 13, 16]). Recent breakthroughs in [2, 1] leverage the insight from optimization ([21]) and the special structure of packing and covering problems, and get the first width-independent algorithms using first order optimization methods. In particular, [2] gives a parallel algorithm that takes $\tilde{O}(\frac{1}{\epsilon^3})$ time and $\tilde{O}(\frac{N}{\epsilon^3})$ work. Here N is the size of the input, i.e., the total number of non-zeros in the constraint matrices $\boldsymbol{P}$ and $\boldsymbol{C}$. The result can be improved to run in $\tilde{O}(\frac{1}{\epsilon^2})$ time and $\tilde{O}(\frac{N}{\epsilon^2})$ work with simple modifications [17]. As for sequential algorithms, the remarkable result in [1] combines width-independence with Nesterov-like acceleration ([13, 14]), and gets a randomized algorithm with running time $\tilde{O}(\frac{N}{\epsilon})$. However, both results

[1] $\tilde{O}(f(n))$ is often used to denote $O(f(n)\log^{O(1)}(f(n)))$, we modify it to include an additional factor of $\log^{O(1)} n$.

in [2, 1] are limited to pure packing and pure covering problems, and prior to our work no methods are able to obtain a time of $\tilde{O}(\frac{1}{\epsilon^3})$ or better for mixed covering and packing LPs [19].

The other approach is based on the Lagrangian-relaxation framework, where, similar to the optimization approach, certain hard constraints are replaced by a soft scalar-value penalty function, and the partial solution is iteratively updated to satisfy the remaining constraints while minimizing the increase of the penalty function. The analysis of the Lagrangian-relaxation algorithms have more of a combinatorial flavor compared to the optimization schemes. Examples include the seminal work of Luby and Nisan [10], which gives the first width-independent algorithm for packing and covering, as well as subsequent works which improve the Luby and Nisan result in various ways [6, 18, 19, 7, 4, 11]. Among them, only [18, 19, 11] work with mixed packing and covering LPs, while others only work in the pure packing and pure covering setting. For algorithms working on mixed packing and covering, the results in [18, 19] have the best theoretical guarantee on parallel running time, with $\tilde{O}(\frac{1}{\epsilon^4})$ running time and $\tilde{O}(\frac{N}{\epsilon^2})$ total work. The result in [11] has worse bounds, but is stateless, which is a computational model on distributed algorithms with more restrictions on the processors (see [4]).

1.2 Our results

In this paper, we present a parallel algorithm that, given a mixed packing and covering LP with m variables and n total constraints, in $\tilde{O}(\frac{1}{\epsilon^3})$ iterations computes a $(1+\epsilon)$-approximate solution, or correctly reports the original mixed packing and covering LP is infeasible. The algorithm is deterministic and width-independent.

The bottleneck of each iteration is a matrix-vector multiplication, and can be implemented in $O(\log N)$ depth, in which case the running time of our algorithm is $\tilde{O}(\frac{1}{\epsilon^3})$. The total work of the algorithm we present in the paper is $\tilde{O}(\frac{N}{\epsilon^3})$. In particular, our result improves upon the current fastest parallel algorithm of mixed packing and covering LPs in [18, 19], where the running time is $\tilde{O}(\frac{1}{\epsilon^4})$. The work of the parallel algorithm in [18, 19] is $\tilde{O}(\frac{N}{\epsilon^2})$. We note that using a simple lazy update modification on the algorithm, which is the same technique used in [18, 19], we can reduce the work of our algorithm to $\tilde{O}(\frac{N}{\epsilon^2})$. Same as in [18, 19], this comes at the cost of requiring a centralized step in the parallel algorithm. Since the iteration count is the more interesting side of this line of work, we will not incorporate the lazy update in our algorithm for simplicity.

Furthermore, in the case of pure packing problem or pure covering problem, our algorithm allows a similar but simplified analysis, and will converge in $\tilde{O}(\frac{1}{\epsilon^2})$ iterations. This matches the running time achieved by the line of work [2, 17], but has the advantage of being deterministic and without centralized steps. We note that the technique we use in the analysis of the potential function in this work can be applied in a straightforward way to improve the result of [2] to have $\tilde{O}(\frac{1}{\epsilon^2})$ running time.

2 Technical overview

To compute $(1+\epsilon)$-approximation of a mixed packing and covering LP in the optimization form (1), via standard reduction and scaling (e.g., see [18]), it suffices to solve a $(1+O(\epsilon))$-feasibility problem as specified in (3) and (4).

At a high level, our work follows the Lagrangian-relaxation approach as in [18, 19]. In particular, we replace the hard packing and covering constraints with a scalar-valued potential function, which is continuous and smooth. The potential function measures how far away

the current solution is from satisfying all the captured constraints. As in [18], we use the soft-max $\operatorname{lmax}(\boldsymbol{P}\boldsymbol{x})$ and soft-min $\operatorname{lmin}(\boldsymbol{C}\boldsymbol{x})$ in our potential function

$$\operatorname{lmax}(\boldsymbol{P}\boldsymbol{x}) = \ln(\sum_j \exp(\boldsymbol{P}\boldsymbol{x})_j), \text{ and } \operatorname{lmin}(\boldsymbol{C}\boldsymbol{x}) = -\ln(\sum_j \exp(-\boldsymbol{C}\boldsymbol{x})_j).$$

In particular, these functions give smooth approximation to $\max_j(\boldsymbol{P}\boldsymbol{x})_j$ and $\min_j(\boldsymbol{C}\boldsymbol{x})_j$:

$$\begin{aligned} \max_j(\boldsymbol{P}\boldsymbol{x})_j \leq \operatorname{lmax}(\boldsymbol{P}\boldsymbol{x}) \leq \max_j(\boldsymbol{P}\boldsymbol{x})_j + \ln n \\ \min_j(\boldsymbol{C}\boldsymbol{x})_j \geq \operatorname{lmin}(\boldsymbol{C}\boldsymbol{x}) \geq \min_j(\boldsymbol{C}\boldsymbol{x})_j - \ln n. \end{aligned} \tag{2}$$

The potential function we use will be

$$f(\boldsymbol{x}) = \operatorname{lmax}(\boldsymbol{P}\boldsymbol{x}) - \operatorname{lmin}(\boldsymbol{C}^{(t)}\boldsymbol{x}),$$

which is approximately the difference between $\max_j(\boldsymbol{P}\boldsymbol{x})_j$ and $\min_j(\boldsymbol{C}\boldsymbol{x})_j$.

The overall framework is to start with a $\boldsymbol{x}$ of very small values, and iteratively increase $\boldsymbol{x}$ while keeping $f(\boldsymbol{x})$ small. Roughly, when $\boldsymbol{x}$ is large enough so that

$$\max\{\max_j(\boldsymbol{P}\boldsymbol{x})_j, \min_j(\boldsymbol{C}\boldsymbol{x})_j\} \geq \frac{1}{\epsilon} f(\boldsymbol{x}),$$

we know that $\max_j(\boldsymbol{P}\boldsymbol{x})_j \leq (1 + O(\epsilon)) \min_j(\boldsymbol{C}\boldsymbol{x})_j$.

Same as in [18, 19], each iteration a subset of the variables are picked based on the gradients of the potential function, and are updated within a local smooth region so we can bound the change of the potential function. In particular, for each variable $\boldsymbol{x}_i$ we compute the packing gradient $\boldsymbol{a}_i = \nabla_i \operatorname{lmax}(\boldsymbol{P}\boldsymbol{x})$, and the covering gradient $\boldsymbol{b}_i = \nabla_i \operatorname{lmin}(\boldsymbol{C}\boldsymbol{x})$. We want to update variables without increasing $f(\boldsymbol{x})$, and since $\nabla_i f(\boldsymbol{x}) = \boldsymbol{a}_i - \boldsymbol{b}_i$, a variable will be included in the update subset only when its covering gradient $\boldsymbol{b}_i$ is larger than its packing gradient $\boldsymbol{a}_i$.

However, unlike the parallel algorithm in [18, 19] that multiplicatively updates all variables in the subset with a uniform step size, we further incorporate the gradients $\boldsymbol{a}$ and $\boldsymbol{b}$ into step sizes of individual variables' updates. This discriminative multiplicative step size allows more aggressive updates on average, and is directly motivated by the line of works using gradient based optimization methods [2, 1, 17]. However, we move away from the optimization oriented view of these update steps in favor of more localized and adhoc analyses, which was developed to analyze direct adaptations of Young's algorithm for purely-packing SDPs [15], leading to bounds similar to the optimization based approaches [20].

Similar to Young's algorithm [18], the overall progress of the algorithm is captured by how large the constraints become. A sufficient termination condition for the algorithm is when a variable is increased by more than a certain amount, so we know $\max_j(\boldsymbol{P}\boldsymbol{x})_j$ and $\min_j(\boldsymbol{C}\boldsymbol{x})_j$ are large enough. To bound the number of iterations before any variable gets too large, we combine the notion of phases from [18] with the more refined analysis of gradient updates from more recent works [17]. This is owing to the clearer combinatorial structure of our interpretation of discriminative multiplicative steps.

On a high level, the analysis considers *phases*, where each phase is a consecutive sequence of iterations. The definition of a phase captures a local window, where the algorithm only makes limited global progress. The limited global progress ensures that inside a single phase the landscape doesn't change too much, which translate to certain monotonicity-like property on the gradients within the interactions captured by a single phase. In [18], each phase is defined to cover very little overall progress, which gives a very strong monotonicity-like

property. In particular, any variable being increased at the last iteration of a phase must have been increased in every iteration of the phase, which, coupled with a lower bound on each increase, gives a bound of the number of iterations in a phase.

In our analysis, we significantly expand the phases to capture larger global progress, leading to a smaller number of phases. The larger phases lead to a weaker monotonicity-like property on the gradients within a phase, and we develop a new approach to bound the number of iterations in our phase. We divide the iterations into two groups: some initial warm-up *bad* iterations followed by subsequent *good* iterations containing more interesting segments of the path to convergence (see Definition 7 for formal definitions). The bad iterations are ones where packing gradients are much smaller than covering gradients. These are the easy iterations to deal with, since a small ratio of the packing gradient over the covering gradient is a clear signal to increase a variable by a lot. An analysis identical to Young's algorithm [18] shows that they must occur near the very start of a phase, and there cannot be too many of them. In the subsequent good iterations, the packing gradients for all variables are relatively large comparing to their covering counterparts. These iterations capture the more difficult part of the path to convergence, since we only get weak signals as to which variables to update, and we can only increase them by small steps. We can show that as long as the problem is feasible, there cannot be too many good iterations in a phase. Intuitively, if the primal LP is feasible, the dual solution certifies that there must be some key variable(s) we increase during the phase to achieve the fixed global progress. Particularly, we know that there is at least one variable that on average has smaller packing gradients than covering gradients. Moreover, since in the good iterations, the packing gradients are all at least on the same scale as the covering gradients, an argument in the spirit of Markov's inequality then implies that the corresponding variable was increased by a large amount, which in turn leads to a bound on the number of iterations of a phase.

2.1 Remarks

We note that the phases in our result are virtual: we only need them in the analysis, but not in the actual execution of the algorithm. In particular, this modification to Young's algorithm [18] removes the dependency of updates on the phase of the overall algorithm as well as the current gradient. We believe this direct removal of phases also apply to other variants of Young's algorithm [19].

Furthermore, we believe that there is a more natural variant of the analysis that does not rely on phases, and treats all the iterations in a completely symmetric manner. Such an analysis is likely crucial for extending our results to the SDP setting, where the gradients exhibit much weaker monotonicity behaviors [20]. We are optimistic that it will lead to an $\tilde{O}(\frac{1}{\epsilon^2})$ bound for the mixed packing-covering case, which we believe is the more likely asymptotic behaviors of phase-less, gradient update variants of Young's algorithm [18, 19].

3 Parallel Algorithm for Mixed Packing and Covering LPs

3.1 Preliminaries

To compute $(1+\epsilon)$-approximation of a mixed packing and covering LP in the optimization form (1), via standard reduction and scaling (e.g., see [18]), it suffices to solve the following $(1+O(\epsilon))$-feasibility problem, that is, either find $\boldsymbol{x} \geq 0$ such that

$$0 < \max_j (\boldsymbol{P}\boldsymbol{x})_j \leq (1+\epsilon) \min_j (\boldsymbol{C}\boldsymbol{x})_j. \tag{3}$$

or conclude the following LP is infeasible

$$\begin{aligned} \boldsymbol{C}\boldsymbol{x} &\geq \mathbf{1} \\ \boldsymbol{P}\boldsymbol{x} &\leq (1-10\epsilon)\mathbf{1} \\ \boldsymbol{x} &\geq 0. \end{aligned} \tag{4}$$

We present our parallel $\tilde{O}(1/\epsilon^3)$ routine in Algorithm 1 for solving the $(1+O(\epsilon))$-feasibility problem above, that is, either find $\boldsymbol{x} \geq 0$ satisfying (3), or certify the infeasibility of (4). The input contains a packing constraint matrix $\boldsymbol{P} \in \mathbb{R}_{\geq 0}^{n_P \times m}$, a covering constraint matrix $\boldsymbol{C} \in \mathbb{R}_{\geq 0}^{n_C \times m}$, and an error parameter $\epsilon > 0$. That is, there are m variables, n_P packing constraints, and n_C covering constraints. We also use $n = n_P + n_C$ to denote the total number of constraints.

To certify that (4) is infeasible, we rely on the dual LP of (4).

▶ **Lemma 1.** *By duality,* (4) *is infeasible if there exists* $\boldsymbol{y}, \boldsymbol{z} \geq 0$ *s.t.*

$$(1-10\epsilon)\frac{\boldsymbol{C}^T\boldsymbol{z}}{\mathbf{1}^T\boldsymbol{z}} < \frac{\boldsymbol{P}^T\boldsymbol{y}}{\mathbf{1}^T\boldsymbol{y}}. \tag{5}$$

Proof. Eqn. (5) is a direct reformulation of the dual LP of (4). Since we only need the sufficient condition, the result is by weak duality. If there exists any $\boldsymbol{x} \geq 0$ satisfying (4), we have

$$\begin{aligned} (1-10\epsilon)\frac{\boldsymbol{x}^T\boldsymbol{C}^T\boldsymbol{z}}{\mathbf{1}^T\boldsymbol{z}} &\geq (1-10\epsilon)\frac{\mathbf{1}^T\boldsymbol{z}}{\mathbf{1}^T\boldsymbol{z}} = 1-10\epsilon, \\ \frac{\boldsymbol{x}^T\boldsymbol{P}^T\boldsymbol{y}}{\mathbf{1}^T\boldsymbol{y}} &\leq (1-10\epsilon)\frac{\mathbf{1}^T\boldsymbol{y}}{\mathbf{1}^T\boldsymbol{y}} = 1-10\epsilon. \end{aligned}$$

Together they give $1 < 1$, contradiction. ◀

3.2 Algorithm

We start with small $\boldsymbol{x}_i^{(0)} = \frac{1}{m\|\boldsymbol{P}_{:,i}\|_\infty}, \forall\, i \in [m]$, and keep increasing $\boldsymbol{x}$ properly, until it reaches the termination condition in line 4, that is, $\max\{\max_j(\boldsymbol{P}\boldsymbol{x})_j, \min_j(\boldsymbol{C}\boldsymbol{x})_j\} \geq K = \frac{10\ln n}{\epsilon}$. The reason of the chosen K value is stated in Lemma 5.

In each iteration of the while-loop, we first delete all covering constraints which have already reached K. Since $\boldsymbol{x}$ never decreases, we know that once a row is deleted, we no longer need to look at it. Note the covering matrix cannot be empty, since we enter the iteration with $\min_j(\boldsymbol{C}\boldsymbol{x})_j < K$. We compute the vectors $\boldsymbol{y}, \boldsymbol{z}$, which are exponentials of the values of the packing and covering constraints respectively. We then compute $\boldsymbol{a}$ and $\boldsymbol{b}$, which can be considered as gradients of $\mathrm{lmax}(\boldsymbol{P}\boldsymbol{x})$ and $\mathrm{lmin}(\boldsymbol{C}\boldsymbol{x})$ respectively, and use them to guide our update on $\boldsymbol{x}$. In particular, we update $\boldsymbol{x}_i$ if $\boldsymbol{a}_i \leq (1-\epsilon/50)\boldsymbol{b}_i$ (i.e., $i \in B$). Furthermore, we update $\boldsymbol{x}_i$ multiplicatively by a factor depends on the ratio of $\frac{\boldsymbol{a}_i}{\boldsymbol{b}_i}$, as specified in Eqn. (6) and line 12. Note that the smallest update in our algorithm is by a factor of $(1+\Omega(\frac{\epsilon^2}{\ln n}))$, which is the same as the fixed update step size in [19], and in general our updates take larger steps.

Note that in our analysis, we equivalently view $\boldsymbol{z}$ as the full n_C-dimensional vector, where the coordinates corresponding to deleted constraints are filled by 0's. In particular, the matrix-vector product of the original $\boldsymbol{C}$ with the n_C-dimensional $\boldsymbol{z}$ will be the same as the product of the reduced covering matrix $\boldsymbol{C}^{(t)}$ and reduced $\boldsymbol{z}$.

Algorithm 1 Parallel algorithm for mixed packing and covering LPs

Input: $\boldsymbol{P}, \boldsymbol{C}, \epsilon$

Output: "infeasible" or $\boldsymbol{x} \geq 0$ s.t. $\max_j(\boldsymbol{P}\boldsymbol{x})_j \leq (1+\epsilon)\min_j(\boldsymbol{C}\boldsymbol{x})_j$

1: Let $K = \frac{10\ln n}{\epsilon}$, $\alpha = \frac{1}{K}$, where n is the number of constraints.
2: Initialize $\boldsymbol{x}_i^{(0)} = \frac{1}{m\|\boldsymbol{P}_{:,i}\|_\infty}, \forall\ i \in [m]$, where m is the number of variables.
3: Let $t = 0$.
4: **while** $\max_j(\boldsymbol{P}\boldsymbol{x})_j < K$ and $\min_j(\boldsymbol{C}\boldsymbol{x})_j < K$ **do**
5: Let $\boldsymbol{C}^{(t)}$ be $\boldsymbol{C}$ with rows j such that $\left(\boldsymbol{C}\boldsymbol{x}^{(t)}\right)_j \geq K$ deleted.
6: Let $\boldsymbol{y}^{(t)} = \exp\left(\boldsymbol{P}\boldsymbol{x}^{(t)}\right), \boldsymbol{z}^{(t)} = \exp\left(-\boldsymbol{C}^{(t)}\boldsymbol{x}^{(t)}\right)$.
7:
8: $\boldsymbol{a}^{(t)} = \frac{\boldsymbol{P}^T\boldsymbol{y}^{(t)}}{\boldsymbol{1}^T\boldsymbol{y}^{(t)}}, \boldsymbol{b}^{(t)} = \frac{(\boldsymbol{C}^{(t)})^T\boldsymbol{z}^{(t)}}{\boldsymbol{1}^T\boldsymbol{z}^{(t)}}$.
9: Define $B^{(t)} = \{i : \boldsymbol{a}_i^{(t)} \leq (1-\frac{\epsilon}{50})\boldsymbol{b}_i^{(t)}\}$.
10: If $B^{(t)} = \emptyset$, then return "infeasible".
11: Let

$$\Delta_i^{(t)} = \begin{cases} \frac{1}{2}(1-\frac{\boldsymbol{a}_i^{(t)}}{\boldsymbol{b}_i^{(t)}}) \in [\epsilon/100, \frac{1}{2}] & \text{if } i \in B^{(t)} \\ 0 & \text{if } i \notin B^{(t)} \end{cases} \tag{6}$$

12: $\boldsymbol{x}_i^{(t+1)} \leftarrow \boldsymbol{x}_i^{(t)}(1+\alpha\Delta_i^{(t)})$.
13: $t \leftarrow t+1$.
14: **end while**
15: **return** $\boldsymbol{x} = \frac{\boldsymbol{x}^{(t)}}{K}$.

3.3 Proof of Correctness

In this section we will show Algorithm 1 will terminate, and output the correct answer.

Lemma 2 shows that empty B certifies the infeasibility of the input instance (4), which proves the correctness if we end up in the case of line 10.

▶ **Lemma 2.** *If the problem instance* (4) *is feasible, then*

$$\forall\ \boldsymbol{x} \geq 0, B = \{i : \boldsymbol{a}_i \leq (1-\frac{\epsilon}{50})\boldsymbol{b}_i\} \neq \emptyset.$$

Proof. Assume by contradiction, $\exists\ \boldsymbol{x} \geq 0, \forall\ i \in [m], \boldsymbol{a}_i^{(t)} > (1-\frac{\epsilon}{50})\boldsymbol{b}_i^{(t)}$. By definition of $\boldsymbol{a}, \boldsymbol{b}$, it is equivalent to $\exists\ \boldsymbol{y}, \boldsymbol{z} \geq 0$ such that

$$(1-\frac{\epsilon}{50})\frac{\boldsymbol{C}^T\boldsymbol{z}}{\boldsymbol{1}^T\boldsymbol{z}} < \frac{\boldsymbol{P}^T\boldsymbol{y}}{\boldsymbol{1}^T\boldsymbol{y}}.$$

Then the result follows directly from Lemma 1. ◀

If Algorithm 1 does not terminate with line 10, it must increase at least one variable by at least a factor of $(1+\frac{\epsilon^2}{10\ln n})$ each iteration, so the algorithm must reach the termination condition of the while loop at some point, and we need to show the output $\boldsymbol{x}$ satisfies (3). Recall that we use the potential function,

$$f(\boldsymbol{x}^{(t)}) = \text{lmax}(\boldsymbol{P}\boldsymbol{x}^{(t)}) - \text{lmin}(\boldsymbol{C}^{(t)}\boldsymbol{x}^{(t)}) = \ln(\boldsymbol{1}^T\boldsymbol{y}^{(t)}) + \ln(\boldsymbol{1}^T\boldsymbol{z}^{(t)}).$$

We first quantify the changes of lmax and lmin when we update the variables. This type of smoothness analysis is standard in analyzing algorithms that make updates using gradient information. Similar results are derived in other works on packing and covering (see [2, 18]). The particular analysis we develop can deal with larger gradient steps. In particular, the approach of our analysis allows updates that may move the gradients of some variables out of their respective coordinate-wise smooth regions, as long as we can still bound the combined impact on the potential function from updates of all variables. This approach can extend straightforwardly to show larger updates also work in [2], and improve their pure packing algorithm to run in $\tilde{O}(\frac{1}{\epsilon^2})$ iterations. Since the proof is straightforward but technically tedious, we omit it.

▶ **Lemma 3.** *At each iteration t,*

$$\operatorname{lmax}(\boldsymbol{P}\boldsymbol{x}^{(t+1)}) \le \operatorname{lmax}(\boldsymbol{P}\boldsymbol{x}^{(t)}) + \alpha\langle \boldsymbol{a}^{(t)}, (1+\Delta^{(t)}) \circ \Delta^{(t)} \circ \boldsymbol{x}^{(t)}\rangle$$

and

$$\operatorname{lmin}(\boldsymbol{C}^{(t+1)}\boldsymbol{x}^{(t+1)}) \ge \operatorname{lmin}(\boldsymbol{C}^{(t)}\boldsymbol{x}^{(t)}) + \alpha\langle \boldsymbol{b}^{(t)}, (1-\Delta^{(t)}) \circ \Delta^{(t)} \circ \boldsymbol{x}^{(t)}\rangle,$$

where $\Delta \circ \boldsymbol{x}$ is the entry-wise product vector, i.e., $(\Delta \circ \boldsymbol{x})_i = \Delta_i \boldsymbol{x}_i$.

With the above bounds on the changes of the two components $\operatorname{lmax}(\boldsymbol{P}\boldsymbol{x})$ and $\operatorname{lmin}(\boldsymbol{C}\boldsymbol{x})$, we can show how our updates move the potential function $f(\boldsymbol{x})$.

▶ **Lemma 4.** *Given $\max_j(\boldsymbol{P}\boldsymbol{x}^{(t)})_j < \frac{10\ln n}{\epsilon}$ and $\min_j(\boldsymbol{C}\boldsymbol{x}^{(t)})_j < \frac{10\ln n}{\epsilon}$, we always have $f(\boldsymbol{x}^{(t)}) \le 2\ln n$ during the execution of Algorithm 1.*

Proof. Initially, $\boldsymbol{x}_i^{(0)} = \frac{1}{m\|\boldsymbol{P}_{:,i}\|_\infty}$, we have $\boldsymbol{P}\boldsymbol{x}^{(0)} \le \boldsymbol{1}$ and $\boldsymbol{C}\boldsymbol{x} \ge 0$, thus $f(\boldsymbol{x}^{(0)}) \le 2\ln n$. To show $f(\boldsymbol{x}) \le 2\ln n$ for all iterations t before terminate, it suffices to show that $f(\boldsymbol{x})$ is non-increasing during the process. From Lemma 3,

$$\begin{aligned} f(\boldsymbol{x}^{(t+1)}) - f(\boldsymbol{x}^{(t)}) &\le \alpha\langle \boldsymbol{a}, (1+\Delta)\circ\Delta\circ\boldsymbol{x}^{(t)}\rangle - \alpha\langle \boldsymbol{b}, (1-\Delta)\circ\Delta\circ\boldsymbol{x}^{(t)}\rangle \\ &= \sum_i \alpha\Delta_i\boldsymbol{x}_i(\boldsymbol{a}_i(1+\Delta_i) - \boldsymbol{b}_i(1-\Delta_i)). \end{aligned}$$

For each $i \in [m]$, by our update rule (6), either Δ_i, or $\Delta_i = \frac{1}{2}(1 - \frac{\boldsymbol{a}_i}{\boldsymbol{b}_i})$, in which case

$$\boldsymbol{a}_i(1+\Delta_i) - \boldsymbol{b}_i(1-\Delta_i) = \frac{3\boldsymbol{a}_i\boldsymbol{b}_i - \boldsymbol{a}_i^2}{2\boldsymbol{b}_i} - \frac{\boldsymbol{a}_i + \boldsymbol{b}_i}{2} = \frac{2\boldsymbol{a}_i\boldsymbol{b}_i - \boldsymbol{a}_i^2 - \boldsymbol{b}_i^2}{2\boldsymbol{b}_i} \le 0,$$

so all the summands are non-positive, thus $f(\boldsymbol{x})$ is non-increasing. ◀

The above lemma guarantees that the difference between $\operatorname{lmax}(\boldsymbol{P}\boldsymbol{x})$ and $\operatorname{lmin}(\boldsymbol{C}\boldsymbol{x})$ is bounded by $2\ln n$, which by Eqn. (2) suggests $\max_j(\boldsymbol{P}\boldsymbol{x})_j \le \min_j(\boldsymbol{C}\boldsymbol{x})_j + O(\ln n)$. Then when the two terms are large at termination, we are approximately feasible as the difference is a factor of ϵ smaller.

▶ **Lemma 5.** *If Algorithm 1 terminates with line 15, then it returns an $\boldsymbol{x} \ge 0$ with $0 < \max_j(\boldsymbol{P}\boldsymbol{x})_j \le (1+\epsilon)\min_j(\boldsymbol{C}\boldsymbol{x})_j$.*

Proof. Suppose the algorithm terminates at iteration T, that is, $\max_j(\boldsymbol{P}\boldsymbol{x}^{(T)})_j \ge \frac{10\ln n}{\epsilon}$ or $\min_j(\boldsymbol{C}\boldsymbol{x}^{(T)})_j \ge \frac{10\ln n}{\epsilon}$. Consider iteration $T-1$, the covering matrix is not empty (otherwise, the algorithm terminates before iteration T). Since $\boldsymbol{x}^{(T)} = \boldsymbol{x}^{(T-1)} \circ (1 + \alpha\Delta^{(T-1)}) \le (1 + \frac{5\epsilon}{\ln n})\boldsymbol{x}^{(T-1)}$, we have $\max_j(\boldsymbol{P}\boldsymbol{x}^{(T-1)})_j \ge \frac{5\ln n}{\epsilon}$ or $\min_j(\boldsymbol{C}\boldsymbol{x}^{(T-1)})_j \ge \frac{5\ln n}{\epsilon}$.

By Lemma 4,

$$\begin{aligned}\max_j(\boldsymbol{P}\boldsymbol{x}^{(T-1)})_j &\leq \operatorname{lmax}(\boldsymbol{P}\boldsymbol{x}^{(T-1)}) \leq \operatorname{lmin}(\boldsymbol{C}^{(T-1)}\boldsymbol{x}^{(T-1)}) + 2\ln n \\ &\leq \min_j(\boldsymbol{C}\boldsymbol{x}^{(T-1)})_j + 2\ln n.\end{aligned}$$

Since $2\ln n \leq \epsilon \cdot \frac{5\ln n}{\epsilon}$, we have

$$\max_j(\boldsymbol{P}\boldsymbol{x}^{(T-1)})_j \leq (1+\epsilon)\min_j(\boldsymbol{C}\boldsymbol{x}^{(T-1)})_j.$$

This also gives $\max_j(\boldsymbol{P}\boldsymbol{x}^{(T)})_j \leq (1+\epsilon)\min_j(\boldsymbol{C}\boldsymbol{x}^{(T)})_j$, since $\boldsymbol{x}^T$ is within in multiplicative factor $1+\frac{\epsilon}{10\ln n}$ of $\boldsymbol{x}^{T-1}$. Since we start with $\boldsymbol{x} > 0$, and only increase $\boldsymbol{x}$, we also have $\max_j(\boldsymbol{P}\boldsymbol{x})_j > 0$. So the $\boldsymbol{x}$ we return at the end satisfies (3). ◀

3.4 Analysis of Convergence

So far we have proved that Algorithm 1 will terminate, and will either output $\boldsymbol{x}$ satisfying (3) at the end, or terminate earlier and correctly certify (4) is infeasible. In this section we show that if (4) is feasible, Algorithm 1 must finish with the first case in $\tilde{O}(\frac{1}{\epsilon^3})$ iterations, so if the algorithm takes more than $\frac{1000\ln n\ln(\frac{m}{\epsilon})}{\epsilon^3}$ iterations to complete, we can terminate it, and correctly output that (4) is infeasible.

We adapt the concept *phase* from Young's algorithm. Note phase is only used in our analysis, and our algorithm does not contain phase. Formally, phase s contains the iterations t such that

$$\frac{n_P}{n_C}\cdot 2^s \leq \frac{\mathbf{1}^T\boldsymbol{y}^{(t)}}{\mathbf{1}^T\boldsymbol{z}^{(t)}} < \frac{n_P}{n_C}\cdot 2^{s+1}$$

where n_P is the number of packing constraints and n_C is the number of covering constraints.

Since we only increase $\boldsymbol{x}$, $\frac{\mathbf{1}^T\boldsymbol{y}}{\mathbf{1}^T\boldsymbol{z}}$ is monotonically increasing, so each phase covers a consecutive sequence of iterations. Furthermore, as $\ln(\frac{\mathbf{1}^T\boldsymbol{y}}{\mathbf{1}^T\boldsymbol{z}}) = \operatorname{lmax}(\boldsymbol{P}\boldsymbol{x}) + \operatorname{lmin}(\boldsymbol{C}\boldsymbol{x})$ measures global progress towards termination, each phase captures a fixed amount of progress. From our definition of phases, and the termination condition, we have the following lemma.

▶ **Lemma 6.** *The total number of phases in Algorithm 1 is* $O(\frac{\log n}{\epsilon})$.

Proof. Since $\boldsymbol{x}$ is monotonically increasing, $\boldsymbol{y} = \exp(\boldsymbol{P}\boldsymbol{x})$ and $\boldsymbol{z} = \exp(-\boldsymbol{C}\boldsymbol{x})$ are monotonically increasing and decreasing respectively, which implies that the quantity $\frac{\mathbf{1}^T\boldsymbol{y}}{\mathbf{1}^T\boldsymbol{z}}$ is monotonically increasing. Initially $\boldsymbol{P}\boldsymbol{x}^{(0)} \geq 0$, $\boldsymbol{C}\boldsymbol{x}^{(0)} \geq 0$, we know $\frac{\mathbf{1}^T\boldsymbol{y}^{(0)}}{\mathbf{1}^T\boldsymbol{z}^{(0)}} \geq \frac{n_P}{n_C}$. By the termination condition in Algorithm 1, the ratio never goes beyond $n_P\exp(\frac{10\log n}{\epsilon})$. Therefore, the total number of phases is $O(\frac{\log n}{\epsilon})$. ◀

We now bound the number of iterations in a single phase. The iterations of a phase are divided into two groups, the bad iterations and the good iterations, formally defined as follows.

▶ **Definition 7.** If in an iteration t, we have for all i

$$\frac{\boldsymbol{a}_i^{(t)}}{\boldsymbol{b}_i^{(t)}} > \frac{1}{3}, \tag{7}$$

then we call it a *good* iteration. Otherwise we call it a *bad* iteration.

Note that it is also possible for a phase to contain only bad iterations or only good iterations. We bound the total number of iterations in the two groups separately.

As discussed earlier, the bad iterations capture the initial warm-up iterations of a phase, where in any bad iteration, we can identify some variable $\boldsymbol{x}_i$ with a strong signal (i.e., $\frac{\boldsymbol{a}_i}{\boldsymbol{b}_i} \leq \frac{1}{3}$), so we can increase the variable by a lot. This restricts the warm-up sequence from getting too long, and we formalize the intuition in the following lemma.

▶ **Lemma 8.** *In a single phase, the number of bad iterations is at most* $O(\ln n \ln(\frac{m}{\epsilon})/\epsilon)$.

Proof. We will prove the result by showing that there cannot be any bad iteration after the initial $100 \ln n \ln(\frac{m}{\epsilon})/\epsilon$ iterations of a phase. By contradiction, if for any variable i, after $\Omega(\ln n \ln(\frac{m}{\epsilon})/\epsilon)$ iterations of a phase, we have at iteration t such that for some i,

$$\frac{\boldsymbol{a}_i^{(t)}}{\boldsymbol{b}_i^{(t)}} = \frac{(\boldsymbol{P}^T\boldsymbol{y}^{(t)})_i}{\boldsymbol{1}^T\boldsymbol{y}^{(t)}} \frac{\boldsymbol{1}^T\boldsymbol{z}^{(t)}}{(\boldsymbol{C}^T\boldsymbol{z}^{(t)})_i} \leq \frac{1}{3},$$

then this ratio is at most $\frac{2}{3}$ in all previous iterations of this phase, since $\frac{(\boldsymbol{P}^T\boldsymbol{y})_i}{(\boldsymbol{C}^T\boldsymbol{z})_i}$ is monotonically increasing, and $2^s \leq \frac{\boldsymbol{1}^T\boldsymbol{y}}{\boldsymbol{1}^T\boldsymbol{z}} < 2^{s+1}$ in this phase. Equivalently, this is saying $\boldsymbol{a}_i \leq \frac{2}{3}\boldsymbol{b}_i$, so $i \in B$ in all previous $\Omega(\ln n \ln(\frac{m}{\epsilon})/\epsilon)$ iterations of the phase, and $\Delta_i \geq \frac{1}{6}$ in all those iterations.

Each iteration the multiplicative update on $\boldsymbol{x}_i$ is $(1+\alpha\Delta_i)$, which is $(1+\Theta(\frac{\epsilon}{10\ln n}))$ since $\Delta_i \geq \frac{1}{6}$. As $\boldsymbol{x}_i$ starts with $\frac{1}{m\|P_{:,i}\|_\infty}$, after $100 \ln n \ln(\frac{m}{\epsilon})/\epsilon$ updates, we have $\boldsymbol{x}_i \gg \frac{10\ln n}{\epsilon\|P_{:,i}\|_\infty}$, which gives $\max_j(\boldsymbol{P}\boldsymbol{x})_j \gg \frac{10\ln n}{\epsilon}$, so the algorithm must have terminated. ◀

The above lemma guarantees that all iterations after the first $100 \ln n \ln(\frac{m}{\epsilon})/\epsilon$ must be good iterations, so we proceed to bound the number of these good iterations in a single phase. Without loss of generality, we index these good iterations in a phase as $1, \ldots, T$ by shifting t.

We first identify one variable that must be updated extensively in these iterations.

▶ **Lemma 9.** *Suppose the instance* (4) *is feasible, then There exists* $i \in [m]$ *such that*

$$\sum_{t=1}^{T} \boldsymbol{b}_i^{(t)} - \boldsymbol{a}_i^{(t)} \geq 10\epsilon \sum_{t=1}^{T} \boldsymbol{b}_i^{(t)}. \tag{8}$$

Proof. Define $\overline{\boldsymbol{y}}$ and $\overline{\boldsymbol{z}}$ to be the sum of the normalized gradients of iterations $1, \ldots, T$, that is,

$$\overline{\boldsymbol{y}} = \sum_{t=1}^{T} \frac{\boldsymbol{y}^{(t)}}{\boldsymbol{1}^T\boldsymbol{y}^{(t)}}, \quad \overline{\boldsymbol{z}} = \sum_{t=1}^{T} \frac{\boldsymbol{z}^{(t)}}{\boldsymbol{1}^T\boldsymbol{z}^{(t)}}.$$

Note $\boldsymbol{1}^T\overline{\boldsymbol{y}} = \boldsymbol{1}^T\overline{\boldsymbol{z}} = T$. Recall $\boldsymbol{a}_i^{(t)}$ and $\boldsymbol{b}_i^{(t)}$ are respectively $\frac{(\boldsymbol{P}^T\boldsymbol{y}^{(t)})_i}{\boldsymbol{1}^T\boldsymbol{y}^{(t)}}$ and $\frac{(\boldsymbol{C}^T\boldsymbol{z}^{(t)})_i}{\boldsymbol{1}^T\boldsymbol{z}^{(t)}}$, then

$$\sum_{t=1}^{T} \boldsymbol{a}_i^{(t)} = \frac{T(\boldsymbol{P}^T\overline{\boldsymbol{y}})_i}{\boldsymbol{1}^T\overline{\boldsymbol{y}}}, \quad \sum_{t=1}^{T} \boldsymbol{b}_i^{(t)} = \frac{T(\boldsymbol{C}^T\overline{\boldsymbol{z}})_i}{\boldsymbol{1}^T\overline{\boldsymbol{z}}}.$$

Assume by contradiction, $\forall\, i \in [m]$, $\sum_{t=1}^{T} \boldsymbol{a}_i^{(t)} > (1-10\epsilon)\sum_{t=1}^{T} \boldsymbol{b}_i^{(t)}$, that is,

$$\frac{\boldsymbol{P}^T\overline{\boldsymbol{y}}}{\boldsymbol{1}^T\overline{\boldsymbol{y}}} > (1-10\epsilon)\frac{\boldsymbol{C}^T\overline{\boldsymbol{z}}}{\boldsymbol{1}^T\overline{\boldsymbol{z}}}.$$

By Lemma 1, $\overline{\boldsymbol{y}}, \overline{\boldsymbol{z}}$ certify infeasibility of the instance (4), which contradicts the assumption. ◀

The above claim gives us a variable that on average has smaller packing gradients than covering gradients in this iteration. Together with the property we have on the good iterations (7), we can bound the number of good iterations.

▶ **Lemma 10.** *In a single phase, the number of good iterations is at most* $O(\ln n \ln(\frac{m}{\epsilon})/\epsilon^2)$.

Proof. Let $\boldsymbol{x}_i$ be a variable satisfying Eqn. (8). We want to turn Eqn. (8) into some lower bound on the total multiplicative update on $\boldsymbol{x}_i$ through these iterations. Intuitively, a bad case is that in some iteration t, $\boldsymbol{a}_i^{(t)}, \boldsymbol{b}_i^{(t)}$ are much larger than the values in other iterations, since they can dominate the terms from other iterations in Eqn. (8), but not much to the total update of $\boldsymbol{x}_i$, since their ratio is what matters to the update. However, since we are inside one single phase, and only looking at good iterations, we can show the bad scenario will not show up.

Formally, let $l = \boldsymbol{a}_i^{(1)}$ and $u = \boldsymbol{b}_i^{(1)}$. Since $(\boldsymbol{P}^T\boldsymbol{y})_i$ monotonically increases, and $\mathbf{1}^T\boldsymbol{y}$ will increase but not by more than a factor of 2 in a phase, we have

$$\boldsymbol{a}_i^{(t)} = \frac{(\boldsymbol{P}^T\boldsymbol{y}^{(t)})_i}{\mathbf{1}^T\boldsymbol{y}^{(t)}} \geq l/2 \qquad \forall t = 1, \ldots, T. \tag{9}$$

Similarly, we have

$$\boldsymbol{b}_i^{(t)} = \frac{(\boldsymbol{C}^T\boldsymbol{z}^{(t)})_i}{\mathbf{1}^T\boldsymbol{z}^{(t)}} \leq 2u \qquad \forall t = 1, \ldots, T. \tag{10}$$

Furthermore, since we are looking at the good iterations, we have

$$l \geq \frac{1}{3}u. \tag{11}$$

The inequalities above allow us to turn the difference-based guarantee from Eqn. (8) into lower bounds on ratios we need.

By the update (6), we have

$$\Delta_i^{(t)} \geq \frac{(1-\frac{\epsilon}{50})\boldsymbol{b}_i^{(t)} - \boldsymbol{a}_i^{(t)}}{2\boldsymbol{b}_i^{(t)}}.$$

So we can lower bound the total update on $\boldsymbol{x}_i$ as follows

$$\begin{aligned}
\boldsymbol{x}_i^{(T)} \geq& \boldsymbol{x}_i^{(1)} \exp\left(\frac{\alpha\sum_t \Delta_i^{(t)}}{2}\right) \\
=& \boldsymbol{x}_i^{(1)} \exp\left(\frac{\alpha}{4}\sum_t \frac{(1-\frac{\epsilon}{50})\boldsymbol{b}_i^{(t)} - \boldsymbol{a}_i^{(t)}}{\boldsymbol{b}_i^{(t)}}\right) \\
\geq& \boldsymbol{x}_i^{(1)} \exp\left(\frac{\alpha}{4}\sum_t \left(\frac{\boldsymbol{b}_i^{(t)} - \boldsymbol{a}_i^{(t)}}{2u} - \frac{\epsilon}{50}\right)\right)
\end{aligned}$$

where we used (10) in the last line.

From Eqn. (8), we have

$$\begin{aligned}
\sum_t \boldsymbol{b}_i^{(t)} - \boldsymbol{a}_i^{(t)} \geq& 10\epsilon \sum_i \boldsymbol{b}_i^{(t)} \\
\geq& \frac{10\epsilon}{1-10\epsilon}\sum_t \boldsymbol{a}_i^{(t)} \\
\geq& \frac{\epsilon u T}{1-10\epsilon} \geq \epsilon u T.
\end{aligned}$$

The first two lines both follow from Eqn. (8), the next line follows from $\boldsymbol{a}_i^{(t)} \geq l/2 \geq u/6$.

Thus

$$\boldsymbol{x}_i^{(T)} \geq \boldsymbol{x}_i^{(1)} \exp\left(\frac{\epsilon\alpha T}{8} - \frac{\epsilon\alpha T}{200}\right) \geq \frac{1}{m\left\|\boldsymbol{P}_{:,i}\right\|_\infty} \exp\left(\frac{\epsilon\alpha T}{10}\right).$$

If $T \geq \frac{100 \ln n \ln \frac{m}{\epsilon}}{\epsilon^2} \geq \frac{100 \ln \frac{m}{\epsilon}}{\epsilon\alpha}$, we have $\boldsymbol{x}_i^{(T)} \gg \frac{10 \ln n}{\epsilon\left\|\boldsymbol{P}_{:,i}\right\|_\infty}$. So the algorithm must have terminated since $\max_j(\boldsymbol{P}\boldsymbol{x})_j \gg \frac{10 \ln n}{\epsilon}$. ◀

Lemma 8 and Lemma 10 bound the total number of iterations in a phase by $\tilde{O}(\frac{1}{\epsilon^2})$, together with the bound on the number of phases, which is $\tilde{O}(\frac{1}{\epsilon})$, we guarantee the total number of iterations in Algorithm 1 is $\tilde{O}(\frac{1}{\epsilon^3})$ if the LP in (4) is feasible.

▶ **Theorem 11.** *Algorithm 1 solves the $(1+\epsilon)$-feasibility problem correctly. It runs in parallel time $\tilde{O}(1/\epsilon^3)$ with the total work $\tilde{O}(N/\epsilon^3)$, where N is the number of non-zero entries in the constraint matrix.*

Proof. The correctness and convergence follows from the lemmas in the prior sections. We only need to look at the running time and total work.

At each iteration, we compute all updated values in $O(\log N)$ parallel time. Since the total number of iterations is $\tilde{O}(\frac{1}{\epsilon^3})$, the algorithm terminates in parallel time $\tilde{O}(\frac{1}{\epsilon^3})$.

To see the total work, consider the following implementation. For each $i \in [m]$, we maintain $\boldsymbol{P}_{ji}\boldsymbol{x}_i$ if $\boldsymbol{P}_{ij} \neq 0$; similarly we maintain $\boldsymbol{C}_{ji}\boldsymbol{x}_i$ if $\boldsymbol{C}_{ij} \neq 0$. Besides, we maintain the values of $\boldsymbol{y}, \boldsymbol{z}, \boldsymbol{P}^T\boldsymbol{y}, \boldsymbol{C}^T\boldsymbol{z}, \mathbf{1}^T\boldsymbol{y}$ and $\mathbf{1}^T\boldsymbol{z}$. When we update $\boldsymbol{x}_i$, we update these values accordingly, with work proportional to the number of non-zero entries in the ith column of the constraint matrix. For each fixed variable $\boldsymbol{x}_i$, the total time of updates is at most $\tilde{O}(\frac{1}{\epsilon^2})$. Thus, the work on this part is $\tilde{O}(\frac{N}{\epsilon^2})$. Additionally, we need to compute the $\boldsymbol{a}_i, \boldsymbol{b}_i$ for all variables at the beginning of each iteration to determine which variables to update, this takes $\tilde{O}(N)$ work each iteration, so the total work is $\tilde{O}(\frac{N}{\epsilon^3})$. ◀

▶ Remark. We see the majority of the work is actually on computing the gradients for the variables we may not update. We point out that we can implement the same lazy update as in [19], which on a high level is just that if a variable has a large $\frac{\boldsymbol{a}_i}{\boldsymbol{b}_i}$ in an iteration, and is not updated, we do not recompute its gradients, until $\frac{\mathbf{1}^T\boldsymbol{y}}{\mathbf{1}^T\boldsymbol{z}}$ grows by more than a factor of $1+\epsilon$. This can reduce the work to $\tilde{O}(\frac{N}{\epsilon^2})$, but requires a centralized step to control the phases. We omit the details as it is a straightforward adaptation.

4 Pure Packing and Pure Covering LPs

We point out that in the case of pure packing or pure covering LPs, Algorithm 1 converges in $\tilde{O}(\frac{1}{\epsilon^2})$ iterations. This improves upon the result of [17], since our algorithm is deterministic, and does not need centralized steps.

The analysis follows the same approach as the mixed case, but the result of Lemma 10 can be improved to bound the total number of good iterations over all phases by $O(\ln n \ln(\frac{m}{\epsilon})/\epsilon^2)$, since for pure packing (or pure covering) LPs, the $\boldsymbol{a}_i$'s (or the $\boldsymbol{b}_i$'s) are constants through the algorithm. We omit the details as the proof is a straightforward adaptation.

Abstract

We study two fundamental problems in computational geometry: finding the maximum inscribed ball (MaxIB) inside a bounded polyhedron defined by m hyperplanes, and the minimum enclosing ball (MinEB) of a set of n points, both in d-dimensional space. We improve the running time of iterative algorithms on

MaxIB from $\widetilde{O}(md\alpha^3/\varepsilon^3)$ to $\widetilde{O}(md + m\sqrt{d}\alpha/\varepsilon)$, a speed-up up to $\widetilde{O}(\sqrt{d}\alpha^2/\varepsilon^2)$, and[1]
MinEB from $\widetilde{O}(nd/\sqrt{\varepsilon})$ to $\widetilde{O}(nd + n\sqrt{d}/\sqrt{\varepsilon})$, a speed-up up to $\widetilde{O}(\sqrt{d})$.

Our improvements are based on a novel saddle-point optimization framework. We propose a new algorithm `L1L2SPSolver` for solving a class of regularized saddle-point problems, and apply a randomized Hadamard space rotation which is a technique borrowed from compressive sensing. Interestingly, the motivation of using Hadamard rotation solely comes from our optimization view but not the original geometry problem: indeed, it is not immediately clear why MaxIB or MinEB, as a geometric problem, should be easier to solve if we rotate the space by a unitary matrix. We hope that our optimization perspective sheds lights on solving other geometric problems as well.

1 Introduction

The goal of this paper is to bridge the fields of optimization and computational geometry using a simple unified saddle-point framework. As two immediate products of this new connection, we obtain faster iterative algorithms to approximately solve two fundamental problems in computational geometry: the maximum inscribed ball problem (MaxIB) and the

minimum enclosing ball problem (MinEB). Our methods are composed of simple updating rules on vectors and therefore do not require geometric operations that are found in classical algorithms. This is another example of surprisingly good results obtained using optimization insights following the current trend of theoretical computer science.

In the rest of this introduction, we describe the definitions of the MaxIB and MinEB problems and review prior work. In the next three sections, we describe our saddle-point formulation and algorithms for MaxIB and MinEB.

Maximum Inscribed Ball (MaxIB). In the MaxIB problem, we are given a polyhedron P in $\mathbb{R}^d$ defined by m halfspaces $\{H_1, \ldots, H_m\}$. Each halfspace H_j is characterized by a linear constraint $\langle A_j, x\rangle + b_j \geq 0$. As in prior work [20], we assume that P is bounded (so $m \geq d$) and a common point is known to be contained in P – without loss of generality, let it be the origin O. Let $\alpha \geq 1$ be an upper bound on the aspect ratio of P, i.e., the ratio between the radii of the minimum enclosing ball and the maximum inscribed ball of P, and $\varepsilon > 0$ be a desired error bound.

The goal of MaxIB is to find a point $x \in P$ such that its minimum distance to all the bounding hyperplanes H_j is at least $(1-\varepsilon)r_{\mathsf{opt}}$, where r_{opt} is the radius of a maximum inscribed ball of P.

Besides the applications in computational geometry, MaxIB has also been used in the column generation method [13] and the sphere method [14] for linear programming, and the central cutting-plane method for convex programming [9].

When the dimension is a constant, the ε-kernel technique (see the survey [1]) yields a linear-time approximation algorithm for MaxIB based on core-set construction. However, its running time is proportional to $\varepsilon^{-\Omega(d)}$. In high dimensions, finding the maximum inscribed ball remains a challenging problem in theoretical computer science and operations research. One can reduce this problem to a linear program [9] and rely on existing LP solvers, however, the so-obtained algorithm can be too slow for practical purposes (although still in polynomial time).

In an influential paper, Xie, Snoeyink, and Xu [20] obtained an approximation algorithm for MaxIB with running time $O(md\alpha^3/\varepsilon^3 + md\alpha\log\alpha) = \widetilde{O}(md\alpha^3/\varepsilon^3)$. Their algorithm is based on a number of interesting geometric observations, as well as a dual transformation to reduce the MaxIB problem to a sequence of minimum enclosing ball (MinEB) instances, which they solve by applying known core-set techniques [6, 12]. Unfortunately, their cubic dependence on α and $1/\varepsilon$ undermines the practical applicability of their algorithm.

In Section 3, we use saddle-point optimization techniques to obtain an algorithm `MaxIBSPSolver` with running time $\widetilde{O}\big(md + m\sqrt{d}\alpha/\varepsilon\big)$. In other words, we reduce the dependence on both α and $1/\varepsilon$ from cubic to linear, and improve the running time by a factor up to $\sqrt{d}\alpha^2/\varepsilon^2$. We emphasize that our improvement could be significant in the views of theoretical computer scientists, operations researchers, as well as experimentalists:

- In theoretical computer science, one usually views α and ε as large constants so our improvement can be seen as $\widetilde{\Omega}(\sqrt{d})$ if one ignores the input reading time $O(md)$.
- In operations research or statistics, one usually concentrate on the convergence rate which is the ε dependence (recall that the seminal work of Nesterov is only to reduce $1/\varepsilon$ to $1/\sqrt{\varepsilon}$ [15]). Our improvement in this paper is from $1/\varepsilon^3$ to $1/\varepsilon$.
- In practice, if α is 10 for the polyhedron, ε is 10%, and the dimension $d = 100$, our method could potentially be 10^5 times faster than that of [20]. We leave it a future work to inspect the practical performance of our method on real-life datasets.

In the full version of this paper [3], we also apply convex (rather than saddle-point)

optimization and obtain a *parallel* algorithm `MaxIBConvexSolver` with slightly slower *total* running time $\widetilde{O}(md\alpha/\varepsilon)$. However, in terms of *parallel* running time (i.e., the number of parallelizable iterations, a classical benchmark used by iterative solvers [4]), `MaxIBConvexSolver` improves the result of [20] by a factor $\widetilde{\Omega}(\alpha^2/\varepsilon^2)$.

Minimum Enclosing Ball (MinEB). In the MinEB problem, we are given a set $\{a_1, a_2, \ldots, a_n\} \subseteq \mathbb{R}^d$ of points in the d-dimensional space and are asked to find a point $x \in \mathbb{R}^d$ so that its maximum distance to all the n points is at least $(1+\varepsilon)R_{\mathsf{opt}}$, where R_{opt} is the radius of a minimum enclosing ball that contains all the points in this set.

As originally studied by Sylvester in [18], the problem of MinEB has found numerous applications in fields such as data mining, learning, statistics, and computer graphics. In particular, the relationship between MinEB and support vector machines (SVMs) has been recently emphasized by [11, 10, 7, 17]. Efficient algorithms for this problem are both of theoretical and practical importance.

If the dimension d is constant, the algorithm of Welzl [19] solves MinEB exactly in linear time. Unfortunately, its dependency on d is exponential.

For large dimensions, a sequence of works based on the core-set technique [6, 12, 5, 21, 7] has given algorithms whose best known running time is $O(nd/\varepsilon)$. This running time is tight for the core-set technique, as, in the worst-case, the size of a coreset of MinEB is at least $\Omega(1/\varepsilon)$ [5]. Another type of algorithm due to Clarkson, Hazan, and Woodruff [8] achieves a running time of $\widetilde{O}(n/\varepsilon^2 + d/\varepsilon)$. This algorithm is fast for large values of ε, but may not be suitable for very small ε. All these cited algorithms converge at best in $O(1/\varepsilon)$ iterations.

Recently, Saha, Vishwanathan, and Zhang [17] designed two algorithms for MinEB that successfully overcame this $1/\varepsilon$ barrier. Using our ε-notation for multiplicative error, they give one algorithm which works in the ℓ_2-norm and achieves a running time of $O(ndQ/\sqrt{\varepsilon})$, and another algorithm which works in the ℓ_1-norm and achieves a running time of $O(nd\sqrt{\log n}L/\sqrt{\varepsilon})$. While the values of Q and L depend on the input structure, we observe that Q can be as large as $O(\sqrt{n})$, while L is never larger than a constant. In other words, their proposed algorithms have worst-case running times $O(n^{1.5}d/\sqrt{\varepsilon})$ and $O(nd\sqrt{\log n}/\sqrt{\varepsilon})$. The key component behind the result of Saha, Vishwanathan, and Zhang is the excessive gap framework of Nesterov [16], which is a primal-dual first-order approach for structured non-smooth optimization problems.

In Section 4, we rewrite MinEB as a saddle-point optimization problem, and obtain an algorithm `MinEBSPSolver` that runs in $\widetilde{O}(nd + n\sqrt{d}/\sqrt{\varepsilon})$. This is faster than the previous algorithm [17] by a factor up to $\sqrt{d}$, and faster than the popular core-set algorithm by a factor up to $\sqrt{d}/\sqrt{\varepsilon}$.

As an additional result, in the full version of this paper [3], we also observe that MinEB can be directly formulated as a convex (rather than saddle-point) optimization problem, and get an algorithm `MinEBConvexSolver` matching the running time of [17] but with much simpler analysis.

Remark. For both MaxIB and MinEB, one can also use interior-point types of algorithms to obtain a convergence rate of $\log(1/\varepsilon)$. However, this fast convergence rate comes at the cost of having expensive iterations: each iteration typically requires solving a linear equation system in the input size, making it impractical for very-large-scale inputs. Therefore, in this paper, we choose to focus on iterative methods whose iterations run in nearly-linear time.

1.1 Our Techniques

Our `MaxIBSPSolver` and `MinEBSPSolver` rely on (min-max) saddle-point optimization to solve MaxIB and MinEB respectively. More specifically, we reduce MaxIB and MinEB to solving the regularized saddle-point program:

$$\max_{x\in\mathbb{R}^d}\min_{y\in\Delta_m}\frac{1}{d}y^TAx+\frac{1}{d}y^Tb+\lambda H(y)-\frac{\gamma}{2}\|x\|_2^2\ ,$$

where $H(\cdot)$ is the entropy function over m-dimensional probabilities vectors, and $\lambda,\gamma>0$ are fixed regularization parameters. We call this ℓ_1-ℓ_2 saddle-point optimization because, borrowing language from optimization, this objective is strongly convex with respect to the ℓ_1 norm on the y side and strongly concave with respect to the ℓ_2 norm on the x side.

To solve this saddle-point problem efficiently, we iteratively update x and y. In particular, in each iteration we update x by a *random coordinate*, and update y fully using multiplicative weight updates. Therefore, this method can be viewed as an *accelerated, coordinate-based*, first-order method for saddle-point optimization. To the best of our knowledge, the only previously known accelerated, coordinate-based method on saddle-point optimization was SPDC [22], one of the state-of-the-art algorithms used for empirical risk minimizations in machine learning. We call our algorithm `L1L2SPSolver`.

A Surprising Hadamard Rotation. Unfortunately, solely applying `L1L2SPSolver` does not solve MinEB or MaxIB fast enough. In particular, the running time of `L1L2SPSolver` relies on the largest absolute values of A's entries. If the entries of A are very non-uniform – say, with a few very large entries and mostly small ones – the performance could be somewhat unsatisfactory. (In particular, we no longer have a $\sqrt{d}$ factor speed-up.)

To overcome this difficulty, we apply a randomized Hadamard transformation on A to uniformize its entries, so that all entries of A are relatively small. This transformation is inspired by the fast Johnson-Lindenstrauss transform [2] proposed for numerical linear algebra and compressive sensing purposes, and is another crucial ingredient behind our running time improvements.

Surprisingly, this Hadamard rotation comes solely from our optimization view but not the geometry. Indeed, it is not immediately clear why MaxIB or MinEB, as geometric problems, should be easier to solve if we rotate the space by a unitary (Hadamard) matrix.

Our Contributions. We summarize the main contributions of this paper as follows:

- We provide significantly faster algorithms on MaxIB and MinEB.
- This is the first time coordinate-based saddle-point optimization algorithm is applied to MaxIB, MinEB, or perhaps to any computational geometry problem.
- Since the ℓ_1-ℓ_2 saddle-point problem seems very natural, our `L1L2SPSolver` method can potentially lead to other applications in the future.
- The speed-up we obtained from the Hadamard rotation is an algebraic technique but applied to geometric problems. It sheds lights on solving perhaps more geometric problems faster using optimization insights.

Abstract

We study weighted α-fair packing problems, that is, the problems of maximizing the objective functions (i) $\sum_j w_j x_j^{1-\alpha}/(1-\alpha)$ when $\alpha > 0$, $\alpha \neq 1$ and (ii) $\sum_j w_j \ln x_j$ when $\alpha = 1$, over linear constraints $Ax \leq b$, $x \geq 0$, where w_j are positive weights and A and b are non-negative. We consider the distributed computation model that was used for packing linear programs and network utility maximization problems. Under this model, *we provide a distributed algorithm for general* α that converges to an $\varepsilon-$approximate solution in time (number of distributed iterations) that has an inverse polynomial dependence on the approximation parameter ε and poly-logarithmic dependence on the problem size. *This is the first distributed algorithm for weighted α-fair packing with poly-logarithmic convergence in the input size.* The algorithm uses simple local update rules and is stateless (namely, it allows asynchronous updates, is self-stabilizing, and allows incremental and local adjustments). We also obtain a number of structural results that characterize α-fair allocations as the value of α is varied. These results deepen our understanding of fairness guarantees in α-fair packing allocations, and also provide insight into the behavior of α-fair allocations in the asymptotic cases $\alpha \to 0$, $\alpha \to 1$, and $\alpha \to \infty$.

1 Introduction

Over the past two decades, *fair resource allocation* problems have received considerable attention in many application areas, including Internet congestion control [32], rate control in software defined networks [36], scheduling in wireless networks [45], multi-resource allocation and scheduling in datacenters [12, 20, 24, 21], and a variety of applications in operations research, economics, and game theory [11, 23]. In most of these applications, positive linear (packing) constraints arise as a natural model of the allowable allocations.

* The full version of the paper can be found at `http://arxiv.org/abs/1502.03372v3`. This work was partially supported by the NSF grants CNS-14-23105, CCF-1349602, and CCF-1421161, and the People Programme (Marie Curie Actions) of the European Union's Seventh Framework Programme (FP7/2007-2013) under REA grant agreement n°[PIIF-GA-2013-629740].11.

In this paper, we focus on the problem of finding an *α-fair* vector on the set determined by packing constraints $Ax \leq \mathbb{1}, x \geq 0$ where all $A_{ij} \geq 0$.[1] We refer to this problem as α-fair packing. For a vector of positive weights w and $\alpha \geq 0$, an allocation vector x^* of size n is weighted α-fair , if it maximizes $p_\alpha(x) = \sum_j w_j f_\alpha(x_j)$ [38], where:

$$f_\alpha(x_j) = \begin{cases} \ln(x_j), & \text{if } \alpha = 1 \\ \frac{x_j^{1-\alpha}}{1-\alpha}, & \text{if } \alpha \neq 1 \end{cases}. \tag{1}$$

α-fairness provides a trade-off between efficiency (sum of allocated resources) and fairness (minimum allocated resource) as a function of α: the higher the α, the higher the fairness and the lower the efficiency [4, 11, 31]. Important special cases are max-min fairness ($\alpha \to \infty$) and proportional fairness ($\alpha = 1$). When $\alpha = 0$, we have the "unfair" case of linear optimization.

Distributed algorithms for α-fair packing are of particular interest, as many applications are inherently distributed (e.g., network congestion control), while others require parallelization due to the large problem size (e.g., resource allocation in datacenters). We adopt the model of distributed computation commonly used in packing linear programming (LP) algorithms [7, 3, 8, 29, 33, 41] and which generalizes the model from network congestion control [26]. In this model, an agent j controls the variable x_j and has information about: (i) the j^{th} column of the $m \times n$ constraint matrix A, (ii) the weight w_j, (iii) upper bounds on global problem parameters $m, n, w_{\max}$, and $A_{\max}$, where $w_{\max} = \max_j w_j$, and $A_{\max} = \max_{ij} A_{ij}$, and (iv) in each round, the relative slack of each constraint i in which x_j takes part.

Distributed algorithms for α-fair resource allocations have been most widely studied in the network congestion control literature, using a control-theoretic approach [25, 26, 45, 38, 32]. Such an approach yields continuous-time algorithms that converge after "finite" time; however, the convergence time of these algorithms as a function of the input size is poorly understood. Some other distributed pseudo-polynomial-time approximation algorithms that can address α-fair packing are described in Table 1. These algorithms all have convergence times that are at least linear in the parameters describing the problem.

No previous work has given truly fast (poly-log iterations) distributed algorithms for the general case of α-fair packing. Only for the unfair $\alpha = 0$ case (packing LPs), are such algorithms known [7, 33, 8, 46, 29, 3].

Our Results. *We provide the first efficient, distributed, and stateless algorithm for weighted α-fair packing*, namely, for the problem $\max\{p_\alpha(x) : Ax \leq \mathbb{1}, x \geq 0\}$, where distributed agents update the values of x_j's asynchronously and react only to the current state of the constraints. We assume that all non-zero entries A_{ij} of matrix A satisfy $A_{ij} \geq 1$. Considering such a normalized form of the problem is without loss of generality (see Appendix A in [35]).

The approximation provided by the algorithm, to which we refer as the ε-approximation, is (i) $(1+\varepsilon)$-multiplicative for $\alpha \neq 1$, and (ii) $W\varepsilon$-additive[2] for $\alpha = 1$, where $W = \sum_j w_j$. The main results are summarized in the following theorem, where, to unify the statement of the results, we treat α as a constant that is either equal to 1 or bounded away from 0 and 1, and we also loosen the bound in terms of $\varepsilon^{-1}, n, m, R_w = \max_{j,k} w_j/w_k$, and $A_{\max}$. For a more detailed statement, see Theorems 4.1–4.3.

[1] Although in the network congestion control literature A is commonly assumed to be a 0-1 matrix [25, 26, 45, 38, 32], important applications (such as, e.g., multi-resource allocation in datacenters) are modeled by a more general constraint matrix A with arbitrary non-negative elements [12, 20, 24, 21].

[2] Note that W cannot be avoided here, as additive approximation is not invariant to the objective scaling.

▶ **Theorem 1.1** (Main Result). *Given a weighted α-fair packing problem* $\max\{\sum_j w_j f_\alpha(x_j) : Ax \leq \mathbb{1}, x \geq 0\}$*, there exists a stateless and distributed algorithm (α-FairPSolver) that computes an ε-approximate solution in $O(\varepsilon^{-5}\ln^4(R_w nmA_{\max}\varepsilon^{-1}))$ rounds.*

To the best of our knowledge, for any constant approximation parameter ε, our algorithm is the first distributed algorithm for weighted α-fair packing problems with a poly-logarithmic convergence time.[3] The algorithm is *stateless* according to the definition given by Awerbuch and Khandekar [7, 6]: it starts from any initial state, the agents update the variables x_j in a cooperative but uncoordinated manner, reacting only to the current state of the constraints that they observe, and without access to a global clock. Statelessness implies various desirable properties of a distributed algorithm, such as: asynchronous updates, self-stabilization, and incremental and local adjustments [7, 6].

We also obtain the following structural results that characterize α-fair packing allocations as a function of the value of α:

- We derive a lower bound on the minimum coordinate of the α-fair packing allocation as a function of α and the problem parameters (Lemma 4.12). This bound deepens our understanding of how the fairness (a minimum allocated value) changes with α.
- We prove that for $\alpha \leq \frac{\varepsilon/4}{\ln(nA_{\max}/\varepsilon)}$, α-fair packing can be $O(\varepsilon)-$approximated by any $\varepsilon-$approximation packing LP solver (Lemma 4.13).
- We show that for $|\alpha-1| = O(\varepsilon^2/\ln^2(\varepsilon^{-1}R_w mnA_{\max}))$, α-fair allocation is $\varepsilon-$approximated by a $1-$fair allocation returned by our algorithm (Lemmas 4.14 and 4.15).
- We show that for $\alpha \geq \ln(R_w nA_{\max})/\varepsilon$, the α-fair packing allocation x^* and the max-min fair allocation z^* are ε-close to each other: $(1-\varepsilon)z^* \leq x^* \leq (1+\varepsilon)z^*$ element-wise. This result is especially interesting as (i) max-min fair packing is not a convex problem, but rather a multi-objective problem (see, e.g., [27, 43]) and (ii) the result yields the first convex relaxation of max-min fair allocation problems with a $1 \pm \varepsilon$ gap.

We now overview some of the main technical details of α-FairPSolver. In doing so, we point out connections to the two main bodies of previous work, from packing LPs[7] and network congestion control [25]. We also outline the new algorithmic ideas and proofs.

The algorithm and KKT conditions. The algorithm maintains primal and dual feasible solutions and updates each primal variable x_j whenever a Karush-Kuhn-Tucker (KKT) condition ${x_j}^\alpha \sum_i y_i A_{ij} = w_j$ is not *approximately* satisfied. In previous work, relevant update rules include: [25] (for $\alpha = 1$), where the update of each variable x_j is proportional to the difference $w_j - x_j \sum_i y_i A_{ij}$, and [7] (for $\alpha = 0$), where each x_j is updated by a multiplicative factor $1 \pm \beta$, whenever $\sum_i y_i A_{ij} = w_j$ is not approximately satisfied. For our techniques (addressing a general α) such rules do not suffice and we introduce the following modifications: (i) in the $\alpha < 1$ case we use multiplicative updates by factors $(1+\beta_1)$ and $(1-\beta_2)$, where $\beta_1 \neq \beta_2$ and (ii) we use additional threshold values δ_j to make sure that x_j's do not become too small. These thresholds guarantee that we maintain a feasible solution, but they significantly complicate (compared to the linear case) the argument that each step makes a significant progress.

[3] The total amount of work per (distributed) round is linear in the number of non-zero entries of the constraint matrix A, which matches the best bound achieved in previous work on distributed packing LPs [7, 33, 8, 46, 29, 3] and distributed network utility maximization [9, 39].

Table 1 Comparison among distributed algorithms for α-fair packing.

Paper	Number of Distributed Iterations[4]	Statelessness	Notes
[15]	$\Omega(\varepsilon^{-1}nA_{\max})$	Semi-stateless[5]	Only for $\alpha = 1$
[9]	$\Omega(\varepsilon^{-1}mn{A_{\max}}^2)$	Not stateless	
[39]	$\text{poly}(\varepsilon^{-1}, m, n, A_{\max})$	Semi-stateless	
[this work]	$O(\varepsilon^{-5}\ln^4(R_w mnA_{\max}/\varepsilon))$	Stateless	

Dual Variables. In α-FairPSolver, a dual variable y_i is an exponential function of the i^{th} constraint's relative slack: $y_i(x) = C \cdot e^{\kappa(\sum_j A_{ij}x_j - 1)}$, where C and κ are functions of global input parameters $\alpha, w_{\max}, n, m$, and $A_{\max}$. Packing LP algorithms [7, 3, 42, 8, 18, 17, 28] use similar dual variables with $C = 1$. Our work requires choosing C to be a function of $\alpha, w_{\max}, n, m, A_{\max}$ rather than a constant.

Convergence Argument. The convergence analysis of α-FairPSolver relies on the appropriately chosen concave potential function that is bounded below and above for $x_j \in [\delta_j, 1]$, $\forall j$, and that increases with every primal update. The algorithm can also be interpreted as a gradient ascent on a regularized objective function (the potential function), using a generalized entropy regularizer (see [3, 1]). A similar potential function was used in many works on packing and covering linear programs, such as, e.g., in [7] and (implicitly) in [46]. The Lyapunov function from [25] is also equivalent to this potential function when $y_i(x) = C \cdot e^{\kappa(\sum_j A_{ij}x_j - 1)}$, $\forall i$. As in these works, the main idea in the analysis is to show that whenever a solution x is not "close" to the optimal one, the potential function increases substantially. However, our work requires several new ideas in the convergence proofs, the most notable being *stationary rounds*. A stationary round is roughly a time when the variables x_j do not change much and are close to the optimum. Poly-logarithmic convergence time is then obtained by showing that: (i) there is at most a poly-logarithmic number of non-stationary rounds where the potential function increases additively and the increase is "large enough", and (ii) in all the remaining non-stationary rounds, the potential function increases multiplicatively. Our use of stationary rounds is new, as is the use of Lagrangian duality and all the arguments that follow (see [35] for a detailed discussion).

Relationship to Previous Work. Very little progress has been made in the design of efficient distributed algorithms for the general class of α-fair objectives. Classical work on distributed rate control algorithms in the networking literature uses a control-theoretic approach to optimize α-fair objectives. While such an approach has been extensively studied [25, 26, 45, 38, 32], it has never been proven to lead to a polynomial convergence time.

Since α-fair objectives are concave, their optimization over a region determined by linear constraints is solvable in polynomial time in a centralized setting through convex programming (see, e.g., [13, 40]). Distributed gradient methods for network utility maximization problems, such as e.g., [9, 39] summarized in Table 1, can be applied to α-fair packing. However, the convergence times of these algorithms depend on the dual gradient's Lipschitz constant to produce good approximations. While [9, 39] provide a better dependence on the accuracy ε than our work, the dependence on the dual gradient's Lipschitz constant, in general, leads to at least linear convergence time as a function of n, m, and $A_{\max}$.

As mentioned before, some special cases have been addressed, particularly max-min fairness ($\alpha \to \infty$) and packing LPs ($\alpha = 0$). Relevant work on max-min fairness includes

[10, 22, 30, 27, 37, 34, 14], but none of these works have poly-logarithmic convergence time. There is a long history of interesting work on packing LPs in both centralized and distributed settings, e.g., [1, 42, 28, 18, 7, 33, 8, 46, 29, 3, 19]. Only a few of these works are stateless, including the packing LP algorithm of Awerbuch and Khandekar [7], flow control algorithm of Garg and Young [19], and the algorithm of Awerbuch, Azar, and Khandekar [5] for the special case of load balancing in bipartite graphs. Additionally, the packing LP algorithm of Allen-Zhu and Orecchia [3] is "semi-stateless"; the lacking property to make it stateless is that it requires synchronous updates. The $\alpha = 1$ case of α-fair packing problems is equivalent to the problem of finding an equilibrium allocation in Eisenberg-Gale markets with Leontief utilities [15]. Similar to the aforementioned algorithms, the algorithm from [15] converges in time linear in ε^{-1} but also (at least) linear in the input size (see Table 1).

2 Preliminaries

Weighted α-Fair Packing. Consider the following optimization problem with positive linear (packing) constraints: $(Q_\alpha) = \max\{p_\alpha(x) \equiv \sum_{j=1}^{n} w_j f_\alpha(x_j) : Ax \leq b, x \geq 0\}$, where $f_\alpha(x_j)$ is given by (1), $x = (x_1, \ldots, x_n)$ is the vector of variables, A is an $m \times n$ matrix with non-negative elements, and $b = (b_1, \ldots, b_m)$ is a vector with strictly positive[6] elements. We refer to (Q_α) as the weighted α-fair packing. The following definition and lemma introduced by Mo and Walrand [38] characterize weighted α-fair allocations. In the rest of the paper, we will use the terms weighted α-fair and α-fair interchangeably.

▶ **Definition 2.1** ([38]). Let w be a vector with positive entries and $\alpha > 0$. A vector x is weighted α-fair, if it is feasible and for any other feasible vector x: $\sum_{j=1}^{n} w_j \frac{x_j - x_j^*}{x_j^{*\alpha}} \leq 0$.

▶ **Lemma 2.2** ([38]). *A vector x^* solves (Q_α) if and only if it is weighted α-fair.*

Notice in (Q_α) that since $b_i > 0$, $\forall i$, and the partial derivative of the objective with respect to any of the variables x_j goes to ∞ as $x_j \to 0$, the optimal solution must lie in the positive orthant. Moreover, since the objective is strictly concave and maximized over a convex region, the optimal solution is unique and (Q_α) satisfies strong duality (see, e.g., [13]). The same observations are true for the scaled version of the problem denoted by (P_α) and introduced in the following subsection.

Normalized Form. We consider weighted α-fair packing in the normalized form:

$$(P_\alpha) = \max\{p_\alpha(x) : Ax \leq \mathbb{1}, x \geq 0\},$$

where $p_\alpha(x) = \sum_{j=1}^{n} w_j f_\alpha(x_j)$, f_α is defined by (1), $w = (w_1, \ldots, w_n)$ is a vector of positive weights, $x = (x_1, \ldots, x_n)$ is the vector of variables, A is an $m \times n$ matrix with non-negative entries, and $\mathbb{1}$ is a size-m vector of 1's. We let $A_{\max}$ denote the maximum element of the constraint matrix A, and assume that every entry A_{ij} of A is non-negative, and moreover, that $A_{ij} \geq 1$ whenever $A_{ij} \neq 0$. The maximum weight is denoted by $w_{\max}$ and the minimum weight is denoted by $w_{\min}$. The sum of the weights is denoted by W and the ratio $\frac{w_{\max}}{w_{\min}}$ by R_w. We remark that considering (Q_α) in the normalized form (P_α) is without loss of generality: any problem (Q_α) can be scaled to this form by (i) dividing both sides of each inequality i by b_i and (ii) working with scaled variables $c \cdot x_j$, where $c = \min\{1, \min_{\{i,j:A_{ij}\neq 0\}} \frac{A_{ij}}{b_i}\}$. Moreover, such scaling preserves the approximation (see [35]).

[6] If, for some i, $b_i = 0$, then trivially $x_j = 0$, for all j such that $A_{ij} \neq 0$.

Model of Distributed Computation. We adopt the same model of distributed computation as [7, 3, 8, 29, 33, 41], described as follows. We assume that for each $j \in \{1, \ldots, n\}$, there is an agent controlling the variable x_j. Agent j is assumed to have information about the following problem parameters: (i) the j^{th} column of A, (ii) the weight w_j, and (iii) (an upper bound on) $m, n, w_{\max}$, and $A_{\max}$. In each round, agent j collects the relative slack[7] $1 - \sum_{j=1}^{n} A_{ij}x_j$ of all constraints i for which $A_{ij} \neq 0$.

We remark that this model of distributed computation is a generalization of the model considered in network congestion control problems [26] where a variable x_j corresponds to the rate of node j, A is a 0-1 routing matrix, such that $A_{ij} = 1$ if and only if a node j sends flow over link i, and b is the vector of link capacities. Under this model, the knowledge about the relative slack of each constraint corresponds to each node collecting (a function of) congestion on each link that it utilizes. Such a model was used in network utility maximization problems with α-fair objectives [25] and general strongly-concave objectives [9].

KKT Conditions and Duality Gap. We will denote the Lagrange multipliers for (P_α) as $y = (y_1, \ldots, y_m)$ and refer to them as "dual variables". The KKT conditions for (P_α) are:

$$\sum_{j=1}^{n} A_{ij}x_j \leq 1,\ \forall i \in \{1, \ldots, m\};\ x_j \geq 0,\ \forall j \in \{1, \ldots, n\} \text{ (primal feasibility)} \tag{K1}$$

$$y_i \geq 0,\ \forall i \in \{1, \ldots, m\} \text{ (dual feasibility)} \tag{K2}$$

$$y_i \cdot \Big(\sum_{j=1}^{m} A_{ij}x_j - 1 \Big) = 0,\ \forall i \in \{1, \ldots, m\} \text{ (complementary slackness)} \tag{K3}$$

$${x_j}^{\alpha} \sum_{i=1}^{m} y_i A_{ij} = w_j,\ \forall j \in \{1, \ldots, m\} \text{ (gradient conditions)} \tag{K4}$$

The duality gap for $\alpha \neq 1$ is (see Appendix B in [35]):

$$G_\alpha(x, y) = \sum_{j=1}^{n} w_j \frac{{x_j}^{1-\alpha}}{1-\alpha} \left({\xi_j}^{\frac{\alpha-1}{\alpha}} - 1 \right) + \sum_{i=1}^{m} y_i - \sum_{j=1}^{n} w_j x_j^{1-\alpha} \cdot {\xi_j}^{\frac{\alpha-1}{\alpha}}, \tag{2}$$

where $\xi_j = \frac{{x_j}^{\alpha} \sum_{i=1}^{m} y_i A_{ij}}{w_j}$, while for $\alpha = 1$:

$$G_1(x, y) = -\sum_{j=1}^{n} w_j \ln \left(\frac{x_j \sum_{i=1}^{m} y_i A_{ij}}{w_j} \right) + \sum_{i=1}^{m} y_i - W. \tag{3}$$

3 Algorithm

The pseudocode for the α-FairPSolver algorithm run at each node j is provided in Fig. 1. The basic intuition is that the algorithm keeps KKT conditions (K1) and (K2) satisfied and works towards (approximately) satisfying the remaining two KKT conditions (K3) and (K4) to minimize the duality gap. The algorithm can run in the distributed setting described in Section 2. In each round, an agent j updates the value of x_j based on the relative slack of all the constraints in which j takes part, as long as the KKT condition (K4) of agent j is not approximately satisfied. The updates need not be synchronous: we will require that all agents make updates at the same speed, but without access to a global clock.

[7] The slack is "relative" because in a non-scaled version of the problem where one could have $b_i \neq 1$, agent j would need to have information about $\frac{b_i - \sum_{j=1}^{n} A_{ij}x_j}{b_i}$.

α-FairPSolver(ε)

(Parameters $\delta_j, C, \kappa, \gamma, \beta_1$, and β_2 are set as described in the text below the algorithm.)

In each round of the algorithm:

1: $x_j \leftarrow \max\{x_j, \delta_j\}$, $x_j = \min\{x_j, 1\}$

2: Update the dual variables: $y_i = C \cdot e^{\kappa\left(\sum_{j=1}^{n} A_{ij}x_j - 1\right)}$ $\forall i \in \{1, \ldots, m\}$

3: **if** $\frac{{x_j}^{\alpha} \cdot \sum_{i=1}^{m} y_i A_{ij}}{w_j} \leq (1-\gamma)$ **then**

4: $\quad x_j \leftarrow x_j \cdot (1+\beta_1)$

5: **else**

6: $\quad$ **if** $\frac{{x_j}^{\alpha} \cdot \sum_{i=1}^{m} y_i A_{ij}}{w_j} \geq (1+\gamma)$ **then**

7: $\quad\quad x_j \leftarrow \max\{x_j \cdot (1-\beta_2), \delta_j\}$

Figure 1 Pseudocode of α-FairPSolver algorithm.

To allow for self-stabilization and dynamic changes, the algorithm runs forever at all the agents, which is a standard requirement for self-stabilizing algorithms (see, e.g., [16]). The convergence of the algorithm is measured as the number of rounds between the round in which the algorithm starts from some initial solution and the round in which it reaches an $\varepsilon-$approximate solution, assuming that there are no hard reset events or node/constraint insertions/deletions in between.

Without loss of generality, we assume that the input parameter ε that determines the approximation quality satisfies $\varepsilon \leq \min\{\frac{1}{6}, \frac{9}{10\alpha}\}$ for any α, and $\varepsilon \leq \frac{1-\alpha}{\alpha}$ for $\alpha < 1$. The parameters $\delta_j, C, \kappa, \gamma$, β_1, and β_2 are set as follows. For technical reasons (mainly due to reinforcing dominant multiplicative updates of the variables x_j), we set the values of the lower thresholds δ_j below the actual lower bound of the optimal solution that we derive in Lemma 4.12:

$$\delta_j = \left(\frac{1}{2} \cdot \frac{w_j}{w_{\max}}\right)^{1/\alpha} \cdot \begin{cases} \left(\frac{1}{m \cdot n^2 \cdot A_{\max}}\right)^{1/\alpha}, & \text{if } 0 < \alpha \leq 1 \\ \frac{1}{m \cdot n^2 {A_{\max}}^{2-1/\alpha}}, & \text{if } \alpha > 1 \end{cases}.$$

We denote $\delta_{\max} \equiv \max_j \delta_j$, $\delta_{\min} \equiv \min_j \delta_j$. The constant C that multiplies the exponent in the dual variables y_i is chosen as $C = \frac{W}{\sum_{j=1}^{n} {\delta_j}^{\alpha}}$. Because δ_j only depends on w_j and on global parameters, we also have $C = \frac{w_j}{{\delta_j}^{\alpha}}$, $\forall j$. The parameter κ that appears in the exponent of the y_i's is chosen as $\kappa = \frac{1}{\varepsilon} \ln\left(\frac{CmA_{\max}}{\varepsilon w_{\min}}\right)$. The "absolute error" of (K4) γ is set to $\varepsilon/4$. For $\alpha \geq 1$, we set $\beta_1 = \beta_2 = \beta$, where the choice of β is described below. For $\alpha < 1$, we set $\beta_1 = \beta$, $\beta_2 = \beta^2(\ln(\frac{1}{\delta_{\min}}))^{-1}$.

Similar to [7], we choose the value of β so that if we set $\beta_1 = \beta_2 = \beta$, in any round the value of each $\frac{{x_j}^{\alpha} \sum_{i=1}^{m} y_i(x) A_{ij}}{w_j}$ changes by a multiplicative factor of at most $(1 \pm \gamma/4)$. Since the maximum increase over any x_j in each iteration is by a factor $1+\beta$, and x is feasible in each round (see Lemma 4.4), we have that $\sum_{j=1}^{n} A_{ij}x_j \leq 1$, and therefore, the maximum increase in each y_i is by a factor of $e^{\kappa\beta}$. A similar argument holds for the maximum decrease. Hence, we choose β so that:

$$(1+\beta)^{\alpha} e^{\kappa\beta} \leq 1 + \gamma/4 \quad \text{and} \quad (1-\beta)^{\alpha} e^{-\kappa\beta} \geq 1 - \gamma/4,$$

and it suffices to set:

$$\beta = \begin{cases} \frac{\gamma}{5(\kappa+1)}, & \text{if } \alpha \leq 1 \\ \frac{\gamma}{5(\kappa+\alpha)}, & \text{if } \alpha > 1 \end{cases}.$$

▶ Remark. In the $\alpha < 1$ cases, since $\beta_2 = \beta^2(\ln(1/\delta_{\min}))^{-1}$, the maximum decrease in $\frac{{x_j}^\alpha \sum_i y_i(x)A_{ij}}{w_j}$ is by a factor $(1 - (\gamma/4) \cdot \beta(\ln(1/\delta_{\min}))^{-1})$, $\forall j$.

4 Convergence Analysis

In this section, we analyze the convergence time of α-FairPSolver. We first state our main theorems and provide some general results that hold for all $\alpha > 0$. We show that starting from an arbitrary solution, the algorithm reaches a feasible solution within poly-logarithmic (in the input size) number of rounds, and maintains a feasible solution forever after. Similar to [7, 46, 25], we use a concave potential function that, for feasible x, is bounded below and above and increases with any algorithm update. Then, we sketch the proof of Theorem 4.3 ($\alpha > 1$), while we defer the full proofs of the three theorems to the full paper [35]. The main proof idea in all the cases is as follows. With an appropriate definition of a *stationary round* for each of the three cases $\alpha < 1$, $\alpha = 1$, and $\alpha > 1$, we show that in every stationary round, x approximates "well" the optimal solution by bounding the duality gap. On the other hand, for any non-stationary round, we show that the potential increases substantially. This large increase in the potential leads to the conclusion that there cannot be too many non-stationary rounds, thus bounding the overall convergence time.

We make a few remarks here. First, we require that α be bounded away from zero. This requirement is without loss of generality because we show that when $\alpha \leq \frac{\varepsilon/4}{\ln(nA_{\max}/\varepsilon)}$, any $\varepsilon-$approximation LP provides a $3\varepsilon-$approximate solution to (P_α) (Lemma 4.13). Thus, when $\alpha \leq \frac{\varepsilon/4}{\ln(nA_{\max}/\varepsilon)}$ we can switch to the algorithm of [7], and when $\alpha > \frac{\varepsilon/4}{\ln(nA_{\max}/\varepsilon)}$, the convergence time remains poly-logarithmic in the input size and polynomial in ε^{-1}. Second, the assumption that $\varepsilon \leq \frac{1-\alpha}{\alpha}$ in the $\alpha < 1$ case is also without loss of generality, because we show that when α is close to 1 (roughly, $1 - O(\varepsilon^2/\ln^2(R_w mnA_{\max}/\varepsilon))$), we can approximate (P_α) by switching to the $\alpha = 1$ case of the algorithm (Lemma 4.14). Finally, when $\alpha > 1$, the algorithm achieves an $\varepsilon-$approximation in time $O(\alpha^4\varepsilon^{-4}\ln^2(R_w nmA_{\max}\varepsilon^{-1}))$. We believe that a polynomial dependence on α is difficult to avoid in this setting, because by increasing α, the gradient of the α-fair utilities f_α blows up on the interval $(0, 1)$: as α increases, $f_\alpha(x)$ quickly starts approaching a step function that is equal to $-\infty$ on the interval $(0, 1]$ and equal to 0 on the interval $(1, \infty]$. To characterize the behavior of α-fair allocations as α becomes large, we show that when $\alpha \geq \varepsilon^{-1}\ln(R_w nA_{\max})$, all the coordinates of the α-fair vector are within a $1 \pm \varepsilon$ multiplicative factor of the corresponding coordinates of the max-min fair vector (Lemma 4.17).

Main Results. Our main results are summarized in the following three theorems. The objective is denoted by $p_\alpha(x)$, x^t denotes the solution at the beginning of round t, and x^* denotes the optimal solution.

▶ **Theorem 4.1** (Convergence for $\alpha < 1$)**.** α-FairPSolver *solves* (P_α) *approximately for* $\alpha < 1$ *in time that is polynomial in* $\frac{\ln(nmA_{\max})}{\alpha\varepsilon}$*. In particular, after at most*

$$O\left(\alpha^{-2}\varepsilon^{-5}\ln^2\left(R_w mnA_{\max}\right)\ln^2\left(\varepsilon^{-1}R_w mnA_{\max}\right)\right) \tag{4}$$

rounds, there exists at least one round t such that $p_\alpha(x^*) - p_\alpha(x^t) \leq \varepsilon p_\alpha(x^t)$. Moreover, the total number of rounds s in which $p_\alpha(x^*) - p_\alpha(x^s) > \varepsilon p_\alpha(x^s)$ is also bounded by (4).

▶ **Theorem 4.2** (Convergence for $\alpha = 1$)**.** α-FairPSolver *solves* (P_1) *approximately in time that is polynomial in* $\varepsilon^{-1}\ln(R_w nmA_{\max})$*. In particular, after at most*

$$O\left(\varepsilon^{-5}\ln^2\left(R_w nmA_{\max}\right)\ln^2\left(\varepsilon^{-1}R_w nmA_{\max}\right)\right) \tag{5}$$

rounds, there exists at least one round t such that $p(x^*) - p(x^t) \leq \varepsilon W$. Moreover, the total number of rounds s in which $p(x^*) - p(x^s) > \varepsilon W$ is also bounded by (5).

▶ **Theorem 4.3** (Convergence for $\alpha > 1$)**.** α-FairPSolver *solves (P_α) approximately for $\alpha > 1$ in time that is polynomial in $\varepsilon^{-1} \ln(nmA_{\max})$. In particular, after at most:*

$$O\left(\alpha^4 \varepsilon^{-4} \ln\left(R_w nmA_{\max}\right) \ln\left(\varepsilon^{-1} R_w nmA_{\max}\right)\right) \tag{6}$$

rounds, there exists at least one round t such that $p_\alpha(x^*) - p_\alpha(x^t) \leq \varepsilon(-p_\alpha(x^t))$. Moreover, the total number of rounds s in which $p_\alpha(x^*) - p_\alpha(x^s) > \varepsilon(-p_\alpha(x^s))$ is also bounded by (6).

Proofs of Theorem 4.1 and Theorem 4.2 are provided in the full paper [35]. We sketch the proof of Theorem 4.3 in Section 4.1.

Feasibility and Approximate Complementary Slackness. The following three lemmas are preliminaries for the convergence time analysis. Lemma 4.4 shows that starting from a feasible solution, the algorithm always maintains a feasible solution. Lemma 4.5 shows that any violated constraint becomes feasible within poly-logarithmic number of rounds, and remains feasible forever after. Combined with Lemma 4.4, Lemma 4.5 allows us to focus only on the rounds with feasible solutions x. Lemma 4.6 shows that after a poly-logarithmic number of rounds, approximate complementary slackness (KKT condition (K3)) holds in an aggregate sense: $\sum_{i=1}^m y_i(x)\left(\sum_{j=1}^n A_{ij}x_j - 1\right) \approx 0$. Proofs are provided in [35].

▶ **Lemma 4.4.** *If the algorithm starts from a feasible solution, then the algorithm maintains a feasible solution x: $x_j \geq 0$, $\forall j$ and $\sum_{j=1}^n A_{ij}x_j \leq 1$, $\forall i$, in each round.*

▶ **Lemma 4.5.** *If for any i: $\sum_{j=1}^n A_{ij}x_j > 1$, then after at most $\tau_1 = O(\frac{1}{\beta_2} \ln(nA_{\max}))$ rounds, it is always true that $\sum_{j=1}^n A_{ij}x_j \leq 1$.*

▶ **Lemma 4.6.** *If the algorithm starts from a feasible solution, then after at most $\tau_0 = \frac{1}{\beta} \ln\left(\frac{1}{\delta_{\min}}\right)$ rounds, it is always true that:*

1. *At least one constraint is approximately tight: $\max_i \left\{\sum_{j=1}^n A_{ij}x_j\right\} \geq 1 - (1 + 1/\kappa)\varepsilon$,*
2. *$\sum_{i=1}^m y_i \leq (1 + 3\varepsilon) \sum_{j=1}^n x_j \sum_{i=1}^m y_i A_{ij}$, and*
3. *$(1 - 3\varepsilon) \sum_{i=1}^m y_i \leq \sum_{j=1}^n x_j \sum_{i=1}^m y_i A_{ij} \leq \sum_{i=1}^m y_i$.*

Lemmas analogous to 4.4 and 4.6 also appear in [7]. However, the proofs of Lemmas 4.4 and 4.6 require new ideas compared to the proofs of the corresponding lemmas in [7]. We need to be much more careful in our choice of lower thresholds δ_j and constant C in the dual variables, particularly by choosing C as a function of several variables, rather than as a constant. The choice of δ_j's is also sensitive as smaller δ_j's would make the potential function range too large, while larger δ_j's would cause more frequent decrease of "small" variables. In either case, the convergence time would increase.

Decrease of Small Variables. The following lemma is also needed for the convergence analysis. It shows that if some variable x_j decreases by less than a multiplicative factor $(1 - \beta_2)$, i.e., $x_j < \frac{\delta_j}{1-\beta_2}$ and x_j decreases, then x_j must be part of at least one approximately tight constraint. This lemma will be used later to show that in any round the increase in the potential due to the decrease of "small" variables is dominated by the decrease of "large" variables (i.e., the variables that decrease by a multiplicative factor $(1 - \beta_2)$). The proof of Lemma 4.7 is provided in [35].

▶ **Lemma 4.7.** *Consider the rounds that happen after the initial* $\tau_1 = O(\frac{1}{\beta_2}\ln(nA_{\max}))$ *rounds. If in some round there is a variable* $x_j < \frac{\delta_j}{1-\beta_2}$ *that decreases, then in the same round for some* i *with* $A_{ij} \neq 0$ *it holds that:* $y_i(x) \geq \frac{\sum_{l=1}^{m} A_{lj} y_l(x)}{m A_{\max}}$ *and* $\sum_{k=1}^{n} A_{ik} x_k > 1 - \frac{\varepsilon}{2}$.

Potential. We use the following potential function to analyze the convergence time:

$$\Phi(x) = p_\alpha(x) - \frac{1}{\kappa}\sum_{i=1}^{m} y_i(x),$$

where $p_\alpha(x) = \sum_{j=1}^{n} w_j f_\alpha(x_j)$ and f_α is defined by (1). The potential function is strictly concave and its partial derivative with respect to any variable x_j is:

$$\frac{\partial \Phi(x)}{\partial x_j} = \frac{w_j}{{x_j}^\alpha} - \sum_{i=1}^{m} y_i(x) A_{ij} = \frac{w_j}{{x_j}^\alpha}\left(1 - \frac{{x_j}^\alpha \sum_{i=1}^{m} y_i(x) A_{ij}}{w_j}\right). \tag{7}$$

The following fact (given in a similar form in [7]), which follows directly from the Taylor series representation of concave functions, will be useful for the potential increase analysis:

▶ **Fact 4.8.** For a differentiable concave function $f : \mathbb{R}^n \to \mathbb{R}$ and any two points $x^0, x^1 \in \mathbb{R}^n$:

$$\sum_{j=1}^{n} \frac{\partial f(x^0)}{\partial x_j}(x_j^1 - x_j^0) \geq f(x^1) - f(x^0) \geq \sum_{j=1}^{n} \frac{\partial f(x^1)}{\partial x_j}(x_j^1 - x_j^0).$$

Using Fact 4.8 and (7), we show the following lemma:

▶ **Lemma 4.9.** *Starting with a feasible solution and throughout the course of the algorithm, the potential function* $\Phi(x)$ *never decreases. Letting* x^0 *and* x^1 *denote the values of* x *before and after a round update, respectively, the potential function increase is lower-bounded as:*

$$\Phi(x^1) - \Phi(x^0) \geq \sum_{j=1}^{n} w_j \frac{\left|x_j^1 - x_j^0\right|}{(x_j^1)^\alpha}\left|1 - \frac{(x_j^1)^\alpha \sum_{i=1}^{m} y_i(x^1) A_{ij}}{w_j}\right|.$$

4.1 Proof Sketch of Theorem 4.3

In this section, we outline the main ideas of the proof of Theorem 4.3, while the technical details are omitted and are instead provided in [35]. First, we show that in any round of the algorithm the variables that decrease by a multiplicative factor $(1 - \beta_2)$ dominate the potential increase due to *all the variables* that decrease (see Lemma 4.21 in [35]). This result is then used in Lemma 4.10 to show the following lower bound on the potential increase:

▶ **Lemma 4.10.** *Let* x^0 *and* x^1 *denote the values of* x *before and after any fixed round, respectively, and let* $S^+ = \{j : x_j^1 > x_j^0\}$, $S^- = \{j : x_j^1 < x_j^0\}$. *The potential increase in the round is lower bounded as:*

1. $\Phi(x^1) - \Phi(x^0) \geq \Omega(\beta\gamma)\sum_{j\in\{S^+\cup S^-\}} x_j^0 \sum_{i=1}^{m} y_i(x^0) A_{ij}$;
2. $\Phi(x^1) - \Phi(x^0) \geq \Omega\left(\frac{\beta}{(1-\beta)^\alpha}\right)\left(\sum_{j=1}^{n} x_j^0 \sum_{i=1}^{m} y_i(x^0) - (1+\gamma)\sum_{j=1}^{n} w_j (x_j^0)^{1-\alpha}\right)$;
3. $\Phi(x^1) - \Phi(x^0) \geq \Omega\left(\frac{\beta}{(1+\beta)^\alpha}\right)\left((1-\gamma)\sum_{j=1}^{n} w_j (x_j^0)^{1-\alpha} - \sum_{j=1}^{n} x_j^0 \sum_{i=1}^{m} y_i(x^0)\right)$.

Observe that for $\alpha > 1$ the objective function $p_\alpha(x)$, and, consequently, the potential function $\Phi(x)$, is negative for any feasible x. To yield a poly-logarithmic convergence time in R_w, m, n, and $A_{\max}$, the idea is to show that the negative potential $-\Phi(x)$ decreases by some

multiplicative factor whenever x is not a "good" approximation to x^* – the optimal solution to (P_α). This idea, combined with the fact that the potential never decreases (and therefore $-\Phi(x)$ never increases) and with upper and lower bounds on the potential then leads to the desired convergence time. Consider the following definition of a stationary round:

▶ **Definition 4.11** (Stationary round)**.** A round is stationary, if both:

1. $\sum_{j\in\{S^+\cup S^-\}} x_j^0 \sum_{i=1}^m y_i(x)A_{ij} < \gamma \sum_{j=1}^n w_j (x_j^0)^{1-\alpha}$, and
2. $(1-2\gamma)\sum_{j=1}^n w_j (x_j^0)^{1-\alpha} \le \sum_{j=1}^n x_j^0 \sum_{i=1}^m y_i(x^0)A_{ij}$,

where $S^+ = \{j : x_j^1 > x_j^0\}$, $S^- = \{j : x_j^1 < x_j^0\}$. Otherwise, the round is non-stationary.

Recall the expression for the negative potential: $-\Phi(x) = \frac{1}{\alpha-1}\sum_j w_j {x_j}^{1-\alpha} + \frac{1}{\kappa}\sum_i y_i(x)$. Then, using Lemma 4.10, it suffices to show that in a non-stationary round the decrease in the negative potential $-\Phi(x)$ is a multiplicative factor of the larger of the two terms $\frac{1}{\alpha-1}\sum_j w_j {x_j}^{1-\alpha}$ and $\frac{1}{\kappa}\sum_i y_i(x)$. The last part of the proof shows that the solution x that corresponds to any stationary round is close to the optimal solution. This part is done by appropriately upper-bounding the duality gap. Denoting by $S^+ \cup S^-$ the set of coordinates j for which x_j either increases or decreases in the observed stationary round and using Definition 4.11, we show that the terms $j \in \{S^+ \cup S^-\}$ contribute to the duality gap by no more than $O(\varepsilon\alpha)\cdot(-p_\alpha(x))$. The terms corresponding to $j \notin \{S^+ \cup S^-\}$ are bounded recalling (from α-FairPSolver) that for such terms $\frac{x_j^\alpha \sum_{i=1}^m y_i(x)A_{ij}}{w_j} \in (1-\gamma, 1+\gamma)$.

4.2 Structural Properties

Lower Bound on the Minimum Allocated Value. Recall (from Section 2) that the optimal solution x^* to (P_α) must lie in the positive orthant. We show in Lemma 4.12 that not only does x^* lie in the positive orthant, but the minimum element of x^* can be bounded below as a function of the problem parameters. This lemma motivates the choice of parameters δ_j in α-FairPSolver (Section 3). The proof is provided in [35].

▶ **Lemma 4.12.** *Let $x^* = (x_1^*, \ldots, x_n^*)$ be the optimal solution to (P_α). Then $\forall j \in \{1,\ldots,n\}$:*

- $x_j^* \ge \left(\frac{w_j}{w_{\max} M}\min_{i:A_{ij}\neq 0}\frac{1}{n_i A_{ij}}\right)^{1/\alpha}$, *if* $0 < \alpha \le 1$,
- $x_j^* \ge {A_{\max}}^{(1-\alpha)/\alpha}\left(\frac{w_j}{w_{\max} M}\right)^{1/\alpha}\min_{i:A_{ij}\neq 0}\frac{1}{n_i A_{ij}}$, *if* $\alpha > 1$,

where $n_i = \sum_{j=1}^n \mathbb{1}_{\{A_{ij}\neq 0\}}$[8] *is the number of non-zero elements in the i^{th} row of the constraint matrix A, and $M = \min\{m,n\}$.*

Asymptotics of α-Fair Allocations. The following lemma states that for sufficiently small (but not too small) α, the values of the linear and the α-fair objectives at their respective optimal solutions are approximately the same. This statement will then lead to a conclusion that to $\varepsilon-$approximately solve an α-fair packing problem for a very small α, one can always use an $\varepsilon-$approximation packing LP algorithm.

▶ **Lemma 4.13.** *Let (P_α) be an α-fair packing problem with optimal solution x^*, and (P_0) be the LP with the same constraints and the same weights w as (P_α) and an optimal solution z^*. Then if $\alpha \le \frac{\varepsilon/4}{\ln(nA_{\max}/\varepsilon)}$, we have that $\sum_j w_j z_j^* \ge (1-3\varepsilon)\sum_j \frac{(x_j^*)^{1-\alpha}}{1-\alpha}$, where $\varepsilon \in (0, 1/6]$.*

[8] With the abuse of notation, $\mathbb{1}_{\{e\}}$ is the indicator function of the expression e, i.e., 1 if e holds, and 0 otherwise.

Observing that for any $\alpha \in (0,1)$, $\frac{(z_j^*)^{1-\alpha}}{1-\alpha} \geq z_j^*$ (since, due to the scaling, $z_j^* \in [0,1]$), a simple corollary of Lemma 4.13 is that an $\varepsilon-$approximation z to (P_0) ($\sum_j w_j z_j \geq (1-\varepsilon)\sum_j w_j z_j^*$) is also an $O(\varepsilon)-$approximation to (P_α), for $\alpha \leq \frac{\varepsilon/4}{\ln(nA_{\max}/\varepsilon)}$. Thus, to find an $\varepsilon-$approximate solution for $\alpha \leq \frac{\varepsilon/4}{\ln(nA_{\max}/\varepsilon)}$, the packing LP algorithm of [7] can be run, which means that there is a stateless distributed algorithm that converges in $\text{poly}(\ln(\varepsilon^{-1}R_w mnA_{\max})/\varepsilon)$ time for α arbitrarily close to zero.

The following two lemmas show that when α is sufficiently close to 1, (P_α) can be $\varepsilon-$approximated by $\varepsilon-$approximately solving (P_1) with the same constraints and weights.

▶ **Lemma 4.14.** *Let x be an $\varepsilon-$approximate solution to a 1-fair packing problem (P_1) returned by α-FairPSolver. Then, for any $\alpha \in [1-1/\tau_0, 1)$, where $\tau_0 = \frac{1}{\beta}\ln(\frac{1}{\delta_{\min}})$, x is also a $2\varepsilon-$approximate solution to (P_α), where the only difference between (P_1) and (P_α) is in the value of α in the objective.*

▶ **Lemma 4.15.** *Let x be an $\varepsilon-$approximate solution to a 1-fair packing problem (P_1) returned by α-FairPSolver. Then, for any $\alpha \in (1, 1+1/\tau_0]$, where $\tau_0 = \frac{1}{\beta}\ln(\frac{1}{\delta_{\min}})$, x is also a $2\varepsilon-$approximate solution to (P_α), where the only difference between (P_1) and (P_α) is in the value of α in the objective.*

Finally, we consider the asymptotics of α-fair allocations, as α becomes large. This result complements the result from [38] that states that α-fair allocations approach the max-min fair one as $\alpha \to \infty$ by showing how fast the max-min fair allocation is reached as a function of α, R_w, n, and $A_{\max}$. First, for completeness, we provide the definition of max-min fairness.

▶ **Definition 4.16.** (Max-min fairness [10].) Let $\mathcal{R} \subset \mathbb{R}_+^n$ be a compact and convex set. A vector $x \in \mathcal{R}$ is max-min fair on $\mathcal{R}$ if for any vector $z \in \mathcal{R}$ it holds that: if for some $j \in \{1,\ldots,n\}$ $z_j > x_j$, then there exists $k \in \{1,\ldots,n\}$ such that $z_k < x_k$ and $x_k \leq x_j$.

On a compact and convex set $\mathcal{R} \subset \mathbb{R}^n$, the max-min fair vector is unique [44, 43]. The following lemma shows that for $\alpha \geq \varepsilon^{-1}\ln(R_w nA_{\max})$, the α-fair vector and the max-min fair vector are $\varepsilon-$close to each other. Notice that because of a very large gradient of $p_\alpha(x)$ as α becomes large, the max-min fair solution gives only an $O(\varepsilon\alpha)-$approximation to (P_α).

▶ **Lemma 4.17.** *Let x^* be the optimal solution to $(P_\alpha) = \max\{p_\alpha(x) : Ax \leq 1, x \geq 0\}$, z^* be the max-min fair solution for the convex and compact set determined by the constraints from (P_α). Then if $\alpha \geq \varepsilon^{-1}\ln(R_w nA_{\max})$, we have that:*
1. *$p_\alpha(x^*) \leq (1-\varepsilon(\alpha-1))p_\alpha(z^*)$, i.e., z^* is an $\varepsilon(\alpha-1)-$approximate solution to (P_α), and*
2. *$(1-\varepsilon)z_j^* \leq x_j^* \leq (1+\varepsilon)z_j^*$, for all $j \in \{1,\ldots,n\}$.*

5 Conclusion

We presented an efficient stateless distributed algorithm for the class of α-fair packing problems. To the best of our knowledge, this is the first algorithm with poly-logarithmic convergence time in the input size. Additionally, we obtained results that characterize the fairness and asymptotic behavior of allocations in weighted α-fair packing problems that may be of independent interest. An interesting open problem is to determine the class of objective functions for which the presented techniques yield fast and stateless distributed algorithms, together with a unified convergence analysis. This problem is especially important in light of the fact that α-fair objectives are not Lipschitz continuous, do not have a Lipschitz gradient, and their dual gradient's Lipschitz constant scales at least linearly with n and $A_{\max}$.

Therefore, the properties typically used in fast first-order methods are lacking [40, 2]. Finally, for applications of α-fair packing that do not require stateless updates, it seems plausible that the dependence on ε^{-1} in the convergence bound can be improved from ε^{-5} to ε^{-3} by relaxing the requirement for asynchronous updates, similarly as was done in [3] over [7].

All-Pairs Approximate Shortest Paths and Distance Oracle Preprocessing

Christian Sommer

Apple Inc., Cupertino, CA, USA
csommer@apple.com

Abstract

Given an undirected, unweighted graph G on n nodes, there is an $O(n^2 \text{poly} \log n)$-time algorithm that computes a data structure called *distance oracle* of size $O(n^{5/3} \text{poly} \log n)$ answering approximate distance queries in constant time. For nodes at distance d the distance estimate is between d and $2d + 1$.

This new distance oracle improves upon the oracles of Pătraşcu and Roditty (FOCS 2010), Abraham and Gavoille (DISC 2011), and Agarwal and Brighten Godfrey (PODC 2013) in terms of preprocessing time, and upon the oracle of Baswana and Sen (SODA 2004) in terms of stretch. The running time analysis is tight (up to logarithmic factors) due to a recent lower bound of Abboud and Bodwin (STOC 2016).

Techniques include dominating sets, sampling, balls, and spanners, and the main contribution lies in the way these techniques are combined. Perhaps the most interesting aspect from a technical point of view is the application of a spanner without incurring its constant additive stretch penalty.

1 Introduction

Given a graph $G = (V, E)$ on $n := |V|$ vertices, the *All-Pairs Shortest Path (APSP)* problem asks for pairwise distances $d(u, v)$ among all pairs of nodes $u, v \in V$. The fastest known algorithms to compute these $\binom{n}{2}$ distance values (in this paper, we restrict ourselves to undirected, unweighted graphs) use fast matrix multiplication [16, 18, 29, 34] or run in roughly cubic time [12, 20, 33, 37]. Depending on the number of edges $m := |E|$, computing n independent shortest-path trees (breadth-first search trees for unweighted graphs) in $O(mn)$ may be faster.

Algorithms for All-Pairs *Approximate* Shortest Paths (*APASP*) trade accuracy for speed. Their worst-case approximation guarantee is called *stretch*. Stretch (α, β) means that for any pair of nodes $u, v \in V$ at distance d the algorithm's estimate is between d and $\alpha \cdot d + \beta$ (typically, when $\beta > 0$, graphs are assumed to be unweighted or β depends on the largest edge weight).

Aingworth, Chekuri, Indyk, and Motwani [5] introduced a technique to handle high-degree nodes using *dominating sets*. They apply their technique to derive a $(1, 2)$-stretch algorithm that runs in time $\tilde{O}(n^{5/2})$ (as usual, $\tilde{O}(\cdot)$ hides logarithmic factors). Their dominating-set technique has been used in many subsequent algorithms. Dor, Halperin, and Zwick [17] improved the running time to $\tilde{O}(\min\{n^{3/2}m^{1/2}, n^{7/3}\})$. Furthermore, they also gave a reduction, proving that an APASP algorithm with multiplicative stretch strictly less than 2

Table 1 A selection of related work on the all-pairs approximate shortest path problem and constant-time approximate distance oracles for unweighted graphs. Some results hold for weighted graphs as well, and some methods guarantee better bounds for sparse graphs. To simplify the comparison for dense graphs, the bounds in this table are for $m = n^2$ (except for the sub-quadratic algorithm of [6]). Stretch (α, β) means that for pairs at distance d the distance estimate is between d and $\alpha d + \beta$.

or constant additive stretch serves as an algorithm for boolean matrix multiplication. After this reduction, most research efforts have been focused on stretch 2 or higher. Cohen and Zwick [15] provided various tradeoffs such as an $\tilde{O}(n^2)$ algorithm with stretch $\alpha = 3$. Berman and Kasiviswanathan [10] further improved the stretch to $(2, 1)$. See also the survey by Zwick [38].

A *distance oracle* is a *compact* representation of the AP(A)SP matrix of a graph $G = (V, E)$. The main quantities of interest are the *construction time* (also called *preprocessing time*), the *space consumption*, the *query time*, and the *stretch*. Thorup and Zwick [31] coined the term *distance oracle*, and they also provided an oracle with constant query time, multiplicative stretch $\alpha = 3$, space $O(n^{3/2})$, and preprocessing time $\tilde{O}(mn^{1/2})$, as well as more general tradeoffs for all odd integers $\alpha > 3$, which are not discussed any further in this paper.[1] For $\alpha = 3$, their space bound is asymptotically optimal due to the existence of dense graphs with large girth [11, 24, 32]. The preprocessing time was subsequently improved in a line of work: Baswana and Sen [9] improved the preprocessing time to $O(n^2)$ for unweighted graphs, Baswana and Kavitha [8] obtained $O(n^2)$ preprocessing time for weighted graphs, and Baswana, Gaur, Sen, and Upadhyay [6] gave a sub-quadratic preprocessing algorithm for stretch $(3, 10)$. See also the survey by Sen [26].[2]

Is stretch $\alpha = 3$ the best we can expect of a distance oracle with sub-quadratic space? Pătraşcu and Roditty [21][3] provide an oracle with constant query time, stretch $(2, 1)$, space $O(n^{5/3})$, and polynomial preprocessing time. The tradeoff between stretch and space is asymptotically optimal assuming the hardness of set intersection [21, 22]. Less well known, the work of Baswana, Goyal, and Sen [7] contains a data structure that is remarkably similar

[1] For larger stretch values, Wulff-Nilsen [36] provides the fastest preprocessing times and Chechik [13, 14] provides the fastest query times; for a survey, see [27].

[2] Again for larger stretch values, Wulff-Nilsen [36] further improved the preprocessing times.

[3] See also Abraham and Gavoille [2] for a distributed distance oracle, also known as a *distance labeling scheme*, as well as Agarwal and Brighten Godfrey [4].

to the distance oracle in the result of Pătraşcu and Roditty [21], implicitly providing an $\tilde{O}(mn^{2/3})$ bound on the preprocessing time for $(2,1)$-approximate distance oracles.[4] They also provide an $\tilde{O}(n^2)$-time algorithm for a data structure with stretch $(2,3)$ instead of the optimal $(2,1)$. Again, the space bound is not stated explicitly as a distance oracle result. For an overview, see Table 1.

What is the fastest preprocessing time that can be achieved for distance oracles with multiplicative stretch $\alpha < 3$? We propose an algorithm that runs in quadratic time (up to polylogarithmic factors) and computes a $(2,1)$-approximate distance oracle. Analogous to the distance oracles by Abraham and Gavoille [2], the distance oracle can also be distributed as *distance labels*.

▶ **Theorem 1.** *Given an undirected, unweighted graph G on n nodes, there is an $\tilde{O}(n^2)$-time algorithm that computes a $(2,1)$-approximate distance oracle of size $\tilde{O}(n^{5/3})$ with query time $O(1)$.*

Previously known quadratic-time algorithms either produce data structures with quadratic space ([10, 15, 17], see also Section 2.4) or with worst-case stretch $(2,3)$ (see [7]). Probably the most interesting technical aspect of the result is the use of an additive spanner *free of charge*, i.e., without incurring its typical stretch penalty (the query time has a linear dependency on the additive stretch of the spanner). The argument works for any spanner with constant additive stretch, and hence is tight due to a recent lower bound by Abboud and Bodwin [1].

For general graphs, Theorem 1 seems hard to improve upon (modulo logarithmic factors) for two reasons (beyond the obvious reason that the algorithm needs to read the graph with potentially $\Omega(n^2)$ edges): the space-stretch tradeoff is essentially tight due to a set intersection lower bound [21, 22], and the preprocessing-stretch-query tradeoff is essentially tight as for distance oracles with quadratic preprocessing time and $\tilde{O}(1)$ query time (but independent of the space), any improvement of the multiplicative stretch below 2 would imply a (quasi-)quadratic algorithm for boolean matrix multiplication [3, 17] (the fastest known combinatorial algorithm runs in roughly cubic time [37]).

For sparse graphs, I am not aware of any arguments against even faster preprocessing time $\tilde{O}(m + n^{5/3})$ (and no additive $+1$ stretch if $m = \tilde{O}(n)$ [21]). As mentioned above, Baswana, Goyal, and Sen [7] implicitly prove an $\tilde{O}(mn^{2/3})$ bound on the preprocessing time (Theorem 5), which for $m = \tilde{O}(n)$ is asymptotically optimal. The optimal preprocessing time for m between $\tilde{\omega}(n)$ and $\tilde{o}(n^2)$ remains open.

The distance oracle of Theorem 1 roughly works as follows (the description omits $\tilde{O}$-notation and assumes familiarity with the techniques described in the preliminaries (Section 2)): short distances are exact by storing balls and their intersection (as in [2, 7, 21]); long distances are triangulations via *landmarks*. However, we cannot afford to compute exact distances for each node and all $n^{2/3}$ landmarks. Instead, we group landmarks by degree (using dominating sets), where paths from/to the 2^i landmarks with degree $n/2^i$ are computed in graphs with $n^2/2^i$ edges plus the edges of an $(1,6)$-spanner [35]. The spanner ensures that distances do not deteriorate too much. For each node v, we compute a set of *portals* by sparsifying its set of (up to $\log n$) nearest landmarks to include a landmark with degree $n/2^j$ if and only if it is closer to v than all landmarks with higher degree $n/2^i$ (i.e., for all $i < j$). At query time, a constant number of landmarks per node is sufficient to guarantee

[4] An important reference I unfortunately failed to include when writing [27].

stretch $(2, 1)$: the query algorithm triangulates via landmarks by increasing degree, and each subsequent landmark implies that the target distance increases by at least 1.

The overall framework is described in Section 3. The main part of the argument is formalized as a distance oracle for *heavy paths*, where a path is defined to be heavy if it passes through two consecutive high-degree nodes, see Section 4.

2 Preliminaries

2.1 Spanners

Spanners [23] are relatively sparse subgraphs with additional properties such as stretch bounds on shortest-path distances. A spanner is deemed to have *stretch* (α, β) if $d_H(u, v) \leqslant \alpha \cdot d_G(u, v) + \beta$. Note that, since H is a subgraph, $d_G(u, v) \leqslant d_H(u, v)$. While there are no known distance oracles or distance labeling schemes with constant additive stretch (and are unlikely to exist [19, 21, 28]), such spanners can be computed efficiently. The preprocessing algorithm in this paper invokes the following spanner construction as a subroutine.

▶ **Theorem 2** (Woodruff [35]). *Given an undirected, unweighted graph G on n nodes, there is an $\tilde{O}(n^2)$-time algorithm that computes a $(1, 6)$-spanner with $\tilde{O}(n^{4/3})$ edges.*

Recently, Abboud and Bodwin [1] proved that Theorem 2 is tight in a very strong way. Any spanner with constant additive stretch must have essentially $n^{4/3}$ edges. More precisely, they prove the following.

▶ **Theorem 3** (Abboud and Bodwin [1]). *For all $\epsilon > 0$ there exists a $\delta > 0$ and an infinite family of graphs $G = (V, E)$ such that for any subgraph $H = (V, E')$ with $|E'| = O(n^{4/3-\epsilon})$, there exist nodes $u, v \in V$ with $d_H(u, v) = d_G(u, v) + \Omega(n^{\delta})$.*

Their result illustrates the limitations of the construction in this paper. There is no better spanner than Woodruff's for our purposes (as long as we are indifferent to log factors in the $\tilde{O}(\cdot)$ notation).

2.2 Balls and Clusters

While long distances can be approximated well using triangulation via *landmarks*, many distance oracles handle short-range distances using *balls* and *clusters* [2, 21, 22, 31].

▶ **Definition 4** (Balls and Clusters). Given a graph $G = (V, E)$ and a set of landmarks $L \subseteq V$, the *ball* of a node v with respect to L is $B_L(v) := \{u : d(v, u) < d(v, L)\}$. The *cluster* of a node u with respect to L is $C_L(u) := \{v : d(v, u) < d(v, L)\}$.

Note that $v \in C_L(u)$ if and only if $u \in B_L(v)$.

For any $0 < \ell < n$, random sampling with probability ℓ/n yields ℓ landmarks (in expectation) and *average* ball and cluster sizes of $O(n/\ell)$. A sampling algorithm of Thorup and Zwick [30] computes a set of landmarks L such that no node cluster $C_L(u)$ is larger than $O(n/\ell)$ and $|L| = O(\ell \log n)$. The running time of their algorithm is bounded by $O((mn \log n)/\ell)$. Abraham and Gavoille [2] extend the Thorup-Zwick sampling algorithm to also guarantee worst-case bounds on balls $|B_L(v)| = O(n/\ell)$.

Roditty, Thorup, and Zwick [25] provide a deterministic algorithm (based on hitting sets) to select landmarks. They also claim (without proof due to lack of space) that their algorithm can be used to de-randomize the quadratic-time preprocessing algorithm of Baswana and Sen [9].

2.3 Stretch-2 Distance Oracles

In the following, we give a brief description of the distance oracles by [2, 4, 21] for unweighted graphs. Similar arguments were also used in the analysis for all-pairs approximate shortest path algorithms [7].

The preprocessing algorithm starts by selecting a set of landmarks L of size roughly $|L| = \tilde{O}(n^{2/3})$ such that $|B_L(u)|, |C_L(u)| = \tilde{O}(n^{1/3})$ for all $u \in V$ (see sampling algorithm above). Long-range distances (global queries) are answered by triangulation using the landmark closest to either of the query nodes. To prepare for those queries, the preprocessing algorithm computes distances for all pairs of nodes in $V \times L$. Short-range distances (local queries) are answered using *super balls* $S_L(\cdot)$. For each node u, the algorithm computes the distance to all nodes in its ball $B_L(u)$ as well as all nodes v whose balls $B_L(v)$ intersect with $B_L(u)$, i.e., $S_L(u) := B_L(u) \cup \bigcup_{w \in B_L(u)} C_L(w)$. Since the sizes of both $B_L(\cdot)$ and $C_L(\cdot)$ are bounded by $\tilde{O}(n^{1/3})$, super balls contain at most $|S_L(u)| = \tilde{O}(n^{2/3})$ nodes.

The query algorithm for source s and target t checks whether $t \in S_L(s)$ or $s \in S_L(t)$. If so, the exact distance has been pre-computed (a local query). Otherwise, let l_s and l_t denote the landmarks closest to s and t, respectively. The long-range distance $\min\{d(s, l_s) + d(l_s, t), d(s, l_t) + d(l_t, t)\}$ is returned.

For the stretch analysis, we need to bound the distance returned for global queries. Without loss of generality, let us assume $d(t, l_t) \leqslant d(s, l_s)$. Since $B_L(s)$ and $B_L(t)$ do not intersect, $d(s, t) + 1 \geqslant d(s, l_s) + d(t, l_t) \geqslant 2d(t, l_t)$. By the triangle inequality, $d(s, l_t) \leqslant d(s, t) + d(t, l_t)$, hence the distance estimate is at most $d(s, t) + 2d(t, l_t)$, which is bounded by $2d(s, t) + 1$.

Baswana, Goyal, and Sen [7, Theorem 5.1] provide a randomized preprocessing algorithm with expected running time $O(m^{2/3} n \log n + n^2)$. More generally, they prove the following.

▶ **Theorem 5** (Baswana, Goyal, and Sen [7]). *For any $p \in (0, 1)$, an undirected unweighted graph $G = (V, E)$ can be preprocessed in expected $O(m \log n + n^2 + (n/p^2) \log n + mnp \log n)$ time to build a data structure that can report $(2, 1)$-approximate distances in constant time.*

Instead of super balls, a so-called *overlap matrix* is pre-computed to decide whether two balls intersect $B_L(u) \cap B_L(v) \stackrel{?}{=} \emptyset$. The landmark set L is computed using the sampling algorithm of Thorup and Zwick [30] (see also Section 2.2) to ensure that balls and their intersections are not too large.

2.4 High-Degree Dominating Sets

Recall that a dominating set of a graph G is a subset of nodes $D \subseteq V(G)$ such that each node is in D or has a neighbor in D. Aingworth, Chekuri, Indyk, and Motwani [5] prove that for a set of high-degree nodes there is an algorithm that can find a small dominating set (the algorithm is a greedy algorithm with logarithmic approximation ratio).

▶ **Theorem 6** (Aingworth et al. [5]). *Let $G = (V, E)$ be an undirected graph with $n := |V|$ and $m := |E|$, and let $V_\delta := \{v \in V : \deg(v) \geqslant \delta\}$. There is an algorithm that finds a dominating set for V_δ with size $O((n \log n)/\delta)$ in time $O(m + n\delta)$.*

Building on this theorem, they derive an $\tilde{O}(n^{5/2})$-time algorithm computing all-pairs approximate shortest paths with stretch $(1, 2)$. The dominating-set technique has been used extensively in algorithms for APASP (and related algorithms). Dor, Halperin, and Zwick [17, Theorem 6.2] compute an $(1, 2)$-approximate *spanner* in time $\tilde{O}(n^2)$ as follows (Algorithm 1): for decreasing node degrees $(n/2^i)$, split the nodes into high-degree and low-degree nodes,

compute a dominating set for the high-degree nodes (as in Theorem 6), compute a BFS tree from each node in the dominating set in the subgraph with edges adjacent to at least one low-degree node, and return the union of all these BFS trees.

1: **for** $i \in \{0, 1, 2, 3, \ldots, \lceil \log_2 \sqrt{n} \rceil\}$ **do**
2: $\quad \delta_i = n/2^i$
3: $\quad V_i = \{v \in V : \deg(v) \geqslant \delta_i\}$, $E_i = \{uv \in E : \deg(u) < 2\delta_i \text{ or } \deg(v) < 2\delta_i\}$
4: $\quad D_i = \mathsf{dominate}(V_i)$ (as in Theorem 6)
5: $\quad$ **for** $p \in D_i$ **do**
6: $\quad\quad T_i(p) = \mathsf{bfs}_{(V,E_i)}(p)$ (where T_i denotes the edges of the breadth-first tree)
7: $\quad$ **end for**
8: **end for**
9: **return** $\bigcup_{i,l \in D_i} T_i(p)$

Algorithm 1: Spanner construction by Dor, Halperin, and Zwick [17, Figure 7].

Cohen and Zwick [15] and Baswana and Kavitha [8] also provide algorithms similar to Algorithm 1 with different parameters and analysis.

Yet another instantiation of the above algorithm and framework is due to Berman and Kasiviswanathan [10]. Their all-pairs approximate shortest path algorithm computes $(2, 1)$-approximate distances in time $O(n^2 \log^2 n)$. Their main loop is essentially as in Algorithm 1, Lines 1–8 for i up to $\lceil \log_2 n \rceil$. Each node v remembers its nearest landmark $l_i(v)$ (for each level i, and with arbitrary tie breaking). Distance estimates $\tilde{d}(s, t)$ are computed as the minimum over all i of the triangulation via the landmark of s or via the landmark of t. We apply and extend their argument in Section 4.2.2.

3 Proof of Theorem 1

We split the problem into a dense case and a sparse case, where sparse means $O(n^{4/3})$ edges. The overall distance oracle simply returns the minimum from both data structures.

As in most shortest-path algorithms using dominating sets (see Section 2.4), edges uv are classified by minimum degree of their adjacent vertices u and v:

▶ **Definition 7** (Edge Degree)**.** The *degree* of an edge $uv \in E(G)$, denoted by $\deg(uv)$, is defined as $\deg(uv) := \min_{u,v} \{\deg(u), \deg(v)\}$.

Let G_δ denote the subgraph of G induced by all edges uv for which $\deg(uv) \leqslant \delta$. Note that $|E(G_\delta)| = O(n \cdot \delta)$, since each edge contributes to the degree of two nodes. As degree threshold in our proof, let Δ be the smallest power of 2 greater than $n^{1/3}$.

For the sparse case, we run the $O(n^2 + m^{2/3} n \log n)$-time algorithm of Baswana, Goyal, and Sen [7] (Theorem 5) on G_Δ. For $m = O(n^{4/3})$, the running time is $O(n^2)$. As mentioned in the introduction, their data structure is similar to the distance oracles by Pătraşcu and Roditty [21] and Abraham and Gavoille [2]. See Section 2.3 for more details.

For the dense case, we compute a data structure for G called *Heavy Path Oracle*. It is essentially an approximate distance oracle but limited in the following way: it can only return *heavy* paths.

▶ **Definition 8** (Heavy Paths)**.** A path is called δ-*heavy* if and only if it contains an edge uv with degree $\deg(uv) \geqslant \delta$.

Quite naturally, and analogously to a shortest path, there is a shortest δ-heavy path between any pair of nodes $s, t \in V(G)$. Let the *shortest δ-heavy distance* between s and t be the length of a shortest δ-heavy path between s and t.

The distance oracle for the dense case handles those pairs correctly for which any shortest path is Δ-heavy. If no shortest path between s and t is Δ-heavy, any shortest path must be in G_Δ, and hence the distance oracle for the sparse case provides an accurate estimate.

The remainder of this paper is devoted to the proof of the following lemma, which concludes the proof of Theorem 1.

▶ **Lemma 9** (Heavy Path Oracle). *Given an undirected, unweighted graph G on n nodes, let Δ denote the smallest power of 2 greater than $n^{1/3}$. There is an $\tilde{O}(n^2)$-time algorithm that computes a data structure of size $\tilde{O}(n^{5/3})$ with query time $O(1)$ that returns $(2,1)$-approximations for shortest Δ-heavy distances.*

4 Heavy Path Oracle

We prove Lemma 9 by adapting the APASP algorithms of Dor, Halperin, and Zwick [17] and Berman and Kasiviswanathan [10].

As typical in distance oracles, each node $v \in V$ stores distances to a set of *landmarks*, chosen as the union of hierarchical dominating sets (details below). Furthermore, each node stores a constant-size subset of nearby landmarks called *portals*. At query time, triangulation happens via portals.

4.1 Preprocessing Algorithm

For a pseudo-code description, see Algorithm 2. Given $G = (V, E)$, the algorithm begins by computing a sparse $(1, 6)$-spanner $H = (V, S)$ as in Theorem 2. Recall that G_δ is defined to be the subgraph of G induced by all edges uv for which $\deg(uv) \leqslant \delta$. In the remainder of the preprocessing algorithm, each breadth-first search in a subgraph $G_\delta = (V, E_\delta)$ of $G = (V, E)$ shall also consider the edges of the spanner, i.e., the breadth-first search is executed in $G_\delta + H = (V, E_\delta \cup S)$.

Independent of the spanner, the edge set E is organized into $\lceil \log n^{2/3} \rceil$ hierarchical classes: for $\delta_i = n/2^i$, let $V_i := \{v \in V : \deg(v) \geqslant \delta_i\}$. Class E_i consists of all edges uv for which u or v has degree $< 2\delta_i$. The algorithm then finds a dominating set for V_i, denoted by L_i (the union of all L_i is the *landmark set*). For each node $\ell \in L_i$, the algorithm runs a breadth-first search in $(V, E_i \cup S)$, computing and storing distances $d_{(V,E_i \cup S)}(\ell, \cdot)$. Each node v remembers its nearest landmark as a *portal* $p_i(v)$ if and only if it is closer than all portals $p_j(v)$ on previous levels $j < i$. This selection of portals is essential for the query time and stretch analysis. Let $K \geqslant 12$ (twice the additive stretch of the spanner). For each node v, let $P(v)$ denote the set that contains the $K + 1$ portals closest to v.

4.1.1 Space and Running Time Analysis

We have $O(\log n)$ distance tables $L_i \times V$. The dominating sets are small $|L_i| \leqslant \tilde{O}(n^{2/3})$, hence the distance tables can be kept (and stored in a distributed way at the non-landmark node to also enable distance labels).

For each level i, each node v stores distances to all nodes of the dominating set L_i. This dominating set L_i has size $O(2^i \log n)$ due to Theorem 6. The last level has the largest dominating set of size $O(n^{2/3} \log n)$. The overall space consumption is thus bounded by $O(n^{5/3} \log^2 n)$.

Algorithm 2: Preprocessing of graph $G = (V, E)$

For each level i, the dominating set is computed in time at most $O(n^2)$ by Theorem 6. For each $\ell \in L_i$ the algorithm computes a breadth-first search in a graph with at most $|E_i| = O(n^2/2^i)$ plus $|S| = \tilde{O}(n^{4/3})$ edges (the latter are the edges of the $(1, 6)$-spanner). Hence, the running time per level is at most $O(n^2 + |L_i| \cdot (|E_i| + |S|)) = \tilde{O}(n^2)$.

Summing up over all levels, the running time is $\tilde{O}(n^2)$ plus the time to compute the spanner, which is $\tilde{O}(n^2)$ by Theorem 2, plus the time to select the portals per node, which is at most $O(n^2 \log n)$ (since they are already generated in sorted order).

4.2 Query Algorithm

Distance estimates $\tilde{d}(s, t)$ are computed as the minimum over all the triangulations via portals of s and t: $\min_{p \in P(s) \cup P(t)} \{\tilde{d}(s, p) + \tilde{d}(p, t)\}$, where $\tilde{d}(s, p)$ and $\tilde{d}(p, t)$ denote the distances stored at s and t, respectively, to/from landmark p.

4.2.1 Query Time

There are $K + 1$ portals per node, each triangulation requires two table lookups for landmark distances (one for $\tilde{d}(s, p)$ and the other one for $\tilde{d}(p, t)$), hence the query time is $O(K)$ (using perfect hashing). For the stretch analysis to work, we need $K \geqslant 12$ (twice the additive stretch of the spanner), hence the query time is constant.

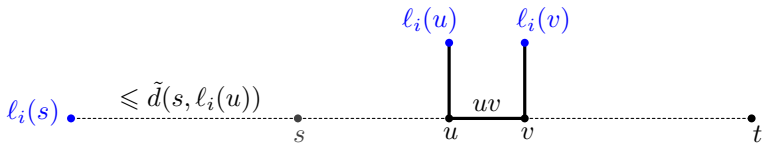

Figure 1 Worst-case stretch when triangulating via landmark $\ell_i(s)$. Distances are in $G = (V, E_i \cup S)$. Solid lines depict edges, dashed lines depict paths (which may have no, one, or multiple edge(s)). Edge uv is an edge on the shortest path with highest degree $\deg(uv)$. In this illustration, query node s is closer to uv than t. Since $\ell_i(s)$ is the nearest landmark for s, we have that $\tilde{d}(s, \ell_i(s)) \leqslant \tilde{d}(s, \ell_i(u))$.

4.2.2 Stretch Analysis

The stretch bound for the distance estimate $\tilde{d}(s,t)$ is derived as follows.

First, let us assume that, instead of triangulating via portals $P(\cdot)$ we were to triangulate via all closest landmarks of s and t, respectively. For each level i we compute the triangulation via the nearest landmark of s, i.e., $\tilde{d}(s, \ell_i(s)) + \tilde{d}(\ell_i(s), t)$, and via the nearest landmark of t, i.e., $\tilde{d}(s, \ell_i(t)) + \tilde{d}(\ell_i(t), t)$ and return the minimum.

The following argument is illustrated in Figure 1. Let E_i be the set that contains all the edges of the shortest s-t path and maximizes i. Let $uv \in E_i$ be an edge on this shortest path that is not in E_{i+1} (an edge between two high-degree nodes). The shortest-path length is $d(s,u) + 1 + d(v,t)$. Suppose $d(s,u) \leqslant d(v,t)$ (the other case is symmetric). Let us consider s and its nearest landmark $\ell_i(s)$. Since $u \in V_i$, u or its neighbor is in L_i, hence $\tilde{d}(s, \ell_i(s)) = d(s, \ell_i(s)) \leqslant d(s,u) + 1$. Triangulating via $\ell_i(s)$ increases the path length by at most $2d(s,u) + 2 \leqslant d(s,u) + d(v,t) + 2$, which yields stretch $(2,1)$. The same argument is also used by Berman and Kasiviswanathan [10].

However, we cannot afford to try all landmarks $\ell_i(\cdot)$ at query time since there may be logarithmically many for each query node. Instead, the preprocessing algorithm filters landmarks into a set of portals. For a node u, a landmark $\ell_i(u)$ is defined to *dominate* landmark $\ell_j(u)$ if $i < j$ and $\tilde{d}(u, \ell_i(u)) \leqslant \tilde{d}(u, \ell_j(u))$, which means that distances from $\ell_j(u)$ were computed in a subgraph of the one for which distances from $\ell_i(u)$ were computed. Let $D(u,i)$ denote the set of all landmarks $\ell_j(u)$ that dominate $\ell_i(u)$.

Again, let E_i be the set that contains all the edges of the shortest s-t path and maximizes i. We distinguish three cases. The first two cases are both fairly straightforward and could be combined. The most difficult case is the third, where query nodes are far away from the dense part of the graph, and hence also far away from the heavy edge uv.

- $\ell_i(s) \in P(s)$ and $\ell_i(t) \in P(t)$. The argument above applies since the query algorithm triangulates via both landmarks and computes a $(2,1)$-approximation.
- $\ell_i(s) \in P(s)$ or $D(s,i) \cap P(s) \neq \emptyset$, and the same holds for t. Let $\ell_j(s)$ be the landmark in $P(s)$ that dominates $\ell_i(s)$. When triangulating via $\ell_j(s)$, the stretch cannot increase since $d_{(V,E_j \cup S)}(s, \ell_j(s)) \leqslant d_{(V,E_i \cup S)}(s, \ell_i(s))$. In Figure 1, simply re-label $\ell_i(s)$ with $\ell_j(s)$. Since $E_i \subseteq E_j$ graph distances cannot increase. Analogous for t.
- Neither the landmark nor a dominating landmark are in the portal set. Now the spanner comes into play. At least one of the nodes must have had more than $K+1$ candidate portals (without loss of generality it is s), otherwise $\ell_i(s)$ or a landmark $\ell_j(s)$ dominating $\ell_i(s)$ would have to be in $P(s)$. The preprocessing algorithm truncated the portal list. Let $p^{(0)}(s), p^{(1)}(s), \ldots p^{(K)}(s)$ be the sequence of portals for s, ordered by increasing distance from s, and let $x := d(s, p^{(0)}(s))$. Each subsequent portal $p^{(j)}(s)$ increases the distance

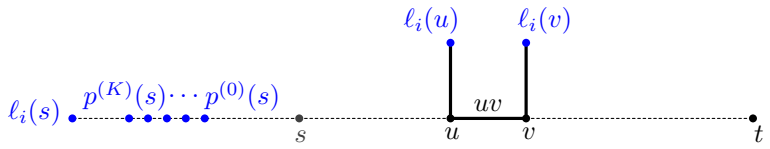

Figure 2 Worst-case stretch when triangulating via portal $p^0(s)$. There are $K+1$ portals closer than $\ell_i(s)$. When computing distances from/to these portals, the edges of the $(1,6)$-spanner were used, hence the distortion is bounded.

by at least 1, hence the last portal considered by the query algorithm is at distance at least $d(s, p^{(K)}(s)) \geqslant d(s, p^{(0)}(s)) + K$. Note that the best landmark for triangulation, $\ell_i(s)$, is even farther away, i.e., $d(s, \ell_i(s)) > d(s, p^{(K)}(s)) \geqslant d(s, p(0)(s)) + K = x + K$, otherwise it would have dominated $p^{(K)}(s)$. The shortest-path distance $d(s,t)$ is thus at least $x + K + y$, where $y := d(t, p^{(0)}(t))$. Without loss of generality, let us assume that s has a portal no farther than t has, i.e., $x \leqslant y$. Since the distance is long, we can safely triangulate using the first portal $p^{(0)}(s)$, which is relatively close to s. Due to always including the edges S of the $(1,6)$-spanner, the additive stretch when triangulating via $p^{(0)}(s)$ is at most $2(x+6)$, hence the estimate will be at most $(x + K + y) + 2(x + 6)$. Multiplicative stretch $(2,1)$ means the estimate can be $2(x + K + y) + 1$. Since $x \leqslant y$, the bound follows for $K \geqslant 12$. See Figure 2.

5 Conclusion

Distance oracles with stretch $(2,1)$ can be computed in quadratic time (modulo logarithmic factors) even for dense graphs. The main technical contribution is the use of a spanner without paying for its stretch penalty (the additive stretch of the spanner only affects the query time of the distance oracle). Previous attempts using a spanner increased the stretch to $(2,3)$, see [7].

The main difficulty lies in computing distances from/to landmarks. Since there are $n^{2/3}$ landmarks, we cannot afford to compute exact distances to all of them. Our algorithm allows constant additive distortion using a spanner. Other than pre-computing a spanner, the main bottleneck of the preprocessing algorithm in this paper is computing distances from $n^{2/3}$ nodes in a graph with $n^{4/3}$ edges. If there were a way to compute a spanner with additive stretch and fewer edges, there might be ways to push the preprocessing time below quadratic (if the number of edges m is sub-quadratic of course). However, Abboud and Bodwin [1] recently showed that Woodruff's spanner [35] is essentially as good as it gets for constant additive stretch. For stretch-3 distance oracles, there are sub-quadratic algorithms, increasing the stretch by a small additive constant [6]. For stretch-2 distance oracles, it seems like any further improvement to preprocessing times may have to find a way around landmarks or additive spanners.

Another open question is whether the result can be generalized to weighted graphs. The APASP algorithm of Berman and Kasiviswanathan [10] guarantees stretch $(2, w)$, where w denotes the largest edge length/weight on the shortest path. There are two main points where the algorithm and its analysis do not generalize: *a)* the additive spanner is insensitive to edge lengths, and *b)* each subsequent portal $p^{(i)}(\cdot)$ increases the distance by 1, which would not necessarily be true when edge lengths come into play.

Acknowledgments. Thanks to the anonymous reviewers for their feedback on earlier versions.

Total Space in Resolution Is at Least Width Squared*

Abstract

Given an unsatisfiable k-CNF formula φ we consider two complexity measures in Resolution: width and total space. The width is the minimal W such that there exists a Resolution refutation of φ with clauses of at most W literals. The total space is the minimal size T of a memory used to write down a Resolution refutation of φ, where the size of the memory is measured as the total number of literals it can contain. We prove that $T = \Omega((W-k)^2)$.

1 Introduction

Resolution is a well known propositional proof system introduced by Blake in [16] and proposed by Robinson in [38] for automated theorem proving. Since then this proof system became the most studied proof system in the sub-area of complexity theory that is *Proof Complexity*. Given a set of clauses φ, that is a set of disjunctions of literals or, equivalently, given a formula in Conjunctive Normal Form, *Resolution* is a method to infer new clauses according to the following inference rule:

$$\frac{C \vee x \quad D \vee \neg x}{C \vee D}, \tag{1}$$

where C, D are clauses and x is a variable. Resolution is sound and complete, that is it is possible to derive the empty clause $\perp$ if and only if φ is unsatisfiable. A Resolution *refutation* of φ is then just a sequence of clauses $C_1, \ldots, C_\ell$ with $C_\ell = \perp$ and each clause of the sequence is either a clause from φ or it is inferred by previous clauses in the sequence according to the inference rule in equation (1).

Nowadays, the main reason for the interest in Resolution comes from a practical perspective: it is at the core of most of the state-of-the-art SAT solvers since the introduction of the DPLL algorithm [22, 23] and its improvements, the so called *Conflict Driven Clause Learning* (CDCL) algorithms [4, 32, 40]. The track of the running of such algorithms on unsatisfiable instances produces a (particular form of) Resolution proofs. Hence Resolution is a valuable tool to study their performances and limitations. In this work we are interested in more theoretical questions about the Resolution proof system and the reader interested

in more details on the connections between Resolution and SAT solvers could look at the recent survey [35].

Given an unsatisfiable φ we are interested in measuring how complex a Resolution proof of φ must be. Certainly there are many ways of measuring the complexity of proofs and in this work we are interested in connecting two of such measures. The main complexity measure we can associate to φ in Resolution, and by far the most important, is the minimal length of a Resolution refutation of φ. This measure is denoted with $\mathsf{size}(\varphi \vdash \bot)$ and, since a long time now, we know that there are certain formulas φ_n requiring exponentially long proofs, e.g. the encodings of the Pigeonhole Principle [28] or Tseitin formulas [39, 42]. Another, easier to study, complexity measure is the *width*. Suppose that we focus on Resolution refutations of a formula φ with clauses up to a certain length w. The minimal w such that we have a refutation of φ with clauses of length at most w is the *width*, $\mathsf{width}(\varphi \vdash \bot)$. We have a trivial upper bound connecting size and width, that is for every set of clauses φ in n variables

$$\mathsf{size}(\varphi \vdash \bot) \leqslant n^{O(\mathsf{width}(\varphi \vdash \bot))},$$

and indeed this trivial bound could be asymptotically tight, cf. [3]. Another, more useful, connection between width and size is the following result from the seminal paper by Ben-Sasson and Wigderson [12]:

$$\log_2 \mathsf{size}(\varphi \vdash \bot) \geqslant \frac{(\mathsf{width}(\varphi \vdash \bot) - k)^2}{16n}, \tag{2}$$

where φ is a collection of clauses over n variables and each of them has at most k literals. Hence, if $\mathsf{width}(\varphi \vdash \bot) = \omega(\sqrt{n \log n})$ then, immediately by the previous inequality, $\mathsf{size}(\varphi \vdash \bot)$ is super-polynomial. Moreover this size-width inequality is essentially optimal [21].

Regarding the space complexity of proofs, its investigation was proposed in 1998 by Armin Haken as a natural analogue of the space complexity in the context of Turing machines and the first definitions of space measures in Resolution were given in [25, 1]. When talking about space, Resolution proofs are seen as a sequence of memory configurations $\mathfrak{M}_0, \ldots, \mathfrak{M}_\ell$, where each $\mathfrak{M}_i$ is a set of clauses, $\bot \in \mathfrak{M}_\ell$ and each $\mathfrak{M}_{i+1}$ derive from $\mathfrak{M}_i$ in one of the two following ways:

Axiom download: $\mathfrak{M}_{i+1} \subseteq \mathfrak{M}_i \cup \{C\}$, where $C \in \varphi$;

Inference: $\mathfrak{M}_{i+1} = \mathfrak{M}_i \cup \{D \vee E\}$, where both $D \vee x$ and $E \vee \neg x$ belong to $\mathfrak{M}_i$, for some variable x.

We then have some notions of how "spacious" a memory configuration can be. The most natural space measure for a memory configuration is of course the number of bits needed to write down it. Unfortunately it turns out that this notion of space is quite hard to study and hence some alternative notions of space were introduced [25, 1]. For example, the *clause space* of a memory configuration is the number of distinct clauses it can contain. The *total space*[1] of a memory configuration instead is the total number of literals it can contain. The minimal s such that we have a refutation of φ with memory configurations with total space at most s is the *Total Space* (needed to refute φ), $\mathsf{TSpace}(\varphi \vdash \bot)$. Similarly for the clause space we obtain $\mathsf{CSpace}(\varphi \vdash \bot)$. A more formal definition of $\mathsf{TSpace}(\varphi \vdash \bot)$, to avoid misunderstandings, is provided in Section 2.

[1] In [1] this space complexity measure is called *variable space*, but we follow [10, 9, 33, 11, 34] in calling it *total space*. This is due to distinguish it from a different space complexity measure in which different occurrences of the same variable are not counted, the *variable space*, investigated for instance in [43].

We now recall some known results about space complexity measures. Given any unsatisfiable set of clauses φ in n variables, in [25] it was proven that

$$\mathsf{CSpace}(\varphi \vdash \bot) \leqslant n + 1,$$

and, as a trivial consequence, we have that

$$\mathsf{TSpace}(\varphi \vdash \bot) \leqslant n(n + 1).$$

Both upper bounds are asymptotically tight, for example for random k-CNF formulas [8, 20]. Regarding lower bounds, in [2] it is proved that

$$\mathsf{CSpace}(\varphi \vdash \bot) \geqslant \mathsf{width}(\varphi \vdash \bot) - k + 1, \tag{3}$$

where φ consists of clauses of at most k literals. Clearly $\mathsf{TSpace}(\varphi \vdash \bot) \geqslant \mathsf{CSpace}(\varphi \vdash \bot)$ and whenever $\mathsf{TSpace}(\varphi \vdash \bot) = \omega(\mathsf{CSpace}(\varphi \vdash \bot))$ we say to have a *non-trivial* total space lower bound.

The total space measure was introduced in [1] and there the first non-trivial lower bounds were proven, for two particular class of formulas the Complete Tree formulas and the Pigeonhole Principle formulas. After that, in [20] it was introduced a technique to prove total space lower bounds in Resolution. That technique was sufficiently strong to prove asymptotically optimal total space lower bounds for instance for random k-CNFs [20, 13] but the proofs given there are quite long and involved. This paper, as a corollary, deeply simplify such proofs. Space complexity measures are also studied concerning trade-offs with other complexity measures, see for example [9, 36, 11, 34, 7, 5].

1.1 Contributions

This work is about proving an analogue of the inequality in (3) for the total space. This will add a nice bit to our knowledge of the lattice of relations between complexity measures in Resolution; it will simplify the proofs of existing total space lower bounds and it will imply new non-trivial total space lower bounds.

▶ **Theorem 1.** *Let φ be a k-CNF formula, then*

$$\mathsf{TSpace}(\varphi \vdash \bot) \geqslant \frac{1}{16} \left(\mathsf{width}(\varphi \vdash \bot) - k - 4\right)^2.$$

The general idea of the proof is the following: given a Resolution refutation, we identify a memory configuration where some small clause appear and then show that before that moment there must have been some memory configuration with a lot of clauses (and hence with large total space). This idea was originally used in [1] in some particular cases and in more generality in [20]. Indeed the proof we show has some close structural similarities with the total space lower bound from [20] and essentially it is a simplification of the proof of Theorem 2.5 from the author's PhD. Thesis [17]. The proof we give is not direct since it involves another, less studied, complexity measure: the *asymmetric width*, $\mathsf{awidth}(\varphi \vdash \bot)$, and families of assignments closely related to it. The asymmetric width was introduced in [29, 30] and the definition is quite technical so we defer it to Section 2 where we collect all the preliminary definitions and notations. The proof of Theorem 1 is purely combinatorial and implicitly uses some properties from a characterization of the asymmetric width from [15], cf. Section 3 for more details, together with a result tightly connecting the width and the asymmetric width, Theorem 2 (Lemma 8.5 from [29]).

Although defined quite differently, asymmetric width and width indeed share many properties. For instance, an analogue of the size-width inequality by Ben-Sasson and Wigderson [12]: given an unsatisfiable CNF formula φ in n variables

$$\ln\left(\mathsf{size}(\varphi \vdash \bot)\right) \geqslant \frac{\mathsf{awidth}(\varphi \vdash \bot)^2}{8n},$$

cf. Theorem 6.12 of [31]. For more information and history on the asymmetric width we refer to [15].

1.2 Examples of applications (and limitations) of Theorem 1

Since the seminal work of Ben-Sasson and Wigderson [12], the width measure has become one of the main tool to study Resolution proofs and their complexity. Hence we already have many relevant width lower bounds for many interesting class of formulas and then the range of applications of Theorem 1 is quite large. Below we recall some relevant examples.

Tseitin formulas. Given a d-regular graph G over n vertices, the Tseitin formula over G, $\mathsf{Tseitin}(G)$, is a CNF formula over $dn/2$ variables based on a propositional encoding of the fact that the total degree in any graph is even, see for example [12] for a formal definition. Such formulas were used by Tseitin to prove the first super-polynomial size lower bound for Resolution size [41]. Since then, Tseitin formulas became one of the standard tools in proof complexity to prove lower bounds and trade-offs, see for example [39, 43, 12, 25, 7]. In particular given a connected 3-regular graph G over n vertices which is an expander, we have that $\mathsf{width}(\mathsf{Tseitin}(G) \vdash \bot) \geqslant \Omega(n)$, cf. [12]. Hence, by Theorem 1, we have an asymptotically optimal total space lower bound: $\mathsf{TSpace}(\mathsf{Tseitin}(G) \vdash \bot) = \Theta(n^2)$. This answers the open question 4 from [1] in the case of Resolution.

Random k-CNFs. A random k-CNF with n variables and clause density Δ is a CNF formula picked as follows: choose independently uniformly at random Δn clauses from the set of all possible clauses in the variables $\{x_1, \ldots, x_n\}$ containing exactly k literals. If $\Delta = o(n^{1/4})$, Beame et al. [6] showed that random k-CNFs require exponential size Resolution proofs. Such result was simplified in [12] by showing a lower bound on width: if φ is a random k-CNF ($k \geqslant 3$) in n variables and Δn clauses, and Δ is a constant for simplicity, then with high probability $\mathsf{width}(\varphi \vdash \bot) \geqslant \Omega(n)$. Hence, by Theorem 1, with high probability $\mathsf{TSpace}(\varphi \vdash \bot) \geqslant \Omega(n^2)$. That is, almost every k-CNF require asymptotically optimal total space to be refuted in Resolution. This result was proven in [20] for $k \geqslant 4$ and for $k = 3$ in [13] with some explicit but quite involved constructions. Instead, as we saw, an asymptotically optimal total space lower bound for such formulas follows immediately from Theorem 1.

Formulas with short proofs. Bonet and Galesi [21] showed that the size-width inequality by Ben-Sasson and Wigderson [12] is essentially optimal. That is they showed that there are arbitrarily large 3-CNF formulas φ_n with $\Theta(n^3)$ clauses, $\Theta(n^2)$ variables and such that

- $\mathsf{width}(\varphi_n \vdash \bot) = \Theta(n)$,
- $\mathsf{CSpace}(\varphi_n \vdash \bot) = \Theta(n)$,

but φ_n has some Resolution proof of size $O(n^3)$, width $O(n)$ and clause space $O(n)$. Theorem 1 in this case tells us that $\mathsf{TSpace}(\varphi_n \vdash \bot) = \Omega(n^2)$, which is just a linear lower bound in the number of variables of φ_n. On the other hand this is a non-trivial total space lower bound since $\mathsf{TSpace}(\varphi_n \vdash \bot) = \omega(\mathsf{CSpace}(\varphi_n \vdash \bot))$.

Regarding the limitations, Theorem 1 suffers from the same kind of limitations of size-width inequality, equation (2), and the clause space-width inequality, equation (3). That is it became trivially vacuous for CNF formulas in n variables with clauses with many literals. For example we see such phenomenon when considering encodings of the negation of the Pigeonhole Principle as CNFs having clauses of n literals, the PHP_n^{n+1} formulas. For such formulas $\mathsf{width}(\mathsf{PHP}_n^{n+1} \vdash \bot) = \Theta(n)$ and hence no size lower bound or clause space lower bound could be implied directly from equations (2) - (3). The same applies for Theorem 1. On the other hand, by different techniques, we still have size lower bounds [42, 37], $\mathsf{size}(\mathsf{PHP}_n^{n+1} \vdash \bot) \geqslant 2^{\Omega(n)}$, clause space lower bounds [1], $\mathsf{CSpace}(\mathsf{PHP}_n^{n+1} \vdash \bot) \geqslant n$, and total space lower bounds [1, 20], $\mathsf{TSpace}(\mathsf{PHP}_n^{n+1} \vdash \bot) \geqslant \frac{1}{4}n^2$.

1.3 Organization of the paper

Section 2 contains all the preliminary definitions and notations needed for the proof of Theorem 1. In Section 3 we prove Theorem 1 and we give some more detailed comments on the proof. Section 4 contains some open questions about total space.

2 Preliminaries

We consider fixed a set of variables X and, given a natural number n, we denote as $[n]$ the set $\{1, \dots, n\}$. Given a set A, $\binom{A}{\leqslant 2}$ is the subset of the power set of A consisting of all the subsets of size at most 2.

Partial assignments. Given a set of variables X, a *partial (Boolean) assignment over* X is a function $\alpha : X \to \{0, 1\} \cup \{\star\}$. The *domain* of α is $\mathrm{dom}(\alpha) = \alpha^{-1}(\{0, 1\})$ and we say that α assigns a value to x if $x \in \mathrm{dom}(\alpha)$. Given two partial assignments over X, α and β we say that α extends β, $\beta \subseteq \alpha$, if for all $x \in X$, $\beta(x) \in \{\alpha(x), \star\}$. We denote by $\{x \mapsto b\}$ the partial assignment with domain the variable x mapped to $b \in \{0, 1\}$. Given two partial assignments α and β with disjoint domains, with $\alpha \cup \beta$ we denote the partial assignment with domain $\mathrm{dom}(\alpha) \cup \mathrm{dom}(\beta)$ such that for each $x \in \mathrm{dom}(\alpha) \cup \mathrm{dom}(\beta)$

$$\alpha \cup \beta(x) = \begin{cases} \alpha(x) & \text{if } x \in \mathrm{dom}(\alpha), \\ \beta(x) & \text{if } x \in \mathrm{dom}(\beta). \end{cases}$$

CNF formulas. A *literal* is a variable in X or the negation of a variable in X. A clause C is a formula of the form $\ell_1 \vee \cdots \vee \ell_k$, where the ℓ_i are literals and m is the *width* of the clause C, denoted as $|C|$. A formula in *Conjunctive Normal Form* (CNF) is a formula φ with variables in X of the form $C_1 \wedge \cdots \wedge C_m$, where the C_js are clauses. A k-CNF formula is a CNF formula where each clause has at most k distinct literals. With $\mathrm{var}(\varphi)$ we denote the set of variables occurring in the formula φ.

Given a CNF formula φ over a set of variables X and a partial assignment α over X, we can apply α to φ, obtaining a new CNF formula, denoted as $\varphi \restriction_\alpha$ or $\alpha(\varphi)$, in the following way: for each variable $x \in \mathrm{dom}(\alpha)$ substitute each occurrence of x in φ with $\alpha(x)$. Then simplify the resulting CNF according to the following rules: $\neg 0 \equiv 1$, $\neg 1 \equiv 0$, $0 \vee A \equiv A$, $1 \vee A \equiv 1$, $1 \wedge A \equiv A$, $0 \wedge A \equiv 0$. We say that α *satisfies* φ if $\alpha(\varphi) = 1$ and we say that α *falsifies* φ if $\alpha(\varphi) = 0$. Similarly, we can apply a partial assignment α to set of formulas $A = \{C_1, \dots, C_\ell\}$ component-wise: $A \restriction_\alpha = \{C_1 \restriction_\alpha, \dots, C_1 \restriction_\alpha\}$. Given a set of formulas F and a partial assignment α we say that α satisfies F, $\alpha \models F$, if and only if for every formula $\varphi \in F$, $\alpha(\varphi) = 1$.

Resolution proofs. A *Resolution derivation* of a clause C from a CNF formula φ is a sequence of clauses $\pi = (C_1, \ldots, C_\ell)$ such that $C_\ell = C$ and each C_i is either a clause from φ or it is inferred from C_j, C_k with $j, k < i$ and such that $\frac{C_j \quad C_k}{C_i}$ is a valid instance of the Resolution rule:

$$\frac{C \vee x \quad D \vee \neg x}{C \vee D}$$

where C, D are clauses and x is a variable; or, C_i is inferred from a C_j with $j < i$ and such that $\frac{C_j}{C_i}$ is a valid instance of the *weakening* inference rule[2]

$$\frac{C}{C \vee D}$$

where C, D are clauses. A *Resolution refutation* of a CNF formula φ is a Resolution derivation of the empty clause $\bot$ from φ. Resolution is sound and complete, that is it is possible to infer the empty clause $\bot$ from φ if and only if φ is unsatisfiable.

Width. Given a sequence of clauses $\pi = (C_1, \ldots, C_\ell)$ we recall that

$$\mathsf{width}(\pi) = \max_{C_j \in \pi} |C_j|$$

and the minimal width needed to refute φ in Resolution is

$$\mathsf{width}(\varphi \vdash \bot) = \min_{\pi} \mathsf{width}(\pi),$$

where the min is taken over all refutations of φ in Resolution[3].

Asymmetric width. The notion of *asymmetric width* was introduced in [30, 31]. Let φ be a CNF formula and $\pi = (C_1, \ldots, C_\ell)$ be a Resolution derivation from φ. To define the asymmetric width of π, $\mathsf{awidth}(\pi)$ we preliminary need the notion of *witness function*. A *witness function for* $\pi = (C_1, \ldots, C_\ell)$ is a function $\sigma : [\ell] \to \binom{[\ell]}{\leqslant 2} \cup \{\star\}$ witnessing the fact that π is a derivation from φ, that is such that

- $\sigma(i) = \{j, k\}$ implies that $j, k < i$ and $\frac{C_j \quad C_k}{C_i}$ is a valid instance of the inference rule of Resolution and if $j = k$ we require $\frac{C_j}{C_i}$ to be a valid instance of the weakening rule; and
- $\sigma(i) = \star$ implies that C_i is a clause from φ.

Given $\pi = (C_1, \ldots, C_\ell)$ a Resolution derivation from φ and a witness function σ for π, the *asymmetric width of* C_i *with respect to* π *and* σ, $aw_{\pi,\sigma}(C_i)$, is defined as follows

$$aw_{\pi,\sigma}(C_i) = \begin{cases} 0 & \text{if } \sigma(i) = \star, \text{ that is } C_i \in \varphi, \\ \min_{j \in \sigma(i)} |C_j| & \text{otherwise.} \end{cases}$$

Then $\mathsf{awidth}(\pi)$ is the minimum over all the possible functions σ witnessing the validity of π of the maximum over i of $aw_{\pi,\sigma}(C_i)$, that is

$$\mathsf{awidth}(\pi) = \min_{\sigma} \max_{C_i \in \pi} aw_{\pi,\sigma}(C_i).$$

---

[2] Notice that the weakening rule is not really needed but it will make simpler the exposition when dealing with restrictions of Resolution proofs.

[3] If φ is a satisfiable CNF formula then is customary to define $\mathsf{width}(\varphi \vdash \bot) = \infty$.

Finally, the asymmetric width needed to refute φ, $\mathsf{awidth}(\varphi \vdash \bot)$, is the minimum of $\mathsf{awidth}(\pi)$ over all possible sequence of clauses $\pi = (C_1, \ldots, C_\ell)$ that are Resolution refutations of φ.

Clearly it holds that $\mathsf{awidth}(\varphi \vdash \bot) \leqslant \mathsf{width}(\varphi \vdash \bot)$. Interestingly, the width cannot be much bigger than the asymmetric width.

▶ **Theorem 2** (Lemma 8.5 of [29]). *Let φ be an unsatisfiable k-CNF formula, then*

$$\mathsf{width}(\varphi \vdash \bot) \leqslant \mathsf{awidth}(\varphi \vdash \bot) + \max\{\mathsf{awidth}(\varphi \vdash \bot), k\}.$$

A self-contained proof of this result, essentially based on [14], is proven in the full version of this paper [18].

Total Space. As we saw in the introduction, a Resolution refutation of a CNF formula φ can be seen as a sequence of memory configurations $\pi = (\mathfrak{M}_0, \ldots, \mathfrak{M}_\ell)$, where each $\mathfrak{M}_i$ is a set of clauses, $\bot \in \mathfrak{M}_\ell$ and each $\mathfrak{M}_{i+1}$ derive from $\mathfrak{M}_i$ in one of the two following ways:
Axiom download: $\mathfrak{M}_{i+1} \subseteq \mathfrak{M}_i \cup \{C\}$, where $C \in \varphi$;
Inference: $\mathfrak{M}_{i+1} = \mathfrak{M}_i \cup \{D \vee E\}$, where both $D \vee x$ and $E \vee \neg x$ belong to $\mathfrak{M}_i$, for some variable x.
Given π as above, the *total space* of π is

$$\mathsf{TSpace}(\pi) = \max_{i \in [\ell]} \sum_{C \in \mathfrak{M}_i} |C|$$

and given an unsatisfiable CNF formula φ, the total space needed to refute φ in Resolution is

$$\mathsf{TSpace}(\varphi \vdash \bot) = \min_{\pi} \mathsf{TSpace}(\pi),$$

where the min is taken over all the possible Resolution refutations of φ given as a sequence of memory configurations[4].

3 Proof of Theorem 1

First let's prove the main result of this work, Theorem 1, for convenience of the reader restated below. We postpone more detailed comments on the proof after the proof itself.

▶ **Restated Theorem 1.** *Let φ be a k-CNF formula, then*

$$\mathsf{TSpace}(\varphi \vdash \bot) \geqslant \frac{1}{16} \left(\mathsf{width}(\varphi \vdash \bot) - k - 4\right)^2.$$

Proof. Let $\mathsf{awidth}(\varphi \vdash \bot) = r + 1$. We prove that

$$\mathsf{TSpace}(\varphi \vdash \bot) \geqslant \frac{1}{4}(r-1)^2,$$

or, more precisely, we prove that every Resolution refutation of φ must pass through a memory configuration of at least $(r-1)/2$ clauses each of width at least $(r-1)/2$. Once we prove this, the desired lower bound between total space and width follows:

$$\mathsf{TSpace}(\varphi \vdash \bot) \geqslant \frac{1}{4}(r-1)^2 \geqslant \frac{1}{16} \left(\mathsf{width}(\varphi \vdash \bot) - k - 4\right)^2,$$

[4] If φ is a satisfiable CNF formula then is customary to define $\mathsf{TSpace}(\varphi \vdash \bot) = \infty$.

where the last inequality uses that $\mathsf{width}(\varphi \vdash \bot) \leqslant 2(r+1)+k$, a consequence of Theorem 2.

Let Ξ and Ψ be two functions respectively mapping subsets of clauses into subsets of partial assignments and viceversa. Given a set of clauses A,

$$\Xi(A) = \{\alpha \text{ partial assignment} : \forall C \in A, \alpha(C) \neq 0\},$$

and given a set of partial assignments F,

$$\Psi(F) = \{C \text{ clause} : \exists \alpha \in F, \alpha(C) = 0\}.$$

Notice that, by construction, for every set of clauses A, $A \cap \Psi \circ \Xi(A) = \emptyset$ and $\bot \in \Psi(F)$ whenever F is non-empty. We consider the following special set:

$$W_r = \{C \text{ clause} : \mathsf{awidth}(\varphi \vdash C) \leqslant r\},$$

and its images $\Xi(W_r)$ and $\mathcal{S} = \Psi \circ \Xi(W_r)$. The main reason to consider the set $\Xi(W_r)$ is the following property:

▶ **Claim 3** (Extension Property of $\Xi(W_r)$)**.** *Let α be a $\subseteq$-maximal partial assignment in $\Xi(W_r)$ and x a variable not in $\mathrm{dom}(\alpha)$, then for every $\beta \subseteq \alpha$ such that $|\mathrm{dom}(\beta)| < r$ both $\beta \cup \{x \mapsto 0\}$ and $\beta \cup \{x \mapsto 1\}$ are in $\Xi(W_r)$.*

Proof. By contradiction let $\beta \subseteq \alpha$ such that $|\mathrm{dom}(\beta)| < r$ and $b \in \{0,1\}$ such that $\beta_b = \beta \cup \{x \mapsto b\} \notin \Xi(W_r)$. Without loss of generality we can restrict to consider $b = 0$. Since $\beta_0 \notin \Xi(W_r)$ it means that there exists a clause D in W_r such that $\beta_0(D) = 0$ but $\alpha(D) \neq 0$. This means that $D = D' \vee x$, $|D| \leqslant r$ and $\beta(D') = \alpha(D') = 0$. By maximality of α then both $\alpha_0 = \alpha \cup \{x \mapsto 0\} \notin \Xi(W_r)$ and $\alpha_1 = \alpha \cup \{x \mapsto 1\} \notin \Xi(W_r)$. In particular there exists a clause $E \in W_r$ such that $\alpha_1(E) = 0$, so, as before, we must have that $E = E' \vee \neg x$ and $\alpha(E') = 0$. But now

$$\frac{D' \vee x \quad E' \vee \neg x}{D' \vee E'}$$

is a valid instance of the Resolution rule. Hence, by definition of asymmetric width,

$$\mathsf{awidth}(\varphi \vdash D' \vee E') \leqslant \max\{\mathsf{awidth}(\varphi \vdash D), \mathsf{awidth}(\varphi \vdash E), r\} \leqslant r,$$

since both D and E belong to W_r and $|D| \leqslant r$. So $D' \vee E' \in W_r$ and $\alpha(D' \vee E') = 0$ which is a contradiction. ◀

Let $\pi = (\mathfrak{M}_0, \ldots, \mathfrak{M}_\ell)$ be a Resolution refutation of φ given as a sequence of memory configurations. By definition of W_r, $\bot \notin W_r$ and hence the empty partial assignment is in $\Xi(W_r)$, so, in particular $\bot \in \mathcal{S}$. Hence the following set is non-empty:

$$\mathcal{A} = \{i \in [\ell] \ : \ \exists C \in \mathfrak{M}_i \cap \mathcal{S}, \ |C| < (r-1)/2\}.$$

Let $t = \min \mathcal{A}$ and let $C \in \mathfrak{M}_t \cap \mathcal{S}$ be a clause of width less than $(r-1)/2$. Since $C \in \mathcal{S}$ there must exists a partial assignment $\alpha \in \Xi(W_r)$ that falsifies C and let α_C be the minimal partial assignment contained in α falsifying C. Notice that $|\mathrm{dom}(\alpha_C)| = |C| < (r-1)/2$. Our goal now is to show that there exists some $i < t$ such that $|\mathfrak{M}_i \cap \mathcal{S}| \geqslant (r-1)/2$. Since for every $i < t$ every clause in $\mathfrak{M}_i \cap \mathcal{S}$ has width at least $(r-1)/2$, this will give the desired result.

For sake of contradiction, suppose that for each $i < t$, $|\mathfrak{M}_i \cap \mathcal{S}| < (r-1)/2$. We inductively construct a sequence of assignments $\beta_0, \ldots, \beta_t$ in $\Xi(W_r)$ such that for each $i \leqslant t$ we have

that $\alpha_C \subseteq \beta_i$ and that $\beta_i \models \mathfrak{M}_i \cap \mathcal{S}$. This immediately give a contradiction when we reach β_t, since α_C falsifies the clause $C \in \mathfrak{M}_t \cap \mathcal{S}$ and $\beta_t \supseteq \alpha_C$.

The first memory configuration $\mathfrak{M}_0$ is empty, so we can put $\beta_0 = \alpha$. Supposing that $0 \leq i < t$ and that we already have a suitable β_i, we construct β_{i+1} distinguishing between two cases.

Axiom download case. $\mathfrak{M}_{i+1} \subseteq \mathfrak{M}_i \cup \{D\}$, where D is a clause from φ. Since each clause D from φ belongs to W_r and we have that $W_r \cap \mathcal{S} = \emptyset$, then $\mathfrak{M}_i \cap \mathcal{S} = \mathfrak{M}_{i+1} \cap \mathcal{S}$ and hence we can simply put $\beta_{i+1} = \beta_i$.

Inference case. $\mathfrak{M}_{i+1} \subseteq \mathfrak{M}_i \cup \{D \vee E\}$ where $D \vee E$ follows by Resolution on some variable x from two clauses $D \vee x$ and $E \vee \neg x$ in $\mathfrak{M}_i$. Then, by the inductive hypothesis, there exists $\beta_i \in \Xi(W_r)$ such that $\beta_i \models \mathfrak{M}_i \cap \mathcal{S}$, let $\bar{\beta}_i \in \Xi(W_r)$ be a $\subseteq$-maximal partial assignment containing β_i and let β be an assignment contained in $\bar{\beta}_i$ $\subseteq$-minimal such that $\alpha_C \subseteq \beta$ and $\beta \models \mathfrak{M}_i \cap \mathcal{S}$. We have that

$$|\mathrm{dom}(\beta)| \leqslant |\mathrm{dom}(\alpha_C)| + |\mathfrak{M}_i \cap \mathcal{S}| < (r-1)/2 + (r-1)/2 = r - 1,$$

where the first inequality follows easily from the fact that to satisfy a clause $F \in \mathfrak{M}_i \cap \mathcal{S}$ an assignment just have to satisfy a single literal in F. Notice that since $|\mathrm{dom}(\beta)| \leqslant r-2$ the extension property from Claim 3 can be applied twice and we will use this later. The main property of β that we now use is the following:

▶ **Claim 4.** *Let $\gamma \in \Xi(W_r)$ and F be any clause in $\mathfrak{M}_i$, if $\mathrm{var}(F) \subseteq \mathrm{dom}(\gamma)$ and $\beta \subseteq \gamma$, then $\gamma \models F$.*

Proof. Since $\mathrm{var}(F) \subseteq \mathrm{dom}(\gamma)$, then $\gamma(F) \in \{0, 1\}$. If by contradiction $\gamma(F) = 0$, then, by construction $F \in \mathcal{S}$ and, again by construction, $\beta \models \mathfrak{M}_i \cap \mathcal{S}$. So $\beta \models F$, which is is a contradiction since $\beta \subseteq \gamma$. ◀

The remaining part of the proof is just case analysis. If there is some variable y in $D \vee E$ unassigned by $\bar{\beta}_i$ then we can use the extension property (Claim 3) extending β to some $\beta' \in \Xi(W_r)$ setting y and satisfying $D \vee E$.

If $\mathrm{var}(D \vee E) \subseteq \mathrm{dom}(\beta)$ then we can extend β to some assignment $\beta' \in \Xi(W_r)$ setting x to some value (either by choosing $\bar{\beta}_i$ if $x \in \mathrm{dom}(\bar{\beta}_i)$ or otherwise by the extension property). Then $\mathrm{var}(D \vee x) \subseteq \mathrm{dom}(\beta')$, and, by the previous claim, $\beta' \models D \vee x$. The same happens for $E \vee \neg x$ and hence $\beta' \models D \vee E$ by the soundness of the Resolution rule.

The only remaining possibility is that $\mathrm{var}(D \vee E) \not\subseteq \mathrm{dom}(\beta)$ but $\mathrm{var}(D \vee E) \subseteq \mathrm{dom}(\bar{\beta}_i)$, and without loss of generality suppose that $\mathrm{var}(D) \not\subseteq \mathrm{dom}(\beta)$. If $x \in \mathrm{dom}(\bar{\beta}_i)$ then, by the previous claim $\bar{\beta}_i \models (D \vee x) \wedge (E \vee \neg x)$ so $\bar{\beta}_i \models D \vee E$. Suppose then that $x \notin \mathrm{dom}(\bar{\beta}_i)$. By Claim 3 we have that $\beta' = \beta \cup \{x \mapsto 0\} \in \Xi(W_r)$. Take a $\subseteq$-maximal assignment in $\Xi(W_r)$ containing β', let $\bar{\beta}'$ be such assignment. If $\mathrm{var}(D \vee x) \subseteq \mathrm{dom}(\bar{\beta}')$ then, by the previous claim, $\bar{\beta}_i \models D \vee x$, but $\beta'(x) = 0$ so $\bar{\beta}' \models D$ and hence $\bar{\beta}' \models D \vee E$. If $\mathrm{var}(D \vee x) \not\subseteq \mathrm{dom}(\bar{\beta}')$ then there is some variable y in $D \vee x$ not assigned by $\bar{\beta}'$ and since $|\mathrm{dom}(\beta')| = |\mathrm{dom}(\beta)| + 1 < r$ we can apply the extension property to β' extending it setting y and satisfying D. ◀

First of all notice that we proved something actually stronger, that is we proved that given an unsatisfiable CNF formula φ, every Resolution refutation of φ must pass through a memory configuration of at least $\frac{1}{2}(\mathsf{awidth}(\varphi \vdash \bot) - 2)$ clauses each of width at least $\frac{1}{2}(\mathsf{awidth}(\varphi \vdash \bot) - 2)$.

A crucial point in the proof of Theorem 1 is Claim 3. It is related with the following characterization of asymmetric width in Resolution by [15].

▶ **Theorem 5** (Theorem 22 from [15]). *Let φ be an unsatisfiable CNF formula, then the followings are equivalent:*

1. $\mathsf{awidth}(\varphi \vdash \bot) > r$.
2. *There exists a non-empty set $\mathcal{F}$ of partial assignments such that:*
   Consistency: *For every $\alpha \in \mathcal{F}$ and every clause C of φ, $\alpha(C) \neq 0$;*
   Extension: *If $\alpha \in \mathcal{F}$ and $\beta \subseteq \alpha$ is such that $|\mathrm{dom}(\beta)| < r$, then for every variable $x \notin \mathrm{dom}(\alpha)$ and for every $\epsilon \in \{0,1\}$ there exist $\beta_\epsilon \in \mathcal{F}$ with $\beta \subseteq \beta_\epsilon$ such that $\beta_\epsilon(x) = \epsilon$.*

Claim 3 is based on the proof of the implication from 1. to 2. in the previous theorem. The other implication (easier to prove) is not needed for Theorem 1. Indeed it is easy to see that given 1. the set of $\subseteq$-maximal partial assignments in $\Xi(W_r)$ satisfies the properties claimed in 2., and the crucial extension property is essentially Claim 3.

4 Open questions

We conclude this work with some open questions about the behaviour of the total space measure. Most of the questions are motivated by some analogy with the behaviour of the clause space measure.

On super-linear lower bounds. Is there any family of k-CNF formulas φ_n in n variables and $n^{O(1)}$ clauses such that $\mathsf{size}(\varphi_n \vdash \bot) = n^{O(1)}$ and $\mathsf{TSpace}(\varphi_n \vdash \bot) = \Theta(n^2)$?

For the formulas from [21] we saw in Section 1.2 we just have a linear total space lower bound. If we could find some formulas ψ_n with polynomial size Resolution proofs[5] but such that $\mathsf{width}(\psi_n \vdash \bot) = \omega(\sqrt{n})$ then, by Theorem 1, we would have that $\mathsf{TSpace}(\psi_n \vdash \bot) = \omega(n)$. This is anyway quite far from the question we are asking here and it seems that a positive answer should need some new techniques.

On simpler proofs for total space lower bounds. Is there a simpler more direct proof of a total space-width lower bound?

The clause space inequality $\mathsf{CSpace}(\varphi \vdash \bot) \geqslant \mathsf{width}(\varphi \vdash \bot) - k + 1$, where φ is a k-CNF, can be proven using some families of assignments and a characterization of Resolution width [2] or it can be proven (with some small loss in an additive constant) via some operation on Resolution proofs [26]. The proof we have of Theorem 1 is in a sense similar to the proof of the clause-width lower bound in [2] although not quite simple as that since we pass trough the asymmetric width and more complicated families of assignments.

Beyond Resolution. Space measures are defined in [1] also for proof systems stronger than Resolution. For example for Polynomial Calculus, a proof system where instead of clauses we infer polynomials, or $\mathsf{Res}(k)$, a (stronger) version of Resolution where instead of clauses k-DNF can be inferred, or Frege systems. In all such systems very little is known about space especially when it comes to total space. Regarding other space measures something is known for example for $\mathsf{Res}(k)$ [10, 24] and for Polynomial Calculus [1, 19, 27]. In [1] it is

[5] Equation 2 in this case implies that $\mathsf{width}(\psi_n \vdash \bot) = O(\sqrt{n \log n})$.

proven that in Frege system the total space is always at most linear and regarding Polynomial Calculus, the only lower bounds known for total space are from [1] and those are for the PHP_n^{n+1} formulas and the Complete Tree formulas. Is there any family of k-CNF formulas in n variables φ_n with $n^{O(1)}$ clauses requiring $\omega(n)$ total space to be refuted say in Polynomial Calculus?

Acknowledgements. The main question about width and total space is the result of some discussions had at the Dagstuhl seminar 15171: we want to thank Schloss Dagstuhl for the inspiring environment and the kind hospitality. We want to thank Jakob Nordström and Nicola Galesi for several long discussions on space complexity.

Supercritical Space-Width Trade-Offs for Resolution

Christoph Berkholz[*1] **and Jakob Nordström**[†2]

2 **KTH Royal Institute of Technology, Stockholm, Sweden**

Abstract

We show that there are CNF formulas which can be refuted in resolution in both small space and small width, but for which any small-width resolution proof must have space exceeding by far the linear worst-case upper bound. This significantly strengthens the space-width trade-offs in [Ben-Sasson 2009], and provides one more example of trade-offs in the "supercritical" regime above worst case recently identified by [Razborov 2016]. We obtain our results by using Razborov's new hardness condensation technique and combining it with the space lower bounds in [Ben-Sasson and Nordström 2008].

1 Introduction

Propositional proof complexity studies the problem of how to provide concise, polynomial-time checkable certificates that formulas in conjunctive normal form (CNF) are unsatisfiable. Research in this area was initiated in [20] as a way of attacking the problem of showing that NP $\neq$ coNP, and hence P $\neq$ NP, and it is therefore natural that the main focus has been on proving upper and lower bounds on proof length/size. More recently, however, other complexity measures have also been investigated, and this study has revealed a rich and often surprising web of connections.

Resolution Length, Width, and Space. Arguably the most thoroughly studied proof system in proof complexity is *resolution*, which appeared in [15] and began to be investigated in connection with automated theorem proving in the 1960s [21, 22, 33]. Because of its simplicity this proof system is well suited for proof search, and it lies at the heart of current state-of-the-art SAT solvers based on so-called conflict-driven clause learning [4, 26, 27].

* Part of the work of the first author was performed while at KTH Royal Institute of Technology supported by a fellowship within the Postdoc-Programme of the German Academic Exchange Service (DAAD).
† The research of the second author was supported by the European Research Council under the European Union's Seventh Framework Programme (FP7/2007–2013) / ERC grant agreement no. 279611 and by Swedish Research Council grants 621-2010-4797 and 621-2012-5645.

It is not hard to show that any unsatisfiable CNF formula over n variables can be proven unsatisfiable, or *refuted*, by a resolution refutation containing $\exp(\mathrm{O}(n))$ clauses, and this holds even in the restricted setting of *tree-like resolution*, where each intermediate clause in the refutation has to be rederived from scratch every time it is used. In a breakthrough result, Haken [24] obtained a length lower bound on the form $\exp\big(\Omega\big(n^{\delta}\big)\big)$ for general resolution refutations of so-called pigeonhole principle formulas, and this paper was later followed by truly exponential lower bounds $\exp(\Omega(n))$ for other formula families in, e.g., [6, 18, 35].

In a seminal paper [12], Ben-Sasson and Wigderson identified *width*, measured as the largest size of any clause appearing in a refutation, as another interesting complexity measure for resolution. Clearly, any unsatisfiable CNF formula over n variables can be refuted in width at most n. Moreover, any refutation in width w need never be longer than $n^{\mathrm{O}(w)}$, since this is an upper bound on the number of distinct clauses of width w (and this naive counting argument is essentially tight [3]). What Ben-Sasson and Wigderson showed is that strong enough *lower* bounds on width also imply lower bounds on length; in particular that linear $\Omega(n)$ width lower bounds imply exponential $\exp(\Omega(n))$ length lower bounds. This connection can be used to rederive almost all currently known resolution length lower bounds.

Motivated by questions in SAT solving, where efficient memory management is a major concern, a more recent line of research in proof complexity has examined a third complexity measure on proofs, namely *space*. This study was initiated by Esteban and Torán [23], who defined the *(clause) space* of a resolution proof as the maximal number of clauses needed to be kept in memory during verification of the proof.[1] It can be shown that a CNF formula over n variables can always be refuted in space $n + \mathrm{O}(1)$ even in tree-like resolution [23], although the refutation thus obtained might have exponential length. Linear space lower bounds matching the worst-case upper bound up to constant factors were obtained for a number of formula families in [1, 9, 23].

These space lower bounds also matched known lower bounds on width, and in a strikingly simple and beautiful result Atserias and Dalmau [2] showed that in fact the resolution width of refuting a k-CNF formula F provides a lower bound for the clause space required. [2] This allows to recover the space lower bounds mentioned above as immediate consequences of width lower bounds shown in [12]. Furthermore, it follows from [2] that for $k = \mathrm{O}(1)$ any k-CNF formula that can be refuted by just keeping a constant number of clauses in memory can also be refuted in polynomial length and constant width. In the sequence of papers [28, 30, 10] it was shown, however, that there are formula families that have high space complexity although they have refutations in linear length and constant width.

Resolution Trade-offs. As was discussed above, a resolution proof in sufficiently small width will by necessity also be short, whereas the linear worst-case upper bound on space is achieved by a proof in exponential length. It is natural to ask, therefore, given a formula F, whether there exists a single refutation that can simultaneously optimize these different complexity measures. This question was first raised by Ben-Sasson [8], who gave a strong negative answer for space versus width. He showed that there are formulas which are refutable separately in constant width and in constant space, but for which any resolution proof minimizing one of the measures must exhibit almost worst-case linear behaviour with respect to the other.

---

[1] For completeness, we want to mention that for resolution there is also a *total space* measure counting the total number of literals in memory (with repetitions), which has been studied in [1, 13, 16, 17]. In this paper, however, "space" will always mean "clause space" in the sense of [23] unless otherwise stated.

[2] Note that this is a nontrivial connection since lower bound on width, i.e., the *number of literals* in a clause, is shown to imply essentially the same lower bound on the *number of clauses* needed.

A question that arises in the context of SAT solving is whether it is possible to simultaneously optimize size and space (corresponding to running time and memory usage). In [8] Ben-Sasson also proved a size-space trade-off for tree-like resolution, and building on [8, 10] it was shown in [11] that there are formulas which have refutations in linear length and also in small space, but for which any space-efficient refutation must have superpolynomial or even exponential length in general resolution. Beame et al. [5] and Beck et al. [7] exhibited formulas over n variables refutable in length polynomial in n where bringing the space down to linear, or even just shaving a constant factor of the polynomial space bound that follows immediately from the length bound, incurs a superpolynomial penalty in proof length.

Regarding length versus width, what was shown in [12] is that a short refutation can be converted to a refutation of small width, but this conversion blows up the length exponentially. Thapen [34] proved that this is inherent by exhibiting formulas refutable in small width and small length, but for which any small-width refutation has to have exponential length. For the restricted case of tree-like resolution, Razborov [32] recently showed that there are formulas refutable in small width for which any tree-like refutation even doing slightly better than the trivial linear upper bound with respect to width must by necessity have doubly exponential length.

We want to highlight an intriguing property of the trade-off results in [5, 7, 32] that sets them apart from the other trade-offs surveyed above. Namely, for most trade-off results between complexity measures it is the case that the trade-off plays out in the region between the worst-case upper bounds for the measures, where as one measure decreases the other measure has to approach its critical worst-case value. However, the short resolution proofs in [5, 7] require space even polynomially larger than the worst-case upper bound, and the small-width tree-like proofs in [32] require proofs of length exponential in the exponential upper bound for tree-like length. To underscore the dramatic nature of such trade-off results, Razborov refers to them as *ultimate* in the preliminary version [31] of [32], although in this paper we will instead use the term *supercritical trade-offs* to indicate that one of the complexity measures is pushed up into the supercritical regime above worst case when the other measure is decreased.

Our Contribution. Answering Razborov's call in [32] for more examples of the type of trade-offs discussed above, we prove a supercritical trade-off between space and width in resolution. As already observed, any refutation in width w of a CNF formula over n variables in general resolution need not contain more than $\mathrm{O}(n^w)$ clauses, which is also a trivial upper bound on the space complexity of such a refutation. Our main result is that this bound is essentially tight, and is also somewhat robust. Namely, we show that there are n-variable formulas that can be refuted in width w, but for which any refutation in width even up to almost a multiplicative logarithmic factor larger than this requires space $n^{\Omega(w)}$.

▶ **Theorem 1.1.** *For any constant $\varepsilon > 0$ and any non-decreasing function $\ell(n)$, $6 \leq \ell(n) \leq n^{\frac{1}{2}-\epsilon}$, there is a family $\{F_n\}_{n\in\mathbb{N}}$ of n-variable CNF formulas which can be refuted in resolution width $\ell(n)$ but for which any refutation in width $\mathrm{o}(\ell(n)\log n)$ requires space $n^{\Omega(\ell(n))}$.*

Techniques. In one sentence, we obtain our results by using Razborov's hardness condensation technique in [32] and combining it with the space lower bounds in [10].

In slightly more detail, our starting point are the so-called *pebbling formulas* defined in [12]. These formulas are refutable in constant width, but it was observed in [8] that space lower bounds for pebble games on directed acyclic graphs (DAGs) carry over to lower bounds on the number of *variables* kept simultaneously in memory in resolution refutations

of pebbling formulas defined over these DAGs. It was shown in [10] that substituting every variable in such formulas by an exclusive or of two new variables and expanding out to CNF produces a new family of formulas which are still refutable in constant width but for which the variable space lower bounds have been amplified to clause space lower bounds.

The result in [10] is one of several examples of how *XOR substitution*, or *XORification*, has been used to amplify weak proof complexity lower bounds to much stronger lower bounds. In all of these applications distinct variables of the original formula are replaced by disjoint sets of new variables. The wonderfully simple (with hindsight) but powerful new idea in [32] is to instead do XOR substitution with overlapping sets of variables from a much smaller variable pool (but with exclusive ors of higher arity).

This recycling of variables has the consequence that hardness amplification as in [10] no longer works, since it crucially depends on the fact that all new substitution variables are distinct. What Razborov showed in [32] was essentially that if the pattern of overlapping variable substitutions is described by a strong enough bipartite expander, then locally there are enough distinct new variables to make tree-like amplification lower bounds as in [8] go through over a fairly wide range of the parameter space, yielding supercritical trade-offs between width and tree-like length. Since in addition the number of variables in the formula has decreased significantly, this can be viewed as a kind of *hardness condensation*.

We use Razborov's idea of XORification with recycled variables, but since we want to obtain results for general, DAG-like resolution the technical details of our proofs are somewhat different. At a high level, we start with formulas over N variables that are refutable in constant width but require space $\Omega(N/\log N)$, to which we apply w-wise XORification using a much smaller set of n variables. We then show that from any refutation in width $O(w)$ of this new, XORified formula it is possible to recover a refutation of the original formula with comparable space complexity. But this means that any small-width refutation of the XORified formula must have space complexity roughly $\Omega(N/\log N)$. Choosing parameters so that $N \approx n^w$ yields the bound stated in Theorem 1.1.

We should point out that compared to [32] we get significantly less robust trade-offs, which break down already for a multiplicative logarithmic increase in width. This is mainly due to the fact that we deal not with tree-like resolution as in [32], but with general, DAG-like resolution. We share with [32] the less desirable feature that although our formulas only have n variables they contain on the order of n^w clauses. Thus, measured in terms of formula size our space-width trade-offs do not improve on [8], and the width of our formulas is not constant but scales linearly with w. Still, since the number of variables provides a worst-case upper bound on space (independently of formula size), measured in terms of variables it seems fair to say that the trade-off result in Theorem 1.1 is fairly dramatic.

Organization of This Paper. We start by reviewing some preliminaries in Section 2. In Section 3 we prove our main result assuming a hardness condensation lemma, and this lemma is then established in Section 4. We conclude in Section 5 with a discussion of possible directions for future research. Due to space constraints, we omit some of the proofs in this extended abstract, referring the reader to the upcoming full-length version for the missing details.

2 Preliminaries

A *literal* over a Boolean variable x is either the variable x itself (a *positive literal*) or its negation $\overline{x}$ (a *negative literal*). We define $\overline{\overline{x}} = x$. A *clause* $C = a_1 \vee \cdots \vee a_k$ is a disjunction

of literals over pairwise disjoint variables. A clause C' *subsumes* another clause C if every literal from C' also appears in C. A *k-clause* is a clause that contains at most k literals. A *CNF formula* $F = C_1 \wedge \cdots \wedge C_m$ is a conjunction of clauses. A *k-CNF formula* is a CNF formula consisting of k-clauses. We write $\mathit{Vars}(F)$ to denote the set of variables appearing in a formula F. We think of clauses and CNF formulas as sets: the order of elements is irrelevant and there are no repetitions.

A *resolution refutation* $\pi : F \vdash \bot$ of an unsatisfiable CNF formula F, which can also be referred to as a *resolution proof* for (the unsatisfiability of) F, is an ordered sequence of clauses $\pi = (D_1, \ldots, D_\tau)$ such that $D_\tau = \bot$ is the empty clause containing no literals, and each clause D_i, $i \in [\tau] = \{1, \ldots, \tau\}$, is either one of the clauses in F (an *axiom*) or is derived from clauses D_j, D_k in π with $j, k < i$ by the *resolution rule*

$$\frac{B \vee x \quad C \vee \overline{x}}{B \vee C} \ . \tag{2.1}$$

For technical reasons, it will also be convenient to permit a *weakening rule*

$$\frac{B}{B \vee C} \tag{2.2}$$

allowing to derive a strictly weaker clause from a clause already derived, although this rule is not essential.

With every resolution proof π we can associate a DAG G_π by having a sequence of vertices v_i on a line in order of increasing i, labelled by the clauses $D_i \in \pi$, and with directed edges (v_j, v_i) and (v_k, v_i) if the clause D_i was derived by resolution from D_j and D_k or an edge (v_j, v_i) if D_i was derived from D_j by weakening. Note that there might be several occurrences of a clause D in the proof π, and if so each occurrence gets its own vertex in G_π.

The *length* $L(\pi)$ of a resolution proof π is the number of clauses in it (counted with repetitions). The *width* $W(C)$ of a clause C is $|C|$, i.e., the number of literals, and $W(\pi)$ is the size of a largest clause in π. The *(clause) space* at step i is the number of clauses C_j, $j < i$, with edges to clauses C_k, $k \geq i$ in G_π plus 1 for the clause C_i derived at this step. Intuitively, space measures the number of clauses we need to keep in memory at step i, since they were derived before step i but are used to infer new clauses at or after step i. The space $\mathit{Sp}(\pi)$ of a proof π is the maximum space over all steps in π. Taking the minimum over all refutations, we define the length, width, and space of refuting F, respectively, as $L(F \vdash \bot) = \min_{\pi : F \vdash \bot}\{L(\pi)\}$, $W(F \vdash \bot) = \min_{\pi : F \vdash \bot}\{W(\pi)\}$, and $\mathit{Sp}(F \vdash \bot) = \min_{\pi : F \vdash \bot}\{\mathit{Sp}(\pi)\}$. We remark that any applications of the weakening rule (2.2) can always be eliminated from a refutation without increasing the length, width, or space.

When reasoning about space, it is sometimes convenient to use a slightly different, but equivalent, description of resolution that makes explicit what clauses are in memory at each point in time. We say that a *configuration-style resolution refutation* is a sequence $(\mathbb{D}_0, \ldots, \mathbb{D}_\tau)$ of sets of clauses, or *configurations*, such that $\mathbb{D}_0 = \emptyset$, $\bot \in \mathbb{D}_\tau$, and for all $t \in [\tau]$ the configuration $\mathbb{D}_t$ is obtained from $\mathbb{D}_{t-1}$ by one of the following *derivation steps*:

Axiom Download $\mathbb{D}_t = \mathbb{D}_{t-1} \cup \{C\}$, where C is a clause $C \in F$.

Inference $\mathbb{D}_t = \mathbb{D}_{t-1} \cup \{D\}$ for a clause D derived by resolution or weakening from clauses in $\mathbb{D}_{t-1}$.

Erasure $\mathbb{D}_t = \mathbb{D}_{t-1} \setminus \mathbb{D}'$ for some $\mathbb{D}' \subseteq \mathbb{D}_{t-1}$.

The length of a configuration-style refutation $\pi = (\mathbb{D}_0, \ldots, \mathbb{D}_\tau)$ is the number of axiom downloads and inference steps, the width is the size of a largest clause, as before, and the space is $\max_{t \in [\tau]}\{|\mathbb{D}_t|\}$. Given a refutation as an ordered sequence of clauses $\pi = (D_1, \ldots, D_\tau)$, we can construct a configuration-style refutation in the same length, width, and space by

deriving each clause D_i via an axiom download or inference step, and interleave with erasures of clauses C_j, $j < i$, as soon as they have no edges to clauses C_k, $k \geq i$ in the associated DAG G_π. In the other direction, taking a configuration-style refutation and listing the sequence of axiom download and inference steps yields a standard resolution refutation in the same length, width and space (assuming that clauses are erased as soon as possible). Thus, we can switch freely between these two ways of describing resolution refutations.

In fact, it will be convenient for us to limit our attention to a (slightly non-standard) restricted form of resolution refutations as described next. Let us say that a *homogeneous resolution refutation* is a refutation where every resolution rule application is of the form

$$\frac{C \vee x \quad C \vee \overline{x}}{C} \ . \tag{2.3}$$

The requirement of homogeneity is essentially without loss of generality, since we need to insert at most two weakening steps before each application of the resolution rule, which increases the width by at most 1, and the weakened clauses can then immediately be forgotten. We state this observation formally for the record.

▶ **Observation 2.1.** *If a CNF formula F has a standard resolution refutation without weakening steps in length L, width w, and space s, then it has a homogeneous refutation in length at most $3L$, width at most $w + 1$, and space at most $s + 2$.*

As already mentioned, a useful trick to obtain hard CNF formulas for different proof systems and complexity measures, which will play a key role also in this paper, is *XOR-ification*, i.e., substituting variables by exclusive ors of new variables and expanding out in the canonical way to obtain a new CNF formula. For example, the standard way to define binary XOR substitution for a positive literal x is

$$x[\oplus_2] = (x_1 \vee x_2) \wedge (\overline{x}_1 \vee \overline{x}_2) \ , \tag{2.4}$$

for a negative literal $\overline{y}$ we have

$$\overline{y}[\oplus_2] = (y_1 \vee \overline{y}_2) \wedge (\overline{y}_1 \vee y_2) \ , \tag{2.5}$$

and applying binary XOR substitution to the clause $x \vee \overline{y}$ we obtain the CNF formula

$$\begin{aligned}(x \vee \overline{y})[\oplus_2] = x[\oplus_2] \vee \overline{y}[\oplus_2] = \quad & (x_1 \vee x_2 \vee y_1 \vee \overline{y}_2) \wedge (x_1 \vee x_2 \vee \overline{y}_1 \vee y_2) \\ & \wedge (\overline{x}_1 \vee \overline{x}_2 \vee y_1 \vee \overline{y}_2) \wedge (\overline{x}_1 \vee \overline{x}_2 \vee \overline{y}_1 \vee y_2) \ .\end{aligned} \tag{2.6}$$

The XORification of a CNF formula F is the conjunction of all the formulas corresponding to the XORified clauses of F. We hope that the reader excuses our slightly informal definition by example and has no problems generalizing it to substitutions with XOR of arbitrary arity (but see, e.g., Definition 2.12 in [29] for a more rigorous treatment).

Usually, the way XORification is done is that any two variables in the original formula are replaced by exclusive ors over disjoint sets of new variables. Razborov [32] observed that it can sometimes be useful to allow XORification with overlapping sets of variables. Let us define this concept more carefully.

▶ **Definition 2.2** (XORification with recycling [32])**.** Let F be a CNF formula over the set of variables $u_1, \ldots, u_N$ and let $\mathcal{G} = (U \dot\cup V, E)$ be a bipartite graph with left vertex set $U = \{u_1, \ldots, u_N\}$ and right vertex set $V = \{v_1, \ldots, v_n\}$. Then for the variables u_i we define the XORified literals $u_i[\mathcal{G}] = \bigoplus_{v \in \mathcal{N}(u_i)} v$ and $\overline{u}_i[\mathcal{G}] = \neg \bigoplus_{v \in \mathcal{N}(u_i)} v$ (where $\mathcal{N}(u_i)$ denotes the neighbours in V of u_i), for clauses $C \in F$ we define $C[\mathcal{G}] = \bigvee_{a \in C} a[\mathcal{G}]$ expanded out to CNF as in (2.6), and the *XORification of F with respect to $\mathcal{G}$* is defined to be $F[\mathcal{G}] = \bigwedge_{C \in F} C[\mathcal{G}]$.

Note that if F is an N-variable k-CNF with m clauses and $\mathcal{G} = (\{u_1, \ldots, u_N\} \dot\cup \{v_1, \ldots, v_n\}, E)$ is a bipartite graph of left degree d, then $F[\mathcal{G}]$ is an n-variable kd-CNF formula with most $2^{d-1}m$ clauses. We conclude this section with two simple observations that will be useful in what follows.

▶ **Observation 2.3.** *If F has a (homogeneous) resolution refutation in width w and $\mathcal{G}$ has left degree bounded by d, then $F[\mathcal{G}]$ can be refuted in (homogeneous) resolution in width $2dw$.*

This is not hard to show, and follows, e.g., from Theorem 2 in [11] (strictly speaking, this theorem is for XORification *without* recycling, but recycling can only decrease the width).

▶ **Observation 2.4.** *If F has a (homogeneous) resolution refutation π such that the associated DAG G_π has depth (i.e., longest path) s, then π can be carried out (in homogeneous resolution) in space $s + 2$ (possibly by repeating and/or reordering clauses in π).*

This second observation is essentially due to [23]. The proof DAG G_π can be turned into a binary tree of the same depth by repeating vertices/clauses, and it is then straightforward to show that any tree-like proof DAG in depth s can be realized in space at most $s + 2$.

3 Proof of Main Theorem

In this section we present a proof of Theorem 1.1. The proof makes use of the following hardness condensation lemma, which will be established in the next section and is the main technical contribution of the paper.

▶ **Lemma 3.1** (Hardness condensation lemma). *For all $k \in \mathbb{N}^+$ and $\varepsilon > 0$ there exist $n_0 \in \mathbb{N}^+$ and $\delta > 0$ such that the following holds. Let ℓ and n be integers satisfying $n \geq n_0$ and $k \leq \ell \leq n^{\frac{1}{2}-\varepsilon}$, and suppose that F is an unsatisfiable k-CNF formula over $N = \lfloor n^{\delta\ell} \rfloor$ variables which requires width $W(F \vdash \bot) = k$ and space $Sp(F \vdash \bot) = s$ to be refuted in resolution.*

Then there is a bipartite graph $\mathcal{G} = (U \dot\cup V, E)$ with $|U| = N$ and $|V| = n$ such that the n-variable CNF formula $F[\mathcal{G}]$ has the following properties:

- *$F[\mathcal{G}]$ can be refuted in width ℓ.*
- *Any refutation $\pi : F[\mathcal{G}] \vdash \bot$ in width $w \leq \frac{\ell}{4k} \log n$ requires space $Sp(\pi) \geq (s - w - 3)2^{-w}$.*

We want to apply this lemma to formulas of low width complexity but high space complexity as stated next.

▶ **Theorem 3.2** ([10]). *There is a family $\{F_N\}_{N\in\mathbb{N}}$ of N-variable 6-CNF formulas of size $\Theta(N)$ which can be refuted in width 6 but require space $Sp(F_N \vdash \bot) = \Omega(N/\log N)$.*

Combining Lemma 3.1 and Theorem 3.2, we can prove our main result.

Proof of Theorem 1.1. Recall that we want to prove that for any constant $\varepsilon > 0$ and any non-decreasing function $\ell(n) \leq n^{\frac{1}{2}-\epsilon}$ there is a family $\{F_n\}_{n\in\mathbb{N}}$ of n-variable CNF formulas which have a resolution refutation of width $\ell(n)$ but for which any refutation of width $o(\ell(n) \log n)$ requires clause space $n^{\Omega(\ell(n))}$.

From Theorem 3.2 we obtain constants $\varepsilon' > 0$ and $N_0 \in \mathbb{N}^+$ and a family of N-variable 6-CNF formulas F_N that require clause space $\varepsilon' N/\log N$ for all $N \geq N_0$. We want to apply Lemma 3.1 to these formulas. Let $\varepsilon > 0$ be given in Theorem 1.1 and fix $k = 6$. Plugging this into Lemma 3.1 yields $\delta > 0$ and $n_0 \in \mathbb{N}^+$, where in addition we choose n_0 large enough so that $\lfloor n_0^{\delta\ell(n_0)} \rfloor \geq N_0$ (this is always possible since $\delta\ell(n_0) \geq 6\delta > 0$).

For any $n \geq n_0$, set $N = \lfloor n^{\delta\ell(n)} \rfloor \geq N_0$ and let $\mathcal{G} = (U \dot\cup V, E)$ with $|U| = N$ and $|V| = n$ be the bipartite graph guaranteed by Lemma 3.1. Then the lemma says that $F_N[\mathcal{G}]$ is an n-variable formula which can be refuted in width ℓ, but for for which every refutation of width $w \leq \frac{\ell}{4k} \log n$ requires clause space of $(s - w - 3)2^{-w}$, where $s \geq \varepsilon' N / \log N = \varepsilon' \lfloor n^{\delta\ell(n)} \rfloor / \log \lfloor n^{\delta\ell(n)} \rfloor$ is the space lower bound for F_N. Choosing $w \leq \min\left(\frac{1}{4k}, \frac{\delta}{2}\right) \cdot \ell(n) \log n$ (recall that $w = \mathrm{o}(\ell(n) \log n)$ by assumption), the sequence of calculations

$$(s - w - 3)2^{-w} \geq \left(\varepsilon' \lfloor n^{\delta\ell(n)} \rfloor / \log \lfloor n^{\delta\ell(n)} \rfloor - \tfrac{\delta}{2}\ell(n) \log n\right) 2^{-\frac{\delta}{2}\ell(n)\log n} \geq \Omega\left(n^{\frac{\delta}{2}\ell(n)}\right) \quad (3.1)$$

yields the desired space lower bound. ◀

If one looks more closely at what is going on inside the proof of Theorem 1.1, where Lemma 3.1 and Theorem 3.2 come together, one can make the following somewhat intriguing observation. As discussed in the introduction, Theorem 3.2 is shown by using so-called pebbling formulas. Given a DAG $\mathcal{D}$ with sources S and a unique sink z, and with all non-sources having fan-in 2, we let every vertex in $\mathcal{D}$ correspond to a variable and define the *pebbling formula* $Peb_{\mathcal{D}}$ to consist of the following clauses:

- for all $s \in S$, a clause s,
- For all non-source vertices v with predecessors u_1, u_2, the clause $\overline{u}_1 \vee \overline{u}_2 \vee v$,
- for the sink z, the clause $\overline{z}$.

Applying standard binary XOR substitution (without recycling) as in (2.6) to these formulas amplifies weak lower bounds on the number of variables in memory $\mathit{VarSp}(\mathit{Peb}_{\mathcal{D}} \vdash \bot)$ (which follow from properties of the chosen DAG $\mathcal{D}$) to stronger lower bounds on the number of clauses $\mathit{Sp}(\mathit{Peb}_{\mathcal{D}}[\oplus_2] \vdash \bot)$. In Lemma 3.1 we then do another round of XOR substitution, this time with recycling, to decrease the number of variables while maintaining the space lower bound for small-width refutations. It is not entirely clear why we would need two separate rounds of XORification to achieve this result. In one sense, it would seem more satisfying to get a clean one-shot argument that just takes pebbling formulas and yields the supercritical trade-offs by only one round of XORification.

In fact, if we are willing to accept a slightly weaker bound, we could make such a one-shot argument and apply substitution with recycling directly to the pebbling formulas. The reason for this is that one can actually prove a somewhat stronger version of hardness condensation than in Lemma 3.1, as we will see in Section 4. There is no need to require that the original formula should have high space complexity unconditionally, but it suffices that the formula exhibits a strong trade-off between width and clause space. Since the number of clauses times the maximal width of any clause is an upper bound on the total number of distinct variables in memory, for any resolution refutation π we have the inequality $\mathit{Sp}(\pi) \cdot W(\pi) \geq \mathit{VarSp}(\pi)$. In [8] a variable space lower bound $\mathit{VarSp}(\mathit{Peb}_{\mathcal{D}} \vdash \bot) = \Omega(N/\log N)$ was presented (for appropriately chosen DAGs $\mathcal{D}$), implying that any width-w refutation requires clause space at least $\Omega(N/(w \log N))$. Since our hardness condensation step incurs a loss of a factor $1/2^w$, by starting with standard pebbling formulas and applying XORification with recycling directly we could obtain asymptotically similar bounds in one shot.

However, one can also argue that by combining Lemma 3.1 and Theorem 3.2 in the way done above one obtains a more modular proof, which shows that any formulas satisfying the conditions in Theorem 3.2 can be used for hardness condensation in a black-box fashion. This is why we chose to present the proof in this way.

4 Hardness Condensation

Let us now prove the hardness condensation lemma. We prove a slightly stronger version of the lemma below, which clearly subsumes Lemma 3.1.

▶ **Lemma 4.1** (Hardness condensation lemma, strong version). *For all $k \in \mathbb{N}^+$ and $\varepsilon > 0$ there are $n_0 \in \mathbb{N}^+$ and $\delta > 0$ such that the following holds. Let ℓ and n be integers satisfying $n \geq n_0$ and $k \leq \ell \leq n^{\frac{1}{2}-\varepsilon}$ and suppose that F is an unsatisfiable k-CNF formula over $N = \lfloor n^{\delta\ell} \rfloor$ variables which requires width $W(F \vdash \bot) = k$ to be refuted in resolution.*

Then there is a bipartite graph $\mathcal{G} = (U \dot\cup V, E)$ with $|U| = N$ and $|V| = n$ such that the n-variable CNF formula $F[\mathcal{G}]$ has the following properties:

- *$F[\mathcal{G}]$ can be refuted in width ℓ.*
- *Any refutation $\pi : F[\mathcal{G}] \vdash \bot$ of the XORified formula $F[\mathcal{G}]$ in width $w \leq \frac{\ell}{4k} \log n$ requires space $Sp(\pi) \geq (s - w - 3)2^{-w}$, where s is the minimal space of any refutation $\pi' : F \vdash \bot$ of the original formula F in width at most w.*

Clearly, the key to obtain Lemma 4.1 is to choose the right kind of graphs. As in [32], we use boundary expander graphs where the right-hand side is significantly smaller than the left-hand side. Let us start by giving a proper definition of these graphs and reviewing the properties of them that we need. Most of our discussion of boundary expanders can be recovered from [32], but since our setting of parameters is slightly different we give a self-contained presentation below. We refer to the full-length version of this paper for any missing proofs.

In what follows, we will let $\mathcal{G} = (U \dot\cup V, E)$ denote a bipartite graph with left vertices U and right vertices V. We write $\mathcal{N}(U') = \{v \mid \{u, v\} \in E(\mathcal{G}), u \in U'\}$ to denote the set of right neighbours of a left vertex subset $U' \subseteq U$ (and vice versa for right vertex subsets).

▶ **Definition 4.2** (Boundary expander). A bipartite graph $\mathcal{G} = (U \dot\cup V, E)$ is an $N \times n$ (r, c)-*boundary expander*, or *unique neighbour expander*, if $|U| = N$, $|V| = n$, and for every set $U' \subseteq U$, $|U'| \leq r$, it holds that $|\partial(U')| \geq c|U'|$, where $\partial(U') = \{v \in \mathcal{N}(U') : |\mathcal{N}(v) \cap U'| = 1\}$ is the *boundary* or the set of *unique neighbours* of U'. An (r, d, c)-boundary expander is an (r, c)-boundary expander where additionally $|\mathcal{N}(u)| \leq d$ for all $u \in U$, i.e., the left degree is bounded by d.

For a right vertex subset $V' \subseteq V$ in $\mathcal{G} = (U \dot\cup V, E)$ we define the *kernel* $\mathrm{Ker}(V') \subseteq U$ of V' to be the set of all left vertices whose entire neighbourhood is contained in V', i.e., $\mathrm{Ker}(V') = \{u \in U \mid \mathcal{N}(u) \subseteq V'\}$. We write $\mathcal{G} \setminus V'$ to denote the subgraph of $\mathcal{G}$ induced on $(U \setminus \mathrm{Ker}(V')) \dot\cup (V \setminus V')$. That is, we obtain $\mathcal{G} \setminus V'$ from $\mathcal{G}$ by first deleting V' and afterwards all isolated vertices from U.

A key property of boundary expanders is that for any small enough right vertex set V' we can always find a *closure* $\gamma(V') \supseteq V'$ with a small kernel on the left such that the subgraph $\mathcal{G} \setminus \gamma(V')$ has good boundary expansion. This is very similar to an analogous lemma in [32]. We omit the proof due to space constraints.

▶ **Lemma 4.3** ([32]). *Let $\mathcal{G}$ be an $(r, 2)$-boundary expander. Then for every $V' \subseteq V$ with $|V'| \leq r/2$ there exists a subset $\gamma(V') \supseteq V'$ such that $|\mathrm{Ker}(\gamma(V'))| \leq |V'|$ and the induced subgraph $\mathcal{G} \setminus \gamma(V')$ is an $(r/2, 1)$-boundary expander.*

The next lemma states that there exists $N \times n$ $(r, d, 2)$-boundary expanders where the size n of the right-hand side is significantly smaller than the size $N = n^{\Theta(d)}$ of the left-hand side. This can be proven by a standard application of the probabilistic method.

▶ **Lemma 4.4.** *Fix constants $\varepsilon, \delta, d_0 > 0$ such that $\delta + \frac{1}{d_0} < \varepsilon/2$. Then there exists an $n_0 \in \mathbb{N}^+$ such that for all n, d, and r satisfying $n \geq n_0$, $d_0 \leq d \leq n^{\frac{1}{2}-\varepsilon}$, and $r \leq d \log n$ there are $\lfloor n^{\delta d} \rfloor \times n$ $(r, d, 2)$-boundary expanders.*

After this review of boundary expanders and their properties we now come to the core argument of the paper, namely that space lower bounds are preserved for small-width proofs when we apply XORification as in Definition 2.2 with respect to an $(r, 2)$-boundary expander. To get cleaner technical arguments in the proofs we will restrict our attention to homogeneous resolution refutations as in (2.3), which for our purposes is without loss of generality by Observation 2.1.

▶ **Lemma 4.5.** *Let F be a CNF-formula and $\mathcal{G}$ an $(r, 2)$-boundary expander and suppose that $\pi : F[\mathcal{G}] \vdash \bot$ is a homogeneous resolution refutation in width $w \leq r/2$ of the XORified formula $F[\mathcal{G}]$. Then there is a homogeneous refutation $\pi' : F \vdash \bot$ of the original formula F in width at most w and space $Sp(\pi') \leq 2^w Sp(\pi) + w + 3$.*

Proof. Assume that $\pi = (\mathbb{C}_0, \mathbb{C}_1, \ldots, \mathbb{C}_\tau)$ is a configuration-style homogeneous resolution refutation of $F[\mathcal{G}]$ in width $W(\pi) = w \leq r/2$. We will show how to transform π into a refutation π' of the original formula F in width and space as claimed in the lemma. To help the reader navigate the proof, we remark that in what follows we will use the notational conventions that B and C denote clauses over $\mathit{Vars}(F[\mathcal{G}])$, D denotes a clause over $\mathit{Vars}(F)$, and A denotes an axiom clause from the original formula F before XORification.

Recall that for clauses $C \in F[\mathcal{G}]$ we have $\mathit{Vars}(C) \subseteq V$. For convenience, we will overload notation and write $\mathrm{Ker}(C) = \mathrm{Ker}(\mathit{Vars}(C))$, which is a subset of the variables U of the original formula F. Furthermore, for every clause $C \in \pi$ we fix $\gamma(C) := \gamma(\mathit{Vars}(C)) \subseteq V$ to be a minimal closure with properties as guaranteed by Lemma 4.3 (such closures exist since all clauses $C \in \pi$ have width at most w). An important notion in what follows will be that of *simultaneous falsifiability*, where we say that two CNF formulas F and G are *simultaneously falsifiable* if there is a truth value assignment that at the same time falsifies both F and G.

To transform the resolution refutation π of $F[\mathcal{G}]$ into a refutation π' of F we let $\mathbb{D}_t$ be obtained from $\mathbb{C}_t$ by replacing every clause $C \in \mathbb{C}_t$ by the set of clauses

$$\mathcal{G}^{-1}(C) := \{D \mid \mathit{Vars}(D) = \mathrm{Ker}(\gamma(C));\ D[\mathcal{G}] \text{ and } C \text{ are simultaneously falsifiable}\} \quad (4.1)$$

and defining

$$\mathbb{D}_t := \bigcup_{C \in \mathbb{C}_t} \mathcal{G}^{-1}(C) \quad (4.2)$$

(where the notation $\mathcal{G}^{-1}(C)$ is chosen to suggest that this is in some intuitive sense the inverse operation of XORification with respect to $\mathcal{G}$).

Every clause in $D \in \mathcal{G}^{-1}(C)$ has width at most w, because $|\mathit{Vars}(D)| = |\mathrm{Ker}(\gamma(C))| \leq W(C) \leq w$, where the first inequality is guaranteed by Lemma 4.3. Furthermore, we have $|\mathcal{G}^{-1}(C)| \leq 2^w$, since all clauses in $\mathcal{G}^{-1}(C)$ are over the same set of variables and each variable appears positively or negatively in every clause, and hence $\left|\mathbb{D}_t\right| \leq 2^w Sp(\pi)$. We want to argue that the sequence $\mathbb{D}_0, \mathbb{D}_1, \ldots, \mathbb{D}_\tau$ is the "backbone" of a resolution refutation π' of F, by which we mean that for every t it holds that $\mathbb{D}_{t+1}$ can be derived from $\mathbb{D}_t$ by a sequence of intermediate steps without affecting any proof complexity measure too much.

To show that this is so, we first observe that for $\mathbb{C}_0 = \emptyset$ we obviously get $\mathbb{D}_0 = \emptyset$ by (4.2). Moreover, it holds that $\mathcal{G}^{-1}(\bot) = \{\bot\}$ and hence $\bot \in \mathbb{D}_\tau$, since the unique minimal closure of the empty set is the empty set itself. We want to show that for every $0 \leq t < \tau$ the configuration $\mathbb{D}_{t+1}$ can be obtained from $\mathbb{D}_t$ by a resolution derivation

$(\mathbb{D}_t = \mathbb{D}_t^0, \mathbb{D}_t^1, \ldots, \mathbb{D}_t^{j_t} = \mathbb{D}_{t+1})$ where the space of every intermediate configuration is bounded by $\max\{Sp(\mathbb{D}_t), Sp(\mathbb{D}_{t+1}) + w\}$.

If $\mathbb{C}_{t+1}$ is obtained from $\mathbb{C}_t$ by erasing a clause C, then $\mathbb{D}_{t+1}$ can be obtained from $\mathbb{D}_t$ by erasing all clauses $\mathcal{G}^{-1}(C) \setminus \mathbb{D}_{t+1}$. Suppose that $\mathbb{C}_{t+1}$ is obtained from $\mathbb{C}_t$ by downloading an axiom $C \in F[\mathcal{G}]$. We claim that every clause in $\mathcal{G}^{-1}(C)$ is either an axiom or a weakening of an axiom from F. By the definition of $F[\mathcal{G}]$, every axiom $C \in F[\mathcal{G}]$ is a clause in the CNF formula $A[\mathcal{G}]$ for some original axiom $A \in F$. Fix any axiom $A \in F$ such that $C \in A[\mathcal{G}]$. Then for all $D \in \mathcal{G}^{-1}(C)$ it holds by (4.1) that $\mathit{Vars}(D) = \mathrm{Ker}(\gamma(C)) \supseteq \mathrm{Ker}(C) \supseteq \mathit{Vars}(A)$ and that there is an assignment falsifying both $D[\mathcal{G}]$ and C. To see that this implies that A subsumes D, suppose that there is a variable x appearing positively in A such that $\overline{x} \in D$. Any truth value assignment falsifying $D[\mathcal{G}]$ must falsify $a[\mathcal{G}]$ for all literals $a \in D$, and hence in particular $\overline{x}[\mathcal{G}]$. But this means that $x[\mathcal{G}]$ is satisfied by the same assignment, and then so is all of the formula $A[\mathcal{G}]$ including C. But this is a contradiction, and so not only does it hold that $\mathit{Vars}(A) \subseteq \mathit{Vars}(D)$ but A is in fact a subclause of D as claimed. From this we see that we can add the clauses $\mathcal{G}^{-1}(C)$ to $\mathbb{D}_t$ using axiom download and weakening. After applying a weakening step we immediately delete the old clause. Hence, the additional weakening might increase the space by at most one. It follows that the space of the intermediate configurations need never exceed $Sp(\mathbb{D}_{t+1}) + 1$.

It remains to check that $\mathbb{D}_{t+1}$ can be derived from $\mathbb{D}_t$ when $\mathbb{C}_{t+1}$ is obtained from $\mathbb{C}_t$ by an inference step. This is stated in the following two claims regarding applications of the resolution and weakening rules. Here graph expansion comes heavily into play, but due to space constraints we have to defer the proofs to the full-length version of this paper.

▶ **Claim 4.6.** *Every clause $D \in \mathcal{G}^{-1}(C)$ can be derived from $\mathcal{G}^{-1}(C \vee x) \cup \mathcal{G}^{-1}(C \vee \overline{x})$ by a homogeneous resolution derivation of width w and depth $w + 1$.*

▶ **Claim 4.7.** *For any two clauses $B \subseteq C$ it holds that every clause $D \in \mathcal{G}^{-1}(C)$ can be derived from $\mathcal{G}^{-1}(B)$ by a homogeneous derivation of width w and depth $w + 1$.*

Because the depth of a refutation is an upper bound on the clause space by Observation 2.4, it follows that in both cases we can derive all clauses in the clause set $\mathcal{G}^{-1}(C)$ one by one by using additional space $w+3$ to perform the derivations in depth $w+1$. It follows that F has a homogeneous resolution refutation π' of width w and clause space $Sp(\pi') \leq 2^w Sp(\pi) + w + 3$.

This concludes the proof of Lemma 4.5. ◀

We can now combine the construction in Lemma 4.5 with the existence of good boundary expanders in Lemma 4.4 to prove the hardness condensation in Lemma 4.1.

Proof of Lemma 4.1. Given $\varepsilon > 0$ and $k \in \mathbb{N}^+$ we choose $\delta := \frac{\varepsilon}{10k}$. Suppose ℓ and n are parameters such that $k \leq \ell \leq n^{\frac{1}{2}-\varepsilon}$ and let F be an unsatisfiable k-CNF formula over $N = \lfloor n^{\delta\ell} \rfloor$ variables that can be refuted in width k. To apply Lemma 4.4 we set $d_0 := \frac{5}{\varepsilon}$ and verify that $\delta + \frac{1}{d_0} = \frac{\varepsilon}{10k} + \frac{\varepsilon}{5} < \frac{\varepsilon}{2}$. We choose the degree of the expander to be $d := \frac{\ell}{2k}$ and set the expansion guarantee to $r := d \log n$. By the bound on ℓ we have $d \leq \ell \leq n^{\frac{1}{2}-\varepsilon}$.

Now we have two cases. The first, and interesting, case is when $d \geq d_0$ holds. Then Lemma 4.4 guarantees that there exists an $N \times n$ $(r, d, 2)$-boundary expander $\mathcal{G}$. Applying XORification with respect to $\mathcal{G}$, we obtain an ℓ-CNF formula $F[\mathcal{G}]$ with n variables. By Observation 2.3 it holds that $F[\mathcal{G}]$ has a resolution refutation of width $2dk \leq \ell$. Now suppose that $\pi : F[\mathcal{G}] \vdash \bot$ is a refutation of width w. Because $w \leq \frac{\ell}{4k} \log n = r/2$ the space lower bound follows from Lemma 4.5.

The second case is when $d < d_0$. Then we do not actually need any XORification but can use the original formula. Formally, let $\mathcal{G} = (U \dot\cup (V \cup V'), E)$ be a matching between two sets

U and V of size $|U| = |V| = N$ plus some isolated vertices V' on the right-hand side such that $|V \cup V'| = n$. To check that this is well defined we have to verify that $N \leq n$, which follows from the calculations $N = \lfloor n^{\delta\ell} \rfloor = \lfloor n^{\frac{\varepsilon}{10k}2kd} \rfloor \leq \lfloor n^{\frac{\varepsilon}{10k}2kd_0} \rfloor = \lfloor n^{\frac{\varepsilon}{10k}2k\frac{5}{\varepsilon}} \rfloor = n$. Thus, we obtain $F[\mathcal{G}] = F$ (plus some left-over dummy variables) and we have $W(F[\mathcal{G}] \vdash \bot) = W(F \vdash \bot) = k \leq \ell$ as well as $Sp(\pi) \geq s \geq (s - w - 3)2^{-w}$. ◀

5 Concluding Remarks

In this paper we prove that there are CNF formulas over n variables exhibiting an $n^{\Omega(w)}$ clause space lower bound for resolution refutations in width w. This lower bound is optimal (up to constants in the exponent) as every refutation in width w has length, and hence space, at most $n^{\mathrm{O}(w)}$. Our lower bounds do not only hold for the minimal refutation width w but remain valid for any refutations in width $\mathrm{o}(w \log n)$. Measured in terms of the number of variables n, this is a major improvement over the previous space-width trade-off result in [8], and provides another example of trade-offs in the supercritical regime above worst-case recently identified in [32].

A first open problem is whether the range of applicability can be extended even further so that the space lower bound holds true up to width $\mathrm{o}(n)$. It is clear that the lower bound has to break down at some point, since if one is allowed maximal width n any formula can be refuted in clause space $n + 2$. A supercritical trade-off on resolution proof depth over width ranging from w all the way up to $n^{(1-\epsilon)}/w$ was shown in [32], suggesting that the above goal might not be completely out of reach.

Another intriguing open problem from the complexity-theoretic point of view is to prove space trade-offs that are superlinear not only in terms of the number of variables but measured also in formula size. Such lower bounds cannot be obtained by the techniques used in this paper, but they are likely to exist as the following argument shows (see [25] for a more detailed discussion). Suppose that every refutation in width $w(n)$ can be transformed into a refutation that has width $w(n)$ and clause space polynomial in the size of the formula. Then we can find such a refutation non-deterministically in polynomial space by keeping the current configuration in memory and guessing the inference steps. Thus, by Savitch's theorem, finding refutations of width $w(n)$ would be in deterministic PSPACE. On the other hand, it has been shown by the first author that the problem of finding resolution refutations of bounded width is EXPTIME-complete [14]. Hence, unless EXPTIME = PSPACE there are formulas where every refutation of minimal width needs clause space that is superpolynomial in the size of the formula.

Finally, it would be interesting to study if the supercritical trade-offs between clause space and width in resolution shown in this paper could be extended to similar trade-offs between monomial space and degree for polynomial calculus or polynomial calculus resolution as defined in [1, 19].

Acknowledgements. We wish to thank Alexander Razborov for patiently explaining the hardness condensation technique in [32] during numerous and detailed discussions.

Abstract

Given a set of numbers, the k-SUM problem asks for a subset of k numbers that sums to zero. When the numbers are integers, the time and space complexity of k-SUM is generally studied in the word-RAM model; when the numbers are reals, the complexity is studied in the real-RAM model, and space is measured by the number of reals held in memory at any point.

We present a time and space efficient deterministic self-reduction for the k-SUM problem which holds for both models, and has many interesting consequences. To illustrate:

- 3-SUM is in deterministic time $O(n^2 \lg\lg(n)/\lg(n))$ and space $O\left(\sqrt{\frac{n\lg(n)}{\lg\lg(n)}}\right)$. In general, any polylogarithmic-time improvement over quadratic time for 3-SUM can be converted into an algorithm with an identical time improvement but low space complexity as well.
- 3-SUM is in deterministic time $O(n^2)$ and space $O(\sqrt{n})$, derandomizing an algorithm of Wang.
- A popular conjecture states that 3-SUM requires $n^{2-o(1)}$ time on the word-RAM. We show that the 3-SUM Conjecture is in fact equivalent to the (seemingly weaker) conjecture that every $O(n^{.51})$-space algorithm for 3-SUM requires at least $n^{2-o(1)}$ time on the word-RAM.
- For $k \geq 4$, k-SUM is in deterministic $O(n^{k-2+2/k})$ time and $O(\sqrt{n})$ space.

1 Introduction

We consider the k-SUM problem: given a list S of n values, determine whether there are distinct $a_1, \ldots, a_k \in S$ such that $\sum_{i=1}^{k} a_i = 0$. This classic problem is a parameterized version of the Subset Sum problem, which is among Karp's original NP-Complete problems.[1]

The brute-force algorithm for k-SUM runs in $O(n^k)$ time, and it is known [22] that an $n^{o(k)}$ time algorithm (where the little-o depends on k) would violate the Exponential Time

[1] Karp's definition of the Knapsack problem is essentially Subset Sum [19].

Hypothesis [18]. A faster meet-in-the-middle algorithm reduces the k-SUM problem on n numbers to 2-SUM on $O(n^{\lceil k/2 \rceil})$ numbers, which can then be solved by sorting and binary search in $O(n^{\lceil k/2 \rceil} \log n)$ time. The belief that this meet-in-the-middle approach is essentially time-optimal is at the heart of many conditional 3-SUM-hardness results in computational geometry (e.g. [15]) and string matching (e.g. [5, 2]).

The space usage of the meet-in-the-middle approach is prohibitive: the $O(n \log n)$ time solution for 2-SUM uses linear space, which causes the fast k-SUM algorithm to need $\Omega(n^{\lceil k/2 \rceil})$ space. However, the brute-force algorithm needs only $O(k \log n)$ space. This leads to the natural question: *how well can one trade off time and space in solving k-SUM?*

Schroeppel and Shamir [23] first studied time-space trade-off algorithms for Subset Sum. They showed how to reduce Subset Sum to an instance of k-SUM for any $k \geq 2$: split the elements into k sets of n/k elements each; for each set, compute $2^{n/k}$ sums corresponding to the subsets of the set; this forms a k-SUM instance of size $2^{n/k}$. Since the k-SUM instance does not have to be explicitly stored, any time $T(N)$, space $S(N)$ algorithm for $k-$SUM immediately implies a time $T(2^{n/k})$, space $S(2^{n/k})$ algorithm for Subset Sum. Furthermore, Schroeppel and Shamir gave a deterministic $\tilde{O}(n^2)$ time, $\tilde{O}(n)$ space algorithm for 4-SUM, implying a $O^*(2^{n/2})$ time, $O^*(2^{n/4})$ space algorithm for Subset Sum.[2] They also generalized the algorithm to provide a smooth time-space trade-off curve, with extremal points at $O^*(2^{n/2})$ time, $O^*(2^{n/4})$ space and $O^*(2^n)$ time, $O^*(1)$ space.

A recent line of work leading up to Austrin et al. [6] has improved this long-standing trade-off curve for Subset Sum via *randomized* algorithms, resulting in a more complex curve. Wang [25] moved these gains to the k-SUM setting. In particular, for 3-SUM he obtains an $\tilde{O}(n^2)$ time, $\tilde{O}(\sqrt{n})$ space Las Vegas algorithm.

Despite the recent progress on the problem, all of the improved algorithms for the general case of k-SUM have heavily relied on randomization, either utilizing hashes or random prime moduli. These improvements also all rely heavily on the values in the lists being integers. For the general case of k-SUM, the previous best *deterministic* k-SUM results (even for integer inputs) are the brute-force algorithm, the meet-in-the-middle algorithm, and the Schroeppel and Shamir 4-SUM algorithm, and simple combinations thereof.

1.1 Our Results

We consider new ways of trading time and space in solving k-SUM, on both integer and real inputs (on the word-RAM and real-RAM respectively), without the use of randomization. Our improvements for k-SUM naturally extend to improvements to Subset Sum as well.

Our main result is a deterministic self-reduction for k-SUM. Informally, we show how to deterministically decompose a list of n numbers into a small collection of shorter lists, such that the k-SUM solution is preserved. This result is shown for $k = 3$ in Section 4. It is shown for general k in Section 5.

▶ **Theorem 1.** *Let g be any integer between 1 and n. k-SUM on n numbers can be reduced to $O(kg^{k-1})$ instances of k-SUM on n/g numbers. The reduction uses $O(ng^{k-1})$ additional time and $O(n/g)$ additional words of space.*

Theorem 1 has several interesting applications. First, it leads to more efficient k-SUM algorithms. For example, Gold and Sharir, building on other recent advances, report a deterministic algorithm for 3-SUM that works in both the word-RAM and real-RAM models

[2] The notation $\tilde{O}$ suppresses polylogarithmic factors in n, and O^* suppresses polynomial factors in n.

and which runs in time $O(n^2 \lg\lg(n)/\lg(n))$ [16]. However, this algorithm uses a considerable amount of space to store a table of permutations. Applying Theorem 1 in multiple ways and calling their algorithm, we recover the *same* asymptotic running time but with drastically better space usage:

▶ **Theorem 2.** *There is an $O(n^2 \lg\lg(n)/\lg(n))$ time deterministic algorithm for 3-SUM that stores at $O(\sqrt{\frac{n\lg(n)}{\lg\lg(n)}})$ numbers in memory at point. (An analogous statement holds for 3-SUM over the integers.)*

Theorem 1 also directly leads to a derandomization of Wang's space-efficient algorithm for 3-SUM:

▶ **Theorem 3.** *For all $s \in [0, 1/2]$ there is a deterministic time $O(n^{3-2s})$, algorithm which uses $O(n^s)$ words of space for 3-SUM.*

From Theorem 1 we can also derive a more space-efficient algorithm for 4-SUM, and lift it to a new algorithm for k-SUM:

▶ **Theorem 4.** *For $k \geq 4$, k-SUM is solvable in deterministic $O(n^{k-2+2/(k-3)})$ time and $O(\sqrt{n})$ space in terms of words.*

A more plausible 3-SUM conjecture

A rather popular algorithmic conjecture is the *3-SUM Conjecture* that 3-SUM on n integers requires $n^{2-o(1)}$ time on a word-RAM with $O(\log n)$ bit words. This conjecture has been used to derive conditional lower bounds for a variety of problems [15, 5, 2, 20, 3], and appears to be central to our understanding of lower bounds in low-polynomial time. To refute the conjecture, one could conceivably construct an algorithm that runs in $O(n^{1.99})$ time, but utilizes $\Omega(n^{1.99})$ space in some clever way. Here we consider a seemingly weaker (and thus more plausible) conjecture:

▶ **Conjecture 5** (The Small-Space 3-SUM Conjecture)**.** *On a word-RAM with $O(\log n)$-bit words, there exists an $\epsilon > 0$ such that every algorithm that solves 3-SUM in $O(n^{1/2+\epsilon})$ space must take at least $n^{2-o(1)}$ time.*

This conjecture looks weaker than the original 3-SUM Conjecture, because we only have to prove a quadratic-time lower bound for all algorithms that use slightly more than $\sqrt{n}$ space. Proving time lower bounds is generally much easier when space is severely restricted (e.g. [9, 14, 12, 26, 8]).

Our self-reduction for 3-SUM yields the intriguing consequence that the original 3-SUM Conjecture is *equivalent* to the Small-Space 3-SUM conjecture! That is, the non-existence of a truly subquadratic-time 3-SUM algorithm is equivalent to the non-existence of a truly subquadratic-time $n^{0.51}$-space 3-SUM algorithm, even though the latter appears to be a more plausible lower bound. We prove:

▶ **Theorem 6.** *If 3-SUM is solvable in time $O(n^{2-\epsilon})$ time, then for every $\alpha > 0$ there is a $\delta > 0$ such that 3-SUM is solvable in $O(n^{2-\delta})$ time and space $O(n^{1/2+\alpha})$ in terms of words.*

Theorem 6 is interesting, regardless of the veracity of the 3-SUM conjecture. On the one hand, the theorem reduces the difficulty of proving the 3-SUM Conjecture if it is true, because we only have to rule out small-space sub-quadratic time algorithms. On the other hand, the theorem means that refuting the 3-SUM conjecture immediately implies a truly-subquadratic time algorithm for 3-SUM using small space as well, which would be an algorithmic improvement.

2 Preliminaries

2.1 k-SUM and Selection

We will use the following version of the k-SUM problem:

▶ **Definition 7.** In the *k-SUM problem*, we are given an unsorted list L of n values (over $\mathbb{Z}$ or $\mathbb{R}$) and want to determine if there are $a_1, \ldots, a_k \in L$ such that $\sum_{i=1}^{k} a_i = 0$.

One fundamental case is the 3-SUM problem. Sometimes 3-SUM is presented with three separate lists, which we denote as 3-SUM', but the two are reducible to each other in linear time, and with no impact on space usage.

▶ **Definition 8.** In the *3-SUM problem*, we are given an unsorted list L of n values and want to know if there are $a, b, c \in L$ such that $a + b + c = 0$. In the *3-SUM' problem*, we are given three unsorted lists A, B, and C of values, where $|A| = |B| = |C| = n$, and want to know if there are $a \in A, b \in B, c \in C$ such that $a + b + c = 0$.

As part of our k-SUM algorithms, the classical *Selection Problem* will also arise:

▶ **Definition 9.** In the *s-Select problem*, we are given an unsorted list L of n values and a natural number s, and want to determine the s^{th} smallest value in L.

2.2 Computational Model

As standard when discussing sub-linear space algorithms, the input is provided in read-only memory, and the algorithm works with auxiliary read/write memory which counts towards its space usage.

Computation on Integers. When the input values are integers, we work in the word-RAM model of computation: the machine has a word size w, and we assume all input numbers can be represented with w bits so that they fit in a word. Arithmetic operations $(+, -, *)$ and comparisons on two words are assumed to take $O(1)$ time. Space is counted in terms of the number of words used.

Computation on Reals. When the input values are real numbers, we work in a natural *real-RAM* model of computation, which is often called the *comparison-addition model* (see, for example, [21]). Here, the machine has access to registers that can store arbitrary real numbers; addition of two numbers and comparisons on real numbers take $O(1)$ time. Space is measured in terms of the number of reals stored.

Time-Space Complexity Notation. We say that k-SUM is solvable in $\mathsf{TISP}(T(n), S(n))$ if k-SUM on lists of length n can be solved by a single algorithm running in deterministic $O(T(n))$ time and $O(S(n))$ space simultaneously on the real-RAM (and if the lists contain integers, on the word-RAM).

2.3 Other Prior Work

Baran, Demaine and Patrascu [7] obtained randomized slightly subquadratic time algorithms for Integer 3-SUM in the word-RAM. Grønlund and Pettie [17] studied 3-SUM over the reals, presenting an $O(n^2/(\log n/\log\log n))$ time randomized algorithm, as well as a deterministic algorithm running in $O(n^2/(\log n/\log\log n)^{2/3})$ time. Recently, Gold and Sharir [16]

improved this deterministic running time to $O(n^2/(\log n/\log\log n))$. Abboud, Lewi and Williams [1] showed that Integer k-SUM is W[1]-complete under randomized FPT reductions (and under some plausible derandomization hypotheses, the reductions can be made deterministic). In the linear decision tree model of computation, k-SUM over the reals is known to require $\Omega(n^{\lceil k/2\rceil})$ depth k-linear decision trees [13, 4], but the problem can be solved with $O(n^{k/2}\sqrt{\log n})$ depth $(2k-2)$-linear decision trees [17]. The randomized decision tree complexity was improved by Gold and Sharir [16] to $O(n^{k/2})$.

3 Building Blocks

In this section, we describe two tools we use to obtain our main self-reduction lemma for k-SUM and 3-SUM. The first tool helps us guarantee that we don't have to generate too many subproblems in our reduction; the second will allow us to find these subproblems in a time and space efficient way.

3.1 Domination Lemma

Our deterministic self-reduction for k-SUM will split lists of size n into g sublists of size n/g, then solve subproblems made up of k-tuples of these sublists. Naively, this would generate g^k subproblems to enumerate all k-tuples. In this section, we show that we only need to consider $O(kg^{k-1})$ subproblems.

First, we define a partial ordering on k-tuples on $[n]^k$. For $t, t' \in [n]^k$, we say that $t \prec t'$ if $t[i] < t'[i]$ for all $i = 1, \ldots, k$. (Geometrically, the terminology is that t' *dominates* t.)

▶ **Lemma 10** (Domination Lemma). *Suppose all tuples in a subset $S \subseteq [n]^k$ are incomparable with respect to $\prec$. Then $|S| \leq kn^{k-1}$.*

The Domination Lemma can be seen as an extension of a result in [24] (also used in [11] in a different context) which covers the $k = 3$ case.

Proof. We will give a cover of all elements in $[n]^k$ with few chains under $\prec$. Then by Dilworth's theorem, any set of incomparable elements under $\prec$ can only have one element from each chain.

Take any k-tuple $t \in [n]^k$ such that $t[i] = 1$ for some $i = 1, \ldots, k$. Letting $\ell \in [n]$ be the largest element in t, we define the chain $C(t) = \{t_0, t_1, \ldots, t_{n-\ell}\}$, where each t_j is given by $t_j[i] = t[i] + j$ for all $i = 1, \ldots, k$. Clearly $C(t)$ forms a chain in $[n]^k$ under $\prec$. Moreover these chains cover all elements of $[n]^k$: observe that the tuple t appears in the chain $C(t')$ where $t'[i] = t[i] - \min_j t[j] + 1$ for all $i = 1, \ldots, k$.

The number of chains is exactly the number of k-tuples with a 1 in at least one coordinate. This number is less than k times the number of tuples that have a 1 in dimension i. The number of tuples with a 1 in dimension i is n^{k-1}. Thus, the total number of chains is $\leq kn^{k-1}$. ◀

The Domination Lemma can be applied to show that in any list of numbers, not too many k-SUM subproblems can have k-SUM solutions. In the following, let g divide n for simplicity. Given a list L of n numbers divided into g groups of size n/g, a *subproblem of L* is simply the union of a k-tuple of groups from L. Note that a subproblem contains at most kn/g numbers.

▶ **Corollary 11.** *Given a k-SUM instance L, suppose L is divided into g groups $L_1, \ldots, L_g$ where $|L_i| = n/g$ for all i, and for all $a \in L_i$ and $b \in L_{i+1}$ we have $a \leq b$. Then there are*

$O(k \cdot g^{k-1})$ subproblems L' of L such that the smallest k-sum of L' is less than zero and the largest k-sum of L' is greater than zero. Furthermore, if some subproblem of L has its largest or smallest k-sum equal to 0, then the corresponding k-SUM solution can be found in $O(g^k)$ time.

Proof. We associate each subproblem of L with a corresponding k-tuple $(x_1, \ldots, x_k) \in [g]^k$ corresponding to the k sublists $(L_{x_1}, \ldots, L_{x_k})$ of L.

Let $m[i]$ be the element in position $i \cdot (n/g)$ when L is in sorted order. Consider any subproblem with $\sum_{i=1}^{k} m[x_i] > 0$ (smallest k-sum greater than zero) or $\sum_{i=1}^{k} m[x_i + 1] < 0$ (largest k-sum less than zero). We call such a subproblem *trivial*, since it cannot contain k-SUM solutions.

In $O(g^k)$ time, we can determine whether any subproblem has $\sum_{i=1}^{k} m[x_i] = 0$, and return the corresponding k-SUM solution if this is the case. Otherwise, we can assume that for each subproblem either it is trivial, or $\sum_{i=1}^{k} m[x_i] < 0 < \sum_{i=1}^{k} m[x_i + 1]$.

Consider the set of non-trivial subproblems. Because for all $a \in L_i$ and $b \in L_{i+1}$ we have $a \leq b$, if for two subproblem k-tuples we have $t \prec t'$, then the smallest k-sum of the subproblem t' is at least the largest k-sum of the subproblem t. This implies that at least one of the two subproblems must be trivial. In other words, the set of nontrivial problems corresponds to a set of incomparable k-tuples in $[g]^k$. Applying Lemma 10, the number of nontrivial subproblems is $O(kg^k)$. ◀

3.2 Bucket Retrieval and Space-Efficient Selection

A randomized algorithm for k-SUM can partition a list of numbers by choosing a hash function at random, then loop over the hash function range to partition a given list into smaller buckets. Given a hash and a bucket number, it is easy to retrieve the contents of that bucket by scanning the list.

To derandomize this process, we could try to create small "hash" buckets by grouping the n/g smallest elements together, then the next n/g smallest elements, and so on, *without actually sorting the list*. However, retrieving the contents of a bucket may now be difficult to do with small space: we need to know the smallest and largest elements of a bucket to retrieve its elements, and we may not be able to store all of these extrema. We require an efficient algorithm to compute the largest element of a bucket, given the smallest element and the bucket size.

This problem is equivalent to the *selection problem*, also known as s-SELECT, which asks for the s^{th} smallest element of a list, when we set $s = n/g$. To reduce from our problem to s-SELECT, pretend that every entry less than our smallest element is ∞. (To reduce from s-SELECT to our problem, we can pretend our smallest element is $-\infty$.)

The classic median-of-median algorithm can solve s-SELECT in $O(n)$ time and $O(n)$ space [10]. Since we care about space usage, we provide an algorithm below which has $O(n)$ running time, but uses much less space. This algorithm turns out to be optimal for our purposes, since retrieving the bucket afterwards will already take $O(n)$ time and $O(s)$ space.

▶ **Lemma 12.** *s-SELECT can be solved in $O(n)$ time and $O(s)$ space.*

Proof. The plan is to scan through the elements of the list, inserting them to a data structure D which will allow us to track the smallest s elements. We perform n insertions, then query D to ask for the smallest s elements it contains. To get the claimed algorithm for selection, we give a data structure can handle these operations in $O(1)$ amortized update time and $O(s)$ query time, with a data structure using only $O(s)$ space.

One first attempt might be to build a heap of $s+1$ elements, which throws away the largest element whenever it gets full. Since heaps have logarithmic update time and linear space usage, this results in $O(\log s)$ update time, $O(s)$ query time, and $O(s)$ space.

We can improve the update time by batching when we throw out large elements. Suppose instead we keep an array which can hold up to $2s$ elements. When the array gets full, we throw out the largest s elements. To do this, we first compute the $(s+1)^{th}$ smallest element in the array. This can be done in $O(s)$ time and $O(s)$ space via the classical median-of-medians algorithm. We then do a linear scan of the array, and write all elements strictly less than the median to a new array. To handle ties, we write a copy of the median to the new array, until it has s elements. When we are given our final query, we again throw out large elements so that we only have s elements left, and then return those.

Updates now take amortized constant time: after s updates, we take $O(s)$ time to clear out the large elements. The final query takes $O(s)$ time, since we again need to throw out large elements. The space usage is $O(s)$ since we store up to $2s$ elements, and running median-of-medians takes $O(s)$ space. This completes the proof. ◀

We will call the above algorithm NextGroup. NextGroup takes as input a value v, a natural number s, and a list of numbers L, and outputs the next s elements of L in sorted order after the value v.

4 Subquadratic 3-SUM implies Subquadratic small-space 3-SUM

We will begin by using our building blocks to prove a self reduction for 3-SUM. Then we will show three intriguing consequences of this self reduction. First, the self reduction can be used to show a general theorem that takes subquadratic algorithms for 3-SUM and produces subquadratic time algorithms that run in nearly $\sqrt{n}$ space. Second, we show that algorithms for 3-SUM that are subquadratic by polylog factors can be used to obtain 3-SUM algorithms with the same asymptotic running time and simultaneously small space. Finally, we will prove that the Small-Space 3-SUM conjecture is equivalent to the 3-SUM conjecture.

4.1 3-SUM Self Reduction

We now proceed to solve 3-SUM using our bucket retrieval subroutine. We will use $\max S$ and $\min S$ to refer to the maximum and minimum elements of a list S, respectively.

As anticipated, we split the three arrays into groups of size n/g, and solve 3-SUM on subproblems of this size. Naively there are $O(g^3)$ subproblems to solve, but we use Corollary 11 to argue we only get $O(g^2)$ subproblems.

▶ **Theorem 13** (3-SUM Self-Reduction Theorem). *If 3-SUM is solvable in* $\mathit{TISP}(T(n), S(n))$ *then for any g, 3-SUM can be solved in* $\mathit{TISP}(g^2(n + T(n/g)), n/g + S(n/g))$.

Proof. Consider the following algorithm.

Algorithm 1: 3-SUM Algorithm

```
Set preva = −∞;
for i ∈ [0, g − 1] do
    Set A′ = NextGroup(A, preva, n/g + 1);
    Set prevb = −∞;
    for j ∈ [0, g − 1] do
        Set B′ = NextGroup(B, prevb, n/g + 1);
        Set C′ = NextGroup(C, − max A′ − max B′, n/g + 1);
        while min C′ ≤ − min A′ − min B′ do
            if 3-SUM(A′, B′, C′) returns true then
                return true;
            Set C′ = NextGroup(C, max C′, n/g + 1);
        Set prevb = max B′;
    Set preva = max A′;
return false;
```

Algorithm 1 is correct because we consider all possible elements of C where the sum of elements from A' and B' could land, and the choices of A' and the choices of B' cover all of A and B, respectively. If there are multiple copies of a value in a list we will fail to list all copies only if it already appeared in a previous sublist. This will not affect correctness because the value will have already been analyzed.

It's easy to see that the algorithm calls NextGroup $O(g)$ times for A', $O(g^2)$ times for B'. We claim that we also only call it $O(g^2)$ times for C'. To show this, we want to apply Corollary 11. Unfortunately, the groups of C that we extract don't always line up with our ideal n/g division; since we start at $-\max A' - \max B'$, we may not align at the endpoints of blocks. Fortunately, we've only introduced an extra $O(1)$ possibilities of C' for every (A', B') pair, or $O(g^2)$ extras total. Hence we still only make $O(g^2)$ calls to NextGroup. By Lemma 12, these calls will require $O(ng^2)$ time and $O(n/g)$ space.

Our algorithm also calls the $\mathsf{TISP}(T(n), S(n))$ algorithm for 3-SUM $O(g^2)$ times on instances of size $O(n/g)$, which requires $O(g^2 T(n/g))$ time and $O(S(n/g))$ space.

We have shown Algorithm 1 is correct and has the desired runtime and space usage, so this completes the proof. ◀

4.2 General Theorem for Space Reduction

Our self-reduction for 3-SUM yields the following intriguing consequence: *subquadratic-time algorithms for* 3*-SUM imply subquadratic-time small-space algorithms for* 3*-SUM*. Plugging this connection into known 3-SUM algorithms, we can automatically obtain more space-efficient 3-SUM algorithms for free. From a complexity-theoretic point of view, the consequence is perhaps even more intriguing: it means that the 3-SUM Conjecture is *equivalent* to the statement that there is no subquadratic-time $n^{0.51}$-space 3-SUM algorithm, even though the latter appears to be a more plausible lower bound(!).

We begin by stating our generic space reduction theorem.

▶ **Theorem 14** (3-SUM Space Reduction)**.** *Suppose* 3*-SUM is solvable in* $n^2/f(n)$ *time, where* $1 \le f(n) \le n$*. Then* 3*-SUM is solvable by an algorithm running in* $O(n^2/f(n/g))$ *time and*

$O(n/h)$ space simultaneously, where $g(n), h(n) \in [1, n]$ satisfy the relations

$$g(n) \geq \Omega\left(\sqrt{\frac{n}{f(n/g(n))}}\right) \quad \text{and} \quad h^2 + \frac{n}{f(n/(hg(n/h)))} \leq O\left(\frac{n}{f(n/g(n))}\right).$$

Proof. We will apply our Self-Reduction Theorem for 3-SUM (Theorem 13) in two different ways. First, we will use the self-reduction (and the constraint on $g(n)$) to convert our 3-SUM algorithm into a linear-space algorithm, with a modest increase in running time (if at all). Pushing the linear-space algorithm through the self-reduction once more will reduce the space bound further, without increasing the running time asymptotically (using the constraint on $h(n)$).

Let $T(n) := n^2/f(n)$. Set the parameter $g(n) \geq 1$ to satisfy

$$T(n/g) = \frac{n^2/g^2}{f(n/g)} = O(n); \quad \text{or, equivalently} \quad g = \Omega\left(\sqrt{\frac{n}{f(n/g)}}\right). \tag{1}$$

Assuming g satisfies (1), applying the 3-SUM Self-Reduction (Theorem 13) with $T(n) = S(n)$ and g, we can then solve 3-SUM in

$$\mathsf{TISP}\left(g^2(n + T(n/g)), n/g + T(n/g)\right) = \mathsf{TISP}\left(\frac{n^2}{f(n/g)}, n\right). \tag{2}$$

Now, set new time and space bounds $T(n) := n^2/f(n/g(n))$, $S(n) = n$ from (2). Then, applying the 3-SUM Self-Reduction (Theorem 13) with the new $T(n)$, $S(n)$ and some parameter h, we can then solve 3-SUM in $\mathsf{TISP}(h^2(n + T(n/h)), n/h + S(n/h)) =$

$$\mathsf{TISP}\left(h^2\left(n + \frac{n^2/h^2}{f(n/(hg(n/h)))}\right), n/h\right) \subseteq \mathsf{TISP}\left(\frac{n^2}{f(n/g)}, n/h\right),$$

by our hypothesis on h. ◀

4.3 Space-Efficient Fast 3-SUM

When we apply Theorem 14 directly to known algorithms, we obtain immediate space improvements with negligible loss in running time. Very recently, Gold and Sharir [16] have given a faster 3-SUM algorithm in the real-RAM model, building on the work of Gronlund and Pettie [17]:

▶ **Theorem 15** (Gold and Sharir [16]). *3-SUM can be solved in $O(n^2 \lg\lg(n)/\lg(n))$ time over the reals and integers.*

As discussed in the introduction, their novel approach uses quite a bit of space. Applying Theorem 14, we can reduce the space usage to only $O\left(\sqrt{n\lg(n)/\lg\lg(n)}\right)$, with the same asymptotic running time of Gold and Sharir.

▶ **Corollary 16** (Space-Efficient 3-SUM Algorithm). *3-SUM is in $\mathsf{TISP}\left(n^2\frac{\lg\lg(n)}{\lg(n)}, \sqrt{\frac{n\lg(n)}{\lg\lg(n)}}\right)$.*

Proof. We shall apply Theorem 14. First, set $f(n) := \lg(n)/\lg\lg(n)$, so that 3-SUM is solvable in $O(n^2/f(n))$ time by Theorem 15.

Set $g(n) := \sqrt{\frac{n\lg\lg(n)}{\lg(n)}}$ and $h(n) := \sqrt{\frac{n\lg\lg(n)}{\lg(n)}}$. By our choice of $f(n)$ and basic properties of logarithms, observe that

$$f(n/g) = f(\tilde{O}(\sqrt{n})) = \Theta(f(n)), \tag{3}$$

and furthermore

$$f(n/(hg(n/h))) = f\left(\tilde{O}(\sqrt{n})/\tilde{O}(n^{1/4})\right) = \Theta(f(n)). \tag{4}$$

By (3), we have

$$g = \sqrt{\frac{n\lg\lg(n)}{\lg(n)}} \geq \Omega\left(\sqrt{\frac{n}{f(n/g)}}\right), \text{ so the first constraint of Theorem 14 is satisfied.}$$

Moreover, by (4) we have

$$h^2 + \frac{n}{f(n/(hg(n/h)))} = \frac{n\lg\lg(n)}{\lg(n)} + \frac{n}{\Theta(f(n))}, \text{ which is } O\left(\frac{n}{f(n/g)}\right) \text{ by (3).}$$

Therefore the second constraint of Theorem 14 is also satisfied, and 3-SUM is solvable by an algorithm running in $O(n^2/f(n))$ time and $O\left(\sqrt{nf(n)}\right)$ space simultaneously. ◀

In general, Theorem 14 provides a generic *reduction* from faster 3-SUM algorithms to faster space-efficient 3-SUM algorithms. To illustrate:

▶ **Corollary 17.** *If 3-SUM is solvable in $O(n^2/\lg^a(n))$ time for some constant $a > 0$, then 3-SUM is in $\mathsf{TISP}(n^2/\lg^a(n), \sqrt{n}\lg^{a/2}(n))$.*

Proof. We apply Theorem 14. By assumption we have 3-SUM in $O(n^2/f(n))$ time, where $f(n) = \lg^a n$. Set $g(n) := \sqrt{n}/\lg^{a/2}(n)$, and $h(n) := \sqrt{n}/\lg^{a/2}(n)$. Note that $f(n/g(n)) = \Theta(\lg^a(n))$ and $f(n/(h(n)\cdot g(n/h(n)))) = \Theta(\lg^a(n))$, similar to Corollary 16. Therefore

$$g(n) = \sqrt{n}/\lg^{a/2}(n) \geq \Omega\left(\sqrt{\frac{n}{f(n/g(n))}}\right)$$

and

$$h^2 + \frac{n}{f(n/(hg(n/h)))} \leq O\left(\frac{n}{\lg^a n}\right) \leq O\left(\frac{n}{f(n/g(n))}\right).$$

Hence Theorem 14 applies to these settings of the parameters, and 3-SUM is in $O(n^2/f(n/g)) = O(n^2/\lg^a(n))$ time and $O(n/h) = O(\sqrt{n}\lg^{a/2}(n))$ space. ◀

4.4 The 3-SUM Conjecture and Small Space

Finally, we use the Space Reduction Theorem (Theorem 14) to show that the 3-SUM conjecture is false, then it is also false with respect to small-space algorithms.

▶ **Lemma 18.** *If 3-SUM is in $O(n^{2-\epsilon})$ time for some $\epsilon > 0$, then for every $\alpha > 0$, there is a $\delta > 0$ such that 3-SUM is solvable in $O(n^{2-\delta})$ time and $O(n^{1/2+\alpha})$ space, simultaneously.*

Proof. The proof of Theorem 14 applies the 3-SUM Self Reduction (Theorem 13) twice. We will basically perform the first part of the proof of Theorem 14, but instead of applying the second part of the proof, we have to choose a different setting of parameters, focused on minimizing the space usage instead of preserving running time.

Let $T(n) := n^2/f(n)$ with $f(n) = n^\epsilon$. We first reduce the space usage of the algorithm to linear. To this end, set $g(n) := n^{(1-\epsilon)/(2-\epsilon)}$. Then, applying the 3-SUM Self-Reduction (Theorem 13) with $T(n) = S(n)$ and $g(n)$, we can then solve 3-SUM in

$$\mathsf{TISP}(g^2(n + T(n/g)), n/g + T(n/g)) = \mathsf{TISP}\left(\frac{n^2}{f(n/g)}, n\right) = \mathsf{TISP}\left(\frac{n^2}{n^{\epsilon/(2-\epsilon)}}, n\right).$$

Now reset $f(n) := n^{\epsilon/(2-\epsilon)}$, and reset $g(n) := n^{1/2+\alpha}$ with $\alpha \in (0, 1/2)$. Applying the 3-SUM Self-Reduction (Theorem 13) with $T(n) = n^2/f(n)$, $S(n) = n$, and $g(n)$ as above, we find an algorithm for 3-SUM in

$$\mathsf{TISP}\left(n^{2-2\alpha} + n^{2-(1/2-\alpha)\epsilon/(2-\epsilon)}, n^{1/2+\alpha}\right).$$

Note that for all $\epsilon > 0$ and $\alpha \in (0, 1/2)$, the running time bound is truly subquadratic. Further note that for any $\alpha \geq 1/2$, we only have more space to work with, so we clearly obtain $O(n^{2-\delta})$ time and $O(n^{1/2+\alpha})$ space (for some $\delta > 0$) in that case as well. ◀

This lemma can be applied to show that the 3-SUM Conjecture is equivalent to seemingly much weaker statement:

The Small-Space 3-SUM Conjecture (Conjecture 5). *On a word-RAM with $O(\log n)$-bit words, there exists an $\epsilon > 0$ such that every algorithm that solves 3-SUM in $O(n^{1/2+\epsilon})$ space must take at least $n^{2-o(1)}$ time.*

▶ **Theorem 19.** *The Small-Space 3-SUM Conjecture is equivalent to the 3-SUM Conjecture.*

Proof. It suffices to show that the 3-SUM Conjecture if true implies the Small-Space 3-SUM Conjecture and that the refutation of the 3-SUM Conjecture implies the Small-Space 3-SUM Conjecture. First, we observe that the 3-SUM Conjecture trivially implies the Small-Space 3-SUM Conjecture.

Suppose the 3-SUM Conjecture is false. Then a $O(n^{2-\epsilon})$ time algorithm for 3-SUM exists, and Lemma 18 implies that for every $\alpha > 0$, there is a $\delta > 0$ such that 3-SUM is solvable in $O(n^{2-\delta})$ time and $O(n^{1/2+\alpha})$ space, simultaneously. But this means that for any choice of $\epsilon' > 0$ for the Small-Space 3-SUM Conjecture, we can find a truly-subquadratic 3-SUM algorithm that uses only $O(n^{1/2+\epsilon'/2})$ space. This would falsify the Small-Space 3-SUM Conjecture. ◀

We conclude that, in order to prove the 3-SUM conjecture, it is sufficient to prove that no algorithm can solve 3-SUM in $\mathsf{TISP}(n^{2-\epsilon}, n^{0.51})$ for some $\epsilon > 0$.

5 k-SUM

5.1 k-SUM Self-Reduction

We now generalize from 3-SUM to k-SUM. Again, we plan to split the lists into g groups of size $O(n/g)$. By Corollary 11, we will have only $O(g^{k-1})$ subproblems of size $O(n/g)$. Unlike 3-SUM, where we just used the naive algorithm to solve subproblems, in this section we use a general algorithm; we reduce from k-SUM to itself (albeit on smaller instances).

▶ **Theorem 20.** *Suppose real k-SUM can be solved in $\mathsf{TISP}(T(n), S(n))$. Then for any g, it can also be solved in $\mathsf{TISP}(g^{k-1}(n + T(n/g)), n/g + S(n/g))$.*

Proof. This follows from a generalized analysis of the proof of Theorem 13. We brute force over which groups the first $k-1$ elements are in. We then extract groups where the negative sum of elements from these first $k-1$ groups could land. By Corollary 11 and similar reasoning as before, there are only $O(g^{k-1})$ tuples of blocks. For each tuple, we make a call to NextGroup and to our input k-SUM algorithm on a subproblem of size $O(n/g)$. This gives the desired time and space, completing the proof. ◀

5.2 Applying our k-SUM Self-Reduction

We want to apply the self-reduction on efficient deterministic algorithms. One of the best starting points is the Schroeppel-Shamir 4-SUM algorithm, which we note is actually deterministic and works on reals because it simply uses priority queues and reduces to the classic 2-SUM algorithm, both of which only use comparisons.

▶ **Lemma 21** (From [23]). *Real 4-SUM is solvable in* $\mathit{TISP}(n^2, n)$.

Another useful fact observed by Wang is that an algorithm for k-SUM can be transformed into an algorithm for $(k+1)$-SUM by brute-forcing one element:

▶ **Lemma 22** (From [25]). *If Real k-SUM is solvable in* $\mathit{TISP}(T(n), S(n))$ *then real $k+1$-SUM is solvable in* $\mathit{TISP}(nT(n), S(n)+1)$.

Suppose we want to use our results to derive a linear-space algorithm for k-SUM. We will assume k is a multiple of 4, although Lemma 22 allows us to fill in for the other values of k. By writing down sums of $k/4$ elements, we can transform k-SUM to 4-SUM, yielding a $\mathsf{TISP}(n^{k/2}, n^{k/4})$ algorithm. We can then apply Theorem 20 with $g = n^{(k-4)/k}$ to get a $\mathsf{TISP}(n^{k-3+4/k}, n)$ algorithm. Notice that this algorithm runs significantly faster than $O(n^k)$ time; we get $O(n^{11/2})$ for 8-SUM and $O(n^{28/3})$ for 12-SUM. As a coarse upper bound, we can apply Lemma 22 and round down our savings (to make things cleaner), compensating for k which are not a multiple of 4, we get:

▶ **Corollary 23.** *For $k \geq 4$, k-SUM is solvable in* $\mathit{TISP}(n^{k-3+4/(k-3)}, n)$.

Suppose we wanted to use $O(\sqrt{n})$ space instead. We get smaller subproblems by making more groups; choosing $g = n^{(k-2)/k}$ instead yields a $\mathsf{TISP}(n^{k-2+2/k}, \sqrt{n})$. Similarly applying Lemma 22 and round down our savings to compensate for k which are not a multiple of 4, we get another coarse upper bound:

▶ **Corollary 24.** *For $k \geq 4$, k-SUM is solvable in* $\mathit{TISP}(n^{k-2+2/k}, \sqrt{n})$.

6 Future Work

We would like to extend these results to derandomize other known randomized algorithms for k-SUM. To do that, it seems we require a "deterministic simulation" of the hash functions used in those results. Baran, Demaine, and Patrascu use hashing to get subquadratic algorithms for 3-SUM [7]; Patrascu uses it to reduce 3-SUM to Convolution 3-SUM [20]; Wang uses it to produce a family of linear-space algorithms for k-SUM [25]. Which of these results, if any, can be derandomized?

The hash families involved have three crucial properties: load-balancing (the hash buckets are not "too large"), few subproblems (the number of k-tuples of hash buckets examined is "small"), and few false positives (there are few non-k-SUM solutions mapped to k-tuples of hash buckets examined). Our s-Select algorithm (Lemma 12) and Domination Lemma (Lemma 10) are used to achieve the first two properties, without using randomization. Can the last property also be simulated deterministically? (Note that it's not entirely clear what it would mean to simulate "few false positives" deterministically.) If so, it is likely that all these results can be derandomized efficiently.

Semi-Streaming Algorithms for Annotated Graph Streams*

Justin Thaler†

Yahoo Labs, New York, USA

Abstract

Considerable effort has been devoted to the development of streaming algorithms for analyzing massive graphs. Unfortunately, many results have been negative, establishing that a wide variety of problems require $\Omega(n^2)$ space to solve. One of the few bright spots has been the development of *semi-streaming* algorithms for a handful of graph problems – these algorithms use space $O(n \cdot \text{polylog}(n))$.

In the annotated data streaming model of Chakrabarti et al. [7], a computationally limited client wants to compute some property of a massive input, but lacks the resources to store even a small fraction of the input, and hence cannot perform the desired computation locally. The client therefore accesses a powerful but untrusted service provider, who not only performs the requested computation, but also *proves* that the answer is correct.

We consider the notion of *semi-streaming algorithms for annotated graph streams* (semi-streaming annotation schemes for short). These are protocols in which both the client's space usage and the length of the proof are $O(n \cdot \text{polylog}(n))$. We give evidence that semi-streaming annotation schemes represent a more robust solution concept than does the standard semi-streaming model. On the positive side, we give semi-streaming annotation schemes for two dynamic graph problems that are intractable in the standard model: (exactly) counting triangles, and (exactly) computing maximum matchings. The former scheme answers a question of Cormode [22]. On the negative side, we identify for the first time two natural graph problems (connectivity and bipartiteness in a certain edge update model) that can be solved in the standard semi-streaming model, but cannot be solved by annotation schemes of "sub-semi-streaming" cost. That is, these problems are as hard in the annotations model as they are in the standard model.

1 Introduction

The rise of cloud computing has motivated substantial interest in protocols for *verifiable data stream computation*. These protocols allow a computationally weak client (or *verifier*), who lacks the resources to locally store a massive input, to outsource the storage and processing of that input to a powerful but untrusted service provider (or *prover*). Such protocols provide a guarantee that the answer returned by the prover is correct, while allowing the verifier to make only a single streaming pass over the input.

Several recent works have introduced closely related models capturing the above scenario [18, 7, 8, 19, 6, 20, 12, 13, 11]. Collectively, these works have begun to reveal a rich theory, leveraging algebraic techniques developed in the classical theory of interactive proofs [23, 29, 4, 16] to obtain efficient verification protocols for a variety of problems that require linear space in the standard streaming model (sans prover).

The primary point of difference among the various models of verifiable stream computation that have been proposed is the amount of interaction that is permitted between the verifier and prover. The *annotated data streaming* model of Chakrabarti et al. [7] (subsequently studied in [12, 19, 6, 11]) is non-interactive, requiring the correctness proof to consist of just a single message from the prover to the verifier, while other models, such as the *Arthur–Merlin streaming protocols* of Gur and Raz [18, 6] and the *streaming interactive proofs* of Cormode et al. [13, 8] permit the prover and verifier to exchange two or more messages. Our focus in this paper is on the annotated data streaming model of Chakrabarti et al. – owing to their non-interactive nature, protocols in this model possess a number of desirable properties not shared by their interactive counterparts, such as reusability (see Section 2 for details). We are concerned with protocols for problems on graph streams, described below.

Graph Streams. The ubiquity of massive relational data sets (derived, e.g., from the Internet and social networks) has led to detailed studies of data streaming algorithms for analyzing graphs. In this setting, the data stream consists of a sequence of edges, defining a graph G on n nodes, and the goal is to compute various properties of G (is G connected? How many triangles does G contain?). Unfortunately, many results on graph streaming have been negative: essentially any graph problem of the slightest practical interest requires $\Omega(n)$ space to solve in the standard streaming model, and many require $\Omega(n^2)$ space even to approximate. Due to their prohibitive cost in the standard streaming model, many basic graph problems are ripe for outsourcing.

One of the few success stories in the study of graph streams has been the identification of the *semi-streaming* model as something of a "sweet spot" for streaming algorithms[26, 24]. The semi-streaming model is characterized by an $O(n \cdot \operatorname{polylog} n)$ space restriction, i.e., space proportional to the number of nodes rather than the number of edges. For dense graphs this represents considerably less space than that required to store the entire graph. It has long been known that problems like connectivity and bipartiteness possess semi-streaming algorithms when the stream consists only of edge insertions, with no deletions. Recently, semi-streaming algorithms have been provided for these and other problems even for dynamic graph streams, which contain edge deletions as well as insertions [1, 2, 14]. We direct the interested reader toward the recent survey of McGregor [25] on graph stream algorithms.

In this work, we consider the notion of *semi-streaming annotation schemes* for graph problems. Here, the term "scheme" refers to a protocol in the annotated data streaming model. A scheme's total cost is defined to be the sum of the verifier's space usage (referred to as the *space cost* of the scheme) and the length of the proof (referred to as the scheme's *help cost*). A scheme is said to be semi-streaming if its total cost is $O(n \cdot \operatorname{polylog} n)$.

We give evidence that semi-streaming annotation schemes represent a substantially more robust solution concept (i.e., a "sweeter spot") for graph problems than does the standard semi-streaming model. First, we give novel semi-streaming annotation schemes for two challenging dynamic graph problems, counting triangles and maximum matching, that require $\Omega(n^2)$ space in the standard streaming model. The total cost of these schemes is provably optimal up to a logarithmic factor. Second, we show that two canonical problems that do possess semi-streaming algorithms in the standard streaming model (connectivity

Table 1 Comparison of our new scheme for TRIANGLES to prior work.

Reference	TRIANGLES Scheme Costs (help cost, space cost)	Total Cost Achieved
[7]	$(n^2 \log n, \log n)$	$O(n^2 \log n)$
[7]	$(x \log n, y \log n)$ for any $x \cdot y \geq n^3$	$O(n^{3/2} \log n)$
Theorem 1	$(n \log n, n \log n)$	$O(n \log n)$

and bipartiteness in a certain edge update model) are *just as hard* in the annotations model. Formally, we show that any scheme for these problems with space cost $O(n^{1-\delta})$ requires a proof of length $\Omega(n^{1+\delta})$ for any $\delta > 0$. Thus, for these problems, giving a streaming algorithm access to an untrusted prover does not allow for a significant reduction in cost relative to what is achievable without a prover. This gives further evidence for the robustness of semi-streaming annotation schemes as a solution concept: while several fundamental problems that cannot be solved by standard semi-streaming algorithms can be solved by semi-streaming annotation schemes, there are problems that do have semi-streaming solutions in the standard model that cannot be solved by schemes of sub-semi-streaming cost.

1.1 Summary of Contributions and Techniques

Throughout this informal overview, n will denote the number of nodes in the graph defined by the data stream, and m the number of edges. To avoid boundary cases in the statement of our lower bounds, we assume that the help cost of any scheme is always at least 1 bit.

1.1.1 New Semi-Streaming Annotation Schemes

Prior work has given semi-streaming annotation schemes for two graph problems that require $\Omega(n^2)$ space in the standard semi-streaming model: bipartite perfect matching [7], and shortest s-t path in graphs of polylogarithmic diameter [12]. As discussed above, we give semi-streaming schemes for two more challenging problems: maximum matching (MAXMATCHING) and counting triangles (TRIANGLES). Both schemes apply to dynamic graph streams. We begin by describing our result for TRIANGLES.

▶ **Theorem 1** (Informal Version of Theorem 4). *There is a scheme for* TRIANGLES *with total cost $O(n \log n)$. Every scheme requires the product of the space and help costs to be $\Omega(n^2)$, and hence has total cost $\Omega(n)$.*

Theorem 1 affirmatively answers a question of Cormode [22], resolves the Merlin-Arthur communication complexity of the problem up to a logarithmic factor, and improves over the best previous bound of $O(n^{3/2} \log n)$, due to [7] (see Table 1 for a comparison).

As is the case for essentially all non-trivial protocols for verifiable stream computation, the scheme of Theorem 1 uses algebraic techniques related to the famous *sum-check protocol* of Lund et al. [23] from the classical theory of interactive proofs. Yet, our scheme deviates in a significant way from all earlier annotated data stream and interactive proof protocols [15, 8, 7, 29]. Roughly speaking, in previous protocols, the verifier's updates to her memory state were commutative, in the sense that reordering the stream tokens would not change the final state reached by the verifier. However, our new verifier is inherently non-commutative: her update to her state at time i depends on her actual state at time i, and reordering the stream tokens can change the final state reached by the verifier. The full version of the paper contains further discussion of this point.

Table 2 Comparison of our new scheme for MaxMatching to prior work.

Reference	MaxMatching Scheme Costs (help cost, space cost)	Total Cost Achieved
[12]	$(m \log n, \log n)$	$O(m \log n)$
Theorem 5	$(n \log n, n \log n)$	$O(n \log n)$

▶ **Theorem 2** (Informal Version of Theorem 5). *There is a scheme for* MaxMatching *with total cost $O(n \log n)$. Every scheme for* MaxMatching *requires the product of the space and help costs to be $\Omega(n^2)$, and hence has total cost $\Omega(n)$.*

Our scheme combines the Tutte-Berge formula with algebraic techniques to allow the prover to establish matching upper and lower bounds on the size of a maximum matching in the input graph. Schemes for maximum matching had previously been studied by Cormode et al. [12], but this prior work only gave schemes with help cost proportional to the number of edges, which is $\Omega(n^2)$ in dense graphs (like us, Cormode et al. exploited the Tutte-Berge formula, but did not do so in a way that achieved help cost sublinear in the input size). Prior work had also given a scheme achieving optimal tradeoffs between help and space costs for *bipartite perfect matching* [7, Theorem 7.5] – our scheme for MaxMatching can be seen as a broad generalization of [7, Theorem 7.5].

1.1.2 New Lower Bounds

On the other hand, we identify, for the first time, natural graph problems that possess standard semi-streaming algorithms, but in a formal sense are just as hard in the annotations model as they are in the standard streaming model. The problems that we consider are connectivity and bipartiteness in a certain edge update model that we call the XOR update model. In this update model, the stream $\langle e_1, \ldots, e_m \rangle$ is a sequence of edges from $[n] \times [n]$, which define a graph $G = (V, E)$ via: $e \in E \iff |\{i : e_i = e\}| = 1 \mod 2$. Intuitively, each stream update e_i is interpreted as changing the status of edge e_i: if it is currently in the graph, then the update causes e_i to be deleted; otherwise e_i is inserted. Our lower bound holds for schemes for connectivity and bipartiteness in the XOR update model, even under the promise that $e_1, \ldots, e_{m-n}$ are all unique (hence, all but the last n stream updates correspond to edge insertions), and the last n updates are all incident to a single node.

▶ **Theorem 3** (Informal Version of Corollary 7). *Consider any scheme for* Connectivity *or* Bipartiteness *in the XOR update model with help cost c_a and and space cost c_v. Then $(c_a + n) \cdot c_v \geq n^2$, even under the promise that the first $m - n$ stream updates are all unique, and the last n stream updates are all incident to a single node. In particular, the total cost of any annotation scheme for these problems is $\Omega(n)$.*

Both connectivity and bipartiteness in the XOR update model possess standard semi-streaming algorithms [1].[1] Hence, Theorem 3 implies that the total cost of any annotation scheme is at most a polylogarithmic factor smaller than the problems' space complexity in the standard streaming model. Like all prior work establishing lower bounds on the cost of

[1] The algorithms of [1] are described in the turnstile update model, in which each stream update explicitly specifies whether to insert or delete a (copy of) an edge. However, these algorithms are easily modified to apply to the XOR update model as well. In brief, these algorithms have L_0-sampling algorithms at their core. Existing L_0-samplers are in turn built on top of sparse recovery algorithms (see, e.g., [10]), and many sparse recovery algorithms can be implemented in the XOR update model directly (see, e.g., [17]).

protocols for verifiable stream computation, our lower bounds are established using notions of *Merlin-Arthur communication complexity* [7, 12, 19, 8, 18].

Prior to this work, only one other problem was known to be as hard (up to logarithmic factors) in the annotations model as in the standard streaming model [6, Corollary 3.3]. The problem considered in [6, Corollary 3.3] was an "exponentially sparse" variant of the classic INDEX problem, in which the data stream consists of a vector $x \in \{0,1\}^n$ promised to have Hamming weight $O(\log n)$, followed by an index $i \in [n]$, and the goal is to output the value x_i. Connectivity and bipartiteness are arguably more natural problems, and are qualitatively different, as we now explain.

On an informal level, the reason the exponentially sparse INDEX problem is hard in the annotations model is that any "useful" annotation must at least specify a single index into the vector x, which requires $\log n$ bits of annotation. And since x is exponentially sparse, $\log n$ is actually equal (up to a constant factor) to the space complexity of a standard streaming algorithm for the problem. In our view, BIPARTITENESS and CONNECTIVITY are hard in the annotations for a different reason – roughly speaking, any useful annotation for these problems must at least specify, for each node u, the side of the bipartition or the connected component in which u resides.

Overview of the Proof. Our proof of Theorem 3 works by specifying a reduction from the INDEX problem on inputs of length n^2, for which a lower bound of $\Omega(n^2)$ on the product of the help and space costs of any annotation scheme was established in [7], to CONNECTIVITY and BIPARTITENESS on graphs with n nodes and $\Theta(n^2)$ edges.

Notice that in the standard (sans prover) streaming model, the INDEX problem on n^2 variables is strictly harder than connectivity and bipartiteness problems on graphs with n nodes, as the former requires $\Omega(n^2)$ space, while the latter two problems require only $O(n \cdot \text{polylog}(n))$ space. Yet Theorem 3 establishes that in the annotations model, all three problems are of essentially equivalent difficulty (in particular, schemes of total cost $\tilde{O}(n)$ are necessary and sufficient to solve all three problems). To establish such a result, it is necessary to use a reduction that is specifically tailored to the annotations model, in the sense that the reduction must not apply in the standard streaming model (since INDEX and CONNECTIVITY are not of equivalent difficulty in the standard setting). Namely, in our reduction from INDEX to connectivity, the prover *helps the verifier* transform an instance of the INDEX problem into a CONNECTIVITY instance. This "help" consists of $\Theta(n)$ bits, and this is why our lower bound is of the form $(c_a + n) \cdot c_v \geq n^2$. This is in contrast to prior lower bounds, which, with the exception of [6, Corollary 3.3], were of the form $c_a \cdot c_v = \Omega(C)$ for some quantity C.

1.2 Other Related Work

As discussed above, several recent papers [11, 8, 13, 19, 20, 18, 6, 7, 12] have all studied annotated data streams and closely related models for verifiable stream computation. Refinements and implementations [11, 31] have demonstrated genuine practicality for many of the protocols developed in this line of work. Protocols for verifiable stream computation have also been studied in the cryptography community [9, 27]. These works only require security against cheating provers that run in polynomial time, whereas we require security to hold even against computationally unbounded provers. In exchange for the weaker security guarantee, these protocols may achieve properties that are unattainable in our information-theoretic setting. For example, some of these protocols achieve a stronger form of reusability than we do (see Section 2 for our definition of reusability) – they remain secure for many uses even if the prover learns all of the verifier's accept/reject decisions. The work of Chung et al. [9]

uses fully homomorphic encryption (FHE), which remains far from practical at this time. Papamanthou et al. [27] avoid the use of FHE, but handle only much simpler queries (e.g., point queries and range search) than the graph problems we consider here.

2 Models of Streaming Computation

Our presentation of data streaming models closely follows Chakrabarti et al. [6]. Recall that a (standard) data stream algorithm computes a function f of an input sequence $\mathbf{x} \in \mathcal{U}^m$, where m is the number of stream updates, and $\mathcal{U}$ is some data universe. The algorithm has only sequential access to $\mathbf{x}$, uses a limited amount of space, and has access to a random string. The function f may or may not be Boolean. An annotated data stream algorithm, or a *scheme*, is a pair $\mathcal{A} = (\mathfrak{h}, V)$, consisting of a help function $\mathfrak{h} : \mathcal{U}^m \times \{0,1\}^* \to \{0,1\}^*$ used by a *prover* and a data stream algorithm run by a *verifier*, V. The prover provides $\mathfrak{h}(\mathbf{x})$ as annotation to be read by the verifier. We think of $\mathfrak{h}$ as being decomposed into $(\mathfrak{h}_1, \ldots, \mathfrak{h}_m)$, where the function $\mathfrak{h}_i : \mathcal{U}^m \to \{0,1\}^*$ specifies the annotation supplied after the arrival of the ith token x_i. That is, $\mathfrak{h}$ acts on $\mathbf{x}$ to create an *annotated stream* $\mathbf{x}^{\mathfrak{h}}$ defined as follows:

$$\mathbf{x}^{\mathfrak{h}} := (x_1, \mathfrak{h}_1(\mathbf{x}), x_2, \mathfrak{h}_2(\mathbf{x}), \ldots, x_m, \mathfrak{h}_m(\mathbf{x})) .$$

Note that this is a stream over $\mathcal{U} \cup \{0,1\}$, of length $m + \sum_i |\mathfrak{h}_i(\mathbf{x})|$. The streaming verifier, who has access to a (private) random string r, then processes this annotated stream, eventually giving an output $\text{out}^V(\mathbf{x}^{\mathfrak{h}}, r)$.

We say a scheme is *online* if each function $\mathfrak{h}_i$ depends only on $(x_1, \ldots, x_i)$. The scheme $\mathcal{A} = (\mathfrak{h}, V)$ is said to be δ_s-sound and δ_c-complete for the function F if the following hold:

1. For all $\mathbf{x} \in \mathcal{U}^m$, we have $\Pr_r[\text{out}^V(\mathbf{x}^{\mathfrak{h}}, r) \neq F(\mathbf{x})] \leq \delta_c$.
2. For all $\mathbf{x} \in \mathcal{U}^m$, $\mathfrak{h}' = (\mathfrak{h}'_1, \mathfrak{h}'_2, \ldots, \mathfrak{h}'_m) \in (\{0,1\}^*)^m$, we have $\Pr_r[\text{out}^V(\mathbf{x}^{\mathfrak{h}'}, r) \notin \{F(\mathbf{x})\} \cup \{\perp\}] \leq \delta_s$.

An output of "$\perp$" indicates that the verifier rejects the prover's claims in trying to convince the verifier to output a particular value for $F(\mathbf{x})$. We define $\text{err}(\mathcal{A})$ to be the minimum value of $\max\{\delta_s, \delta_c\}$ such that the above conditions are satisfied. We define the *annotation length* $\text{hc}(\mathcal{A}) = \max_{\mathbf{x}} \sum_i |\mathfrak{h}_i(\mathbf{x})|$, the total size of the prover's communications, and the *verification space cost* $\text{vc}(\mathcal{A})$ to be the space used by the verifier. We say that $\mathcal{A}$ is an online (c_a, c_v) scheme if $\text{hc}(\mathcal{A}) = O(c_a)$, $\text{vc}(\mathcal{A}) = O(c_v)$, and $\text{err}(\mathcal{A}) \leq \frac{1}{3}$ (the constant 1/3 is arbitrary and chosen by convention).

Chakrabarti et al. [7] also define the notion of a *prescient* scheme, which is the same as an online scheme, except the annotation at any time i is allowed to depend on data which the verifier has not seen yet. Prescient schemes have the undesirable property that the prover may need to "see into the future" to convince the verifier to produce the correct output. Note that even though our Triangles and MaxMatching protocols are online, they are optimal up to logarithmic factors *even among prescient schemes* (see Theorems 4 and 5).

While the annotated data streams model allows the prover to interleave the annotation with the stream, in all of the schemes we present in this paper, all of the annotation comes at the end of the stream. This property avoids any need for fine-grained coordination between the annotation and the stream, and permits the prover to send the annotation as a single email attachment, or post it to a website. We clarify that the *lower bounds* for Connectivity and Bipartiteness that we establish in Section 4 apply to any online scheme, even those which interleave the annotation with the stream.

The schemes we present in this work permit a natural form of *reusability*: if the verifier wants to compute a function f on a given dataset $\mathbf{x}$, the verifier can receive $f(\mathbf{x})$ (with

a correctness proof), and check the validity of the proof using a "secret state" that she computed while observing the stream $\mathbf{x}$. Further updates to the stream $\mathbf{x}$ can then occur, yielding a (longer) stream $\mathbf{x}'$, and the verifier can update her secret in a streaming fashion. The verifier may then receive the answer $f(\mathbf{x}')$ (with a correctness proof) on the updated dataset, and check its correctness using the updated secret state. The probability that the verifier gets fooled into outputting an incorrect answer on even a single query grows only linearly with the number of times the prover sends the verifier an answer. Such reusability is not possible with interactive solutions [13, 8, 20], which require the verifier to reveal information about r over the course of the protocol.

3 Upper Bounds

Graph Streams in the Strict Turnstile Model. The annotation schemes of this section apply to graph streams in the strict turnstile update model. In this model, a data stream σ consists of a sequence of undirected edges, accompanied by (signed) multiplicities: $\langle (e_1, \Delta_1), \ldots, (e_m, \Delta_m) \rangle$. Each edge $e_i \in [n] \times [n]$, and each $\Delta_i \in \mathbb{Z}$. An update (e_i, Δ_i) with $\Delta_i > 0$ is interpreted as an insertion of Δ_i copies of edge e_i into graph G. If $\Delta_i < 0$, the update is interpreted as a deletion of Δ_i copies of edge e_i. It is assumed that at the end of the stream, no edge has been deleted more times than it has been inserted (all of our protocols work even if this property does not hold at *intermediate* time steps, as long as the property holds after the final stream update has been processed).[2] When analyzing the time costs of our schemes, we assume that any addition or multiplication in a finite field of size poly(n) takes one unit of time.

3.1 A Semi-Streaming Scheme for Counting Triangles

In the TRIANGLESproblem, the goal is to determine the number of unordered triples of distinct vertices (u, v, z) such that edges (u, v), (v, z), and (z, u) all appear in G. More generally, if these edges appear with respective multiplicities M_1, M_2, and M_3, we view triple (u, v, z) as contributing $M_1 \cdot M_2 \cdot M_3$ triangles to the total count.[3] Computing the number of triangles is a well-studied problem [3] and there has been considerable interest in designing algorithms in a variety of models including the data stream model [5, 28], MapReduce [30], and the quantum query model [21]. One motivation is the study of social networks where important statistics such as the clustering coefficient and transitivity coefficient are based on the number of triangles. Understanding the complexity of counting triangles captures the ability of a model to perform a non-trivial correlation within large graphs. Chakrabarti et al. [7] gave two annotated data streaming protocols for this problem. The first protocol had help cost $O(n^2 \log n)$, and space cost $O(\log n)$. The second protocol achieved help cost $O(x \log n)$ and space cost $O(y \log n)$ for any x, y such that $x \cdot y \geq n^3$. In particular, by setting $x = y = n^{3/2}$, the second protocol of Chakrabarti et al. ensured that both help cost and space cost equaled $O\left(n^{3/2} \log n\right)$. Cormode [22] asked whether it is possible to achieve an annotated data streaming protocol in which both the help cost and space cost are $\tilde{O}(n)$. We

[2] We do not consider edges with negative weights at the end of the stream because it is unclear what is the most meaningful way to define problems like TRIANGLES and MAXMATCHING in this setting. See Footnotes 3 and 4.

[3] The TRIANGLESscheme of Theorem 3.1 gives meaningful results even if the M_i's may be negative: a triangle with an odd (even) number of edges of negative multiplicity contributes a negative (positive) number to the total triangle count.

answer this question in the affirmative.

▶ **Theorem 4** (Formal Statement of Theorem 1)**.** *Assume there is an a priori upper bound $B \leq \text{poly}(n)$ on the multiplicity of any edge in G. There is an online scheme for* Triangles *with space and help costs $O(n \log n)$. Every scheme (online or prescient) requires the product of the space and help costs to be $\Omega(n^2)$, and hence total cost $\Omega(n)$, even for $B = 1$, and even if G is promised to have exactly 0 or 1 triangles.*

Discussion. Before proving Theorem 4, it is instructive to consider a simple *interactive* streaming verification protocol for Triangles(described in detail in the full version of the paper). At a high level, the interactive protocol applies the sum-check protocol of Lund et al. [23] to a suitably defined multivariate polynomial h. The space and communication costs of this protocol are comparable to that of Theorem 4; the advantage of Theorem 4 over this simple interactive solution is that Theorem 4 gives a protocol that is *non-interactive*, and comes with the associated reusability benefits described in Section 2. Theorem 4 below effectively removes the interaction from the simple interactive protocol as follows. We identify a *univariate* polynomial $g(Z)$ of degree $O(n)$ such that the number of triangles in G equals $\sum_{z \in [n]} g(Z)$. Moreover, we show that the verifier can evaluate $g(r)$ for any point $r \in \mathbb{F}$ in space $O(n \log |\mathbb{F}|)$ with a single streaming pass over the input. It follows that applying the sum-check protocol to g yields a scheme with costs claimed in Theorem 4. The polynomial g that we identify is defined as a sum of m constituent polynomials, one per stream update.

Proof of Theorem 4. The lower bound was proved in [7, Theorem 7.1]. Details of the upper bound follow. Let G_i denote the graph defined by the first i stream updates $\langle (e_1, \Delta_1), \ldots, (e_i, \Delta_i) \rangle$, and let $E_i \colon [n] \times [n] \to \mathbb{Z}$ denote the function that outputs the multiplicity of the edge (u, v) in graph G_{i-1}. On edge update $e_i = (u_i, v_i)$, notice that the number of triangles that e_i *completes* in E_i is precisely $\Delta_i \cdot \sum_{z \in [n]} E_i(u_i, z) E_i(v_i, z)$. Thus, the total number of triangles in the graph $G = G_m$ is precisely $\sum_{i \leq m} \Delta_i \sum_{z \in [n]} E_i(u_i, z) E_i(v_i, z)$. Let $\mathbb{F}$ denote a field of prime order $6(B \cdot n)^3 \leq |\mathbb{F}| \leq 12(B \cdot n)^3$, and let $\tilde{E}_i(X, Y)$ denote the unique polynomial over $\mathbb{F}$ of degree at most n in each variable X, Y such that $\tilde{E}_i(u, v) = E_i(u, v)$ for all $(u, v) \in [n] \times [n]$. Then the number of triangles in G equals

$$\sum_{i \leq m} \Delta_i \sum_{z \in [n]} E_i(u_i, z) E_i(v_i, z) = \sum_{i \leq m} \Delta_i \sum_{z \in [n]} \tilde{E}_i(u_i, z) \tilde{E}_i(v_i, z) = \sum_{z \in [n]} \sum_{i \leq m} \Delta_i \tilde{E}_i(u_i, z) \tilde{E}_i(v_i, z). \tag{1}$$

In turn, the right hand side of Equation (1) can be written as $\sum_{z \in [n]} g(z)$, where g denotes the *univariate* polynomial defined via: $g(Z) = \sum_{i \leq m} \Delta_i \cdot \tilde{E}_i(u_i, Z) \tilde{E}_i(v_i, Z)$. Notice $g(Z)$ is a univariate polynomial of degree at most $2n$. Our scheme proceeds as follows.

Prover's computation. At the end of the stream, the prover sends a univariate polynomial $s(Z)$ of degree at most $2n$, where $s(Z)$ is claimed to equal $g(Z)$. Notice that since $s(Z)$ has degree at most $2n$, $s(Z)$ can be specified by sending its values on all inputs in $\{0, \ldots, 2n\}$ – this requires help cost $O(n \log |\mathbb{F}|) = O(n \log n)$.

Verifier's computation. At the start of the stream, the verifier picks a random field element $r \in \mathbb{F}$, and keeps the value of r secret from the prover. We will show below that the verifier can evaluate $g(r)$ with a single streaming pass over the input, using space $O(n \log n)$. The

verifier checks whether $s(r) = g(r)$. If this check fails, the verifier halts and rejects. If the check passes, the verifier outputs $\sum_{z \in [n]} s(z)$ as the correct answer.

We now explain how the verifier can evaluate $g(r)$ with a single streaming pass over the input. The high-level idea is as follows. $g(r)$ is defined as a sum of m terms, where the ith term equals $\Delta_i \cdot \tilde{E}_i(u_i, r)\tilde{E}_i(v_i, r)$. For each $u \in [n]$, we will show how the verifier can incrementally maintain the quantity $\tilde{E}_i(u, r)$ at all times i. The verifier will maintain all n of these quantities, resulting in a total space cost of $O(n \log |\mathbb{F}|) = O(n \log n)$. With these quantities in hand, it is straightforward for the verifier to incrementally maintain the sum $\sum_{j \leq i} \Delta_j \cdot \tilde{E}_j(u_j, r)\tilde{E}_j(v_j, r)$ at all times i: upon the ith stream update, the verifier simply adds $\Delta_i \cdot \tilde{E}_i(u_i, r) \cdot \tilde{E}_i(v_i, r)$ to the running sum.

To maintain the quantity $\tilde{E}_i(u, r)$, we begin by writing the bivariate polynomial $\tilde{E}_i(X, Y)$ in a convenient form. Given a pair $(u, v) \in [n] \times [n]$, let $\tilde{\delta}_{(u,v)}$ denote the following (Lagrange) polynomial: $\tilde{\delta}_{(u,v)}(X, Y) = \left(\frac{\prod_{1 \leq u' \leq n : u' \neq u}(X - u')}{\prod_{1 \leq u' \leq n : u' \neq u}(u - u')}\right)\left(\frac{\prod_{1 \leq v' \leq n : v' \neq v}(Y - v')}{\prod_{1 \leq v' \leq n : v' \neq v}(v - v')}\right)$. Notice that $\tilde{\delta}_{(u,v)}$ evaluates to 1 on input (u, v), and evaluates to 0 on all other inputs $(x, y) \in [n] \times [n]$. Thus, we may write $\tilde{E}_i(X, Y) = \sum_{j \leq i} \tilde{\delta}_{(u_j, v_j)}(X, Y)$. In particular, for each node $u \in [n]$,

$$\tilde{E}_i(u, r) = \tilde{E}_{i-1}(u, r) + \tilde{\delta}_{(u_i, v_i)}(u, r) + \tilde{\delta}_{(v_i, u_i)}(u, r).$$

Thus, the verifier can incrementally maintain the quantity $\tilde{E}_i(u, r)$ in a streaming manner using space $O(\log |\mathbb{F}|)$: while processing the ith stream update, the verifier simply adds $\tilde{\delta}_{(u_i, v_i)}(u, r) + \tilde{\delta}_{(v_i, u_i)}(u, r)$ to the running sum tracking $\tilde{E}_i(u, r)$.

Completeness. It is evident that if the prover sends the true polynomial $g(Z)$, then the verifier's check will pass, and the verifier will output the correct number of triangles.

Soundness. If the prover sends a polynomial $s(Z) \neq g(Z)$, then with probability at least $1 - 2n/|\mathbb{F}| \geq 1 - 1/(3n^2)$ over the verifier's random choice of $r \in \mathbb{F}$, it will hold that $s(r) \neq g(r)$. Hence, with probability at least $1 - 1/(3n^2) \geq 2/3$, the verifier's check will fail. ◀

Several remarks regarding Theorem 4 are in order.

- **Verifier Time.** The verifier in the protocol of Theorem 4 can process each stream update in constant time as follows. On stream update $e_i = (u_i, v_i)$, the verifier must add $\tilde{\delta}_{(u_i, v_i)}(u, r) + \tilde{\delta}_{(v_i, u_i)}(u, r)$ to each of the $\tilde{E}_i(u, r)$ values. However, it is straightforward to check that $\tilde{\delta}_{(u_i, v_i)}(u, r) = 0$ for all $u \neq u_i$, so the verifier need only update two quantities at time i: $\tilde{E}_i(u_i, r)$ and $\tilde{E}_i(v_i, r)$. We explain how both of these updates can be computed in constant time. It can be seen that $\tilde{\delta}_{(u_i, v_i)}(u_i, r) = \frac{\prod_{1 \leq v' \leq n : v' \neq v_i}(r - v')}{\prod_{1 \leq v' \leq n : v' \neq v_i}(v_i - v')}$. The right hand side of this equation can be computed in $O(1)$ time if the verifier maintains a pre-computed lookup table consisting of $O(n)$ field elements. Specifically, for each $v \in [n]$, it suffices for the verifier to maintain the quantities $q_1(v) := \prod_{1 \leq v' \leq n : v' \neq v}(r - v')$ and $q_2(v) = \left(\prod_{1 \leq v' \leq n : v' \neq v}(v - v')\right)^{-1}$. All $O(n)$ of these quantities can be computed in pre-processing in total time $O(n \log n)$, where the $\log n$ term is due to the time required to compute a multiplicative inverse in the field $\mathbb{F}$. Indeed, $q_1(1)$ and $q_2(1)$ can be computed naively in $O(n)$ time, and then for any $v > 1$, $q_1(v)$ and $q_2(v)$ can be computed in $O(\log n)$ time from $q_1(v-1)$ and $q_2(v-1)$ via the identities $q_1(v) = q_1(v-1) \cdot (r - v)^{-1} \cdot (r - v + 1)$ and $q_2(v) = q_2(v-1) \cdot (v-1)^{-1} \cdot (v - 1 - n)$.

Table 3 Statement of Time Costs For Our TrianglesScheme (Theorem 4).

Verifier Pre-Processing Time	Verifier Time Per Stream Update	Verifier Time to Process Proof	Prover Total Time
$O(n \log n)$	$O(1)$	$O(n)$	$O(m \cdot n)$

Finally, the verifier can process the proof in time $O(n)$. Recall that the proof consists of the values $s(x)$ for $x \in \{0, \ldots, 2n\}$, and the verifier simply needs to compute $\sum_{1 \leq x \leq n} s(x)$ as well as $s(r)$. The first quantity can trivially be computed in time $O(n)$, and the second can be computed in time $O(n)$ as well using standard techniques (see, e.g., [11]).

- **Prover Time.** The honest prover in the protocol of Theorem 4 can be implemented to run in time $O(m \cdot n)$. Indeed, the honest prover needs to evaluate $g(x)$ for $O(n)$ points $x \in \mathbb{F}$, and we have explained above how $g(x)$ can be computed in $O(m)$ time (in fact, in $O(1)$ time per stream update). This is comparable to the naive triangle counting algorithm that, for each edge and node combination, tests whether the two edges incident on the edge and node exist in the graph.
  The time costs for both the prover and verifier are summarized in Table 3.
- **MA communication.** Theorem 4 implies that the (online) MA communication complexity of counting triangles is $O(n \log n)$ (see Section 4.1 for the definition of the (online) MA communication model). This essentially matches an $\Omega(n)$ lower bound on the (even non-online) MA communication complexity of the problem, proved by Chakrabarti et al. [7] via a standard reduction to Set-Disjointness, and answers a question of Cormode [22].
- **Extensions: Counting Structures Other Than Triangles.** Let H be a graph on k vertices. It is possible to extend the protocol of Theorem 4 to count the number of occurrences of H as a subgraph of G. The protocol requires $k - 2$ rounds, and its help and space costs are $O(k^3 n \log n)$ and $O(kn \log n)$. Details are deferred to the full version.

3.2 A Semi-Streaming Scheme for Maximum Matching

We give a semi-streaming scheme for the MaxMatching problem in general graphs.[4] Due to space constraints, the proof of Theorem 5 is deferred to the full version.

▶ **Theorem 5** (Formal Version of Theorem 2). *Assume there is an a priori upper bound $B \leq \text{poly}(n)$ on the multiplicity of any edge in G. There is an online scheme for* MaxMatching *of total cost $O(B \cdot n \log n)$. Every scheme for* MaxMatching *(online or prescient) requires the product of the space and help costs to be $\Omega(n^2)$, and hence total cost $\Omega(n)$, even for $B = 1$.*

4 Lower Bounds for Connectivity and Bipartiteness

In this section, we establish our lower bounds on the cost of online schemes for Connectivity and Bipartiteness in the XOR update models. Like almost all previous lower bounds for data stream computations, our lower bounds use reductions from problems in communication complexity. To model the prover in a scheme, the appropriate communication setting is Merlin-Arthur communication, which we now introduce.

[4] It is possible to modify our scheme to give meaningful answers on graphs with edges of negative multiplicity. Specifically, the modified scheme can treat edges of negative multiplicity as having strictly positive multiplicity. We omit the details for brevity.

4.1 Merlin-Arthur Communication

Consider a communication game involving three parties, named Alice, Bob, and Merlin. Alice holds an input $x \in \mathcal{X}$, Bob and input $y \in \mathcal{Y}$, and Merlin is omniscient (he sees both x and y) but untrusted. Alice and Bob's goal is to compute $f(x,y)$ for some agreed upon function $f : \mathcal{X} \times \mathcal{Y} \to \{0,1\}$. In an MA communication protocol $\mathcal{P}$, Merlin first broadcasts a message m_M to both Alice and Bob. Alice and Bob then engage in a randomized communication protocol, before outputting a single bit. To clarify, Merlin does not learn the randomness that Alice and Bob use until after sending the message $m_M(x,y)$. For each input (x,y), the protocol $\mathcal{P}$ defines a game between Merlin, Alice, and Bob, in which Merlin's goal is to make Alice and Bob output 1. We define $\mathbf{Val}^{\mathcal{P}}(x,y)$ to be Merlin's probability of winning with optimal play. Given a Boolean function f, we say that $\mathcal{P}$ computes f if, for all (x,y) we have (1) $f(x,y)=0 \Longrightarrow \mathbf{Val}^{\mathcal{P}}(x,y) \leq 1/3$, and (2) $f(x,y)=1 \Longrightarrow \mathbf{Val}^{\mathcal{P}}(x,y) \geq 2/3$. We refer to the Property (1) as *soundness* and Property (2) as *completeness*.

The *help cost*, or $\mathrm{hc}(\mathcal{P})$, of $\mathcal{P}$ is $\max_{(x,y)} |m_M(x,y)|$, i.e., the maximum length of Merlin's message in bits. The *verification cost*, or $\mathrm{vc}(\mathcal{P})$, of $\mathcal{P}$ is the maximum number of bits that Alice and Bob exchange, where the maximum is taken over all inputs (x,y), all possible Merlin messages m_M, and all choices of Alice and Bob's randomness. The *total cost* of $\mathcal{P}$ is the sum of the help and verification costs of $\mathcal{P}$.

In an *online* MA (OMA) communication protocol, neither Merlin nor Bob can talk to Alice. Given any online scheme for a function f, we naturally obtain an OMA protocol $\mathcal{P}$ for the communication problem in which Alice holds a prefix of a stream, Bob holds a suffix, and the goal is to evaluate f on the concatenated stream $x \circ y$. Hence, if we establish lower bounds on the help and verification costs of any OMA protocol for f, an equivalent lower bound on the help and space costs of any online scheme for f follows.

In this section, we establish lower bounds on the help and verification costs of any OMA protocol for the Disconnectivity and Bipartiteness problems in the XOR update model. More precisely, we consider the communication problems Disconnectivity$^{\mathrm{cc}}$ and Bipartiteness$^{\mathrm{cc}}$ in which Alice holds the first $m-n$ tuples in a graph stream in the XOR update model, Bob holds the length n tuples, and the output function evaluates to 1 if and only if the resulting graph is disconnected or bipartite, respectively.[5]

4.2 The Lower Bound

▶ **Theorem 6.** *Consider any OMA protocol $\mathcal{P}$ for* Disconnectivity$^{\mathrm{cc}}$ *or* Bipartiteness$^{\mathrm{cc}}$. *Then it holds that* $(\mathrm{hc}(\mathcal{P})+n)\cdot \mathrm{vc}(\mathcal{P}) = \Omega(n^2)$. *This holds even under the promise that the first $m-n$ stream updates (i.e., Alice's input) are all unique, and the last n stream updates (i.e., Bob's input) are all incident to a single node. In particular, the total cost of $\mathcal{P}$ is $\Omega(n)$.*

Proof. We prove the lower bound Disconnectivity$^{\mathrm{cc}}$problem. The proof for Bipartiteness$^{\mathrm{cc}}$is similar, and is deferred to the full version of the paper. Let $\mathcal{P}$ denote any OMA protocol for Disconnectivity$^{\mathrm{cc}}$that works on graphs with $n+1$ nodes, under the promise

[5] The reason that we consider Disconnectivity$^{\mathrm{cc}}$ rather than Connectivity$^{\mathrm{cc}}$ is the asymmetric way that inputs in $F^{-1}(0)$ and $F^{-1}(1)$ in the definition of OMA communication complexity. Recall that the OMA communication problem for a decision problem F requires only that if $F(x)=1$ then there is some prover that will cause the verifier to accept with high probability, and if $F(x)=0$ then there is no such prover. (By contrast, our definition of a scheme for a function F requires there to be a convincing proof of the value of $F(x)$ for all values $F(x)$.) Hence, the OMA communication complexities of Disconnectivity$^{\mathrm{cc}}$ and Connectivity$^{\mathrm{cc}}$ may not be equal, and indeed our lower bound argument applies only to Disconnectivity$^{\mathrm{cc}}$.

described in the theorem hypothesis. As discussed in the outline of Section 1.1.2, our proof will use a reduction from the INDEX problem on $\binom{n}{2}$ inputs. In this problem, Alice's input consists of a bitstring $\mathbf{x}$ of length $\binom{n}{2}$, Bob's input is an index $i^* \in [\binom{n}{2}]$, and the goal is to output $\mathbf{x}_{i^*}$. It was established in [7] that any OMA protocol $\mathcal{Q}$ for INDEX on $\binom{n}{2}$ inputs requires $\text{hc}(\mathcal{Q}) \cdot \text{vc}(\mathcal{Q}) = \Omega(n^2)$. We show how to use $\mathcal{P}$ to construct a protocol $\mathcal{Q}$ for INDEX on $\binom{n}{2}$ inputs with $\text{hc}(\mathcal{Q}) = n + \text{hc}(\mathcal{P})$ and $\text{vc}(\mathcal{Q}) = \text{vc}(\mathcal{P})$. It will then follow from the lower bound for INDEX that $(\text{hc}(\mathcal{P}) + n) \cdot \text{vc}(\mathcal{P}) \geq n^2$.

Description of $\mathcal{Q}$. In $\mathcal{Q}$, Alice interprets her input $\mathbf{x} \in \{0,1\}^{\binom{n}{2}}$ as an undirected graph G_1 with n nodes as follows. She associates each index $i \in \binom{n}{2}$ with a unique edge (u_i, v_i) out of the set of all $\binom{n}{2}$ possible edges that could appear in G_1. Alice also adds to G_1 a special node v^*, and connects v^* to every other node in G_1. Denote the resulting graph on $n+1$ nodes by G_2. Notice that G_2 is always connected, as every node is connected to v^* by design.

Likewise, Bob interprets his input $i^* \in [\binom{n}{2}]$ as an edge (u_{i^*}, v_{i^*}). Clearly, determining whether $\mathbf{x}_{i^*} = 1$ is equivalent to determining whether edge (u_{i^*}, v_{i^*}) appears in Alice's graph G_2. Merlin sends Bob a list L claimed to equal all edges incident to node u_{i^*} in G_2. This requires only n bits of "help", since there are only n nodes to which u_{i^*} might be adjacent. Bob treats L as his input to the DISCONNECTIVITY$^{\text{cc}}$problem.

Alice, Bob, and Merlin now run the DISCONNECTIVITY$^{\text{cc}}$ protocol $\mathcal{P}$ (with Alice's input equal to G_2 and Bob's input equal to L). Bob outputs 1 iff the protocol $\mathcal{P}$ outputs 1, and L contains the edge (u_{i^*}, v_{i^*}).

Costs of $\mathcal{Q}$. The help cost of $\mathcal{Q}$ is equal to $n + \text{hc}(\mathcal{P})$, since the honest Merlin sends Bob the list L, and then behaves as he would in the protocol $\mathcal{P}$. The verification cost of $\mathcal{Q}$ is just $\text{vc}(\mathcal{Q})$, since the only message Alice sends to Bob is the message she would send in $\mathcal{P}$.

Completeness and Soundness of $\mathcal{Q}$. Let G_3 denote the graph obtained from G_2 by XORing all the edges in the list L. Let $I(u_{i^*})$ denote the set of edges incident to u_{i^*} in G_3. We claim that G_3 is disconnected if and only if L is equal to $I(u_{i^*})$. For the first direction, suppose that L is equal to $I(u_{i^*})$. Then by XORing the edges in G_3 with the edges in L, every edge incident to node u_{i^*} is deleted from the graph. Hence, u_{i^*} is an isolated vertex in G_3, implying that G_3 is disconnected. For the second direction, suppose that L is not equal to $I(u_{i^*})$. Let (u_{i^*}, v) denote an edge in $L \setminus I(u_{i^*})$. Then (u_{i^*}, v) is in G_3. Moreover, v is adjacent to node v^*, as are all nodes in G_3 other than u_{i^*}. Hence G_3 is connected.

To finish the proof of completeness of $\mathcal{Q}$, note that if $\mathbf{x}_{i^*} = 1$, then the edge (u_{i^*}, v_{i^*}) is in G_3. If Merlin sends $L = I(u_{i^*})$, then G_3 will be disconnected, and by the the completeness of $\mathcal{P}$, Merlin can convince Bob that G_3 is disconnected with probability at least 2/3. In this event, Bob will output 1, because (u_{i^*}, v_{i^*}) will be in the list L.

To finish the proof of soundness of $\mathcal{Q}$, note that if $\mathbf{x}_{i^*} = 0$, then the edge (u_{i^*}, v_{i^*}) is not in G_3. Hence, if Merlin sends $L = I(u_{i^*})$, then Bob will reject automatically, because (u_{i^*}, v_{i^*}) will not be in the list L. On the other hand, if Merlin sends a list L that is *not* equal to $I(u_{i^*})$, then G_3 will be connected. By the the soundness of $\mathcal{P}$, Merlin can convince Bob that G_3 is disconnected with probability at most 1/3. Hence, Bob will output 1 in $\mathcal{Q}$ with probability at most 1/3, completing the proof for DISCONNECTIVITY$^{\text{cc}}$. ◀

Because any online scheme for CONNECTIVITY or BIPARTITENESS can be simulated by an OMA communication protocol, we obtain the following corollary.

▶ **Corollary 7** (Formal Version of Theorem 3). *Consider any online scheme for* Connectivity *or* Bipartiteness *in the XOR update model with help cost c_a and and space cost c_v. Then $(c_a + n) \cdot c_v \geq n^2$, even under the promise that the first $m - n$ stream updates are all unique, and the last n stream updates are all incident to a single node. In particular, the total cost of any annotation scheme is $\Omega(n)$.*

Abstract

We study the composition question for bounded-error randomized query complexity: Is $R(f \circ g) = \Omega(R(f)R(g))$? We show that inserting a simple function h, whose query complexity is only $\Theta(\log R(g))$, in between f and g allows us to prove $R(f \circ h \circ g) = \Omega(R(f)R(h)R(g))$.

We prove this using a new lower bound measure for randomized query complexity we call randomized sabotage complexity, $\mathrm{RS}(f)$. Randomized sabotage complexity has several desirable properties, such as a perfect composition theorem, $\mathrm{RS}(f \circ g) \geq \mathrm{RS}(f)\,\mathrm{RS}(g)$, and a composition theorem with randomized query complexity, $R(f \circ g) = \Omega(R(f)\,\mathrm{RS}(g))$. It is also a quadratically tight lower bound for total functions and can be quadratically superior to the partition bound, the best known general lower bound for randomized query complexity.

Using this technique we also show implications for lifting theorems in communication complexity. We show that a general lifting theorem from zero-error randomized query to communication complexity implies a similar result for bounded-error algorithms for all total functions.

1 Introduction

1.1 Composition theorems

A basic structural question that can be asked in any model of computation is whether there can be savings in complexity when computing the same function on several independent inputs. We say a direct sum theorem holds in a model of computation if solving a problem on n independent inputs requires roughly n times the resources needed to solve one instance. A direct sum theorem is known to hold for deterministic and randomized query complexity [9], and two-player refereed games [17], is known to fail for circuit size [16], and remains open for deterministic communication complexity [11].

More generally, instead of merely outputting the n answers, we could compute another function of these n answers. If f is an n-bit Boolean function and g is an m-bit Boolean function, we define the composed function $f \circ g$ to be an nm-bit Boolean function such that $f \circ g(x_1, \ldots, x_n) = f(g(x_1), \ldots, g(x_n))$, where each x_i is an m-bit string. The composition question now asks if there can be significant savings in computing $f \circ g$ compared to simply

running the best algorithm for f and using the best algorithm for g to evaluate the input bits needed to compute f. If we let f be the identity function on n bits that just outputs all its inputs, we recover the direct sum problem.

Composition theorems are harder to prove and are known for only a handful of models, such as deterministic and quantum query complexity. Proving this for randomized query complexity remains a major open problem. More precisely, if $D(f)$, $R(f)$, and $Q(f)$ denote the deterministic, randomized, and quantum query complexities of f, then we know for all partial Boolean functions f and g, $D(f \circ g) = D(f)D(g)$ [18, 15] and $Q(f \circ g) = \Theta(Q(f)Q(g))$ [14, 12]. (Such theorems often fail for functions with non-Boolean output, and hence we only consider functions with Boolean output in this paper.) In contrast, in the randomized setting we have only the upper bound $R(f \circ g) = O(R(f)R(g) \log R(f))$.

▶ **Open Problem 1.** Does it hold that $R(f \circ g) = \Omega(R(f)R(g))$ for all Boolean f and g?

In this paper we prove something close to a composition theorem for randomized query complexity. While we cannot rule out the possibility of synergistic savings in computing $f \circ g$, we show that a composition theorem does hold if we insert a small gadget in between f and g to obfuscate the output of g. Our gadget is "small" in the sense that its randomized (and even deterministic) query complexity is $\Theta(\log R(g))$. Specifically we choose the index function, which on an input of size $k+2^k$ interprets the first k bits as an address into the next 2^k bits and outputs the bit stored at that address. The index function's query complexity is $k+1$ and we choose $k = \Theta(\log R(g))$ in our construction.

▶ **Theorem 1.** *Let f and g be partial Boolean functions and let* IND *be the index function with* $R(\text{IND}) = \Theta(\log R(g))$. *Then* $R(f \circ \text{IND} \circ g) = \Omega(R(f)R(\text{IND})R(g)) = \Omega(R(f)R(g) \log R(g))$.

Theorem 1 can be used instead of a true composition theorem in many applications. For example, recently a composition theorem for randomized query complexity was needed in the special case when f is the AND function [2, 5] or when g is the AND function [1]. Our composition theorem would suffice for both applications.

We prove Theorem 1 by introducing a new lower bound technique for randomized query complexity. This is not surprising since the composition theorems for deterministic and quantum query complexities are also proved using powerful lower bound techniques for these models, namely the adversary argument and the general adversary bound [7] respectively.

1.2 Sabotage complexity

To describe the new lower bound technique, consider the problem of computing a Boolean function f on an input $x \in \{0,1\}^n$ in the query model. In this model we have access to an oracle, which when queried with an index $i \in [n]$ responds with $x_i \in \{0,1\}$. Now imagine a saboteur damages the oracle making some of the input bits unreadable; for these input bits the oracle simply responds with a $*$. We can now view the oracle as storing a string $p \in \{0,1,*\}^n$ as opposed to a string $x \in \{0,1\}^n$. Although it is not possible to determine the true input x from the oracle string p, it may still be possible to compute $f(x)$ if all input strings consistent with p evaluate to the same f value. On the other hand, it is not possible to compute $f(x)$ if p is consistent with a 0-input and a 1-input to f, and we call such a string $p \in \{0,1,*\}^n$ a *sabotaged input*. For example, let f be the OR function that computes the logical OR of its bits. Then $p = 00*0$ is a sabotaged input since it is consistent with the 0-input 0000 and the 1-input 0010. However, $p = 01*0$ is not a sabotaged input since it is only consistent with 1-inputs to f.

Now consider a new problem in which the input is promised to be sabotaged (with respect to a function f) and our job is to find the location of a $*$. Intuitively, any algorithm that solves the original problem f when run on a sabotaged input must discover at least one $*$, since otherwise it would answer the same on 0- and 1-inputs consistent with the sabotaged input. This can be formalized and leads to a lower bound measure for several models of computation, including deterministic, randomized, and quantum query complexity.

As it stands the problem of finding a $*$ in a sabotaged input has multiple valid outputs, as the location of any star in the input is a valid output. For convenience we define a decision version of this problem by imaging there are two saboteurs, one of whom has sabotaged our input. The first saboteur, Asterix, replaces input bits with an asterisk ($*$) and the second, Obelix, uses an obelisk (†). Promised that the input has been sabotaged exclusively by one of Asterix or Obelix, our job is to identify the saboteur. This is now a decision problem since there are only two valid outputs. We call this decision problem f_{sab}, the *sabotage problem* associated with f.

We now define lower bound measures for various models using f_{sab}. For example, we can define the *deterministic sabotage complexity of* f as $\text{DS}(f) := D(f_{\text{sab}})$ and in fact, $\text{DS}(f) = D(f)$ as we show in the full version of this paper. We could define the *randomized sabotage complexity of* f as $R(f_{\text{sab}})$, but instead we define it as $\text{RS}(f) := R_0(f_{\text{sab}})$, where R_0 denotes zero-error randomized query complexity, since $R(f_{\text{sab}})$ and $R_0(f_{\text{sab}})$ are equal up to constant factors. Besides lower bounding $R(f)$, $\text{RS}(f)$ has the following desirable properties:

1. (Perfect composition) For all f and g, $\text{RS}(f \circ g) \geq \text{RS}(f)\,\text{RS}(g)$ (Theorem 15)
2. (Composition with R) For all f and g, $R(f \circ g) = \Omega(R(f)\,\text{RS}(g))$ (Theorem 17)
3. (Quadratically tight) For all total f, $R(f) = O(\text{RS}(f)^2 \log \text{RS}(f))$ (Theorem 28)
4. (Superior to $\text{prt}(f)$) There exists a total f with $\text{RS}(f) \geq \text{prt}(f)^{2-o(1)}$ (Theorem 26)

Here $\text{prt}(f)$ denotes the partition bound [8, 10], which subsumes most other lower bound techniques such as approximate polynomial degree and randomized certificate complexity. In fact, we are unaware of any total function f for which $\text{RS}(f) = o(R(f))$, leaving open the intriguing possibility that this lower bound technique is tight.

1.3 Lifting theorems

Using randomized sabotage complexity we are also able to show a relationship between lifting theorems in communication complexity. A lifting theorem relates the query complexity of a function f with the communication complexity of a related function created from f. Recently, Göös, Pitassi, and Watson [6] showed that there is a communication problem G with communication complexity $\Theta(\log n)$ such that for any function f on n bits, $D^{\text{cc}}(f \circ G) = \Omega(D(f) \log n)$, where D^{cc} denotes deterministic communication complexity.

Analogous lifting theorems are known for some complexity measures, but no such theorem is known for either zero-error randomized or bounded-error randomized query complexity. Our second result shows that a lifting theorem for zero-error randomized query complexity implies one for bounded-error randomized query complexity for total functions. We use R_0^{cc} and R^{cc} to denote zero-error and bounded-error communication complexity respectively.

▶ **Theorem 2.** *Let G be the communication gadget from [6] with $D^{\text{cc}}(G) = \Theta(\log n)$. If it holds that for all n-bit (possibly partial) functions f, $R_0^{\text{cc}}(f \circ G) = \Omega(R_0(f)/\operatorname{polylog} n)$, then it holds that for all n-bit total Boolean functions f, $R^{\text{cc}}(f \circ G) = \Omega(R(f)/\operatorname{polylog} n)$.*

Proving a lifting theorem for bounded-error randomized query complexity remains an important open problem, and would imply super-quadratic separations between randomized and quantum communication complexity [1], and a nearly quadratic separation between

randomized communication complexity and partition number [2]. Our result shows that it is sufficient to prove a lifting theorem for zero-error randomized protocols instead.

2 Preliminaries

We now define some basic notions in query complexity. Note that all the functions in this paper have Boolean output. In the model of query complexity, we wish to compute an n-bit Boolean function f on an input x given query access to the bits of x. The function f may be total, i.e., $f : \{0,1\}^n \to \{0,1\}$, or partial, which means it is defined only on a subset of $\{0,1\}^n$, which we denote by $\mathrm{Dom}(f)$. The goal is to output $f(x)$ using as few queries to the bits of x as possible. The number of queries used by the best possible deterministic algorithm (over worst-case choice of x) is denoted $D(f)$.

A randomized algorithm is a probability distribution over deterministic algorithms. The worst-case cost of a randomized algorithm is the worst-case number of queries made by the algorithm on any input x. The expected cost of the algorithm is the expected number of queries made by the algorithm maximized over all inputs x. A randomized algorithm has error at most ϵ if it outputs $f(x)$ on every x with probability at least $1-\epsilon$.

We use $R_\epsilon(f)$ to denote the worst-case cost of the best randomized algorithm that computes f with error ϵ. Similarly, we use $\overline{R}_\epsilon$ to denote the expected cost of the best randomized algorithm that computes f with error ϵ. When ϵ is unspecified it is taken to be $\epsilon = 1/3$. Thus $R(f)$ denotes the bounded-error randomized query complexity of f. Finally, we also define zero-error randomized query complexity, which is $\overline{R}_0(f)$, which we also denote by $R_0(f)$ to be consistent with the literature. For precise definitions of these measures as well as the definition of quantum query complexity $Q(f)$, see [3]. We also need two simple properties of randomized algorithms, which we prove in the full version of this paper.

▶ **Lemma 3.** *If A is a randomized algorithm that uses T expected queries and finds a certificate with probability $1-\epsilon$, then repeating A when it fails turns it into a zero-error algorithm that uses at most $T/(1-\epsilon)$ expected queries.*

▶ **Lemma 4.** *Let f be a partial function and A be an ϵ-error randomized algorithm for f that uses at most T expected queries. For $x, y \in \mathrm{Dom}(f)$ if $f(x) \neq f(y)$ then when A is run on x, it must query an entry on which x differs from y with probability at least $1-2\epsilon$.*

3 Sabotage complexity

Given a (partial or total) n-bit Boolean function f, let $P_f \subseteq \{0,1,*\}^n$ be the set of all partial assignments of f that are consistent with both a 0-input and a 1-input; that is, for each $p \in P_f$, there exist $x, y \in \mathrm{Dom}(f)$ such that $f(x) \neq f(y)$ and $x_i = y_i = p_i$ whenever $p_i \neq *$. Let $P_f^\dagger \subseteq \{0,1,\dagger\}^n$ be the same as P_f, except using the symbol $\dagger$ instead of $*$. Observe that P_f and $P_f^\dagger$ are disjoint. Let $Q_f = P_f \cup P_f^\dagger \subseteq \{0,1,*,\dagger\}^n$. We then define f_{sab} as follows.

▶ **Definition 5.** Let f be an n-bit partial function. We define $f_{\mathrm{sab}} : Q_f \to \{0,1\}$ as $f_{\mathrm{sab}}(q) = 0$ if $q \in P_f$ and $f_{\mathrm{sab}}(q) = 1$ if $q \in P_f^\dagger$.

See Section 1.2 for more discussion and motivation for this definition. Now that we have defined f_{sab}, we can define sabotage complexity for various models.

▶ **Definition 6.** Let f be a partial function. Then $\mathrm{DS}(f) := D(f_{\mathrm{sab}})$ and $\mathrm{RS}(f) := R_0(f_{\mathrm{sab}})$.

We will primarily focus on $\mathrm{RS}(f)$ in this work. To justify defining $\mathrm{RS}(f)$ as $R_0(f_{\mathrm{sab}})$ instead of $R(f_{\mathrm{sab}})$, we now show these definitions are equivalent up to constant factors.

▶ **Theorem 7.** *Let f be a partial function. Then $R_0(f_{\mathrm{sab}}) \geq \overline{R}_\epsilon(f_{\mathrm{sab}}) \geq (1-2\epsilon)R_0(f_{\mathrm{sab}})$.*

Proof. The first inequality follows trivially. For the second, let $x \in Q_f$ be any valid input to f_{sab}. Let x' be the input x with asterisks replaced with obelisks and vice versa. Then since $f_{\mathrm{sab}}(x) \neq f_{\mathrm{sab}}(x')$, by Lemma 4 any ϵ-error randomized algorithm that solves f_{sab} must find a position on which x and x' differ with probability at least $1-2\epsilon$. The positions at which they differ are either asterisks or obelisks. Since x was an arbitrary input, the algorithm must always find an asterisk or obelisk with probability at least $1-2\epsilon$. Since finding an asterisk or obelisk is a certificate for f_{sab}, by Lemma 3, we get a zero-error algorithm for f_{sab} that uses $\overline{R}_\epsilon(f_{\mathrm{sab}})/(1-2\epsilon)$ expected queries. Thus $R_0(f_{\mathrm{sab}}) \leq \overline{R}_\epsilon(f_{\mathrm{sab}})/(1-2\epsilon)$, as desired. ◀

Finally, we prove that $\mathrm{RS}(f)$ is indeed a lower bound on $R(f)$, i.e., $R(f) = \Omega(\mathrm{RS}(f))$.

▶ **Theorem 8.** *Let f be an n-bit partial function. Then $R_\epsilon(f) \geq \overline{R}_\epsilon(f) \geq (1-2\epsilon)\,\mathrm{RS}(f)$.*

Proof. Let A be a randomized algorithm for f that uses $\overline{R}_\epsilon(f)$ randomized queries and outputs the correct answer on every input in $\mathrm{Dom}(f)$ with probability at least $1-\epsilon$. Now fix a sabotaged input x, and let p be the probability that A finds a $*$ or † when run on x. Let q be the probability that A outputs 0 if it doesn't find a $*$ or † when run on x. Let x_0 and x_1 be inputs consistent with x such that $f(x_0) = 0$ and $f(x_1) = 1$. Then A outputs 0 on x_1 with probability at least $q(1-p)$, and A outputs 1 on x_0 with probability at least $(1-q)(1-p)$. These are both errors, so we have $q(1-p) \leq \epsilon$ and $(1-q)(1-p) \leq \epsilon$. Summing them gives $1-p \leq 2\epsilon$, or $p \geq 1-2\epsilon$.

This means A finds a $*$ entry within $\overline{R}_\epsilon(f)$ expected queries with probability at least $1-2\epsilon$. By Lemma 3, we get $\frac{1}{1-2\epsilon}\overline{R}_\epsilon(f) \geq \mathrm{RS}(f)$, or $\overline{R}_\epsilon(f) \geq (1-2\epsilon)\,\mathrm{RS}(f)$. ◀

We also define a variant of RS where the number of asterisks (or obelisks) is exactly one. Specifically, let $U \subseteq \{0,1,*,\dagger\}^n$ be the set of all partial assignments with exactly one $*$ or †.

▶ **Definition 9.** Let f be a partial function. We define f_{usab} as the restriction of f_{sab} to U, the set of strings with only one asterisk or obelisk. I.e., f_{usab} has domain $Q_f \cap U$, but is equal to f_{sab} on its domain. We then define $\mathrm{RS}_1(f) := R_0(f_{\mathrm{usab}})$. If $Q_f \cap U$ is empty, we define $\mathrm{RS}_1(f) := 0$.

The measure RS_1 will play a key role in our lifting result in Section 6. Since f_{usab} is a restriction of f_{sab} to a promise, it is clear that its zero-error randomized query complexity is smaller, so $\mathrm{RS}_1(f) \leq \mathrm{RS}(f)$. Another interesting property is the following theorem, which says $\mathrm{RS}_1(f)$ equals $\mathrm{RS}(f)$ for total functions. In other words, when f is total, we may assume without loss of generality that its sabotaged version has only one asterisk or obelisk.

▶ **Theorem 10.** *If f is a total function, then $\mathrm{RS}_1(f) = \mathrm{RS}(f)$.*

Proof. We showed that $\mathrm{RS}(f) \geq \mathrm{RS}_1(f)$. To show $\mathrm{RS}_1(f) \geq \mathrm{RS}(f)$, we argue that any zero-error algorithm A for f_{usab} also solves f_{sab}. The main observation is that any input to f_{sab} can be completed to an input to f_{usab} by replacing some asterisks or obelisks with 0s and 1s. To see this, let x be an input to f_{sab}. Without loss of generality, $x \in P_f$. Then there are two strings $y, z \in \mathrm{Dom}(f)$ that are consistent with x, satisfying $f(y) = 0$ and $f(z) = 1$.

The strings y and z disagree on some set of bits B, and x has a $*$ or † on all of B. Consider starting with y and flipping the bits of B one by one, until we reach the string z. At the beginning, we have $f(y) = 0$, and at the end, we reach $f(z) = 1$. This means that at

some point in the middle, we must have flipped a bit that flipped the string from a 0-input to a 1-input. Let w_0 and w_1 be the inputs where this happens. They differ in only one bit. If we replace that bit with $*$ or †, we get a partial assignment w consistent with both, so $w \in P_f$. Moreover, w is consistent with x. This means we have completed an arbitrary input to f_{sab} to an input to f_{usab}, as claimed.

Now, the algorithm A must find an asterisk or obelisk in any input to f_{usab}. But since each input to f_{sab} can be viewed as an input to f_{usab} with added asterisks and obelisks, the algorithm A also finds an asterisk or obelisk in any input to f_{sab}. Thus $\text{RS}(f) = R_0(f_{\text{sab}}) \leq R_0(f_{\text{usab}}) = \text{RS}_1(f)$. ◀

4 Direct Sum and Composition Theorems

In this section, we establish some composition theorems for RS. To do so, we first need to establish direct sum theorems for the problem f_{sab}. In fact, our direct sum theorems hold more generally for zero-error randomized query complexity of partial functions (and even relations). We will require Yao's minimax theorem [19]:

▶ **Theorem 11** (Yao). *Let f be a partial function. There is a distribution μ over inputs in $\text{Dom}(f)$ such that all zero-error algorithms for f use at least $R_0(f)$ expected queries on μ.*

4.1 Direct Sum Theorems

We start by defining the m-fold direct sum of a function f, which is simply the function that accepts m inputs to f and outputs f evaluated on all of them.

▶ **Definition 12.** Let $f : \text{Dom}(f) \to \mathcal{Z}$, where $\text{Dom}(f) \subseteq \mathcal{X}^n$ be a partial function with input and output alphabets $\mathcal{X}$ and $\mathcal{Z}$. The m-fold direct sum of f is the partial function $f^{\oplus m} : \text{Dom}(f)^m \to \mathcal{Z}^m$ such that for all $x_i \in \text{Dom}(f)$,

$$f(x_1, x_2, \ldots, x_m) = (f(x_1), f(x_2), \ldots, f(x_m)). \tag{1}$$

We can now prove a direct sum theorem for zero-error randomized query complexity. We prove these results for partial functions, although they also hold for relations.

▶ **Theorem 13** (Direct sum). *For any n-bit partial function f and any positive integer m, we have $R_0(f^{\oplus m}) = mR_0(f)$. Moreover, if μ is the hard distribution for f given by Theorem 11, then $\mu^{\otimes m}$ is a hard distribution for $f^{\oplus m}$.*

Proof. The upper bound follows from running the $R_0(f)$ algorithm on each of the m inputs to f. By linearity of expectation, this solves all m inputs after $mR_0(f)$ expected queries.

We now prove the lower bound. Let A be a zero-error randomized algorithm for $f^{\oplus m}$ that uses T expected queries when run on inputs from $\mu^{\otimes m}$. We convert A into an algorithm B for f that uses T/m expected queries when run on inputs from μ.

Given an input $x \sim \mu$, the algorithm B generates $m-1$ additional "fake" inputs from μ. B then shuffles these together with x, and runs A on the result. The input to A is then distributed according to $\mu^{\otimes m}$, so A uses T queries (in expectation) to solve all m inputs. B then reads the solution to the true input x.

Note that most of the queries A makes are to fake inputs, so they don't count as real queries. The only real queries B has to make happen when A queries x. But since x is shuffled with the other (indistinguishable) inputs, the expected number of queries A makes to x is the same as the expected number of queries A makes to each fake input; this must equal T/m. Thus B makes T/m queries to x (in expectation) before solving it.

Since B is a zero-error randomized algorithm for f that uses T/m expected queries on inputs from μ, we must have $T/m \geq R_0(f)$ by Theorem 11. Thus $T \geq mR_0(f)$. ◀

For our applications, however, we will need a strengthened version of this theorem, which we call a threshold direct sum theorem for R_0.

▶ **Theorem 14** (Threshold direct sum). *Given an input to $f^{\oplus m}$ sampled from $\mu^{\otimes m}$, we consider solving only some of the m inputs to f. We say an input x to f is solved if a z-certificate was queried that proves $f(x) = z$. Then any randomized algorithm that takes an expected T queries and solves an expected k of the m inputs when run on inputs from $\mu^{\otimes m}$ must satisfy $T \geq kR_0(f)$.*

Proof. Let A be such an algorithm. We convert A into an algorithm B for solving f on inputs from μ. The algorithm B is very similar to the algorithm in the proof of Theorem 13: on input $x \sim \mu$, it generates $m-1$ additional inputs from μ, shuffles them, and feeds them into A. The algorithm A uses an expected T queries, but since x is shuffled with the fake inputs, it gets queried only T/m times in expectation. Moreover, the algorithm A solves an expected k of the m inputs, so the expected number of times it solves x is k/m. This means B solves x with probability k/m.

Moreover, when B solves x, it also finds a certificate. So by Lemma 3, we get a zero-error algorithm with expected query complexity $(T/m)/(k/m) = T/k$. We conclude that $T/k \geq R_0(f)$, so $T \geq kR_0(f)$, as desired. ◀

4.2 Composition Theorems

Using the direct sum and threshold direct sum theorems we have established, we can now prove composition theorems for randomized sabotage complexity. We start with the behavior of RS itself under composition.

▶ **Theorem 15.** *Let f and g be partial functions. Then* $\mathrm{RS}(f \circ g) \geq \mathrm{RS}(f)\,\mathrm{RS}(g)$.

Proof. Let A be any algorithm for $(f \circ g)_{\mathrm{sab}}$, and let T be the expected query complexity of A (maximized over all inputs). We turn A into an algorithm B for f_{sab}.

B takes a sabotaged input x for f. It then runs A on a sabotaged input to $f \circ g$ constructed as follows. Each 0 bit of x is replaced with a 0-input to g, each 1 bit of x is replaced with a 1-input to g, and each $*$ or † of x is replaced with a sabotaged input to g. The sabotaged inputs are generated from μ, the hard distribution for g_{sab} obtained from Theorem 11. The 0-inputs are generated by first generating a sabotaged input, and then selecting a 0-input consistent with that sabotaged input. The 1-inputs are generated analogously.

This is implemented in the following way. On input x, the algorithm B generates n sabotaged inputs from μ (the hard distribution for g_{sab}), where n is the length of the string x. Call these inputs $y_1, y_2, \ldots, y_n$. B then runs the algorithm A on this collection of n strings, pretending that it's an input to $f \circ g$, with the following caveat: whenever A tries to query a $*$ or † in an input y_i, B instead queries x_i. If x_i is 0, B selects an input from $f^{-1}(0)$ consistent with y_i, and replaces y_i with this input. It then returns to A an answer consistent with the new y_i. If x_i is 1, B selects a consistent input from $f^{-1}(1)$ instead. If x_i is a $*$ or †, B returns a $*$ or † respectively.

Now, by Theorem 14, if A makes T expected queries, the expected number of $*$ or † entries it finds among $y_1, y_2, \ldots, y_n$ is at most $T/\mathrm{RS}(g)$. It follows that the expected number of queries B makes to x is at most $T/\mathrm{RS}(g)$. Thus we have $\mathrm{RS}(f) \leq T/\mathrm{RS}(g)$, which gives $T \geq \mathrm{RS}(f)\,\mathrm{RS}(g)$. ◀

Using this we can lower bound the randomized query complexity of composed functions. We use f^n to denote the function f composed with itself n times, i.e., $f^1 = f$ and $f^{i+1} = f \circ f^i$.

▶ **Corollary 16.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a partial function. Then $R(f^n) \geq \mathrm{RS}(f)^n/3$.*

This follows straightforwardly from observing that $R(f^n) = R_{1/3}(f^n) \geq (1 - 2/3)\,\mathrm{RS}(f^n)$ (using Theorem 8) and $\mathrm{RS}(f^n) \geq \mathrm{RS}(f)^n$ (using Theorem 15).

We can also prove a composition theorem for randomized query complexity in terms of randomized sabotage complexity. In particular this yields a composition theorem for $R(f \circ g)$ when $R(g) = \Theta(\mathrm{RS}(g))$.

▶ **Theorem 17.** *Let f and g be partial functions. Then $\overline{R}_\epsilon(f \circ g) \geq \overline{R}_\epsilon(f)\,\mathrm{RS}(g)$.*

Proof. The proof follows a similar argument to the proof of Theorem 15. Let A be a randomized algorithm for $f \circ g$ that uses T expected queries and makes error ϵ. We turn A into an algorithm B for f by having B generate inputs from μ, the hard distribution for g_{sab}, and feeding them to A, as before. The only difference is that this time, the input x to B is not a sabotaged input. This means it has no $*$ or † entries, so all the sabotaged inputs that B generates turn into 0- or 1-inputs if A tries to query a $*$ or † in them.

Since A uses T queries, by Theorem 14, it finds at most $T/\,\mathrm{RS}(g)$ asterisks or obelisks (in expectation). Therefore, B makes at most $T/\,\mathrm{RS}(g)$ expected queries to x. Since B is correct whenever A is correct, its error probability is at most ϵ. Thus $\overline{R}_\epsilon(f) \leq T/\,\mathrm{RS}(g)$, and thus $T \geq \overline{R}_\epsilon(f)\,\mathrm{RS}(g)$. ◀

Setting ϵ to 0 yields the following corollary.

▶ **Corollary 18.** *Let f and g be partial functions. Then $R_0(f \circ g) \geq R_0(f)\,\mathrm{RS}(g)$.*

For the more commonly used $R(f \circ g)$, we obtain the following composition result.

▶ **Corollary 19.** *Let f and g be partial functions. Then $R(f \circ g) \geq R(f)\,\mathrm{RS}(g)/10$.*

This follows from $R(f \circ g) \geq \overline{R}_{1/3}(f \circ g) \geq \overline{R}_{1/3}(f)\,\mathrm{RS}(g) \geq R(f)\,\mathrm{RS}(g)/10$, where we used $\overline{R}_{1/3}(f) \geq R(f)/10$, which can be shown by error reduction and Markov's inequality.

Finally, we can also show an upper bound composition result for randomized sabotage complexity. We defer the proof to the full version of this paper.

▶ **Theorem 20.** *Let f and g be partial functions. Then $\mathrm{RS}(f \circ g) \leq \mathrm{RS}(f)R_0(g)$. We also have $\mathrm{RS}(f \circ g) = O(\mathrm{RS}(f)R(g)\log \mathrm{RS}(f))$.*

5 Composition with the index function

To prove the composition result, we require the strong direct product theorem for randomized query complexity that was established by Drucker [4].

▶ **Theorem 21** (Drucker)**.** *Let f be a partial Boolean function, and let k be a positive integer. Then any randomized algorithm for $f^{\oplus k}$ that uses at most $\gamma^3 kR(f)/11$ queries has success probability at most $(1/2 + \gamma)^k$, for any $\gamma \in (0, 1/4)$.*

The first step to proving the main result that $R(f \circ \textsc{Ind} \circ g) = \Omega(R(f)R(\textsc{Ind})R(g))$ is to show that $R(\textsc{Ind} \circ g)$ equals $\mathrm{RS}(\textsc{Ind} \circ g)$ up to constants if the index gadget is large enough.

▶ **Theorem 22.** *Let f be a partial Boolean function, and let $m = \Omega(R(f)^{1.1})$. Then $\mathrm{RS}(\textsc{Ind}_m \circ f) = \Omega(R(f)\log m) = \Omega(R(\textsc{Ind}_m)R(f))$.*

Moreover, if $f^{\oplus c}_{\mathrm{ind}}$ is the defined as the index function on $c + 2^c$ bits composed with f in only the first c bits, we have $\mathrm{RS}_1(f^{\oplus c}_{\mathrm{ind}}) = \Omega(cR(f))$ when $c = 1.1\log R(f) + \Omega(1)$.

Proof. Consider what the inputs to $(\textsc{Ind}_m \circ f)_{\text{sab}}$ look like. We can split an input to $\textsc{Ind}_m$ into a small index section and a large array section. To sabotage an input to $\textsc{Ind}_m$, it suffices to sabotage the array element that the index points to (using only a single star). It follows that to sabotage an input to $\textsc{Ind}_m \circ f$, it suffices to sabotage the input to f at the array element that the index points to. In other words, the only stars in the input will be in one array cell, whose index is the output of the first $\log m$ copies of f.

We now convert an $\mathrm{RS}(\textsc{Ind}_m \circ f)$ algorithm into a randomized algorithm for $f^{\log m}$. First, using Markov's inequality, we get a $2\,\mathrm{RS}(\textsc{Ind}_m \circ f)$ query randomized algorithm that finds a $*$ or † with probability $1/2$ if the input is sabotaged. Next, consider running this algorithm on a non-sabotaged input. It makes $2\,\mathrm{RS}(\textsc{Ind}_m \circ f)$ queries. With probability $1/2$, one of these queries will be in the array cell whose index is the true answer to $f^{\log m}$ evaluated on the first $n \log m$ bits. We can then consider a new algorithm A that runs the above algorithm for $2\,\mathrm{RS}(\textsc{Ind}_m \circ f)$ queries, then picks one of the $2\,\mathrm{RS}(\textsc{Ind}_m \circ f)$ queries at random, and if that query is in an array cell, it outputs the index of that cell. Then A uses $2\,\mathrm{RS}(\textsc{Ind}_m \circ f)$ queries and evaluates $f^{\log m}$ with probability at least $\mathrm{RS}(\textsc{Ind}_m \circ f)^{-1}/4$.

Next, Theorem 21 implies that for any $\gamma \in (0, 1/4)$, either A's success probability is smaller than $(1/2+\gamma)^{\log m}$, or else A uses at least $\gamma^3(\log m)R(f)/11$ queries. This means either $\mathrm{RS}(\textsc{Ind}_m \circ f)^{-1}/4 \le (1/2+\gamma)^{\log m}$ or $2\,\mathrm{RS}(\textsc{Ind}_m \circ f) \ge \gamma^3(\log m)R(f)/11$, which means

$$\mathrm{RS}(\textsc{Ind}_m \circ f) = \Omega\left(\gamma^3 \min\left\{\left(\frac{2}{1+2\gamma}\right)^{\log m}, R(f)\log m\right\}\right). \tag{2}$$

Now, we have

$$\left(\frac{2}{1+2\gamma}\right)^{\log m} = m^{\log(2/(1+2\gamma))} = m^{1-\log(1+2\gamma)} \ge m^{1-2(\log e)\gamma} \ge m^{1-3\gamma}. \tag{3}$$

If $m \ge (R(f)\log R(f))^{(1-3\gamma)^{-1}}$, the above is at least $R(f)\log R(f) = \Omega(R(f)\log m)$, which means $\mathrm{RS}(\textsc{Ind}_m \circ f) = \Omega(\gamma^3 R(f)\log m)$.

Note that $(1-3\gamma)^{-1} \le 1 + 12\gamma$ for all $\gamma \le 1/4$. Setting $r = 13\gamma$, we get

$$m = \Omega(R(f)^{1+r}) \Rightarrow \mathrm{RS}(\textsc{Ind}_m \circ f) = \Omega(r^3 R(f)\log m) \tag{4}$$

for all r satisfying $r = O(1)$ and $r = \Omega(\log\log R(f)/\log R(f))$. Setting $r = 0.1$ gives the desired result. The lower bound on $\mathrm{RS}_1(f^{\oplus}_{\text{ind}})$ follows similarly once we observe that sabotaging the array cell indexed by the outputs to the c copies of f introduces only one asterisk or obelisk, so the above argument lower bounds RS_1 and not only RS. ◀

Finally, we can prove Theorem 1, more precisely stated as follows.

▶ **Theorem 23.** *Let f and g be (possibly partial) functions, and let $m = \Omega(R(g)^{1.1})$. Then $R(f \circ \textsc{Ind}_m \circ g) = \Omega(R(f)R(g)\log m) = \Omega(R(f)R(\textsc{Ind}_m)R(g))$.*

Proof. By Corollary 19, we have $R(f \circ \textsc{Ind}_m \circ g) \ge R(f)\,\mathrm{RS}(\textsc{Ind}_m \circ g)/10$. Combining with Theorem 22 gives $R(f \circ \textsc{Ind}_m \circ g) = \Omega(R(f)R(g)\log m)$, as desired. ◀

6 Lifting theorem

To establish the connection between lifting theorems, we start with the following lemma, which gives a sabotage lower bound in the communication complexity setting.

▶ **Lemma 24.** *Let f be a (possibly partial) Boolean function on n bits, and let G_b be the index gadget on $\{0,1\}^b \times \{0,1\}^{2^b}$, with $b = O(\log n)$. Then*

$$R^{\mathrm{cc}}(f \circ G_b) = \Omega\left(\frac{R_0^{\mathrm{cc}}(f_{\mathrm{usab}} \circ G'_b)}{\log n \log\log n}\right), \tag{5}$$

where G'_b is the index gadget mapping $\{0,1\}^b \times \{0,1,*,\dagger\}^{2^b}$ to $\{0,1,*,\dagger\}$.

Proof. We'll use a randomized protocol A for $f \circ G_b$ to construct a zero-error protocol B for $f_{\mathrm{usab}} \circ G'_b$. Note the given input to $f_{\mathrm{usab}} \circ G'_b$ must have a unique copy of G'_b that evaluates to $*$ or $\dagger$, with all other copies evaluating to 0 or 1. The goal of B is to find this copy and determine if it evaluates to $*$ or $\dagger$. This will evaluate $f_{\mathrm{usab}} \circ G'_b$ with zero error.

Note that if we replace all $*$ and $\dagger$ symbols in Bob's input with 0 or 1, we'd get a valid input to to $f \circ G_b$, which we can evaluate using A. Moreover, there is a single special $*$ or $\dagger$ in Bob's input that governs the value of this input to $f \circ G_b$. Without loss of generality, we assume that if the special symbol is replaced by 0, the function $f \circ G_b$ evaluates to 0, and if it is replaced by 1, it evaluates to 1.

We can now binary search to find this special symbol. There are at most $n2^b$ asterisks and obelisks in Bob's input. We can set the left half to 0 and the right half to 1, and evaluate the resulting input using A. If the answer is 0, the special symbol is on the left half; otherwise, it is on the right half. We can proceed to binary search in this way, until we've zoomed in on one gadget that must contain the special symbol. This requires narrowing down the search space from n possible gadgets to 1, which requires $\log n$ rounds. Each round requires a call to A, times a $O(\log\log n)$ factor for amplification. We can therefore find the right gadget with bounded error, using $O(R^{\mathrm{cc}}(f \circ G_b) \log n \log\log n)$ bits of communication.

Once we've found the right gadget, we can certify its validity by having Alice send the right index to Bob, using b bits of communication. Since we found a certificate with constant probability, we can use Lemma 3 to turn this into a zero-error algorithm. Thus

$$R_0^{\mathrm{cc}}(f_{\mathrm{usab}} \circ G'_b) = O(b + R^{\mathrm{cc}}(f \circ G_b) \log n \log\log n). \tag{6}$$

Since $b = O(\log n)$, we get $R_0^{\mathrm{cc}}(f_{\mathrm{usab}} \circ G'_b) = O(R^{\mathrm{cc}}(f \circ G_b) \log n \log\log n)$. ◀

Equipped with this lemma we can prove the connection between lifting theorems (Theorem 2), stated more precisely as follows.

▶ **Theorem 25.** *Suppose that for all partial Boolean functions f on n bits, we have*

$$R_0^{\mathrm{cc}}(f \circ G_b) = \tilde{\Omega}(R_0(f)) \tag{7}$$

with $b = O(\log n)$. Then for all partial functions Boolean functions, we also have

$$R^{\mathrm{cc}}(f \circ G_{2b}) = \tilde{\Omega}(R(f)). \tag{8}$$

The loss in the $\tilde{\Omega}$ for the R result is only $\log n \log\log^2 n$ worse than the loss in the R_0 hypothesis.

Proof. First, we note that for any function f and positive integer c,

$$R^{\mathrm{cc}}(f \circ G_{2b}) = \Omega\left(\frac{R^{\mathrm{cc}}(f_{\mathrm{ind}}^{\oplus c} \circ G_{2b})}{c \log c}\right). \tag{9}$$

To see this, note that we can solve $f_{\mathrm{ind}}^{\oplus c} \circ G_{2b}$ by solving the c copies of $f \circ G_{2b}$ and then examining the appropriate cell of the array. This uses $cR^{\mathrm{cc}}(f \circ G_{2b})$ bits of communication, times $O(\log c)$ since we must amplify the randomized protocol to an error of $O(1/c)$.

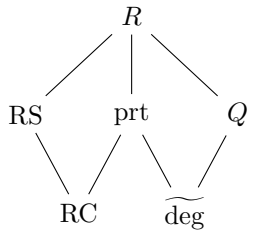

Figure 1 Lower bounds on $R(f)$.

Next, we apply Lemma 24 on $R^{\mathrm{cc}}(f_{\mathrm{ind}}^{\oplus c} \circ G_{2b})$ to get

$$R^{\mathrm{cc}}(f \circ G_{2b}) = \Omega\left(\frac{R^{\mathrm{cc}}(f_{\mathrm{ind}}^{\oplus c} \circ G_{2b})}{c \log c}\right) = \Omega\left(\frac{R_0^{\mathrm{cc}}((f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}} \circ G'_{2b})}{c \log c \log n \log\log n}\right). \tag{10}$$

From here we want to use the assumed lifting theorem for R_0. However, there is a technicality: the gadget G'_{2b} is not the standard index gadget, and the function $(f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}}$ does not have Boolean alphabet. To remedy this, we use two bits to represent each of the symbols $\{0, 1, *, \dagger\}$. Using this representation, we define a new function $(f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}}^{\mathrm{bin}}$ on twice as many bits.

We now compare $(f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}}^{\mathrm{bin}} \circ G_b$ to $(f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}} \circ G'_{2b}$. Note that the former uses two pointers of size b to index two bits, while the latter uses one pointer of size $2b$ to index one symbol in $\{0, 1, *, \dagger\}$ (which is equivalent to two bits). It's not hard to see that the former function is equivalent to the latter function restricted to a promise. This means the communication complexity of the former is smaller, so

$$R^{\mathrm{cc}}(f \circ G_{2b}) = \Omega\left(\frac{R_0^{\mathrm{cc}}((f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}} \circ G'_{2b})}{c \log c \log n \log\log n}\right) = \Omega\left(\frac{R_0^{\mathrm{cc}}((f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}}^{\mathrm{bin}} \circ G_b)}{c \log c \log n \log\log n}\right). \tag{11}$$

We're ready to use the assumed lifting theorem for R_0. To be more precise, let's suppose a lifting result that states $R_0^{\mathrm{cc}}(f \circ G_b) = \Omega(bR_0(f)/\log^k n)$ for some integer k. Applying this to the above gives

$$R^{\mathrm{cc}}(f \circ G_{2b}) = \Omega\left(\frac{R_0^{\mathrm{cc}}((f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}}^{\mathrm{bin}} \circ G_b)}{c \log c \log n \log\log n}\right) = \Omega\left(\frac{bR_0((f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}}^{\mathrm{bin}})}{c \log c \log^{k+1} n \log\log n}\right). \tag{12}$$

We note that

$$R_0((f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}}^{\mathrm{bin}}) = \Omega(R_0((f_{\mathrm{ind}}^{\oplus c})_{\mathrm{usab}})) = \Omega(\mathrm{RS}_1(f_{\mathrm{ind}}^{\oplus c})). \tag{13}$$

Setting $c = 1.1 \log R(f) + \Omega(1)$, we have $\mathrm{RS}_1(f_{\mathrm{ind}}^{\oplus c}) = \Omega(cR(f))$ by Theorem 22. Thus

$$R^{\mathrm{cc}}(f \circ G_{2b}) = \Omega\left(\frac{bcR(f)}{c \log c \log^{k+1} n \log\log n}\right) = \Omega\left(\frac{bR(f)}{\log^{k+1} n \log\log^2 n}\right). \tag{14}$$

This gives the desired lifting theorem for R, with parameters at most $\log n \log\log^2 n$ worse than the assumed R_0 lifting theorem. ◀

7 Comparison with other lower bound methods

In this section we compare $\mathrm{RS}(f)$ with other lower bound techniques for bounded-error randomized query complexity. Figure 1 shows the two most powerful lower bound techniques for $R(f)$, the partition bound ($\mathrm{prt}(f)$) and quantum query complexity ($Q(f)$), which subsume

all other general lower bound techniques. The partition bound and quantum query complexity are incomparable, since there are functions for which the partition bound is larger, e.g., the OR function, and functions for which quantum query complexity is larger [2]. Another common lower bound measure, approximate polynomial degree ($\widetilde{\deg}$) is smaller than both.

Randomized sabotage complexity (RS) can be much larger than the partition bound and quantum query complexity as we show in this section. We also show that randomized sabotage complexity is always as large as randomized certificate complexity (RC), which itself is larger than block sensitivity, another common lower bound technique. Lastly, we also show that $R_0(f) = O(\mathrm{RS}(f)^2 \log \mathrm{RS}(f))$, showing that RS is a quadratically tight lower bound, even for zero-error randomized query complexity.

7.1 Partition bound and quantum query complexity

We start by showing the superiority of randomized sabotage complexity against the two best lower bounds for $R(f)$. Informally, what we show is that any separation between $R(f)$ and a lower bound measure like $Q(f)$, $\mathrm{prt}(f)$, or $\widetilde{\deg}(f)$ readily gives a similar separation between $\mathrm{RS}(f)$ and the same measure.

▶ **Theorem 26.** *There exist total functions f and g such that $\mathrm{RS}(f) \geq \mathrm{prt}(f)^{2-o(1)}$ and $\mathrm{RS}(g) = \widetilde{\Omega}(Q(g)^{2.5})$. There also exists a total function h with $\mathrm{RS}(h) \geq \widetilde{\deg}(h)^{4-o(1)}$.*

Proof. These separations were shown with $R(f)$ in place of $\mathrm{RS}(f)$ in [1] and [2]. To get a lower bound on RS, we can simply compose IND with these functions and apply Theorem 22. This increases RS to be the same as R (up to logarithmic factors), but it does not increase prt, $\widetilde{\deg}$, or Q more than logarithmically, so the desired separations follow. ◀

As it turns out, we didn't even need to compose IND with these functions. It suffices to observe that they all use the cheat sheet construction, and that an argument similar to the proof of Theorem 22 implies that $\mathrm{RS}(f_{\mathrm{CS}}) = \widetilde{\Omega}(R(f))$ for all f (where f_{CS} denotes the cheat sheet version of f, as defined in [1]). In particular, cheat sheets can never be used to separate RS from R (by more than logarithmic factors).

7.2 Randomized certificate complexity

Randomized certificate complexity, $\mathrm{RC}(f)$, is a lower bound for $R(f)$ first studied in [**?**]. We can show that for any partial function f, randomized sabotage complexity upper bounds randomized certificate complexity.

▶ **Theorem 27.** *Let f be a partial function. Then $\mathrm{RS}(f) \geq \mathrm{RC}(f)/4$.*

We defer the definition of $\mathrm{RC}(f)$ and the proof of this theorem to the full version of the paper.

7.3 Zero-error randomized query complexity

▶ **Theorem 28.** *Let f be a total function. Then $R_0(f) = O(\mathrm{RS}(f)^2 \log \mathrm{RS}(f))$ or alternately, $\mathrm{RS}(f) = \Omega(\sqrt{R_0(f)/\log R_0(f)})$.*

Proof. Let A be the $\mathrm{RS}(f)$ algorithm. The idea is to run A on an input to x for long enough that we can ensure it queries a bit in every sensitive block of x; this will mean A found a certificate for x. That will allow us to turn the algorithm into a zero-error algorithm for f.

Let x be any input and let b be a block of x. If we replace the bits of x specified by b with stars, then we can find a $*$ with probability $1/2$ by running A for $2\,\mathrm{RS}(f)$ queries by Markov's inequality. This means that if we run A on x for $2\,\mathrm{RS}(f)$ queries, it has at least $1/2$ probability of querying a bit in any given block of x. Repeating this k times, we get a $2k\,\mathrm{RS}(f)$ query algorithm that queries a bit in any given block of x with probability at least $1 - 2^{-k}$.

Now, by [13], the number of sensitive blocks in x is at most $\mathrm{RC}(f)^{\mathrm{bs}(f)}$ for a total function f. Our probability of querying a bit in all of these blocks is at least $1 - 2^{-k}\,\mathrm{RC}(f)^{\mathrm{bs}(f)}$ by the union bound. When $k \geq 1 + \mathrm{bs}(f)\log_2 \mathrm{RC}(f)$, this is at least $1/2$. Since a bit from every block is a certificate, by Lemma 3, we can turn this into a zero-error randomized algorithm with expected query complexity at most $4(1 + \mathrm{bs}(f)\log_2 \mathrm{RC}(f))\,\mathrm{RS}(f)$, which gives $R_0(f) = O(\mathrm{RS}(f)\,\mathrm{bs}(f)\log \mathrm{RC}(f))$. Since $\mathrm{bs}(f) \leq \mathrm{RC}(f) \leq \mathrm{RS}(f)$ by Theorem 27, we have $R_0(f) = O(\mathrm{RS}(f)^2 \log \mathrm{RS}(f))$, or $\mathrm{RS}(f) = \Omega(\sqrt{R_0(f)/\log R_0(f)})$. ◀

Abstract

We consider the question of interactive communication, in which two remote parties perform a computation while their communication channel is (adversarially) noisy. We extend here the discussion into a more general and stronger class of noise, namely, we allow the channel to perform *insertions* and *deletions* of symbols. These types of errors may bring the parties "out of sync", so that there is no consensus regarding the current round of the protocol.

In this more general noise model, we obtain the first interactive coding scheme that has a constant rate and tolerates noise rates of up to $1/18-\varepsilon$. To this end we develop a novel primitive we name *edit distance tree code*. The edit distance tree code is designed to replace the Hamming distance constraints in Schulman's tree codes (STOC 93), with a stronger edit distance requirement. However, the straightforward generalization of tree codes to edit distance does not seem to yield a primitive that suffices for communication in the presence of synchronization problems. Giving the "right" definition of edit distance tree codes is a main conceptual contribution of this work.

1 Introduction

In the setting of interactive communication two remote parties, Alice and Bob, wish to run a distributed protocol utilizing a noisy communication channel. The study of this problem was initiated by the seminal work of Schulman [22, 23, 24] who showed a coding scheme for interactive protocols in which the communication complexity of the resilient protocol is larger than the communication of the input (noiseless) protocol by only a constant factor. Schulman's coding schemes tolerates *random noise* where each bit is flipped with a small probability, as well as some *adversarial noise* where the only restriction on the noise is the amount of bits being flipped by the adversary. Subsequently, many works considered the question of interactive communication, obtaining coding schemes reaching optimality in terms of their computational efficiency [13, 14, 2, 4, 3, 15], communication efficiency [19, 17, 12], and noise resilience, both in the standard setting [7, 8, 6, 15], and in various other noise models and settings [21, 10, 11, 16, 15, 1, 5, 9].

The recent successes in developing the theory of interactive error-correcting codes brought the study of two-way interactive coding to nearly match what we know about good codes against adversarial noise in the one-way setting.

So far, all works focused on either substitutions (where Eve can substitute a sent symbol with a different symbol from the alphabet) or erasures (where Eve can substitute a sent symbol with a $\perp$). In this work we extend the question of coding for interactive communication over noisy channels to a more general type of noise. Namely, we consider channels with *insertions and deletions* (indels). In the one-way setting, this corresponds to the insertion and deletion model, where Eve is allowed to completely remove transmitted symbols, or inject new symbols. Note that this model is stronger than the substitution model, since a substitution can always be implemented as a deletion followed by an insertion. Even in the one-way regime, this model is more difficult to analyze than the model with substitution errors. As an example, Schulman and Zuckerman [25] gave a polynomial-time encodable and decodable codes for insertion/deletion errors. Their code can tolerate around $\frac{1}{100}$ fraction of insertion/deletion errors. This should be contrasted with efficient codes in the standard noise setting, e.g., [18], tolerating about $\frac{1}{4}$ fraction of bit flips.

The major additional challenge in dealing with indels in the interactive setting compared to the non-interactive indel model and the interactive substitutions model, is that we can no longer assume that Alice and Bob are synchronized: at a given time they may be at different stages of their sides of the protocol! Indeed, if Eve deletes Alice's transmission to Bob and additionally injects a 'spoofed' reply from Bob back to Alice, then while Bob has received no message and assumes the protocol hasn't advanced yet, Alice has received a spoofed reply, and proceeds to the next step of her protocol. From this point and on, unless the insertion/deletion is detected, the parties are unsynchronized, as they run different steps of the protocol. The challenge in dealing with this model is to design a protocol that manages to succeed even without knowing whether the two parties are synchronized.

1.1 Modeling insertions and deletions

Some care is required when dealing with insertion and deletion noise patterns, as certain choices make the model too strong or too weak. For example, consider the case where Alice and Bob send each other symbols in an alternating way. Then, even if a single deletion of a symbol is allowed the noise can cause the protocol to "hang": Bob will be waiting for a symbol from Alice, while Alice will be waiting for Bob's response. Clearly, such a model is

too strong for our purpose, and we should restrict the allowed noise patterns to preserve the protocol's liveliness.

There are two main paradigms for distributed protocol in which parties are not fully-synchronized. The first is a *message-driven* paradigm, in which each party "sleeps" until the arrival of a new message that triggers it into performing some computation and sending a message to the other party. The second is *clock-driven*, where each party holds a clock: each clock tick, the party wakes up, checks the incoming messages queue, performs some computation, and sends a message to the other side. The issue here is that different parties may have mismatching or skewed clocks. Then, instead of acting in an alternating manner, one party may wake up several times while the other party is still asleep.

We emphasize that if the parties have matching clocks, then no insertions and deletions are possible – channel corruption in this case has either the effect of changing one symbol to another (as in a standard noisy channel), or causing a detectible corruption, i.e., an erasure. Both these types of noise are substantially weaker than insertions and deletions, and were already analyzed in previous work (e.g., [24, 8, 11, 9]).

Our noise model, which we describe shortly, makes sense for both the above paradigms: it guarantees liveliness in a message-driven setting; for the clock-driven model, we can show that any such settings reduces to our model, that is, any resilient protocol in our model can be used to obtain a resilient protocol in the clock-driven setting. The skewness of the clocks in that case, is related to the noise-resilience of the protocol in our model. See the full version for the complete details.

In this work we assume a message-driven setting, where the parties normally speak in alternating manner. Any corruption in our model must be a deletion which is followed by an insertion. We name each such tampering as an *edit corruption*.

▶ **Definition 1** (Edit Corruption)**.** An edit-corruption is a single deletion followed by a single insertion (whether the inserted symbol is aimed at the same or the opposite party as the deleted message).

This gives rise to two types of attacks Eve can perform: (i) delete a symbol and replace it with a different symbol (insert a symbol at the same direction as the deleted symbol; a substitution attack); (ii) delete a symbol, and insert a spoofed reply from the other side (insert a symbol at the opposite direction of the deleted symbol). The second type of corruption has an effect of making the parties 'out-of-sync': one party advances one step in the protocol, while the other does not; see Figure 1. Note that a substitution has a cost a single corruption, i.e., it is counted as a single deletion followed by a single insertion. Also note that although an outside viewer can split Eve's attack into pairs of deletion-and-insertion, the string that a certain party receives, from that party's own view, suffers an *arbitrary* pattern of insertions/deletions.

1.2 Our Results and Techniques

Tree codes with edit distance. When only a single message is to be transmitted (i.e., in the one-way setting), codes that withstand insertions and deletions were first considered by Levenshtein [20]. In such codes, each two codewords must be far away in their *edit distance*, a notion of distance that captures the amount of insertions/deletions it takes to convert one codeword to another. The edit distance replaces the Hamming distance, which essentially counts the amount of bit flips required to turn one codeword to another.

A key ingredient in interactive-communication schemes is the *tree code* [24], a labeled tree such that the labels on each descending path in the tree can be seen as a codeword. The

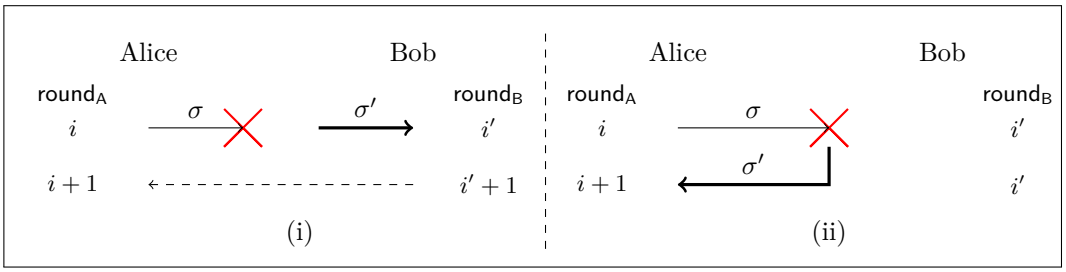

Figure 1 An illustration of the two insertion/deletion attacks: (i) a deletion followed by an insertion in the same direction (a substitution); (ii) a deletion followed by an insertion to the opposite direction (an out-of-sync attack). The deleted transmission is marked with a cross, and the inserted transmission is marked with a bold arrow. The dashed arrow denotes a possible (non-interrupted) reply.

tree code is parametrized by a distance parameter α, and it holds that any two codewords whose paths diverge from the same node, are at least α-apart in their Hamming distance. Encoding a message via a tree code allows a party to *eventually* obtain the message sent by the other side, as long as not too many errors have happened. This in turn allows the parties to correct errors that previously occurred in the simulation, and revert the simulation back into a correct state [24, 8]. In order to keep the communication overhead a constant factor when tree code encoding is used in interactive schemes, it is required that each label of the tree comes from an alphabet of constant size (that is, the size of the alphabet is independent of the tree's depth and thus independent of the length of protocol to simulate).

It is only natural to believe that we could obtain interactive-communication schemes that withstand insertions/deletions by replacing tree codes with a stronger notion of codes, namely, *edit distance tree codes*. In edit distance tree codes, each two codewords (possibly of different lengths) which diverge at a certain point, are required to be far apart in their edit distance rather than their Hamming distance. Yet, since the parties are not synchronized, new difficulties arise. To give a simple example, assume Alice sends one of the two following encodings $s_1 = ABCAAABBB$ and $s_2 = ABCABCAAA$, and assume Bob has receives the string $ABCBBB$. If Bob knew that Alice thinks she is in round 6 of the protocol, he would decode to s_2; if he knew that Alice thinks she is in round 9, he would decode to s_1. Alas, he does not know which is the case!

To mitigate situations in which not being synchronized may hurt us, we require an even stronger property, namely, we wish that the suffixes (of arbitrary lengths) of any two overlapping codewords will have appropriately large edit distance (see Definitions 14 and 15 for the precise condition). This stronger property guarantees that two "branches" in the tree are far apart in their edit distance, even when they are shifted with respect to each other due to lack of synchronization possibly caused by previous indels. We can then show that as long as not too many indels occurred in the *suffix* of the received codeword, the tree-code succeeds to recover the entire sent message. Crucial in this approach is a notion of distance we call *suffix distance* (Definition 21), that measures the amount of noise in a codewords' suffix. This generalizes a distance measure by Franklin et al. [10, 11] (see also Braverman and Efremenko [6]) to the case where the received word may be misaligned with respect to the sent word, due to indels.

Alas, while (Hamming distance) tree codes over a constant alphabet were shown to exist by Schulman [24], it is not clear if such trees exist for edit distance, and if so, for which distance parameter α, as Schulman's proof doesn't carry over to the edit distance case.

Our first result (Section 3) shows the existence of edit distance tree codes, for any distance parameter α,

▶ **Theorem 2** (Informal). *For any $\alpha < 1$ and any $d, n \in \mathbb{N}$ there exists a d-ary edit distance tree code of depth n over a constant-size alphabet.*

As in the case of standard tree codes, finding an *efficient* construction for such trees remains an important open question. Building on the techniques of Gelles, Moitra and Sahai [13, 14] we give in the full version an efficient randomized construction of a relaxed notion for edit-distance tree codes, we call a *potent edit distance* tree codes. These trees satisfy the edit-distance guarantee *almost* everywhere, and are good enough to replace the tree-code notion of Theorem 2 in most applications.

▶ **Theorem 3** (Informal). *For any $\alpha < 1$ and any $d, n \in \mathbb{N}$ there exists a randomized construction of a d-ary potent edit distance tree code of length n over a constant-size alphabet. The construction is efficient and succeeds with overwhelming probability (in n).*

While in the rest of the paper (namely, for our coding scheme) we assume the edit-distance notion of Theorem 2, all our schemes work the same when the tree is replaced with a potent one; see the full version for further details.

Interactive-communication schemes tolerating insertions/deletions. Equipped with edit distance tree codes, we show a protocol that solves the *pointer jumping problem* over a noisy channel with insertions and deletions and exhibits linear communication complexity in the noiseless communication. Since the pointer jumping problem is complete for two-party interactive communication, this implies a coding scheme that can simulate any protocol over a channel that may introduce insertion/deletions. Specifically, in Sections 4 and 5 we show that for any $\varepsilon > 0$ and any noiseless protocol π and inputs x, y, there is a scheme that correctly simulates π (that is, produces the transcript $\pi(x, y)$ at both parties), withstands $1/18 - \varepsilon$ fraction of edit-corruptions, and has a linear communication complexity with respect to the communication of the protocol π.

▶ **Theorem 4.** *For any $\varepsilon > 0$, and for any binary (noiseless) protocol π with communication $CC(\pi)$, there exists a noise-resilient coding scheme with communication $O_\varepsilon(CC(\pi))$ that succeeds in simulating π as long as the adversarial edit-corruption rate is at most $1/18 - \varepsilon$.*

Our coding scheme and analysis follows ideas by Braverman and Rao [8] and by Braverman and Efremenko [6] – first focusing on channels with polynomial-size alphabet and then generalizing to channels with constant-size alphabet – however, the analysis in the light of insertions and deletions is more complicated and subtle. In particular, similar to [6], our analysis uses the notion of suffix distance for relating the effect of the noise to the progress of the simulation.

We note again that due to out-of-sync attacks, it is possible that the parties' belief of the "current" round of the protocol is different. In the worst case, while Alice reaches the end of the coding protocol (say, round N), it is possible that Bob has only reached round $(1-2\rho)N$, e.g., due to $2\rho N$ deletions in his received communication (ρ is the fraction of edit-corruptions in that instance). Therefore, if we wish to tolerate a ρ-fraction of edit-corruptions, it is imperative that the parties output the correct answer already at round $(1-2\rho)N$. Our coding scheme (Theorem 4) satisfies even this more strict requirement.

Finally, we show that for a family of rigid protocols, in which we require *both* parties to output the correct value at round $(1-2\rho)N$, then $\rho = 1/6$ is an upper bound on the admissible edit-corruption rate. Details can be found in the full version.

▶ **Theorem 5** (Informal). *If both parties are required to give output at round* $(1-2\rho)N$*, then no coding scheme of length* N *can tolerate an edit-corruption rate of* $\rho = 1/6$*.*

Closing the gap between the upper bound of 1/6, and the resilience 1/18 achieved by the scheme of Theorem 4 is left for future work.

2 Preliminaries

For any finite set S, we denote by $x \underset{U}{\leftarrow} S$ the case that x is uniformly distributed over S. All logarithms are taken to base 2. We denote the set $\{1, 2, \ldots, n\}$ by $[n]$. For a set Σ we denote $\Sigma^{\leq n} = \cup_{0 \leq i \leq n} \Sigma^i$, and $\Sigma^* = \cup_{i \geq 0} \Sigma^i$. Let $s \in \Sigma^l$ be a string of length $|s| = l$. For $1 \leq i \leq j \leq l$, we use $s[i]$ to denote the i-th symbol of s and $s[i..j]$ to denote the string $s[i] \circ s[i+1] \circ \cdots \circ s[j]$.

▶ **Definition 6** (Pointer Jumping Problem). Any communication protocol of T rounds where the parties alternately exchange bits can be reduced to the following *pointer jumping problem* $PJP(T)$: Let $\mathcal{T}$ be a binary tree of depth T. Alice's input X is a set of *consistent* edges leaving vertices at even depths. Bob's input Y is a set of consistent edges leaving odd-level vertices. A set of edges is *consistent* on a specified set of vertices, if it contains exactly one edge leaving every vertex in that specified set. Due to being consistent on all the nodes, $X \cup Y$ defines a unique root-to-leaf path. The parties' goal is to output this unique path. Note that T alternating rounds of communication suffice to compute this path, assuming noiseless channels.

▶ **Definition 7** (Protocols). An interactive protocol π for a function $f(x, y)$ is a distributed algorithm that dictates for each party, at every round, the next message (symbol) to send given the party's input and the messages received so far. Each transmitted symbol is assumed to be out of a fixed alphabet Σ. The protocol runs for N rounds (also called the length of the protocol), after which the parties give output. An instance of the protocol, on inputs x, y is said to be *correct* if both parties output $f(x, y)$ at the end of the protocol.

In this work we focus on *alternating* protocols, where as long as there is no noise, the protocol runs for $2N$ rounds in which Alice and Bob send symbols alternately. In the presence of ρ-fraction of edit corruptions (i.e., at most $2\rho N$ insertion/deletion errors), it is possible that some party receives only $N(1-2\rho)$ symbols throughout the protocol. We say that the protocol is correct in presence of ρ-fraction of edit corruption if both parties output $f(x, y)$ by round $N(1-2\rho)$ (according to their own round counting, which may differ from the count of the other party).

▶ **Definition 8** (String Matching). We say that $\tau = (\tau_1, \tau_2)$ is a string matching between a sent message sm and a received message rm (denoted $\tau : sm \to rm$), if $|\tau_1| = |\tau_2|$, $del(\tau_1) = sm$, $del(\tau_2) = rm$, and $\tau_1[i] \approx \tau_2[i]$ for all $i = 1, \ldots, |\tau_1|$. Here del is a function that deletes all the $*$'s in the string and two characters a and b satisfy $a \approx b$ if $a = b$ or one of a and b is $*$. We assume that $*$ is a special symbol that does not appear in sm and rm.

▶ **Definition 9** (Edit Distance). The edit distance of between $sm \in \Sigma^*$ and $rm \in \Sigma^*$ is defined as $ED(sm, rm) = \min_{\tau : sm \to rm} sc(\tau_1) + sc(\tau_2)$. Here $sc(\tau_1)$ is the number of $*$'s in τ_1.

▶ **Fact 10** (Triangle Inequality). *For any three strings* x, y, z*,* $ED(x, y) \leq ED(x, z) + ED(y, z)$*.*

▶ **Fact 11.** *For any two strings* x, y*,* $ED(x, y) = |x| + |y| - 2 \cdot LCS(x, y)$*. Here* $LCS(x, y)$ *is the longest common substring of* x *and* y*.*

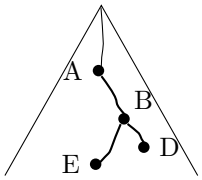

Figure 2 An illustration of lambda structure.

▶ **Lemma 12.** *Let $x \in \Sigma^m$ be some given string, $m \geq n$ and $|\Sigma| \geq 4$. For any constant $\alpha \in [0,1]$, $\Pr_{y \underset{U}{\leftarrow} \Sigma^n}[ED(x,y) \leq \alpha \cdot m] \leq |\Sigma|^{-\frac{(1-\alpha)m}{2}}$.*

The proof of the above Lemma, along with other missing proofs, are deferred to the full version of this work.

3 Edit-distance tree code

In this section we recall the notion of tree-codes [24] and provide a novel primitive, namely, the edit-distance tree-code.

▶ **Definition 13** (Prefix Code)**.** A prefix code $C : \Sigma_{in}^n \to \Sigma_{out}^n$ is a code such that $C(x)[i]$ only depends on $x[1..i]$. C can be also considered as a $|\Sigma_{in}|$-ary tree of depth n with symbols written on edges of the tree using an alphabet size $|\Sigma_{out}|$. On this tree, each tree path from the root of length l corresponds to a string $x \in \Sigma_{in}^l$ and the symbol written on the deepest edge of this path corresponds to $C(x)[l]$.

▶ **Definition 14** (α-bad Lambda)**.** We say that a prefix code C contains an α-bad lambda if when you consider this prefix code as a tree, there exist four tree nodes A,B,D,E such that $B \neq D$, $B \neq E$, B is D and E's common ancestor, A is B's ancestor or B itself, and $ED(AD, BE) \leq \alpha \cdot \max(|AD|, |BE|)$. Here AD and BE are strings of symbols along the tree path from A to D and the tree path from B to E. See Figure 2.

▶ **Definition 15** (Edit-distance Tree Code)**.** We say that a prefix code C: $\Sigma_{in}^n \to \Sigma_{out}^n$ is a α-edit-distance tree code if C does not contain an α-bad lambda.

Our main theorem in this section is the existence of edit-distance tree codes,

▶ **Theorem 16.** *For any $d \geq 2$, $n > 0$ and $0 < \alpha < 1$, there exists an α-edit-distance tree code of depth n with alphabet size $|\Sigma_{in}| = d$ and $|\Sigma_{out}| = (176 \cdot d)^{4/(1-\alpha)}$.*

Proof. We prove this theorem by induction on n. To this end we define a slightly stronger notion than α-bad lambda free, which we call "excellent". Intuitively, if a tree-code C is excellent, then with a good probability, C will not cause a bad lambda in a tree-code that contains C as a subtree. This would allow us to construct lambda-free trees of length n building on lambda-free trees with a smaller depth as subtrees.

▶ **Definition 17** (Potential Probability)**.** For any prefix code $C : \Sigma_{in}^n \to \Sigma_{out}^n$, and any $i \geq 0$, consider C as a tree and define a new (non-regular) tree C' by connecting a simple path of length i to the root of C, making the other end of this path the root of C'. Label each edge along the new path with a symbol from Σ_{out} chosen uniformly and independently.

The potential probability $P_i(C)$ is defined as the probability that the new tree C' has a α-bad lambda with $A =$ the root of C' and $B =$ the root of C.

▶ **Definition 18** (Excellent)**.** For a constant $c_1 > 1$, which we will fix shortly, we say that a prefix code C is excellent if $\forall i \geq 0$, $P_i(C) \cdot (d \cdot c_1)^i < 1$ and C is α-bad-lambda-free.

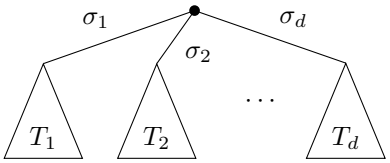
In the proof, we are going to construct a set called S_n which would contain only excellent d-ary prefix codes of depth n with alphabet size $d^{O_\alpha(1)}$. Since excellent is a stronger notion than α-bad lambda-free, if we can construct S_n and show that for any $n > 0$ it is non-empty, then we are done. In each S_n, all codes use the same Σ_{in} and Σ_{out}. We have $|\Sigma_{in}| = d$ and $|\Sigma_{out}| = s$ where the conditions we put on s thorough the following proof are given by:

$$s = \max\left\{ \frac{\alpha d}{(1-\alpha)} \cdot (d \cdot c_1)^{\frac{\alpha}{1-\alpha}} + 1, d^2, (\frac{4d}{c_2})^{\frac{4}{1-\alpha}}, (c_1 \cdot d \cdot 4)^{\frac{4}{1-\alpha}} \right\}.$$

Here $c_1 = 44$, and $c_2 = \frac{1}{11}$. Therefore, taking $s \geq (176d)^{4/(1-\alpha)}$ satisfies all the above conditions.

Let us now inductively construct S_n. For notation convenience, let $S_0 = \{\text{a single node}\}$. For $n > 0$, let

$$\tilde{S}_n = \left\{ T = \right.$$



$$\left| \begin{array}{l} T_1, T_2, ..., T_d \in S_{n-1} \text{ and} \\ \sigma_1, \sigma_2, ..., \sigma_d \in \Sigma_{out} \end{array} \right\}.$$

and define $S_n = \{C \in \tilde{S}_n |\ C \text{ is excellet}\}$. From this definition, we directly have that every $C \in S_n$ is excellent, and we are only left to show that S_n is non-empty. Actually, we are going to prove the following claim by induction.

▶ **Claim 19.** *For all n, $\frac{|S_n|}{|\tilde{S}_n|} \geq c_2 = \frac{1}{11}$.*

Base case ($n = 1$): Consider the following set.

$$S_1' = \{C \mid C \text{ is a } d\text{-ary prefix code of depth 1 and } d \text{ different codewords}\}$$

We want to show that $S_1' \subseteq S_1$. For any $C \in S_1'$, it is clear that C does not have any α-bad lambda. Because in this depth 1 tree, one can only pick $A = B$ to be the root, and D, E to be some different leaves. Then $ED(AD, BE) = 2$ and $|AD| = |BE| = 1$. So $ED(AD, BE) > \alpha \cdot \max(|AD|, |BE|)$. Now let's consider the potential probability $P_i(C)$. Suppose there exists an α-bad lambda in the tree after adding a path of length i. Then in this α-bad lambda, B is the original root, AB is the path added to the root and D and E are two different leaves of the tree. There are two cases to consider:

1. $i = |AB| > \alpha/(1-\alpha)$: In this case, since $|BE| = 1$, $(|AD| - |BE|)/|AD| = 1 - \frac{1}{1+|AB|} > \alpha$. So it is not possible that $ED(AD, BE) < \alpha \cdot |AD|$. Thus $P_i(C) = 0$.
2. $i = |AB| \leq \alpha/(1-\alpha)$: In this case, let W be the event that one of the labels along the path AB equals to one of the d codewords of C. Clearly, when W does not happen, $ED(AD, BE) = |AD| + |BE| > \alpha \cdot |AD|$. It is also immediate that $\Pr[W] \leq i \cdot \frac{d}{s}$. We require $s > \frac{\alpha d}{(1-\alpha)} \cdot (d \cdot c_1)^{\frac{\alpha}{1-\alpha}}$, and get that $P_i(C) \cdot (d \cdot c_1)^i \leq \Pr[W] \cdot (d \cdot c_1)^i \leq \frac{\alpha d}{(1-\alpha)s} \cdot (d \cdot c_1)^{\frac{\alpha}{1-\alpha}} < 1$.

Therefore, we have proved that all the prefix codes in S_1' are excellent and therefore in S_1. Then because $s \geq d^2$, we get $\frac{|S_1|}{|\tilde{S}_1|} \geq \frac{|S_1'|}{|\tilde{S}_1|} = \frac{s(s-1)\times\cdots\times(s-d+1)}{s^d} \geq (1 - 1/d)^d > 1/11 = c_2$.

Inductive step: Suppose we already know that for $1 \le i < n$, $\frac{|S_i|}{|\tilde{S}_i|} \ge c_2$, and let us prove that $\frac{|S_n|}{|\tilde{S}_n|} \ge c_2$. We will use the following lemma, whose proof is quite straightforward.

▶ **Lemma 20.** *If for all* $1 \le i < n$, $\frac{|S_i|}{|\tilde{S}_i|} \ge c_2$. *Then for any* $x \in \Sigma_{out}^j$ *where* $0 < j \le n$ *and* $y \in \Sigma_{in}^n$, *it holds that* $\Pr_{C \xleftarrow[U]{} \tilde{S}_n}[C(y)[1..j] = x] \le c_2^{1-j} s^{-j}$.

In order to show that $\frac{|S_n|}{|\tilde{S}_n|} \ge c_2$, we can choose C randomly from $\tilde{S}_n$, and show that $\Pr[C \text{ is excellent}] \ge c_2$. To this end, consider the conditions of being excellent in turn:

1. Let's first consider $\Pr[P_i(C) \cdot (d \cdot c_1)^i \ge 1]$. By Lemma 20 and Lemma 12, we get

$$\begin{aligned}
&\mathbb{E}_{C \xleftarrow[U]{} \tilde{S}_n}[P_i(C)] \\
\le &\sum_{1 \le n_1, n_2 \le n} \sum_{\substack{x \in \Sigma_{in}^{n_1}, y \in \Sigma_{in}^{n_2}, \\ x[1] \ne y[1]}} \Pr_{\substack{z \xleftarrow[U]{} \Sigma_{out}^i \\ C \xleftarrow[U]{} \tilde{S}_n}} [ED(z \circ C(x), C(y)) \le \alpha \cdot \max(i + n_1, n_2)] \\
\le &\sum_{1 \le n_1, n_2 \le n} d^{n_1+n_2} \cdot c_2^{2-n_1-n_2} \Pr_{x \xleftarrow[U]{} \Sigma_{out}^{n_1}, y \xleftarrow[U]{} \Sigma_{out}^{n_2}, z \xleftarrow[U]{} \Sigma_{out}^i} [ED(z \circ x, y) \le \alpha \cdot \max(i + n_1, n_2)] \\
\le &\sum_{1 \le n_1, n_2 \le n} \left(\frac{d}{c_2}\right)^{n_1+n_2} s^{-\frac{1-\alpha}{2} \cdot \frac{n_1+n_2+i}{2}} \le \sum_{1 \le n_1, n_2 \le n} \left(\frac{d}{c_2} \cdot s^{-\frac{1-\alpha}{4}}\right)^{n_1+n_2} s^{-\frac{(1-\alpha)i}{4}} \\
\le &\sum_{1 \le n_1, n_2 \le n} \left(\frac{1}{4}\right)^{n_1+n_2} (c_1 \cdot d \cdot 4)^{-i} \le \sum_{j=2}^{\infty} \frac{j}{4^j} \cdot (c_1 \cdot d \cdot 4)^{-i} = \frac{7}{36} (c_1 \cdot d \cdot 4)^{-i}
\end{aligned}$$

   By Markov's inequality, $\Pr[P_i(C) \cdot (d \cdot c_1)^i \ge 1] \le \frac{7}{36} \cdot \frac{1}{4^i}$. Then $\sum_{i=0}^{\infty} \Pr[P_i(C) \cdot (d \cdot c_1)^i \ge 1] \le \frac{7}{36} \sum_{i=0}^{\infty} \frac{1}{4^i} = \frac{7}{27} < \frac{5}{11} = \frac{1-c_2}{2}$.
2. Now let's consider the event that C has an α-bad lambda with $A = B = root$. It is easy to see that this event is equivalent to $P_0(C) \ge 1$. Therefore it is covered by the previous case.
3. Now let's consider the event that C has an α-bad lambda with $A = root$ and $B \ne root$. By Lemma 20 and Definition 18, we have

$$\begin{aligned}
&\Pr[C \text{ has an } \alpha\text{-bad lambda with } A = root, B \ne root] \\
&\le \sum_{n_1 \le n} d^{n_1} \cdot c_2^{1-n_1} \cdot (d \cdot c_1)^{-n_1} \le \sum_{n_1=1}^{\infty} (\frac{1}{c_1 c_2})^{n_1} = \sum_{n_1=1}^{\infty} (\frac{1}{4})^{n_1} = \frac{1}{3} < \frac{5}{11} = \frac{1-c_2}{2}.
\end{aligned}$$

4. Finally let's consider the case that C has an α-bad lambda with $A \ne root$. It is easy to see that this event never happens because C's subtrees rooted at depth 1 in C are all excellent.

Therefore by union bound, $\Pr[C \text{ is excellent}]$ is at least

$$\begin{aligned}
&\ge 1 - \sum_{i=0}^{\infty} \Pr[P_i(C) \cdot (d \cdot c_1)^i \ge 1] - \Pr[C \text{ has an } \alpha\text{-bad lambda with } A = root, B \ne root] \\
&\ge 1 - \frac{1-c_2}{2} - \frac{1-c_2}{2} = c_2.
\end{aligned}$$

◀

3.1 Decoding of edit-distance tree codes

The decoding of a codeword $rm \in \Sigma_{out}^j$ via an edit-distance tree-code C amounts to finding a message whose encoding minimizes the suffix distance to rm, i.e., $\mathsf{DEC}(rm) = \arg\min_{m \in \Sigma_{in}^{\le n}} SD(rm, C(m))$, where the suffix distance $SD(\cdot, \cdot)$ is defined as follows.

▶ **Definition 21** (Suffix Distance). Given any two strings $sm, rm \in \Sigma^*$, the suffix distance between sm and rm is $SD(sm, rm) = \min_{\tau: sm \to rm} \max_{i=1}^{|\tau_1|} \frac{sc(\tau_1[i..|\tau_1|]) + sc(\tau_2[i..|\tau_2|])}{|\tau_1| - i + 1 - sc(\tau_1[i..|\tau_1|])}$.

The following lemma, which plays an important role in the analysis of the simulation protocols that we present in the next sections, shows that if a message sm is encoded by some α-edit-distance tree code and the received message rm satisfies $SD(sm, rm) \leq \frac{\alpha}{2}$, then the receiver can recover the entire sent message correctly.

▶ **Lemma 22.** *Let $C\colon \Sigma_{in}^n \to \Sigma_{out}^n$ be an α-edit-distance tree code, and let $rm \in \Sigma_{out}^m$ (m can be different from n). There exists at most one $sm \in \cup_{i=1}^n C(\Sigma_{in}^n)[1..i]$ such that $SD(sm, rm) \leq \frac{\alpha}{2}$.*

4 A coding scheme with a polynomial alphabet size

In this section, we show a protocol π that solves $PJP(T)$ in $O(T)$ rounds over channels with alphabet size $poly(T)$, and is resilient to (a constant fraction of) insertion/deletion errors. Since the $PJP(T)$ is complete for interactive communication, this implies that any binary protocol with T rounds can be simulated in $O(T)$ rounds over a channel with polynomially-large alphabet that corrupts at most a fraction $1/18 - \varepsilon$ of the transmissions. While this protocol does not exhibit a constant rate, it contains all the main ideas for the constant-rate protocol of Theorem 4, and thus we focus on this simple variant first. Then, in Section 5 we discuss how to reduce the alphabet size and achieve a protocol with $O(T)$ communication complexity with the same resilience guarantees.

Assume π has $2N$ alternating rounds, that is, Alice and Bob send N symbols each, assuming there are no errors. We would like the protocol to resist a fraction of ρ edit-corruptions, that is, the protocol should succeed as long as there are at most $2\rho N$ insertion/deletion errors. Due our assumption that the adversary never causes the protocol to "get stuck", this amounts to at most $2\rho N$ deletions, where each deletion is followed by an insertion.

We assume that Alice and Bob share some fixed α-edit-distance tree code $C : \Sigma_{in}^N \to \Sigma_{out}^N$ given by Theorem 16. We will set the values of N, α, and Σ_{in} later. Currently we only need to know $N = poly(T)$.

Let us begin with a high-level outline of the protocol π. The protocol basically progresses by sending edges in the tree $\mathcal{T}$ of the underlying $PJP(T)$, interactively constructing the joint path (similar to [8]). To communicate an edge e, the parties encode it as a pair of numbers (n, s), where $0 \leq n \leq N$ and $s \in \{1, 2, 3, 4\}$. The value n indicates the number of some previous round in which some edge e' was sent, and the value s determines e as the s-grandchild of e'. That is, we always send an edge e by linking it to an edge e' that was previously sent, such that e' is located two levels above in unique path leading from the root to e. If e does not have a grandparent (e.g., it is the at the first or second level in $\mathcal{T}$), we will set $n = 0$. Sometimes the parties have no edge to send, in which case they set $n = N$ and say that e is an empty edge. We take Σ_{in} to be all the possible encodings (n, s). As $0 \leq n \leq N$ and $1 \leq s \leq 4$, we have $|\Sigma_{in}| = poly(N) = poly(T)$. As $|\Sigma_{out}|$ is polynomial in $|\Sigma_{in}|$ (Theorem 16), we also have $|\Sigma_{out}| = poly(N) = poly(T)$.

The protocol π is described in Protocol 1. The description is for Alice side; Bob's part is symmetric. Here we explain more than the pseudocode on how to get $E(d_A)$. Basically d_A is a string of symbols in Σ_{in} and those symbols are in the form (n, s). $E(d_A)$ will be the set of edges these symbols in d_A represent. To get the edge each symbol (n, s) represents, we will first find the edge sent in n-th round and get its proper grandchild according to s. If n is not in the correct range then we consider d_A as not valid.

Protocol 1 The protocol π

Let $\mathcal{T}$ be given by $PJP(T)$. Recall that Alice's input is X. Assume the parties share some fixed α-edit-distance tree code $C : \Sigma_{in}^N \to \Sigma_{out}^N$.

Initially we set the counter $i = 0$. For any leaf node v in $\mathcal{T}$ we initialize a counter $s(v) = 0$. Run the following for N times.

1. $i \leftarrow i + 1$.
2. Receive a symbol $r_A[i]$ from the other party. (For Alice, if $i = 1$, skip this step)
3. Find $d_A \in \Sigma_{in}^*$ which minimizes $SD(d_A, r_A[1 \dots i])$.
4. If $E(d_A) \cup X$ has a unique path from the root in $\mathcal{T}$, do the following. Here $E(d_A)$ is the set of edges indicated by d_A, if d_A is not a valid string of symbols, $E(d_A) = \emptyset$.
   a. If this path reaches a leaf node v, then $s(v) \leftarrow s(v) + 1$.
   b. Let e be the deepest edge on the the unique path from root. If $e \in X$, and e is either an edge in the first or second level of $\mathcal{T}$ or e's grandparent has been sent, set $s_A[i]$ to be encoding of e, otherwise set $s_A[i]$ to be encoding of an empty edge.
5. If $E(d_A) \cup X$ does not have a unique path from the root in $\mathcal{T}$, set $s_A[i]$ to be encoding of an empty edge.
6. If $i = N(1 - 2\rho)$, output the leaf node v with the largest $s(v)$.
7. Send $C(s_A[1 \dots i])[i]$ to Bob.

We now analyze Protocol 1 and prove it resists up to $(1/18-\varepsilon)$-fraction of edit corruptions. Let N_A and N_B be the counter i of Alice and Bob respectively, when one of them reaches the end of the protocol π. Let $\tau_A = (\tau_1, \tau_2)$ be the string matching between $s_B[1..N_B]$ and $r_A[1..N_A]$ that is consistent with the protocol. Let $\tau_B = (\tau_3, \tau_4)$ be the string matching between $s_A[1..N_A]$ and $r_B[1..N_B]$. Recall that we use $sc(\tau)$ to denote the number of $*$'s in the string. By definition, $sc(\tau_1) + sc(\tau_3) \le 2\rho N$ and $sc(\tau_2) + sc(\tau_4) \le 2\rho N$.

In the analysis we count the number of rounds in which Alice correctly decodes the entire (current) set of edges sent by Bob. We call each such round a *good decoding*.

▶ **Definition 23** (Good Decoding)**.** When a party decodes a message, we say it is a *good decoding* if the decoded messages is exactly the one sent by the other side (i.e., $d_A = s_B[1..i]$ or $d_B = s_A[1..i]$, assuming the other side is at round i), and the symbol just received is not an adversarial insertion. If a decoding is not good, we call it a bad decoding.

In the following lemma show that as long as noise is small enough, there will be many rounds with good decodings. The proof can be found in the full version.

▶ **Lemma 24.** *Alice has at least* $N_A + (1 - \frac{2}{\alpha})sc(\tau_2) - (1 + \frac{2}{\alpha})sc(\tau_1)$ *good decodings. Bob has at least* $N_B + (1 - \frac{2}{\alpha})sc(\tau_4) - (1 + \frac{2}{\alpha})sc(\tau_3)$ *good decodings.*

After we have established that Alice and Bob will have many good decodings, we show that this implies they will have good progress in constructing their joint path in the underlying $PJP(T)$. Consider the $N_A + N_B$ decodings that happen during the protocol, and sort them in a natural order; we say that these decodings occur at "times" $t = 1, 2, \dots, N_A + N_B$. Note that the decodings need not be alternating – Eve's insertions and deletions may cause one party to perform several consecutive decodings while the other party does not receive any symbol, and performs no decoding. We also assume that for each decoding, the sending of the next symbol happens at the same "time" as the decoding. Let $e_A(t)$ be the set of edges Alice has sent at time t and $e_B(t)$ be the set of edges Bob has sent at time t. Let P be the correct path of length T of $PJP(T)$. Define $l(t)$ to be the length of the longest path from

the root using edges in $P \cap (e_A(t) \cup e_B(t))$. Basically $l(t)$ measures how much progress Alice and Bob have made. Let us also define $m(i)$ to be the first time t such that $l(t) \geq i$. For notation convenience, let $m(0) = 0$.

The following lemma shows that if the parties do not make progress, many bad decodings (and thus, many errors) must have occurred. The proof can be found in the full version.

▶ **Lemma 25.** *For $i = 0, \ldots, T-1$, if $m(i+1) \neq m(i)+1$, then during times $m(i)+1, \ldots, m(i+1)-1$, the following is true.*

1. *If i is odd, then there are no good decodings of Bob. The number of good decodings of Alice is at most the number of bad decodings of Bob.*
2. *If i is even, then there are no good decodings of Alice. The number of good decodings of Bob is at most the number of bad decodings of Alice.*

Combining the above lemmas, we get the main theorem for protocols with polynomial size alphabet.

▶ **Theorem 26.** *For any $\varepsilon > 0$, the protocol π of Protocol 1 with $N = \lceil \frac{T}{16\varepsilon} \rceil$, and a $(1-\varepsilon)$-edit tree code, solves $PJP(T)$ and is resilient to a $(1/18 - \varepsilon)$-fraction of edit corruptions.*

Proof. Set $\rho = \frac{1}{18} - \varepsilon$ and $\alpha = 1 - \varepsilon$. Let g_A be the number of good decodings of Alice, $b_A = N_A - g_A$ be the number of bad decodings of Alice. Similarly, let g_B be the number of good decodings of Bob, and let $b_B = N_B - g_b$. Recall that $sc(\tau_1) + sc(\tau_3) = sc(\tau_2) + sc(\tau_4) \leq 2\rho N$, then by Lemma 24, we have

$$b_A + b_B \leq \frac{2}{\alpha}(sc(\tau_1) + sc(\tau_2)) + sc(\tau_1) - sc(\tau_2) + \frac{2}{\alpha}(sc(\tau_3) + sc(\tau_4)) + sc(\tau_3) - sc(\tau_4),$$

thus $b_A + b_B \leq 8\rho N/\alpha$. Then we have,

$$\begin{aligned} g_A = N_A - b_A &\geq N_A - \frac{8\rho N}{\alpha} \geq (N_A - N(1-2\rho)) + N(1-2\rho) - \frac{8\rho N}{\alpha} \\ &\geq b_A + b_B - \frac{8\rho N}{\alpha} - (N_A - N(1-2\rho)) + N(1-2\rho) + \frac{8\rho N}{\alpha} \\ &> b_A + b_B + (N_A - N(1-2\rho)) + N(1-(1-18\varepsilon)(1+2\varepsilon)) \\ &\geq b_A + b_B + (N_A - N(1-2\rho)) + 16\varepsilon N \geq b_A + b_B + (N_A - N(1-2\rho)) + T. \end{aligned}$$

Similarly we have $g_B > b_A + b_B + (N_B - N(1-2\rho)) + T$.

Using Lemma 25 we deduce that by time $m(T)$ the number of good decodings Alice may have is bounded by $T + b_B$. From this point and on, every good decoding at Alice's side adds one vote for the correct leaf, making at least $g_A - (T + b_B) > b_A + (N_A - N(1-2\rho))$ votes for that node by the end of the protocol, and at least $b_A + 1$ votes until Alice reaches round $N(1-2\rho)$ when she gives her output. On the other hand, any wrong output can get at most b_A votes, thus Alice outputs the correct leaf node at round $N(1-2\rho)$. By a similar reasoning, Bob also outputs the correct leaf node when he reaches round $N(1-2\rho)$. ◀

5 A coding scheme with a constant alphabet size

Based on the protocol in Section 4, with some modifications, we obtain a protocol that has a constant size alphabet and a constant rate. To this end, we show how to encode each edge using varying-length encoding over a constant size alphabet. Although substantially more technically involved, this protocol is quite a straightforward extension of the protocol presented above. We thus defer the detailed analysis of this protocol to the full version.

▶ **Theorem 27.** *For any $\varepsilon > 0$, there exists a simulation protocol π' with $N = \lceil \frac{T}{\varepsilon^2} \rceil$, and a $(1-\varepsilon)$-edit distance tree code, solves $PJP(T)$ and is resilient to a $(1/18-\varepsilon)$-fraction of edit corruptions.*

Since $PJP(T)$ is complete for interactive communication, the above theorem proves Theorem 4.

Abstract

The Moran process, as studied by Lieberman, Hauert and Nowak, is a randomised algorithm modelling the spread of genetic mutations in populations. The algorithm runs on an underlying graph where individuals correspond to vertices. Initially, one vertex (chosen uniformly at random) possesses a mutation, with fitness $r > 1$. All other individuals have fitness 1. During each step of the algorithm, an individual is chosen with probability proportional to its fitness, and its state (mutant or non-mutant) is passed on to an out-neighbour which is chosen uniformly at random. If the underlying graph is strongly connected then the algorithm will eventually reach *fixation*, in which all individuals are mutants, or *extinction*, in which no individuals are mutants. An infinite family of directed graphs is said to be *strongly amplifying* if, for every $r > 1$, the extinction probability tends to 0 as the number of vertices increases. Strong amplification is a rather surprising property – it means that in such graphs, the fixation probability of a uniformly-placed initial mutant tends to 1 even though the initial mutant only has a fixed selective advantage of $r > 1$ (independently of n). The name "strongly amplifying" comes from the fact that this selective advantage is "amplified". Strong amplifiers have received quite a bit of attention, and Lieberman et al. proposed two potentially strongly-amplifying families – superstars and metafunnels. Heuristic arguments have been published, arguing that there are infinite families of superstars that are strongly amplifying. The same has been claimed for metafunnels. We give the first rigorous proof that there is an infinite family of directed graphs that is strongly amplifying. We call the graphs in the family "megastars". When the algorithm is run on an n-vertex graph in this family, starting with a uniformly-chosen mutant, the extinction probability is roughly $n^{-1/2}$ (up to logarithmic factors). We prove that all infinite families of superstars and metafunnels have larger extinction probabilities (as a function of n). Finally, we prove that our analysis of megastars is fairly tight – there is no infinite family of megastars such that the Moran algorithm gives a smaller extinction probability (up to logarithmic factors). Also, we provide a counter-example which clarifies the literature concerning the isothermal theorem of Lieberman et al. A full version [11] containing detailed proofs is available at `http://arxiv.org/abs/1512.05632`. Theorem-numbering here matches the full version.

1 Introduction

This paper is about a randomised algorithm called the Moran process. This algorithm was introduced in biology [20, 16] to model the spread of genetic mutations in populations. Similar algorithms have been used to model the spread of epidemic diseases, the behaviour of voters, the spread of ideas in social networks, strategic interaction in evolutionary game theory, the emergence of monopolies, and cascading failures in power grids and transport networks [2, 3, 12, 15, 17].

There has been past work about analysing the expected convergence time of the algorithm [7, 8]. In fact, the fast-convergence result of [7] implies that when the algorithm is run on an undirected graph, and the "fitness" of the initial mutation is some constant $r > 1$, there is an FPRAS for the "fixation probability", which is the probability that a randomly-introduced initial mutation spreads throughout the whole graph.

This paper answers an even more basic question, originally raised in [16], about the long-term behaviour of the algorithm when it is run on directed graphs. In particular, the question is whether there even exists an infinite family of (directed) graphs such that, when the algorithm is run on an n-vertex graph in this family, the fixation probability is $1 - o(1)$, as a function of n. A heuristic argument that this is the case was given in [16], but a counter-example to the argument (and to the hypothesized bound on the fixation probability) was given in [6]. A further heuristic argument (with a revised bound) was given in [14]. Here we give the first rigorous proof that there is indeed a family of "amplifiers" with fixation probability $1 - o(1)$. Before describing this, and the other results of this paper, we describe the model.

The Moran algorithm has a parameter r which is the fitness of "mutants". All non-mutants have fitness 1. The algorithm runs on a directed graph. In the initial state, one vertex is chosen uniformly at random to become a mutant. After this, the algorithm runs in discrete steps as follows. At each step, a vertex is selected at random, with probability proportional to its fitness. Suppose that this is vertex v. Next, an out-neighbour w of v is selected uniformly at random. Finally, the state of vertex v (mutant or non-mutant) is copied to vertex w.

If the graph is finite and strongly connected then with probability 1, the process will either reach the state where there are only mutants (known as *fixation*) or it will reach the state where there are only non-mutants (*extinction*). In this paper, we are interested in the probability that fixation is reached, as a function of the mutant fitness r, given the topology of the underlying graph. If $r < 1$ then the single initial mutant has lower fitness than the non-mutants that occupy every other vertex in the initial configuration, so the mutation is overwhelmingly likely to go extinct. If $r = 1$, an easy symmetry argument shows that the fixation probability is $\frac{1}{n}$ in any strongly connected graph on n vertices [7, Lemma 1].[1] Because of this, we restrict attention to the case $r > 1$. Perhaps surprisingly, a single advantageous mutant can have a very high probability of reaching fixation, despite being heavily outnumbered in the initial configuration.

A directed graph is said to be *regular* if there is some positive integer d so that the in-degree and out-degree of every vertex is d. In a strongly connected regular graph on n vertices, the fixation probability of a mutant with fitness $r > 1$ when the Moran algorithm is run is given by

$$\rho_{\mathrm{reg}}(r, n) = (1 - \tfrac{1}{r})/(1 - \tfrac{1}{r^n}), \tag{1}$$

[1] The result is stated in [7] for undirected graphs but the proof goes through unaltered for strongly connected directed graphs.

so the extinction probability of such a mutant is given by

$$\zeta_{\mathrm{reg}}(r,n) = (\tfrac{1}{r} - \tfrac{1}{r^n})/(1 - \tfrac{1}{r^n}). \tag{2}$$

Thus, in the limit, as n tends to ∞, the extinction probability tends to $1/r$. To see why (1) and (2) hold, note that, for every configuration of mutants, the number of edges from mutants to non-mutants is the same as the number of edges from non-mutants to mutants. Suppose that the sum of the individuals' fitnesses is W and consider an edge (u, v). If u is a mutant in the current state, it is selected to reproduce with probability r/W, and, if this happens, the offspring is placed at v with probability $1/d$. Similarly, if u is not a mutant, reproduction happens along (u, v) with probability $1/(dW)$. So, in any state, the number of mutants is r times as likely to increase at the next step of the process as it is to decrease. If we observe the number of mutants every time it changes, the resulting stochastic process is a random walk on the integers, that starts at 1, absorbs at 0 and n, increases with probability $\frac{r}{r+1}$ and decreases with probability $\frac{1}{r+1}$. It is well known that this walk absorbs at n with probability (1) and at 0 with probability (2). In particular, the undirected n-vertex complete graph is regular. Thus, by (2), its extinction probability tends to $1/r$.

When the Moran process is run on non-regular graphs the extinction probability may be quite a bit lower than $1/r$. Consider the undirected $(n + 1)$-vertex "star" graph, which consists of single centre vertex that is connected by edges to each of n leaves. In the limit as $n \to \infty$, the n-leaf star has extinction probability $\frac{1}{r^2}$ [16, 5]. Informally, the reason that the extinction probability is so small is that the initial mutant is likely to be placed in a leaf, and, at each step, a mutation at a leaf is relatively unlikely to be overwritten.

Lieberman et al. [16] refer to graphs which have smaller extinction probability than (2) (and therefore have larger fixation probability than (1)) as *amplifiers*. The terminology comes from the fact that the selective advantage of the mutant is being "amplified" in such graphs.

The purpose of this paper is to explore the long-term behaviour of the Moran process by quantifying how good amplifiers can be. For this, it helps to have some more formal definitions.

▶ **Definition 1.** Consider a function $\zeta(r,n)\colon \mathbb{R}_{>1} \times \mathbb{Z}_{\geq 1} \to \mathbb{R}_{\geq 0}$. An infinite family Υ of directed graphs is said to be *up-to-ζ fixating* if, for every $r > 1$, there is an n_0 (depending on r) so that, for every graph $G \in \Upsilon$ with $n \geq n_0$ vertices, the following is true: When the Moran process is run on G, starting from a uniformly-random initial mutant, the extinction probability is at most $\zeta(r,n)$.

Equation (2) demonstrates that the infinite family of strongly-connected regular graphs is up-to-ζ_{reg} fixating and since $\zeta_{\mathrm{reg}} \leq 1/r$, this family is also up-to-$1/r$ fixating. Informally, an infinite family of graphs is said to be *amplifying* if it is up-to-ζ fixating for a function $\zeta(r,n)$ which is "smaller" than $\zeta_{\mathrm{reg}}(r,n)$. Here is the formal definition.

▶ **Definition 2.** An infinite family of directed graphs is *amplifying* if it is up-to-ζ fixating for a function $\zeta(r,n)$ which, for every $r > 1$, satisfies $\lim_{n\to\infty} \zeta(r,n) < 1/r$.

The infinite family of graphs containing all undirected stars (which can be viewed as directed graphs with edges in both directions) is up-to-$\zeta(r,n)$ fixating for a function $\zeta(r,n)$ satisfying $\lim_{n\to\infty} \zeta(r,n) = 1/r^2$, so this family of graphs is amplifying.

Lieberman et al. [16] were interested in infinite families of digraphs for which the extinction probability tends to 0, prompting the following definition.

▶ **Definition 3.** An infinite family of directed graphs is *strongly amplifying* if it is up-to-ζ fixating for a function $\zeta(r,n)$ which, for every $r > 1$, satisfies $\lim_{n\to\infty} \zeta(r,n) = 0$.

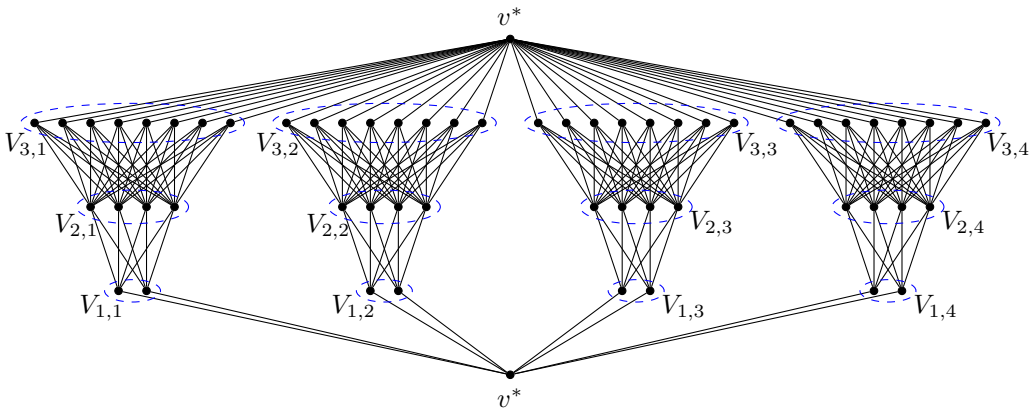

Figure 1 The metafunnel $\mathcal{G}_{3,4,2}$. All edges are directed downwards in the diagram and the centre vertex v^* is shown twice, once at the top and once at the bottom of the diagram. There are $\ell = 4$ copies of the basic unit, each of which consists of $k = 3$ levels $V_{1,j}$, $V_{2,j}$ and $V_{3,j}$, with $|V_{i,j}| = m^i = 2^i$.

Note that the infinite family of undirected stars is not strongly amplifying since the extinction probability of stars tends to $1/r^2$ rather than to 0.

Prior to this paper, there was no (rigorous) proof that a strongly amplifying family of digraphs exists (though there were heuristic arguments, as we explain later). Proving rigorously that there is an infinite family of directed graphs that is strongly amplifying for the Moran algorithm is one of our main contributions.

Lieberman et al. [16] produced good intuition about strong amplification and defined two infinite families of graphs – superstars and metafunnels – from which it turns out that strongly amplifying families can be constructed. It is extremely difficult to analyse the Moran process on these families, due mostly to the complexity of the graphs, and the difficulty of dealing with issues of dependence and concentration. Thus, all previous arguments have been heuristic. For completeness, we discuss these heuristic arguments in Section 6.

In this paper, we define a new family of digraphs called megastars. The definition of megastars is heavily influenced by the superstars of Lieberman et al. Our main theorem is the following.

▶ **Theorem 4.** *There exists an infinite family of megastars that is strongly amplifying.*

Megastars are not easier to analyse than superstars or metafunnels. The reason for our focus on this class of graphs is that it turns out to be provably better amplifying than any of the previously-proposed families. We will present several theorems along these lines. Before doing so, we define the classes of graphs.

2 Metafunnels, superstars and megastars

2.1 Metafunnels

We start by defining the metafunnels of [16]. Let k, ℓ and m be positive integers. The (k, ℓ, m)-*metafunnel* is the directed graph $\mathcal{G}_{k,\ell,m}$ defined as follows. (See Figure 1.)

The vertex set $V(\mathcal{G}_{k,\ell,m})$ is the union of $k+1$ disjoint sets $V_0, \ldots, V_k$. The set V_0 contains the single vertex v^* which is called the *centre vertex*. For $i \in [k]$, V_i is the union of ℓ disjoint

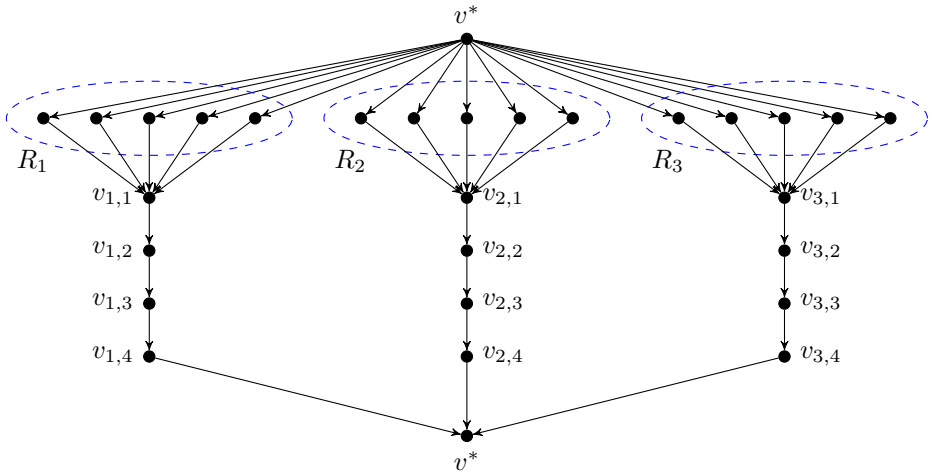

Figure 2 The superstar $\mathcal{S}_{4,3,5}$, with $\ell = 3$ reservoirs R_1, R_2 and R_3, each of size $m = 5$, connected by a path with $k = 4$ vertices to v^*. The centre vertex v^* is shown twice, at both the top and bottom of the diagram.

sets $V_{i,1}, \ldots, V_{i,\ell}$, each of which has size m^i. The edge set of $\mathcal{G}_{k,\ell,m}$ is

$$(V_0 \times V_k) \cup (V_1 \times V_0) \cup \bigcup_{i \in [k-1]} \bigcup_{j \in [\ell]} (V_{i+1,j} \times V_{i,j}) .$$

Lieberman et al. refer to metafunnels with $\ell = 1$ as "funnels".

2.2 Superstars

We next define the superstars of [16]. Let k, ℓ and m be positive integers. The (k, ℓ, m)-*superstar* is the directed graph $\mathcal{S}_{k,\ell,m}$ defined as follows. (See Figure 2.) The vertex set $V(\mathcal{S}_{k,\ell,m})$ of $\mathcal{S}_{k,\ell,m}$ is the disjoint union of ℓ size-m sets $R_1, \ldots, R_\ell$ (called *reservoirs*) together with $k\ell$ vertices $v_{1,1}, v_{1,2}, \ldots, v_{\ell,k}$ and a single centre vertex v^*. The edge set of $\mathcal{S}_{k,\ell,m}$ is given by

$$E(\mathcal{S}_{k,\ell,m}) = \bigcup_{i=1}^{\ell} \Big((\{v^*\} \times R_i) \cup (R_i \times \{v_{i,1}\}) \cup \{(v_{i,j}, v_{i,j+1}) \mid j \in [k-1]\} \cup \{(v_{i,k}, v^*)\} \Big).$$

2.3 Megastars

Finally, we define the new class of megastars, which turn out to be provably-better amplifiers than either metafunnels or superstars. The intuition behind the design of this class of graphs is that the path $v_{i,1}v_{i,2}\ldots v_{i,k}$ linking the i'th reservoir R_i of a superstar to the centre vertex v^* is good for amplifying but that a clique is even better.

Let k, ℓ and m be positive integers. The (k, ℓ, m)-megastar is the directed graph $\mathcal{M}_{k,\ell,m}$ defined as follows. (See Figure 3.) The vertex set $V(\mathcal{M}_{k,\ell,m})$ of $\mathcal{M}_{k,\ell,m}$ is the disjoint union of ℓ sets $R_1, \ldots, R_\ell$ of size m, called reservoirs, ℓ sets $K_1, \ldots, K_\ell$ of size k, called cliques, ℓ "feeder vertices" $a_1, \ldots, a_\ell$ and a single centre vertex v^*. The edge set of $\mathcal{M}_{k,\ell,m}$ consists of the following edges:

- an edge from v^* to every vertex in $R_1 \cup \cdots \cup R_\ell$,
- for each $i \in [\ell]$, an edge from each vertex in R_i to a_i,

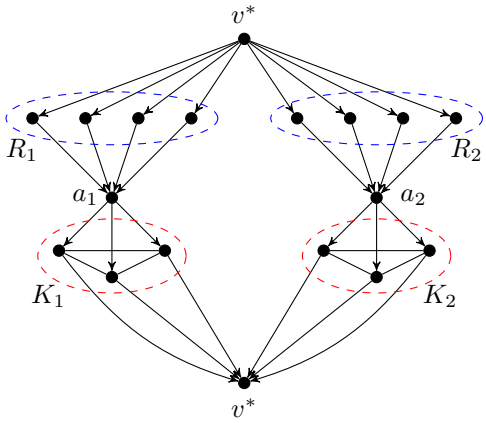

Figure 3 The megastar $\mathcal{M}_{3,2,4}$, with $\ell = 2$ reservoirs R_1 and R_2, each of size $m = 4$. Each reservoir R_i is attached, via the feeder vertex a_i to a clique of size $k = 3$. The centre vertex v^* is shown twice, once at the top and once at the bottom of the diagram. The edges within the cliques K_1 and K_2 are bidirectional.

- for each $i \in [\ell]$, an edge from a_i to each vertex in K_i,
- for each $i \in [\ell]$, edges in both directions between every pair of distinct vertices in K_i,
- an edge from every vertex in $K_1 \cup \cdots \cup K_\ell$ to v^*.

3 Our results

Our main result is that there is an infinite family of megastars that is strongly amplifying, so we start by defining this family. Although megastars are parameterised by three parameters, k, ℓ and m, the megastars in the family that we consider have a single parameter ℓ, so we define k and m to be functions of ℓ.

▶ **Definition 5.** Let $m(\ell) = \ell$ and $k(\ell) = \lceil (\log \ell)^{23} \rceil$. Let $\Upsilon_{\mathcal{M}} = \{\mathcal{M}_{k(\ell),\ell,m(\ell)} \mid \ell \in \mathbb{Z}, \ell \geq 2\}$.

Our main result can then be stated as follows.

▶ **Theorem 6.** *Let $\zeta_{\mathcal{M}}(r,n) = (\log n)^{23} n^{-1/2}$. The family $\Upsilon_{\mathcal{M}}$ is up-to-$\zeta_{\mathcal{M}}$ fixating.*

▶ **Corollary 7.** *The family $\Upsilon_{\mathcal{M}}$ is strongly amplifying.*

The proof of Theorem 6 requires a complicated analysis, accounting for dependencies and concentration. The theorem, as stated here, follows directly from Theorem 75 of the full version.

The reason that we studied megastars rather than the previously-introduced superstars and metafunnels is that megastars turn out to be provably better amplifying than any of the previously-proposed families. To demonstrate this, we prove the following theorem about superstars.

▶ **Theorem 8.** *Suppose that $\zeta(r,n)$ is any function such that, for any $r > 1$, we have $\lim_{n\to\infty} \zeta(r,n)(n \log n)^{1/3} = 0$. Then there is no infinite family of superstars that is up-to-ζ fixating.*

The function $\zeta_{\mathcal{M}}(r,n)$ from Theorem 6 certainly satisfies $\lim_{n\to\infty} \zeta_{\mathcal{M}}(r,n)(n \log n)^{1/3} = 0$, so Theorem 8 shows that there is no infinite family of superstars that is up-to-$\zeta_{\mathcal{M}}$ fixating.

More mundanely, it shows, for example, that if $\zeta(r,n) = n^{-1/3}(\log n)^{-1}$, then no infinite family of superstars is up-to-ζ fixating. Theorem 8 is a direct consequence of Theorem 29 of the full version.

Taken together, Theorems 6 and 8 show that superstars are worse amplifiers than megastars. We next show that metafunnels are *substantially* worse. We start with the following simple-to-state theorem.

▶ **Theorem 9.** *Fix any $\delta > 0$ and let $\zeta(r,n) = n^{-\delta}$. Then there is no infinite family of metafunnels that is up-to-ζ fixating.*

In fact, Theorem 9 can be strengthened by an exponential amount.

▶ **Theorem 10.** *Fix any $\epsilon < 1/2$ and let $\zeta(r,n) = n^{-1/(\log n)^{\epsilon}}$. Then there is no infinite family of metafunnels that is up-to-ζ fixating.*

Theorems 9 and 10 are a direct consequence of Theorem 47 in the full version. In fact, Theorem 47 provides even tighter bounds, as we will see in Section 5, though these are more difficult to state.

The theorems that we have already described (Theorem 6, Theorem 8 and Theorem 10) are the main contributions of the paper. Together, they show that there is a family of megastars that is strongly amplifying, and that there are no families of superstars or metafunnels that amplify as well. For completeness, we present a theorem showing that the analysis of Theorem 6 is fairly tight, in the sense that there are no infinite families of megastars that amplify substantially better than $\Upsilon_{\mathcal{M}}$ – in particular, our bound on extinction probability can only be improved by factors of $\log(n)$. It cannot be improved more substantially.

▶ **Theorem 11.** *Let $\zeta(r,n) = n^{-1/2}/(52r^2)$. There is no infinite family of megastars that is up-to-ζ fixating.*

Theorem 11 follows from Theorem 119 in the full version, which is straightforward. We conclude the paper with a digression which perhaps clarifies the literature. It is stated, and seems to be commonly believed, that an evolutionary graph (a weighted version of the Moran process – see Section 8 of the full version for details) is "isothermal" if and only if the fixation probability of a mutant placed uniformly at random is $\rho_{\text{reg}}(r,n)$. This belief seems to have come from an informal statement of the "isothermal theorem" in the main body of [16] (the formal statement in the supplementary material of [16] is correct, however) and it has spread, for example, as Theorem 1 of [22]. We clear this up by proving the following proposition, which says that there is a counter-example.

▶ **Proposition 12.** *There is an evolutionary graph that is not isothermal, but has fixation probability $\rho_{\text{reg}}(r,n)$.*

4 Proof techniques

As we have seen, it is easy to study the Moran process on a d-regular graph by considering the transition matrix of the corresponding Markov chain (which looks like a one-dimensional random walk). Highly symmetric graphs such as undirected stars can also be handled in a straightforward matter, by directly analysing the transition matrix. Superstars, metafunnels and megastars are more complicated, and the number of mutant-configurations is exponential, so instead we resort to dividing the process into phases, as is typical in the study of randomised algorithms and stochastic processes.

An essential and common trick in the area of stochastic processes (for example, in work on the voter model) is moving to continuous time. Instead of directly studying the discrete-time Moran process, one could consider the following natural continuous-time model which was studied in [8]: Given a set of mutants at time t, each vertex waits an amount of time before reproducing. For each vertex, the period of time before the next reproduction is chosen according to the exponential distribution with parameter equal to the vertex's fitness, independently of the other vertices. If the first vertex to reproduce is v at time $t + \tau$ then, as in the standard, discrete-time version of the process, one of its out-neighbours w is chosen uniformly at random, the individual at w is replaced by a copy of the one at v, and the time at which w will next reproduce is exponentially distributed with parameter given by its new fitness. The discrete-time process is recovered by taking the sequence of configurations each time a vertex reproduces. Thus, the fixation probability of the discrete-time process is *exactly the same* as the fixation probability of the continuous-time process. So moving to the continuous-time model causes no harm. As [8] explains, analysis can be easier in the continuous-time model because certain natural stochastic domination techniques apply in the continuous-time setting but not in the discrete-time setting.

It turns out that moving to the model of [8] does not suffice for our purposes. A major problem in our proofs is dealing with dependencies. In order to make this feasible, we instead study a continuous-time model (see "the clock process" in Section 3.1 of the full version) in which every edge of the underlying graph G is equipped with two Poisson processes, one of which is called a *mutant clock* and the other of which is called a *non-mutant clock*. The clock process is a stochastic process in which all of these clocks run independently. The continuous-time Moran process as defined in [8] can be recovered as a function of the times at which these clocks trigger.

Having all of these clocks available still does not give us the flexibility that we need. We say that a vertex u "spawns a mutant" in the Moran process if, at some point in time, u is a mutant, and it is selected for reproduction. We wish to be able to discuss events such as the event that the vertex u does not spawn a mutant until it has already been a mutant for some particular amount of time. In order to express such events in a clean way, making all conditioning explicit, we define additional stochastic processes called "star-clocks" (see Section 3.3 of the full version). All of the star-clocks run independently in the star-clock process.

In Section 3.4 of the full version we provide a coupling of the star-clock process with the Moran process. The coupling is valid in the sense that the two projections are correct – the projection onto the Moran process runs according to the correct distribution and so does the projection onto the star-clock process. The point of the coupling is that the different star-clocks can be viewed as having their own "local" times. In particular, there is a star-clock $M^*_{(u,v)}$ which controls reproductions from vertex u onto vertex v *during the time that u is a mutant*. Similarly, there is a star-clock $N^*_{(u,v)}$ which controls reproductions from vertex u onto vertex v during the time that u is a non-mutant. The coupling enables us to focus on relevant parts of the stochastic process, making all conditioning explicit.

The processes that we have described so far are all that we need to derive our upper bound on the fixation probability of superstars (Section 4 of the full version). This is the easiest of our main results.

Analysing the Moran process on metafunnels is more difficult. By design, the initial mutant x_0 is likely to be placed in the "top of a funnel" (in the set V_k). In the analysis, it is useful to be able to create independence by considering a "strain" of mutants which contains all of the descendants of a particular mutant spawned by x_0. Like the Moran process itself,

a strain can be viewed as a stochastic process depending on the triggering of the clocks. In order to facilitate the proof, we define a general notion of "mutant process" (Section 3.2 of the full version) – so the Moran process is one example of a mutant process, and a strain is another. The analysis of the Moran process on metafunnels involves both of these and also a third mutant process which is essentially the bottom level of a strain (called its head). Strains and heads-of-strains share some common properties, and they are analysed together as "colonies" in Section 5.4.1 of the full version. The analysis of the metafunnel is the technically most difficult of our results so we discuss it further in the next section.

Fortunately, the analysis of the megastar in Section 6 of the full version does not require three different types of mutant processes – it only requires one. The process that is considered is not the Moran process itself. Instead, it is a modification of the Moran process called the megastar process. The megastar process is similar to the Moran process except that the feeder vertices are forced to be non-mutants, except when their corresponding cliques are completely full or completely empty. It is easy to show (see the proof of Theorem 75 of the full version) that the fixation probability of the Moran process is at least as high as the fixation probability of the megastar process. However, the megastar process is somewhat easier to analyse because the cliques evolve somewhat independently. The proof of the key lemma (Lemma 77 of the full version) is fairly long but it is not conceptually difficult. The point is to prove that, with high probability, the cliques fill up and cause fixation.

5 Sketch of the analysis of metafunnels

The proofs of this paper are fairly technical, so the full version is 98 pages. In order to give a flavour, we give a brief sketch of the proof of Theorem 10 which is our most difficult result. We use $n = 1 + \ell \sum_{i=1}^{k} m^i$ to denote the number of vertices of a (k, ℓ, m)-metafunnel. We use X_t to denote the set of mutants at time t and x_0 to denote the initial mutant so $X_0 = \{x_0\}$. We prove the following theorem, which is slightly stronger than Theorem 10, and implies it.

▶ **Theorem 47.** *Let $r > 1$. Then there is a constant $c_r > 0$, depending on r, such that the following holds for all $k, \ell, m \in \mathbb{Z}_{\geq 1}$ such that the (k, ℓ, m)-metafunnel $\mathcal{G}_{k,\ell,m}$ has $n \geq 3$ vertices. Suppose that the initial state X_0 of the Moran process with fitness r is chosen uniformly at random from all singleton subsets of $V(\mathcal{G}_{k,\ell,m})$. The probability that the Moran process goes extinct is at least $e^{-\sqrt{\log r \cdot \log n}} (\log n)^{-c_r}$.*

Here is the sketch of the proof of Theorem 47. If $k = 1$ then $\mathcal{G}_{k,\ell,m}$ is a star and has extinction probability roughly $1/r^2$ so Theorem 47 follows easily. So for most of the proof (and the rest of this sketch) we assume $k \geq 2$. To prove the theorem, we divide the parameter space into two regimes.

In the (straightforward) first regime, $m \leq r^{\sqrt{\log_r n}}$. Since m is small, V_k is not too large compared to $V_0 \cup \cdots \cup V_{k-1}$. Thus, it is fairly likely that x_0 is born outside V_k, and becomes a non-mutant ("dies") before it can spawn a single mutant.

Most of the proof focusses on the second regime, where $m \geq r^{\sqrt{\log_r n}}$ which, since $n \geq \ell m^k$, implies $k \leq \sqrt{\log_r n}$. In this regime it is likely that a uniformly-chosen initial mutant x_0 is born in V_k (Lemma 49) so we assume that this is the case in most of the proof (and the rest of this sketch). The key lemma is Lemma 74 which shows that, in this case, it is (sufficiently) likely that x_0 dies before v^* spawns a mutant.

In more detail, we define a stopping time T_{pa} which is the first time t that one of the following occurs.

(A1) $X_t = \emptyset$, or
(A2) $|X_t|$ exceeds a given threshold m^* which is a polynomial in $\log n$, or
(A3) By time t, v^* has already become a mutant more than b^* times, where b^* is about half as large as its number ℓm of in-neighbours, or
(A4) t exceeds some threshold t_{max} which is (very) exponentially large in n.

The subscript "pa" is for "pseudo-absorption time" because (A1) implies that the Moran process absorbs by going extinct and (A2) is a prerequisite for absorbing by fixating. The proof of Lemma 74 shows that, with sufficiently high probability, (A2)–(A4) do not hold, and so the Moran process X must go extinct by time T_{pa}.

Conditioning makes it difficult to prove that (A2)–(A4) fail. To alleviate this, we divide the mutants into groups called "strains" which are easier to analyse. In particular, a strain contains all of the descendants of a particular mutant spawned by x_0. Informally, S^i is "born" at the i'th time at which x_0 spawns a mutant. It "dies" when all of the descendants of this spawn have died. It is "dangerous" if one (or more) of these descendants spawns a mutant onto v^* before T_{pa}.

Lemma 53 defines eight events $\mathcal{P}_1$–$\mathcal{P}_8$. These are defined in such a way that we can show (in the proof of Lemma 74) that if $\mathcal{P}_1$–$\mathcal{P}_8$ simultaneously occur, then (A2)–(A4) do not hold. The definitions are engineered in such a way that we can also show that it is fairly likely that they do hold simultaneously – this takes up most of the proof. Informally, the events are defined as follows.

$\mathcal{P}_1$: No star-clock $M^*_{(v^*,v)}$ triggers in the time interval $[0, 1]$.
$\mathcal{P}_2$: For some threshold $t_{x_0} < n$, the star-clock $N^*_{(v^*,x_0)}$ triggers in $[0, t_{x_0} - 2]$.
$\mathcal{P}_3$: v^* is a mutant for at most one unit of time up to time T_{pa}.
$\mathcal{P}_4$: The Moran process absorbs (either fixates or goes extinct) by time $t_{\mathsf{max}}/2$.
$\mathcal{P}_5$: Break $[0, t_{x_0}]$ into intervals of length $(\log n)^2$. During each interval, x_0 spawns at most $2r(\log n)^2$ mutants.
$\mathcal{P}_6$: Define s to be around $3rt_{x_0}$. Each of the strains $S^1, \ldots, S^s$ spawns at most $\log n$ mutants before T_{pa}.
$\mathcal{P}_7$: Each of the strains $S^1, \ldots, S^s$ dies within $(\log n)^2$ steps.
$\mathcal{P}_8$: At most $b^*/\log n$ of $S^1, \ldots, S^s$ are dangerous.

The rough sketch of Lemma 74 is as follows. $\mathcal{P}_1$ and $\mathcal{P}_3$ guarantee that v^* does not spawn a mutant until after T_{pa}. This together with $\mathcal{P}_2$ and $\mathcal{P}_3$ guarantees that the only mutants in the process before time T_{pa} are part of strains that are born before t_{x_0}. By $\mathcal{P}_5$, there are at most s such strains. By $\mathcal{P}_6$, each of these strains only has about $\log n$ mutants. Together with $\mathcal{P}_7$, this implies that (A2) does not hold at $t = T_{\mathsf{pa}}$. $\mathcal{P}_8$ and $\mathcal{P}_6$ imply that (A3) does not hold at $t = T_{\mathsf{pa}}$. Finally, $\mathcal{P}_4$ implies that (A4) does not hold at $t = T_{\mathsf{pa}}$.

The bulk of the proof involves showing (Lemma 53) that $\mathcal{P}_1$–$\mathcal{P}_8$ are sufficiently likely to simultaneously occur. Of these, $\mathcal{P}_3$–$\mathcal{P}_7$ are all so likely to occur that the probability that they do not occur can be subtracted off using a union bound (so conditioning on the other $\mathcal{P}_i$'s is not an issue). The majority of the failure probability comes from the probability that $\mathcal{P}_2$ does not occur. This is handled in the straightforward Lemma 54 which gives a lower bound on the probability that $\mathcal{P}_1$ and $\mathcal{P}_2$ both occur. The remaining event, $\mathcal{P}_8$, is sufficiently unlikely to occur that careful conditioning is required. This is (eventually) handled in Lemma 73, which shows that it is fairly likely to occur, conditioned on the fact that both $\mathcal{P}_1$ and $\mathcal{P}_2$ occur.

In order to get a good estimate on the probability that a strain is dangerous (in $\mathcal{P}_8$), we need to consider the number of mutants spawned from the "layer" of the strain closest to the centre vertex v^*. In order to do this, we define a new mutant process called the "head" of a

strain. Strains and heads of strains share some common properties, and they are analysed together as "colonies". Informally a "colony" is a mutant process Z whose mutants are in $V_1 \cup \cdots \cup V_{k-1}$ (and not in V_0 or V_k). Once a colony becomes empty, it stays empty. Since a colony is a mutant process but not necessarily a Moran process, vertices may enter and/or leave whenever a clock triggers but we say that the colony is *hit* when a vertex leaves a colony specifically because a non-mutant is spawned onto it in the underlying Moran process. We define the "spawning chain" Y^Z of a colony and show that it increases whenever the colony spawns a mutant and that it only decreases when the colony is hit. By analysing the jump chain of a spawning chain we are able to obtain the desired bounds on the probability that $\mathcal{P}_6$, $\mathcal{P}_7$ and $\mathcal{P}_8$ fail to occur.

6 Comparison with previous work

The Moran process is similar to a discrete version of directed percolation known as the contact process. There is a vast literature (e.g., [17, 10, 21, 9]) on the contact process and other related infection processes such as the voter model and susceptible-infected-susceptible (SIS) epidemic models. Often, the questions that are studied in these models are different from the question that we study here. For example, in voter systems [9] the two states (mutant/non-mutant) are often symmetric (similar to our $r = 1$ case) and the models are often studied on infinite graphs where the question is whether the process absorbs or not (both kinds of absorption, fixation and extinction, are therefore called "fixation" in some of this work). The particular details of the Moran process are very important for us because the details of the algorithm determine the long-term behaviour. For example, unlike the Moran process, in the contact process [4], the rate at which a node becomes a non-mutant is typically taken to be 1, whereas the rate at which a node becomes a mutant is proportional to the number of mutant neighbours. In the discrete-time versions of many commonly-studied models, a node is chosen randomly at each step for replacement, rather than (as in the Moran process) for reproduction. In any case, the important point for us is that the details of the algorithm are important – results do not carry over from one algorithm to the other. Therefore, we concentrate in this section on previous work about calculating the fixation probability of the Moran process itself.

Lieberman et al. [16] studied the fixation probability of the Moran process and introduced superstars and metafunnels. Intuitively, a superstar is a good amplifier because (as long as m is sufficiently large) the initial mutation is likely to be placed in a reservoir and (as long as ℓ is sufficiently large) this is unlikely to be killed quickly by the centre vertex. Moreover, the paths of a superstar are good for amplifying the selective advantage of mutants because, after the infection spreads from a reservoir vertex to the beginning of a path, it is likely to "pick up momentum" as it travels down the path, arriving at the centre vertex as a chain of $\Theta(k)$ mutants (which, taken together, are more likely to cause the centre to spread the infection than a single mutant arriving at the centre would be). As we have seen (Theorems 6 and 8) megastars are provably better for amplification than superstars. The reason for this is that a clique is substantially better than a path at doing this "amplification". Nevertheless, the amplifying properties of superstars strongly influenced our decision to study megastars.

Lieberman et al. [16, Equation (2)] claimed[2] that for sufficiently large n, the fixation probability of a superstar with parameter k tends to $1 - r^{-(k+2)}$, and that "similar results

[2] The reader who consults [16] might wonder why "k" as written in Equation (2) of [16] has become $k+2$ here. The reason is just that we use a slightly different parameterisation from that of [16]. To allow appropriate comparison, we describe all previous work using our parameterisation.

hold for the funnel and metafunnel". They provided a heuristic sketch-proof for the superstar, but not for the funnel or metafunnel. Hauert [13, Equation (5)] claims specifically that the fixation probability of funnels tends to $1 - r^{-(k+1)}$. As far as we know, no heuristic arguments have been given for funnels or metafunnels.

In any event, Díaz, Goldberg, Mertzios, Richerby, Serna and Spirakis [6] showed that the $1 - r^{-(k+2)}$ claim for superstars is incorrect for the case $k = 3$. In particular, for this case they showed that the fixation probability is at most $1 - \frac{r+1}{2r^5+r+1}$, which is less than the originally claimed value of $1 - r^{-5}$ for all $r \geq 1.42$.

Subsequently, Jamieson-Lane and Hauert [14, Equation (5)] made a more detailed but still heuristic[3] analysis of the fixation probability of superstars. They claim that for superstars with parameter k and with $\ell = m$, the fixation probability ρ_k has the following bounds for fixed $r > 1$,

$$1 - 1/(r^4(k-1)(1-\tfrac{1}{r})^2) - o(1) \leq \rho_k \leq 1 - 1/(r^4(k-1)) + o(1), \tag{3}$$

where the $o(1)$ terms tend to 0 as $\ell \to \infty$. They claim that their bounds are a good approximation as long as $k \ll \ell = m \sim \sqrt{n}$. It is not clear exactly what "$\ll$" means in this context. Certainly there are parameter regimes where $k = o(\ell)$ and $\ell = m \sim \sqrt{n}$ but nevertheless the extinction probability is much larger than the proposed upper bound $1/(r^4(k-1)(1-1/r)^2)$ from (3). For example, suppose that $\ell = m = k^{3/2}$. In this case (see Lemma 30 of the full version), the extinction probability is at least $k/(2r(m+k)) = 1/(2r(k^{1/2}+1))$ which is larger than $1/(r^4(k-1)(1-1/r)^2)$ for all sufficiently large k. Nevertheless, the bounds proposed by Jamieson-Lane and Hauert (3) seem to be close to the truth when k is very small compared to ℓ and m.

Our Corollary 34 of the full version identifies a wide class of parameters for which the extinction probability is provably at least $1/(1470r^4k)$. This is weaker than the suggested bound of Jamieson-Lane and Hauert by a factor of 1470. This constant factor is explained by the fact that our rigorous proof needs to show concentration of all random variables. We use lots of Chernoff bounds and other bounds on probabilities. In writing the proof, we optimised readability rather than optimising our constants, so our constants can presumably be improved.

There is recent work on other related aspects of the Moran process. For example, [18, 19] give fixation probability bounds on connected *undirected* graphs. [1] studies amplification with respect to adversarial or "temperature-based" placement of the initial mutation, in which the "temperature" of a vertex is proportional to the sum of all incoming edge weights. Also, [19] considers the extent to which the number of "good starts" for fixation can be bounded.

Abstract

In this paper we study the mixing time of evolutionary Markov chains over populations of a fixed size (N) in which each individual can be one of m types. These Markov chains have the property that they are guided by a dynamical system from the m-dimensional probability simplex to itself. Roughly, given the current state of the Markov chain, which can be viewed as a probability distribution over the m types, the next state is generated by applying this dynamical system to this distribution, and then sampling from it N times. Many processes in nature, from biology to sociology, are evolutionary and such chains can be used to model them. In this study, the mixing time is of particular interest as it determines the speed of evolution and whether the statistics of the steady state can be efficiently computed. In a recent result [Panageas, Srivastava, Vishnoi, Soda, 2016], it was suggested that the mixing time of such Markov chains is connected to the geometry of this guiding dynamical system. In particular, when the dynamical system has a fixed point which is a global attractor, then the mixing is fast. The limit sets of dynamical systems, however, can exhibit more complex behavior: they could have multiple fixed points that are not necessarily stable, periodic orbits, or even chaos. Such behavior arises in important evolutionary settings such as the dynamics of sexual evolution and that of grammar acquisition. In this paper we prove that the geometry of the dynamical system can also give tight mixing time bounds when the dynamical system has multiple fixed points and periodic orbits. We show that the mixing time continues to remain small in the presence of several unstable fixed points and is exponential in N when there are two or more stable fixed points. As a consequence of our results, we obtain a phase transition result for the mixing time of the sexual/grammar model mentioned above. We arrive at the conclusion that in the interesting parameter regime for these models, i.e., when there are multiple stable fixed points, the mixing is slow. Our techniques strengthen the connections between Markov chains and dynamical systems and we expect that the tools developed in this paper should have a wider applicability.

1 Introduction

Evolutionary Markov chains and mixing time

In this paper we study Markov chains that arise in the context of evolution and which have also been used to model a wide variety of social, economical and cultural phenomena, see [18]. Typically, in such Markov chains, each state consists of a population of size N where each individual is of one of m *types*. Thus, the state space Ω has size $\binom{N+m-1}{m-1}$. At a very high level, in each iteration, the different types in the current generation reproduce according to their *fitnesses*, the reproduction could be *asexual* or *sexual* and have *mutations* that transform one type into another. This gives rise to an intermediate population that is subjected to the force of *selection*; a sample of size N is selected giving us the new generation. The specific way in which each of the *reproduction*, *mutation* and *selection* steps happen determine the transition matrix of the corresponding Markov chain. The size of the population (N), the number of types (m), the fitness of each type ($\{a_i \geq 0 : i \in [m]\}$), and the probabilities of mutation of one type to another ($\{Q_{ij} \geq 0 : i, j \in [m]\}$) are the parameters of the model. If we make the natural assumption that all the fitnesses are strictly positive and there is a non-zero probability of mutating from any type to the other, $Q_{ij} > 0$ for all $i, j \in [m]$, then the underlying chain is ergodic and has a unique steady state.

Most questions in evolution reduce to understanding the statistical properties of the steady state of an evolutionary Markov chain and how it changes with its parameters. However, in general, there seems to be no way to compute the desired statistical properties other than to sample from (close to) the steady state distribution by running the Markov chain for sufficiently long [5]. In the chains of interest, while there is an efficient way to sample the next state given the current state, typically, the state space is huge[1] This is captured by the notion of its *mixing time*. The mixing time of a Markov chain, t_{mix}, is defined to be the smallest time t such that for all $x \in \Omega$, the distribution of the Markov chain starting at x after t-time steps is within an ℓ_1-distance of $1/4$ of the steady state.[2] Apart from dictating the computational feasibility of sampling procedures, the mixing time also gives us the number of generations required to reach a steady state; an important consideration for validating evolutionary models [24, 5]. However, despite the importance of understanding when an evolutionary Markov chain mixes fast (i.e., is significantly smaller than the size of the state space), until recently, there has been a lack of rigorous mixing time bounds for the full range of evolutionary parameters in even in the simplest of stochastic evolutionary models; see [7, 9, 8] for results under restricted assumptions and [5, 25] for an extended discussion on mixing time bounds in evolutionary Markov chains.

The expected motion of a Markov chain

In a recent result [20], a new approach for bounding the mixing time of such Markov chains was suggested. Towards this, it is convenient to think of each state of an evolutionary Markov chain as a vector which captures the fraction of each type in the current population. Thus, each state is a point the m-dimensional probability simplex Δ_m,[3] and we can think of $\Omega \subseteq \Delta_m$. If $\mathbf{X}^{(t)}$ is the current state, then we define the *expected motion* of the chain at $\mathbf{X}^{(t)}$

[1] For example, even when $m = 40$ and the population is of size $10,000$, the number of states is more than 2^{300}, i.e., more than the number of atoms in the universe!

[2] It is well-known that if one is willing to pay an additional factor of $\log 1/\varepsilon$, one can bring down the error from $1/4$ to ε for any $\varepsilon > 0$; see [14].

[3] The probability simplex Δ_m is defined to be $\{p \in \mathbb{R}^m : p_i \geq 0 \ \forall i, \ \sum_i p_i = 1\}$.

to be the function

$$f(\mathbf{X}^{(t)}) \coloneqq \mathbb{E}\left[\mathbf{X}^{(t+1)}|\mathbf{X}^{(t)}\right]$$

where the expectation is over one step of the chain. Notice that while the domain of f is Ω, its range could be a larger subset of Δ_m. *What can the expected motion of a Markov chain tell us about the mixing time of a Markov chain?* Of course, without imposing additional structure on the Markov chain, we do not expect a very interesting answer. However, [20] suggested that, the expected motion can be helpful in establishing mixing time bounds, at least in the context of evolutionary dynamics. The first observation is that, while in the case of general Markov chains, the expected motion function is only defined at a subset of Δ_m, in the case of evolutionary Markov chains, the expected motion turns out to be a *dynamical system*; defined on *all* points of Δ_m. Further, the Markov chain can be recovered from the dynamical system: it can be shown that given a state $\mathbf{X}^{(t)}$ of the Markov chain, one can generate $\mathbf{X}^{(t+1)}$ *equivalently* by computing the probability distribution $f(\mathbf{X}^{(t)})$ and taking N i.i.d. samples from it. Subsequently, their main result is to prove that if this dynamical system has a *unique stable fixed point* and also all the trajectories converge to this point, then the evolutionary Markov chain mixes rapidly. Roughly, this is achieved by using the geometry of the dynamical system around this unique fixed point to construct a *contractive coupling*. As an application, this enabled them to establish rapid mixing for evolutionary Markov chains in which the reproduction is *asexual*.

What if the limit sets of the expected motion are complex: multiple fixed points – some stable and some unstable, or even periodic orbits? Not only are these natural mathematical questions given the previous work, such behavior arises in several important evolutionary settings; e.g., in the case when the reproduction is sexual (see [3, 17] and Chapter 20 in [11]) and an equivalent model for how children acquire grammar [19, 12]. While we describe these models later, we note that, as one changes the parameters of the model, the limit sets of the expected motion can exhibit the kind of complex behavior mentioned above and a finer understanding of how they influence the mixing time is desired.

Our contribution

In this paper we introduce prove that the geometry of the dynamical system can also give tight mixing time bounds when the dynamical system has multiple fixed points and periodic orbits. This completes the picture left open by the previous work. Recall that [20] proved that when there is a unique stable fixed point, then the mixing time is about $O(\log N)$ when N is large compared to the parameters of the model. We complement their result by proving the following mixing time bounds which depend on the structure of the limit sets of the expected motion:

- One stable fixed point and multiple unstable fixed points – the mixing time is $O(\log N)$, see Theorem 6.
- Multiple stable fixed points – the mixing time is $e^{\Omega(N)}$, see Theorem 7.
- Periodic orbits – the mixing time is $e^{\Omega(N)}$, see Theorem 8.

Thus, we can prove that despite the presence of unstable fixed points the mixing time continues to remain small. On the other hand, if there are two or more stable fixed points, the mixing time can undergo a phase transition and become exponential in N.

As an application, we characterize the mixing time of the dynamics of *grammar acquisition* (or, as explained later, sexual evolution). This Markov chain attempts to model a fascinating and important problem in linguistics; to understand the mechanism by which a child acquires

the capacity to comprehend a language and effectively communicate [16, 10]. Here, a parameter of interest is the *mutation rate* τ which is to be thought of as quantifying the *error of learning*; see Section 2.1. Corresponding to this, the probabilities of mutation $Q_{ij} = \tau$ for all $i \neq j$ and $Q_{ii} = 1 - (m-1)\tau$. We first prove that there is a critical value where the expected motion dynamical system goes through a bifurcation from multiple stable fixed points to one stable fixed point. Our main results then imply that for $\tau < \tau_c$ the mixing time is exponential in N and for $\tau > \tau_c$ it is $O(\log N)$, see Theorem 9. Thus, we arrive at the conclusion that, in the interesting parameter regime for an important and natural dynamics, i.e., when there is a stable fixed point other than the uniform one, the mixing is very slow.

Technically, there have been several influential works in the probability literature that use dynamical systems to analyze stochastic processes, see for example [22, 2, 26, 15]. While the techniques used in these results bear some similarity to ours, to the best of our knowledge, ours is the first paper which studies the question of how the *mixing time* of a Markov chain behaves as a function of the guiding dynamical system formally.

Organization of the paper

The rest of the paper is organized as follows. In Section 2 we present the formal statement of our main theorems and the model of grammar acquisition/sexual evolution. In Section 4, we present an overview of the proofs of our main theorem. Due to space constraints, details of the proofs have been omitted from this version and appear in the full version of this paper.

2 Formal statement of our results

In this section we present formal statements of our main results. We begin by introducing the required notation and preliminaries.

Notation

We use boldface letters, e.g., $\mathbf{x}$, to denote column vectors (points), and denote a vector's i^{th} coordinate by x_i. We use $\mathbf{X}$ and $\mathbf{Y}$ (often with time superscripts and coordinate subscripts as appropriate) to denote random vectors. For a function $f : \Delta_m \to \Delta_m$, by f^n we denote the composition of f with itself n times, namely $\underbrace{f \circ f \circ \cdots \circ f}_{n \text{ times}}$. We use $J_f[\mathbf{x}]$ to denote the Jacobian matrix of f at the point $\mathbf{x}$. When the function f is clear from the context, we omit the subscript and simply denote it by $J[\mathbf{x}]$. Similarly, we sometimes use $J^n[\mathbf{x}]$ to denote the Jacobian of f^n at $\mathbf{x}$. We denote by $\mathrm{sp}\,(A)$ the spectral radius of a matrix A and by $(A\mathbf{x})_i$ the sum $\sum_j A_{ij}x_j$.

Dynamical Systems

Let $\mathbf{x}^{(t+1)} = f(\mathbf{x}^{(t)})$ be a *discrete time* dynamical system with update rule $f : \Delta_m \to \Delta_m$. The point $\mathbf{z}$ is called a *fixed point* of f if $f(\mathbf{z}) = \mathbf{z}$. We call a fixed point $\mathbf{z}$ *stable* if, for the Jacobian $J[\mathbf{z}]$ of f, it holds that $\mathrm{sp}\,(J[\mathbf{z}]) < \rho < 1$. A sequence $(f^t(\mathbf{x}^{(0)}))_{t\in\mathbb{N}}$ is called a *trajectory* of the dynamics with $x^{(0)}$ as starting point. A common technique to show that a dynamical system converges to a fixed point is to construct a function $P : \Delta_m \to \mathbb{R}$ such that $P(f(\mathbf{x})) > P(\mathbf{x})$ unless $\mathbf{x}$ is a fixed point. We call P a *potential* function. One of our results deals with dynamical systems that have stable periodic orbits.

▶ **Definition 1.** $C = \{\mathbf{x}_1, \ldots, \mathbf{x}_k\}$ is called a *periodic orbit* of size k if $\mathbf{x}_{i+1} = f(\mathbf{x}_i)$ for $1 \leq i \leq k-1$ and $f(\mathbf{x}_k) = \mathbf{x}_1$. If $\mathrm{sp}\left(J_{f^k}[\mathbf{x}_1]\right) < \rho < 1$, we call C a *stable* periodic orbit (we also use the terminology *stable limit cycle*).

▶ Remark. Since $f : \Delta_m \to \Delta_m$ and hence $\sum_i f_i(\mathbf{x}) = 1$ for all $\mathbf{x} \in \Delta_m$, if we define $h_i(\mathbf{x}) = \frac{f_i(\mathbf{x})}{\sum_i f_i(\mathbf{x})}$ so that $h(\mathbf{x}) = f(\mathbf{x})$ for all $\mathbf{x} \in \Delta_m$, we get that $\sum_i \frac{\partial h_i(\mathbf{x})}{\partial x_j} = 0$ for all $j \in [m]$. This means without loss of generality we can assume that the Jacobian $J[\mathbf{x}]$ of f has $\mathbf{1}^\top$ (the all-ones vector) as a left eigenvector with eigenvalue 0.

The definition below quantifies the instability of a fixed point as is standard in the literature. Essentially, an α unstable fixed point is repelling in any direction.

▶ **Definition 2.** Let $\mathbf{z}$ be a fixed point of a dynamical system f. The point $\mathbf{z}$ is called *α-unstable* if $|\lambda_{\min}(J[\mathbf{z}])| > \alpha > 1$ where $\lambda_{\min}$ corresponds to the minimum eigenvalue of the Jacobian of f at the fixed point $\mathbf{z}$, excluding the eigenvalue 0 that corresponds to the left eigenvector $\mathbf{1}^\top$.

Stochastic Evolution

▶ **Definition 3.** Given an $f : \Delta_m \to \Delta_m$ which is smooth,[4] and a population parameter N, we define a Markov chain called the *stochastic evolution guided by f* as follows. The state at time t is a probability vector $\mathbf{X}^{(t)} \in \Delta_m$. The state $\mathbf{X}^{(t+1)}$ is then obtained in the following manner. Define $\mathbf{Y}^{(t)} = f(\mathbf{X}^{(t)})$. Obtain N independent samples from the probability distribution $\mathbf{Y}^{(t)}$, and denote by $\mathbf{Z}^{(t)}$ the resulting counting vector over $[m]$. Then

$$\mathbf{X}^{(t+1)} \coloneqq \frac{1}{N}\mathbf{Z}^{(t)} \quad \text{and therefore } \mathbb{E}[\mathbf{X}^{(t+1)}|\mathbf{X}^{(t)}] = f(\mathbf{X}^{(t)}).$$

We call f the *expected motion* of the stochastic evolution.

▶ **Definition 4** (Smooth contractive evolution)**.** A function $f : \Delta_m \to \Delta_m$ is said to be a *smooth contractive evolution* if it is *smooth*[4], has a *unique* fixed point $\mathbf{z}$ in the interior of Δ_m, this unique point is *stable*, and, for every $\varepsilon > 0$, there exists an ℓ such that for any $\mathbf{x} \in \Delta_m$, it holds that $\left\|f^\ell(\mathbf{x}) - \mathbf{z}\right\|_1 < \varepsilon$ (i.e., f converges to the fixed point).

The main result in [20] was Theorem 5 below. This theorem gives a bound on the mixing time of a stochastic evolution guided by a function f that satisfies Definition 4.

▶ **Theorem 5** (Main theorem in [20])**.** *Let f be a smooth contractive evolution, and let $\mathcal{M}$ be the stochastic evolution guided by f on a population of size N. Then, the mixing time of $\mathcal{M}$ is $O(\log N)$.*

Our Results

Given a dynamical system f, one of the main questions that one can ask is does it converge, and if so, how fast. In general, if the behavior of a system is non-chaotic, we expect the system to reach some steady state (e.g., a fixed point or periodic orbit). This steady state might be some (local) optimum solution to a non-linear optimization problem. Therefore, it is important to understand what traits make a dynamical system converge fast. The

[4] For our purposes, we call a function f is *smooth* if it is twice differentiable in the relative interior of Δ_m with bounded second derivative.

existence of many fixed points which are unstable can slow down the speed of convergence of a dynamical system. In the case of the stochastic evolution guided by f, one would expect the existence of multiple unstable fixed points to similarly slow down the mixing time. Nevertheless, our Theorem 6 shows rapid mixing in the presence of α-unstable fixed points. Additionally, we change the assumption *convergence to the fixed point* in 5 to the assumption that for all $\mathbf{x} \in \Delta_m$ the limit $\lim_{t\to\infty} f^t(\mathbf{x})$ exists and is equal to some fixed point $\mathbf{z}$, i.e., as in 5, there are no limit cycles.

▶ **Theorem 6.** *Let $f : \Delta_m \to \Delta_m$ be twice differentiable in the interior of Δ_m with bounded second derivative. Assume that $f(\mathbf{x})$ has a finite number of fixed points $\mathbf{z}_0, \ldots, \mathbf{z}_l$ in the interior, where $\mathbf{z}_0$ is a stable fixed point, i.e., $\mathrm{sp}\,(J[\mathbf{z}_0]) < \rho < 1$ and $\mathbf{z}_1, \ldots, \mathbf{z}_l$ are α-unstable fixed points ($\alpha > 1$). Furthermore, assume that $\lim_{t\to\infty} f^t(\mathbf{x})$ exists for all $\mathbf{x} \in \Delta_m$. Then, the stochastic evolution guided by f has mixing time $O(\log N)$.*

In our second result, we allow f to have multiple stable fixed points (in addition to any number of unstable fixed points). For this setting, we prove that the stochastic evolution guided by f has mixing time $e^{\Omega(N)}$. Our phase transition result on a linguistic/sexual evolution model discussed in Section 2.1 relies crucially on Theorem 7.

▶ **Theorem 7.** *Let $f : \Delta_m \to \Delta_m$ be continuously differentiable in the interior of Δ_m. Assume that $f(\mathbf{x})$ has at least two stable fixed points in the interior $\mathbf{z}_1, \ldots, \mathbf{z}_l$, i.e., $\mathrm{sp}\,(J[\mathbf{z}_i]) < \rho_i < 1$ for $i = 1, 2, \ldots, l$. Then, the stochastic evolution guided by f has mixing time $e^{\Omega(N)}$.*

Finally, we allow f to have a stable limit cycle. We prove that in this setting the stochastic evolution guided by f has mixing time $e^{\Omega(N)}$. This result seems important for evolutionary dynamics as periodic orbits often appear [23, 21].

▶ **Theorem 8.** *Let $f : \Delta_m \to \Delta_m$ be continuously differentiable in the interior of Δ_m. Assume that $f(\mathbf{x})$ has a stable limit cycle with points $\mathbf{w}_1, \ldots, \mathbf{w}_s$ of size $s \geq 2$ in the sense that $\mathrm{sp}\,(\prod_{i=1}^{s} J[\mathbf{w}_{s-i+1}]) < \rho < 1$. Then the stochastic evolution guided by f has mixing time $e^{\Omega(N)}$.*

2.1 Dynamics of grammar acquisition and sexual evolution

We begin by describing the evolutionary processes for grammar acquisition and sexual evolution. As we will explain, the two turn out to be identical and hence we primarily focus on the model for grammar acquisition in the remainder of the paper.

The starting point of the model is Chomsky's *Universal Grammar* theory [4].[5] In his theory, language learning *is facilitated by a predisposition that our brains have for certain structures of language.* This universal grammar (UG) is believed to be innate and embedded in the neuronal circuitry. Based on this theory, an influential model for how children acquire grammar was given by appealing to evolutionary dynamics for infinite and finite populations respectively in [19] and [12]. We first describe the infinite population model, which is a dynamical system that guides the stochastic, finite population model. Each individual speaks exactly one of the m grammars from the set of inherited UGs $\{G_1, \ldots, G_m\}$; denote by x_i the fraction of the population using G_i. The model associates a *fitness* to every individual on the basis of the grammar she *and others* use. Let A_{ij} be the probability that a person who speaks grammar j understands a randomly chosen sentence spoken by an individual

[5] Like any important problem in the sciences, Chomsky's theory is not uncontroversial; see [10] for an in-depth discussion.

using grammar i. This can be viewed as the fraction of sentences according to grammar i that are also valid according to grammar j. Clearly, $A_{ii} = 1$. The pairwise *compatibility* between two individuals speaking grammars i and j is $B_{ij} \coloneqq \frac{A_{ij}+A_{ji}}{2}$, and the fitness of an individual using G_i is $f_i \coloneqq \sum_{j=1}^{m} x_j B_{ij}$, i.e., the probability that such an individual is able to meaningfully communicate with a randomly selected member of the population.

In the reproduction phase each individual produces a number of offsprings proportional to her fitness. Each child speaks one grammar, but the exact learning model can vary and allows for the child to incorrectly learn the grammar of her parent. We define the matrix Q where the entry Q_{ij} denotes the probability that the child of an individual using grammar i learns grammar j (i.e. Q is column stochastic matrix); once a child learns a grammar it is fixed and she does not later use a different grammar. Thus, the frequency x'_i of the individuals that use grammar G_i in the next generation will be

$$x'_i = g_i(\mathbf{x}) \coloneqq \sum_{j=1}^{m} \frac{Q_{ji} x_j (B\mathbf{x})_j}{\mathbf{x}^\top B \mathbf{x}}$$

(with $g : \Delta_m \mapsto \Delta_m$ encoding the update rule). Nowak et al. [19] study the symmetric case, i.e., $B_{ij} = b$ and $Q_{ij} = \tau \in (0, 1/m]$ for all $i \neq j$ and observe a threshold: When τ, which can be thought of as quantifying the *error of learning or mutation*, is above a critical value, the only stable fixed point is the uniform distribution (all $1/m$) and below it, there are multiple stable fixed points.

Finite population models can be derived from the linguistic dynamics in a standard way. We describe the Wright-Fisher finite population model for the linguistic dynamics. The population size remains N at all times and the generations are non-overlapping. The current state of the population is described by the frequency vector $\mathbf{X}^{(t)}$ at time t which is a random vector in Δ_m and notice also that the population that uses G_i is $NX_i^{(t)}$. How does one generate $\mathbf{X}^{(t+1)}$? To do this, in the replication (R) stage, one first replaces the individuals that speak grammar G_i in the current population by $NX_i^{(t)}(B(N\mathbf{X}^{(t)}))_i$ and the total population has size $N^2 \mathbf{X}^{(t)\top} B \mathbf{X}^{(t)}$.[6] In the selection (S) stage, one selects N individuals from this population by sampling independently with replacement. Since the evolution is error prone, in the mutation (M) stage, the grammar of each individual in this intermediate population is mutated independently at random according to the matrix Q to obtain frequency vector $\mathbf{X}^{(t+1)}$. Given these rules, note that

$$\mathbb{E}[\mathbf{X}^{(t+1)} | \mathbf{X}^{(t)}] = g(\mathbf{X}^{(t)}).$$

In other words, in expectation, fixing $\mathbf{X}^{(t)}$, the next generation's frequency vector $\mathbf{X}^{(t+1)}$ is exactly $g(\mathbf{X}^{(t)})$, where g is the linguistic dynamics. Of course, this holds only for one step of the process. This process is a Markov chain with state space $\{(y_1, \ldots, y_m) : y_i \in \mathbb{N}, \sum_i y_i = N\}$ of size $\binom{N+m-1}{m-1}$. If $Q > 0$ then it is ergodic (i.e., it is irreducible and aperiodic) and thus has a unique stationary distribution. In our analysis, we consider the symmetric case as in Nowak et al. [19], i.e., $B_{ij} = b$ and $Q_{ij} = \tau \in (0, 1/m]$ for all $i \neq j$.

Note that the linguistics model described above can also be seen as a (finite population) sexual evolution model: Assume there are N individuals and m types. Let $\mathbf{Y}^{(t)}$ be a vector of frequencies at time t, where $\mathbf{Y}_i^{(t)}$ denotes the fraction of individuals of type i. Let F be a fitness matrix where F_{ij} corresponds to the number of offspring of type i, if an individual of

[6] Here we assume that B_{ij} is an positive integer and thus $N^2 X_i^{(t)} (B\mathbf{X}^{(t)})_i$ is an integer since the individuals are whole entities; this can be achieved by scaling and is without loss of generality.

type i chooses to mate with an individual of type j (assume $F_{ij} \in \mathbb{N}$). At every generation, each individual mates with every other individual. It is not hard to show that the number of offspring after the matings will be $N^2(\mathbf{Y}^{(t)\top} F \mathbf{Y}^{(t)})$ and there will be $N^2 \mathbf{Y}_i^{(t)} (F\mathbf{Y}^{(t)})_i$ individuals of type i. After the reproduction step, we select N individuals at random with replacement, i.e., we sample an individual of type i with probability $\frac{\mathbf{Y}_i^{(t)}(F\mathbf{Y}^{(t)})_i}{\mathbf{Y}^{(t)\top} F \mathbf{Y}^{(t)}}$. Finally in the mutation step, every individual of type i mutates with probability τ (*mutation parameter*) to some type j. Let $F_{ii} = A$, $F_{ij} = B$ for all $i \neq j$ with $A > B$ (this is called homozygote advantage) and set $b = \frac{B}{A} < 1$. It is self-evident that this sexual evolution model is identical with the (finite population) linguistic model described above since both end up having the same reproduction, selection and mutation rule. It holds that $E[\mathbf{X}^{(t+1)} | \mathbf{X}^{(t)}] = g(\mathbf{X}^t)$[7] with

$$g_i(\mathbf{x}) = (1-(m-1)\tau)\frac{N^2 x_i (B\mathbf{x})_i}{N^2(\mathbf{x}^\top B\mathbf{x})} + \sum_{j\neq i} \tau \frac{N^2 x_j (B\mathbf{x})_j}{N^2(\mathbf{x}^T B\mathbf{x})} = (1-m\tau)\frac{x_i(B\mathbf{x})_i}{(\mathbf{x}^\top B\mathbf{x})} + \tau$$

where $B_{ii} = 1, B_{ij} = b$ with $i \neq j$.[8] For the Markov chains described above (symmetric case) we can prove the following phase transition result.

▶ **Theorem 9.** *There is a critical value τ_c of the* error in learning/mutation *parameter τ such that the mixing time is: (i) $\exp(\Omega(N))$ for $0 < \tau < \tau_c$ and (ii) $O(\log N)$ for $\tau > \tau_c$ where N is the size of the population.*

The theorem below will be used to prove the rapid mixing result for the finite linguistic model when $\tau > \tau_c$. It is used to construct a potential function and show that the deterministic dynamics g converges to fixed points.

▶ **Theorem 10 (Baum and Eagon Inequality [1]).** *Let $P(\mathbf{x}) = P(\{x_{ij}\})$ be a polynomial with nonnegative coefficients homogeneous of degree d in its variables $\{x_{ij}\}$. Let $\mathbf{x} = \{x_{ij}\}$ be any point of the domain $D : x_{ij} \geq 0, \sum_{j=1}^{q_i} x_{ij} = 1, i = 1, \ldots, p, j = 1, \ldots, q_i$. For $\mathbf{x} = \{x_{ij}\} \in D$, let $\Xi(\mathbf{x}) = \Xi\{x_{ij}\}$ denote the point of D whose i,j-th coordinate is*

$$\Xi(\mathbf{x})_{ij} = \left(x_{ij} \frac{\partial P}{\partial x_{ij}}\bigg|_{(\mathbf{x})} \right) \cdot \left(\sum_{j=1}^{q_i} x_{ij} \frac{\partial P}{\partial x_{ij}}\bigg|_{(\mathbf{x})} \right)^{-1}.$$

Then $P(\Xi(\mathbf{x})) > P(\mathbf{x})$ unless $\Xi(\mathbf{x}) = \mathbf{x}$.

3 Preliminaries

Couplings and Mixing Times

Let $\mathbf{p}, \mathbf{q} \in \Delta_m$ be two probability distributions on m objects. A *coupling* $\mathcal{C}$ of $\mathbf{p}$ and $\mathbf{q}$ is a distribution on ordered pairs in $[m] \times [m]$, such that its marginal distribution on the first coordinate is equal to $\mathbf{p}$ and that on the second coordinate is equal to $\mathbf{q}$. Couplings allow a very useful dual characterization of the total variation distance, as stated in the following well known lemma.

▶ **Lemma 11 (Coupling lemma [14]).** *Let $\mathbf{p}, \mathbf{q} \in \Delta_m$ be two probability distributions on m objects. Then,*

$$\|\mathbf{p} - \mathbf{q}\|_{\mathrm{TV}} = \frac{1}{2}\|\mathbf{p} - \mathbf{q}\|_1 = \min_{\mathcal{C}} \mathbb{P}_{(A,B)\sim\mathcal{C}}[A \neq B],$$

where the minimum is taken over all valid couplings $\mathcal{C}$ of $\mathbf{p}$ and $\mathbf{q}$.

---

[7] We use same notation for the update rule as before, i.e. g because it turns out to be the same function.
[8] Observe that this rule is invariant under scaling of fitness matrix B.

▶ **Definition 12** (Mixing time [14]). Let $\mathcal{M}$ be an ergodic Markov chain on a finite state space Ω with stationary distribution π. Then, the *mixing time* $t_{\text{mix}}(\varepsilon)$ is defined as the smallest time such that for any starting state $\mathbf{X}^{(0)}$, the distribution of the state $\mathbf{X}^{(t)}$ at time t is within total variation distance ε of π. The term mixing time is also used for $t_{\text{mix}}(\varepsilon)$ for a *fixed* values of $\varepsilon < 1/2$.

A well-known technique for obtaining upper bounds on mixing times is to use the Coupling Lemma above. Suppose $\mathbf{X}^{(t)}$ and $\mathbf{Y}^{(t)}$ are two evolutions of an ergodic chain $\mathcal{M}$ such that their evolutions are coupled according to some coupling $\mathcal{C}$. Let T be the smallest time such that $\mathbf{X}^{(T)} = \mathbf{Y}^{(T)}$. If it can be shown that $\mathbb{P}[T > t] \leq 1/4$ for every pair of starting states $(\mathbf{X}^{(0)}, \mathbf{Y}^{(0)})$, then it follows that $t_{\text{mix}} \coloneqq t_{\text{mix}}(1/4) \leq t$.

Operators, Norms

The following theorem, stated here only in the special case of the $1 \to 1$ norm, relates the spectral radius with other matrix norms.

▶ **Theorem 13** (Gelfand's formula, specialized to the $1 \to 1$ norm [13]). *For any square matrix A, we have*

$$\operatorname{sp}(A) = \lim_{\ell \to \infty} \left\|A^{\ell}\right\|_{1\to 1}^{1/\ell}.$$

Taylor Theorem (First order Remainder)

▶ **Theorem 14.** *Let $f : \mathbb{R}^m \to \mathbb{R}$ be differentiable and $\mathbf{x}, \mathbf{y} \in \mathbb{R}^m$. Then there exists some ξ in the line segment from $\mathbf{x}$ to $\mathbf{y}$ such that $f(\mathbf{y}) = f(\mathbf{x}) + \nabla f(\xi)(\mathbf{y} - \mathbf{x})$.*

Concentration

We also mention some standard Chernoff-Hoeffding type bounds that will be used in our later arguments.

▶ **Theorem 15** (Chernoff-Hoeffding bounds [6]). *Let $Z_1, Z_2, \ldots, Z_N$ be i.i.d. Bernoulli random variables with mean μ. We then have for all $\varepsilon > 0$,*

$$\mathbb{P}\left[\left|\frac{1}{N}\sum_{i=1}^{N} Z_i - \mu\right| > \varepsilon\right] \leq 2\exp\left(-2N\varepsilon^2\right).$$

4 Overview of proofs

We begin by explaining the proof technique of Theorem 5 in [20]. In order to prove a bound on the mixing time, the authors constructed a coupling that contracts the distance between two chains. This contraction does not happen at every step, rather at every k steps where k is some constant and depends on the function f. Essentially, it is shown that given two chains $\mathbf{X}^{(t)}, \mathbf{Y}^{(t)}$ that are close to the unique fixed point $\mathbf{z}$ of f, it holds that

$$\left\|\mathbf{X}^{(t+1)} - \mathbf{Y}^{(t+1)}\right\|_1 \approx \left\|J[\mathbf{z}](\mathbf{X}^{(t)} - \mathbf{Y}^{(t)})\right\|_1 \leq \|J[\mathbf{z}]\|_1 \left\|(\mathbf{X}^{(t)} - \mathbf{Y}^{(t)})\right\|_1$$

with high probability due to Chernoff bounds. Thus, the ℓ_1 norm of the Jacobian captures the contraction if it indeed exists. However it might be the case that $\|J[\mathbf{z}]\|_1 > 1$. On the positive side, using Gelfand's Theorem they were able to show a k-step contraction, since

$$\left\|J^k[\mathbf{z}]\right\|_1 \approx \left(\operatorname{sp}(J[\mathbf{z}])\right)^k < \rho^k < 1$$

for some $k \in \mathbb{N}$. Our proofs also use the idea of Gelfand's formula to show contraction/expansion (in Theorems 7 and 6 respectively) and also make use of Theorem 5). Nevertheless, there are important technical barriers that need to be crossed in order to prove our results as explained below.

4.1 Overview of Theorem 6

The main difficulty to prove this theorem is the existence of multiple unstable fixed points in the simplex from which the Markov chain should get away fast. As before, we study the time T required for two stochastic evolutions with arbitrary initial states $\mathbf{X}^{(0)}$ and $\mathbf{Y}^{(0)}$, guided by some function f, to collide. By the conditions of Theorem 6, function f has a unique stable fixed point $\mathbf{z}_0$ with

$$\mathrm{sp}\left(J[\mathbf{z}_0]\right) < \rho < 1.$$

Additionally, it has α-unstable fixed points. Moreover, for all starting points $\mathbf{x}_0 \in \Delta_m$, the sequence $(f^t(\mathbf{x}_0))_{t\in\mathbb{N}}$ has a limit. We can show that there exists constant c_0 such that $\mathbb{P}\left[T > c_0 \log N\right] \leq \frac{1}{4}$, from which it follows that $t_{\mathrm{mix}}(1/4) \leq c_0 \log N$. In order to show collision after $O(\log N)$ steps, it suffices first to run each chain *independently* for $O(\log N)$ steps. We first show that with probability $\Theta(1)$, each chain will reach $B(\mathbf{z}_0, \frac{1}{N^{1-\varepsilon}})$ after at most $O(\log N)$ steps, for some $\varepsilon > 0$.[9] As long as this is true, the coupling constructed in [20] can be used to show collision (see Section 3 for the definition of a coupling). To explain why our claim holds, we break the proof into three parts.

(a) First, it is shown that as long as the state of the Markov chain is within $o\left(\frac{\log^{2/3} N}{\sqrt{N}}\right)$ in ℓ_1 distance from some α-unstable fixed point $\mathbf{w}$, then, with probability $\Theta(1)$, it reaches distance $\Omega\left(\frac{\log^{2/3} N}{\sqrt{N}}\right)$ after $O(\log N)$ steps. Step (a) has the technical difficulty that as long as a chain starts from a $o(\frac{1}{\sqrt{N}})$ distance from an unstable fixed point, the variance of the process dominates the expansion due to the fact the fixed point is unstable.

(b) Assuming (a), we show that with probability $1 - \frac{1}{\mathrm{poly}(N)}$ the Markov chain reaches distance $\Theta(1)$ from any unstable fixed point after $O(\log N)$ steps.

(c) Finally, if the Markov chain has $\Theta(1)$ distance from any unstable fixed point (the fixed points have pairwise ℓ_1 distance independent of N, i.e., they are "well separated"), it will reach some $\frac{1}{N^{1-\varepsilon}}$-neighborhood of the stable fixed point $\mathbf{z}_0$ exponentially fast (i.e., after $O(\log N)$ steps). For showing (a) and (b), we must prove an expansion argument for $\|f^t(\mathbf{x}) - \mathbf{w}\|_1$ as t increases, where $\mathbf{w}$ is an α-unstable fixed point and also taking care of the random perturbations due to the stochastic evolution. Ideally what we want (but is not true) is the following to hold:

$$\left\|f^{t+1}(\mathbf{x}) - \mathbf{w}\right\|_1 \geq \alpha \left\|f^t(\mathbf{x}) - \mathbf{w}\right\|_1,$$

i.e., one step expansion. The first important fact is that f^{-1} is well-defined in a small neighborhood of $\mathbf{w}$ due to the Inverse Function Theorem, and it also holds that

$$\left\|f^t(\mathbf{x}) - \mathbf{w}\right\|_1 \approx \left\|J^{-1}[\mathbf{w}](f^{t+1}(\mathbf{x}) - \mathbf{w})\right\|_1 \leq \left\|J^{-1}[\mathbf{w}]\right\|_1 \left\|f^{t+1}(\mathbf{x}) - \mathbf{w}\right\|_1,$$

where $\mathbf{x}$ is in some neighborhood of $\mathbf{w}$ and $J^{-1}[\mathbf{w}]$ is the *pseudoinverse* of $J[\mathbf{w}]$ (see the remark in Section 2). However even if $\mathbf{w}$ is α-unstable and $\mathrm{sp}\left(J^{-1}[\mathbf{w}]\right) < \frac{1}{\alpha}$, it can hold that

[9] $B(\mathbf{x}, r)$ denotes the open ball with center $\mathbf{x}$ and radius r in ℓ_1, which we call an *r-neighborhood* of $\mathbf{x}$.

$\left\|J^{-1}[\mathbf{w}]\right\|_1 > 1$. At this point, we use Gelfand's formula (Theorem 13) as in the proof of [20]. Since $\lim_{t\to\infty}(\|A^t\|_1)^{1/t} \to \mathrm{sp}\,(A)$, for all $\varepsilon > 0$, there exists a k_0 such that for all $k \geq k_0$ we have

$$\left|\left\|A^k\right\|_1 - (\mathrm{sp}\,(A))^k\right| < \varepsilon.$$

We use this important theorem to show that for small $\varepsilon > 0$, there exists a k such that

$$\left\|f^t(\mathbf{x}) - \mathbf{w}\right\|_1 \approx \left\|(J^{-1}[\mathbf{w}])^k(f^{t+k}(\mathbf{x}) - \mathbf{w})\right\|_1 \leq \frac{1}{\alpha^k}\left\|f^{t+k}(\mathbf{x}) - \mathbf{w}\right\|_1,$$

where we used the fact that

$$\left\|(J^{-1}[\mathbf{w}])^k\right\|_1 < (\mathrm{sp}\left(J^{-1}[\mathbf{w}]\right))^k - \varepsilon \leq \frac{1}{\alpha^k}.$$

By taking advantage of the continuity of the $J^{-1}[\mathbf{x}]$ around the unstable fixed point $\mathbf{w}$, we can show expansion for every k steps of the dynamical system. It remains to show for (a) and (b) how one can handle the perturbations due to the randomness of the stochastic evolution. In particular, if $\left\|\mathbf{X}^{(0)} - \mathbf{w}\right\|_1$ is $o\left(\frac{1}{\sqrt{N}}\right)$, even with the expansion we have from the deterministic dynamics (as discussed above), variance dominates. We examine case (b) first, which is relatively easy (the *drift* dominates at this step). Due to Chernoff bounds, the difference $\left\|\mathbf{X}^{(t+k)} - \mathbf{w}\right\|_1 - \left\|f^k(\mathbf{X}^{(t)}) - \mathbf{w}\right\|_1$ is $O\left(\sqrt{\frac{\log N}{N}}\right)$ (this captures the deviation on running the stochastic evolution for k steps vs running the deterministic dynamics for k steps, both starting from $\mathbf{X}^{(t)}$) with probability $1 - \frac{1}{\mathrm{poly}(N)}$. Since $\left\|\mathbf{X}^{(t)} - \mathbf{w}\right\|_1$ is $\Omega\left(\frac{\log^{2/3} N}{\sqrt{N}}\right)$, then

$$\left\|\mathbf{X}^{(t+k)} - \mathbf{w}\right\|_1 \geq (\alpha^k - o_N(1))\left\|\mathbf{X}^{(t)} - \mathbf{w}\right\|_1.$$

For (a), first we show that with probability $\Theta(1)$, after one step the Markov chain has distance $\Omega(\frac{1}{\sqrt{N}})$ of $\mathbf{w}$. This claim just uses properties of the multinomial distribution. After reaching distance $\Omega\left(\frac{1}{\sqrt{N}}\right)$, we can use again the idea of expansion and being careful with the variance and we can show expansion with probability at least $\frac{1}{2}$, every k steps. Then we can show that with probability at least $\frac{1}{\log^{2/3} N}$, distance $\frac{\log^{2/3} N}{\sqrt{N}}$ is reached after $O(\log\log N)$ steps and basically we finish with (b). For (c), we use a couple of technical lemmas from [20], we explain in words below: Let Δ be some compact subset of Δ_m, where we have excluded all the α-unstable fixed points along with some open ball around each unstable fixed point of constant radius. We can show that given that the initial state of the Markov chain belongs to Δ, it reaches a $B(\mathbf{z}_0, \frac{1}{N^{1-\varepsilon}})$ for some $\varepsilon > 0$ as long as the dynamical system converges for all starting points in Δ (and it should converge to the stable fixed point $\mathbf{z}_0$). We have roughly that the dynamical system converges exponentially fast for every starting point in B to the stable fixed point $\mathbf{z}_0$ and that with probability $1 - \frac{1}{\mathrm{poly}(n)}$ two arbitrary chains independently will reach a $\frac{1}{N^{\varepsilon}}$ neighborhood of the stable fixed point $\mathbf{z}_0$. Therefore by $(a), (b), (c)$ and the coupling from [20], we conclude the proof of Theorem 6.

4.2 Overview of Theorems 7 and 8

To prove Theorem 8, we make use of Theorem 7, i.e., we reduce the case of the stable limit cycle to the case of multiple stable fixed points. If s is the length of the limit cycle, roughly the bound $e^{\Omega(N)}$ on the mixing time loses a factor $\frac{1}{s}$ compared to the case of multiple stable

fixed points. We now present the ideas behind the proof of Theorem 7. First as explained above, we can show contraction after k steps (for some constant k) for the deterministic dynamics around a stable fixed point $\mathbf{z}$ with $\text{sp}(\text{J}[\mathbf{z}]) < \rho < 1$, i.e.,

$$\left\|f^{t+k}(\mathbf{x}) - \mathbf{z}\right\|_1 \approx \left\|J^k[\mathbf{z}]\right\|_1 \left\|f^t(\mathbf{x}) - \mathbf{z}\right\|_1 \leq \rho^k \left\|f^t(\mathbf{x}) - \mathbf{z}\right\|_1 .$$

To do that, we use Gelfand's formula, Taylor's theorem and continuity of $J[\mathbf{x}]$ where $\mathbf{x}$ lies in a neighborhood of the fixed point $\mathbf{z}$. Hence, due to the above contraction of the ℓ_1 norm and the concentration of Chernoff bounds, it takes a long time for the chain $\mathbf{X}^{(t)}$ to get out of the region of attraction of the fixed point $\mathbf{z}$. Technically, the error that aggregates due to the randomness of the stochastic evolution guided by f does not become large due to the convergence of the series $\sum_{i=0}^{\infty} \rho^i$. Hence, we focus on the error probability, namely the probability the stochastic evolution guided by f deviates a lot from the dynamical system with rule f if both have same starting point after one step. Since this probability is exponentially small, i.e., it holds that

$$\left\|f(\mathbf{X}^{(0)}) - \mathbf{X}^{(1)}\right\|_1 > \varepsilon m$$

with probability at most $2me^{-2\varepsilon^2 N}$, an exponential number of steps is required for the above to be violated. Finally, as we have shown that it takes exponential time to get out of the region of attraction of a stable fixed point $\mathbf{z}$ we do the following easy (common) trick. Since the function has at least two fixed points, we start the Markov chain very close to the fixed point that its neighborhood has mass at most $1/2$ in the stationary distribution (this can happen since we have at least 2 fixed points that are well separated). Then, after exponential number of steps, it will follow that the total variation distance between the distribution of the chain and the stationary will be at least $1/4$.

4.3 Overview of Theorem 9

Below we give the necessary ingredients of the proof of Theorem 9. Our previous results, along with some analysis on the fixed points of g (function of Linguistic Dynamics) suffice to show the phase transition result. To prove Theorem 9, initially we show that the model (finite population) is essentially a stochastic evolution (see Definition 3) guided by g as defined in Section 2.1 and proceed as follows: We prove that in the interval $0 < \tau < \tau_c$, the function g has multiple fixed points whose Jacobian have spectral radius less than 1. Therefore due to Theorem 7 discussed above, the mixing time will be exponential in N. For $\tau = \tau_c$ a bifurcation takes place which results in function g of linguistic dynamics having only one fixed point inside simplex (specifically, the uniform point $(1/m, \ldots, 1/m)$). In dynamical systems, a local bifurcation occurs when a parameter (in particular the mutation parameter τ) change causes two (or more) fixed points to collide or the stability of an equilibrium (or fixed point) to change. To prove fast mixing in the case $\tau_c < \tau \leq 1/m$, we make use of the result in [20] (see Theorem 5). One of the assumptions is that the dynamical system with g as update rule needs to converge to the unique fixed point for all initial points in simplex. To prove convergence to the unique fixed point, we define a Lyapunov function P such that

$$P(g(\mathbf{x})) > P(\mathbf{x}) \text{ unless } \mathbf{x} \text{ is a fixed point.} \tag{1}$$

As a consequence, the (infinite population) linguistic dynamics converge to the unique fixed point $(1/m, \ldots, 1/m)$. To show Equation (1), we use an inequality that dates back in 1967 (see Theorem 10, [1]), which intuitively states the discrete analogue of proving that for a gradient system $\frac{d\mathbf{x}}{dt} = \nabla V(\mathbf{x})$ it is true that $\frac{dV}{dt} \geq 0$.

Abstract

In this paper, we study information cascades on graphs. In this setting, each node in the graph represents a person. One after another, each person has to take a decision based on a private signal as well as the decisions made by earlier neighboring nodes. Such information cascades commonly occur in practice and have been studied in complete graphs where everyone can overhear the decisions of every other player. It is known that information cascades can be fragile and based on very little information, and that they have a high likelihood of being wrong.

Generalizing the problem to arbitrary graphs reveals interesting insights. In particular, we show that in a random graph $G(n, q)$, for the right value of q, the number of nodes making a wrong decision is logarithmic in n. That is, in the limit for large n, the fraction of players that make a wrong decision tends to zero. This is intriguing because it contrasts to the two natural corner cases: empty graph (everyone decides independently based on his private signal) and complete graph (all decisions are heard by all nodes). In both of these cases a constant fraction of nodes make a wrong decision in expectation. Thus, our result shows that while both too little and too much information sharing causes nodes to take wrong decisions, for exactly the right amount of information sharing, asymptotically everyone can be right. We further show that this result in random graphs is asymptotically optimal for any topology, even if nodes follow a globally optimal algorithmic strategy. Based on the analysis of random graphs, we explore how topology impacts global performance and construct an optimal deterministic topology among layer graphs.

1 Introduction

An Information Cascade occurs when a person observes the actions of others and then – in spite of possible contradictions to his/her own private information – follows these same actions. A cascade develops when people "abandon their own information in favor of inferences based on earlier people's actions"[12]. Information Cascades frequently occur in everyday life. Commonly cited examples include the choice of restaurants when being in an unknown place people choose the restaurant that already has many guests over a comparatively empty restaurant, or hiring interview loops where interviewers follow earlier interviewer's decisions if they are not sure about the candidate. Notice that information cascades are not irrational behavior; on the contrary, they occur precisely because people rationally decide based on inferences derived from earlier people's actions.

The simple herding experiment by Anderson and Holt illustrates Information Cascades [3, 4](see also Chapter 16 in [12]). In this experiment, an urn contains three marbles, either two red and one blue (majority red), or one red and two blue (majority blue). The players do not know whether the urn is majority red or blue. One by one, the players privately pick one marble from the urn, check its color, return it to the urn, and then publicly announce their guess as to whether the urn is majority red or majority blue. The first and second player will naturally base their guesses on the colors of the marble they picked, thus their guesses reveals their private signals. For any subsequent player however, her rational guess may not reflect her own signal. For example, suppose the first two players both guess *red*. In this case, it is rational for the third player to also guess *majority-red* regardless of the color of the marble she picked. Indeed, the third player makes her decision on a rational inference based on the first two guesses. Since her guess does therefore not reveal any further information about the urn to any subsequent player, *every* subsequent player will guess the urn to be *majority-red*. The example shows that information cascades can be based on very little actual information and thus fragile; and they can be wrong. Indeed, in the above example with urns, it can be shown that with probability 1/5, a "wrong cascade" occurs, i.e., all players (except from possibly a few at the beginning) will guess wrongly.

The standard model for information cascades studies the process in which players make decisions sequentially based on their own private signals as well as the set of decisions made by earlier players [6, 7, 23]. In this paper, we interpret and generalize the traditional information cascade setting as a game in a graph. Each player is a node, and an edge between two nodes v and w means that w can hear about v's guess (assuming w is after v in the order of decision-making). Thus the traditional information cascade model corresponds to a complete graph (all players hear the decisions of all other players). At the other end of the spectrum, the empty graph means that every player decides independently of all other players, purely based on their own private signal. Casting the information cascade problem in this graph setting allows us to study the range in between the two extreme points of complete and empty graphs.

Studying this range in between reveals fascinating insights. Figure 1 shows the expected number of wrong guesses in the above 3-marble-urn experiment in a random graph $G(n, q)$ topology, for different values of n and q. In the empty graph ($q = 0$), if all nodes take their decisions independently, 1/3 of the players are wrong. In the complete graph ($q = 1$), 1/5 of the players are wrong on average as discussed above. However, the interesting thing is that for some values in between these two extremes, the number of wrong decisions is significantly less. Indeed, it seems that for the right value of q and $n \to \infty$, the number of wrong decisions tends to 0.

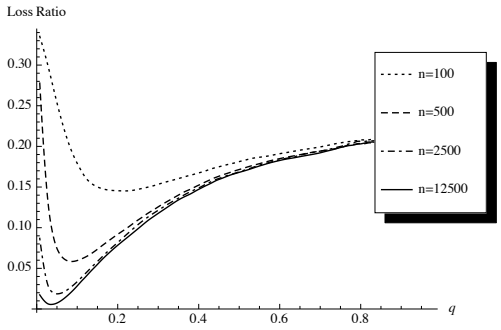

Figure 1 Performance of random graphs for different q and n.

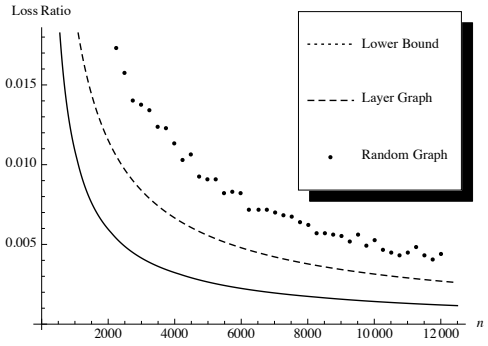

Figure 2 Performance of different topologies and strategies.

These observations are intriguing: It looks like that if people share too much information, a constant fraction of the population is wrong because of bad information cascades occurring. If people share too little information, a larger constant fraction of the population is wrong because the players take their decisions too independently, relying too much on their private signal which has a constant probability of being wrong. But, if exactly the right amount of information is shared, then it seems that in the limit, *all players* (at least asymptotically) take the correct decision.

In this paper, we study this phenomenon. We prove that, indeed, in a random graph the number of wrong nodes is at most $O(\log n)$ for the optimal value of q (Section 3). We then study arbitrary graph topologies and show that $O(\log n)$ wrong nodes is optimal in a strong sense (Section 4). Specifically, even in the best possible topology, there are at least $\Omega(\log n)$ wrong nodes. This result holds even if a global oracle tells each node whether it should (a) base its decision solely on its private signal (thus revealing this signal as additional information to all its neighbors) or (b) base its decision on the majority of private signal and neighboring decisions as in the cascade model above. In other words, even if nodes can "sacrifice" themselves to reveal additional information to their neighbors and even in the best possible topology $\Omega(\log n)$ wrong nodes is a lower bound. Finally, we derive an optimal deterministic topology from among a family of *layer graphs* (Section 5). Detailed proofs and analysis can be found in [22].

2 Related Work

Sequential decision-making has been studied in various areas including politics, economics and computer science[21, 6, 7, 14, 12]. The primary concern on the Bayesian learning model[7, 19, 6, 23, 20, 5, 1] is under what conditions asymptotically correct information cascades occur. For specific graph topologies such as complete graphs and line graphs, conditions on the private signals were addressed to guarantee the correctness of cascades[19, 9]. For arbitrary graph topologies, the approach of Acemoglu et al. [1] is intuitively quite consistent to our k-layer topology(see Section 6) and can be used to explain why our random network and selfishless decision-making algorithm achieve global optimality. While their approach focuses on the asymptotic probability of correct cascades, our result can quantitatively bound the expectation number of incorrect nodes.

There has been research on different sequential decision making models in graphs. For example, Chierichetti et al. [10] study different algorithms for finding appropriate orderings

to maximize the fraction making correct decisions and Hajiaghayi et al. [16] and Hajiaghayi et al. [15] generalizes the model and improve related bounds. However, notice that the threshold decision-making processes studied in these works fundamentally differ from the information cascade setting we consider in this work. Indeed, the effect of too little/too much information sharing being bad as shown in Figure 1 is not observed in such threshold models.

There also exists an impressive body of work on sequential and non-sequential decision on arbitrary graphs that however do not capture information cascades as exemplified in Anderson and Holt's herding experiment. Typically, each node updates its opinion through repeated averaging with neighbors. General conditions for convergence to consensus have been developed[2, 11, 13]. Intrigued by the observation that consensus is usually not reached in real world[18], Bindal et al. [8] use a game theoretic approach to study the equilibrium of the dynamical process and measure the cost of disagreement via the Price of Anarchy[17].

3 Preliminaries

We introduce the formal definitions of our model. There are n nodes (numbered $1, 2, \cdots n$) whose neighboring relationship is depicted by a graph $G = ([n], E)$. All nodes make decisions sequentially according to their numbers in order to guess a global ground truth value $b \in \{0, 1\}$. When making its decision, each node can only obtain a random partial information on b. That is, when node i observes b, it can only get a *private signal* s_i which equals b with probability $p > 0.5$ or equals $1 - b$ with probability $1 - p$. The decision-making of a node not only depends on its private signal observed from b, but also on the decisions made by its previous neighbors. Note that the neighboring decisions may or may not be based on those nodes' private signals. More formally, let c_i be the *output decision* or *guess* of node i and c^i be the *decision vector* $(c_1, c_2, \cdots, c_i)$, if $L_i : \{0, 1\}^{i-1} \times \{0, 1\} \to \{0, 1\}$ is the *decision-making algorithm* for node i, we have in general $c_i = L_i(c^{i-1}, s_i)$.

Given the graph G and decision-making algorithms $L_1, L_2, \cdots, L_n$, we use $\mathcal{E}_G(L_1, \cdots, L_n)$ to denote the expected number of nodes that output the wrong value $1 - b$. When it is clear from the context, we may abbreviate this notation to $\mathcal{E}_G$, $\mathcal{E}(L_1, \cdots, L_n)$, or simply $\mathcal{E}$. The global objective of this sequentially decision-making process is to minimize $\mathcal{E}_G(L_1, \cdots, L_n)$, which is equivalent to maximizing the expected number of nodes who guess the ground truth value correctly. We will show that such an optimization task can be achieved by adjusting the graph topology or the decision-making algorithms.

Let $\mathcal{E}_i$ be the *failure probability* that node i outputs $1 - b$. As a node often makes inferences based on others' decisions without knowing their private signals, it is intuitively understandable that a node's probability of correct decision-making can be quantified by the number of private signals it can infer.

In reality, the Majority Algorithm is one of the most popular and practical algorithms for decision-makings. This kind of "following the herd" algorithm can often achieve a locally optimal effect. In this paper, we use Maj_k to denote the Majority Algorithm taking input bits of length k. We just use Maj if k is clear from the context. In Chapter 16 of [12], Easley and Kleinberg shows that the Majority Algorithm is optimal when a node observes multiple independent signals.

▶ **Claim 1.** *For any node i seeking to maximize $\mathcal{E}_i$, when it observes multiple signals(including its own private signal), its optimal algorithm is to output the majority of these observed signals.*

However, Anderson and Holt's experiment shows that if all nodes apply the Majority Algorithm, it is possible that essentially all of the nodes guess incorrectly, leading to an

information cascade on the wrong side. In this paper, we address this problem and analyze the impact of topology and algorithms on information cascades.

4 Random Graphs

In this section, we analyze the performance of the Majority Algorithm on random graphs. Conventionally, $G(n,q)$ denotes the random graph model that generates a random graph with n nodes and each pair of nodes are connected by an edge with probability q. Different connection probabilities induces completely different topologies, and thus dramatic changes in $\mathcal{E}_{G(n,q)}$. As introduced in Section 1, when q equals 0 or 1 corresponding to the empty or complete topology, the expected number of wrong output decisions are both $\Theta(n)$.

In this section, we show that there exists a q such that the Majority Algorithm can achieve only $\Theta(\log n)$ expected wrong output decisions:

▶ **Theorem 2.** *There exists a connection probability $q = \Theta(1/\log n)$ such that in $G(n,q)$, when all nodes apply the Majority Algorithm, we have $\mathcal{E}_{G(n,q)} = \Theta(\log n)$.*

We can also demonstrate the optimality of this connection probability by showing a lower bound for the expected number of wrong decisions:

▶ **Theorem 3.** *For any connection probability q, when all nodes apply the Majority Algorithm, the expected number of wrong outputs in $G(n,q)$ is lower bounded by $\Theta(\log n)$, i.e. $\mathcal{E}_{G(n,q)} = \Omega(\log n)$.*

A key ingredient to our proof is to bound the failure probability $\mathcal{E}_i$ for each node. Applying the Chernoff Bound and the Union Bound, we can further bound the overall $\mathcal{E}_{G(n,q)}$. The following are two technical lemmas for bounding the failure probabilities:

▶ **Lemma 4.** *If a constant fraction $f > 0.5$ of the first i nodes are correct (resp. wrong), node $i+1$'s failure (resp. correct) probability $\mathcal{E}_{i+1}$ is upper bounded by $e^{-\Theta(iq)}$.*

▶ **Lemma 5.** *If a constant fraction $f > 0.5$ of the first i nodes are correct, s.t. $\frac{f}{1-f} \geq \sqrt{\frac{q}{1-q}}$, then node $i+1$'s failure probability is upper bounded by p.*

4.1 Proof of Theorem 2

In this subsection, we provide a detailed proof of Theorem 2.

The reason why random graphs behave well for the right value of q is that randomness defers the process of information cascades. The fewer neighbors, the more likely a not will output its private signal, thereby 1) having a high probability of being wrong, but 2) revealing important information to its neighbors. When $q = \Theta(1/\log n)$, with high probability each of the first $\Theta(\log n)$ nodes have at most one neighbor. By definition of Majority Algorithm, any node with only one neighbor will be forced to output its own private signal.

Using Lemma 4, we can prove that an established cascade among the first $\log n/q$ nodes decides the outputs of all later nodes with high probability:

▶ **Lemma 6.** *If among the first $\log n/q$ nodes, only a small constant fraction $f < 0.5$ output wrongly, then for the later $n - (\log n/q)$ nodes, the expected number of wrong outputs is at most $O(1)$.*

Lemma 6 is insufficient to bound the $\Theta(\log n)$ expected failure nodes as required by Theorem 2, in that it only bounds the loss of later nodes in the sequence. It could be the

case that the first $\log n/q = \Theta(\log^2 n))$ nodes all fail. To bound the overall $\mathcal{E}$, it is essential to analyze the performance of the first $\log n/q$ nodes. We can use an induction argument to show that for the optimal q, the first $\log n/q$ nodes are majority-correct with high probability:

▶ **Lemma 7.** *Let* $\delta = \frac{1}{2}(p + \frac{\sqrt{p}}{\sqrt{p}+\sqrt{1-p}})$. *There exists connection probability* $q_{opt} = \Theta(1/\log n)$ *such that the first* $\Theta(\log n/q)$ *nodes contains at least* δ *portion of correct outputs with probability* $1 - O(n^{-1}\log n)$.

Proof. We can prove Lemma 7 by induction. Consider dividing the first $\Theta(\log n/q)$ nodes into $\Theta(\log n)$ segments, where each segment contains $\Theta(1/q) = \Theta(\log n)$ many nodes. We analyze each segment independently and show that

- There exists $q_1 = \Theta(1/\log n)$, such that the first segment contains δ portion of correct outputs with probability at least $1 - O(n^{-1})$.
- If the first i segments contain δ portion of correct outputs, then the $(i+1)^{th}$ segment will also contain δ portion of correct outputs with probability $1 - O(n^{-1})$.

By a single Union Bound, we can combine these two results and show that the first $\Theta(\log n/q)$ nodes contain δ portion of correct outputs with probability $1 - \log n \cdot O(n^{-1})$. ◀

Lemma 7 and 4 together imply a $\Theta(\log n)$ upper bound for the expected number of wrong outputs among the first $\Theta(\log n/q)$ nodes:

▶ **Lemma 8.** *If* $q = q_{opt}$, *the first* $\Theta(\log n/q)$ *nodes' expect to have at most* $\Theta(\log n)$ *many wrong outputs.*

Proof of Theorem 2. With Lemma 6, 7 and 8 proved, the expected number of wrong output decisions under connection probability q_{opt} is bounded by

$$\begin{aligned}\mathcal{E}_{G(n,q)} = \sum_{i=1}^{n}\mathcal{E}_i &= \sum_{i=1}^{\log n/q}\mathcal{E}_i + \sum_{i=\log n/q+1}^{n}\mathcal{E}_i \\ &\leq \Theta(\log n) + (1 - O(n^{-1}\log n)) \cdot O(1) + O(n^{-1}\log n) \cdot n = \Theta(\log n).\end{aligned} \tag{1}$$

which completes the proof. ◀

4.2 Proof of Theorem 3

In the previous section, we prove that for the optimal connection probability $q_{opt} = \Theta(1/\log n)$, the expected number of wrong outputs is reduced to $\Theta(\log n)$. However, it remains a problem whether we can move beyond $\Theta(\log n)$. In this section, we prove Theorem 3 which states that the bound in Theorem 2 is asymptotically optimal.

Proof of Theorem 3. We prove this theorem for two separate cases, namely when $q = O(1/\log n)$ and $q = \omega(1/\log n)$.

When $q = O(1/\log n)$, the intuition is that we need at least $\Theta(1/q)$ nodes before accumulating an actual influential cascade. For the i^{th} nodes where $i \leq 1/q$, its chance of being isolated is $(1-q)^i + iq(1-q)^{i-1} \geq (1-q)^{1/q} \sim 1/e$. Therefore the node's failure probability is at least $\mathcal{E}_i = (1-p) \cdot \Pr[\text{isolated}] = (1-p)/e$. This lower bounds the expected number of failure nodes by $(1-p)/(eq) = \Theta(1/q)$.

When $q = \omega(1/\log n)$, a wrong cascade occurs with high probability, thus resulting in a significant number of failure nodes. With probability $(1-p)^{\Theta(1/q)}$, all of the first $\Theta(1/q)$ nodes observe a wrong signal and output the wrong guesses. Using Lemma 4, we can show that with high probability, the majority of later nodes follow this wrong cascade. Therefore, the total number of failure nodes is at least $(1-p)^{\Theta(1/q)} \cdot \Theta(n) = n^{1-o(1)} = \Omega(\log n)$. ◀

5 General Lower Bound

In this section, we design a non-constructive scheme that finds the optimal decision-making algorithms for general graphs. Given the graph $G = ([n], E)$, our goal is to find the set of algorithms $\{L_i\}_{i=1}^n$ such that $(L_1, \cdots, L_n) = \arg\min_{L'_1,\cdots,L'_n} \mathcal{E}_G(L'_1, \cdots, L'_n)$.

An important use of the non-constructive scheme is to provide a general lower bound for arbitrary topology. For any set of decision-making algorithms in a topology G, we can simulate it on a complete graph by considering only edges in G. Thus the minimal $\mathcal{E}$ for complete graphs is a general lower bound for arbitrary topology:

▶ **Theorem 9.** *The expected number of wrong nodes $\mathcal{E}$ under the optimal decision-making algorithms of complete graphs lower bounds the $\mathcal{E}$ of any algorithms in any topology.*

From our previous discussion on random graphs, we know that the expected number of wrong guesses $\mathcal{E}$ highly depends on the number of nodes revealing their private signals. This inspires us to make the following definitions:

▶ **Definition 10.** Node i reveals **valid** information under c^{i-1} if and only if node i outputs its private signal under c^{i-1}, i.e. $c_i = L_i(c^{i-1}, s_i) = s_i$. Furthermore, we denote Valid$(\cdot)$ as a function that extracts a vector of valid information out of a decision vector, i.e. c_j is in the vector Valid(c^i) if and only if c_j is valid.

▶ **Definition 11.** A node i's **reveal set** RS_i is the set of c^{i-1} which causes node i to reveal **valid** information.

Note that any valid information is correct with probability p and is independent of other nodes. Using the same Bayesian argument[12], we can prove a similar lemma as Claim 1 in Section 3, which states that a node's guess is beneficial for later nodes if and only if the guess is valid:

▶ **Lemma 12.** *For a node i seeking to minimize its failure probability $\mathcal{E}_i$, the optimal decision-making algorithm is to perform the Majority Algorithm on Valid$(c^{i-1}) \bigcup \{s_i\}$, i.e. $c_i = Maj($ Valid$(c^{i-1}), s_i)$.*

5.1 A non-constructive optimal algorithm scheme for general graphs

In this section, we provide a general scheme for finding the optimal decision-making algorithms of all nodes in arbitrary topologies. Our scheme is non-constructive in that it neither explicitly specifies what the optimal algorithms are, nor shows how to find them efficiently.

Given the underlying topology, all the nodes decide their algorithms sequentially in a *greedy* way as follows. Node 1 publicly announces L_1, based on its own rationality, then node 2 announces L_2 with the knowledge of L_1, etc(see Algorithm 1). Any node i will base its knowledge on $L_1, \cdots, L_{i-1}$ when deciding L_i. Each node designs its own decision-making algorithm in order to locally minimizes the failure probability. Denote this construction scheme as $GC(\cdot)$, the abbreviation of "greedy construction", then for node i, we have $L_i = GC(L_1, \cdots, L_{i-1})$. We can prove by contradiction that such a locally optimal scheme lead to an overall optimality:

▶ **Theorem 13.** *$L_1, L_2, \ldots, L_n$ constructed as in Algorithm 1 minimizes the expected number of wrong nodes, i.e. $\mathcal{E}(L_1, L_2, \ldots, L_n)$.*

Algorithm 1 A non-constructive optimal algorithm scheme for general graphs

1: Given $L_1, \cdots, L_{n-1}$, node n constructs L_n that aims at minimizing its own failure probability $\mathcal{E}_n$.
2: Given $L_1, \cdots, L_{n-2}$, and also the fact that node n is greedy, node $n-1$ constructs L_{n-1} such that the overall loss of him and node n is minimized.
3: This process continues. Each L_i greedily minimizes the expected number of wrong nodes after among $\{i, \cdots, n\}$ given $L_1, \cdots, L_{i-1}$.
4: Node 1 knows that all later nodes are "greedy". Their algorithms $L_2, \cdots, L_n$ can all be written as a function of L_1. It then constructs L_1 such that $\mathcal{E}$ is minimized.
5: Knowing what L_1 is, we can backtrack L_2, and recursively all the output algorithms L_i.

5.2 Optimal algorithms for complete graphs

In this section, we specify the optimal decision-making algorithms for complete graphs and thus provide a general lower bound for our model(by Theorem 17). Several intrinsic properties regarding information cascades in complete graph will also be presented.

We start with a lemma showing that optimal algorithm will either reveal **valid** information or perform Majority Algorithm on all previous guesses.

▶ **Lemma 14.** *In the optimal algorithm, a node either reveals **valid** information or apply Majority Algorithm on all previous outputs, i.e.*

$$L_i = \begin{cases} s_i & c^{i-1} \in RS_i \\ Maj(c^{i-1}) & c^{i-1} \notin RS_i \end{cases}.$$

It is worth pointing out several non-trivial points of Lemma 14 : (a) the Majority Algorithm is performed on previous guesses only and ignores its own private signal; (b) the Majority Algorithm is performed on *all* previous guesses, not only on the valid guesses. An established result in the proof of Lemma 14 is that the Majority Algorithm will cascade on complete graphs, i.e. if a node performs Majority Algorithm, all later nodes will also perform Majority Algorithm. This implies the existence of a switching point, where all nodes prior to this point reveal their private signals, and all later nodes perform Majority Algorithm based on former nodes' signals. If we can estimate the position of this switching point, then an estimation of $\mathcal{E}$ is achieved.

Lemma 14 specifies a node's action outside the reveal set. However, to get an explicit representation of L_i, an understanding of the reveal set itself is required. We introduce the following lemma that fills this gap.

Denote $\text{diff}(c^{i-1}) = (\#\ 1 \text{ in Valid}(c^{i-1})) - (\#\ 0 \text{ in Valid}(c^{i-1}))$, which serves as a criteria to measure the strength of valid information in previous decision vector $c^{i-1} = (c_1, \cdots, c_{i-1})$.

▶ **Lemma 15.** *The reveal set of a node i can be explicitly expressed with respect to some parameters $\delta_n(\cdot)$, where $RS_i = \{c^{i-1} : |diff(c^{i-1})| \geq \delta_n(i)\}$.*

Proof. This lemma follows from the fact that a node outputs based on the Bayesian probability for the ground truth bit b, which depends solely upon $\text{diff}(c^{i-1})$. Given c^{i-1}, the Bayesian probability for b is

$$\begin{cases} \Pr[b=0|c^{i-1}] = \frac{1}{1+(\frac{p}{1-p})^{\text{diff}(c^{i-1})}} \\ \Pr[b=1|c^{i-1}] = \frac{1}{1+(\frac{1-p}{p})^{\text{diff}(c^{i-1})}} \end{cases}. \tag{2}$$

Lemma 14 implies that for each node, (a) if the previous decision vector convinces it that b equals $\text{Maj}(c^{i-1})$ with high probability, it follows the majority of former output decisions; (b) otherwise, it tries to provide more information by revealing its own private signal. As implied by Equation (2), the larger $|\text{diff}(c^{i-1})|$ is, the more likely $b = \text{Maj}(\text{Valid}(c^{i-1}))$. This lead us to conclude the existence of a threshold $\delta_n(i)$ such that L_i applies Majority Algorithm if and only if $|\text{diff}(c^{i-1})| \geq \delta_n(i)$. ◀

Finally, given i and n as input, we show how to efficiently derive $\delta_n(i)$ in average $O(\log n)$ time. Denote $\mathcal{E}(i,d)$ to be the expected number of wrong nodes given that $|\text{diff}(c^{i-1})| = d$. The idea is to use recursion to derive $\mathcal{E}(i,d)$ for all i and d, in the process of which $\{\delta_n(i)|i\}$ may be calculated. If a node k chooses to reveal its private signal, $\mathcal{E}(k,d)$ is updated as

$$\mathcal{E}(k,d) = q_1 \cdot \mathcal{E}(k+1, d+1) + (1-q_1) \cdot \mathcal{E}(k+1, d-1),$$

where q_1 is the probability that node k's private signal matches the majority of former guesses. Similarly, if node k chooses to do Majority Algorithm, $\mathcal{E}(k,d)$ is updated as

$$\mathcal{E}(k,d) = q_2 \cdot \left(n - \frac{k+d}{2}\right) + (1-q_2) \cdot \frac{k+d}{2},$$

where q_2 is the probability that the majority of former outputs is correct. Therefore, we can calculate $\{\mathcal{E}(i,d)\}$ in time $O(n^2)$. A further improvement can be made by exploiting the properties of $\delta_n()$: $\delta_n(i+1) - 1 \leq \delta_n(i) \leq \delta_n(i+1) + 1$, Thus to calculate $\{\delta_n(i)\}$, it suffices to calculate $\{\mathcal{E}(i,d) \mid d < \delta_n(i), i \geq n\}$, which requires only $n \cdot \max_i\{\delta_n(i)\} = O(n \log n)$ time complexity.

▶ **Lemma 16.** *Given n as input, we can calculate the set $\{\delta_n(i)\}$ in $O(n \log n)$ time.*

5.3 General lower bound for our model

Finally we analyze the expected number of wrong nodes for the optimal algorithms in complete graphs, and provide a general $\Theta(\log n)$ lower bound for the model.

▶ **Theorem 17.** *The expected number of wrong nodes $\mathcal{E}$ for any topology and any algorithm is at least $\Theta(\log n)$.*

Proof. It suffices to prove that the $\mathcal{E}$ of the optimal algorithms in complete graph is bounded by $\Theta(\log n)$. In the proof of Lemma 14, we develop the concept of a "switching point", where all nodes prior to this point reveal valid information and all nodes afterwards perform Majority Algorithm. Denote m as a random variable of the switching point's position. We prove that at least one of the following happens: (a) $m \geq (\log_{p/(1-p)} n)/2$; or (b) $\mathcal{E}$ is greater than $\sqrt{n}/2$.

If $m < (\log_{p/(1-p)} n)/2$, then from Equation (2), we know that the majority of revealed signals are wrong with probability at least $(1 + (p/(1-p))^m)^{-1} > n^{-0.5}/2$. So the expected number of wrong nodes is lower bounded by $(n-m)/\sqrt{n}$ which is asymptotically greater than $\sqrt{n}/2$. Therefore, for the optimal output algorithms in complete graph, $\mathcal{E}$ is at least

$$\min\left((1-p)\log_{p/(1-p)} n \Big/ 2, \sqrt{n}\Big/2\right) = \Omega(\log n).$$ ◀

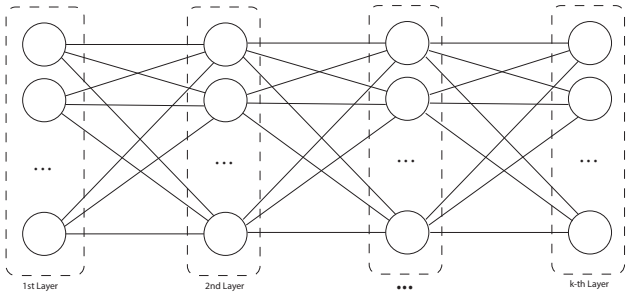

Figure 3 A k-layer graph.

6 Optimal K-Layer Topology

In section 3, we show that the optimal $\mathcal{E}$ for random graphs is $\Theta(\log n)$, which is asymptotically the same as the general lower bound in Theorem 17. Yet the question remains what is the actual optimal topology for the Majority Algorithm.

In this section, we propose a family of layer graphs and search for the optimal topology among this family. We claim, without proof, that the optimal topology of layer graphs is actually the optimal topology for Majority Algorithm.

To find the optimal topology, it helps to first understand the hidden insights behind small overall $\mathcal{E}$. In the optimal algorithms for complete graphs, nodes first judge the strength of the current cascade, and then decide whether to follow the cascade or reveal their own signals to strengthen the cascade. Such a *think-before-acting* way of decision-making guarantees the correctness probability of any established cascade, and thus results in good overall performance. We hope to know whether such *think-before-acting* could make it possible for Majority Algorithm to achieve optimality simply by adjusting the topology. This inspires us the following definition of layer graphs.

▶ **Definition 18** (Definition of layer graphs)**.** A graph is said to have k layers if it can be separated into k disjoint groups, $S_1, \cdots, S_k$, where any node in group S_i is connected to and only to all nodes in S_{i-1}. See Figure 3 for an example.

▶ Algorithm 19. Given a k-layer graph G, we consider how nodes perform in G. First of all, similar to the optimal algorithms in complete graph, we have $|S_1|$ many nodes revealing **valid** information at the very front. If there exists a cascade in S_1 (the number of one choices outmatches another by at least two), then all later nodes follow this cascade. Otherwise, nodes in S_2 reveal their private signals. This process continues until a cascade happens in some layer. In this sense, layer graphs do contains the think-before-acting way of decision-making.

In the following sections, we find the optimal topology among layer graphs, and show that the expected number of wrong nodes $\mathcal{E}$ for such optimal topology is also $\Theta(\log n)$. This optimal $\mathcal{E}$ will be compared to previous bound and results, from which we will be able to glimpse the limit of Majority Algorithm. Throughout this section, if not otherwise mentioned, we will assume that the output algorithm is Majority Algorithm. We denote the expected number of wrong nodes on a k-layer topology $(S_1, \cdots, S_n)$ as $\mathcal{E}(|S_1|, \cdots, |S_n|)$.

6.1 Optimal topology for layer graphs

Remark 19 provides an intuitive way to calculate the $\mathcal{E}$ of any layer graph. Given i independent signals, we denote $p_w(i)$ as the probability that these signals generate a wrong cascade,

and $p_n(i)$ as the probability that these signals does not generate cascade in either side. A recursion regarding $\mathcal{E}$ of any layer graph can be shown to be:

$$\mathcal{E}(a_1, \cdots, a_k) = (1-p) \cdot a_1 + p_w(a_1) \cdot (n - a_1) + p_n(a_1) \cdot \mathcal{E}(a_2, \cdots, a_k), \tag{3}$$

where $(1-p)a_1$ is the expected number of wrong nodes among the first layer, $n - a_1$ is the expected number of wrong nodes among later layers under wrong cascade, and $\mathcal{E}(a_2, \cdots, a_k)$ is the expected number of wrong nodes of later layers under no cascade. By extending the recursive term, we can simplify Equation (3) into

$$\mathcal{E}(a_1, \cdots, a_k) = \sum_{i=1}^{k} \Big(\prod_{j=1}^{i-1} p_n(a_j) \cdot \Big((1-p) \cdot a_i + p_w(a_i) \cdot (n - \sum_{j=1}^{i-1} a_j) \Big) \Big). \tag{4}$$

▶ Algorithm 20. Our goal is to estimate $\mathcal{E}$ of the optimal layer graph to the $\Theta(\log n)$ level. Any approximation of $\mathcal{E} + o(\log n)$ would be satisfying. This relaxation releases us from getting an exact optimum and allows us to make proper adjustments that greatly reduce the difficulty of the calculation. For example, in the derivation of Equation (3) and (4), we assume without loss of generality that each layer has an even number of nodes. This will result in $O(1)$ changes in the optimal parameters, which is tolerable.

To find a set of parameters $\{k, a_1, \cdots, a_k\}$ such that $\mathcal{E}(a_1, \cdots, a_k)$ is minimized, we need the following basic steps:

- We first show that in Equation (3), the contribution of $p_n(a_1)\mathcal{E}(a_2, \cdots, a_k)$ is limited and may be discarded without much change to the optimal parameters. Therefore, it suffices to consider the optimization of a_1 in the equation

$$\arg\min_{a_1} f(a_1) = \arg\min_{a_1} \Big((1-p) \cdot a_1 + p_w(a_1) \cdot (n - a_1) \Big). \tag{5}$$

- We then solve the equation $f(x+1) - f(x) = 0$, which has a unique solution. It can be shown that $f(a_1)$ first decreases then increases with respect to a_1. Thus the solution for $f(x+1) - f(x) = 0$ offers an approximation to the optimal a_1 with only $O(1)$ error.
- After solving the optimal size of the first layer, we can apply this method recursively to calculate the optimal size of all layers.

The proof for the above three results are complex and brute-force. First, we present a lemma that addresses result 2. It is worth pointing out that Equation 5 is the expected loss when we have only two layers, with the first layer of size a_1 and the second layer of size $n - a_1$. Therefore, result 2 is equivalent to finding an optimal topology among two layer graphs. For convenience, we denote $s = 1/(4p(1-p))$.

▶ **Lemma 21.** *For the optimal topology among two layer graphs, its first layer has size*

$$\log_s n - \log_s(\log_s n)/2 + O(1).$$

▶ **Theorem 22.** *The optimal layer topology has $k = n/\log_s n + o(n/\log_s n)$ many layers. The first layer has $a_1 = \log_s n$ many nodes. The size of layer i may be written as a recursion of the size of layer $i-1$,*

$$a_i \sim \log_s(s^{a_{i-1}} - a_{i-1}). \tag{6}$$

In other words, the optimal topology satisfies the following structural properties:

- *The sizes of layers gradually decrease, and the number of layers with size $\log_s n - i$ is $(s-1)n/(s^{i+1}(\log_s n - i))$.*

- *The first* $(s-1)n/(s\log_s n)$ *layers have size* $\log_s n$.
- *The following* $(s-1)n/(s^2(\log_s n-1))$ *layers have size* $\log_s n-1$, *and so on.*

We believe that the layer topology provided in Theorem 22 is actually the optimal topology for Majority Algorithm. However, we have not yet come up with any rigorous proof to verify our conjecture. We will leave this as an open problem for future work.

▶ **Conjecture 23.** *The layer topology provided in Theorem* 22 *is the optimal topology for Majority Algorithm.*

6.2 Experiments on the optimal parameters

For layer graphs, Equation (6) can be used to calculate the optimal parameters with high precision. Thus the results in Theorem 22 is a very tight approximation, which works flawlessly if we only seek to analyze the complexity of $\mathcal{E}$. However, in real life, users might wish to achieve the exact optimal parameters. In this case, the constant error in our equations can not be neglected. Here, we introduce an algorithm that searches for the exact optimal topology in average $O(1)$ run time.

Recall that layer graphs satisfy the following properties. For a k-layer structure $(a_1,\cdots,a_k)$, if the first layer cascades, the rest of the nodes follow this cascaded result. Otherwise, the rest of the nodes become equivalent to a $(k-1)$-layer structure, with each layer's size being $(a_2,\cdots,a_k)$ (or $(a_2+1,\cdots,a_k)$ if a_1 is odd). Therefore, for a fixed a_1, the optimal k and $a_2,\cdots,a_k$ should be chosen such that,

- If a_1 is even,

$$(k-1,a_2,\cdots,a_k)=\arg\max_{k',a_1',\cdots,a_k'}\mathcal{E}\Big(a_1',\cdots,a_k'\Big|\sum_{i=1}^{k'}a_i'=n-a_1\Big). \tag{7}$$

- If a_1 is odd,

$$(k-1,a_2+1,\cdots,a_k)=\arg\max_{k',a_1',\cdots,a_k'}\mathcal{E}\Big(a_1',\cdots,a_k'\Big|\sum_{i=1}^{k'}a_i'=n-a_1+1\Big). \tag{8}$$

This implies that given the optimal layer topologies for all $n'<n$, calculating the optimal layer topology for n should be easy. We can simplify the problem into an optimization over a_1, instead of the optimization over many parameters. A further analysis shows that the optimal layer topology for n nodes and $n+1$ nodes cannot differ by too much. More specifically, denote the optimizing parameter for n nodes as $(k_n,a_1^n,\cdots,a_{k_n}^n)$, then $|a_1^n-a_1^{n+1}|\le 1$. Using this, together with the recursive idea in Equation 7 and 8, we can design an algorithm that runs in time $O(n)$, and find the optimal layer topology for all $n'\le n$. The amortized running time of this algorithm is only $O(1)$.

7 Conclusion

In this paper, we discussed information cascades on various network topologies. We provide a non-constructive optimal algorithm scheme for general graphs, solve the scheme for complete graph and achieve a general lower bound for our model. We also studied Majority Algorithm in random graphs and layer graphs, the minimal $\mathcal{E}$ of which was shown to be asymptotically the same with our general lower bound. From the experiment results, a gap between the general lower bound and layer graphs can be observed. We believe this to be a result of

the difference in the model setting, i.e. Majority Algorithm is weaker than optimal general algorithms.

Future work in this area may include the study of the following scenarios.

- The nodes' order of decision-making is no longer fixed and given, but instead randomly sampled from all permutations.
- The topology is fixed and we are only able to add or remove a fixed portion of the edges. The goal is to minimize $\mathcal{E}$ under this constraint.
- *Plant nodes* in the network. These nodes could sacrifice themselves to reveal their true private signal. How should a topology designer control and position these plant nodes in the topology?

Analysing Survey Propagation Guided Decimation on Random Formulas*†

Samuel Hetterich

Goethe University, Mathematics Institute, Frankfurt, Germany
hetterich@math.uni-frankfurt.de

Abstract

Let $\vec{\Phi}$ be a uniformly distributed random k-SAT formula with n variables and m clauses. For clauses/variables ratio $m/n \leq r_{k\text{-SAT}} \sim 2^k \ln 2$ the formula $\vec{\Phi}$ is satisfiable with high probability. However, no efficient algorithm is known to provably find a satisfying assignment beyond $m/n \sim 2k\ln(k)/k$ with a non-vanishing probability. Non-rigorous statistical mechanics work on k-CNF led to the development of a new efficient "message passing algorithm" called *Survey Propagation Guided Decimation* [Mézard et al., Science 2002]. Experiments conducted for $k = 3, 4, 5$ suggest that the algorithm finds satisfying assignments close to $r_{k\text{-SAT}}$. However, in the present paper we prove that the basic version of Survey Propagation Guided Decimation fails to solve random k-SAT formulas efficiently already for $m/n = 2^k(1+\varepsilon_k)\ln(k)/k$ with $\lim_{k\to\infty}\varepsilon_k = 0$ almost a factor k below $r_{k\text{-SAT}}$.

1 Introduction

Random k-SAT instances have been known as challenging benchmarks for decades [9, 28, 33]. The simplest and most intensely studied model goes as follows. Let $k \geq 3$ be an integer, fix a density parameter $r > 0$, let n be a (large) integer and let $m = \lceil rn \rceil$. Then $\Phi = \Phi_k(n, m)$ signifies a k-CNF chosen uniformly at random among all $(2n)^{km}$ possible formulas. With k, r fixed the random formula is said to enjoy a property *with high probability* if the probability that the property holds tends to 1 as $n \to \infty$.

The conventional wisdom about random k-SAT has been that the problem of finding a satisfying assignment is computationally most challenging for r below but close to the *satisfiability threshold* $r_{k-\text{SAT}}$ where the random formula ceases to be satisfiable w.h.p. [28]. Whilst the case $k = 3$ may be the most accessible from a practical (or experimental) viewpoint, the picture becomes both clearer and more dramatic for larger values of k. Asymptotically the k-SAT threshold reads $r_{k-\text{SAT}} = 2^k \ln 2 - (1 + \ln 2)/2 + \varepsilon_k$, where $\varepsilon_k \to 0$ in the limit of large k [14]. However, the best current algorithms are known to find satisfying assignments in polynomial time merely up to $r \sim 2^k \ln k/k$ [11]. In fact, standard heuristics such as Unit Clause Propagation bite the dust for even smaller densities, namely $r = c2^k/k$ for a certain

absolute constant $c > 0$ [17]. The same goes (provably) for various DPLL-based solvers [1, 30]. Hence, there is a factor of about $k/\ln k$ between the algorithmic threshold and the actual satisfiability threshold.

In the early 2000s physicists put forward a sophisticated but non-rigorous approach called the *cavity method* to tackle problems such as random k-SAT both analytically and algorithmically. In particular, the cavity method yields a *precise* prediction as to the value of $r_{k-\mathrm{SAT}}$ for any $k \geq 3$ [24, 26], which was recently verified rigorously for sufficiently large values of k [14]. Additionally, the cavity method provided a heuristic explanation for the demise of simple combinatorial or DPLL-based algorithms well below $r_{k-\mathrm{SAT}}$. Specifically, the density $2^k \ln k/k$ marks the point where the geometry of the set of satisfying assignments changes from (essentially) a single connected component to a collection of tiny well-separated clusters [22]. In fact, a typical satisfying assignment belongs to a "frozen" cluster, i.e., there are extensive long-range correlations between the variables. The cluster decomposition as well as the freezing prediction have largely been verified rigorously [29, 3] and we begin to understand the impact of this picture on the performance of algorithms [2].

But perhaps most remarkably, the physics work has led to the development of a new efficient "message passing algorithm" called *Survey Propagation Guided Decimation* to overcome this barrier [6, 21, 27, 31]. More precisely, the algorithm is based on a heuristic that is designed to find whole frozen clusters not only single satisfying assignments by identifying each cluster by the variables determined by long-range correlations and locally "free" variables. Thus, by its very design *Survey Propagation Guided Decimation* is built to work at densities where frozen clusters exist. Although the experimental performance for small k is outstanding this yields no evidence of a relation between the occurrence of frozen clusters and the success of the algorithm. Yet not even the physics methods lead to a precise explanation of these empirical results or to a prediction as to the density up to which we might expect SP to succeed for general values of k. In effect, analysing SP has become one of the most important challenges in the context of random constraint satisfaction problems.

The present paper furnishes the first rigorous analysis of `SPdec` (the basic version of) Survey Propagation Guided Decimation for random k-SAT. We give a precise definition and detailed explanation below. Before we state the result let us point out that two levels of randomness are involved: the choice of the random formula $\vec{\Phi}$, and the "coin tosses" of the randomized algorithm `SPdec`. For a (fixed, non-random) k-CNF Φ let success(Φ) denote the probability that `SPdec`(Φ) outputs a satisfying assignment. Here, of course, "probability" refers to the coin tosses of the algorithm only. Then, if we apply `SPdec` to the *random* k-CNF $\vec{\Phi}$, the success probability success($\vec{\Phi}$) becomes a random variable. Recall that $\vec{\Phi}$ is unsatisfiable for $r > 2^k \ln 2$ w.h.p..

▶ **Theorem 1.** *There is a sequence* $(\varepsilon_k)_{k\geq 3}$ *with* $\lim_{k\to\infty} \varepsilon_k = 0$ *such that for any* k, r *satisfying* $2^k(1+\varepsilon_k)\ln(k)/k \leq r \leq 2^k \ln 2$ *we have* $\mathrm{success}(\vec{\Phi}) \leq \exp(-\Omega(n))$ *w.h.p.*

If the success probability is exponential small in n sequentially running `SPdec` a sub-exponential number of times will not find a satisfying assignment w.h.p. rejecting the hypotheses that `SPdec` solves random k-SAT formulas efficiently for considered clauses/variables ratio. Thus, Theorem 1 shows that `SPdec` does not outclass far simpler combinatorial algorithms for general values of k. Even worse, in spite of being designed for this very purpose, the SP algorithm does *not* overcome the barrier where the set of satisfying assignments decomposes into tiny clusters asymptotically. This is even more astonishing since it is possible to *prove* the existence of satisfying assignments up to the satisfiability threshold rigorously based on the cavity method but algorithms designed by insights of this approach fail far below that threshold. Nevertheless, let me note that the insights gained from Theorem 1

is actually in line with some non-rigorous physics work on the SP algorithm. Still, there is some arguing if there is any connection between the failure of algorithms and either the clustering or the so called freezing phenomenon. Both, neither the connection to clustering nor to freezing have been rigorously proven yet.

We are going to describe the SP algorithm in the following section. Let us stress that Theorem 1 pertains to the "vanilla" version of the algorithm. Unsurprisingly, more sophisticated variants with better empirical performance have been suggested, even ones that involve backtracking [23]. Also the first version introduced by Mézard, Parisi and Zecchina [27] contained a bias towards "frozen" variables for the choice of the variable at each decimation step. However, the basic version of the SP algorithm analysed in the present paper arguably (regarding the physicists picture of freezing, correlation decay, replica symmetry assumption [26]) encompasses all the conceptually important features of the SP algorithm.

The only prior rigorous result on the Survey Propagation algorithm is the work of Gamarnik and Sudan [19] on the k-NAESAT problem (where the goal is to find a satisfying assignment whose complement is satisfying as well). However, Gamarnik and Sudan study a "truncated" variant of the algorithm where only a bounded number of message passing iterations is performed. The main result of [19] shows that this version of Survey Propagation fails for densities about a factor of $k/\ln^2 k$ below the NAE-satisfiability threshold and about a factor of $\ln k$ above the density where the set of NAE-satisfying assignments shatters into tiny clusters. Though, experimental data and the conceptional design of the SP algorithm suggest that it exploits its strength in particular by iterating the message passing iterations a unbounded number of times that depends on n. In particular, to gather information from the set of messages they have to converge to a fixed point which turns out to happen only after a number of iterations of order $\ln(n)$.

An in-depth introduction to the cavity method and its impact on combinatorics, information theory and computer science can be found in [25, 26].

2 The SPdec algorithm

The proof of Theorem 1 is by extension of the prior analysis [10] of the much simpler *Belief Propagation Guided Decimation* algorithm. To outline the proof strategy and to explain the key differences, we need to discuss the SP algorithm in detail. For a k-CNF Φ on the variables $V = \{x_1, \dots, x_n\}$ we generally represent truth assignments as maps $\sigma : V \to \{-1, 1\}$, with -1 representing "false" and 1 representing "true". Survey Propagation is an efficient message passing heuristic on the factor graph $G(\Phi)$. The factor graph of Φ is a bipartite graph representation of Φ where each clause and each variable is represented by a vertex. Two vertices are incident if the corresponding variable is contained in the corresponding clause [26].

Before explaining the Survey Propagation heuristic, we explain the simpler Belief Propagation heuristic and emphasize the main extensions later on. To define the messages involved we denote the ordered pair (x, a) with $x \to a$ and similarly (a, x) with $a \to x$ for each $x \in V$ and $a \in N(x)$, where $N(x)$ denotes the neighborhood in the factor graph $G(\Phi)$. The messages are iteratively sent probability distributions $(\mu_{x\to a}(\zeta))_{x\in V_t, a\in N(x), \zeta\in\{-1,1\}}$ over $\{-1, 1\}$. In each iteration messages are sent from variables to adjacent clauses and back. After setting initial messages due to some initialization rule the messages sent are obtained by applying a function to the set of incoming messages at each vertex. Both the initialization and the particular update rules at the vertices are specifying the message passing algorithm. The messages are updated $\omega(n)$ times which may or may not depend on n. A detailed explanation of the Belief Propagation heuristic can be found in [8, p. 519].

It is well known that the Belief Propagation messages on a tree converge after updating the messages two times the depth of the tree to a fixed point. Moreover, in this case for each variable the marginal distribution of the uniform distribution on the set of all satisfying assignments can be computed by the set of the fixed point messages. Since $G(\Phi)$ for constant clauses/variables ratio contains only a small number of short cycles one may expect that on the base of the Belief Propagation messages a good estimate of the marginal distribution of the uniform distribution on the set of all satisfying assignments of Φ could be obtained. Besides the fact that it is not even clear that the messages converge to a fixed point on arbitrary graphs this is of course only a weak heuristic explanation which is refuted by [10]. However, at each decimation step using the Belief Propagation heuristic the Belief Propagation guided decimation algorithm assigns one variable due to the estimated marginal distribution to -1 or 1. Simplifying the formula and running Belief Propagation on the simplified formula and repeating this procedure would lead to a satisfying assignment chosen uniformly at random for sure if the marginals were correct at each decimation step.

Let us now introduce the Survey Propagation heuristic. As mentioned above the geometry of the set of satisfying assignments comes as a collection of tiny well-separated clusters above density $2^k \ln(k)/k$. In that regime a typical solution belongs to a "frozen" cluster. That is all satisfying assignments in such a frozen cluster agree on a linear number of frozen variables. Thus, identifying these frozen variables gives a characterization of the whole cluster. Flipping one of these variables leads to a set of unsatisfied clauses only containing additional frozen variables. Satisfying one of these clauses leads to further unsatisfied clauses of this kind ending up in an avalanche of necessary flippings to obtain a satisfying assignment. This ends only after a linear number of flippings. Given a satisfying assignment with identified frozen variables each satisfying assignment that disagrees on one of these frozen variables has linear distance therefore belonging to a different cluster.

This picture inspires the definition of *covers* as generalized assignments $\sigma \in \{-1, 0, 1\}^n$ such that

- each clause either contains a true literal or two 0 literals and
- for each variable $x \in V$ that is assigned -1 or 1 exists a clause $a \in N(x)$ such that for all $y \in N(a) \setminus \{x\}$ we have $\operatorname{sign}(y, a) \cdot \sigma(y) = -1$.

These two properties mirrors the situation in frozen clusters where assigning a variable to the value 0 indicates that these variable supposes to be free in the corresponding cluster which is obtained by only flipping 0 variables to one of the values -1 or 1. However, implementing the concept of covers, Survey Propagation is a heuristic of computing the marginals over the set of covers by using the Belief Propagation update rules on covers. This leads to the equations given by Figure 1. For a more detailed explanation of the freezing phenomenon we point the reader to [29]. For a deeper discussion on covers we refer to [12].

We are now ready to state the `SPdec` algorithm.

▶ **Algorithm 2.** `SPdec`(Φ)
Input: A k-CNF Φ on $V = \{x_1, \ldots, x_n\}$. *Output:* An assignment $\sigma : V \to \{-1, 1\}$.

0. Let $\Phi_0 = \Phi$.
1. For $t = 0, \ldots, n-1$ do
2. Use SP to compute $\mu^{[\omega]}_{x_{t+1}}(\Phi_t)$.
3. Assign

$$\sigma(x_{t+1}) = \begin{cases} 1 & \text{with probability } \mu^{[\omega]}_{x_{t+1}}(\Phi_t) \\ -1 & \text{with probability } 1 - \mu^{[\omega]}_{x_{t+1}}(\Phi_t). \end{cases} \tag{7}$$

4. Obtain a formula Φ_{t+1} from Φ_t by substituting the value $\sigma(x_{t+1})$ for x_{t+1} and simplifying.
5. Return the assignment σ.

For real numbers $0 \leq x, y \leq 1$ such that $\max\{x, y\} > 0$ we define

$$\psi_\zeta(x,y) = \begin{cases} xy \cdot \Psi(x,y) & \text{if } \zeta = 0 \\ (1-x)y \cdot \Psi(x,y) & \text{if } \zeta = 1 \\ (1-y)x \cdot \Psi(x,y) & \text{if } \zeta = -1 \end{cases}, \qquad \Psi(x,y) = (x+y-xy)^{-1}$$

If $x = y = 0$ set $\psi_0(0) = 0$ and $\psi_{\pm 1}(0) = \frac{1}{2}$. Define for all $x \in V_t, a, b \in N(x), \zeta \in \{-1, 0, 1\}$ and $\ell \geq 0$

$$\mu^{[0]}_{x\to a}(\pm 1) = \frac{1}{2}, \qquad \mu^{[0]}_{x\to a}(0) = 0, \qquad \mu^{[\ell]}_{b\to x}(0) = 1 - \prod_{y \in N(b)\setminus\{x\}} \mu^{[\ell]}_{y\to b}(-\text{sign}(y,b)) \tag{1}$$

$$\pi^{[\ell+1]}_{x\to a}(\pm 1) = \prod_{b \in N(x,\pm 1)\setminus\{a\}} \mu^{[\ell]}_{b\to x}(0) \tag{2}$$

$$\mu^{[\ell+1]}_{x\to a}(\zeta) = (SP(\mu^{[\ell]}))_{x\to a}(\zeta) = \psi_\zeta(\pi^{[\ell]}_{x\to a}(1), \pi^{[\ell]}_{x\to a}(-1)). \tag{3}$$

Let $\omega = \omega(k, r, n) \geq 0$ be any integer-valued function. Define

$$\pi^{[\omega+1]}_x(\Phi_t, \pm 1) = \prod_{b \in N(x,\pm 1)} \mu^{[\omega]}_{b\to x}(0) \tag{4}$$

$$\mu^{[\omega]}_x(\Phi_t, \zeta) = \psi_\zeta(\pi^{[\omega+1]}_x(\Phi_t, 1) \cdot \pi^{[\omega+1]}_x(\Phi_t, -1)) \tag{5}$$

$$\mu^{[\omega]}_x(\Phi_t) = \frac{\mu^{[\omega]}_x(\Phi_t, 1)}{\mu^{[\omega]}_x(\Phi_t, 1) + \mu^{[\omega]}_x(\Phi_t, -1)} = \mu^{[\omega]}_x(\Phi_t, 1) + \frac{1}{2}\mu^{[\omega]}_x(\Phi_t, 0). \tag{6}$$

Figure 1 The Survey Propagation equations that are the Belief Propagation equations on covers.

Let us emphasize that the value $\mu^{[\omega]}_{x_{t+1}}(\Phi_t)$ in Step 2 of `SPdec` is the estimated marginal probability over the set of covers of variable x_{t+1} in the simplified formula to take the value 1 plus one half the estimated marginal probability over the set of covers in the simplified formula to take the value 0. This makes sense since by the heuristic explanation a variable assigned to the value 0 is free to take either value 1 or -1. Thus, our task is to study the SP operator on the decimated formula Φ_t.

3 Proof of Theorem 1

The probabilistic framework used in our analysis of `SPdec` was introduced in [10] for analysing the *Belief Propagation Guided Decimation* algorithm. The most important technique in analysing algorithms on the random formula $\vec{\Phi}$ is the "method of deferred decisions", which traces the dynamics of an algorithm by differential equations, martingales, or Markov chains. It actually applies to algorithms that decide upon the value of a variable x on the basis of the clauses or variables at small bounded distance from x in the factor graph [5]. Unfortunately, the `SPdec` algorithm at step t explores clauses at distance 2ω from x_t where $\omega = \omega(n)$ may tend to infinity with n. Therefore, the "defered decisions" method does not apply and to prove Theorem 1 a fundamentally different approach is needed.

We will basically reduce the analysis of `SPdec` to the problem of analysing the SP operator on the random formula $\vec{\Phi}^t$ that is obtained from $\vec{\Phi}$ by substituting "true" for the first t variables $x_1, \ldots, x_t$ and simplifying (see Theorem 3 below). In the following sections we will prove that this decimated formula has a number of simple to verify quasirandomness

properties with very high probability. Finally, we will show that it is possible to trace the Survey Propagation algorithm on a formula Φ enjoying this properties.

Applied to a fixed, non-random formula Φ on $V = \{x_1, \ldots, x_n\}$, `SPdec` yields an assignment $\sigma : V \to \{-1, 1\}$ that may or may not be satisfying. This assignment is random, because `SPdec` itself is randomized. Hence, for any fixed Φ running `SPdec`(Φ) induces a probability distribution β_Φ on $\{-1, 1\}^V$. With $\mathcal{S}(\Phi)$ the set of all satisfying assignments of Φ, the "success probability" of `SPdec` on Φ is just

$$\mathrm{success}(\Phi) = \beta_\Phi(\mathcal{S}(\Phi)). \tag{8}$$

Thus, to establish Theorem 1 we need to show that in the *random* formula

$$\mathrm{success}(\vec{\Phi}) = \beta_{\vec{\Phi}}(s(\vec{\Phi})) = \exp\left(-\Omega(n)\right) \tag{9}$$

is exponentially small w.h.p. To this end, we are going to prove that the measure $\beta_{\vec{\Phi}}$ is "rather close" to the uniform distribution on $\{-1, 1\}^V$ w.h.p., of which $\mathcal{S}(\vec{\Phi})$ constitutes only an exponentially small fraction. However, to prove Theorem 1 we prove that the entropy of the distribution $\beta_{\vec{\Phi}}$ is large. Let us stress that this is not by Moser's entropy compression argument which works up to far smaller clauses/variables ratios [32].

3.1 Lower bounding the entropy

Throughout the paper we let $\rho_k = (1 + \varepsilon_k)\ln(k)$ where $(\varepsilon_k)_{k\geq 3}$ is the sequence promised by Theorem 1 and let $r = 2^k\rho$ where $\rho \geq \rho_k$.

For a number $\delta > 0$ and an index $i > t$ we say that x_i is (δ, t)-*biased* if

$$\left|\mu_{x_i}^{[\omega]}(\Phi^t, 1) - \frac{1}{2}\left(1 - \mu_{x_i}^{[\omega]}(\Phi^t, 0)\right)\right| > \delta. \tag{10}$$

Moreover Φ is (δ, t)-*balanced* if no more than $\delta(n - t)$ variables are (δ, t)-biased.

If $\vec{\Phi}$ is (δ, t)-balanced, then by the basic symmetry properties of $\vec{\Phi}$ the probability that x_{t+1} is (δ, t)-biased is bounded by δ. Furthermore, given that x_{t+1} is not (δ, t)-biased, the probability that `SPdec` will set it to "true" lies in the interval $[\frac{1}{2} - \delta, \frac{1}{2} + \delta]$. Consequently,

$$\left|\frac{1}{2} - \mathbb{P}\left[\sigma(x_{t+1}) = 1 | \vec{\Phi} \text{ is } (\delta, t)\text{-balanced}\right]\right| \leq 2\delta. \tag{11}$$

Thus, the smaller δ the closer $\sigma(x_{t+1})$ comes to being uniformly distributed. Hence, if (δ, t)-balancedness holds for all t with a "small" δ, then β_Φ will be close to the uniform distribution on $\{-1, 1\}^V$.

To put this observation to work, let $\theta = 1 - t/n$ be the fraction of unassigned variables and define

$$\delta_t = \exp(-c\theta k), \qquad \Delta_t = \sum_{s=1}^{t}\delta_t \qquad \text{and} \qquad \hat{t} = \left(1 - \frac{\ln(\rho)}{c^2 k}\right)n, \tag{12}$$

where $c > 0$ is a small enough absolute constant.

The following result provides the key estimate by providing that at any time t up to $\hat{t}$ with sufficiently high probability $\vec{\Phi}$ is (δ_t, t)-balanced with a sufficiently small δ_t to finally prove Theorem 1.

▶ **Proposition 3.** *For any k, r satisfying $2^k\rho_k/k < r \leq 2k\ln 2$ there is $\xi = \xi(k, r) \in [0, \frac{1}{k}]$ so that for n large enough the following holds. For any $0 \leq t \leq \hat{t}$ we have*

$$\Pr\left[\vec{\Phi} \textit{ is } (\delta_t, t)\textit{-balanced}\right] \geq 1 - \exp\left[-3\xi n - 10\Delta_t\right]. \tag{13}$$

3.2 Tracing the Survey Propagation Operator

To establish Proposition 3 we have to prove that $\vec{\Phi}$ is (δ_t, t)-balanced with probability very close to one. Thus, our task is to study the SP operator defined in (1) to (3) on $\vec{\Phi}^t$. Roughly speaking, Proposition 3 asserts that with probability very close to one, most of the messages $\mu^{[\ell]}_{x\to a}(\pm 1)$ are close to $\frac{1}{2}(1-\mu^{[\ell]}_{x\to a}(0))$. To obtain this bound, we are going to proceed in two steps: we will exhibit a small number of *quasirandomness properties* and show that these hold in $\vec{\Phi}^t$ with the required probability. Then, we prove that *deterministically* any formula that has these properties is (δ_t, t)-balanced.

3.2.1 The "typical" value of $\pi^{[\ell]}_{x\to a}(\zeta)$

First of all recall that the messages sent from a variable x to a clause $a \in N(x)$ are obtained by

$$\psi_\zeta(\pi^{[\ell]}_{x\to a}(1), \pi^{[\ell]}_{x\to a}(-1)) \qquad \text{for } \zeta \in \{-1, 0, 1\}. \tag{14}$$

This in mind, we claim a strong statement that both $\pi^{[\ell]}_{x\to a}(1)$ and $\pi^{[\ell]}_{x\to a}(-1)$ are very close to a "typical" value $\pi[\ell]$ for most of the variables $x \in V_t$ and clauses $a \in N(x)$ at any iteration step ℓ under the assumption that the set of biased variables is small at time $\ell - 1$. Assuming that

$$\pi^{[\ell]}_{x\to a}(1) = \pi^{[\ell]}_{x\to a}(-1) = \pi[\ell]$$

we of course obtain unbiased messages by

$$\mu^{[\ell]}_{x\to a}(\pm 1) = \psi_1(\pi[\ell]) = \psi_{-1}(\pi[\ell]) = \frac{1}{2}(1 - \mu^{[\ell]}_{x\to a}(0)).$$

The products $\pi^{[\ell]}_{x\to a}(\zeta)$ are nothing else but the product of the messages

$$\mu^{[\ell-1]}_{b\to x}(0) = 1 - \prod_{y\in N(b)\setminus\{x\}} \mu^{[\ell-1]}_{y\to b}(-\operatorname{sign}(y,b))$$

sent from all clauses $b \in N(x, \zeta) \setminus \{a\}$ to x. Therefore, we define inductively $0 \le \pi[\ell] \le 1$ to be the product of this kind over a "typical" neighborhood. The term "typical" refers to the expected number of clauses of all lengths that contain at most one additional biased variable. Focusing on those clauses will suffice to get the tightness result of the biases. Moreover, we assume that all of the messages $\mu^{[\ell-1]}_{y\to b}(-\operatorname{sign}(y,b))$ sent from variables to clauses in such a typical neighborhood are $\psi_{\operatorname{sign}(y,b)}(\pi[\ell-1], \pi[\ell-1])$ which is claimed to be a good estimation of most of the messages sent at time $\ell - 1$. Additionally, define $\tau[\ell] = (1 - \psi_0(\pi[\ell]))$ as the estimate of the sum $\mu^{[\ell]}_{x\to a}(1) + \mu^{[\ell]}_{x\to a}(-1)$. Let us emphasize that there is no "unique" $\pi[\ell]$ and the way it is obtained in the following is in some sense the canonical and convenient choice to sufficiently bound the biases for most of the messages.

Generally, let $T \subset V_t$ and $x \in V_t$. Then the expected number of clauses of length j that contain x and at most one other variable from the set T is asymptotically

$$\mu_{j,\le 1}(T) = 2^j\rho \cdot \Pr\left[\operatorname{Bin}(k-1,\theta) = j-1\right] \cdot \Pr\left[\operatorname{Bin}\left(j-1, \frac{|T|}{\theta n}\right) < 2\right]. \tag{15}$$

Indeed, the expected number of clauses of $\vec{\Phi}$ that x appears in equals $km/n = kr = 2^k\rho$. Furthermore, each of these gives rise to a clause of length j in $\vec{\Phi}^t$ iff exactly $j-1$ among the other $k-1$ variables in the clauses are from V_t while the $k-j$ remaining variables are

in $V \setminus V_t$ and occur with negative signs. (If one of them had a positive sign, the clause would have been satisfied by setting the corresponding variable to true. It would thus not be present in $\vec{\Phi}^t$ anymore.) Moreover, at most one of the $j-1$ remaining variables is allowed to be from the set T. The fraction of variables in T in V_t equals $\frac{|T|}{\theta n}$. Finally, since x appears with a random sign in each of these clauses the expected number of clauses of length j that contain x and at most one other variable from the set T is asymptotically $\mu_{j,\leq 1}(t)/2$.

Additionally let $0 \leq p \leq 1$ and define

$$\tau(p) = 1 - \psi_0(p) \qquad \text{and} \qquad \pi(T,p) = \prod_{j=0.1\theta k}^{10\theta k} \left(1 - (2/\tau(p))^{-j+1}\right)^{\mu_{j,\leq 1}(T)/2}. \tag{16}$$

Moreover, let

$$\Pi(T,p) = \sum_{j=0.1\theta k}^{10\theta k} \frac{\mu_{j,\leq 1}(T)}{2} \cdot (2/\tau(p))^{-j+1}$$

be the approximated absolute value of the logarithm of $\pi(T,p)$.

For a fixed variable $x \in V_t$ the expected number of clauses that contain more than one additional variable from a "small" set T for a "typical" clause length $0.1\theta k \leq j \leq 10\theta k$ is very close to the expected number of all clauses of that given length. Thus, the actual size of T will influence $\pi(T,p)$ but this impact is small if T is small and the following bounds on $\pi(T,p)$ can be achieved.

▶ **Lemma 4.** *Let $T \subset V_t$ of size $|T| \leq \delta\theta n$ and $0 \leq p \leq 2\exp(-\rho)$. Then $\exp(-2\rho) \leq \pi(T,p) \leq 2\exp(-\rho)$.*

3.2.2 Bias

First of all let us define the bias not only for the 1 and -1 messages but also for the 0 messages. Hence, for $\ell \geq 0, x \in V_t$ and $a \in N(x)$ let

$$\Delta^{[\ell]}_{x\to a} = \mu^{[\ell]}_{x\to a}(1) - \frac{1}{2}\left(1 - \mu^{[\ell]}_{x\to a}(0)\right) \qquad \text{and} \tag{17}$$

$$E^{[\ell]}_{x\to a} = \frac{1}{2}\left(\mu^{[\ell]}_{x\to a}(0) - \psi_0(\pi[\ell])\right). \tag{18}$$

We say that $x \in V_t$ is *ℓ-biased* if

$$\max_{a\in N(x)} |\Delta^{[\ell]}_{x\to a}| > 0.1\delta \qquad \text{or} \qquad \max_{a\in N(x)} |E^{[\ell]}_{x\to a}| > 0.1\delta\pi[\ell] \tag{19}$$

and *ℓ-weighted* if

$$\max_{a\in N(x)} |E^{[\ell]}_{x\to a}| > 10\pi[\ell]. \tag{20}$$

Let $B[\ell]$ be the set of all ℓ-biased variables and $B'[\ell]$ be the set of all ℓ-weighted variables. Obviously, by definition, we have $B'[\ell] \subset B'[\ell]$.

Writing $\mu^{[\ell]}_{x\to a}(\mathrm{sign}(x,a))$ in terms of the biases we obtain

$$\begin{aligned}\mu^{[\ell]}_{x\to a}(\mathrm{sign}(x,a)) &= \frac{1}{2}(1-\psi_0(\pi[\ell])) - \left(E^{[\ell]}_{x\to a} + \mathrm{sign}(x,a)\Delta^{[\ell]}_{x\to a}\right)\\ &= \tau[\ell]/2 - \left(E^{[\ell]}_{x\to a} + \mathrm{sign}(x,a)\Delta^{[\ell]}_{x\to a}\right)\end{aligned} \tag{21}$$

We are going to prove that $|\Delta^{[\ell]}_{x\to a}|$ and $|E^{[\ell]}_{x\to a}|$ are small for most x and $a \in N(x)$. That is, given the $\Delta^{[\ell]}_{x\to a}$ and $E^{[\ell]}_{x\to a}$ we need to prove that the biases $\Delta^{[\ell+1]}_{x\to a}$ and $E^{[\ell+1]}_{x\to a}$ do not

"blow up". The proof is by induction where the hypothesis is that at most $\delta_t\theta n$ variables are ℓ-biased and at most $\delta^2\theta n$ variables are ℓ-weighted and our goal is to show that the same holds true for $\ell+1$.

3.2.3 The quasirandomness property

We will now exhibit a few simple quasirandomness properties that $\vec{\Phi}^t$ is very likely to possess. Based only on these graph properties we identify potentially ℓ-biased or ℓ-weighted variables. In turn, we prove that variables in the complement of these sets are surely not ℓ-biased resp. ℓ-weighted. Moreover, we show that these sets are small enough with sufficiently high probability.

To state the quasirandomness properties, fix a k-CNF Φ. Let Φ^t denote the CNF obtained from Φ by substituting "true" for $x_1,\dots,x_t$ and simplifying $(1 \le t \le n)$. Let $V_t = \{x_{t+1},\dots,x_n\}$ be the set of variables of Φ^t. Let $\delta = \delta_t$. With $c > 0$ we let $k_1 = \sqrt{c}\theta k$. For a variable $x \in V_t, \zeta \in \{1,-1\}$ and a set $T \subset V_t$ let

$$\begin{aligned}
\mathcal{N}(x,\zeta) &= \{b \in N(x,\zeta) : 0.1\theta k \le |N(b)| \le 10\theta k\}, \\
\mathcal{N}_{\le 1}(x,T,\zeta) &= \{b \in \mathcal{N}(x,\zeta) : |N(b) \cap T \setminus \{x\}| \le 1\}, \\
\mathcal{N}_i(x,T,\zeta) &= \{b \in \mathcal{N}(x,\zeta) : |N(b) \cap T \setminus \{x\}| = i\} \text{ for } i \in \{0,1\}, \\
N_1(x,T,\zeta) &= \{b \in N(x,\zeta) : |N(b) \setminus T| \ge k_1 \wedge |N(b) \cap T \setminus \{x\}| = 1\}, \\
N_{>1}(x,T,\zeta) &= \{b \in N(x,\zeta) : |N(b) \setminus T| \ge k_1 \wedge |N(b) \cap T \setminus \{x\}| > 1\}.
\end{aligned}$$

Thus, $\mathcal{N}_{\le 1}(x,T,\zeta)$ is the set of all clauses a that contain x with $\operatorname{sign}(x,a) = \zeta$ (which may or may not be in T) and at most one other variable from T. In addition, there is a condition on the length $|N(b)|$ of the clauses b in the decimated formula Φ^t. Having assigned the first t variables, we should "expect" the average clause length to be θk. The sets $\mathcal{N}_i(x,T,\zeta)$ are a partition of $\mathcal{N}_{\le 1}(x,T,\zeta)$ separating clauses that contain exactly one additional variable from $T \setminus \{x\}$ and clauses that contain none.

Q1. No more than $10\delta\theta n$ variables occur in clauses of length less than $\theta k/10$ or greater than $10\theta k$ in Φ_t. Moreover, there are at most $10^{-4}\delta\theta n$ variables $x \in V_T$ such that
$$(\theta k)^3\delta \cdot \sum_{b \in N(x,\zeta)} 2^{-|N(b)|} > 1.$$

Q2. For any set $T \subset V_t$ of size $|T| \le s\theta n$ such that $\delta^5 \le s \le 10\delta$ and any $p \in (0,1]$ there are at most $10^{-3}\delta^2\theta n$ variables x such that for one $\zeta \in \{-1,1\}$ either
$$\left|\Pi(T,p) - \sum_{b \in \mathcal{N}_{\le 1}(x,T,\zeta)} (2/\tau(p))^{1-|N(b)|}\right| > 2\delta/1000 \quad \text{or}$$
$$\sum_{b \in \mathcal{N}_1(x,T,\zeta)} 2^{-|N(b)|} > 10^4\rho\theta k s \quad \text{or}$$
$$\sum_{b \in \mathcal{N}_{\le 1}(x,T,\zeta)} 2^{-|N(b)|} > 10^4\rho.$$

Q3. If $T \subset V_t$ has size $|T| \le \delta\theta n$, then there are no more than $10^{-4}\delta\theta n$ variables x such that at least for one $\zeta \in \{-1,1\}$
$$\sum_{b \in N_{>1}(x,T,\zeta)} 2^{|N(b)\cap T\setminus\{x\}|-|N(b)|} > \delta/(\theta k).$$

Q4. For any $0.01 \le z \le 1$ and any set $T \subset V_t$ of size $|T| \le 100\delta\theta n$ we have
$$\sum_{b : |N(b)\cap T| \ge z|N(b)|} |N(b)| \le \frac{1.01}{z}|T| + 10^{-4}\delta\theta n.$$

Q5. For any set $T \subset V_t$ of size $|T| \leq 10\delta\theta n$, any $p \in (0,1]$ and any $\zeta \in \{-1,1\}$ the linear operator $\Lambda(T,\mu,\zeta) : \mathbb{R}^{V_t} \to \mathbb{R}^{V_t}$,

$$\Gamma = (\Gamma_y)_{y\in V_t} \mapsto \left\{ \sum_{b\in\mathcal{N}_{\leq 1}(x,T,\zeta)} \sum_{y\in N(b)\setminus\{x\}} (2/\tau(p))^{-|N(b)|} \operatorname{sign}(y,b)\Gamma_y \right\}$$

has norm $\| \Lambda(T,\mu,\zeta) \|_\square \leq \delta^4\theta n$, where for a real $b \times a$ matrix Λ we let $\|\Lambda\|_\square = \max_{\zeta\in\mathbb{R}^a\setminus\{0\}} \frac{\|\Lambda\zeta\|_1}{\|\zeta\|_\infty}$.

▶ **Definition 5.** Let $\delta > 0$. We say that Φ is (δ,t)-*quasirandom* if ***Q0-Q5*** are satisfied.

Condition **Q0** simply bounds the number of redundant clauses and the number of variables of very high degree; it is well-known to hold for random k-CNFs w.h.p. Apart from a bound on the number of very short/very long clauses, **Q1** provides a bound on the "weight" of clauses in which variables $x \in V_t$ typically occur, where the weight of a clause b is $2^{-|N(b)|}$. Moreover, **Q2** and **Q3** provide that there is no small set T for which the total weight of the clauses touching that set is very big. In addition, **Q2** (essentially) requires that for most variables x the weights of the clauses where x occurs positively/negatively should approximately cancel. Further, **Q4** provides a bound on the lengths of clauses that contain many variables from a small set T. Finally, the most important condition is **Q5**, providing a bound on the cut norm of a signed, weighted matrix, representation of Φ^t.

▶ **Proposition 6.** *There is a sequence $(\varepsilon_k)_{k\geq 3}$ with $\lim_{k\to\infty}\varepsilon_k = 0$ such that for any k, r satisfying $2^k(1+\varepsilon_k)\ln(k)/k \leq r \leq 2^k \ln 2$ there is $\xi = \xi(k,r) \in [0, \frac{1}{k}]$ so that for n large and $\delta_t, \hat{t}$ as in (12) for any $1 \leq t \leq \hat{t}$ we have*

$$P\left[\Phi \text{ is } (\delta_t,t)\text{-quasirandom}\right] \geq 1 - \exp\left(-10(\xi n + \Delta_t)\right)$$

▶ **Theorem 7.** *There is a sequence $(\varepsilon_k)_{k\geq 3}$ with $\lim_{k\to\infty}\varepsilon_k = 0$ such that for any k, r satisfying $2^k(1+\varepsilon_k)\ln(k)/k \leq r \leq 2^k \ln 2$ and n sufficiently large the following is true.*

Let Φ be a k-CNF with n variables and m clauses that is (δ_t,t)-quasirandom for some $1 \leq t \leq \hat{t}$. Then Φ is (δ_t,t)- balanced.

The proof of Proposition 6 is a necessary evil: it is long, complicated and based on standard arguments. Theorem 7 together with Proposition 6 yields Proposition 3.

3.2.4 Setting up the induction

To prove Theorem 7 we proceed by induction over ℓ. In particular we define sets $T[\ell]$ and $T'[\ell]$ that contain variables that are potentially ℓ-biased or ℓ-weighted only depending on the graph structure and the size of the sets $T[\ell-1]$ and $T'[\ell-1]$. The exact definition of the sets $T[\ell]$ and $T'[\ell]$ which inspired the quasirandomness properties are omitted in this extended abstract. It actually will turn out that $T[\ell] \subset B\ell$ and $T'[\ell] \subset B'\ell$. Since we are going to trace the SP operator on Φ^t iterated from the initial set of messages $\mu^{[0]}_{x\to a}(\pm 1) = \frac{1}{2}$ and $\mu^{[0]}_{x\to a}(0) = 0$ for all $x \in V_t$ and $a \in N(x)$ we set $T[\ell] = T'[\ell] = \emptyset$ and $\pi[0] = 0$ such that $\tau[0] = 1$. Now we define inductively

$$\pi[\ell+1] = \pi\left(T[\ell], \pi[\ell]\right), \quad \Pi[\ell+1] = \Pi\left(T[\ell], \pi[\ell]\right) \quad \text{and} \quad \tau[\ell+1] = \tau\left(\pi[\ell+1]\right).$$

▶ **Proposition 8.** *Assume that $\pi[\ell] \leq 2\exp(-\rho)$. We have $B[\ell] \subset T[\ell]$ and $B'[\ell] \subset T'[\ell]$ for all $\ell \geq 0$.*

Furthermore, we establish the following bounds on the size of $T[\ell]$ and $T'[\ell]$. Since the sets are defined by graph properties independent from the actual state of the algorithm the quasirandomness properties suffice to obtain

▶ **Proposition 9.** *If Φ is (δ_t, t)-quasirandom, we have $T[\ell] < \delta\theta n, T'[\ell] < \delta^2\theta n$ and $\pi[\ell] \leq 2\exp(-\rho)$ for all $\ell \geq 0$.*

Finally, let us give an idea how this is actually proved. We aim to prove that for most variables $x \in V_t$ for all $a \in N(x)$ simultaneously for both $\zeta \in \{-1, 1\}$ the values $\pi^{[\ell]}_{x\to a}(\zeta)$ are close to a typical value which is estimated by $\pi[\ell]$ for each iteration. Let us define for $x \in V_t, a \in N(x)$ and $\zeta \in \{1, -1\}$

$$\begin{aligned} P^{[\ell+1]}_{\leq 1}(x \to a, \zeta) &= \prod_{b \in \mathcal{N}_{\leq 1}(x, T[\ell], \zeta)\setminus\{a\}} \mu^{[\ell]}_{b\to x}(0) \\ P^{[\ell+1]}_{>1}(x \to a, \zeta) &= \prod_{b \in N(x,\zeta)\setminus(\{a\}\cup\mathcal{N}_{\leq 1}(x,T[\ell],\zeta))} \mu^{[\ell]}_{b\to x}(0). \end{aligned}$$

We obtain

$$\pi^{[\ell]}_{x\to a}(\zeta) = P^{[\ell]}_{\leq 1}(x \to a, \zeta) \cdot P^{[\ell]}_{>1}(x \to a, \zeta). \tag{22}$$

We show that the first factor representing the product over messages sent by clauses of typical length (regarding the decimation time t) and exposed to at most one additional variable from $T[\ell]$ is close to $\pi[\ell+1]$ simultaneously for $\zeta \in \{-1, 1\}$ for all variables $x \in V \setminus T'[\ell+1]$ and all $a \in N(x)$. Additionally, we prove that the second factor representing the product over messages sent by clauses of atypical length or exposed to at least two additional variables from $T[\ell]$ is close to one simultaneously for $\zeta \in \{-1, 1\}$ for all variables $x \in V \setminus T[\ell+1]$ and all $a \in N(x)$.

Acknowledgements I thank my supervisor Amin Coja-Oghlan for supportive conversations and helpful comments on the final version of this paper.

Abstract

In the *aversion k-clustering problem*, given a metric space, we want to cluster the points into k clusters. The cost incurred by each point is the distance to the furthest point in its cluster, and the cost of the clustering is the sum of all these per-point-costs. This problem is motivated by questions in generating automatic abstractions of extensive-form games.

We reduce this problem to a *"local" k-median problem* where each facility has a prescribed radius and can only connect to clients within that radius. Our main results is a constant-factor approximation algorithm for the aversion k-clustering problem via the local k-median problem. We use a primal-dual approach; our technical contribution is a non-local rounding step which we feel is of broader interest.

1 Introduction

In this paper, we consider the following clustering problem: given a metric space (X, D) with a set of clients, and a parameter k, the goal is to group the clients into k clusters. For each client j, the cost incurred by j is its distance to the furthest client in its cluster. The cost of the clustering is the sum over all clients, more precisely, of the cost incurred by the client. We call this problem the *aversion k-clustering problem*.

This question is motivated by a problem in developing abstractions of extensive-form games. Since finding equilibria in large extensive form games is computationally expensive, one appealing approach if speeding things up is to develop an abstraction of this game. Since the abstraction is typically much smaller, existing algorithms can be used to solve them to find optimal strategies, which can be mapped back to the original game. However, there is often some loss in going to the abstraction. Recent work of Kroer and Sandholm [19] on automated abstraction algorithms proposed a following way to model this: since several states of the original game may be collapsed into a single state in the abstraction, the loss for each original state is its distance (in a suitably defined metric) to the furthest state that is collapsed with it. The overall loss is the sum of per-state losses. This is precisely the aversion k-clustering problem we study in this paper.

* This work was done in part when M. Schmidt was visiting the Computer Science Department at Carnegie Mellon University, supported by the German Academic Exchange Service (DAAD). A. Gupta and G. Guruganesh were supported in part by NSF awards CCF-1319811 and CCF-1536002

To the best of our knowledge, no prior approximation algorithms were known for the aversion k-clustering problem. Although it is related in spirit to several other clustering problems, it has some interesting and unique features. Indeed, something that makes this problem difficult is its high "sensitivity". To explain this, observe that in problems like k-median, if we re-assign a single client j to a new cluster C, loosely this changes the cost by the distance of the client to the new cluster. However, in aversion k-clustering, reassigning client j to a new cluster C may also significantly change the cost of all other clients in C, since j may become their new furthest client. This creates problems for most standard techniques used for facilty-location problems. Another facility-location problem with a similar high-sensitivity property is the *min-sum clustering* problem, for which only logarithmic approximations are known via HST embeddings and a non-trivial dynamic program [4, 5]. Since our objective is not linear (due to each client paying the distance to its furthest cluster-mate), we cannot even use tree embeddings.

The main result of the paper is the following:

▶ **Theorem 1.** *There is a constant-factor algorithm for the aversion k-clustering problem.*

1.1 Our Techniques

A few words about our techniques. To solve aversion k-clustering, we first move to a related problem that is more convenient to deal with: in the *local k-median problem*, each potential facility location in the metric space has a "range" R_i associated with it. Like in k-median, we need to open k facilities, to minimize the sum of distances from clients to their assigned facilities. However, we now additionally require that each client j is assigned to some facility i at distance at most R_i. This problem is NP-hard to approximate, but for our purpose it is sufficient to solve the relaxed version where clients can still connect at distance $O(\mathsf{R}_i)$.

The (relaxed) locality restriction causes many of the standard techniques for k-median, like local-search and LP-rounding, not to extend to this problem. (In fact, we do not know of a constact factor approximation algorithm for local k-median which only violates locaility constraints by a constant factor). However, we are successful in extending a primal-dual technique to the instances which arise from the aversion k-clustering problem. The following theorem is our main technical result, from which Theorem 1 follows immediately.

▶ **Theorem 2.** *There is an approximation algorithm for the local k-median problem that achieves a constant-factor approximation for instances arising from the aversion k-clustering problem. Its solutions violate the locality constraints by a constant factor.*

We use the primal-dual framework of Jain and Vazirani: we find two solutions that open k_1 and k_2 facilities (such that $k_1 < k < k_2$) such that the "average" of these two solutions has low cost and opens k facilities. This part of the analysis is well-understood by now and we omit details because of space limitations. We can view this average solution as a "well-behaved" LP solution, which we now have to round to integrally open k facilities.

The main problem with this rounding is the locality constraint — typical algorithms tend to round some fractional facility up to 1, round down close-by fractional facilities to zero to maintain the total facility mass at k, and reroute clients to the newly opened facility without increasing the cost by much. However, the locality constraint in our problem means that such simple rounding approaches fail. For example, the facility that we open may have a very small R_i value, and can only serve clients that are very close to it. However, the clients who want to be rerouted may be too far from this facility to satisfy the locality constraint, even if it is relaxed to $\gamma\mathsf{R}_i$ for some constant γ.

Our main technical contribution, and the novel ingredient of our rounding algorithm is a *non-local rounding approach*. We first transform the fractional solution so that its support is a forest. Then we partition this forest into carefully chosen subtrees, so that all the clients in each particular subtree can be reassigned simultaneously without violating the locality. Now choosing the least expensive of these subtrees to reassign gives us a solution with k facilities and a constant-factor approximation for instances arising from the aversion k-clustering problem. We feel that this non-local rounding will be useful in other contexts, and hence be of independent interest.

Related work. Approximation algorithms for facility location problems have been studied for a long time. Indeed, many approximation techniques have been developed while investigating these problems (see [22]). The problem closest to the *local k-median problem* is naturally the *metric k-median* problem. The first constant-factor for this problem was due to Charikar et al. [8] via rounding the LP; subsequently, primal-dual algorithms were given by Jain and Vazirani [17] and Charikar and Guha [7], a local-search algorithm was given by Arya et al. [2]. The recent approach of Li and Svensson [21] gave a $2.73+\varepsilon$-approximation, which was improved to $2.675+\varepsilon$ by Byrka et al. [6]. The current NP-hardness is a $1+2/e$-factor due to Jain, Mahdian, Saberi [16]. The related problem of *uncapacitated metric facility location* has constant-factor approximations via most approximation techniques: see, e.g., the book of [22]. The current best approximation factor is 1.488 due to Li [20], and the hardness is an 1.463-factor due to Guha and Khuller [13].

The k-median problem sums over each cluster, the sum of distances of clients to their cluster center. Instead of taking the sum of distances within each cluster, we could take the maximum distance within each cluster; this gives the *sum of cluster diameters* problem, for which a $O(1)$-factor is due to Charikar and Panigrahy [9]. And instead of summing diameters over the clusters, if we take the maximum diameter over all clusters, we get the *k-center* problem, for which a 2-approximation is due to Gonzalez [12], and Hochbaum and Shmoys [14], and a matching hardness is due to Hsu and Nemhauser [15].

Another related problem is the *min-sum clustering problem*, where we sum over the clusters of the distances between all pairs within the cluster. Bartal et al. [4] give a $O(\varepsilon^{-1}\log^{1+\varepsilon} n)$-approximation, which was recently improved to $O(\log n)$ by Behsaz [5]. There are easy examples where these problems differ from aversion k-clustering by arbitrarily large factors. Moreover, the non-linearity of our objective function means that we cannot use tree embedding results to even get a logarithmic approximation.

Our algorithm takes a primal-dual approach pioneered by Jain and Vazirani [17]; while solving the Lagrangian relaxation and getting a Lagrangian-multiplier preserving algorithm follows relatively easily, the main contribution is in the non-local rounding algorithm. This adds to the body of work exploring such primal-dual techniques, which include the work of Charikar and Panigrahy [9] to give a $O(1)$-factor approximation for the sum of cluster diameters, and Chuzhoy and Rabani [10] in their $O(1)$-factor bicriteria approximation for the capacitated k-median problem. Non-local roundings of a different flavor were also recently used for the capacitated k-center problem by Cygan et al. [11] and An et al. [1]. To the best of our understanding, our rounding technique is different from these previous works.

2 Preliminaries

Let (X, D) be a metric space and let $C \subseteq X$ be the set of *clients* and $F \subseteq X$ be the set of *facilities*. The *aversion k-clustering problem* is the task to partition C into a collection $\mathcal{C}$ of

k disjoint subsets $C_1, \dots, C_k$ with $C = \cup_{i=1}^{k} C_i$ such that

$$c_a(\mathcal{C}) := \sum_{\ell=1}^{k} \sum_{j_1 \in C_\ell} \max_{j_2 \in C_\ell} D(j_1, j_2) \tag{P1}$$

is minimized.

For the *local k-median problem*, we additionally get a *radius* (or *range*) R_i for every $i \in F$. We seek a set $\mathcal{F} \subseteq F$ of k facilities that minimizes

$$c_l(\mathcal{F}) := \sum_{j \in C} \min_{\substack{i \in \mathcal{F}, \\ D(i,j) \leq \mathsf{R}_i}} D(i, j).$$

This differs from the classical k-median problem in that a client can only be assigned to a facility if it lies within the facility's radius. It is possible that there is no set of k facilities which can service all clients. If this is the case, we define the minimum clustering cost as infinity. In the following claim, we show that it is NP-hard to decide whether we are in this case or not.

▶ **Claim 1.** Deciding feasibility of a local k-median instance is NP-hard.

Proof. We use a well-known reduction from set cover. Let $\mathcal{S}$ be a set of sets over a universe $\mathcal{U}$. We construct a metric space that contains a facility i_S for every set $S \in \mathcal{S}$ and a client j_u for every element $u \in \mathcal{U}$. The distance between j_u and i_S is one if $u \in S$ and two otherwise. Observe that this is a metric. We set the radius R_{i_S} of all facilities to one. Observe that there is a feasible solution for this local k-median instance if and only if the set cover instance has a solution with at most k sets. Since deciding whether a set cover instance has a solution with at most k sets is NP-hard [18], it is also NP-hard to decide whether there is a feasible solution for the local k-median problem. ◀

Any approximation algorithm has to decide whether there is a feasible solution or not. Hence, we allow the locality constraint to be violated; i.e. a client may connect to a facility i if it is within a radius of $\gamma \mathsf{R}_i$ for a constant γ. We say a solution is a (γ, ψ) bicriteria solution if the solution violates the locality constraints by a factor of γ and has cost at most ψ times the optimal (with respect to the original problem).

3 Solving the aversion k-clustering problem via the local k-median problem

We show that the aversion k-clustering problem can be reduced to the local k-median problem by sacrificing a constant factor. The idea is to identify a cluster C_ℓ with a pair of points with largest distance and to use this information to represent clusters by an artificial facility with appropriate radius. More precisely, we define the following metric space. Set $F := \{p_{j_1 j_2} \mid j_1, j_2 \in C\}$ and refer to $p_{j_1 j_2}$ as the *midpoint* of clients j_1 and j_2. To extend D from C to $C \cup F$, we set

$$D(j_1, p_{j_1 j_2}) := D(j_2, p_{j_1 j_2}) = \frac{D(j_1, j_2)}{2} \text{ and } D(p_{j_1 j_2}, p_{j_1 j_2}) := 0$$

for all $j_1, j_2 \in C$. So far, no metric property is violated. Now imagine the incompletely defined metric as a weighted undirected graph G on the vertices $C \cup F$ where some edges are missing. Let D be defined as the shortest path metric in G. This is a metric by definition. It

coincides with the previously defined distances since in a metric, the direct edge must be a shortest path. For the missing edges, we get that

$$D(j, p_{j_1 j_2}) = D(p_{j_1 j_2}, j) = \min\{D(j, j_1), D(j, j_2)\} + \frac{D(j_1, j_2)}{2} \tag{1}$$

for all $j \in C$: The point $p_{j_1 j_2}$ is only connected to j_1 and j_2, thus any path between j and $p_{j_1 j_2}$ has to travel over one of them. Since the edge lengths form a metric, the direct connection between j and j_1 or j_2 is shortest, so either $(j, j_1), (j_1, p_{j_1 j_2})$ or $(j, j_2), (j_2, p_{j_1 j_2})$ is a shortest path. Analogously, we get that

$$D(p_{j_1 j_2}, p_{j_3 j_4}) = D(j_1, j_2)/2 + D(j_3, j_4)/2 + \min\{D(j_1, j_3), D(j_1, j_4), D(j_2, j_3), D(j_2, j_4)\}$$

for all $j_1, j_2, j_3, j_4 \in C$. Finally, we define

$$\mathsf{R}_{p_{j_1 j_2}} := D(j_1, j_2)/2 \tag{2}$$

for all $p_{j_1 j_2} \in F$. Notice that our definition of F allows that $j_1 = j_2$. This ensures that singleton clusters can be expressed. Furthermore, notice that $\mathsf{R}_{p_{j_1 j_1}} = 0$, so the facility $p_{j_1 j_1}$ can only serve j_1 (or clients at the same location).

For any facility p_{j_1, j_2}, we will drop the reference to j_1 and j_2 when it is clear from the context. Hence, $p \in F$ refers to the midpoint of some two clients j_1 and j_2 and the radius of the facility R_p simply refers to half the distance between these points. Intuitively, each new "facility" corresponds to a midpoint of two clients in the original problem. These midpoints allow us to cast the current problem as a k-median problem with the addition of locality constraints placed on each facility.

We now show how solutions for the aversion k-clustering problem and (γ, α) bicriteria solutions for the local k-median problem are related. For a client j, let $F_j^\gamma := \{i \in F \mid D(i, j) \leq \gamma \mathsf{R}_i\}$ be the set of facilities that j is allowed to connect to. The following integer linear program (ILP) which is a (natural) modification of the ILP proposed in [3] minimizes over all feasible (γ, α) bicriteria solutions.

$$\begin{aligned}
\min \sum_{j \in C} \sum_{i \in F_j^\gamma} D(i, j) \cdot x_{i,j} & & & \text{(ILP}^\gamma\text{)} \\
\sum_{i \in F} y_i &\leq k & & \\
\sum_{i \in F_j^\gamma} x_{i,j} &\geq 1 & \forall j \in C & \\
y_i - x_{i,j} &\geq 0 & \forall j \in C, i \in F_j^\gamma & \\
x_{i,j}, y_i &\in \{0, 1\} & \forall j \in C, i \in F_j^\gamma &
\end{aligned}$$

ILP$^\gamma$ has a variable y_i for each $i \in F$ that indicates whether the 'facility' i is opened, and a variable $x_{i,j}$ for any combination of an original point j and a facility $i \in F_j^\gamma$ that says whether j is connected to i.

Let (x, y) be any solution of ILP$^\gamma$ and let $c(x, y)$ be the cost of the solution. We relate the solutions of ILP$^\gamma$ to the problem (P1) by the following lemmas.

▶ **Lemma 3.** *Given a solution (x, y) of ILP$^\gamma$, there exists a solution $\mathcal{C} = \{C_l\}_{l=1}^k$ to* (P1) *which has cost no more than $c_a(\mathcal{C}) \leq (\gamma + 1)c(x, y)$.*

Proof. Since (x, y) is an integral solution, let $\{p_1, \dots, p_k\} \subseteq F$ denote the facilities which are opened. We define the cluster C_i to be the set of clients j such that $x_{p_i,j} = 1$. For any client $j \in C_i$, let $j' \in C_i$ be the client which maximizes $D(j, j')$. Since D is a metric, we know that $D(j, j') \leq D(p_i, j) + D(p_i, j')$. By the locality constraint, it holds that $D(p_i, j') \leq \gamma \mathsf{R}_{p_i}$. By definition of D and R_{p_i}, we know $D(p_i, j) \geq \mathsf{R}_{p_i}$, which implies $D(p_i, j') \leq \gamma D(p_i, j)$. Hence, $D(j, j') \leq (\gamma + 1)D(p_i, j)$. Summing this over all clients, we conclude that $c_a(\mathcal{C}) \leq (\gamma + 1)c(x, y)$. ◀

▶ **Lemma 4.** *Given a solution $\mathcal{C}$ to* (P1)*, we can construct a solution (x, y) to ILP$^\gamma$ (where $\gamma \geq 3$) which has cost $\frac{1}{2}c_a(\mathcal{C}) \leq c(x, y) \leq 2c_a(\mathcal{C})$.*

Proof. Fix a cluster C_i, let $j_1, j_2 \in C_i$ be two clients which maximize $D(j_1, j_2)$. Open facility $p_{j_1 j_2}$ and connect all clients in C_i to it. Notice that it holds $D(j, p_{j_1 j_2}) = \mathsf{R}_{p_{j_1 j_2}} + \min\{D(j, j_1), D(j, j_2)\} \leq 3\mathsf{R}_{p_{j_1 j_2}}$ because $D(j_1, j_2)$ is the maximum distance between two clients in C_i and because $D(j_1, j_2) = 2\mathsf{R}_{p_{j_1 j_2}}$. Thus, the solution is feasible for $\gamma = 3$.

For any client $j \in C_i$, let $j' \in C_i$ be the element which maximizes $D(j, j')$. For the first inequality notice that each client j will pay at least $D(j, p_{j_1 j_2}) \geq \frac{1}{2}D(j_1, j_2) \geq \frac{1}{2}D(j, j')$. Observe that $D(j, j') \geq \max\{D(j, j_1), D(j, j_2)\} \geq (D(j, j_1) + D(j, j_2))/2 \geq D(j_1, j_2)/2$. Combining this with the observation that $D(j, j') \geq \min\{D(j, j_1), D(j, j_2)\}$, we get that

$$D(p_{j_1 j_2}, j) = \min\{D(j, j_1), D(j, j_2)\} + D(j_1, j_2)/2 \leq 2 \cdot D(j, j').$$

Summing over all clients gives the second inequality. ◀

Let opt^γ_{ilp} be the optimal value for ILP$^\gamma$ and let opt_a be the value of an optimal solution for (P1). Lemma 4 implies that $opt^3_{ilp} \leq 2 \cdot opt_a$. Assuming we compute an ψ-approximate solution to the optimal ILP^3 solution that violates the locality constraint by an additional factor of ϱ. Then this solution costs at most $\psi \cdot opt^3_{ilp} \leq 2\psi \cdot opt_a$ and violates the locality constraints by 3ϱ. By Lemma 3, we can then construct a feasible solution for (P1) that costs at most $(3\varrho + 1) \cdot 2\psi \cdot opt_a$.

3.1 Good fractional solutions for the local k-median problem

Since problem ILP$^\gamma$ is NP-hard, we relax the integrality constraints to obtain a linear program. The only difference between the standard k-median relaxation and LP$^\gamma_{\mathcal{P}}$ is the locality constraint, i.e., each client j can only connect to facilities in F^γ_j.

$$\begin{aligned}
\min \quad & \sum_{i,j} D(i,j)x_{i,j} && (\mathrm{LP}^\gamma_{\mathcal{P}}) \\
\text{s.t.} \quad & \sum_{i \in F^\gamma_j} x_{i,j} \geq 1 && \forall j \in C \\
& y_i - x_{i,j} \geq 0 && \forall j \in C, i \in F^\gamma_j \\
& \sum_{i \in F} -y_i \geq -k \\
& x, y \geq 0.
\end{aligned}$$

$$\begin{aligned}
\max \quad & \sum_j \alpha_j - kZ && (\mathrm{LP}^\gamma_{\mathcal{D}}) \\
\text{s.t.} \quad & \\
& \alpha_j \leq D(i,j) + \beta_{i,j} && \forall j \in C, i \in F^\gamma_j \\
& \sum_{j : i \in F_j} \beta_{i,j} \leq Z && \forall i \in F \\
& \alpha, \beta, Z \geq 0.
\end{aligned}$$

The above LP is very similar to the LP for facility location and this fact was exploited by Jain and Vazirani to show that primal-dual solutions to the facility location problem can be transformed into the solutions for the k-median problem. Let LP-F$^\gamma_{\mathcal{P}}$ be the facility location variant of LP$^\gamma_{\mathcal{P}}$, and let LP-F$^\gamma_{\mathcal{D}}$ be its dual:

$$\min \sum_{i\in F, j\in C} D(i,j)x_{i,j} + \sum_{i\in F} f_i y_i \qquad \text{(LP-F}^{\gamma}_{\mathcal{P}}\text{)}$$
$$\text{s.t.} \sum_{i\in F^{\gamma}_j} x_{i,j} \geq 1 \qquad \forall j \in C$$
$$y_i - x_{i,j} \geq 0 \qquad \forall j \in C, i \in F^{\gamma}_j$$
$$x, y \geq 0.$$

$$\max \sum_j \alpha_j \qquad \text{(LP-F}^{\gamma}_{\mathcal{D}}\text{)}$$
$$\text{s.t.}$$
$$\alpha_j \leq D(i,j) + \beta_{i,j} \;\forall j \in C, i \in F^{\gamma}_j$$
$$\sum_{j: i\in F^{\gamma}_j} \beta_{i,j} \leq f_i \qquad \forall i \in F$$
$$\alpha, \beta \geq 0.$$

Augmenting ideas introduced by Jain and Vazirani [17], we obtain integer solutions to LP-F$^{\gamma}_{\mathcal{P}}$. This produces two solutions (x^1, y^1) and (x^2, y^2) that are nearly feasible for LP$^{3\gamma}_{\mathcal{P}}$, but $\sum_i y^1_i = k_1 < k$ and $\sum_i y^2_i = k_2 > k$. A suitable convex combination of the two is a feasible solution for LP$^{3\gamma}_{\mathcal{P}}$ and is a constant factor away from the optimal value of LP$^{\gamma}_{\mathcal{P}}$.

▶ **Lemma 5.** *Given any $\epsilon > 0$ and $\gamma > 0$, there exists a polynomial time algorithm which finds two feasible integer solutions $(x^1, y^1), (x^2, y^2)$ for LP-F$^{3\gamma}_{\mathcal{P}}$ with the following properties:*

1. *$\sum_i y^1_i = k_1$ and $\sum_i y^2_i = k_2$ for two integers $k_1 < k < k_2$.*
2. *Set $\rho = \frac{k_2 - k}{k_2 - k_1}$. The solution $(\hat{x}, \hat{y}) = \rho(x^1, y^1) + (1-\rho)(x^2, y^2)$ is feasible for LP$^{3\gamma}_{\mathcal{P}}$ with cost at most $(3+\epsilon)$ times the optimal solution to LP$^{\gamma}_{\mathcal{P}}$.*

Since the essential ideas behind this lemma use standard techniques, we omit the full proof because of space limitations. The main differences to the standard Jain-Vazirani primal-dual process are as follows: When finding the initial set of open facilities, we restrict clients to paying and connecting only to facilities whose radius they lie in. In the clean-up step, the Jain-Vazirani algorithm selects the finally open facilities by finding an arbitrary independent set of facilities in some graph. We use the freedom to choose any independent set and choose a set that ensures that clients that have to be reassigned (because their original facility was closed) can always be routed to an open facility with higher radius than their original facility.

3.2 Rounding

Given any two integer solutions (x_1, y_1) and (x_2, y_2) for LP-F$^{\gamma}_{\mathcal{P}}$, which open $A, B \subseteq F$ facilities, respectively, we define a weighted bipartite graph $G(x_1, y_1, x_2, y_2)$ as follows. The graph is defined on the vertex set with bipartitions A and B. We connect $i \in A$ to $i' \in B$ if there exists a client j such that $x^1_{i,j} = 1$ and $x^2_{i',j} = 1$. The weight of an edge (i, i') is the number of clients j which satisfy the above requirement.

▶ **Lemma 6.** *The following holds for local k-median instances that arise from the aversion k-clustering problem. Given two integer solutions $(x^1, y^1), (x^2, y^2)$ for LP-F$^{\gamma}_{\mathcal{P}}$ which open facilities $A, B \subseteq F$, respectively, we can construct solutions $(\tilde{x}^1, \tilde{y}^1), (\tilde{x}^2, \tilde{y}^2)$ that satisfy:*

1. *$(\tilde{x}^1, \tilde{y}^1)$ opens facilities A and $(\tilde{x}^2, \tilde{y}^2)$ opens facilities B.*
2. *If $(x_1, y_1), (x_2, y_2)$ are feasible for LP-F$^{\gamma}_{\mathcal{P}}$, then $(\tilde{x}^1, \tilde{y}^1), (\tilde{x}^2, \tilde{y}^2)$ are feasible solutions to LP-F$^{3\gamma}_{\mathcal{P}}$, and they satisfy $c(\tilde{x}^1, \tilde{y}^1) \leq 3\gamma c(x^1, y^1)$ and $c(\tilde{x}^2, \tilde{y}^2) \leq 3\gamma c(x^2, y^2)$.*
3. *The graph $G(\tilde{x}^1, \tilde{y}^1, \tilde{x}^2, \tilde{y}^2)$ is a forest.*

Proof. We will assume that all radii are distinct (we can ensure this, e.g., by adding a tiny amount of noise to all the radii, or by breaking ties consistently). We say that

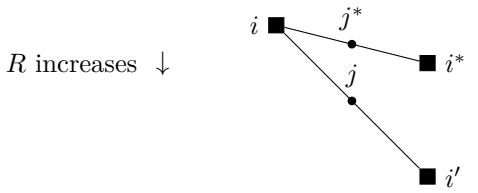

Figure 1 Removing all but one down edge for client i.

an edge $\{i, i'\}$ in $G(x^1, y^1, x^2, y^2)$ is a *down edge for* i if $\mathsf{R}_{i'} > \mathsf{R}_i$. For $i \in A \cup B$, let $\mathfrak{D}(i) := \{i' \mid \{i, i'\}$ is a down edge$\}$ be the set of facilities that are connected to i by down edges. Furthermore, for every $i \in A \cup B$, let i^* be a facility that minimizes $\{\mathsf{R}_i \mid i \in \mathfrak{D}(i)\}$, i.e., i^* is the endpoint of a 'highest' down edge. For each $i \in A \cup B$, we modify assignments as follows. For all clients $j \in C$ connected to i, and to some facility $i' \in \mathfrak{D}(i)$ in (x_1, y_1), (x_2, y_2), we reassign them to now connect to i and i^* in $(\tilde{x}^1, \tilde{y}^1), (\tilde{x}^2, \tilde{y}^2)$. Thus, for all clients $j \in C$ originally connected to i and i^*, the assignment does not change.

Let us calculate the costs of the resulting assignment. Let $i' \in \mathfrak{D}(i)$ be a facility with $i' \neq i^*$ and let j be a client that is reconnected from i' to i^*. Notice that $D(i, i^*) \le \gamma\mathsf{R}_i + \gamma\mathsf{R}_{i^*}$ since at least one client lies within the (γ-expanded) radius of i and i^* simultaneously. We observe that $D(j, i^*) \le D(j, i) + D(i, i^*) \le \gamma(\mathsf{R}_i + \mathsf{R}_i + \mathsf{R}_{i^*}) \le 3\gamma \cdot \mathsf{R}_{i^*}$ by the triangle inequality and by $\mathsf{R}_{i^*} \ge \mathsf{R}_i$. Thus, the new solution violates the locality constraint for j by a factor of at most 3. Since R_{i^*} is the smallest radius for all facilities in $\mathfrak{D}(i)$, it holds that $\mathsf{R}_{i^*} \le \mathsf{R}_{i'}$. Thus, we also have $D(j, i^*) \le 3\gamma\mathsf{R}_{i'}$. Moreover, since the instances arise from local k-median, equations (1) and (2) imply that $D(j, i') \ge \mathsf{R}_{i'}$. (This is the only part of the proof that relies on the local k-median instances arising from aversion k-clustering). Hence we have $D(j, i^*) \le 3\gamma\mathsf{R}_{i'} \le 3\gamma D(j, i')$. Thus the cost of each client j is increased by a factor of at most 3γ, which immediately proves Property 2. (Figure 1 visualizes this calculation).

We do not open or close any facilities, thus Property 1 is true. To see Property 3 holds, note that by the distinct radii assumption, any cycle would contain a facility with two down edges, which is no longer possible after the reassignment. ◀

Lemma 6 transforms our solution such that it corresponds to a forest T on the vertices $A \cup B$. We first assume that T is a tree and later deal with each connected component separately. We use the tree structure to define a depending rounding procedure to combine A and B into an integral solution C with low cost. It will be crucial to look at the difference between the number of vertices from B and A in subtrees of T.

▶ **Definition 7.** For any subtree of $T' \subseteq T$, we define the *deficiency* of T' to be $\mathsf{df}(T') = |B(T')| - |A(T')|$ where $B(T')$ (and $A(T')$) are the vertices from B (and A) in this subtree.

We start with $C = B$. Then we find a subtree T' with $\mathsf{df}(T') = 1$, i.e., one node more from B than from A. We want to close all facilities in $B(T')$, open all facilities in $A(T')$ and reconnect the affected clients. We want that the reassignment follows the assignments in $(\tilde{x}^1, \tilde{x}^2)$, so all facilities in A that are adjacent to $B(T')$ must be contained in $A(T')$. We then iterate this process with more subtrees until C has exactly k vertices. Since we gain one for every subtree, we need $t := k_2 - k$ subtrees until $|C|$ was reduced from k_2 to k. The subtrees must be disjoint on the B side, while the vertices from A can overlap. The following lemma shows that we can find a large set of suitable subtrees from which we can choose the cheapest t later. Figure 2 visualizes two examples.

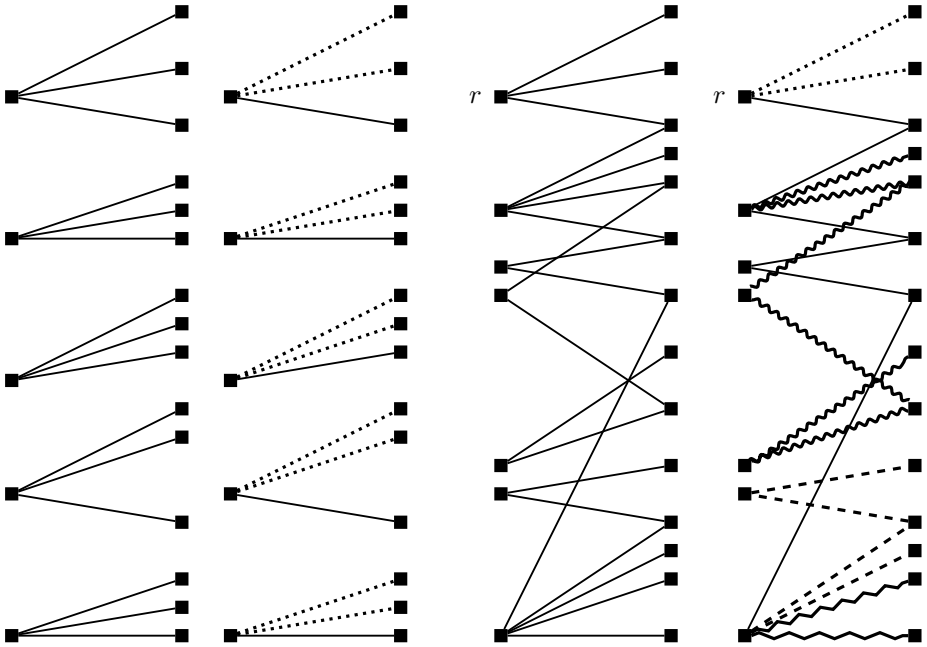

Figure 2 Examples on finding subtrees of $G(x^1, y^1, x^2, y^2)$ with $\mathsf{df}(T_i) = 1$. The two left pictures show a simple special case that also is a worst case for the number of subtrees: The deficiency of the shown forest F is $\mathsf{df}(F) = 2k = 10$ and we get $\mathsf{df}(F)/2 = 5$ subtrees by pairing the nodes from B. The two right pictures show a connected tree T with $\mathsf{df}(T) = 7$ and 4 subtrees with $\mathsf{df}(T_i) = 1$.

▶ **Lemma 8.** *Given any tree T with $\lceil \mathsf{df}(T)/2 \rceil = l$ and root $r \in A$, we can find l subtrees $T_1, \ldots, T_l$ of T with*

1. $\mathsf{df}(T_i) = 1$
2. $B(T_i) \cap B(T_j) = \emptyset$
3. $A(\delta(B(T_i))) \subseteq A(T_i)$

where we use $\delta(X)$ to denote the set of edges from X to $\bar{X}$.

Proof. Let r be the root of T and $c_1, \ldots, c_\nu$ be the children of r. Our proof will proceed with induction on the height of T. By *removing* a subtree T' we mean that we remove all edges that are in T' from T and all vertices except the root of T'.

Induction Hypothesis: There exist subtrees $T_1, \ldots, T_z$, $z \in \mathbb{N}_0$, of T that satisfy:

1. Each subtree T_i is rooted at a vertex in A and satisfies that $\mathsf{df}(T_i) = 1$.
2. After removing $T_1, \ldots, T_z$ from T, the following holds. If $r \in B$ then $\mathsf{df}(T) \leq 1$. If $r \in A$ then $\mathsf{df}(T) \leq 0$.

Base Case: T has height 0 or 1, i.e., it is a star. If $r \in B$, then $\mathsf{df}(T) \leq 1$ because there is only one node from B. If $r \in A$, then we can remove the children in pairs until there are no pairs left. This is because the subtree consisting of r and any two of its children has deficiency 1. Therefore, each pair and the root will correspond to a subtree (one of T_i mentioned in the IH) that we remove. After removing them, T consists of only r or r and one node from B. In both cases, $\mathsf{df}(T) \leq 0$.

Induction Step:

Case $r \in B$: By the induction hypothesis (IH), we can remove some subtrees to ensure that each subtree rooted at $c_1 \ldots c_\nu$ will have deficiency at most 0. Since $\mathsf{df}(T) = \sum_{i=1}^{\nu} \mathsf{df}(T_{\text{rooted at } c_i}) + 1 \leq 1$, we can conclude that this satisfies the first property in the

IH. Since we didn't remove any additional subtrees, the second property is vacuously satisfied.

Case $r \in A$: By the IH, we know that the subtree rooted at each child c_i has deficiency $\mathsf{df}(c_i) \leq 1$. Without loss of generality, let $c_1, \ldots, c_p$ be the children which have deficiency 1 and $c_{p+1} \ldots c_\nu$ have deficiency ≤ 0. If $p \leq 1$, then $\mathsf{df}(T) \leq 0$. If $p \geq 2$, then we remove pairs of children with positive deficiency. Observe that the subtree rooted at r containing only the children c_1 and c_2 has deficiency exactly 1. Hence, these satisfy the second property in the IH. We continue this process until there is at most 1 child which has positive deficiency, at which point the the first property is satisfied. This ensures that the induction step is satisfied.

Notice that each removed subtree has deficiency one. Since we keep the root, the deficiency decreases by two for each removed subtree. When $r \in A$ as assumed in the lemma, then $\mathsf{df}(T)$ is decreased to at most zero. Thus, at least $\lceil \mathsf{df}(T)/2 \rceil$ subtrees are removed. ◀

For a forest F consisting of trees $F_1, \ldots, F_x$, set $\mathsf{df}(F) := \sum_{j=1}^{x} \mathsf{df}(F_j)$. We can find $\lceil \mathsf{df}(F_j)/2 \rceil$ subtrees satisfying the properties of Lemma 8 for every every F_j. Thus, we get

$$\sum_{j=1}^{x} \left\lceil \frac{\mathsf{df}(F_i)}{2} \right\rceil \geq \left\lceil \frac{1}{2} \sum_{j=1}^{x} \mathsf{df}(F_i) \right\rceil = \lceil \mathsf{df}(F)/2 \rceil$$

subtrees, giving the following corollary.

▶ **Corollary 9.** *Given any forest F with $\lceil \mathsf{df}(F)/2 \rceil = l$, we can find l subtrees $T_1, \ldots, T_l$ of F satisfying the properties from Lemma 8.*

We now show Theorem 2. We are given an instance of the local k-median problem that arises from the aversion k-clustering problem. We know that the solutions for the local k-median problem that are induced by the aversion k-clustering instance are feasible for LP-F$^3_{\mathcal{P}}$. Thus, we set $\gamma := 3$. Then we use Lemma 5 and Lemma 6 to get two solutions (x^1, y^1) and (x^2, y^2) so that the graph $G(x^1, y^1, x^2, y^2)$ is a forest, (x^1, y^1) opens k_1 facilities and (x^2, y^2) opens $k_2 \geq k_1$ facilities. Both Lemma 5 and Lemma 6 induce a factor of 3 in the radius violation, so (x^1, y^1) and (x^2, y^2) are feasible for LP-F$^{9\gamma}_{\mathcal{P}}$. Furthermore, the intermediate solutions $(\hat{x}^1, \hat{y}^1)$ and $(\hat{x}^2, \hat{y}^2)$ coming from Lemma 5 have the property that for $\rho = (k_2 - k)/(k_2 - k_1)$, it holds that $\rho \cdot c(\hat{x}^1, \hat{y}^1) + (1 - \rho) \cdot (\hat{x}^2, \hat{y}^2) \leq (3 + \varepsilon) \cdot opt^\gamma_l$. Applying Lemma 6 increases the cost bound by a factor of 3γ. Thus, we know that

$$\rho \cdot c(x^1, y^1) + (1 - \rho) \cdot c(x^2, y^2) \leq (3 + \varepsilon) \cdot 3\gamma \cdot opt^\gamma_l := c^{mix}$$

for $\rho = (k_2 - k)/(k_2 - k_1)$. If (x^1, y^1) or (x^2, y^2) opens exactly k facilities, we are done. Otherwise, $k_1 < k < k_2$. If $\rho \geq 1/2$, simply output (x^1, y^1) which then costs $c(x^1, y^1) \leq 2\rho \cdot c(x^1, y^1) \leq 2c^{mix}$. We assume that this is not the case, i.e., $\rho < 1/2$.

We build a solution C and start with $C = B$. Using Corollary 9, we find $\frac{1}{2}(k_2 - k_1)$ subtrees $T_1, \ldots, T_\ell$ of $G(x^1, y^1, x^2, y^2)$. For each subtree T_i, we can reassign the clients from the facilities in $B(T_i)$ to the facilities in $A(T_i)$. We denote the connection cost for assigning the clients to $A(T_i)$ by $c(T_i)$. Notice that $c(x^1, y^1) \geq \sum_{s=1}^{\ell} c(T_i)$ because every edge of T can only appear in one subtree (since the $B(T_i)$ are pairwise disjoint). Thus, if we choose the $t = k_2 - k$ subtrees $T_{i_1}, \ldots, T_{i_t}$ with the cheapest $c(T_i)$, then

$$\sum_{z=1}^{t} c(T_{i_z}) \leq \frac{t}{\ell} \sum_{s=1}^{\ell} c(T_i) \leq \frac{t}{\ell} c(x^1, y^1) = \frac{k_2 - k}{\frac{1}{2}(k_2 - k_1)} c(x^1, y^1) = 2\rho \cdot c(x^1, y^1).$$

The cost of C starts at $c(x^2, y^2)$ and is increased by at most $2\rho \cdot c(x^1, y^1)$. Thus, the solution costs at most $2\rho \cdot c(x^2, y^2) + c(x^2, y^2) \leq 2\rho \cdot c(x^2, y^2) + 2(1-\rho) \cdot c(x^2, y^2) \leq 2 \cdot c^{mix}$ where we recall that $\rho < 1/2$. Thus, we get an integer solution of cost $2 \cdot (3+\varepsilon) \cdot 3\gamma \cdot opt_l^\gamma$ that is feasible for $\mathrm{LP}_{\mathcal{P}}^{9\gamma}$. That induces a solution for the aversion k-clustering instance that is a constant factor approximation as we described below Lemma 4.

3.3 Improving the Approximation Factor

To improve the final approximation ratio for the aversion k-clustering problem, we observe that the dual variables computed by the primal-dual algorithm can be directly related to the objective of the aversion k-clustering problem. We split each such dual: Let $\alpha_O(j)$ denote the amount that client j pays to open a facility (the subscript O stands for "open"). Using the terminology of Jain and Vazirani, we say a client j is directly connected to facility i if $\beta_{i,j} > 0$ and facility i is open. In this case, $\alpha_O(j) := \beta_{i,j}$. Otherwise, $\alpha_O(j) = 0$. Define $\alpha_C(j) := \alpha(j) - \alpha_O(j)$ (intuitively, this is the connection cost—the subscript C is for connection—that the client has paid for, but for indirectly connected clients we only know that $D(i,j) \geq \alpha_C(j) \geq (1/3)D(i,j)$ is true. For directly connected clients, $\alpha_C(j) = D(i,j)$.).

▶ **Lemma 10.** *At the end of the primal-dual algorithm, if client j connects to facility i, then $\alpha_C(j) \geq \mathsf{R}_i$.*

Proof. If j is directly connected to i, then it is immediate that $\alpha_C(j) = D(i,j) \geq \mathsf{R}_i$.

Suppose that j is indirectly connected to facility i'. In this case, let i be the facility that j was first connected to. Since j is indirectly connected, there has to be a client j' that has special edges to both i and i'. We use $t(i)$ and $t(i')$ to denote the times at which facilities i and i' were respectively opened. Notice that $\alpha_C(j) = \alpha(j)$ by definition of α_C for indirectly connected clients and that $\alpha(j) = t(i)$ because j was connected to i before.

Case $t(i) \geq t(i')$: In this case we know that $\alpha_C(j) = t(i) \geq t(i') \geq D(i', j') \geq \mathsf{R}_{i'}$.

Case $t(i) < t(i')$: Since j' has special edges to i and i', it had tight edges to both before either was opened, i.e., $D(i', j') \leq t(i)$. Thus we can say $\alpha_C(j) = t(i) \geq D(i', j') \geq \mathsf{R}_{i'}$. ◀

Once again, we may assume that the Jain-Vazirani algorithm returns two solutions (x^1, y^1), (x^2, y^2) and their duals (α^1, Z^+) and (α^2, Z^-). It follows from Jain and Vazirani's analysis that the solutions have the following properties.

1. $\sum_i y_i^1 = k_1$ and $\sum_i y_i^2 = k_2$.
2. $\sum_j \alpha_C^1(j) = \sum_j \alpha_j^1 - k_1 \cdot Z^+$ and $\sum_j \alpha_C^2(j) = \sum_j \alpha_j^2 - k_2 \cdot Z^-$
3. $x_{i,j}^1 = 1$ or $x_{i,j}^2 = 1 \implies D(i,j) \leq 3\gamma \mathsf{R}_i$
4. $|Z^+ - Z^-| \leq \epsilon$
5. For $\rho = \frac{k_2 - k}{k_2 - k_1}$, $\rho(\alpha^1, Z^+) + (1-\rho)(\alpha^2, Z^-)$ is feasible for $\mathrm{LP}_{\mathcal{D}}^\gamma$.

For property 2, notice that $\alpha_C^1(j) = \alpha_j^1$ for indirectly connected clients, that $\alpha^1 C(j) = \alpha_j^1 - \beta_{\phi(j)j}$ for directly connected clients (where $\phi(j)$ is the center j is connected to) and that the sum of $\beta_{\phi(j)j}$ over all directly connected clients is just $k_1 Z^+$. The same holds for the second solution. Using property 5, we get that $\rho(\sum_j \alpha_j^1 - k \cdot Z^+) + (1-\rho)(\sum_j \alpha_j^2 - k_2 \cdot Z^-)$ is a lower bound for the optimal value of $\mathrm{LP}_{\mathcal{D}}^\gamma$ and thus also for the optimal value of $\mathrm{LP}_{\mathcal{P}}^\gamma$. Using property 2 and 4, this implies that $\rho(\sum_j \alpha_C^1(j)) + (1-\rho)(\sum_j \alpha_C^2(j)) \leq opt(\mathrm{LP}_{\mathcal{P}}^\gamma) + \varepsilon$. We apply Lemma 6 to replace x^1 and x^2 to ensure that the resulting graph $G(x^1, y^1, x^2, y^2)$ is a forest. Note that the procedure only reassigns the clients to facilities with smaller radius than their currently connected facility. Hence, we can still assume that $x_{i,j}^1 = 1 \implies \alpha_C^1(j) \geq \mathsf{R}_i$

(similarly $x^2_{i,j} = 1 \implies \alpha^2_C(j) \geq \mathsf{R}_i$). However, we may now have solutions that violate the locality constraints by a factor of 9γ.

Now we use the procedure described in Lemma 8 to partition the graph $G(x^1, y^1, x^2, y^2)$ into subtrees $T_1, \ldots T_\ell$ with $\mathsf{df}(T_p) = 1$ for $p \in \{1, \ldots, \ell\}$ and $\ell = \frac{k_2 - k_1}{2}$. Each tree has the property that $A(\delta(B(T_p))) \subseteq A(T_p)$ for all $p \in \{1, \ldots, \ell\}$. Since each edge in this tree represents some set of clients, we use the notation $j \in T_p$ to denote that j is associated with an edge in T_p. Define the cost of the subtree T_p as $\sum_{j \in T_p} \alpha^1_C(j)$. We choose the $k_2 - k$ cheapest such trees. Since choosing all ℓ subtrees will result in a cost of $\sum_j \alpha^1_C(j)$, we can say that the cost of these chosen subtrees is at most $\frac{2(k_2-k)}{k_2-k_1} \sum_j \alpha^1_C(j) = 2\rho \sum_j \alpha^1_C(j)$.

Our rounded solution $(\hat{x}, \hat{y})$ opens all facilities from A that are part of the chosen subtrees and all facilities from B that are not part of any chosen subtree. Notice that since we open $k_2 - k$ subtrees and these satisfy $\mathsf{df}(T_p) = 1$, $\hat{y}$ opens exactly k facilities. The assignments of clients to facilities follow x^1 and x^2, respectively.

Analogously to Lemma 3, we construct a solution to the aversion k-clustering problem based on $\hat{x}, \hat{y}$. In this solution, each client assigned to a facility $p_i \in A$ pays at most

$$D(j, j') \leq D(p_i, j) + D(p_j, j') \leq 9\gamma \mathsf{R}_i + 9\gamma \mathsf{R}_i \leq (2 \cdot 9\gamma)\alpha^1_C(j)$$

where j' is the furthest away client among all that are assigned to p_i. Thus, by our choice of subtrees, all clients assigned to A pay at most $(2 \cdot 9\gamma)2\rho \sum_j \alpha^1_C(j)$ in total. The remaining clients pay at most $(2 \cdot 9\gamma)(\sum_j \alpha^2_C(j))$. As before, we can assume that $\rho \leq 1/2$. We conclude that the cost of $(\hat{x}, \hat{y})$ is bounded by

$$\begin{aligned}
&(2 \cdot 9\gamma)\big(2\rho \sum_j \alpha^1_C(j) + \sum_j \alpha^2_C(j)\big) \\
&\leq 2(2 \cdot 9\gamma)(1+\varepsilon)\big(\rho \sum_j \alpha^1_C(j) + (1-\rho) \sum_j \alpha^2_C(j)\big) \\
&\leq 2(2 \cdot 9\gamma)(1+\varepsilon) opt(\mathrm{LP}^\gamma_{\mathcal{P}}) \\
&\leq 2(2 \cdot 9\gamma)2(1+\varepsilon) opt_a
\end{aligned}$$

where opt_a is the optimal value for the aversion k-clustering instance and the last inequality follows by Lemma 4. Since $\gamma = 3$, the approximation factor is bounded by $216 + \varepsilon$.

4 Final Thoughts and Conclusions

This paper shows a $(216+\epsilon)$-approximation to the aversion k-clustering problem. Our results rely on achieving a constant factor bicriteria approximation for local k-median instances arising from aversion k-clustering problem. Lemma 6 is the only place in our proof where we use that the local k-median instances are generated from aversion k-clustering instances. It remains an open question if we can get a constant factor bicriteria approximation for arbitrary instances of local k-median.

Acknowledgments. We thank Christian Kroer for introducing us to the aversion k-clustering problem, and for enlightening discussions. We thank anonymous reviewers for constructive feedback, in particular for pointing out an oversight in Lemma 6 in an earlier draft.

Abstract

In this paper, we introduce and study the Non-Uniform k-Center (NUkC) problem. Given a finite metric space (X, d) and a collection of balls of radii $\{r_1 \geq \cdots \geq r_k\}$, the NUkC problem is to find a placement of their centers on the metric space and find the minimum dilation α, such that the union of balls of radius $\alpha \cdot r_i$ around the ith center covers all the points in X. This problem naturally arises as a min-max vehicle routing problem with fleets of different speeds, or as a wireless router placement problem with routers of different powers/ranges.

The NUkC problem generalizes the classic k-center problem when all the k radii are the same (which can be assumed to be 1 after scaling). It also generalizes the k-center with outliers (kCwO for short) problem when there are k balls of radius 1 and ℓ balls of radius 0. There are 2-approximation and 3-approximation algorithms known for these problems respectively; the former is best possible unless P=NP and the latter remains unimproved for 15 years.

We first observe that no $O(1)$-approximation is to the optimal dilation is possible unless P=NP, implying that the NUkC problem is more non-trivial than the above two problems. Our main algorithmic result is an $(O(1), O(1))$-*bi-criteria* approximation result: we give an $O(1)$-approximation to the optimal dilation, however, we may open $\Theta(1)$ centers of each radii. Our techniques also allow us to prove a simple (uni-criteria), optimal 2-approximation to the kCwO problem improving upon the long-standing 3-factor. Our main technical contribution is a connection between the NUkC problem and the so-called firefighter problems on trees which have been studied recently in the TCS community. We show NUkC is as hard as the firefighter problem. While we don't know if the converse is true, we are able to adapt ideas from recent works [4, 1] in non-trivial ways to obtain our constant factor bi-criteria approximation.

1 Introduction

Source location and vehicle routing problems are extremely well studied [20, 24, 10] in operations research. Consider the following location+routing problem: we are given a set of k ambulances with speeds $s_1, s_2, \ldots, s_k$ respectively, and we have to find the depot locations for these vehicles in a metric space (X, d) such that any point in the space can be served by some ambulance as fast as possible. If all speeds were the same, then we would place the ambulances in locations S such that $\max_{v \in X} d(v, S)$ is minimized – this is the famous

43rd International Colloquium on Automata, Languages, and Programming (ICALP 2016).

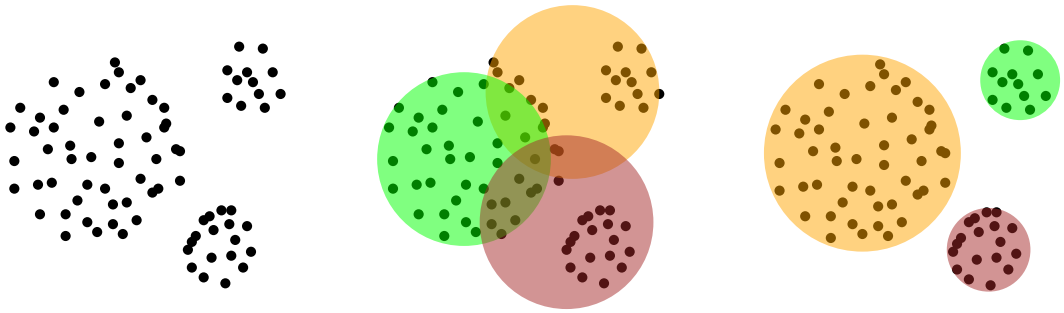

Figure 1 The left figure shows the dataset, the middle figure shows a traditional k-center clustering, and the right figure depicts a non-uniform clustering

k-center problem. Differing speeds, however, leads to non-uniformity, thus motivating the titular problem we consider.

▶ **Definition 1** (The Non-Uniform k-Center Problem (NUkC))**.** The input to the problem is a metric space (X, d) and a collection of k balls of radii $\{r_1 \geq r_2 \geq \cdots \geq r_k\}$. The objective is to find a placement $C \subseteq X$ of the centers of these balls, so as to minimize the dilation parameter α such that the union of balls of radius $\alpha \cdot r_i$ around the ith center covers all of X. Equivalently, we need to find centers $\{c_1, \ldots, c_k\}$ to minimize $\max_{v \in X} \min_{i=1}^{k} \frac{d(v,c_i)}{r_i}$.

As mentioned above, when all r_i's are the same (and equal to 1 by scaling), we get the k-center problem. The k-center problem was originally studied by Gonzalez [11] and Hochbaum and Shmoys [14] as a clustering problem of partitioning a metric space into different clusters to minimize maximum intra-cluster distances. One issue (see Figure 1 for an illustration and refer to [12] for a more detailed explanation) with k-center (and also k-median/means) as an objective function for clustering is that it favors clusters of similar sizes with respect to cluster radii. However, in presence of qualitative information on the differing cluster sizes as is often the case in certain applications, the non-uniform versions of the problem can arguably provide more nuanced solutions. One extreme special case was considered as the "clustering with outliers" problem [8] where a fixed number/fraction of points in the metric space need not be covered by the clusters. In particular, Charikar et al [8] consider (among many problems) the k-center with outlier problem (kCwO, for short) and show a 3-approximation for this problem. It is easy to see that kCwO is a special case of NUkC when there are k balls of radius 1 and ℓ (the number of outliers) balls of radius 0.

Motivated by the aforementioned reasons (both from facility location as well as from clustering settings) In this paper, we investigate the worst-case complexity of the NUkC problem. Gonzalez [11] and Hochbaum and Shmoys [14] give 2-approximations for the k-center problem, and also show that no better factor is possible unless P = NP. Charikar et al [8] give a 3-approximation for the kCwO problem, and this has been the best factor known for 15 years. Given these algorithms, it is natural to wonder if a simple $O(1)$-approximation exists for the NUkC problem. In fact, our first result shows a qualitative distinction between NUkC and these problems: constant-approximations are impossible for NUkC unless P=NP.

▶ **Theorem 2.** *For any constant $c \geq 1$, the* NUkC *problem does not admit a c-factor approximation unless $P = NP$, even when the underlying metric is a tree metric.*

The hardness result is by a reduction from the so-called *resource minimization for fire containment* problem on trees (RMFC-T, in short), a variant of the firefighter problem. To

circumvent the above hardness, we give the following bi-criteria approximation algorithm which is the main result of the paper, and which further highlights the connections with RMFC-T since our algorithms heavily rely on the recent algorithms for RMFC-T [4, 1]. An (a, b)-factor bi-criteria algorithm for NUkC returns a solution which places at most a balls of each type (thus in total it may use as many as $a \cdot k$ balls), and the dilation is at most b times the optimum dilation for the instance which places exactly one ball of each type.

▶ **Theorem 3.** *There is an $(O(1), O(1))$-factor bi-criteria algorithm for the* NUkC *problem.*

Furthermore, as we elucidate below, our techniques also give uni-criteria results when the number of distinct radii is 2. In particular, we get a 2-approximation for the kCwO problem and a $(1 + \sqrt{5})$-approximation when there are only two distinct types of radii.

▶ **Theorem 4.** *There is a 2-approximation for the* kCwO *problem.*

▶ **Theorem 5.** *There is a $(1 + \sqrt{5})$-approximation for the* NUkC *problem when the number of distinct radii is at most 2.*

1.1 Discussion on Techniques

Our proofs of Theorems 2 and 3 shows a strong connection between NUkC and the so-called *resource minimization for fire containment* problem on trees (RMFC-T, in short). This connection is one of the main findings of the paper, so we first formally define this problem.

▶ **Definition 6** (Resource Minimization for Fire Containment on Trees (RMFC-T))**.** Given a rooted tree T as input, the goal is to select a collection of non-root nodes N from T such that (a) every root-leaf path has at least one vertex from N, and (b) $\max_t |N \cap L_t|$ is minimized, where L_t is the tth-*layer* of T, that is, the vertices of T at exactly distance t from the root.

To understand the reason behind the name, consider a fire starting at the root spreading to neighboring vertices each day; the RMFC-T problem minimizes the number of firefighters needed per day so as to prevent the fire spreading to the leaves of T.

It is NP-hard to decide if the optimum of RMFC-T is 1 or not [9, 18]. Given any RMFC-T instance and any $c > 1$, we construct an NUkC instance on a tree metric such that in the "yes" case there is always a placement with dilation $= 1$ which covers the metric, while in the "no" case even a dilation of c doesn't help. Upon understanding our hardness construction, the inquisitive reader may wonder if the reduction also works in the other direction, i.e., whether we can solve NUkC using a reduction to RMFC-T problem. Unfortunately, we do not know if this is true even for two types of radii. However, as we explain below we still can use positive results for the RMFC-T problem to design good algorithms for the NUkC problem.

Indeed, we start off by considering the natural LP relaxation for the NUkC problem and describe an *LP-aware reduction* of NUkC to RMFC-T. More precisely, given a feasible solution to the LP-relaxation for the given NUkC instance $\mathcal{I}$, we describe a procedure to obtain an instance $\mathcal{I}'$ of RMFC-T, *and* also a feasible fractional solution for the natural LP relaxation of the RMFC-T problem on $\mathcal{I}'$. Moreover, given any feasible *integral* solution to the $\mathcal{I}'$, we can obtain a feasible solution to $\mathcal{I}$ which dilates the radii by a constant factor. An *LP-based* ρ-approximation to RMFC-T would then imply $(\rho, O(1))$-bi-criteria approximation algorithms for NUkC. Plugging in the result of Chalermsook and Chuzhoy [4], we directly obtain an $(O(\log^* n), O(1))$-bi-criteria approximation for NUkC. We can also obtain Theorem 4 and Theorem 5 since the corresponding RMFC-T instances have no integrality gap.

Here we reach a technical bottleneck: Chalermsook and Chuzhoy [4] also show that the integrality gap of the natural LP relaxation for RMFC-T is $\Omega(\log^* n)$. When combined with

our hardness reduction in Theorem 2 , this also implies a $(\Omega(\log^* n), c)$ integrality gap for any constant $c > 1$ for the natural LP relaxation for NUkC. That is, even if we allow a violation of c in the radius dilation, there is a $\Omega(\log^* n)$-integrality gap in terms of the violation in number of balls opened of each type. For RMFC-T though, Adjiashvili, Baggio and Zenklusen [1] recently showed an improved $O(1)$-approximation bypassing the LP integrality gap. At a very high level, the main technique in [1] is to carefully and efficiently "guess" a subset of the optimum solution, such that the natural LP-relaxation for covering only the uncovered leaves has $O(1)$-integrality gap. However, this guessing procedure crucially uses the tree structure of the given RMFC-T instance. Unfortunately for us though, we get the RMFC-T tree only after solving the LP for NUkC, which already has an $\Omega(\log^* n)$-gap! Nevertheless, inspired by the ideas in [1], we show that we can also efficiently "guess" the positions of a certain number of balls in an optimum solution, such that the standard LP-relaxation for covering the uncovered points has $O(1)$-gap. We can then invoke our reduction to RMFC-T to solve our problem. This is quite delicate, and is the most technically involved part of the paper.

1.2 Related Work and Open Questions

The k-center problem [11, 14] and the k-center with outliers [8] probems are classic problems in approximation algorithms and clustering. These problems have also been investigated under various settings such as the incremental model [6, 23], streaming model [5, 23], and more recently in the map-reduce model [15, 22]. Similarly, the k-median [7, 16, 21, 2] and k-means [16, 17, 13, 19] problems are also classic problems studied extensively in approximation algorithms and clustering. The generalization of k-median to a routing+location problem was also studied recently [10]. It would be interesting to explore the complexity of the non-uniform versions of these problems. Another direction would be to explore if the new non-uniform model can be useful in solving clustering problems arising in practice.

2 Hardness Reduction

In this section, we prove Theorem 2 based on the following NP-hardness [18] for RMFC-T.

▶ **Theorem 7** ([18]). *Given a tree T whose leaves are at the same distance from the root, it is NP-hard to distinguish between the following two cases.*
YES: *There is a solution to the* RMFC-T *instance of value* 1.
NO: *All solutions to the* RMFC-T *instance has value* 2.

Given an RMFC-T instance defined by tree T, we now describe the construction of our NUkC instance. Let h be the height of the tree, and let L_t denote the vertices of the tree at distance exactly t from the root. So, the leaves constitute L_h since all leaves are at the same distance from the root. The NUkC instance, $\mathcal{I}(T)$, is defined by the metric space (X, d), and a collection of balls. The points in our metric space will correspond to the leaves of the tree, i.e., $X = L_h$. To define the metric, we assign a weight $d(e) = (2c+1)^{h-i+1}$ for each edge whose one endpoint is in L_i and the other in L_{i-1}; we then define d be the shortest-path metric on X induced by this weighted tree. Finally, we set $k = h$, and define the k radii $r_1 \geq r_2 \geq \ldots \geq r_k$ iteratively as follows: define $r_k := 0$, and for $k \geq i > 1$, set $r_{i-1} := (2c+1) \cdot r_i + 2(2c+1)$. This completes the NUkC instance. Before proceeding we make the simple observation: for any two leaves u and u' with lca $v \in L_t$, we have $d(u, u') = 2(2c + 1 + (2c+1)^2 + \cdots + (2c+1)^{h-t}) = r_t$. The following lemma proves Theorem 2.

▶ **Lemma 8.** *If T is the YES case of Theorem 7, then $\mathcal{I}(T)$ has optimum dilation $= 2$. If T is the NO case of 7, then $\mathcal{I}(T)$ has optimum dilation $\geq 2c$.*

Proof. Suppose T is in the YES case, and there is a solution to RMFC-T which selects at most 1 node from each level L_t. If $v \in L_t$ is selected, then select a center c_v *arbitrarily* from any leaf in the sub-tree rooted at v and open the ball of radius r_t. We now need to show all points in $X = L_h$ are covered by these balls. Let u be any leaf; there must be a vertex v in some level L_t in u's path to the root such that a ball of radius r_t is opened at c_v. However, $d(u, c_v) \leq d(u, v) + d(v, c_v) = 2r_t$ and so the ball of radius $2r_t$ around c_v covers u.

Now suppose T is in the NO case, and the NUkC instance has a solution with optimum dilation $< 2c$. We build a good solution for the RMFC-T instance N as follows: suppose the NUkC solution opens the radius $< 2c \cdot r_t$ ball around center u. Let v be the vertex on the u-root path appearing in level L_t. We then pick this node in N. Observe two things: first, this ball covers all the leaves in the sub-tree rooted at v since $r_t \geq d(u, u')$ for any such u'. Furthermore, since the NUkC solution has only one ball of each radius, we get that $|N \cap L_t| \leq 1$. Finally, since $d(u, w) \geq 2c \cdot r_t$ for all leaves w not in the sub-tree rooted at v, the ball of radius r_t around u doesn't contain any leaves other than those rooted at v. Contra-positively, since all leaves w are covered in some ball, every leaf must lie in the sub-tree of some vertex picked in N. That is, N is a solution to RMFC-T with value $= 1$ contradicting the NO case. ◀

3 LP-aware reduction from NUkC to RMFC-T

For reasons which will be apparent soon, we consider instances $\mathcal{I}$ of NUkC counting multiplicites. That is, we consider an instance to be a collection of tuples $(k_1, r_1), \ldots, (k_h, r_h)$ to indicate there are k_i balls of radius r_i. So we have $r_1 \geq r_2 \ldots \geq r_h$ and $\sum_{t=1}^{h} k_t = k$. Intuitively, the reason we do this is that if two radii r_t and r_{t+1} are "close-by" then it makes sense to round up r_{t+1} to r_t and increase k_t, losing only a constant-factor loss in the dilation.

LP-relaxation for NUkC. We now state the natural LP relaxation for a given NUkC instance $\mathcal{I}$. For each $p \in X$ and radius type r_i, we have a variable $x_{p,i} \geq 0$ denoting the extent to which we place a ball of radius r_i centered at p. By doing a binary search on the optimal dilation and scaling, we may assume that the optimum dilation is 1. Then, the following linear program must be feasible. In what follows, define $B(q, r_i) = \{p : d(p, q) \leq r_i\}$.

$$\forall p \in X, \qquad \sum_{t=1}^{h} \sum_{q \in B(p, r_t)} x_{q,t} \geq 1 \qquad \text{(NUkC LP)}$$

$$\forall t \in 1, \cdots, h \qquad \sum_{p \in X} x_{p,t} \leq k_t$$

LP-relaxation for RMFC-T. Since we reduce fractional NUkC to fractional RMFC-T, we now state the natural LP relaxation for RMFC-T on a tree T of depth $h + 1$. In fact, we will work with the following budgeted-version of RMFC-T (which is equivalent to the original RMFC-T problem — for a proof, see [1]): Instead of minimizing the maximum number of "firefighters" at any level t (that is $|N \cap L_t|$ where N is the chosen solution), suppose we specify a budget limit of k_t on $|N \cap L_t|$. The goal is the minimize the maximum dilation of these budgets. Then the following is a natural LP relaxation for the budgeted RMFC-T problem on trees. Here $L = L_h$ is the set of leaves, and L_t are the layer t-nodes. For a leaf

node v, we let P_v denote the vertex set of the unique leaf-root path excluding the root.

$$\begin{array}{lll} & \min \alpha & \\ \forall v \in L, & \sum_{u \in P_v} y_u & \geq 1 \\ \forall t \in 1, \cdots, h & \sum_{u \in L_t} y_u & \leq \alpha \cdot k_t \end{array} \qquad \text{(RMFC-T LP)}$$

The LP-aware Reduction to Tree metrics. We now describe our main reduction algorithm, which takes as input an NUkC instance $\mathcal{I} = \{(X, d); (k_1, r_1), \ldots, (k_h, r_h)\}$ and a feasible solution x to NUkC LP, and returns a budgeted RMFC-T instance $\mathcal{I}_T$ defined by a tree T along with budgets for each level, and a feasible solution y to RMFC-T LP with dilation 1. The tree we construct will have height $h + 1$ and the budgeted RMFC-T instance will have budgets precisely k_t at level $1 \leq t \leq h$, and the budget for the leaf level is 0. For clarity, throughout this section we use the word *points* to denote elements of the metric space in $\mathcal{I}$, and the word *vertices/nodes* to denote the tree nodes in the RMFC-T instance that we construct. We build the tree T in a bottom-up manner, where in each round, we pick a set of far-away representative points (the distance scale increases as we move up the tree) and cluster all points to their nearest representative. This is similar to a so-called clustering step in many known algorithms for facility location (see e.g., [7]), but whereas an arbitrary set of far-away representatives would suffice in the facility location algorithms, we need to be careful in how we choose this set to make the overall algorithm work.

Formally, each vertex of the tree T is mapped to some point in X, and we denote the mapping of the vertices at level t by $\psi_t : L_t \to X$. We will maintain that each ψ_t will be injective, so $\psi_t(u) \neq \psi_t(v)$ for $u \neq v$ in L_t. So, ψ_t^{-1} is well defined for the range of ψ_t.

The complete algorithm runs in rounds $h + 1$ to 2 building the tree one level per round. To begin with, the ψ_{h+1} mapping is an arbitrary bijective mapping between $L := L_{h+1}$, the set of leaves of the tree, and the points of X (so, in particular, $|L| = |X|$). We may assume it to be the identity bijection. In each round t, the range of the mappings become progressively smaller, that is[1], $\psi_t(L_t) \supseteq \psi_{t-1}(L_{t-1})$. We call $\psi_t(L_t)$ as the **winners at level** t. We now describe round t. Let $\mathsf{Cov}_t(p) := \sum_{q \in B(p, r_t)} x_{q,t}$ denote the fractional amount the point p is covered by radius r_t balls in the solution x. Also define $\mathsf{Cov}_{\geq t}(p) := \sum_{s \geq t} \mathsf{Cov}_s(p)$ denoting the fractional amount p is covered by radius r_t or smaller balls. Let $\mathsf{Cov}_{h+1}(p) = 0$ for all p. Finally, we add a root vertex and connect it to all vertices in L_1. This gives us the final tree T and a solution y which assigns a value to all non-leaf, non-root vertices of the tree T. The following claim asserts well-definedness of the algorithm.

▶ **Lemma 9.** *The solution y is a feasible solution to* RMFC-T *LP on $\mathcal{I}_T$ with dilation* 1.

Proof. The proof is via two claims for the two different set of inequalities.

▶ **Claim 1.** *For all $1 \leq t \leq h$, we have $\sum_{w \in L_t} y_w \leq k_t$.*

Proof. Fix t. Let $W_t \subseteq X$ denote the winners at level t, that is, $W_t = \psi_t(L_t)$. By definition of the algorithm, $\sum_{w \in L_t} y_w = \sum_{p \in W_t} \mathsf{Cov}_t(p)$. Now note that for any two points $p, q \in W_t$, we have $B(p, r_t) \cap B(q, r_t) = \emptyset$. To see this, consider the first point which enters A in the $(t + 1)$th round when L_t was being formed. If this is p, then all points in the radius $2r_t$ ball

[1] We are using the notation $\psi(X) := \bigcup_{x \in X} \psi(x)$.

Algorithm 1 Round t of the LP-aware Reduction.

Input: Level L_t, subtrees below L_t, the mappings $\psi_s : L_s \to X$ for all $t \le s \le h$.
Output: Level L_{t-1}, the connections between L_{t-1} and L_t, and the mapping ψ_{t-1}.

Define $A = \psi_t(L_t)$ the set of points who are winners at level t.
while $A \neq \emptyset$ **do**
(a) Choose the point $p \in A$ with *minimum coverage* $\mathsf{Cov}_{\ge t}(p)$.
(b) Let $N(p) := \{q \in A : d(p,q) \le 2r_{t-1}\}$ be the set of all nearby points in A to p.
(c) Create a new tree vertex $w \in L_{t-1}$ corresponding to p and set $\psi_{t-1}(w) := p$. *Call p a winner at level $t-1$, and each $q \in N(p) \subseteq A$ a loser to p at this level.*
(d) Create edge (w, v) for tree vertices $v \in \psi_t^{-1}(N(p))$ associated with $N(p)$ at level t.
(e) Set $A \leftarrow A \setminus (N(p))$.
(f) Set $y_w = \mathsf{Cov}_{t-1}(p)$.
end while

are deleted from A. Since the balls are disjoint, the second inequality of NUkC LP implies $\sum_{p \in W_t} \sum_{q \in B(p,r_t)} x_{q,t} \le k_t$. The second summand in the LHS is precisely $\mathsf{Cov}_t(p)$. ◀

▶ **Claim 2.** *For any leaf node $w \in L$, we have $\sum_{v \in P_w} y_v \ge 1$.*

Proof. We start with an observation. Fix a level t and a winner point $p \in W_t$. Let $u \in L_t$ such that $\psi_t(u) = p$. Since $W_t \subseteq W_{t+1} \subseteq \cdots \subseteq W_h$, there is a leaf v in the subtree rooted at u corresponding to p. Moreover, by the way we formed our tree edges in step (d), we have that $\psi_s(w') = p$ for all w' in the (u,v)-path and hence $\sum_{w' \in [u,v]\text{-path}} y_{w'} = \mathsf{Cov}_{\ge t}(p)$.

Now, for contradiction, suppose there is some leaf corresponding to, say point p, such that the root-leaf path has total y-assignment less than 1. Then, pick the point, among all such unsatisfied points p, who appears in a winning set W_t with t *as small as possible*.

By the preceding observation, the total y-assignment p receives on its path from level h to level t is exactly $\mathsf{Cov}_{\ge t}(p)$. Moreover, suppose p loses to q at level $t-1$, i.e., $\psi_t^{-1}(p)$ is a child of $\psi_{t-1}^{-1}(q)$. In particular, it means that q has also been a winner up to level t and so the total y-assignment on q's path upto level t is also precisely $\mathsf{Cov}_{\ge t}(q)$. Additionally, since $\psi_{t-1}^{-1}(q)$ became the parent node for $\psi_t^{-1}(p)$, we know that $\mathsf{Cov}_{\ge t}(q) \le \mathsf{Cov}_{\ge t}(p)$ due to the way we choose winners in step (a) of the while loop. Finally, by our maximality assumption on p, we know that q is fractionally satisfied by the y-solution. Therefore, there is fractional assignment of at least $(1 - \mathsf{Cov}_{\ge t}(q))$ on q's path from nodes in level $t-1$ to level 1. Putting these observations together, we get that the total fractional assignment on p's root-leaf path is at least $\mathsf{Cov}_{\ge t}(p) + (1 - \mathsf{Cov}_{\ge t}(q)) \ge 1$, which results in the desired contradiction. ◀

◀

The following lemma shows that any good *integral* solution to the RMFC-T instance $\mathcal{I}_T$ can be converted to a good integral solution for the NUkC instance $\mathcal{I}$.

▶ **Lemma 10.** *Suppose there exists a feasible solution N to $\mathcal{I}_T$ such that for all $1 \le t \le h$, $|N \cap L_t| \le \alpha k_t$. Then there is a solution to the NUkC instance $\mathcal{I}$ that opens, for each $1 \le t \le h$, at most αk_t balls of radius $\le 2r_{\ge t}$, where $r_{\ge t} := r_t + r_{t+1} + \cdots + r_h$.*

Proof. Construct the NUkC solution as follows: for level $1 \le t \le h$ and every vertex $w \in N \cap L_t$, place the center at $\psi_t(w)$ of radius $2r_{\ge t}$. We claim that every point in X is covered by some ball. Indeed, for any $p \in X$, look at the leaf $v = \psi_{h+1}(p)$, and let $w \in N$ be a node in the root-leaf path. Let $w \in L_t$ for some t. Now observe that $d(p, \psi_t(w)) \le 2r_{\ge t}$;

this is because for any edge (u', v') in the tree where u' is in L_t and is the parent of v', we have that $d(\psi_{t+1}(v'), \psi_{t+1}(u')) < 2r_t$. ◀

This completes the reduction, and we now prove a few results using this.

▶ **Theorem 11.** *There is a polynomial time $(\mathcal{O}(\log^* n), 8)$-bi-criteria algorithm for* NUkC.

Proof. Given any instance $\mathcal{I}$ of NUkC, we first club the radii to the nearest power of 2 to get an instance $\mathcal{I}'$ with radii $(k_1, r_1), \cdots, (k_h, r_h)$ such that an (a, b)-factor solution for $\mathcal{I}'$ is an $(a, 2b)$-solution for $\mathcal{I}$. Now, by scaling, we assume that the optimal dilation for $\mathcal{I}'$ is 1; we let x be the feasible solution to the NUkC LP. Then, using Algorithm 1, we can construct the tree $\mathcal{I}'_T$ and a feasible solution y to the RMFC-T LP. We can now use the following theorem of Chalermsook and Chuzhoy [4]: given any feasible solution to the RMFC-T LP, we can obtain a feasible set N covering all the leaves such that for all t, $|N \cap L_t| \leq \mathcal{O}(\log^* n)k_t$. Finally, we can apply Lemma 10 to obtain a $(\mathcal{O}(\log^* n), 4)$ solution to $\mathcal{I}'$ (since $r_{\geq t} \leq 2r_t$). ◀

Proof of Theorem 4 and Theorem 5. We use the following claim regarding the integrality gap of RMFC-T LP for depth 2 trees.

▶ **Claim 3.** *When $h = 2$ and k_t's are integers, given any fractional solution to* RMFC-T *LP, we can find a feasible integral solution as well.*

Proof. Given a feasible solution y to RMFC-T LP, we need to find a set N such that $|N \cap L_t| \leq k_t$ for $t = 1, 2$. There must exist at least one vertex $w \in L_1$ such that $y_w \in (0, 1)$ for otherwise the solution y is trivially integral. If only one vertex $w \in L_1$ is fractional, then since k_1 is an integer, we can raise this y_w to be an integer as well. So at least two vertices w and w' in L_1 are fractional. Now, without loss of generality, let us assume that $|C(w)| \geq |C(w')|$, where $C(w)$ is the set of children of w. Now for some small constant $0 < \epsilon < 1$, we do the following: $y'_w := y_w + \epsilon$, $y'_{w'} := y_{w'} - \epsilon$, $\forall c \in C(w)$, $y'_c := y_c - \epsilon$, and $\forall c \in C(w')$, $y'_c := y_c + \epsilon$. Note that $y(L_1)$ remains unchanged, $y(L_2)$ can only decrease, and root-leaf paths still add to at least 1. We repeat this till we rule out all fractional values. ◀

To see the proof of Theorem 4, note that an instance of the k-center with outliers problem is an NUkC instance with $(k, 1), (\ell, 0)$, that is, $r_1 = 1$ and $r_2 = 0$. We solve the LP relaxation and obtain the tree and an RMFC-T solution. The above claim implies a feasible integral solution to RMFC-T since $h = 2$, and finally note that $r_{\geq 1} = r_1$ for kCwO, implying we get a 2-factor approximation.

The proof of Theorem 5 is similar. If $r_1 < \theta r_2$ where $\theta = (\sqrt{5} + 1)/2$, then we simply run k-center with $k = k_1 + k_2$. This gives a $2\theta = \sqrt{5} + 1$-approximation. Otherwise, we apply Lemma 10 to get a $2(1 + \frac{1}{\theta}) = \sqrt{5} + 1$-approximation. ◀

We end this section with a general theorem, which is an improvement over Lemma 10 in the case when many of the radius types are close to each other, in which case $r_{\geq t}$ could be much larger than r_t. Indeed, the natural way to overcome this would be to group the radius types into geometrically increasing values as we did in the proof of Theorem 11. However, for some technical reasons we will not be able to bucket the radius types in the following section, since we would instead be bucketing the *number of balls* of each radius type in a geometric manner. Instead, we can easily modify Algorithm 1 to build the tree by focusing only on radius types where the radii grow geometrically.

▶ **Theorem 12.** *Given an* NUkC *instance $\mathcal{I} = \{M = (X, d), (k_1, r_1), (k_2, r_2), \ldots, (k_h, r_h)\}$ and an LP solution x for* NUkC *LP, there is an efficient reduction which generates an* RMFC-T *instance $\mathcal{I}_T$ and an LP solution y to* RMFC-T *LP, such that the following holds:*

(i) *For any two tree vertices $w \in L_t$ and $v \in L_{t'}$ where w is an ancestor of v (which means $t \leq t'$), suppose p and q are the corresponding points in the metric space, i.e., $p = \psi_t(w)$ and $q = \psi_{t'}(v)$, then it holds that $d(p,q) \leq 8 \cdot r_t$.*

(ii) *Suppose there exists a feasible solution N to $\mathcal{I}_T$ such that for all $1 \leq t \leq h$, $|N \cap L_t| \leq \alpha k_t$. Then there is a solution to the* NUkC *instance $\mathcal{I}$ that opens, for each $1 \leq t \leq h$, at most αk_t balls of radius at most $8 \cdot r_t$.*

4 Getting an $(O(1), O(1))$-approximation algorithm

In this section, we improve our approximation factor on the number of clusters from $O(\log^* n)$ to $O(1)$, while maintaining a constant-approximation in the radius dilation. As mentioned in the introduction, this requires more ideas since using NUkC LP one cannot get any factor better than $(O(\log^* n), O(1))$-bi-criteria approximation since any integrality gap for RMFC-T LP translates to a $(\Omega(\log^* n), \Omega(1))$ integrality gap for NUkC LP.

Our algorithm is heavily inspired by the recent paper of Adjiashvili et al [1] who give an $O(1)$-approximation for the RMFC-T problem. In fact, the structure of our algorithms follows the same three "steps" of their algorithm. Given an RMFC-T instance, in [1] the authors first "compress" the input tree to get a new tree whose depth is only logarithmic; next, they give a partial rounding result which saves "bottom heavy" leaves, that is, leaves which are fractionally covered to at least a constant fraction by low level tree nodes; and finally, they give a clever *partial enumeration algorithm* for guessing the nodes from the top levels chosen by the optimum solution. We also proceed in these three steps with the first two being very similar. However, the enumeration step requires new ideas for our problem. In particular, the enumeration procedure in [1] crucially uses the tree structure of the firefighter instance, and the way our reduction generates the tree for the RMFC-T instance is by using the optimal LP solution for the NUkC instance, which in itself suffers from the $\Omega(\log^* n)$ integrality gap. Therefore, we need to devise a more sophisticated enumeration scheme inspired by the one in [1]. Throughout this section, we do not optimize for the constants.

4.1 Part I: Radii Reduction

In this part, we describe a preprocessing step which decreases the number of types of radii. This is similar to Theorem 5 in [1].

▶ **Theorem 13.** *Let $\mathcal{I}$ be an* NUkC *instance with radii $\{r_1, r_2, \cdots, r_k\}$. We can efficiently compute instance $\widehat{\mathcal{I}}$ with radii multiplicities $(k_0, \widehat{r}_0), ..., (k_L, \widehat{r}_L)$ and $L = \Theta(\log k)$ such that:*

(i) *$k_i := 2^i$ for all $0 \leq i < L$ and $k_L \leq 2^L$.*

(ii) *If the* NUkC *instance $\mathcal{I}$ has a feasible solution, then there exists a feasible solution for $\widehat{\mathcal{I}}$.*

(iii) *Given an (α, β)-bi-criteria solution to $\widehat{\mathcal{I}}$, we can efficiently obtain a $(3\alpha, \beta)$-bi-criteria solution to $\mathcal{I}$.*

Proof. For an instance $\mathcal{I}$, we construct the compressed instance $\widehat{\mathcal{I}}$ as follows. Partition the radii into $\Theta(\log k)$ classes by defining barriers at $\widehat{r}_i = r_{2^i}$ for $0 \leq i \leq \lfloor \log k \rfloor$. Now to create instance $\widehat{\mathcal{I}}$, we simply round up all the radii r_j for $2^i \leq j < 2^{i+1}$ to the value $\widehat{r}_i = r_{2^i}$. Notice that the multiplicity of $\widehat{r}_i$ is precisely 2^i (except maybe for the last bucket, where there might be fewer radii rounded up than the budget allowed).

Property (i) follows by construction. Property (ii) follows from the way we rounded up the radii. Indeed, if the optimal solution for $\mathcal{I}$ opens a ball of radius r_j around a point p,

then we can open a ball of radius $\widehat{r}_i$ around p, where i is such that $2^i \le j < 2^{i+1}$. Clearly the number of balls of radius $\widehat{r}_i$ is at most 2^i since OPT uses at most one ball of each radius r_j.

For property (iii), suppose we have a solution $\widehat{S}$ for $\widehat{\mathcal{I}}$ which opens $\alpha 2^i$ clusters of radius $\beta\widehat{r}_i$ for all $0 \le i \le L$. Construct a solution S for $\mathcal{I}$ as follows. For each $1 \le i \le L$, let C_i denote the set of centers where $\widehat{S}$ opens balls of radius $\beta\widehat{r}_i$. In the solution S, we also open balls at precisely these centers with 2α balls of radius r_j for every $2^{i-1} \le j < 2^i$. Since $|C_i| \le \alpha \cdot 2^i$, we can open a ball at every point in C_i; furthermore, since $j < 2^i$, we have $r_j \ge \widehat{r}_i$ and so we cover whatever the balls from $\widehat{S}$ covered.

Finally, we also open the α clusters (corresponding to $i = 0$) of radius $\beta r_1 = \beta\widehat{r}_0$ at the respective centers C_0 where $\widehat{S}$ opens centers of radius $\widehat{r}_0$. Therefore, the total number of clusters of radius type is at most 2α with the exception of r_1, which may have 3α clusters. ◀

4.2 Part II: Satisfying Bottom Heavy Points

One main reason why the above height reduction step is useful, is the following theorem from [1] for RMFC-T instances on trees; we provide a proof sketch for completeness.

▶ **Theorem 14** ([1]). *Given a tree T of height h and a feasible solution y to (*RMFC-T *LP), we can find a feasible integral solution N to* RMFC-T *such that for all $1 \le t \le h$, $|N \cap L_t| \le k_t + h$.*

Proof. Let y be a basic feasible solution of (RMFC-T LP). Call a vertex v of the tree *loose* if $y_v > 0$ and the sum of y-mass on the vertices from v to the root (inclusive of v) is < 1. Let V_L be the set of loose vertices of the tree, and let V_I be the set of vertices with $y_v = 1$. Clearly $N = V_L \cup V_I$ is a feasible solution: every leaf-to-root path either contains an integral vertex or at least two fractional vertices with the vertex closer to root being loose. Next we claim that $|V_L| \le h$; this proves the theorem since $|N \cap L_t| \le |V_I \cap L_t| + |V_L| \le k_t + |V_L|$.

The full proof can be found in Lemma 6, [1] – here is a high level sketch. There are $|L| + h$ inequalities in (RMFC-T LP), and so the number of fractional variables is at most $|L| + h$. We may assume there are no $y_v = 1$ vertices. Now, in every leaf-to-root path there must be at least 2 fractional vertices, and the one closest to the leaf must be non-loose. If the closest fractional vertex to each leaf was unique, then that would account for $|L|$ fractional non-loose vertices implying the number of loose vertices must be $\le h$. This may not be true; however, if we look at *linearly independent* set of inequalities that are tight, we can argue uniqueness as a clash can be used to exhibit linear dependence between the tight constraints. ◀

▶ **Theorem 15.** *Suppose we are given an* NUkC *instance $\widehat{\mathcal{I}}$ with radii multiplicities $(k_0, \widehat{r}_0), (k_1, \widehat{r}_1), \ldots, (k_L, \widehat{r}_L)$ with budgets $k_i = 2^i$ for radius type $\widehat{r}_i$, and an LP solution x to* (NUkC LP) *for $\widehat{\mathcal{I}}$. Let $\tau = \log\log L$, and suppose $X' \subseteq X$ be the points covered mostly by small radii, that is, let $\mathsf{Cov}_{\ge\tau}(p) \ge \frac{1}{2}$ for every $p \in X'$. Then, there is an efficient procedure* round *which opens at most $O(k_t)$ balls of radius $O(\widehat{r}_t)$ for $\tau \le t \le L$, and covers all of X'.*

Proof. The procedure round works as follows: we partition the points of X' into two sets, one set X_U in which the points receive at least $\frac{1}{4}$ of the coverage by clusters of radius $\widehat{r}_i$ where $i \in \{\log\log L, \log\log L + 1, \ldots, \log L\}$, and another set X_B in which the points receive $\frac{1}{4}$ coverage from clusters of levels $t \in \{\log L + 1, \log L + 2, \ldots, L\}$. More precisely, $X_U := \{p \in X' : \sum_{t=\tau}^{\log L} \mathsf{Cov}_t(p) \ge 1/4\}$, and $X_B = X' \setminus X_B$.

Now consider the following LP-solution to (NUkC LP) for $\widehat{\mathcal{I}}$ restricted to X_U: we scale x by a factor 4 and zero-out x on radii type $\widehat{r}_i$ for $i \notin \{\log\log L, \ldots, \log L\}$. By definition of X_U this is a feasible fractional solution; furthermore, the LP-reduction algorithm described

in Section 3 will lead to a tree T of height $\leq \log L$ and fractional solution y for (RMFC-T LP) on T were each $k_i \geq 2^{\log\log L} = \log L$. Applying Theorem 14, we can find an integral solution N with at most $O(k_i)$ vertices at levels $i \in \{\log\log L, \ldots, \log L\}$. We can then translate this solution back using Theorem 12 to NUkC and find $O(k_t)$ clusters of radius $O(\widehat{r}_t)$ to cover all the points X_U. A similar argument, when applied to the smaller radius types $\widehat{r}_t$ for $t \in \{\log L, \ldots, L\}$ can cover the points in X_B. ◀

We now show how we can immediately also get a (very weakly) quasi-polynomial time $O(1)$-approximation for NUkC. Indeed, if we could enumerate the set of clusters of radii $\widehat{r}_t$ for $0 \leq t < \log\log L$, we can then explicitly solve an LP where all the uncovered points need to be fractionally covered by only clusters of radius type $\widehat{r}_t$ for $t \geq \log\log L$. We can then round this solution using Corollary 15 to obtain the desired $O(1)$-approximation for the NUkC instance. Moreover, the time complexity of enumerating the optimal clusters of radii $\widehat{r}_t$ for $0 \leq t < \log\log L$ is $n^{O(\log L)} = n^{O(\log\log k)}$, since the number of clusters of radius at least $\widehat{r}_{\log\log L}$ is at most $O(2^{\log\log L}) = O(\log L)$. Finally, there was nothing special in the proof of Corollary 15 about the choice of $\tau = \log\log L$ — we could set $t = \log^{(q)} L$ to be the q^{th} iterated logarithm of L, and obtain an $O(q)$-approximation. As a result, we get the following corollary. Note that this gives an alternate way to prove Theorem 11.

▶ **Corollary 16.** *For any $q \geq 1$, there exists an $(O(q), O(1))$-factor bi-criteria algorithm for* NUkC *which runs in $n^{O(\log^{(q)} k)}$ time.*

4.3 Part III: Clever Enumeration of Large Radii Clusters

In this section, we show how to obtain the $(O(1), O(1))$-factor bi-criteria algorithm. At a high level, our algorithm tries to "guess" the centers[2] A of large radius, that is $\widehat{r}_i$ for $i \leq \tau := \log\log L = \log\log\log k$, which the optimum solution uses. However, this guessing is done in a cleverer way than in Corollary 16. In particular, given a guess which is consistent with the optimum solution (the initial "null set" guess is trivially consistent), our enumeration procedure generates a list of candidate additions to A of size *at most* $2^\tau \approx \text{poly}\log\log k$ (instead of n), one of which is a consistent enhancement of the guessed set A. This reduction in number of candidates also requires us to maintain a guess D of points where the optimum solution *doesn't* open centers. Furthermore, we need to argue that the "depth of recursion" is also bounded by $\text{poly}\log\log k$; this crucially uses the technology developed in Section 3. Altogether, we get the total time is at most $(\text{poly}\log\log k)^{\text{poly}\log\log k} = o(k)$ for large k. In this extended abstract with page limits, we omit all proofs in this subsection, and point the reader to the full version of our paper [3].

We start with some definitions. Throughout, A and D represent sets of tuples of the form (p, t) where $p \in X$ and $t \in \{0, 1, \ldots, \tau\}$. Given such a set A, we associate a partial solution S_A which opens a ball of radius $22\widehat{r}_t$ at the point p for all p s.t. $(p, t) \in A$. For the sake of analysis, fix an optimum solution OPT. We say the set A is **consistent** with OPT if for all $(p, t) \in A$, there exists a *unique* $q \in X$ such that OPT opens a ball of radius $\widehat{r}_t$ at q and $d(p, q) \leq 11\widehat{r}_t$. In particular, this implies that S_A covers all points which this OPT-ball covers. We say the set D is **consistent** with OPT if for all $(q, t) \in D$, OPT *doesn't* open a radius $\widehat{r}_t$ ball at q (it may open a different radius ball at q though). Given a pair of sets

[2] Actually, we end up guessing centers "close" to the optimum centers, but for this introductory paragraph this intuition is adequate.

(A,D), we define the $\mathsf{minLevel}$ of each point p to be the type of largest radius consistent with our guesses which can cover it, i.e.,

$$\mathsf{minLevel}_{A,D}(p) := 1 + \arg\max_t \{(q,t) \in D \text{ for all } q \in B(p, \widehat{r}_t)\}$$

If (A, D) is a consistent pair and $\mathsf{minLevel}_{A,D}(p) = t$, then this implies in the OPT solution, p is covered by a ball of radius $\widehat{r}_t$ or smaller.

Next, we describe a nuanced LP-relaxation for NUkC. Fix a pair of sets (A, D) as described above. Let X_G be the subset of points in X covered by the partial solution S_A. Fix a subset $Y \subseteq X \setminus X_G$ of points. Define the following LP.

$$\begin{aligned}
\forall p \in Y, \quad & \sum_{t=\mathsf{minLevel}(p)}^{L} \sum_{q \in B(p,\widehat{r}_t)} x_{q,t} \geq 1 && (\mathrm{LP}_{\mathsf{NUkC}}(Y, A, D)) \\
\forall t \in 1, \cdots, h \quad & \sum_{q \in Y} x_{q,t} \leq k_t \\
\forall (p,t) \in A, \quad & x_{p,t} = 1
\end{aligned}$$

The following claim encapsulates the utility of the above relaxation.

▶ **Claim 4.** *If (A, D) is consistent with OPT, then $LP_{\mathsf{NUkC}}(X \setminus X_G, A, D)$ is feasible.*

Finally, for convenience, we define a **forbidden set** $F := \{(p, i) : p \in X, 1 \leq i \leq \tau\}$ which if added to D disallows any large radii balls to be placed anywhere.

Now we are ready to describe the enumeration Algorithm 2. We start with A and D being null, and thus vacuously consistent with OPT. The enumeration procedure ensures that: given a consistent (A, D) tuple, either it finds a good solution using LP rounding (Step 10), or generates candidate additions (Steps 18–20) to A or D ensuring that one of them leads to a larger consistent tuple.

Define $\gamma_0 := 4 \log\log k \cdot \log\log\log k$. The algorithm is run with $\mathsf{Enum}(\emptyset, \emptyset, \gamma_0)$. The proof that we get a polynomial time $(O(1), O(1))$-bi-criteria approximation algorithm follows from three lemmas. Lemma 17 shows that if Step 10 is true with a consistent pair (A, D), then the output in Step 13 is a $(O(1), O(1))$-approximation. Lemma 18 shows that indeed Step 10 is true for γ_0 as set. Finally, Lemma 19 shows that the algorithm runs in polynomial time.

▶ **Lemma 17.** *If (A, D) is a consistent pair such that Step 10 is true, then the solution returned is an $(O(1), O(1))$-approximation algorithm.*

▶ **Lemma 18.** $\mathsf{Enum}(\emptyset, \emptyset, \gamma_0)$ *finds consistent (A, D) such that Step 10 is true.*

▶ **Lemma 19.** $\mathsf{Enum}(\emptyset, \emptyset, \gamma_0)$ *runs in polynomial time for large enough k.*

Algorithm 2 $\mathsf{Enum}(A, D, \gamma)$

Let $X_G = \{p : \exists\,(q,i) \in A \text{ s.t } d(p,q) \leq 22\widehat{r}_i\}$ denote points covered by S_A.
if there is **no** feasible solution to $LP_{\mathsf{NUkC}}(X \setminus X_G, A, D)$ **then**
  Abort. *// Claim 4 implies (A, D) is not consistent.*
else
  Let x^* be a feasible solution to $LP_{\mathsf{NUkC}}(X \setminus X_G, A, D)$.
end if
Let $X_B = \{u \in X \setminus X_G : \mathsf{Cov}_{\geq\tau}(u) \geq \frac{1}{2}\}$ denote bottom-heavy points in x^*
Let S_B be the solution implied by Corollary 15.
// This solution opens $O(k_t)$ balls of radius $O(\widehat{r}_t)$ for $\tau \leq t \leq L$ and covers all of X_B.
Let $X_T = X \setminus (X_G \cup X_B)$ denote the top heavy points in x^*
if $LP_{\mathsf{NUkC}}(X_T, A, F \cup D)$ has a feasible solution x_T **then**
  By definition of F, in x_T we have $\mathsf{Cov}_{\geq\tau}(u) = 1$ for all $u \in X_T$.
  Let S_T be the solution implied by Corollary 15.
  // This solution opens $O(k_t)$ balls of radius $O(\widehat{r}_t)$ for $\tau \leq t \leq L$ and covers all of X_T.
  Output $(S_A \cup S_B \cup S_T)$. *//This is a $(O(1), O(1))$-approximation for the* NUkC *instance.*
else
  for every level $0 \leq t \leq \tau$ **do**
    Let $C_t = \{p \in X_T \text{ s.t } \mathsf{minLevel}_{A,D}(p) = t\}$, the set of points in X_T with minLevel t.
    Use the LP-aware reduction from Section 3 using x^* and the set of points C_t to create tree T_t.
    for every winner p at level t in T_t **do**
      $\mathsf{Enum}(A \cup \{(p,t)\}, D, \gamma - 1)$
      $\mathsf{Enum}(A, D \cup \bigcup_{p' \in B(p, 11\widehat{r}_t)} \{(p', t)\}), \gamma - 1)$
    end for
  end for
end if

Abstract

The k-center problem is a canonical and long-studied facility location and clustering problem with many applications in both its symmetric and asymmetric forms. Both versions of the problem have tight approximation factors on worst case instances: a 2-approximation for symmetric k-center and an O(log*(k))-approximation for the asymmetric version. Therefore to improve on these ratios, one must go beyond the worst case.

In this work, we take this approach and provide strong positive results both for the asymmetric and symmetric k-center problems under a very natural input stability (promise) condition called alpha-perturbation resilience [Bilu Linial, 2012], which states that the optimal solution does not change under any alpha-factor perturbation to the input distances. We show that by assuming 2-perturbation resilience, the exact solution for the asymmetric k-center problem can be found in polynomial time. To our knowledge, this is the first problem that is hard to approximate to any constant factor in the worst case, yet can be optimally solved in polynomial time under perturbation resilience for a constant value of alpha. Furthermore, we prove our result is tight by showing symmetric k-center under (2-epsilon)-perturbation resilience is hard unless NP=RP. This is the first tight result for any problem under perturbation resilience, i.e., this is the first time the exact value of alpha for which the problem switches from being NP-hard to efficiently computable has been found.

Our results illustrate a surprising relationship between symmetric and asymmetric k-center instances under perturbation resilience. Unlike approximation ratio, for which symmetric k-center is easily solved to a factor of 2 but asymmetric k-center cannot be approximated to any constant factor, both symmetric and asymmetric k-center can be solved optimally under resilience to 2-perturbations.

1 Introduction

Overview: Traditionally, the theory of algorithms has focused on the analysis of worst-case instances. While this approach has led to many elegant algorithms and strong lower bounds, it tends to be overly pessimistic of an algorithm's performance on the most typical instances of a problem. A recent line of work in the algorithms community, the so called *beyond worst case analysis* of algorithms, considers the question of designing algorithms for instances that satisfy some natural structural properties and has given rise to strong positive results [4, 5, 6, 18, 20, 21, 24]. One of the most appealing properties that has been proposed in this space is the stability of the solution to small changes in the input. Bilu and Linial [10] formalized this property in the notion of α-*perturbation resilience*, which states that the optimal solution does not change under any α-factor perturbation to the input distances.

A large body of work has sought to exploit the power of perturbation resilience in problems such as center-based clustering [5, 8, 10, 22], finding Nash equilibria in game theoretic problems [7], and the traveling salesman problem [23]. These works are focused on providing positive results for exactly solving the corresponding optimization problem under perturbation resilient instances, for example, $1+\sqrt{2}$-perturbation resilience for center based clustering, and $O(\sqrt{\log n}\log\log n)$-perturbation resilience for max-cut. In this paper we continue this line of work and provide a tight result for the canonical and long-studied k-center clustering problem, thereby completely quantifying the power of perturbation resilience for this problem. We show that $\alpha = 2$ is the moment where the problem switches from NP-hard to efficiently computable – specifically, we show that by assuming 2-perturbation resilience, the exact solution for the k-center problem can be found in polynomial time; we also show that k-center under $(2-\epsilon)$-perturbation resilience cannot be solved in polynomial time unless $NP = RP$. Our results apply to both symmetric and asymmetric k-center, illustrating a surprising relationship between symmetric and asymmetric k-center instances under perturbation resilience. Unlike approximation ratio, for which symmetric k-center is easily solved to a factor of 2 but asymmetric k-center cannot be approximated to any constant factor, both symmetric and asymmetric k-center can be solved optimally under resilience to 2-perturbations. Overall, this is the first tight result quantifying the power of perturbation resilience for a canonical combinatorial optimization problem.

The k-center problem is a canonical and long-studied clustering problem with many applications to facility location, data clustering, image classification, and information retrieval [11, 12, 13, 14, 16, 25]. For example, it can be used to solve the problem of placing k fire stations spaced throughout a city to minimize the maximum time for a fire truck to reach any location, given the pairwise travel times between important locations in the city. In the symmetric k-center problem the distances are assumed to be symmetric, while in the asymmetric k-center problem they are not; however in both cases they satisfy the triangle inequality. Formally, given a set of n points S, a distance function $d : S \times S \to R^+$ satisfying the triangle inequality (and symmetry in the symmetric case), and an integer k, our goal is to find k centers $\{c_1, \ldots, c_k\}$ to minimize $\max_{p\in S} \min_i d(c_i, p)$.

Both forms of k-center admit tight approximation bounds. For symmetric k-center, several 2- approximation algorithms have been found starting in the mid 1980s (e.g., [16, 19]). This is the best possible approximation factor by a simple reduction from set cover. On the other hand, the asymmetric k-center problem is a prototypical problem where the best known approximation is superconstant and is matched by a lower bound. For the asymmetric k-center problem, an $O(\log^*(n))$-approximation algorithm was found by Vishwanathan [25], and later improved to $O(\log^*(k))$ by Archer [1]. This approximation ratio was shown to be

asymptotically tight by the work of Chuzhoy et al. [14], which built upon a sequence of papers establishing the hardness of approximating d-uniform hypergraph covering (culminating in [15]).

Perturbation resilience has a natural interpretation for both symmetirc and asymmetric k-center: it can be viewed as a stability condition in the presence of uncertainties involved in measurements. For example, small fluctuations in the travel time between a fire station and locations in the city, which are caused by different levels of traffic at different times of day, should not drastically affect the optimal placement of fire stations. Furthermore, perturbation resilience can be viewed as a condition on an instance under which the optimal solution satisfies a form of privacy. For instance, if the actions of no individuals (such as how they drive to work, or the amount of network traffic they are using in a network application) can affect the overall state of the problem drastically then the individual's actions cannot be detected by looking at the optimal solution.

There is a large body of work on instances satisfying perturbation resilience and other natural notions of stability on problems ranging from clustering to data privacy to social networks to topic modeling [2, 3, 17, 18, 20, 21, 24]. For discussion of related work, see the full version of the paper.

Our Results: In this work we consider both symmetric and asymmetric k-center under perturbation resilience and give tight results for both forms. In addition, we consider more robust and weaker variants of perturbation resilience, and give strong results for these problems as well. A summary of our results and techniques used to achieve them are as follows:

1. *Efficient algorithm for symmetric and asymmetric k-center under 2-perturbation resilience.* This directly improves over the result of Balcan and Liang [8] for symmetric k-center under $1+\sqrt{2}$-perturbation resilience. We show that *any* α-approximation algorithm returns the optimal solution for an α-perturbation resilient instance, thus showing there exists an optimal algorithm for symmetric k-center under 2-perturbation resilience. For the asymmetric result, we first construct a "symmetrized set" by only considering points that demonstrate a rough symmetry. Then we prove strong structural results about the symmetrized set which motivates a novel algorithm for detecting clusters locally.
2. *Hardness of symmetric k-center under $(2-\epsilon)$-perturbation resilience.* This shows that our perturbation-resilience results are tight for both symmetric and asymmetric k-center. For this hardness result, we use a reduction from a variant of perfect dominating set. To show that this variant is itself hard, we construct a chain of parsimonious reductions (reductions which conserve the number of solutions) from 3-dimensional matching to perfect dominating set.
3. *Efficient algorithms for symmetric and asymmetric k-center under $(3,\epsilon)$-perturbation resilience.* A clustering instance satisfies (α,ϵ)-perturbation resilience if $\leq \epsilon n$ points switch clusters under any α-perturbation. We assume the optimal clusters are of size $> 2\epsilon n$ (the problem is NP-hard without this assumption). We show that if any single point p is close to an optimal cluster other than its own, then $k-1$ centers achieve the optimal score under a carefully constructed 3-perturbation. Any other point we add to the set of centers must create a clustering that is ϵ-close to $\mathcal{OPT}$, and we show all of these sets cannot simultaneously be consistent with one another, thus causing a contradiction. A key concept in our analysis is defining the notion of a *cluster-capturing center*, which allows us to reason about which points can capture a cluster when its center is removed.
4. *Efficient algorithm for any center-based clustering objective under weak center proximity.* Weak center proximity asks that each point be closer to its own center than to any point

from any other cluster, but note that it allows a cluster center to be closer to points from different clusters than to its own. Thus it is not at all obvious whether efficient optimal clustering is possible in such a setting. We present a novel linkage-based algorithm that is able to do so. It works by iteratively running single linkage as a subroutine until all clusters are balanced, and then removing all but the very last link.

The novelty of our results are manifold. First, our work is the first to provide a tight perturbation resilience result, thereby painting the complete picture for k-center under perturbation resilience. Second, this is the first result where a problem is not approximable to any constant in the worst-case, but can be optimally solved under resilience to small constant perturbations. Third, we are the first to consider an asymmetric problem under stability. Our results here illustrate a stark contrast between worst-case analysis and analysis of algorithms under stability. Unlike approximation ratio, for which symmetric k-center is easily solved to a factor of 2 but asymmetric k-center cannot be approximated to any constant factor, both symmetric and asymmetric k-center can be solved optimally under the same constant level of resilience.

2 Preliminaries

We define a clustering instance as (S, d), where S is a set of n points and $d : S \times S \to \mathbb{R}_{\geq 0}$ is a distance function. In the k-center problem, the goal is to find a set of points $\vec{p} = \{p_1, \ldots, p_k\} \subseteq S$ called *centers* such that the maximum distance from any point to its closest center is minimized. More formally, in the k-center problem, given a Voronoi partition $\mathcal{P} = \{P_1, \ldots, P_k\}$ induced by a set of centers $\vec{p} = \{p_1, \ldots, p_k\}$ (where for all $1 \leq i \leq k$, $p_i \in P_i$), we refer to $\mathcal{P}$ as a clusering, and define its cost by $\Phi(\mathcal{P}) = \max_{i \in [k]} \max_{v \in P_i} d(p_i, v)$. We indicate by $\mathcal{OPT}$ the clustering $\{C_1, \ldots, \mathcal{C}_k\}$ with minimum cost, we denote the optimal centers $\{c_1, \ldots, c_k\}$, and we denote the optimal cost $\Phi(\mathcal{OPT})$ by r^*, the maximum cluster radius.

We study the k-center clustering of instance (S, d) under two types of distance functions, *symmetric* and *asymmetric*. A symmetric distance function is a metric. An asymmetric distance function satisfies all the properties of a metric space, except for symmetry. That is, it may be the case that for some $p, q \in S$, $d(p, q) \neq d(q, p)$. Note that the k-center objective function for asymmetric instances is the same as the symmetric case, the maximum distance *from the center to the points*, where the order now matters.

We consider *perturbation resilience*, a notion of stability introduced by Bilu & Linial [10]. Perturbation resilience implies that the optimal clustering does not change under small perturbations of the distance measure. Formally, d' is called an α-perturbation of distance function d, if for all $p, q \in S$, $d(p, q) \leq d'(p, q) \leq \alpha d(p, q)$.[1] Perturbation resilience is defined formally as follows.

▶ **Definition 1.** A clustering instance (S, d) satisfies *α-perturbation resilience* for k-center, if for any α-perturbation d' of d, the optimal k-center clustering under d' is unique and equal to $\mathcal{OPT}$.

Note that the optimal centers may change, but the Voronoi partition $C_1, \ldots, C_k$ induced by them must stay the same. We do *not* assume that d' satisfies the triangle inequality.[2] We

[1] WLOG, we only consider perturbations in which the distances increases because we can scale the distances to simulate decreasing distances.

[2] This is well-justified, as the data may be gathered from heuristics or an average of measurements.

also consider a more robust variant of α-perturbation resilience, called (α, ϵ)-perturbation resilience, that allows a small change in the optimal clustering when distances are perturbed. To this end, we say that two clusterings $\mathcal{C}$ and $\mathcal{C}'$ are ϵ-*close*, if only an ϵ-fraction of the input points are clustered differently in the two clusterings, i.e., $\min_\sigma \sum_{i=1}^{k} |C_i \setminus C'_{\sigma(i)}| \leq \epsilon n$, where σ is a permutation on $[k]$. Formally,

▶ **Definition 2.** A clustering instance (S, d) satisfies (α, ϵ)-*perturbation resilience* for k-center, if for any α-perturbation d' of d, any optimal k-center clustering $\mathcal{C}'$ under d' is ϵ-close to $\mathcal{OPT}$.

We use ϵ-*far* to denote two clusters which are not ϵ-close. We also discuss the strictly stronger notion of approximation stability [6], which requires *any* α-approximation (not just a Voronoi partition) to be ϵ-close to $\mathcal{OPT}$. This is formally defined in Section 3.3. In Section 5, we define *center-based* objectives [8], a more general class of clustering functions which includes objective functions such as k-center, k-median, and k-means. Throughout this work, we use $B_r(c)$ to denote a ball of radius r centered at point r. Also for a point p and a set D, $d(p, D)$ denotes the distance from p to the farthest point in D.

3 2-perturbation resilience

In this section, we provide efficient algorithms for finding $\mathcal{OPT}$ for symmetric and asymmetric instances of k-center under 2-perturbation resilience. Our result directly improves on the result of Balcan and Liang for symmetric k-center under $(1 + \sqrt{2})$-perturbation resilience [8]. We also show that it is NP-hard to recover $\mathcal{OPT}$ even in the symmetric k-center instance under $(2 - \epsilon)$-approximation stability. As an immediate consequence, our results are tight for both perturbation resilience and approximation stability, for symmetric and asymmetric k-center instances. This is the first problem for which the exact value of perturbation resilience is found ($\alpha = 2$), where the problem switches from efficiently computable to NP-hard.

In the remainder of this section, first we show that any α-approximation algorithm returns the optimal solution for α-perturbation resilient instances. An immediate consequence is an algorithm for symmetric k-center under 2-perturbation resilience. Then we provide a novel algorithm for asymmetric k-center under 2-perturbation resilience.

3.1 Approximation algorithms under perturbation resilience

The following lemma allows us to reason about a specific type of α-perturbation we construct. This lemma will be important throughout the analysis in this section and in Section 4.

▶ **Lemma 3.** *For all $\alpha \geq 1$, given an α-perturbation d' of d with the following property: for all p, q, if $d(p, q) \geq r^*$ then $d'(p, q) \geq \alpha r^*$. Then the optimal cost under d' is αr^*.*

Proof. Clearly the optimal cost under d' cannot be greater than αr^*, since d' is an α-perturbation. Suppose there exists a set of centers $c'_1, \ldots, c'_k$ under d' that achieves a cost $< \alpha r^*$. Then for all i and all $p \in C'_i$, $d'(c'_i, p) < \alpha r^*$. But then by assumption, $d(c'_i, p) < r^*$. This implies that $c'_1, \ldots, c'_k$ achieve an optimal cost $< r^*$ under d, which is a contradiction. ◀

The following theorem will imply that any α-approximation algorithm for k-center will return the optimal solution on clustering instances that are α-perturbation resilient.

▶ **Theorem 4.** *Given a clustering instance (S, d) satisfying α-perturbation resilience for asymmetric k-center. Given a set C of k centers which is an α-approximation, i.e., $\forall p \in S$, $\exists c \in C$ s.t. $d(c, p) \leq \alpha r^*$. Then the Voronoi partition induced by C is the optimal clustering.*

Proof. For a point $p \in S$, let $c(p) := \text{argmin}_{c \in C} d(c, p)$, the closest center in C to p. The idea is to construct an α-perturbation in which C is the optimal solution by increasing all distances except between p and $c(p)$, for all p. Then the theorem will follow by using the definition of perturbation resilience.

By assumption, $\forall p \in S$, $d(c(p), p) \leq \alpha r^*$. Create a perturbation d' as follows. Increase all distances by a factor of α, except for all $p \in S$, set $d'(c(p), p) = \min(\alpha d(c(p), p), \alpha r^*)$ (recall in Definition 1, the perturbation need not satisfy the triangle inequality). Then no distances were increased by more than a factor of α. And since we had that $d(c(p), p) \leq \alpha r^*$, no distances decrease either. Therefore, d' is an α-perturbation of d. By Lemma 3, the optimal cost for d' is αr^*. Also, C achieves cost $\leq \alpha r^*$ by construction, so C is an optimal set of centers under d'. Then by α-perturbation resilience, the Voronoi partition induced by C under d' is the optimal clustering.

Finally, we show the Voronoi partition of C under d is the same as the Voronoi partition of C under d'. Given $p \in S$ whose closest point in C is $c(p)$ under d, then under d', all distances from p to $C \setminus \{c(p)\}$ increased by exactly α, and $d(p, c(p))$ increased by $\leq \alpha$. Therefore, the closest point in C to p under d' is still $c(p)$. ◀

An immediate consequence is that we have exact algorithms for symmetric k-center under 2-perturbation resilience, and asymmetric k-center under $O(\log^*(k))$-perturbation resilience. Now we show it is possible to substantially improve the latter result.

3.2 Asymmetric k-center algorithm

One of the challenges involved in dealing with asymmetric k-center instances is the fact that even though for all $p \in C_i$, $d(c_i, p) \leq r^*$, $d(p, c_i)$ might be arbitrarily large. Such points for which $d(p, c_i) \gg r^*$ pose a challenge to the structure of the clusters, as they can be very close to points or even centers of other clusters. To deal with this challenge, we first define a set of "good" points, A, such that $A = \{p \mid \forall q, d(q, p) \leq r^* \implies d(p, q) \leq r^*\}$. Intuitively speaking, these points behave similarly to a set of points with symmetric distances up to a distance r^*. To explore this, we define a desirable property of A with respect to the optimal clustering.

▶ **Definition 5.** A is said to *respect the structure of* $\mathcal{OPT}$ if (1) $c_i \in A$ for all $i \in [k]$, and (2) for all $p \in S \setminus A$, if $A(p) := \arg\min_{q \in A} d(q, p) \in C_i$, then $p \in C_i$.

For all i, define $C'_i = C_i \cap A$ (which is in fact the optimal clustering of A, although we do not need to prove this). Satisfying Definition 5 implies that if we can optimally cluster A, then we can optimally cluster the entire instance (formalized in Theorem 8). Thus our goal is to show that A does indeed respect the structure of $\mathcal{OPT}$, and to show how to return $C'_1, \ldots, C'_k$.

Intuitively, A is similar to a symmetric 2-perturbation resilient clustering instance. However, some structure is no longer there, for instance, a point p may be at distance $\leq 2r^*$ from every point in a different cluster, which is not true for 2-perturbation resilient instances. This implies we cannot simply run a 2-approximation algorithm on the set A, as we did in the previous section. However, we show that the remaining structural properties are sufficient to optimally cluster A. To this end, we define two properties and show how they lead to an algorithm that returns $C'_1, \ldots, C'_k$, and help us prove that A respects the structure of $\mathcal{OPT}$.

The first of these properties requires each point to be closer to its center than any point in another cluster. That is, *Property (1): For all $p \in C'_i$ and $q \in C'_j$, $i \neq j$, $d(c_i, p) < d(q, p)$.*

The second property requires that any point within distance r^* of a cluster center belongs to that cluster. That is, *Property (2): For all $i \neq j$ and $q \in C_j$, $d(q, c_i) > r^*$.*[3]

Let us illustrate how these properties allow us to optimally cluster A.[4] Consider a ball of radius r^* around a center c_i. By Property 2, such a ball exactly captures C'_i. Furthermore, by Property 1, any point in this ball is closer to the center than to points outside of the ball. Is this true for a ball of radius r^* around a general point p? Not necessarily. If this ball contains a point $q \in C'_j$ from a different cluster, then q will be closer to a point outside the ball than to p (namely, c_j, which is guaranteed to be outside of the ball by Property 2). This allows us to determine that the center of such a ball must not be an optimal center.

This structure motivates our Algorithm 1 for asymmetric k-center under 2-perturbation resilience. At a high level, we start by constructing the set A (which can be done easily in polynomial time). Then we create the set of all balls of radius r^* around all points in A (if r^* is not known, we can use a guess-and-check wrapper). Next, we prune this set by throwing out any ball that contains a point farther from its center than to a point outside the ball. We also throw out any ball that is a subset of another one. Our claim is that the remaining balls are exactly $C'_1, \ldots, C'_k$. Finally, we add the points in $S \setminus A$ to their closest point in A.

Algorithm 1 Asymmetric k-center algorithm under 2-PR

Input: Asymmetric k-center instance (S, d), distance r^* (or try all possible candidates).

1. Build set $A = \{p \mid \forall q, d(q, p) \leq r^* \implies d(p, q) \leq r^*\}$
2. $\forall c \in A$, construct $G_c = B_{r^*}(c)$ (the ball of radius r^* around c).
3. $\forall G_c$, if $\exists p \in G_c$, $q \notin G_c$ s.t. $d(q, p) < d(c, p)$, then throw out G_c.
4. $\forall p, q$ s.t. $G_p \subseteq G_q$, throw out G_p.
5. $\forall p \notin A$, add p to G_q, where $q = \arg\min_{s \in A} d(s, p)$.

Output: Output the sets $G_1, \ldots, G_k$.

▶ **Lemma 6.** *Properties 1 & 2 hold for asymmetric k-center instances under 2-perturbation resilience.*

Proof sketch. For Property 2, assume that there exists c_i and $q \in C_j$, $i \neq j$, such that $d(q, c_i) \leq r^*$. We construct a 2-perturbation in which q becomes the center for C_i. Increase all distances by a factor of 2, except for the distances from q to C_i, which we increase until they reach $2r^*$. By Lemma 3, this 2-perturbation achieves a cost of $2r^*$. However, q is distance $2r^*$ to C_i, so it must replace c_i as an optimal center. Then q and c_j are no longer in the same cluster, causing a contradiction.

The first property was shown to hold for symmetric instances by Awasthi et al. and the same proof can be used for asymmetric instances. This proof appears in the full version. ◀

▶ **Lemma 7.** *A respects the structure of $\mathcal{OPT}$.*

We defer this proof to the full version of the paper.

[3] Property (1) first appeared in the work of Awasthi et al. [5], for symmetric clustering instances. A weaker variation of Property (2) was introduced by Balcan and Liang [8], which showed that in $1 + \sqrt{2}$-perturbation resilient instances for any cluster C_i with radius r_i, $B_{r_i}(c_i) = C_i$. Our Property (2) shows that this is true *for a universal radius, r^**, even for 2-perturbation resilient instances, *and* even for asymmetric instances.

[4] Other algorithms work, such as single linkage with dynamic programming at the end to find the minimum cost pruning of k clusters. However, our algorithm is able to recognize optimal clusters *locally* (without a complete view of the point set).

▶ **Theorem 8.** *Algorithm 1 returns the exact solution for asymmetric k-center under 2-perturbation resilience.*

Proof. First we must show that after step 4, the remaining sets are exactly $C'_1, \ldots, C'_k = C_1 \cap A, \ldots, C_k \cap A$. We prove this in three steps: the sets G_{c_i} correspond to C'_i, these sets are not thrown out in steps 3 and 4, and all other sets are thrown out in steps 3 and 4. Because of Lemma 6, we can use Properties 1 and 2.

For all i, $G_{c_i} = C'_i$: From Lemma 7, all centers are in A, so G_{c_i} will be created in step 2. For all $p \in C_i$, $d(c_i, p) \leq r^*$. For all $q \notin C'_i$, then by Property 2, $d(q, c_i) > r^*$ (and since $c_i, q \in A$, $d(c_i, q) > r^*$ as well). For all i, G_{c_i} is not thrown out in step 3: Given $s \in G_{c_i}$ and $t \notin G_{c_i}$. Then $s \in C'_i$ and $t \in C'_j$ for $j \neq i$. If $d(t, s) < d(c_i, s)$, then we get a contradiction from Property 1. For all non-centers p, G_p is thrown out in step 3 or 4: From the previous paragraph, $G_{c_i} = C'_i$. If $G_p \subseteq G_{c_i}$, then G_p will be thrown out in step 4 (if $G_p = G_{c_i}$, it does not matter which set we keep, so WLOG say that we keep G_{c_i}). Then if G_p is not thrown out in step 4, $\exists s \in G_p \cap C'_j$, $j \neq i$. If $s = c_j$, then $d(p, c_j) \leq r^*$ and we get a contradiction from Property 2. So, we can assume s is a non-center (and that $c_j \notin G_p$). But $d(c_j, s) < d(p, s)$ from Property 1, and therefore G_p will be thrown out in step 3. Thus, the remaining sets after step 4 are exactly $C'_1, \ldots, C'_k$.

Finally, by Lemma 7, for each $p \in C_i \setminus A$, $A(p) \in C_i$, so p will be added to G_{c_i}. Therefore, the final output is $C_1, \ldots, C_k$. ◀

3.3 Hardness for k-center under $(2 - \epsilon)$-approximation stability

In this section, we consider approximation stability, introduced by Balcan et al. [6], which is strictly stronger than perturbation resilience. We show that if symmetric k-center under $(2-\epsilon)$-approximation stability can be solved in polynomial time, then $NP = RP$, even under the condition that the optimal clusters are all $\geq \frac{n}{2k}$. Because approximation stability is stronger than perturbation resilience, this result implies k-center under $(2 - \epsilon)$-perturbation resilience is hard as well. Similarly, symmetric k-center is a special case of asymmetric k-center, so we get the same hardness results for asymmetric k-center. This proves that Theorem 8 is tight.

Approximation stability requires constant approximations to the optimal cost to differ from $\mathcal{OPT}$ by at most an ϵ-fraction of the points.

▶ **Definition 9.** A clustering instance (S, d) satisfies (α, ϵ)-*approximation stability* for k-center, if for any partition $\mathcal{C}'$ with objective value r' (not necessarily a Voronoi partition), if $r' \leq \alpha r^*$, then $\mathcal{C}'$ is ϵ-close to $\mathcal{OPT}$.

It is not hard to see that (α, ϵ)-approximation stability implies (α, ϵ)-perturbation resilience, as the optimal clustering under any α-perturbation costs at most αr^* under the original distance function, d. So, a violating instance of (α, ϵ)-perturbation resilience induces a partition which costs $\leq \alpha r^*$ and is ϵ-far from $\mathcal{OPT}$, and therefore is not (α, ϵ)-approximation stable.

▶ **Theorem 10.** *There is no polytime algorithm for finding the optimal k-center clustering under $(2 - \epsilon)$-approximation stability, even when assuming all optimal clusters are size $\geq \frac{n}{2k}$, unless $NP = RP$.*

We show a reduction from a special case of Dominating Set which we call Unambiguous-Balanced-Perfect Dominating Set. A reduction from Perfect Dominating Set (Dominating Set with the additional constraint that for all dominating sets of size $\leq k$, each vertex is hit by

exactly one dominator) to the problem of clustering under $(2-\epsilon)$-center proximity was shown in [9] (α-center proximity is the property that for all $p \in C_i$ and $j \neq i$, $\alpha d(c_i, p) < d(c_j, p)$, and it follows from α-perturbation resilience). Our contribution is to show that Perfect Dominating Set remains hard under two additional conditions. First, in the case of a YES instance, each dominator must hit at least $\frac{n}{2k}$ vertices (which translates to clusters having size at least $\frac{n}{2k}$ as well). Second, we are promised that there is at most one dominating set of size $\leq k$ (which is required for establishing approximation stability for the resulting clustering instance).

4 Robust perturbation resilience

In this section, we consider (α, ϵ)-perturbation resilience. We show that under $(3, \epsilon)$-perturbation resilience, there is an algorithm that recovers $\mathcal{OPT}$ for symmetric k-center, and an algorithm that returns a solution that is ϵ-close to $\mathcal{OPT}$ for asymmetric k-center. For both of these results, we assume a lower bound on the size of the optimal clusters, $|C_i| > 2\epsilon n$ for all $i \in [k]$. We show the lower bound on cluster sizes is necessary; in its absence, the problem becomes NP-hard for all values of $\alpha \geq 1$ and $\epsilon > 0$. The theorems in this section require a careful reasoning about sets of centers under different perturbations that cannot all simultaneously be valid.

4.1 Symmetric k-center

We show that for any $(3, \epsilon)$-perturbation resilient k-center instance such that $|C_i| > 2\epsilon n$ for all $i \in [k]$, $\mathcal{OPT}$ can be found by simply thresholding the input graph using distance r^* and outputting the connected components. A nice feature of our result is that the Single Linkage algorithm, a fast algorithm widely used in practice, is sufficient to optimally cluster these instances.

▶ **Theorem 11.** *Given a $(3, \epsilon)$-perturbation resilient k-center instance (S, d) where all optimal clusters are $> \max(2\epsilon n, 3)$. Then the optimal clusters in $\mathcal{OPT}$ are exactly the connected components of the threshold graph G_{r^*} of the input distances.*

Proof idea. Since each optimal cluster center is distance r^* from all points in its cluster, it suffices to show that any two points in different clusters are at least r^* apart from each other. Assume on the contrary that there exist $p \in C_i$ and $q \in C_j$, $i \neq j$, such that $d(p, q) \leq r^*$. First we find a set of $k+2$ points and a 3-perturbation d', such that every size k subset of the points are optimal centers under d'. Then we show how this leads to a contradiction under $(3, \epsilon)$-perturbation resilience.

From our assumption, p is distance $\leq 3r^*$ from every point in $C_i \cup C_j$ (by the triangle inequality). Under a 3-perturbation in which all distances are blown up by a factor of 3 except $d(p, C_i \cup C_j)$, then replacing c_i and c_j with p would still give us a set of $k-1$ centers that achieve the optimal score. But, *would this contradict $(3, \epsilon)$-perturbation resilience?* Indeed, not! Perturbation resilience requires exactly k *distinct* centers.[5] The key challenge is to pick a final "dummy" center to guarantee that the Voronoi partition is ϵ-far from $\mathcal{OPT}$. The dummy center might "accidentally" be the closest center for almost all points in C_i or C_j. Even worse, it might be the case that the new center sets off a chain reaction in which it

[5] This distinction is well-motivated; if for some application, the best k-center solution is to put two centers at the same location, then we could achieve the exact same solution with $k-1$ centers. That implies we should have been running k'-center for $k' = k-1$ instead of k.

becomes center to a cluster C_x, and c_x becomes center to C_j, which would also result in a partition that is not ϵ-far from $\mathcal{OPT}$.

To deal with the chain reactions, we crucially introduce the notion of a *cluster capturing center* (CCC). c_x is a CCC for C_y, if for all but ϵn points $p \in C_y$, $d(c_x, p) \leq r^*$ and for all $i \neq x, y$, $d(c_x, p) < d(c_i, p)$. Intuitively, a CCC exists if and only if c_x is a valid center for C_y when c_y is taken out of the set of optimal centers (i.e., a chain reaction will occur). We argue that if a CCC does not exist then every dummy center we pick must be close to either C_i or C_j, since there are no chain reactions. If there does exist a CCC c_x for C_y, then we cannot reason about what happens to the dummy centers under our d'. However, we can define a new d'' by increasing all distances except $d(c_x, C_y)$, which allows us to take c_y out of the set of optimal centers, and then any dummy center must be close to C_x or C_y. There are no chain reactions because *we already know c_x is the best center for C_y* among the original optimal centers. Thus, whether or not there exists a CCC, we can find $k+2$ points close to the entire dataset by picking points from both C_i and C_j (resp. C_x and C_y).

Because of the assumption that all clusters are size $> 2\epsilon n$, for every 3-perturbation there must be a bijection between clusters and centers, where the center is closest to the majority of points in the corresponding cluster. We show that all size k subsets of the $k+2$ points cannot simultaneously admit bijections that are consistent with one another.

Note that Theorem 10 implies $(2-\delta, \epsilon)$- perturbation resilient k-center is hard for $\delta > 0$, even when the optimal clusters are large. Therefore, the value of α we achieve is within one of optimal. ◀

4.2 Lower bound on cluster sizes

Before moving to the asymmetric case, we show that the lower bound on the cluster sizes in Theorem 11 is necessary. Without this lower bound, clustering becomes hard, even assuming (α, ϵ)-perturbation resilience for any α and ϵ. This reduction follows from k-center (the details appear in the full version).

▶ **Theorem 12.** *For all $\alpha \geq 1$ and $\epsilon > 0$, finding the optimal solution for k-center under (α, ϵ)-perturbation resilience is NP-hard.*

4.3 Asymmetric k-center

In the asymmetric case, we consider the definition of the symmetric set A from Section 3, $A = \{p \mid \forall q, d(q,p) \leq r^* \implies d(p,q) \leq r^*\}$. We might first ask whether A respects the structure of $\mathcal{OPT}$, as it did under 2-perturbation resilience. Namely, whether *Condition 1:* all centers are in A, and *Condition 2:* $\arg\min_{q \in A} d(q,p) \in C_i \implies p \in C_i$ hold. This is not the case for either condition. We explore to what degree these conditions are violated.

We call a center c_i "bad" if it is not in the set A, i.e., $\exists q \notin C_i$ and $d(q, c_i) \leq r^*$. When a bad center c_i exists, we can take it out of the set of optimal centers, and we can pick an arbitrary dummy center which must be close to C_i or a CCC for C_i. In our symmetric argument, we arrived at a contradiction by showing that two dummy centers which capture the same cluster, must be close by the triangle inequality. This logic breaks down for asymmetric distances. In the full version of the paper, we show an example of an instance with a bad center that satisfies (α, ϵ)-perturbation resilience. However, it turns out that *no* instance can have more than 6 bad centers under $(3, \epsilon)$-perturbation resilience, assuming all optimal clusters have size $> 2\epsilon n$. So Condition 1 is satisfied for all but a constant number of centers. However, Condition 2 may not be satisfied for up to ϵn points. Therefore, even if we fully cluster A, we will only get ϵ-close to $\mathcal{OPT}$.

Although up to 6 clusters may have no intersection with A, each point that does belong to A is distance r^* from its center and distance $2r^*$ from its entire cluster. This motivates the following algorithm. First, we run a symmetric k-center 2-approximation algorithm on A, for $k-6 \leq k' \leq k$. For instance, iteratively pick an unmarked point, and mark all points distance $2r^*$ away from it [19]. This gives us a 2-approximation for the centers in A, and thus a 3-approximation for S minus the clusters with no centers in A. Then we brute force search for the remaining ≤ 6 centers to find a 3-approximation for S. Under $(3,\epsilon)$-perturbation resilience, this 3-approximation must be ϵ-close to $\mathcal{OPT}$. We formally state the algorithm and theorem below, and we defer the proof to the full version of this paper. The main technical challenge is in proving that no instance can have more than 6 bad centers.

Algorithm 2 $(3,\epsilon)$-Perturbation Resilient Asymmetric k-center

Input: Asymmetric k-center instance (S,d), r^* (or try all possible candidates).

1. Build set $A = \{p \mid \forall q, d(q,p) \leq r^* \implies d(p,q) \leq r^*\}$.
2. Create the threshold graph G with vertices A, and threshold distance r^*. Define a new symmetric k-center instance with A, using the lengths of the paths in the threshold graph.
3. Run a symmetric k-center 2-approximation algorithm on the symmetrized instance. Start with $k' = k-6$, and increase k' by 1 until the algorithm returns a solution with radius $\leq 2r^*$.
4. Brute force over all size $k-x$ subsets of C and all size x subsets of S for $x \leq 6$, to find a set of size k which is $3r^*$ from all points in S. Denote this set by C'.

Output: Output the Voronoi tiling $G_1, \ldots, G_k$ using C' as the centers.

▶ **Theorem 13.** *Algorithm 2 runs in polytime and outputs a clustering that is ϵ-close to $\mathcal{OPT}$, for $(3,\epsilon)$-perturbation resilient asymmetric k-center instances s.t. all optimal clusters are size $> 2\epsilon n$.*

5 Weak center proximity

In this section, we consider any center-based objective, not just k-center. A clustering objective function is *center-based* if the solution can be defined by choosing a set of centers $\{c_1, c_2, \ldots, c_k\} \subseteq S$, and partitioning S into k clusters $\mathcal{OPT} = \{C_1, C_2, \ldots, C_k\}$ by assigning each point to its closest center. Furthermore:

1. The objective value of a given clustering is a weighted sum or maximum of the individual cluster scores.
2. Given a proposed single cluster, its score can be computed in polynomial time.

k-median, k-means, and k-center are all center-based objectives.

Here, we show a novel algorithm that finds the optimal clustering in instances that satisfy two simple properties: each point is closer to its center than to any point in a different cluster, and we can recognize optimal clusters as soon as they are formed. Formally, we define these properties as:

1. **Weak Center Proximity:** For all $p \in C_i$ and $q \in C_j$, $d(c_i,p) < d(p,q)$.
2. **Cluster Verifiability:** There exists a polytime computable function $f : 2^S \to \mathbb{R}$ that for $B \subseteq S$, if there is $i \in [k]$ such that $B \subset C_i$, then $f(B) < 0$, and if $B \supseteq C_i$, then $f(B) \geq 0$.

Examples of cluster verifiable instances include any instance where all the optimal clusters are the same size ($f(B) = |B| - \frac{n}{k}$), or where all the optimal clusters have the same k-median/k-means cost ($f(B) = \Phi(B) - \Phi(\mathcal{OPT})$).

For any center-based objective, weak center proximity is a consequence of 2-perturbation resilience (i.e., Lemma 6), so, our algorithm relies on a much weaker assumption than α-perturbation resilience for $\alpha \geq 2$, when instances are cluster verifiable.

All existing algorithms and analysis for α-perturbation resilience require that for all $p \in C_i$ and $q \in C_j$, $d(c_i, p) < d(c_i, q)$. It is not at all obvious how one can even proceed without such a property, as in its absence, clusters can 'overlap'. That is, for a cluster with center c_i and radius r, we can not assume that $B_r(c_i)$ only includes points from C_i. Our challenge is then in showing that even in absence of this property, there is still enough structure imposed by the weak center proximity and cluster verifiability to find the optimal clustering efficiently.

Our Algorithm 3 is a novel linkage based procedure. Given a clustering instance (S, d), we will start with a graph $G = (S, E)$ where $E = \emptyset$. In each round, we do single linkage on the components in G, except we do not merge two components if both are supersets of optimal clusters (indicated by $f(B) \geq 0$). Put the single linkage edges from this round in a set A. This will continue until every component is a superset of an optimal cluster. Then we throw away the set A except for the *very last edge* that was added. We will prove this last edge is never between two points from different clusters, so we add that single edge to E and then recur. Here, we present a proof sketch of our main theorem. The details can be found in the full version.

Algorithm 3 Clustering under weak center proximity and cluster verifiability

Input: Clustering instance (S, d), function f, and $k \leq |S|$.

Set $G = (S, E)$ and $E = \emptyset$. While there are more than k components in G, repeat (1) and (2):

1. Set $A = \emptyset$. While there exists a component B in $G' = (S, E \cup A)$ such that $f(B) < 0$, add (p, q) to A, where $d(p, q)$ is minimized such that p and q are in different components in G' and at least one of these components B has $f(B) < 0$.
2. Take the last edge e that was added to A, and put $e \in E$.

Output: Output the components of G.

▶ **Theorem 14.** *Given a center-based clustering instance satisfying weak center proximity and cluster verifiability, Algorithm 3 outputs $\mathcal{OPT}$ in polynomial time.*

Proof Sketch. It suffices to show that step (b) never adds an edge between two points from different clusters. We proceed by induction. Assume it is true up to iteration t of the first while loop. Now assume towards contradiction that in round t, the last edge added to A is between two points $p \in C_i$ and $q \in C_j$, $i \neq j$. WLOG, for the component in G' that includes p, called P', we have $f(P') < 0$, otherwise the merge would not have happened. Furthermore, $c_i \in P'$ by weak center proximity. Then $f(P') < 0$ implies that $C_i \setminus P'$ is nonempty, so call it P. The component(s) in G corresponding to P are strict subsets of C_i, therefore, $f(P) < 0$. So they must merge to another component, and by weak center proximity, the closest component is P', but this contradicts our assumption that (p, q) was the last edge added to A. ◀

6 Conclusions

Our work pushes the understanding of (promise) stability conditions farther in three ways. We are the first to design computationally efficient algorithms to find the optimal clustering under α-perturbation resilience with a constant value of α for a problem that is hard to

approximate to any constant factor in the worst case, thereby demonstrating the power of perturbation resilience. Furthermore, we demonstrate the limits of this power by showing the first tight results in this space for both perturbation resilience and approximation stability. Finally, we show a surprising relation between symmetric and asymmetric instances, in that they are equivalent under resilience to 2-perturbations, which is in stark contrast to their widely differing tight approximation factors.

Abstract

We consider clustering problems with *non-uniform lower bounds and outliers*, and obtain the *first approximation guarantees* for these problems. We have a set $\mathcal{F}$ of facilities with lower bounds $\{L_i\}_{i\in\mathcal{F}}$ and a set $\mathcal{D}$ of clients located in a common metric space $\{c(i,j)\}_{i,j\in\mathcal{F}\cup\mathcal{D}}$, and bounds k, m. A feasible solution is a pair $\big(S\subseteq\mathcal{F}, \sigma:\mathcal{D}\mapsto S\cup\{\mathsf{out}\}\big)$, where σ specifies the client assignments, such that $|S|\leq k$, $|\sigma^{-1}(i)|\geq L_i$ for all $i\in S$, and $|\sigma^{-1}(\mathsf{out})|\leq m$. In the *lower-bounded min-sum-of-radii with outliers* (LBkSRO) problem, the objective is to minimize $\sum_{i\in S}\max_{j\in\sigma^{-1}(i)}c(i,j)$, and in the *lower-bounded k-supplier with outliers* (LBkSupO) problem, the objective is to minimize $\max_{i\in S}\max_{j\in\sigma^{-1}(i)}c(i,j)$.

We obtain an approximation factor of 12.365 for LBkSRO, which improves to 3.83 for the non-outlier version (i.e., $m=0$). These also constitute the *first* approximation bounds for the min-sum-of-radii objective when we consider lower bounds and outliers *separately*. We apply the primal-dual method to the relaxation where we Lagrangify the $|S|\leq k$ constraint. The chief technical contribution and novelty of our algorithm is that, departing from the standard paradigm used for such constrained problems, we obtain an $O(1)$-approximation *despite the fact that we do not obtain a Lagrangian-multiplier-preserving algorithm for the Lagrangian relaxation.* We believe that our ideas have broader applicability to other clustering problems with outliers as well.

We obtain approximation factors of 5 and 3 respectively for LBkSupO and its non-outlier version. These are the *first* approximation results for k-supplier with *non-uniform* lower bounds.

1 Introduction

Clustering is an ubiquitous problem arising in applications in various fields such as data mining, machine learning, image processing, and bioinformatics. Many of these problems involve finding a set S of at most k "cluster centers", and an assignment σ mapping an underlying set $\mathcal{D}$ of data points located in some metric space $\{c(i,j)\}$ to S, to minimize

some objective function; examples include the *k-center* (minimize $\max_{j\in\mathcal{D}} c(\sigma(j),j)$) [20, 21], *k-median* (minimize $\sum_{j\in\mathcal{D}} c(\sigma(j),j)$) [9, 22, 25, 6], and *min-sum-of-radii* (minimize $\sum_{i\in S}\max_{j:\sigma(j)=i} c(i,j)$) [15, 11] problems. Viewed from this perspective, clustering problems can often be viewed as *facility-location* problems, wherein an underlying set of clients that require service need to be assigned to facilities that provide service in a cost-effective fashion. Both clustering and facility-location problems have been extensively studied in the Computer Science and Operations Research literature; see, e.g., [27, 29] in addition to the above references.

We consider clustering problems with (non-uniform) *lower-bound requirements* on the cluster sizes, and where a bounded number of points may be designated as *outliers* and left unclustered. One motivation for considering lower bounds comes from an *anonymity* consideration. In order to achieve data privacy, [28] proposed an anonymization problem where we seek to perturb (in a specific way) some of (the attributes of) the data points and then cluster them so that every cluster has at least L identical perturbed data points, thus making it difficult to identify the original data from the clustering. As noted in [2, 1], this anonymization problem can be abstracted as a lower-bounded clustering problem where the clustering objective captures the cost of perturbing data. Another motivation comes from a facility-location perspective, where (as in the case of *lower-bounded facility location*), the lower bounds model that it is infeasible or unprofitable to use services unless they satisfy a certain minimum demand (see, e.g., [26]). Allowing outliers enables one to handle a common woe in clustering problems, namely that data points that are quite dissimilar from any other data point can often disproportionately (and undesirably) degrade the quality of *any* clustering of the *entire* data set; instead, the outlier-version allows one to designate such data points as outliers and focus on the data points of interest.

Formally, adopting the facility-location terminology, our setup is as follows. We have a set $\mathcal{F}$ of facilities with lower bounds $\{L_i\}_{i\in\mathcal{F}}$ and a set $\mathcal{D}$ of clients located in a common metric space $\{c(i,j)\}_{i,j\in\mathcal{F}\cup\mathcal{D}}$, and bounds k, m. A feasible solution chooses a set $S\subseteq\mathcal{F}$ of at most k facilities, and assigns each client j to a facility $\sigma(j)\in S$, or designates j as an outlier by setting $\sigma(j)=\mathsf{out}$ so that $|\sigma^{-1}(i)|\geq L_i$ for all $i\in S$, and $|\sigma^{-1}(\mathsf{out})|\leq m$. We consider two clustering objectives: minimize $\sum_{i\in S}\max_{j:\sigma(j)=i} c(i,j)$, which yields the *lower-bounded min-sum-of-radii with outliers* (LBkSRO) problem, and minimize $\max_{i\in S}\max_{j:\sigma(j)=i} c(i,j)$, which yields the *lower-bounded k-supplier with outliers* (LBkSupO) problem. We refer to the non-outlier versions of the above problems (i.e., where $m=0$) as LBkSR and LBkSup respectively.

Our contributions. We obtain the *first* results for clustering problems with *non-uniform lower bounds and outliers*. We develop various techniques for tackling these problems using which we obtain *constant-factor approximation guarantees* for LBkSRO and LBkSupO. Note that we need to ensure that none of the *hard* constraints involved here – at most k clusters, non-uniform lower bounds, and at most m outliers – are violated, which is somewhat challenging.

We obtain an approximation factor of 12.365 for LBkSRO (Theorem 7, Section 2.2), which improves to 3.83 for the non-outlier version LBkSR (Theorem 6, Section 2.1). These also constitute the *first* approximation results for the min-sum-of-radii objective when we consider: (a) lower bounds (even uniform bounds) but no outliers (LBkSR); and (b) outliers but no lower bounds. Previously, an $O(1)$-approximation was known only in the setting where there are *no lower bounds and no outliers* (i.e., $L_i=0$ for all i, $m=0$) [11].

For the k-supplier objective (Section 3), we obtain an approximation factor of 5 for LBkSupO (Theorem 16), and 3 for LBkSup (Theorem 15). These are the *first* approximation

results for the k-supplier problem with non-uniform lower bounds. Previously, [1] obtained approximation factors of 4 and 2 respectively for LBkSupO and LBkSup for the special case of *uniform* lower bounds and when $\mathcal{F} = \mathcal{D}$ (often called the k-center version). Complementing our approximation bounds, we prove a factor-3 hardness of approximation for LBkSup (Theorem 17), which shows that our approximation factor of 3 is optimal for LBkSup.

Our techniques. Our main technical contribution is an $O(1)$-approximation algorithm for LBkSRO (Section 2.2). Whereas for the non-outlier version LBkSR (Section 2.1), one can follow an approach similar to that in [11] for the min-sum-of-radii problem without lower bounds or outliers, the presence of outliers creates substantial difficulties whose resolution requires various novel ingredients. As in [11], we view LBkSRO as a *k-ball-selection* (k-BS) problem of picking k suitable balls (see Section 2) and consider its LP-relaxation (P_2). Let OPT denote its optimal value. Following the Jain-Vazirani (JV) template for k-median [22], we move to the version where we may pick any number of balls but incur a fixed cost of z for each ball we pick. The dual LP (D_2) has α_j dual variables for the clients, which "pay" for (i, r) pairs (where (i, r) denotes the ball $\{j \in \mathcal{D} : c(i, j) \leq r\}$). For LB$k$SR (where $m = 0$), as observed in [11], it is easy to adapt the JV primal-dual algorithm for facility location to handle this fixed-cost version of k-BS: we raise the α_js of uncovered clients until all clients are covered by some fully-paid (i, r) pair (see PDAlg). This yields a so-called *Lagrangian-multiplier-preserving* (LMP) 3-approximation algorithm: if F is the primal solution constructed, then $3\sum_j \alpha_j$ can pay for $cost(F) + 3|F|z$; hence, by varying z, one can find two solutions F_1, F_2 for nearby values of z, and combine them to extract a low-cost k-BS-solution.

The presence of outliers in LBkSRO significantly complicates things. The natural adaptation of the primal-dual algorithm is to now stop when at least $|\mathcal{D}| - m$ clients are covered by fully-paid (i, r) pairs. But now, the dual objective involves a $-m \cdot \gamma$ term, where $\gamma = \max_j \alpha_j$, which potentially cancels the dual contribution of (some) clients that pay for the last fully-paid (i, r) pair, say f. Consequently, we *do not obtain an LMP-approximation*: if F is the primal solution we construct, we can only say that (roughly) $3(\sum_j \alpha_j - m \cdot \gamma)$ pays for $cost(F \setminus f) + 3|F \setminus f|z$ (see Theorem 8 (ii)). In particular, this means that *even if the primal-dual algorithm returns a solution with k pairs, its cost need not be bounded*, an artifact that never arises in LBkSR (or k-median). This in turn means that by combining the two solutions F_1, F_2 found for $z_1, z_2 \approx z_1$, we only obtain a solution of cost $O(OPT + z_1)$ (see Theorem 10).

Dealing with the case where $z_1 = \Omega(OPT)$ is technically the most involved portion of our algorithm (Section 2.2.2). We argue that in this case the solutions F_1, F_2 (may be assumed to) have a very specific structure: $|F_1| = k + 1$, and every F_2-ball intersects at most one F_1-ball, and vice versa. We utilize this structure to show that either we can find a good solution in a suitable neighborhood of F_1 and F_2, or F_2 itself must be a good solution.

We remark that the above difficulties (i.e., the inability to pay for the last "facility" and the ensuing complications) also arise in the *k-median problem with outliers*. We believe that our ideas also have implications for this problem and should yield a much-improved approximation ratio for this problem. (The current guarantee is a large (unspecified) constant [12].)

For the k-supplier problem, LBkSupO, we leverage the notion of skeletons and pre-skeletons defined by [14] in the context of *capacitated k-supplier with outliers*, wherein facilities have capacities instead of lower bounds limiting the number of clients that can be assigned to them. Roughly speaking, a skeleton $F \subseteq \mathcal{F}$ ensures there is a low-cost solution (F, σ). A pre-skeleton satisfies some of the properties of a skeleton. We show that if F is a pre-skeleton,

then either F is a skeleton or $F \cup \{i\}$ is a pre-skeleton for some facility i. This allows one to find a sequence of facility-sets such that at least one of them is a skeleton. For a given set F, one can check if F admits a low-cost assignment σ, so this yields an $O(1)$-approximation algorithm.

Related work. There is a vast literature on clustering and facility-location (FL) problems (see, e.g., [27, 29]); we limit ourselves to work that is relevant to LBkSRO and LBkSupO.

The only prior work on clustering problems to incorporate both lower bounds *and* outliers is by Aggarwal et al. [1]. They obtain approximation ratios of 4 and 2 respectively for LBkSupO and LBkSup with *uniform* lower bounds, which they consider as a means of achieving anonymity. They also consider an alternate *cellular clustering* (CellC) objective and devise an $O(1)$-approximation algorithm for lower-bounded CellC with uniform lower bounds, and mention that this can be extended to an $O(1)$-approximation for lower-bounded CellC with outliers.

More work has been directed towards clustering problems involving outliers *or* lower bounds (but not both). Charikar et al. [10] consider (among other problems) the outlier-versions of the uncapacitated FL, k-supplier and k-median problems. They devise constant-factor approximations for the first two problems, and a bicriteria approximation for the k-median problem with outliers. They also proved a factor-3 approximation hardness result for k-supplier with outliers. This nicely complements our factor-3 hardness result for k-supplier with lower bounds but no outliers. Chen [12] obtained the first true approximation for k-median with outliers via a sophisticated combination of the primal-dual algorithm for k-median and local search that yields a large (unspecified) $O(1)$-approximation. Cygan and Kociumaka [14] consider the *capacitated k-supplier with outliers* problem, and devise a 25-approximation algorithm. We leverage some of their ideas in developing our algorithm for LBkSupO.

Lower-bounded clustering and FL problems remain largely unexplored and ill-understood. Besides LBkSup (which has also been studied in Euclidean spaces [16]) another such FL problem that has been studied is *lower-bounded facility location* (LBFL) [23, 19], wherein we seek to open facilities (which have lower bounds) and assign each client j to an open facility $\sigma(j)$ so as to minimize $\sum_{j \in \mathcal{D}} c(\sigma(j), j)$. Svitkina [30] obtained the first true approximation for LBFL, achieving an $O(1)$-approximation; the $O(1)$-factor was subsequently improved by [3]. Both results apply to LBFL with uniform lower bounds, and can be adapted to yield $O(1)$-approximations to the k-median variant (where we may open at most k facilities).

Doddi et al. [15] introduced the min-sum-of-diameters objective, which is closely related to the min-sum-of-radii objective (the former is at most twice the latter). Charikar and Panigrahi [11] devised the first (and current-best) $O(1)$-approximation algorithms for these problems, obtaining approximation ratios of 3.53 and 7.06 for the radii and diameter problems respectively. Various other results are known for specific metric spaces and when $\mathcal{F} = \mathcal{D}$, such as Euclidean spaces [18, 7] and metrics with bounded aspect ratios [17, 5].

The k-supplier and k-center (i.e., k-supplier with $\mathcal{F} = \mathcal{D}$) objectives have a rich history of study. Hochbaum and Shmoys [20, 21] obtained optimal approximation ratios of 3 and 2 for these problems respectively. Capacitated versions of k-center and k-supplier have also been studied: [24] devised a 6-approximation for uniform capacities, [13] obtained the first $O(1)$-approximation for non-uniform capacities, and this $O(1)$-factor was improved to 9 in [4].

Finally, our algorithm for LBkSRO leverages the template based on Lagrangian relaxation and the primal-dual method to emerge from the work of [22, 8] for the k-median problem.

2 Minimizing sum of radii with lower bounds and outliers

Recall that in the *lower-bounded min-sum-of-radii with outliers* (LBkSRO) problem, we have a facility-set $\mathcal{F}$ and client-set $\mathcal{D}$ located in a metric space $\{c(i,j)\}_{i,j\in\mathcal{F}\cup\mathcal{D}}$, lower bounds $\{L_i\}_{i\in\mathcal{F}}$, and bounds k and m. A feasible solution is a pair $\big(S\subseteq\mathcal{F}, \sigma:\mathcal{D}\mapsto S\cup\{\mathsf{out}\}\big)$, where $\sigma(j)\in S$ indicates that j is assigned to facility $\sigma(j)$, and $\sigma(j)=\mathsf{out}$ designates j as an outlier, such that $|S|\leq k$, $|\sigma^{-1}(i)|\geq L_i$ for all $i\in S$, and $|\sigma^{-1}(\mathsf{out})|\leq m$. The cost $cost(S,\sigma)$ of such a solution is $\sum_{i\in S} r_i$, where $r_i := \max_{j\in\sigma^{-1}(i)} c(i,j)$ denotes the *radius* of facility i; the goal is to find a solution of minimum cost. We use LBkSR to denote the non-outlier version where $m=0$.

It will be convenient to consider a relaxation of LBkSRO that we call the *k-ball-selection* (k-BS) problem, which focuses on selecting at most k balls centered at facilities of minimum total radius. More precisely, let $B(i,r) := \{j\in\mathcal{D} : c(i,j)\leq r\}$ denote the ball of clients centered at i with radius r. Let $c_{\max} = \max_{i\in\mathcal{F},j\in\mathcal{D}} c(i,j)$. Let $\mathcal{L}_i := \{(i,r) : |B(i,r)|\geq L_i\}$, and $\mathcal{L} := \bigcup_{i\in\mathcal{F}}\mathcal{L}_i$. The goal in k-BS is to find a set $F\subseteq\mathcal{L}$ with $|F|\leq k$ and $\big|\mathcal{D}\setminus\bigcup_{(i,r)\in F} B(i,r)\big|\leq m$ so that $cost(F) := \sum_{(i,r)\in F} r$ is minimized. (When formulating the LP-relaxation of the k-BS-problem, we equivalently view $\mathcal{L}$ as containing only pairs of the form $(i,c(i,j))$ for some client j, which makes $\mathcal{L}$ finite.) It is easy to see that any LBkSRO-solution yields a k-BS-solution of no greater cost. The key advantage of working with k-BS is that we do not explicitly consider the lower bounds (they are folded into the $\mathcal{L}_i$s) and we do not require the balls $B(i,r)$ for $(i,r)\in F$ to be disjoint. While a k-BS-solution F need not directly translate to a feasible LBkSRO-solution, one can show that it does yield a feasible LBkSRO-solution of cost at most $2\cdot cost(F)$. We prove a stronger version of this statement in Lemma 1. In the following two sections, we utilize this relaxation to devise the *first* constant-factor approximation algorithms for for LBkSR and LBkSRO. To our knowledge, our algorithm is also the first $O(1)$-approximation algorithm for the outlier version of the min-sum-of-radii problem *without* lower bounds.

We consider an LP-relaxation for the k-BS-problem, and to round a fractional k-BS-solution to a good integral solution, we need to preclude radii that are much larger than those used by an optimal solution. We therefore "guess" the t facilities in the optimal solution with the largest radii, and their radii, where $t\geq 1$ is some constant. That is, we enumerate over all $O\big((|\mathcal{F}|+|\mathcal{D}|)^{2t}\big)$ choices $F^O=\{(i_1,r_1),\ldots,(i_t,r_t)\}$ of t (i,r) pairs from $\mathcal{L}$. For each such selection, we set $\mathcal{D}' = \mathcal{D}\setminus\bigcup_{(i,r)\in F^O} B(i,r)$, $\mathcal{L}' = \{(i,r)\in\mathcal{L} : r\leq \min_{p=1,\ldots,t} r_p\}$ and $k' = k-|F^O|$, and run our k-BS-algorithm on the modified k-BS-instance $(\mathcal{F},\mathcal{D}',c,\mathcal{L}',k',m)$ to obtain a k-BS-solution F. We translate $F\cup F^O$ to an LBkSRO-solution, and return the best of these solutions. The following lemma, and the procedure described therein, is repeatedly used to bound the cost of translating $F\cup F^O$ to a feasible LBkSRO-solution. We call pairs $(i,r),(i',r')\in\mathcal{F}\times\mathbb{R}_{\geq 0}$ *non-intersecting*, if $c(i,i')>r+r'$, and *intersecting* otherwise. Note that $B(i,r)\cap B(i',r')=\emptyset$ if (i,r) and (i',r') are non-intersecting. For a set $P\subseteq\mathcal{F}\times\mathbb{R}_{\geq 0}$ of pairs, define $\mu(P) := \{i\in\mathcal{F} : \exists r \text{ s.t. } (i,r)\in P\}$.

▶ **Lemma 1.** *Let $F^O\subseteq\mathcal{L}$, and $\mathcal{D}',\mathcal{L}',k'$ be as defined above. Let $F\subseteq\mathcal{L}$ be a k-BS-solution for the k-BS-instance $(\mathcal{F},\mathcal{D}',c,\mathcal{L}',k',m)$. Suppose for each $i\in\mu(F)$, we have a radius $r'_i\leq\max_{r:(i,r)\in F} r$ such that the pairs in $U := \bigcup_{i\in\mu(F)}(i,r'_i)$ are non-intersecting and $U\subseteq\mathcal{L}'$. Then there exists a feasible LBkSRO-solution (S,σ) with $cost(S,\sigma)\leq cost(F)+\sum_{(i,r)\in F^O} 2r$.*

2.1 Approximation algorithm for LBkSR

We now present our algorithm for the non-outlier version, LBkSR, which introduces many of the ideas underlying our algorithm for LBkSRO (Section 2.2). Let O^* be the cost of an optimal

solution to the given LBkSR instance. For each selection $(i_1, r_1), \ldots, (i_t, r_t)$ of t pairs, we do the following. We set $\mathcal{D}' = \mathcal{D} \setminus \bigcup_{p=1}^{t} B(i_p, r_p)$, $\mathcal{L}' = \{(i,r) \in \mathcal{L} : r \leq R^* := \min_{p=1,\ldots,t} r_p\}$, $k' = k - t$, and consider the k-BS-problem of picking a min-cost set of at most k' pairs from $\mathcal{L}'$ whose corresponding balls cover $\mathcal{D}'$ (but our algorithm k-BSAlg will return pairs from $\mathcal{L}$). Consider the following natural LP-relaxation (P_1) of this problem, and its dual (D_1).

$$\begin{array}{lll} \min & \sum_{(i,r)\in\mathcal{L}'} r \cdot y_{i,r} & (\mathrm{P}_1) \\ \text{s.t.} & \sum_{(i,r)\in\mathcal{L}': j\in B(i,r)} y_{i,r} \geq 1 & \forall j \in \mathcal{D}' \\ & \sum_{(i,r)\in\mathcal{L}'} y_{i,r} \leq k' \quad (1) & \\ & y \geq 0. & \end{array} \qquad \begin{array}{lll} \max & \sum_{j\in\mathcal{D}'} \alpha_j - k' \cdot z & (\mathrm{D}_1) \\ \text{s.t.} & \sum_{j\in B(i,r)\cap\mathcal{D}'} \alpha_j - z \leq r & \forall (i,r) \in \mathcal{L}' \\ & \alpha, z \geq 0. & \end{array} \tag{2}$$

Let OPT denote the common optimal value of (P_1) and (D_1). As in the JV-algorithm for k-median, we Lagrangify constraint (1) and consider the unconstrained problem where we do not bound the number of pairs we may pick, but we incur a fixed cost z for each pair (i,r) that we pick (in addition to r). It is easy to adapt the JV primal-dual algorithm for facility location [22] to devise a simple *Lagrangian-multiplier-preserving* (LMP) 3-approximation algorithm for this problem (see PDAlg and Theorem 3). We use this LMP algorithm within a binary-search procedure for z to obtain two solutions F_1 and F_2 with $|F_2| \leq k' < |F_1|$, and show that these can be "combined" to extract a k-BS-solution F of cost at most $3.83 \cdot OPT + O(R^*)$. This combination step is more involved than in k-median. The main idea here is to use the F_2 solution as a guide to merge some F_1-pairs. We cluster the F_1 pairs around the F_2-pairs and setup a *covering-knapsack problem* whose solution determines for each F_2-pair (i,r), whether to "merge" the F_1-pairs clustered around (i,r) or select all these F_1-pairs (see step B2). Finally, we add back the pairs $(i_1, r_1), \ldots (i_t, r_t)$ selected earlier and apply Lemma 1 to obtain an LBkSR-solution. As required by Lemma 1, to aid in this translation, our k-BS-algorithm returns, along with F, a suitable radius $\mathsf{rad}(i)$ for every facility $i \in \mu(F)$. This yields a $(3.83 + \epsilon)$-approximation algorithm (Theorem 6).

While our approach is similar to the one in [11] for the min-sum-of-radii problem *without* lower bounds (although our combination step is notably simpler), an important distinction that arises is the following. In the absence of lower bounds, the ball-selection problem k-BS is *equivalent* to the min-sum-of-radii problem, but (as noted earlier) this is no longer the case when we have lower bounds since in k-BS we do not insist that the balls we pick be disjoint. Moving from overlapping balls in a k-BS-solution to an LBkSR-solution incurs, in general, a factor-2 blowup in the cost, but we avoid this blowup by exploiting the structure of the k-BS-solution obtained and carefully merging in the pairs $(i_1, r_1), \ldots, (i_t, r_t)$ (see Lemma 1). It is interesting that our approximation factor is quite close to the approximation factor (of 3.53) achieved in [11] for the min-sum-of-radii problem without lower bounds.

We now describe our algorithm in detail and analyze it. We describe a slightly simpler $(6.183 + \epsilon)$-approximation algorithm below (Theorem 2). We sketch the ideas behind the improved approximation ratio at the end of this section and defer the details to the full version.

▶ Algorithm 1.
Input: An LBkSR-instance $\mathcal{I} = \big(\mathcal{F}, \mathcal{D}, \{L_i\}, \{c(i,j)\}, k\big)$, parameter $\epsilon > 0$.
Output: A feasible solution (S, σ).

A1. Let $t = \min\big\{k, \lceil \frac{1}{\epsilon} \rceil\big\}$. For each set $F^O \subseteq \mathcal{L}$ with $|F^O| \leq t$, do the following.

A1.1. Set $\mathcal{D}' = \mathcal{D} \setminus \bigcup_{(i,r)\in F^O} B(i,r)$, $\mathcal{L}' = \{(i',r') \in \mathcal{L} : r \leq R^* = \min_{(i,r)\in F^O} r\}$, $k' = k - |F^O|$.

A1.2. If (P_1) is infeasible, then reject this guess and move to the next set F^O. If $\mathcal{D}' \neq \emptyset$, run k-BSAlg$(\mathcal{D}', \mathcal{L}', k', \epsilon)$ to obtain $\big(F, \{\mathsf{rad}(i)\}_{i\in F}\big)$; else set $(F, \mathsf{rad}) = (\emptyset, \emptyset)$.

A1.3. Apply the procedure in Lemma 1 taking $r'_i = \mathsf{rad}(i)$ for all $i \in \mu(F)$ to obtain (S, σ).

A1. Among all the solutions (S, σ) found in step A1, return the one with smallest cost.

▶ Algorithm k-**BSAlg**$(\mathcal{D}', \mathcal{L}', k', \epsilon)$.
Output: $F \subseteq \mathcal{L}$ with $|F| \leq k'$, a radius $\mathsf{rad}(i)$ for all $i \in \mu(F)$.

B1. Binary search for z.

B1.1. Set $z_1 = 0$ and $z_2 = 2k' c_{\max}$. For $p = 1, 2$, let $(F_p, \{\mathsf{rad}_p(i)\}, \alpha^p) \leftarrow$ PDAlg$(\mathcal{D}', \mathcal{L}', z_p)$, and let $k_p = |F_p|$. If $k_1 \leq k'$, stop and return $\big(F_1, \{\mathsf{rad}_1(i)\}\big)$. We prove in Theorem 3 that $k_2 \leq k'$; if $k_2 = k'$, stop and return $\big(F_2, \{\mathsf{rad}_2(i)\}\big)$.

B1.2. Repeat the following until $z_2 - z_1 \leq \delta_z = \frac{\epsilon OPT}{3n}$, where $n = |\mathcal{F}| + |\mathcal{D}|$. Set $z = \frac{z_1+z_2}{2}$. Let $(F, \{\mathsf{rad}(i)\}, \alpha) \leftarrow$ PDAlg$(\mathcal{D}', \mathcal{L}', z)$. If $|F| = k'$, stop and return $\big(F, \{\mathsf{rad}(i)\}\big)$; if $|F| > k'$, update $z_1 \leftarrow z$ and $(F_1, \mathsf{rad}_1, \alpha^1) \leftarrow (F, \mathsf{rad}, \alpha)$, else update $z_2 \leftarrow z$ and $(F_2, \mathsf{rad}_2, \alpha^2) \leftarrow (F, \mathsf{rad}, \alpha)$.

B2. Combining F_1 and F_2. Let $\pi : F_1 \mapsto F_2$ be any map such that (i',r') and $\pi(i',r')$ intersect $\forall (i',r') \in F_1$. (This exists since every $j \in \mathcal{D}'$ is covered by $B(i,r)$ for some $(i,r) \in F_2$.) Define star $\mathcal{S}_{i,r} = \pi^{-1}(i,r)$ for all $(i,r) \in F_2$ (see Fig. 1). Solve the following *covering-knapsack LP*.

$$\min \quad \sum_{(i,r)\in F_2} \Big(x_{i,r}\big(2r + \textstyle\sum_{(i',r')\in\mathcal{S}_{i,r}} 2r'\big) + (1 - x_{i,r}) \sum_{(i',r')\in\mathcal{S}_{i,r}} r' \Big) \tag{C-P}$$

$$\text{s.t.} \quad \sum_{(i,r)\in F_2} \big(x_{i,r} + |\mathcal{S}_{i,r}|(1 - x_{i,r}) \big) \leq k', \qquad 0 \leq x_{i,r} \leq 1 \quad \forall (i,r) \in F_2.$$

Let x^* be an extreme-point optimal solution to (C-P). The variable $x_{(i,r)}$ has the following interpretation. If $x^*_{i,r} = 0$, then we select all pairs in $\mathcal{S}_{i,r}$. Otherwise, if $\mathcal{S}_{i,r} \neq \emptyset$, we pick a pair in $(i',r') \in \mathcal{S}_{i,r}$, and include $(i', 2r + r' + \max_{(i'',r'')\in\mathcal{S}_{i,r}\setminus\{(i',r')\}} 2r'')$ in our solution. Notice that by expanding the radius of i' to $2r + r' + \max_{(i'',r'')\in\mathcal{S}_{i,r}\setminus\{(i',r')\}} 2r''$, we cover all the clients in $\bigcup_{(i'',r'')\in\mathcal{S}_{i,r}} B(i'',r'')$. Let F' be the resulting set of pairs.

B3. If $cost(F_2) \leq cost(F)$, return (F_2, rad_2), else return $\big(F', \{\mathsf{rad}_1(i)\}_{i\in\mu(F')}\big)$.

▶ Algorithm **PDAlg**$(\mathcal{D}', \mathcal{L}', z)$.
Output: $F \subseteq \mathcal{L}$, radius $\mathsf{rad}(i)$ for all $i \in \mu(F)$, dual solution α.

P1. Dual-ascent phase. Start with $\alpha_j = 0$ for all $j \in \mathcal{D}'$, $\mathcal{D}'$ as the set of *active clients*, and the set T of *tight pairs* initialized to $\emptyset$. We repeat the following until all clients become inactive: we raise the α_js of all active clients uniformly until constraint (2) becomes tight for some (i,r); we add (i,r) to T and mark all active clients in $B(i,r)$ as inactive.

P2. Pruning phase. Let T_I be a maximal subset of non-intersecting pairs in T picked by a greedy algorithm that scans pairs in T in non-increasing order of radius. Note that for each $i \in \mu(T_I)$, there is exactly one pair $(i,r) \in T_I$. We set $\mathsf{rad}(i) = r$, and $r_i = \max\{c(i,j) : j \in B(i',r'),\ (i',r') \in T,\ r' \leq r,\ (i',r')$ intersects (i,r) $((i',r')$ could be $(i,r))\}$. Let $F = \{(i, r_i)\}_{i\in\mu(T_I)}$. Return F, $\{\mathsf{rad}(i)\}_{i\in\mu(T_I)}$, and α.

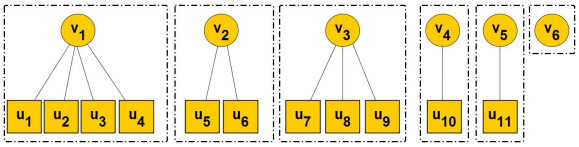

Figure 1 An example of stars formed by F_1 and F_2 where $F_1 = \{u_1, u_2, \ldots, u_{11}\}$ and $F_2 = \{v_1, v_2, \ldots, v_6\}$ depicted by squares and circles, respectively.

Analysis. We prove the following result.

▶ **Theorem 2.** *For any $\epsilon > 0$, Algorithm 1 returns a feasible* LBkSR*-solution of cost at most $\big(6.1821 + O(\epsilon)\big)O^*$ in time $n^{O(1/\epsilon)}$.*

We first prove that PDAlg is an LMP 3-approximation algorithm, i.e., its output (F, α) satisfies $cost(F) + 3|F|z \leq 3\sum_{j\in\mathcal{D}'} \alpha_j$. (Theorem 3). Utilizing this, we analyze k-BSAlg, in particular, the output of the combination step B2, and argue that k-BSAlg returns a feasible solution of cost at most $\big(6.183 + O(\epsilon)\big) \cdot OPT + O(R^*)$ (Theorem 5). For the right choice of F^O, combining this with Lemma 1 yields Theorem 2.

▶ **Theorem 3.** *Suppose* PDAlg$(\mathcal{D}', \mathcal{L}', z)$ *returns* $(F, \{\mathsf{rad}(i)\}, \alpha)$. *Then*

(i) *the balls corresponding to F cover $\mathcal{D}'$;*
(ii) $cost(F) + 3|F|z \leq 3\sum_{j\in\mathcal{D}'} \alpha_j \leq 3(OPT + k'z)$;
(iii) $\big\{(i, \mathsf{rad}(i))\big\}_{i\in\mu(F)} \subseteq \mathcal{L}'$, *is a set of non-intersecting pairs,* $\mathsf{rad}(i) \leq r_i \leq 3R^*\ \forall i \in \mu(F)$;
(iv) *if $|F| \geq k'$ then $cost(F) \leq 3 \cdot OPT$; if $|F| > k'$, then $z \leq OPT$. (Hence, $k_2 \leq k'$ in step B1.1.)*

Let $\big(F, \{\mathsf{rad}(i)\}\big) = k$-BSAlg$(\mathcal{D}', \mathcal{L}', k', \epsilon)$. If k-BSAlg terminates in step B1, then $cost(F) \leq 3 \cdot OPT$ due to part (ii) of Theorem 3, so assume otherwise. Let $a, b \geq 0$ be such that $ak_1 + bk_2 = k'$, $a + b = 1$. Let $C_1 = cost(F_1)$ and $C_2 = cost(F_2)$. Recall that $(F_1, \mathsf{rad}_1, \alpha^1)$ and $(F_2, \mathsf{rad}_2, \alpha^2)$ are the outputs of PDAlg for z_1 and z_2 respectively.

▶ **Claim 4.** *We have $aC_1 + bC_2 \leq (3 + \epsilon)OPT$.*

▶ **Theorem 5.** *k-*BSAlg$(\mathcal{D}', \mathcal{L}', k', \epsilon)$ *returns a feasible solution $\big(F, \{\mathsf{rad}(i)\}\big)$ with $cost(F) \leq \big(6.183 + O(\epsilon)\big) \cdot OPT + O(R^*)$ where $\big\{(i, \mathsf{rad}(i))\big\}_{i\in\mu(F)} \subseteq \mathcal{L}'$ is a set of non-intersecting pairs.*

Proof. The radii $\{\mathsf{rad}(i)\}_{i\in\mu(F)}$ are simply radii obtained from some execution of PDAlg, so $\big\{(i, \mathsf{rad}(i))\big\}_{i\in\mu(F)} \subseteq \mathcal{L}'$ and comprises non-intersecting pairs. If k-BSAlg terminates in step B1, we have a better bound on $cost(F)$. If not, and we return F_2, the cost incurred is C_2.

Otherwise, we return the solution F' found in step B2. Since (C-P) has only one constraint in addition to the bound constraints $0 \leq x_{i,r} \leq 1$, the extreme-point optimal solution x^* has at most one fractional component, and if it has a fractional component, then $\sum_{(i,r)\in F_2} \big(x^*_{i,r} + |\mathcal{S}_{i,r}|(1 - x^*_{i,r})\big) = k'$. For any $(i, r) \in F_2$ with $x^*_{i,r} \in \{0, 1\}$, the number of pairs we include is exactly $x^*_{i,r} + |\mathcal{S}_{i,r}|(1 - x^*_{i,r})$, and the total cost of these pairs is at most the contribution to the objective function of (C-P) from the $x^*_{i,r}$ and $(1 - x^*_{i,r})$ terms. If x^* has a fractional component $(i', r') \in F_2$, then $x^*_{i',r'} + |\mathcal{S}_{i',r'}|(1 - x^*_{i',r'})$ is a *positive* integer. Since we include at most one pair for (i', r'), this implies that $|F'| \leq k'$. The cost of the pair we include is at most $15R^*$, since all $(i, r) \in F_1 \cup F_2$ satisfy $r \leq 3R^*$. Therefore, $cost(F') \leq OPT_{\text{C-P}} + 15R^*$. Also, $OPT_{\text{C-P}} \leq 2bC_2 + (2b + a)C_1 = 2bC_2 + (1 + b)C_1$, since setting $x_{i,r} = b$ for all $(i, r) \in F_2$ yields a feasible solution to (C-P) of this cost.

So when we terminate in step B3, we return a solution F with $cost(F) \leq \min\{C_2, 2bC_2 + (1+b)C_1 + 15R^*\}$. We show that $\min\{C_2, 2bC_2 + (1+b)C_1\} \leq 2.0607(aC_1 + bC_2)$ for all $a, b \geq 0$ with $a + b = 1$. Combining this with Claim 4 yields the bound in the theorem. ◀

Proof. Proof of Theorem 2 It suffices to show that when the selection $F^O = \{(i_1, r_1), \ldots (i_t, r_t)\}$ in step A1 corresponds to the t facilities in an optimal solution with largest radii, we obtain the desired approximation bound. In this case, we have $R^* \leq \frac{O^*}{t} \leq \epsilon O^*$ and $OPT \leq O^* - \sum_{p=1}^{t} r_p$. Combining Theorem 5 and Lemma 1 then yields the theorem. ◀

Improved approximation ratio. The improved approximation ratio comes from a better way of combining F_1 and F_2 in step B2. We observe that the dual solutions α^1 and α^2 are component-wise close to each other (we can control the closeness by controlling δ_z). Thus, we may essentially assume that if $T_{1,I}$, $T_{2,I}$ denote the tight pairs yielding F_1, F_2 respectively, then every pair in $T_{1,I}$ intersects some pair in $T_{2,I}$, because we can augment $T_{2,I}$ to include non-intersecting pairs of $T_{1,I}$. This yields dividends when we combine solutions as in step B2, because we can now ensure that if $\pi(i', r') = (i, r)$, then the pairs of $T_{2,I}$ and $T_{1,I}$ yielding (i, r) and (i', r') respectively intersect, which yields an improved bound on $c_{i,i'}$. This yields an improved approximation of 3.83 for the combination step, and hence for the entire algorithm.

▶ **Theorem 6.** *For any $\epsilon > 0$, our algorithm returns a feasible* LBkSR*-solution of cost at most $(3.83 + O(\epsilon))O^*$ in time $n^{O(1/\epsilon)}$.*

2.2 Approximation algorithm for LBkSRO

We now build upon the ideas in Section 2.1 to devise an $O(1)$-approximation algorithm for the outlier version LBkSR. The high-level approach is similar to the one in Section 2.1. We again "guess" the t (i, r) pairs F^O corresponding to the facilities with largest radii in an optimal solution, and consider the modified k-BS-instance $(\mathcal{D}', \mathcal{L}', k', m)$ (where $\mathcal{D}', \mathcal{L}', k'$ are defined as before). If the LP-relaxation below, (P_2), for the k-BS-problem is infeasible, we move on to the next guess. Otherwise, we design a primal-dual algorithm for the Lagrangian relaxation of the k-BS-problem where we are allowed to pick any number of pairs from $\mathcal{L}'$ (leaving at most m uncovered clients) incurring a fixed cost of z for each pair picked, utilize this to obtain two solutions F_1 and F_2, and combine these to extract a low-cost solution. However, the presence of outliers introduces various difficulties both in the primal-dual algorithm and in the combination step. Consider the following LP-relaxation of the k-BS-problem and its dual.

$$
\begin{array}{lll}
\min & \displaystyle\sum_{(i,r)\in\mathcal{L}'} r \cdot y_{i,r} & (P_2) \\
\text{s.t.} & \displaystyle\sum_{(i,r)\in\mathcal{L}': j\in B(i,r)} y_{i,r} + w_j \geq 1 & \forall j \in \mathcal{D}' \\
& \displaystyle\sum_{(i,r)\in\mathcal{L}'} y_{i,r} \leq k', \quad \sum_{j\in\mathcal{D}'} w_j \leq m & \\
& y, w \geq 0. &
\end{array}
\qquad
\begin{array}{lll}
\max & \displaystyle\sum_{j\in\mathcal{D}'} \alpha_j - k' \cdot z - m \cdot \gamma & (D_2) \\
\text{s.t.} & \displaystyle\sum_{j\in B(i,r)\cap\mathcal{D}'} \alpha_j - z \leq r & \forall (i,r) \in \mathcal{L}' \\
& \alpha_j \leq \gamma & \forall j \in \mathcal{D}' \\
& \alpha, z, \gamma \geq 0. &
\end{array}
\tag{3}
$$

Let OPT denote the optimal value of (P_2). The natural modification of the earlier primal-dual algorithm PDAlg is to now stop the dual-ascent process when the number of active clients is at most m and set $\gamma = \max_{j\in\mathcal{D}'} \alpha_j$. This introduces the significant complication

that one may not be able to pay for the $r+z$-cost of non-intersecting tight pairs selected in the pruning phase by the dual objective value $\sum_{j\in\mathcal{D}'}\alpha_j - m\cdot\gamma$, since clients with $\alpha_j=\gamma$ may be needed to pay for the $r+z$-cost of the last tight pair $f=(i_f,r_f)$ but their contribution gets canceled by the $-m\cdot\gamma$ term. This issue affects us in various guises. First, we no longer obtain an LMP-approximation for the unconstrained problem since we have to account for the $(r+z)$-cost of f separately. Second, unlike Claim 4, given solutions F_1 and F_2 obtained via binary search for $z_1, z_2 \approx z_1$ respectively with $|F_2|\le k'\le|F_1|$, we now only obtain a fractional k-BS-solution of cost $O(OPT+z_1)$. While one can modify the covering-knapsack-LP based procedure in step B2 of k-BSAlg to combine F_1, F_2, this only yields a good solution when $z_1=O(OPT)$. The chief technical difficulty is that z_1 may however be much larger than OPT. Overcoming this obstacle requires various novel ideas and is the key technical contribution of our algorithm. We design a second combination procedure that is guaranteed to return a good solution when $z_1=\Omega(OPT)$. This requires establishing certain structural properties for F_1 and F_2, using which we argue that one can find a good solution in the neighborhood of F_1 and F_2.

We now detail the changes to the primal-dual algorithm and k-BSAlg in Section 2.1, and analyze them to prove the following theorem.

▶ **Theorem 7.** *There exists a $\big(12.365+O(\epsilon)\big)$-approximation algorithm for* LBkSRO *that runs in time $n^{O(1/\epsilon)}$ for any $\epsilon>0$.*

Modified primal-dual algorithm PDAlg$^{\circ}(\mathcal{D}',\mathcal{L}',z)$. This is quite similar to PDAlg (and we again return pairs from $\mathcal{L}$). We stop the dual-ascent process when there are at most m active clients. We set $\gamma=\max_{j\in\mathcal{D}'}\alpha_j$. Let $f=(i_f,r_f)$ be the last tight pair added to the tight-pair set T, and $B_f=B(i_f,r_f)$. We sometimes abuse notation and use (i,r) to also denote the singleton set $\{(i,r)\}$. For a set P of (i,r) pairs, define $\mathsf{uncov}(P):=\mathcal{D}'\setminus\bigcup_{(i,r)\in P}B(i,r)$. Note that $|\mathsf{uncov}(T\setminus f)|>m\ge|\mathsf{uncov}(T)|$. Let Out be a set of m clients such that $\mathsf{uncov}(T)\subseteq Out\subseteq\mathsf{uncov}(T\setminus f)$. Note that $\alpha_j=\gamma$ for all $j\in Out$.

The pruning phase is similar to before, but we only use f if necessary. Let T_I be a maximal subset of non-intersecting pairs picked by greedily scanning pairs in $T\setminus f$ in non-increasing order of radius. For $i\in\mu(T_I)$, set $\mathsf{rad}(i)$ to be the unique r such that $(i,r)\in T_I$, and let r_i be the smallest radius ρ such that $B(i,\rho)\supseteq B(i',r')$ for every $(i',r')\in T\setminus f$ such that $r'\le\mathsf{rad}(i)$ and (i',r') intersects $(i,\mathsf{rad}(i))$. Let $F'=\{(i,r_i)\}_{i\in\mu(T_I)}$. If $\mathsf{uncov}(F')\le m$, set $F=F'$. If $\mathsf{uncov}(F')>m$ and $\exists i\in\mu(F')$ such that $c(i,i_f)\le 2R^*$, then increase r_i so that $B(i,r_i)\supseteq B_f$ and let F be this updated F'. Otherwise, set $F=F\cup f$ and $r_{i_f}=\mathsf{rad}(i_f)=r_f$. We return $(F,f,Out,\{rad(i)\}_{i\in\mu(F)},\alpha,\gamma)$.

▶ **Theorem 8.** *Let $(F,f,Out,\{\mathsf{rad}(i)\},\alpha,\gamma)=\mathsf{PDAlg}^{\circ}(\mathcal{D}',\mathcal{L}',z)$. Then:*
- **(i)** $\mathsf{uncov}(F)\le m$;
- **(ii)** $cost(F\setminus f)+3|F\setminus f|z-3R^*\le 3(\sum_{j\in\mathcal{D}'}\alpha_j-m\gamma)\le 3(OPT+k'z)$;
- **(iii)** $\big\{(i,\mathsf{rad}(i))\big\}_{i\in\mu(F)}\subseteq\mathcal{L}'$, *is a set of non-intersecting pairs,* $\mathsf{rad}(i)\le r_i\le 3R^*\ \forall i\in\mu(F)$;
- **(iv)** *if $|F\setminus f|\ge k'$ then $cost(F)\le 3\cdot OPT+4R^*$, and if $|F\setminus f|>k'$ then $z\le OPT$.*

Modified algorithm k-BSAlg$^{\circ}(\mathcal{D}',\mathcal{L}',k',\epsilon)$. We again use binary search to find solutions F_1, F_2 and extract a low-cost solution from these. The only changes to step B1 are as follows. We start with $z_1=0$ and $z_2=2nk'c_{\max}$; for this z_2, one can argue PDAlg$^{\circ}$ returns at most k' pairs. We stop when $z_2-z_1\le\delta_z:=\frac{\epsilon OPT}{3n2^n}$. We *do not stop* even if PDAlg$^{\circ}$ returns a solution $(F,\ldots)$ with $|F|=k'$ for some $z=\frac{z_1+z_2}{2}$, since *Theorem 8 is not strong enough to bound cost(F) even when this happens!* If $|F|>k'$, we update $z_1\leftarrow z$ and the F_1-solution;

otherwise, we update $z_2 \leftarrow z$ and the F_2-solution. Thus, we maintain that $k_1 = |F_1| > k'$, and $k_2 = |F_2| \leq k'$.

The main change is in the way solutions F_1, F_2 are combined. We adapt step B2 to handle outliers (procedure $\mathcal{A}$ in Section 2.2.1), but the key extra ingredient is that we devise an alternate combination procedure $\mathcal{B}$ (Section 2.2.2) that returns a low-cost solution when $z_1 = \Omega(OPT)$. We return the better of the solutions output by the two procedures. Combining Theorem 9 with Lemma 1 (for the right selection of t (i,r) pairs) yields Theorem 7.

▶ **Theorem 9.** *k-BSAlg$^\circ(\mathcal{D}', \mathcal{L}', k', \epsilon)$ returns a solution (F, rad) with $cost(F) \leq \big(12.365 + O(\epsilon)\big) \cdot OPT + O(R^*)$ where $\big\{(i, \mathsf{rad}(i))\big\}_{i \in \mu(F)} \subseteq \mathcal{L}'$ comprises non-intersecting pairs.*

2.2.1 Combination subroutine $\mathcal{A}\Big((F_1, \mathsf{rad}_1), (F_2, \mathsf{rad}_2)\Big)$

As in step B2, we cluster the F_1-pairs around F_2-pairs in stars. However, unlike before, some $(i', r') \in F_1$ may remain *unclustered* and and we may not pick (i', r') or some pair close to it. Since we do not cover all clients covered by F_1, we need to cover a suitable number of clients from $\mathsf{uncov}(F_1)$. We again setup an LP to obtain a suitable collection of pairs, which is now a 2-dimensional covering knapsack LP, and use the structure of an extreme-point optimal solution to extract from it a good collection of pairs.

▶ **Theorem 10.** *We can obtain a solution $\big(F, \{\mathsf{rad}(i)\}_{i \in \mu(F)}\big)$ to the k-BS-problem with $cost(F) \leq \big(6.1821 + O(\epsilon)\big)(OPT + z_1) + O(R^*)$ where $\big\{(i, \mathsf{rad}(i))\big\}_{i \in \mu(F)} \subseteq \mathcal{L}'$ is a set of non-intersecting pairs.*

2.2.2 Subroutine $\mathcal{B}\Big((F_1, f_1, Out_1, \mathsf{rad}_1, \alpha^1, \gamma^1), (F_2, f_2, Out_2, \mathsf{rad}_2, \alpha^2, \gamma^2)\Big)$

Subroutine $\mathcal{A}$ in the previous section yields a low-cost solution only if $z_1 = O(OPT)$. We complement subroutine $\mathcal{A}$ by now describing a procedure that returns a good solution when z_1 is large. We assume in this section that $z_1 > (1+\epsilon)OPT$. Then $|F_1 \setminus f_1| \leq k'$ (otherwise $z \leq OPT$ by part (iv) of Theorem 8), so $|F_1 \setminus f_1| \leq k' < |F_1|$, which means that $k_1 = k' + 1$ and $f_1 \in F_1$. Hence, $\alpha^1_j = \gamma^1$ for all $j \in B_{f_1} \cap \mathcal{D}'$. We utilize the following *continuity lemma*, which is essentially Lemma 6.6 in [11]; we include a proof in the full version of the paper.

▶ **Lemma 11.** *Let $(F_p, \ldots, \alpha^p, \gamma^p) = \mathsf{PDAlg}^\circ(\mathcal{D}', \mathcal{L}', z_p)$ for $p = 1, 2$, where $0 \leq z_2 - z_1 \leq \delta_z$. Then, $\|\alpha^1_j - \alpha^2_j\|_\infty \leq 2^n\delta_z$ and $|\gamma^1 - \gamma^2| \leq 2^n\delta_z$. Thus, if (3) is tight for some $(i,r) \in \mathcal{L}'$ in one execution, then $\sum_{j \in B(i,r) \cap \mathcal{D}'} \alpha^p_j \geq r + z - 2^n\delta_z$ for $p = 1, 2$.*

First, we take care of some simple cases. If there exists $(i,r) \in F_1 \setminus f_1$ such that $\big|\mathsf{uncov}\big(F_1 \setminus \{f_1, (i,r)\} \cup (i, r + 12R^*)\big)\big| \leq m$, then set $F = F_1 \setminus \{f_1, (i,r)\} \cup (i, r + 12R^*)$. We have $cost(F) = cost(F_1 \setminus f_1) + 12R^* \leq 3 \cdot OPT + 15R^*$ (by part (ii) of Theorem 8). If there exist pairs $(i,r), (i',r') \in F_1$ such that $c(i,i') \leq 12R^*$, take r'' to be the minimum $\rho \geq r$ such that $B(i',r') \subseteq B(i,\rho)$ and set $F = F_1 \setminus \{(i,r), (i',r')\} \cup (i, r'')$. We have $cost(F) \leq cost(F_1 \setminus f_1) + 13R^* \leq 3 \cdot OPT + 16R^*$. In both cases, we return $\big(F, \{\mathsf{rad}_1(i)\}_{i \in \mu(F)}\big)$.

So we assume in the sequel that neither of the above apply. In particular, all pairs in F_1 are well-separated. Let $AT = \{(i,r) \in \mathcal{L}' : \sum_{j \in B(i,r) \cap \mathcal{D}'} \alpha^1_j \geq r + z_1 - 2^n\delta_z\}$ and $AD = \{j \in \mathcal{D}' : \alpha^1_j \geq \gamma^1 - 2^n\delta_z\}$. By Lemma 11, AT includes the tight pairs of $\mathsf{PDAlg}^\circ(\mathcal{D}', \mathcal{L}', z_p)$ for both $p = 1, 2$, and $Out_1 \cup Out_2 \subseteq AD$. Since the tight pairs T_2 used for building solution F_2 are almost tight in $(\alpha^1, \gamma^1, z_1)$, we swap them in and swap out pairs from F_1 one by one while maintaining a feasible solution. Either at some point, we will

be able to remove f, which will give us a solution of size k', or we will obtain a bound on $cost(F_2)$. The following lemma is our main tool for bounding the cost of the solution returned.

▶ **Lemma 12.** *Let $F \subseteq \mathcal{L}'$, and $T_F = \{(i, r'_i)\}_{i \in \mu(F)}$ where $r'_i \leq r$ for each $(i, r) \in F$. Suppose $T_F \subseteq AT$ and consists of non-intersecting pairs. If $|F| \geq k'$ and $|AD \setminus \bigcup_{(i,r)\in F} B(i, r))| \geq m$ then $cost(T_F) \leq (1 + \epsilon)OPT$. Moreover, if $|F| > k'$ then $z_1 \leq (1 + \epsilon)OPT$.*

Define a mapping $\psi : F_2 \to F_1 \setminus f_1$ as follows. Note that any $(i, r) \in F_2$ may intersect with at most one F_1-pair: if it intersects $(i', r'), (i'', r'') \in F_1$, then we have $c(i', i'') \leq 12R^*$. First, for each $(i, r) \in F_2$ that intersects with some $(i', r') \in F_1$, we set $\psi(i, r) = (i', r')$. Let $M \subseteq F_2$ be the F_2-pairs mapped by ψ this way. For every $(i, r) \in F_2 \setminus M$, we arbitrarily match (i, r) with a *distinct* $(i', r') \in F_1 \setminus \psi(M)$. We claim that ψ is in fact a one-one function.

▶ **Lemma 13.** *Every $(i, r) \in F_1 \setminus f_1$ intersects with at most one F_2-pair.*

Let F'_2 be the pairs $(i, r) \in F_2$ such that if $(i', r') = \psi(i, r)$, then $r' < r$. Let $P = F'_2 \cap M$ and $Q = F'_2 \setminus M$. For every $(i', r') \in \psi(Q)$ and $j \in B(i', r')$, we have $j \in \mathsf{uncov}(F_2) \subseteq AD$ (else (i', r') would lie in $\psi(M)$). Starting with $F = F_1 \setminus f_1$, we iterate over $(i, r) \in F'_2$ and do the following. Let $(i', r') = \psi(i, r)$. If $(i, r) \in P$, we update $F \leftarrow F \setminus (i', r') \cup (i, r + 2r')$ (so $B(i, r + 2r') \supseteq B(i', r')$), else we update $F \leftarrow F \setminus (i', r') \cup (i, r)$. Let $T_F = \{(i, \mathsf{rad}_1(i))\}_{(i,r)\in F\cap F_1} \cup \{(i, \mathsf{rad}_2(i))\}_{(i,r)\in F\setminus F_1}$. Note that $|F| = k'$ and $\mathsf{uncov}(F) \subseteq AD$ at all times. Also, since (i, r) intersects only (i', r'), which we remove when (i, r) is added, we maintain that T_F is a collection of non-intersecting pairs and a subset of $AT \subseteq \mathcal{L}'$. This process continues until $|\mathsf{uncov}(F)| \leq m$, or when all pairs of F'_2 are swapped in. In the former case, we argue that $cost(F)$ is small and return $\big(F, \{\mathsf{rad}_1(i)\}_{(i,r)\in F\cap F_1} \cup \{\mathsf{rad}_2(i)\}_{(i,r)\in F\setminus F_1}\big)$. In the latter case, we show that $cost(F'_2)$, and hence $cost(F_2)$ is small, and return (F_2, rad_2).

▶ **Lemma 14.**

(i) *If the algorithm stops with $|\mathsf{uncov}(F)| \leq m$, $cost(F) \leq (9 + 3\epsilon)OPT + 18R^*$.*

(ii) *If case (i) does not apply, then $cost(F_2) \leq (3 + 3\epsilon)OPT + 9R^*$.*

(iii) *The pairs corresponding to the radii returned are non-intersecting, and a subset of $\mathcal{L}'$.*

3 Minimizing the maximum radius with lower bounds and outliers

The *lower-bounded k-supplier with outliers* (LBkSupO) problem is the min max-radius version of LBkSRO. The input and the set of feasible solutions are the same as in LBkSRO: the input is an instance $\mathcal{I} = \big(\mathcal{F}, \mathcal{D}, \{c(i, j)\}, \{L_i\}, k, m\big)$, and a feasible solution is $\big(S \subseteq \mathcal{F}, \sigma : \mathcal{D} \mapsto S \cup \{\mathsf{out}\}\big)$ with $|S| \leq k$, $|\sigma^{-1}(i)| \geq L_i$ for all $i \in S$, and $|\sigma^{-1}(\mathsf{out})| \leq m$. The cost of (S, σ) is now $\max_{i\in S} \max_{j\in\sigma^{-1}(i)} c(i, j)$. The case $m = 0$ is called the *lower-bounded k-supplier* (LBkSup) problem, and the setting where $\mathcal{D} = \mathcal{F}$ is often called the *k-center* version.

Let τ^* denote the optimal value; note that there are only polynomially many choices for τ^*. As is common in the study of min-max problems, we reduce the problem to a "graphical" instance, where given some value τ, we try to find a solution of cost $O(\tau)$ or deduce that $\tau^* > \tau$. We construct a bipartite unweighted graph $G_\tau = \big(V_\tau = \mathcal{D} \cup \mathcal{F}_\tau, E_\tau\big)$, where $\mathcal{F}_\tau = \{i \in \mathcal{F} : |B(i, \tau)| \geq L_i\}$, and $E_\tau = \{ij : c(i, j) \leq \tau, i \in \mathcal{F}_\tau, j \in \mathcal{D}\}$. Let $dist_\tau(i, j)$ denote the shortest-path distance in G_τ between i and j, so $c(i, j) \leq dist_\tau(i, j) \cdot \tau$. We say that an assignment $\sigma : \mathcal{D} \mapsto \mathcal{F}_\tau \cup \{\mathsf{out}\}$ is a *distance-α assignment* if $dist_\tau(j, \sigma(j)) \leq \alpha$ for every client j with $\sigma(j) \neq \mathsf{out}$. We call such an assignment feasible, if it yields a feasible LBkSupO-solution, and we say that G_τ is feasible if it admits a feasible distance-1 assignment. It is not hard to see that given $F \subseteq \mathcal{F}_\tau$, the problem of finding a feasible

distance-α-assignment $\sigma : \mathcal{D} \mapsto F \cup \{\mathsf{out}\}$ in G_τ (if one exists) can be solved by creating a network-flow instance with lower bounds and capacities.

Observe that an optimal solution yields a feasible distance-1 assignment in G_{τ^*}. We devise an algorithm that for every τ, either finds a feasible distance-α assignment in G_τ for some constant α, or detects that G_τ is not feasible. This yields an α-approximation algorithm since the smallest τ for which the algorithm returns a feasible LBkSupO-solution must be at most τ^*. We obtain Theorems 15 and 16 via this template, and complement these via a hardness result (Theorem 17) showing that our approximation factor for LBkSup is tight.

▶ **Theorem 15.** *There is a* 3*-approximation algorithm for* LBkSup.

▶ **Theorem 16.** *There is a* 5*-approximation algorithm for* LBkSupO.

▶ **Theorem 17.** *It is NP-hard to approximate* LBkSup *within a factor better than* 3.

Finding a distance-5 assignment for LBkSupO. The goal is to find a set $F \subseteq \mathcal{F}_\tau$ of at most k centers that are close to the centers in $F^* \subseteq \mathcal{F}_\tau$ for some feasible distance-1 assignment $\sigma^* : \mathcal{D} \mapsto F^* \cup \{\mathsf{out}\}$ in G_τ. If centers in F do not share a neighbor in G_τ, then clients in $N(i)$ can be assigned to i for each $i \in F$ to satisfy the lower bounds.

▶ **Definition 18** ([14])**.** Given the graph G_τ, a set $F \subseteq \mathcal{F}$ is called a *skeleton* if it satisfies the following properties.

(a) (*Separation property*) For $i, i' \in F$, $i \neq i'$, we have $dist_\tau(i, i') \geq 6$;

(b) There exists a feasible distance-1 assignment $\sigma^* : \mathcal{D} \mapsto F^* \cup \{\mathsf{out}\}$ in G_τ such that

- (*Covering property*) For all $i^* \in F^*$, $dist_\tau(i^*, F) \leq 4$, where $dist_\tau(i^*, F) = \min_{i \in F} dist_\tau(i^*, i)$.
- (*Injection property*) There exists $f : F \mapsto F^*$ such that $dist_\tau(i, f(i)) \leq 2$ for all $i \in F$.

If F satisfies the separation and injection properties, it is called a *pre-skeleton*.

▶ **Lemma 19.** *Let F be a pre-skeleton in G_τ. Define $U = \{i \in \mathcal{F}_\tau : dist_\tau(i, F) \geq 6\}$ and let $i = \arg\max_{i' \in U} |N(i')|$. Then, either F is a skeleton, or $F \cup \{i\}$ is a pre-skeleton.*

Suppose $F \subseteq \mathcal{F}_\tau$ is a skeleton and satisfies the properties with respect to a feasible distance-1 assignment (F^*, σ^*). The separation property ensures that the neighbor sets of any two locations $i, i' \in F$ are disjoint. The covering property ensures that F^* is at distance at most 4 from F, so there are at least $|\mathcal{D}| - m$ clients at distance at most 5 from F. Finally, the injection and separation properties together ensure that $|F| \leq k$. Thus, if F is a skeleton, then we can obtain a feasible distance-5 assignment $\sigma : \mathcal{D} \mapsto F \cup \{\mathsf{out}\}$.

If G_τ is feasible, then $\emptyset$ is a pre-skeleton. A skeleton can have size at most k. So using Lemma 19, we can find a sequence $\mathcal{F}'$ of at most $k+1$ subsets of $\mathcal{F}_\tau$ by starting with $\emptyset$ and repeatedly applying Lemma 19 until we either have a set of size k or the set U in Lemma 19 is empty. By Lemma 19, if G_τ is feasible then one of these sets must be a skeleton. So for each $F \in \mathcal{F}'$, we check if there exists a feasible distance-5 assignment $\sigma : \mathcal{D} \mapsto F \cup \{\mathsf{out}\}$, and if so, return (F, σ). Otherwise we return that G_τ is not feasible.

Abstract

We give a 2-approximation algorithm for the Maximum Agreement Forest problem on two rooted binary trees. This NP-hard problem has been studied extensively in the past two decades, since it can be used to compute the Subtree Prune-and-Regraft (SPR) distance between two phylogenetic trees. Our result improves on the very recent 2.5-approximation algorithm due to Shi, Feng, You and Wang (2015). Our algorithm is the first approximation algorithm for this problem that uses LP duality in its analysis.

1998 ACM Subject Classification F.2.2 Analysis of algorithms and problem complexity

1 Introduction

Evolutionary relationships are often modeled by a rooted tree, where the leaves are a set of species, and internal nodes are (putative) common ancestors of the leaves below the internal node. Such phylogenetic trees date back to Darwin [5], who used them in his notebook to elucidate his thoughts on evolution.

The topology of phylogenetic trees can be based on different sources of data, e.g., morphological data, behavioral data, genetic data, etc., which can lead to different phylogenetic trees on the same set of species. Different measures have been proposed to measure the similarity of (or distance between) different phylogenetic trees on the same set of species (or individuals). Using the size of a maximum subtree common to both input trees as a similarity measure was proposed by Gordon [8]. The problem of finding such a subtree is now known as the Maximum Agreement Subtree Problem, and has been studied extensively.

Steel and Warnow [14] are the first to give a polynomial-time algorithm for this problem. Their approach is refined to an $O(n^{1.5} \log n)$-time algorithm by Farach and Thorup [6], who subsequently show their algorithm is optimal, unless unweighted bipartite matching can be solved in near linear time [7].

There exist non-tree-like evolutionary processes that preclude the existence of a phylogenetic tree, so-called reticulation events (such as hybridization, recombination and horizontal gene transfer). In this context, a particularly meaningful measure of comparing phylogenetic trees is the SPR-distance measure (where SPR is short for Subtree Prune-and-Regraft): this measure provides a lower bound on a certain type of these non-tree evolutionary events. The problem of finding the exact value of this measure for a set of species motivated the formulation of the Maximum Agreement Forest Problem (MAF) by Hein, Jian, Wang and Zhang [9]. Since the introduction by Hein et al., MAF has been extensively studied, including several variants, such as the problem where the input consists of more than two trees, whether the input trees are rooted or unrooted, binary or non-binary. In our paper, we concentrate on MAF on two rooted binary trees.

For ease of defining the solutions to MAF on two rooted binary trees, we think of the input trees as being directed, where all edges are directed away from the root. Given two rooted binary trees on the same leaf set $\mathcal{L}$, the MAF problem asks to find a minimum set of edges to delete from the two trees, so that the directed trees in the resulting two forests can be paired up into pairs of "isomorphic" trees. Two trees are isomorphic if they contain the same nodes from $\mathcal{L}$ and recursively removing nodes of out-degree zero that are not in $\mathcal{L}$ and contracting two arcs incident to a node of in-degree and out-degree one, results in the same binary tree. An alternative (but equivalent) definition will be given in Section 2.

The problem of finding a MAF on two rooted binary trees has been extensively studied, although unfortunately some of the published results later turned out to have subtle errors. First of all, Allen and Steel [1] point out that the claim by Hein et al. that solving MAF on two rooted directed trees computes the SPR-distance between the trees is incorrect. Bordewich and Semple [4] show how to redefine MAF for rooted directed trees so that it is indeed the case that the optimal objective value of MAF is equal to the SPR-distance. In the paper in which they introduce MAF, Hein et al. [9] proved NP-hardness and they give an approximation algorithm for the problem, the approximation guarantee of which turned out to be slightly higher than what was claimed. Bordewich and Semple [4] show that, for their corrected definition of MAF, NP-hardness continues to hold. Other approximation algorithms followed [11, 2, 3]. The current best approximation ratio for MAF is 2.5, due to Shi, Feng, You and Wang [13], and Rodrigues [10] has shown that MAF is MAXSNP-hard. In addition, there is a body of work on other approaches, such as Fixed-Parameter Tractable (FPT) algorithms (e.g., [16, 15]) and Integer Programming [17, 18].

In this paper we give an improved approximation algorithm for MAF with an analysis based on linear programming duality. Our 2-approximation algorithm differs from previous works in two aspects. First of all, in terms of bounding the optimal value, we construct a feasible dual solution, rather than arguing more locally about the objective of the optimal solution. Secondly, our algorithm itself also takes a more global approach, whereas the algorithms in previous works mainly consider local substructures of at most four leaves. In particular, we identify a minimal subtree[1] of one of the two input trees for which the leaf set is incompatible, i.e., when deleting all other leaves from both trees, the remaining two trees

[1] By subtree of a rooted tree, we mean a tree containing the leaves that are descendents of some particular node in the rooted tree (including this node itself), and all edges between them.

are not isomorphic (such a minimal subtree can be found efficiently). We then use "local" operations which repeatedly look at two "sibling" leaves in the minimal incompatible subtree, and perform similar operations as those suggested by previous authors.

Preliminary tests were conducted using a proof-of-concept implementation of our algorithm in Java. Our preliminary results indicate that our algorithm finds a dual solution that in 44% of the 1000 runs is equal to the optimal dual solution, and in 37% of the runs is 1 less than the optimal solution. The observed average approximation ratio is about 1.92; following our algorithm with a simple greedy search algorithm decreases this to less than 1.28.

The remainder of our paper is organized as follows. In Section 2, we formally define the problem. In Section 3, we give a 3-approximation algorithm for MAF that introduces the dual linear program that is used throughout the remainder of the paper and gives a flavor of the arguments used to prove the approximation ratio of two. In Section 4, we give an overview of the 2-approximation algorithm and the key ideas in its analysis. In Section 5 we give more details on the randomly generated instances that we used to obtain our preliminary experimental results, and we conclude in Section 6 with some directions for future research.

The full version of this paper [12] contains further details on the algorithm and a complete analysis that shows that its approximation ratio is 2.

2 Preliminaries

The input to the Maximum Agreement Forest problem (MAF) consists of two rooted binary trees T_1 and T_2, where the leaves in each tree are labeled with the same label set $\mathcal{L}$. Each leaf has exactly one label, and each label in $\mathcal{L}$ is assigned to exactly one leaf in T_1, and one leaf in T_2. For ease of exposition, we sometimes think of the edges in the trees as being directed, so that there is a directed path from the root to each of the leaves.

We call the non-leaf nodes the internal nodes of the trees, and we let V denote the set of all nodes (internal nodes and leaves) in $T_1 \cup T_2$. Given a tree containing u and v, we let $\text{lca}(u, v)$ denote the lowest (closest to the leaves, furthest from the root) common ancestor of u and v. We let $\text{lca}_1(u, v)$ and $\text{lca}_2(u, v)$ denote $\text{lca}(u, v)$ in tree T_1, respectively, T_2. We extend this notation to $\text{lca}(U)$ which will denote the lowest common ancestor of a set of leaves U. For three leaves u, v, w and a rooted tree T, we use the notation $uv|w$ in T to denote that $\text{lca}(u, v)$ is a descendent of $\text{lca}(\{u, v, w\})$. A triplet $\{u, v, w\}$ of labeled leaves is *consistent* if $uv|w$ in $T_1 \Leftrightarrow uv|w$ in T_2. The triplet is called *inconsistent* otherwise. We call a set of leaves $L \subseteq \mathcal{L}$ a *compatible set*, if it does not contain an inconsistent triplet.

For a compatible set $L \subseteq \mathcal{L}$, define $V[L] := \{v \in V$: there exists a pair of leaves u, u' in L so that v is on the path between u and u' in T_1 or $T_2\}$. Then, a partitioning $L_1, L_2, \ldots, L_p$ of $\mathcal{L}$ corresponds to a feasible solution to MAF with objective value $p - 1$, if the sets $L_1, L_2, \ldots, L_p$ are compatible, and the sets $V[L_j]$ for $j = 1, \ldots, p$ are node disjoint. Using this definition, we can write the following Integer Linear Program[2] for MAF: Let $\mathcal{C}$ be the collection of all compatible sets of leaves, and introduce a binary variable x_L for every compatible set $L \in \mathcal{C}$, where the variable takes value 1 if the optimal solution to MAF has a tree with leaf set L. The constraints ensure that each leaf $v \in \mathcal{L}$ is in some tree in the optimal forest, and each internal node $v \in V \setminus \mathcal{L}$ is in at most one tree in the optimal forest. The objective encodes the fact that we need to delete $\sum_{L \in \mathcal{C}} x_L - 1$ edges from each of T_1

[2] This ILP was obtained in discussions with Neil Olver and Leen Stougie.

and T_2 to obtain forests with $\sum_{L\in\mathcal{C}} x_L$ trees.

$$\begin{array}{lll} \text{minimize} & \sum_{L\in\mathcal{C}} x_L - 1, & \\ \text{s.t.} & \sum_{L:v\in L} x_L = 1 & \forall v \in \mathcal{L}, \\ & \sum_{L:v\in V[L]} x_L \leq 1 & \forall v \in V \setminus \mathcal{L}, \\ & x_L \in \{0,1\} & \forall L \in \mathcal{C}. \end{array}$$

Remark

The definition of MAF we use is *not* the definition that is now standard in the literature, but any (approximation) algorithm for our version can be used to get the same (approximation) result for the standard formulation: The standard formulation was introduced by Bordewich and Semple [4] in order to ensure that the objective value of MAF is equal to the rooted SPR distance. They note that for this to hold, we need the additional requirement that the two forests must also agree on the tree containing the original root; in other words, the original roots of T_1 and T_2 should be contained in a tree with the same (compatible) subset of leaves. An easy reduction shows that we can solve this problem using our definition of MAF: given two rooted binary trees for which we want to compute the SPR distance, we can simply add one new label ρ, and for each of the two input trees, we add a new root which has an edge to the original root and an edge to a new node with label ρ.[3] A solution to "our" MAF problem on this modified input defines a solution to Bordewich and Semple's problem on the original input with the same objective value and vice versa.

3 Duality Based 3-Approximation Algorithm

3.1 Algorithm

The algorithm we describe in this section is a variant of the algorithm of Rodrigues et al. [11] (see also Whidden and Zeh [16]). The algorithm maintains two forests, T_1' and T_2' on the same leaf set $\mathcal{L}'$, and iteratively deletes edges from these forests. At the start, T_1' is set equal to T_1, T_2' to T_2 and $\mathcal{L}'$ to $\mathcal{L}$. The leaves in $\mathcal{L}'$ are called the *active* leaves. The algorithm will ensure that the leaves that are not active, will have been resolved in one of the two following ways: (1) they are part of a tree that contains only inactive leaves in both T_1' and T_2'; these two trees then have the same leaf set, which is compatible, and they will be part of the final solution; or (2) an inactive leaf is *merged* with another leaf which is active, and in the final solution this inactive leaf will be in the same tree as the leaf it was merged with.

A tree is called active if it contains a leaf in $\mathcal{L}'$, and the tree is called inactive otherwise. An invariant of the algorithm is that there is a single active tree in T_1'.

We define the parent of a set of active leaves W in a tree of a forest, denoted by $p(W)$, as the lowest node in the tree that is a common ancestor of W and at least one other active node. (That is, $p(W)$ is undefined if there are no other active leaves in the tree that contains the leaves in W.) Note that the parent of a node is defined with respect to the current state of the algorithm, and not with respect to the initial input tree. If $W = \{u\}$ is a singleton, we will also use the notation $p(u) = p(\{u\})$. For a given tree or forest T_i', for $i \in \{1,2\}$, we use the notation $p_i(W)$ to denote $p(W)$ in T_i'.

[3] This is essentially the formulation that is common in the literature, except that in order to ensure that *only leaves have labels*, we give the label ρ to a new leaf that is an immediate descendent of the new root in both trees, rather than to the new root itself.

The operation in the algorithm that deletes edges from forest T_i' is *cut off a subset of leaves* W in T_i'. The edge that is deleted by this operation is the edge directly below $p_i(W)$ towards W (provided $p_i(W)$ is defined). Note that this means that the algorithm maintains the property that each internal node has a path to at least one leaf in $\mathcal{L}$. This ensures that the number of trees with leaves in $\mathcal{L}$ in T_i' is equal to the number of edges cut in T_i' plus 1. It also ensures that the only leaves (nodes with outdegree 0) are the nodes in $\mathcal{L}$.

We will call two leaves u and v *a sibling pair* or *siblings* in a forest, if they belong to the same tree in the forest, and they are the only two leaves in the subtree rooted at the lowest common ancestor $\text{lca}(u, v)$. Similarly, u and v are an *active* sibling pair in a forest, if they belong to the same tree in the forest, and are the only two *active* leaves in the subtree rooted at the lowest common ancestor $\text{lca}(u, v)$ (an equivalent definition is that $p(u) = p(v)$ in the forest).

If leaves u and v are an active sibling pair in both T_1' and T_2', we *merge* one of the leaves (say u) with the other (v). This means that from that point on v represents the subtree containing both u and v, instead of just the leaf v itself. This is accomplished by just making u inactive. Note that this merge operation can be performed recursively, where one or both of the leaves involved in the operation can already be leaves that represent subtrees. It is not hard to see that the subtree that is represented by an active leaf v is one of the two subtrees rooted at the child of $p(v)$, namely the subtree that contains v.

If leaves u and v are not active siblings in T_2' (and they are active siblings in T_1'), we can choose to *cut off an active subtree* between leaves u and v. To describe this operation, let $W_1, W_2, \ldots, W_k$ be the active leaves of the active trees that would be created by deleting the path between u and v (both the nodes and the edges) in T_2'. Note that $p_2(W_\ell)$ is on the path between u and v for all $\ell \in \{1, 2, \ldots, k\}$, because u and v are not active siblings. Cutting off an active subtree between leaves u and v now means cutting off any such a set W_ℓ.

The algorithm is given in Algorithm 1. The boxed expressions refer to updates of the dual solution which will be discussed in Section 3.2.2. These expressions are only necessary for the analysis of the algorithm.

▶ **Theorem 1.** *Algorithm 1 is a 3-approximation algorithm for the Maximum Agreement Forest problem.*

The proof of this theorem is given in the next subsection. It is clear the algorithm can be implemented to run in polynomial time. In Section 3.2.1, we show that the algorithm returns an agreement forest and we show that the number of edges deleted from T_2 by the algorithm can be upper bounded by three times the objective value of a feasible solution to the dual of a linear programming (LP) relaxation of MAF.

3.2 Analysis of the 3-Approximation Algorithm

3.2.1 Correctness

We need to show that the algorithm outputs an agreement forest. The trees of T_1' and T_2' each give a partitioning of $\mathcal{L}$, and clearly any internal node v belongs to $V[L]$ for at most one set in the partitioning. It remains to show that the two forests give the *same* partitioning of $\mathcal{L}$ and that each set in the partitioning is compatible.

The algorithm ends with all trees in T_1' and T_2' being inactive, and the algorithm maintains that the set of leaves represented by an active leaf u (i.e., the leaves that were merged with u (recursively), and u itself) form the leaf set of a subtree in both T_1' and T_2'. To be precise, it is the subtree rooted at one of the children of $p(u)$, namely the subtree that contains u.

1 $\boxed{y_v \leftarrow 0 \text{ for all } v \in V.}$
2 **while** *there exist at least 2 active leaves* **do**
3 Find an active sibling pair u, v in the active tree in T_1'.
4 **if** *u or v is the only active leaf in its tree in T_2'* **then**
5 Cut off this node (say u) in T_1' as well and make it inactive. $\boxed{y_u \leftarrow 1.}$
6 **else**
7 **if** *u and v are active siblings in T_2'* **then**
8 Merge u and v (i.e., make u inactive to "merge" it with v).
9 **else**
10 **if** *u and v are in the same tree in T_2', and this tree contains an active leaf w such that $uv|w$ in T_2* **then**
11 Cut off an active subtree W between u and v in T_2'. $\boxed{\text{Decrease } y_{p_2(W)} \text{ by 1.}}$
12 **end if**
13 Cut off u and cut off v in T_1' and T_2' and make them inactive.
$\boxed{y_u \leftarrow 1,\ y_v \leftarrow 1, \text{ decrease } y_{\mathrm{lca}_1(u,v)} \text{ by 1.}}$
14 **end if**
15 **end if**
16 **end while**
17 Make the remaining leaf (say v) inactive. $\boxed{y_v \leftarrow 1.}$

Algorithm 1: A 3-Approximation for Maximum Agreement Forest. The boxed text refers to updates of the dual solution as discussed in Section 3.2.2.

Furthermore note that this leaf set is compatible. This is easily verified by induction on the number of merges.

When u is the only active leaf in its tree in both forests, then the trees containing u in the two forests are thus guaranteed to have the same, compatible, set of leaves. Now, an inactive tree is created exactly when both T_1' and T_2' have an active tree in which some u is the only active leaf (lines 5, 13 and 17), and thus the two forests indeed induce the same partition of $\mathcal{L}$ into compatible sets.

3.2.2 Approximation Ratio

In order to prove the claimed approximation ratio, we will construct a feasible dual solution to the dual of the relaxation of the ILP given in Section 2. The dual LP is given in Figure 1(a). The dual LP has an optimal solution in which $0 \leq y_v \leq 1$ for all $v \in \mathcal{L}$. The fact that $\{v\}$ is a compatible set implies that $y_v \leq 1$ must hold for every $v \in \mathcal{L}$. Furthermore, note that changing the equality constraints of the primal LP to $\geq$-inequalities does not change the optimal value, and hence we may assume $y_v \geq 0$ for $v \in \mathcal{L}$.

It will be convenient for our analysis to rewrite this dual by introducing additional variables for every (not necessarily compatible) set of labeled leaves. We will adopt the convention to use the letter A to denote a set of leaves that is not necessarily compatible, and the letter L to denote a set of leaves that is compatible (i.e., $L \in \mathcal{C}$). The dual LP can then be written as in Figure 1(b). Any solution to this new LP can be transformed into a solution to the original dual LP by, for each A such that $z_A > 0$, taking some leaf $v \in A$ and setting $y_v = y_v + z_A$ and $z_A = 0$. This is feasible because the left-hand side of the first family of inequalities will not increase for any compatible set L, and it will decrease for L such that $A \cap L \neq \emptyset$ and $v \notin L$. Conversely, a solution to the original dual LP is feasible for this new LP by setting $z_A = 0$, for every set of labeled leaves A.

$$\begin{array}{lll} \max & \sum_v y_v - 1, & \\ \text{s.t.} & \sum_{v \in V[L]} y_v \leq 1 & \forall L \in \mathcal{C}, \\ & y_v \leq 0 & \forall v \in V \setminus \mathcal{L}. \end{array}$$

(a) Dual LP

$$\begin{array}{lll} \max & \sum_v y_v + \sum_{A \subseteq \mathcal{L}} z_A - 1, & \\ \text{s.t.} & \sum_{v \in V[L]} y_v + \sum_{A : A \cap L \neq \emptyset} z_A \leq 1 & \forall L \in \mathcal{C}, \\ & y_v \leq 0 & \forall v \in V \setminus \mathcal{L}, \\ & y_v \geq 0 & \forall v \in \mathcal{L}, \\ & z_A \geq 0 & \forall A \subseteq \mathcal{L}. \end{array}$$

(b) Reformulated dual LP

Figure 1 The dual of the LP relaxation for the ILP given in Section 2. The reformulated dual LP will be referred to as (D).

We will refer to the left-hand side of the first family of constraints, i.e., $\sum_{v \in V[L]} y_v + \sum_{A : A \cap L \neq \emptyset} z_A$, as the *load* on set L.

▶ **Definition 2.** The dual solution associated with a forest T_2', obtained from T_2 by edge deletions, active leaf set $\mathcal{L}'$, and variables $y = \{y_v\}_{v \in V}$ is defined as (y, z) where $z_A = 1$ exactly when A is the active leaf set of a tree in T_2', and 0 otherwise.

We will sometimes use "the dual solution" to refer to the dual solution associated with $T_2', \mathcal{L}'$ and y when the forest, active leaf set and y-values are clear from the context.

▶ **Lemma 3.** *After every execution of the while-loop of Algorithm 1, the dual solution associated with T_2', $\mathcal{L}'$, and y is a feasible solution to (D) and the objective value of this solution is at least $\frac{1}{3}|E(T_2) \setminus E(T_2')|$.*

Proof. We prove the lemma by induction on the number of iterations. Initially, $z_{\mathcal{L}} = 1$, and all other variables are equal to 0. Clearly, this is a feasible solution with objective value 0.

Observe that the dual solution maintained by the algorithm satisfies that $y_u = 0$ while u is active. Therefore, if there is a single active leaf u in a tree in T_2', then making this leaf u inactive and setting $y_u = 1$ does not affect dual feasibility and the dual objective value, since making u inactive decreases $z_{\{u\}}$ from 1 to 0. Also note that merging two active leaves (and thus making one of the two leaves inactive), replaces the set of active leaves A in an active tree in T_2' by a smaller set $A' \subset A$, with $A' \neq \emptyset$. Hence, the dual solution changes from having $z_A = 1$ to having $z_{A'} = 1$, which clearly does not affect dual feasibility or the dual objective value. Hence, we only need to verify that the dual solution remains feasible and its objective increases sufficiently for operations of the algorithm that cut edges from T_2', i.e., lines 11 and 13.

In line 11, one edge is cut in T_2', $y_{p_2(W)}$ decreases by 1. Let A be the set of active leaves in the tree containing W in T_2' before cutting off W. z_A decreases by 1, $z_{A \setminus W}$ increases by 1, z_W increases by 1. The only sets L for which the left-hand side potentially increases are sets L so that $W \cap L \neq \emptyset$ and $(A \setminus W) \cap L \neq \emptyset$. However, $p_2(W) \in V[L]$ for such sets L, and since $y_{p_2(W)}$ is decreased by 1, the load is not increased for any compatible set L. The dual objective is unchanged, but will change in line 13 of the algorithm, as we will show next.

In line 13, let A_u be the set of active leaves in the tree in T_2' containing u at the start of line 13 in the algorithm, and A_v be the set of active leaves in the tree in T_2' containing v. Note that $A_u \setminus \{u, v\} \neq \emptyset$: if $v \notin A_u$, then this holds because otherwise we would execute line 5, and if $v \in A_u$, then this holds because u, v are not active siblings at the start of line 11, and if u, v became active siblings after executing line 11, then the condition for line 11 implies that there exists $w \in A_u$ such that $uv|w$ in T_2.

The fact that $A_u \setminus \{u, v\} \neq \emptyset$ (and, by symmetry $A_v \setminus \{u, v\} \neq \emptyset$) implies that the total value of $\sum_A z_A + y_u + y_v$ increases by 2. Since we also decrease $y_{\mathrm{lca}_1(u,v)}$ by 1 the total increase in the objective of the dual solution by line 13 is 1. Also, in lines 11 and 13, a total of at most three edges are cut in T_2'.

It remains to show that executing line 13 does not make the dual solution (y, z) infeasible. Note that for each active set A' with $z_{A'} = 1$ before cutting off u and v, there is exactly one unique active subset $A \subseteq A'$ with $z_A = 1$ after cutting off u and v. Therefore the total value of $\sum_{A:A\cap L\neq\emptyset} z_A$ does not increase after cutting off u and v for any $L \subseteq \mathcal{L}$.

For any L that includes one of u, v, and at least one other active leaf, it must be the case that $\mathrm{lca}_1(u, v) \in V[L]$, because all active leaves are in one tree in T_1', and u and v were active siblings in T_1' at the start. Hence the only compatible sets L for which the load on L potentially increases by 1 because of an increase in $\sum_{x\in L} y_x$ are sets L that include both u and v. We discern two cases.

Case 1: An active subtree W was cut off in line 11. In this case, the load on L was decreased by 1 in line 11, compensating for the increase in line 13: $V[L]$ contains all nodes on the path between u and v in T_2, and hence also $p_2(W)$. It cannot contain a leaf $x \in W$, because $\{u, v, x\}$ form an inconsistent triplet (because $uv|x$ in T_1).

Case 2: No active subtree W was cut off in line 11. In this case, the value of $\sum_{A:A\cap L\neq\emptyset} z_A$ is decreased by at least 1: If u and v are in the same tree in T_2' before cutting off u and v, then this tree contains no leaves x such that $uv|x$ in T_2 since otherwise an active subtree W would have been cut off. Hence, L does not contain any active leaf x in the active tree that remains after cutting off u and v in T_2', since any such leaf x does not have $uv|x$ in T_2 and therefore forms an inconsistent triplet with u and v. Since L does contain active leaves in the tree containing u and v in T_2' before cutting off u and v (namely, u and v themselves), the value of $\sum_{A:A\cap L\neq\emptyset} z_A$ indeed decreases by 1.

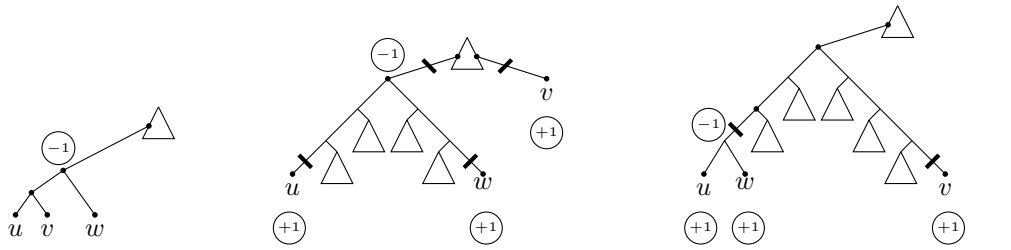
If u and v are not in the same tree in T_2' before cutting off u and v, then a similar argument holds. Since T_2' is obtained from T_2 by deleting edges, at least one of the two active trees containing u and v contains no leaves x such that $uv|x$ in T_2. Without loss of generality, suppose that this holds for the tree containing u. Then, L does not contain any active leaves in the active tree remaining after u is cut off, and hence $\sum_{A:A\cap L\neq\emptyset} z_A$ decreases by at least 1. ◀

By weak duality, we have that the objective value of any feasible solution to (D) provides a lower bound on the objective value of any feasible solution to the LP relaxation of our ILP for MAF, and hence also on the optimal value of the ILP itself. Theorem 1 thus follows from Lemma 3 and the correctness shown in Section 3.2.1.

4 Overview of the 2-Approximation Algorithm

In this section, we begin by giving an outline of the key ideas of our 2-approximation algorithm. We then give an overview of the complete algorithm that we call the "Red-Blue Algorithm".

One of the main ideas behind our 2-approximation is the consideration of the following two "essential" cases. The first "essential" case is the case where we have an active sibling pair u, v in T_1' that are (i) active siblings in T_2', or (ii) in different trees in T_2', or (iii) the tree in T_2' containing u, v does *not* contain an active leaf w such that $uv|w$ in T_2. Then, it is easy to verify, using the arguments in the proof of Lemma 3, that Algorithm 1 "works": it



(a) Subtree in T_1' **(b)** Case (I)(a): Subtree in T_2' **(c)** Case (I)(b): Subtree in T_2'

Figure 2 Dealing with an inconsistent triplet: Circled values denote the y-variables that are set by the algorithm, and bold diagonal lines denote edges that are cut (deleted from T_2'). Triangles denote subtrees with active leaves (that may be empty). Note that there is a distinction between edges that are incident to the root of a subtree represented by a triangle, and edges that are incident to some internal node of the subtree. The latter edges are connected to a dot on the triangle.

increases the dual objective value by at least half of the increase in $|E(T_2) \setminus E(T_2')|$. We will say such a sibling pair u, v is a "success".

The second "essential" case is the case where, in our current forest T_1', there is a subtree containing exactly three active leaves, say u, v, w, where $uv|w$ in T_1, and $\{u, v, w\}$ is an inconsistent triplet; assume without loss of generality that $uw|v$ in T_2, and that the first "essential" case does not apply; in particular, this implies that u, v are in the same tree in T_2'. It turns out that such an inconsistent triplet can be "processed" in a way that allows us to increase the objective value of the dual solution in such a way that it "pays for" half the increase in the number of edges cut from T_2'. There are a number of different cases to consider depending on whether all three leaves u, v, w are in the same tree in T_2' (case I) or not (case II), and whether the tree in T_2' containing w has an active leaf x such that $xw|u$ in T_2' (case (a)) or not (case (b)).

Figure 2 gives an illustration of T_1' and some possible configurations for T_2'. Consider for example case (I)(b). Since $\{u, v, w\}$ is an inconsistent triplet, it is not hard to see that any solution to MAF either has v as a singleton component, or either u or w must be a singleton component. Indeed, we can increase the dual objective by 1, by updating the y-values as indicated by the circled values in Figure 2 (a) and (b). The bold diagonal lines denote two edges that are cut (deleted from T_2'). Similar arguments can be made for the other cases.

Unfortunately, neither of the essential cases may be present in the forests T_1', T_2', and therefore the ideas given above may not be applicable. However, they do work if we generalize our notions. First, we generalize the notion of "active sibling pair in T_1'".

▶ **Definition 4.** A set of active leaves U is an *active sibling set* in T_1' if the leaves in U are the only active leaves in the subtree of T_1' rooted at $\text{lca}_1(U)$. U is a *compatible active sibling set* in T_1' if U is an active sibling set in T_1' that contains no inconsistent triplets.

Note that we will only use the term compatible active sibling set for T_1', and never for T_2'. We will therefore sometimes omit the reference to T_1', and simply talk about a "compatible active sibling set".

We similarly generalize the notion of a subtree in T_1' containing exactly three active leaves that form an inconsistent triplet.

▶ **Definition 5.** A set of active leaves $R \cup B$ is a *minimal incompatible active sibling set* in T_1' if $R \cup B$ is incompatible, R and B are compatible active sibling sets in T_1', and $p_1(R) = p_1(B)$.

The Red-Blue Algorithm now proceeds as follows: it begins by identifying a minimal incompatible active sibling set $R \cup B$ in T_1'. Such a set can be found by checking if the active leaf sets of the left and right subtrees of the root are compatible sets. If yes, then either all active leaves are compatible, or we have found a minimal incompatible active set. If not, then the active leaf set of one of the subtrees is incompatible, and we recurse on this subtree until we find a node in T_1' for which the active leaf sets of the left and right subtrees form a minimal incompatible set $R \cup B$. Note that we can assume $\text{lca}_2(R) = \text{lca}_2(R \cup B)$.

The algorithm will then "distill" R by repeatedly considering sibling pairs u, v in R, and executing operations similar to those in Algorithm 1, except that only one of u and v becomes inactive (and a bit more care has to be taken in certain cases). Procedure 1 gives the procedure ResolvePair the algorithm uses for handling a sibling pair u, v.

```
1  if u and v are in different trees in T_2' then
2      Relabel u and v if necessary so that lca_2(u,v) is not in the tree containing u in T_2'.
3      if the tree containing u in T_2' has other active leaves not in U then
4          FinalCut: Cut off u in T_1' and T_2' and make it inactive. [y_u ← 1.]
5      else
6          Cut off u in T_1' and make it inactive. [y_u ← 1.]
7      end if
8  else
9      if u and v are active siblings in T_2' then
10         Merge u and v (i.e., make u inactive to "merge" it with v).
11     else
12         Relabel u and v if necessary so that p_2(u) ≠ lca_2(u,v).
13         Cut off an active subtree W between u and v by cutting the edge below p_2(u) that is
               not on the path from u to v. [Decrease y_{p_2(u)} by 1.]
14         if u and v are now active siblings in T_2' then
15             Merge-After-Cut: Merge u and v (i.e., make u inactive to "merge" it with v).
                   [y_u ← 1.]
16         else
17             Cut off u in T_1' and T_2' and make u inactive. [y_u ← 1.]
18         end if
19     end if
20 end if
```

Procedure 1: ResolvePair(u, v)

Arguments similar to those in Section 3 show that ResolvePair maintains dual feasibility, *provided that we initially reduce* $y_{\text{lca}_1(R)}$ *by* 1. It is also not hard to verify that ResolvePair increases the dual objective by at least half the increase in the primal objective, and the only thing that is therefore needed to show that the algorithm is a 2-approximation is that we can "make up for" the initial decrease of the dual objective caused by decreasing $y_{\text{lca}_1(R)}$. Let us define the operation of "distilling" R as starting by reducing $y_{\text{lca}_1(R)}$ by 1, and then repeatedly finding a pair of active leaves u, v in R which are siblings in T_1' and executing ResolvePair(u, v) until only two active leaves $\hat{u}, \hat{v}$ in R remain. Since all other leaves in R are inactive, $\hat{u}$ and $\hat{v}$ form an active sibling pair in T_1'.

If pair $\hat{u}, \hat{v}$ is a "success" or if line 4 or 15 was executed at least once during the distilling of R, then there exists an operation that makes at least one of $\hat{u}, \hat{v}$ inactive and updates the dual, so that the total increase in the primal objective is at most twice the total increase in the dual objective caused by the processing of pairs in R. Procedure 2 gives the complete description of the procedure that, if successful, "resolves" set R (and will return "Success"):

▶ **Lemma 6.** *If* ResolveSet(R) *returns* Success *then at least one leaf in* R *became inactive, and the increase in the primal objective* $|E(T_2) \setminus E(T_2')|$ *caused by the procedure is at most twice the increase in the dual objective.*

Lemma 12 of the full version [12] contains a more precise formulation of this lemma.

```
21 Decrease y_{lca_1(R)} by 1.
22 while there exist at least three active leaves in R do
23 |  Find u, v in R that form an active sibling pair in T_1'.
24 |  ResolvePair(u, v).
25 end while
26 Let û, v̂ be the remaining active leaves in R.
27 if û and v̂ are active siblings in T_2' then
28 |  Merge û and v̂ (i.e., make û inactive to "merge" it with v̂). y_û ← 1.
29 |  Return Success.
30 else if (û and v̂ are in different trees in T_2') or (the tree containing û and v̂ does not contain
     an active leaf w such that ûv̂|w in T_2) then
31 |  Cut off û in T_2' (if û's tree contains at least one other active leaf) and in T_1' and make û
   |    inactive. y_û ← 1.
32 |  Cut off v̂ in T_2' (if v̂'s tree contains at least one other active leaf) and in T_1' and make v̂
   |    inactive. y_v̂ ← 1.
33 |  Return Success.
34 else if (At least one FinalCut or Merge-After-Cut was executed in some call to ResolvePair
     in the course of the current ResolveSet procedure) then
35 |  ResolvePair(û, v̂).
36 |  Cut off the last active leaf v̂ in U in T_2' and in T_1' and make v̂ inactive. y_v̂ ← 1.
37 |  Return Success.
38 else
39 |  Return Fail.
40 end if
```

Procedure 2: ResolveSet(R)

If Lemma 6 applies, we have made progress (since we have made at least one leaf inactive), and we will have paid for the increase in the primal objective $|E(T_2) \setminus E(T_2')|$ caused by the procedure by twice the increase in the dual objective.

Otherwise, the last active pair of leaves $\hat{u}, \hat{v}$ in R remain active, and we will have a "deficit" in the sense that the increase in the dual objective is at most half the increase in the primal objective *plus* 1. In this case, we similarly distill B by repeatedly calling ResolvePair(u, v) for pairs u, v in B that are active siblings in T_1' until only a single active leaf in B remains. However, we will show that in order to retain dual feasibility, we do not need to start the distilling of B by decreasing $y_{\text{lca}_1(B)}$ (which would give a total "deficit" of 2), but that we can "move" the initial decrease of $y_{\text{lca}_1(R)}$ to instead decrease $y_{\text{lca}_1(R \cup B)}$. Lemma 13 in the full version [12] shows that this indeed preserves dual feasibility.

Once R and B have both been "distilled", we are left with $\hat{u}, \hat{v}, \hat{w}$ that are an inconsistent triplet and form the active leaf set of a subtree in T_1'. We show how to deal with the triplet $\{\hat{u}, \hat{v}, \hat{w}\}$ (in ways similar to those in Figure 2) and we prove that in the entire processing of $R \cup B$, we have increased the dual objective by half of the number of edges we cut from T_2'.

Algorithm 2 gives an overview of the "Red-Blue Algorithm". It first calls a procedure Preprocess, which executes simple operations that do not affect the primal or dual objective:

merging two leaves if they are active siblings in both forests, and cutting off and deactivating a leaf in T_1' if it is the only active leaf in its tree in T_2'. At the end of an iteration, the Red-Blue algorithm needs to consider different cases for the final triplet. The description of these subroutines can be found in [12].

Set $T_1' \leftarrow T_1$, $T_2' \leftarrow T_2$, $\mathcal{L}' \leftarrow \mathcal{L}$. $y_u \leftarrow 0$ for all $u \in \mathcal{L}$.
PREPROCESS.
while $\mathcal{L}' \neq \emptyset$ **do**
  Find a minimal incompatible active sibling set $R \cup B$, with $\mathrm{lca}_2(R) = \mathrm{lca}_2(R \cup B)$.
  if RESOLVESET(R) *returns* FAIL **then**
    Decrease $y_{\mathrm{lca}_1(R \cup B)}$ by 1, and increase $y_{\mathrm{lca}_1(R)}$ by 1.
    while *there exist at least two active leaves in* B **do**
      Find u, v in B that form an active sibling pair in T_1'.
      RESOLVEPAIR(u, v).
    end while
    Let $\hat{r}_1, \hat{r}_2 \in R$ and $\hat{b} \in B$ be the remaining active leaves.
    Consider three different cases depending on whether $\hat{r}_1, \hat{r}_2$ and $\hat{b}$ are in one, two or three different trees in T_2' (see Section 6.1 and 6.2 in [12] for details).
  end if
  PREPROCESS.
end while

Algorithm 2: Red-Blue Algorithm for Maximum Agreement Forest

▶ **Theorem 7.** *The Red-Blue Algorithm is a 2-approximation algorithm for the Maximum Agreement Forest problem.*

5 Implementation Details

We implemented the Red-Blue approximation algorithm in Java, and tested it on instances with $|\mathcal{L}| = 2000$ leaves that were generated as follows: the number of leaves in the left subtree is set equal to a number between 1 and $|\mathcal{L}| - 1$ drawn uniformly at random, and a subset of this size is chosen uniformly at random from the label set. Then this procedure recurses until it arrives at a subtree with only 1 leaf – this will be the whole subtree.

After generating T_1 as described above, the tree T_2 was created by doing 50 random Subtree Prune-and-Regraft operations (where random means that the root of the subtree that is pruned was chosen uniformly at random, as well as the edge which is split into two edges, so that the new node created can be the parent of the pruned subtree, under the conditions that this is a valid SPR-operation). This construction allows us to deduce an upper bound of 50 on the optimal value. Our algorithm finds a dual solution that in 44% of the 1000 runs is equal to the optimal dual solution, and in 37% of the runs is 1 less than the optimal solution. The observed average approximation ratio is about 1.92. After running our algorithm, we run a simple greedy search algorithm which repeatedly looks for two trees in the agreement forest that can be merged (i.e., such that the resulting forest is still a feasible solution to MAF). The solution obtained after executing the greedy algorithm decreases the observed approximation ratio to less than 1.28. The code is available at `http://frans.us/MAF`.

6 Conclusion

Our algorithm and analysis raise a number of questions. First of all, although we believe that, conceptually, our algorithm is quite natural, the actual algorithm is complicated, and it would be interesting to find a simpler 2-approximation algorithm. Secondly, it is clear that our algorithm can be implemented in polynomial time, but the exact order of the running time is not clear. The bottleneck seems to be the finding of a minimal incompatible active sibling set, although it may be possible to implement the algorithm in a way that simultaneously processes sibling pairs as in ResolvePair, while it is looking for a minimal incompatible active sibling set.

Abstract

Many real-life planning problems require making a priori decisions before all parameters of the problem have been revealed. An important special case of such problem arises in scheduling and transshipment problems, where a set of jobs needs to be assigned to the available set of machines or personnel (resources), in a way that all jobs have assigned resources, and no two jobs share the same resource. In its nominal form, the resulting computational problem becomes the *assignment problem*.

This paper deals with the *Robust Assignment Problem* (RAP) which models situations in which certain assignments are *vulnerable* and may become unavailable after the solution has been chosen. The goal is to choose a minimum-cost collection of assignments (edges in the corresponding bipartite graph) so that if any vulnerable edge becomes unavailable, the remaining part of the solution contains an assignment of all jobs.

We develop algorithms and hardness results for RAP and establish several connections to well-known concepts from matching theory, robust optimization, LP-based techniques and combinations thereof.

1 Introduction

The need for incorporating system reliability into decision making has sprung wide-spread interest in optimization models which incorporate data uncertainty in the last decades. The latter trend has lead to the development of several new theories including the popular field of *Robust Optimization*. In robust optimization the nominal optimization problem is equipped with a set of *scenarios*, representing various possible states of nature that may occur after the solution to the problem is chosen. The goal is to determine a solution that will perform well (in terms of feasibility, or cost) in the *worst case* realization of the state of nature.

The *Assignment Problem* is one of the most fundamental optimization problems arising in many reliability-sensitive systems. In its nominal form, the input consists of a set of

n_T *tasks*, a set of n_R *resources* (with $n_T \leq n_R$), and *assignment costs* $c_{i,j}$ representing the cost associated with assigning resource i to task j. The set of allowed assignments can be represented by a bipartite graph $G := (R \dot\cup T, E)$ where each resource i corresponds to a node $r_i \in R$, each task j corresponds to a node $t_j \in T$, and the edge $\{r_i, t_j\}$ is present in E if the j-th task can be assigned to resource i. The goal is to find a *matching* $M \subseteq E$ of minimal cost that covers all nodes in T, i.e. a set of non-adjacent edges that is incident to every node in T. In the following, a subset M satisfying that property is called *an assignment*.

The Robust Assignment Problem (RAP) is the natural robust counterpart of the assignment problem and defined as follows[1]. An instance of RAP consists of an instance of the nominal assignment problem, i.e. of a bipartite graph $G = (R \dot\cup T, E)$ representing admissible assignments and a non-negative cost vector $c \in \mathbf{R}^E_{\geq 0}$, as well as a collection $F \subseteq E$ of *vulnerable edges*. Each $f \in F$ induces a failure scenario that leads to a deletion of f from G. The goal is to find a subset $X \subseteq E$ of minimal cost with the property that, for every vulnerable edge $f \in F$, the set $X \setminus \{f\}$ contains an assignment of G.

Intuitively, RAP asks to choose a redundant assignment, namely one that contains a feasible assignment, even when an arbitrary single vulnerable edge becomes unavailable. Therefore, the robustness paradigm considered in this paper falls into the topic of *redundancy-based robustness* – a well-motivated and widely studied approach (see e.g. [5, 23] for an overview of different robustness concepts). Some of the problems that fall into this category include the minimum k-edge connected spanning subgraph problem [12, 18] and the robust facility location problem [25, 31, 9]. More recently, Adjiashvili, Stiller and Zenklusen [2] introduced a robustness model called *bulk-robustness*, which combines the standard redundancy based robustness approach with a non-uniform failure model. In its general form, a bulk robust counterpart of a combinatorial optimization problem consists of an instance of the nominal problem, as well as a collection of scenarios, each comprising an arbitrary set of resources that may fail simultaneously. The goal is, as usual, to choose a minimum-cost set of resources that contains a feasible solution, even when the resources in any single failure scenario become unavailable. In the language of bulk-robustness, RAP is the bulk-robust assignment problem restricted to the case of where each scenario is composed of a single edge.

In the remainder of this section we provide a few motivating applications for RAP, establish some connections to related notions in matching theory and discuss results and technical contributions.

1.1 Motivation

The most natural applications of RAP, and redundancy-based robust optimization in general, emerge in situations where resources can not be easily made available on demand. In such applications, any resource that is intended for use at a certain point in time must be *reserved* at an earlier stage, and thus made available for potential deployment. Examples of such applications range from construction of robust power transmission networks [21] to supply chain management [32].

In a nutshell, redundancy-based models deal with the problem of choosing the optimal set of (potentially unreliable) resources to reserve, in order to guarantee that the available set of resources at the time of solution implementation, i.e. the reserved resources that did not fail, contains a feasible solution in every scenario. While we believe that RAP can be a

[1] Several other robust counterparts of the assignment problem have been considered in the literature under the same, or similar names. We review these models in Section 2.

useful model to incorporate robustness in any assignment model with up-front decisions of the latter type, we bring hereafter a few concrete applications.

Staff Training. Large companies often employ intensive training programs for their employees, designed to adapt the available pool of skills to their dynamic needs. For example, large software firms starting a new project involving new technologies, might need to train some employees to use these technologies. It is natural to incorporate the incurred training costs into the task assignment problem. The cost of assigning an employee to perform a given task in the project corresponds to the cost to train the employee to perform this task.

In a more realistic scenario, some employee to task assignments might become unavailable *even if the employee were trained to perform the task*. This type of vulnerability is very common, and can be caused, e.g. by employee dissatisfaction from his task assignment, or by unexpected inability to perform the task (due to injury or unavailability of equipment, etc.). RAP is a suitable model for deciding on robust training programs for the project, where skill sets of the employees allow for reassignments even if any single employee to task assignment becomes unavailable.

Continuity of Service. In industries such as health care and consulting it is often desirable to maintain very stable client to service provider relationships [7]. It is hence natural for a service provider to model the resulting resource allocation problem as an assignment problem, where an available pool of trained employees (nurses, consultants etc.) is matched to the set of customers. In the nominal variant, the company might want to minimize the cost incurred by the assignment, where the cost is computed as the total cost incurred by establishing all relationships in the assignment (establishing such relationships incurs significant costs).

It is however common that certain established relationships go off track in the course of a long interaction (e.g. due to customer or employee dissatisfaction). These relationships correspond to vulnerabilities of individual assignments. With RAP it is possible to account for such vulnerabilities by establishing a cost-effective set of relationships that, even if any nominal interaction becomes unavailable, the organization can quickly adjust the assignment to satisfy all clients.

1.2 Overview of results and techniques

This paper addresses the computational complexity of RAP. In particular, we present approximation algorithms and hardness of approximation results. We justify the study of approximation algorithms by showing that RAP is NP-hard even in very restricted variants. Due to space constraints we omit technical proofs as well as details on the complexity results.

The assignment problem has a well-known natural interpretation as a bipartite matching problem in the graph $G = (R \dot\cup T, E)$. It is hence also natural to view RAP as a robust version of the bipartite matching problem: find a minimum-cost set of edges in $M \subseteq E$ such that for every $f \in F$, the set $M \setminus \{f\}$ contains a matching incident to all nodes in T. Furthermore, if $|R| = |T|$, the problem becomes a robust variant of the *perfect* matching problem. We henceforth adopt this point of view, as it facilitates a clearer exposition of our results, and highlights an inherent connection between RAP and *matching-covered graphs*, a notion that we repeatedly use in our approximation algorithms.

The next statement shows that it suffices to consider RAP on balanced bipartite graphs, implying that we can state the feasibility condition for RAP using perfect matchings.

▶ **Proposition 1.** *Any* RAP *instance can be efficiently transformed to an equivalent weighted* RAP *instance with a balanced bipartite graph such that any α-approximation for the new instance can be used to efficiently construct an α-approximation of the original instance for all $\alpha \geq 1$.*

It is important to note that the transformation in Proposition 1 leads to an instance on a balanced bipartite graph that is equipped with a weighted cost function. Interpreting the resulting instance as an unweighted one may destroy the preservation of the transformation's approximation quality, thus Proposition 1 can not be used as a black box reduction for the unweighted case.

In the following, RAP refers to general instances of the robust assignment problem on balanced bipartite graphs with weighted cost function, while card-RAP is used for the unweighted version of RAP. We denote $n = n_T + n_R$ and $m = |E|$.

We remark that feasibility of a given RAP instance can be efficiently verified as one only needs to check, for each $f \in F$, whether the graph contains a perfect matching not using f. The latter can be done using any polynomial algorithms for finding maximum matchings in bipartite graphs.

1.2.1 Matching-Covered Graphs and Ear Decompositions

Our algorithmic results rely on a tight connection between RAP and *matching-covered graphs*, a well-known notion in matching theory. A graph $G = (V, E)$ is *matching-covered* if every edge $e \in E$ appears in some perfect matching of G.[2]

It turns out that inclusion-wise minimal solutions of any RAP instance are matching-covered as the following proposition states.

▶ **Proposition 2.** *A set $X \subseteq E$ is an inclusion-wise minimal feasible solution to* RAP *if and only if $(R \dot\cup T, X)$ is an inclusion-wise minimal non-empty graph with the properties of being matching-covered and that every isolated edge $e \in X$ is not vulnerable, i.e. $e \notin F$.*

Proposition 2 provides a very useful characterization of minimal solutions of RAP, as it allows us to use various results on matching-covered graphs in our algorithms for RAP. In particular, it allows us to identify feasible subgraphs and augment them to feasible solutions for the entire instance by adding structures that maintain the property of being matching-covered. One particularly useful tool is an *ear decomposition* of a bipartite matching-covered graph, i.e. a certain decomposition of G into edge-disjoint paths of odd length. In the following, we denote by $V[G]$ and $E[G]$ the set of nodes and edges of a graph G, respectively. For two graphs G and H we denote by $G + H$ their union $(V[G] \cup V[H], E[G] \cup E[H])$.

▶ **Definition 3** (Ear Decomposition of a Bipartite Graph)**.** Let H be a bipartite graph, and let H' be a subgraph of H. An *odd ear of H with respect to H'* is a path P in H with an odd number of edges and such that P and H' have exactly two nodes in common. Those two nodes form the end points of P, and belong to different parts of the bipartition.

A *bipartite ear decomposition* is a sequence $P_0, P_1, \ldots, P_q$ of paths in H, such that: (i) $P_0 = (\{v_1, v_2\}, \{\{v_1, v_2\}\})$ is a graph composed of a single edge; (ii) $H = P_0 + \cdots + P_q$; and (iii)µfor every $j = 1, \ldots, q$, the path P_j is an odd ear with respect to $H_{j-1} := P_0 + \cdots + P_{j-1}$.

[2] The notion of matching-covered graphs is originally introduced for connected graphs. In this paper we use this term also for disconnected graphs. Furthermore, note that some authors use synonymously the notion 1-*extendable* or in the bipartite case *elementary* (cf. [28]).

We exploit the following well-known connection between matching-covered bipartite graphs and bipartite ear decompositions.

▶ **Theorem 4** ([28, Thm. 4.1.6]). *A bipartite graph is matching-covered if and only if it has a bipartite ear decomposition.*

1.2.2 Results for card-RAP

Theorem 4 allows us to prove the following results for card-RAP. An instance of RAP is called *uniform* if every edge is vulnerable, i.e. if $F = E$.

▶ **Theorem 5.** card-RAP *admits a polynomial* 1.5*-approximation algorithm in the uniform case, and a* 3*-approximation algorithm in the general case.*

Our algorithm starts by producing an ear decomposition of the input graph. Then, it iteratively selects a certain subset of the edges to be part of the solution, by processing the ears in the decomposition in the order given by the decomposition, and omitting the edges corresponding to ears of length one.

We complement the latter algorithmic result by showing that card-RAP is NP-hard to approximate within some constant $\delta > 1$ even in the restricted case of a uniform scenario set, as stated in the following theorem.

▶ **Theorem 6.** *There exists a constant $\delta > 1$, such that there is no polynomial δ-approximation algorithm for the uniform* card-RAP*, unless* P=NP*.*

Theorems 5 and 6 imply that the true approximability thresholds for uniform card-RAP and card-RAP lie in the intervals $[\delta, 1.5]$ and $[\delta, 3]$, respectively.

To complete the complexity landscape of card-RAP we also consider the case of only two vulnerable edges. This special case comprises the simplest variant of card-RAP that is not equivalent to a standard matching problem[3]. In the following theorem we prove that already this special case is NP-hard, thus drawing a sharp threshold for polynomial solvability of card-RAP.

▶ **Theorem 7.** card-RAP *is* NP*-hard even when restricted to instances with two vulnerable edges, i.e. with $F = \{f_1, f_2\}$.*

To the best of our knowledge, this is the first example of an NP-hard robust counterpart of a polynomial optimization problem, with a constant number of vulnerable resources.[4] To prove Theorem 7 we first show NP-hardness of a problem of partitioning a graph into a cycle containing a given node and a matching whose union covers all nodes, so as to minimize the length of the cycle, a problem that might be interesting in its own right.

1.2.3 Results for RAP

Our main algorithmic result for RAP is a randomized $O(\log n)$-approximation for the general case, as stated hereafter.

[3] Observe that the case of a single vulnerable edge $F = \{f\}$ is solvable by reporting any minimum-cost perfect matching in the graph $(R \dot\cup T, E \setminus \{f\})$ as a solution.

[4] There are many examples of optimization problems that become NP-hard when the robust counterpart is allowed to contain a constant number of scenarios (see e.g. [26]). In all such examples, however, each scenario affects a *non-constant* number of resources.

▶ **Theorem 8.** *RAP admits a randomized polynomial $O(\log n)$-approximation algorithm.*

Our approximation algorithm for RAP builds upon our simple approximation algorithm for card-RAP in that it also iteratively constructs a solution maintaining the invariant that at any point in the algorithm, the edges selected so far form a matching-covered graph. It is however unclear how to arrive at the desired approximation for RAP relying only on properties of matching-covered graphs. We therefore combine the latter techniques with additional tools from linear programming (LP) theory and randomized rounding. Concretely, we start by solving an LP relaxation of RAP, derived from a natural integer linear programming (ILP) formulation of the problem. The obtained fractional solution is used to guide an iterative randomized procedure. In each iteration a fractional bipartite matching corresponding to part of the fractional solution is selected. A decomposition of this fractional matching into a convex combination of integral matchings is then used to randomly pick one matching, and a carefully selected subset of this matching is added to the current solution. To bound the quality it does not suffice to bound the number of iterations, or the expected number of times an edge is part of a candidate matching. Instead we use a discharging argument that assigns costs to nodes depending on the graph selected so far.

We complement our algorithmic results for RAP with hardness of approximation result with the same asymptotic bound, as stated hereafter.

▶ **Theorem 9.** *Provided that* NP $\not\subseteq$ DTIME$(n^{\log\log n})$*, the uniform* RAP *admits no* $c\log n$*-approximation for any* $c < 1$*. RAP unless P=NP.*

2 Related work

Redundancy-based robustness is a paradigm that motivates many well studied problems, including the minimum k-connected subgraph problem [18, 12, 30], survivable and robust network design problems [24, 10, 2, 1], robust clustering problems [25, 31], robust spanner problems [8, 15] and many more. All of the latter models bare a close resemblance to RAP: they assume resources to be vulnerable and ask to find a minimum-cost set of resources that contains a desired structure even in case any vulnerable resource, or set of resources, fails.

A relatively new approach to redundancy based robustness is the incorporation of non-uniform uncertainty sets [2, 1]. RAP is seen as a robust model of this type, as we allow both vulnerable and invulnerable edges in the same instance.

The study of robustness with respect to cost uncertainty was initially studied by Kouvelis and Yu [26], and Yu and Yang [33]. For a survey we refer to Aissi, Bazgan and Vanderpooten [4]. A closely related class of multi-budgeted problems has received considerable attention (see e.g. [19] and references therein). The latter works include variants of the related multi-objective matching problem.

Various variants of robust matching problems have been considered in the literature. Hassin and Rubinstein [22], and Fujita, Kobayashi and Makino [17] study the following notion of an α-robust matching. A perfect matching M in a weighted graph is α-robust (for $\alpha \in (0, 1]$), if for every $p \leq |M|$, the p heaviest edges of the matching have total weight at least α times the weight of a maximum weight matching of size p. Deineko and Woeginger [14] showed that the min-max-robust assignment problem with a fixed number of scenarios is equivalent to the *exact perfect matching problem*, a famous problem with unknown complexity status. In the case of a variable number of scenarios the min-max-robust problem is NP-hard, as was proved by Aissi, Bazgan and Vanderpooten [3]. Additional work on robust variants of the matching problem include models with recovery [16], models with node failures [27], and

the closely related matching interdiction problem [34]. Plesník [29] provided conditions under which an r-regular graph remains perfectly matchable after removing $r-1$ arbitrarily chosen edges. Brigham, Harary, Violin and Yellen [6] and Cheng, Lesniak, Lipman and Liptak [11] studied the minimum number of edges to be removed from a graph to arrive at a graph without a perfect matching.

3 Approximation Algorithms for RAP

3.1 $O(1)$-Approximation for card-RAP

Our algorithm relies on an ear decomposition of the underlying bipartite graph. Similar ideas using ear decompositions were successfully used to approximate various combinatorial optimization problems including, among others, the minimum edge connected subgraph problem and the path traveling salesman problem [12, 30]. Recall, that a balanced bipartite graph admits an ear decomposition (which is by no means unique) if and only if it is matching-covered.

As an initial pre-processing step, a given card-RAP instance consisting of $G = (R \dot\cup T, E)$ and F is transformed into a balanced instance. For this, we introduce a set D of $n_R - n_T$ dummy task nodes, and connect each such node to all nodes from R. Let E_D denote the set of newly introduced edges, and let $G_b = (R \dot\cup (T \cup D), E \cup E_D)$. In a second step we remove from G_b all *dispensable edges*, i.e. all edges not appearing in any perfect matching of G_b. This way, we obtain a graph, that is, by definition, matching-covered. Note that the second step can be implemented in polynomial time using any efficient algorithm for finding bipartite matchings. Moreover, we remark that omitting dispensable edges clearly does not change the underlying card-RAP instance, since such edges can be removed from any feasible solution without breaking feasibility. In the following, we allow some abuse of notation and call the new graph G_b as well. Next, we assume that G (and equivalently G_b) is feasible, i.e. there do not exist any isolated edges. If an isolated edge exists the algorithm terminates and reports that the instance is infeasible. Now let $G_b = P_0 + \cdots + P_q$ be any ear decomposition of G_b with the initial edge P_0 not covering a dummy node from D. We call an ear P_j *trivial* if it is not P_0 and if it consists of a single edge. The next lemma shows that a feasible solution to card-RAP can be obtained from the ear decomposition of G_b by skipping trivial ears.

▶ **Lemma 10.** *Let $J = \{j \in [q] \mid P_j$ is a trivial ear$\}$. Define $G'_b = P_0 + \sum_{i \in [q] \setminus J} P_i$, and $X := E[G'_b] \setminus E_D$. Then, the set X is a feasible solution to the* card-RAP *instance. Furthermore, $|X| \leq 3n_T$.*

Lemma 10 allows us to arrive at an approximation algorithm, summarized as Algorithm 1.

Algorithm 1 : $O(1)$-Approximation for card-RAP

Require: $G = (R \dot\cup T, E)$ and $F \subseteq E$.
Ensure: a feasible solution X to card-RAP on G and F
1: $X \leftarrow \emptyset$
2: Transform G into a balanced graph G_b and remove all dispensable edges
3: Compute an ear decomposition $G_b = P_0 + \ldots + P_q$
4: $X \leftarrow P_0 \cup \bigcup\{E[P_j] \mid P_j$ is not trivial, $j = 1, \ldots, q\}$
5: **return** X

Proof of Theorem 5. According to [13], an ear decomposition of a matching-covered graph can be computed in polynomial time. Furthermore, all other computations can also be

implemented efficiently, such that the running time of Algorithm 1 is polynomial. From Lemma 10, it follows that the set X returned by Algorithm 1 is feasible. For $F = E$, any feasible solution must have at least two edges incident to any node from the set T. Hence, $\mathrm{OPT} \geq 2n_T$. Since $|X| \leq 3n_T$, the approximation guarantee is indeed 1.5. If $F \subsetneq E$, then G can contain a perfect matching not including any edge from F. Thus, we can use $\mathrm{OPT} \geq n_T$ yielding an approximation factor of 3. ◀

3.2 $O(\log n)$-Approximation for RAP

In this section we provide a polynomial $O(\log n)$-approximation algorithm for RAP, thus proving Theorem 8. Again, we assume that the RAP instance is feasible. For a clean presentation, we first describe an algorithm for the uniform case $F = E$ and then explain how it can be extended to the non-uniform case.

Our algorithm is based on an LP-rounding procedure that works with a relaxation of the integer linear formulation of RAP, that is defined as follows. Let $G = (R \dot\cup T, E)$ be a balanced, bipartite graph and let $c \in \mathbf{R}^E_{\geq 0}$ be a non-negative cost vector. Moreover, let $P_G \subseteq \mathbf{R}^E$ denote the perfect matching polytope associated with G (i. e. P_G is the convex hull of all incidence vectors of perfect matchings in G). A standard ILP formulation of RAP contains the following variables: (i) $x^{-f} \in \{0,1\}^E$ representing a perfect matching in $G - f := (R \dot\cup T, E \setminus \{f\})$, for all $f \in F$, and (ii) $y \in \{0,1\}^E$ encoding a feasible solution to RAP. Then, RAP can be modeled as an ILP as follows.

$$
\begin{array}{lrcll}
\min & c^\top y & & & \\
\text{s.t.} & x^{-f} & \in & P_G \cap \{x \in \mathbf{R}^E \mid x_f = 0\}, & \text{for each } f \in F, \\
& y & \geq & x^{-f}, & \text{for each } f \in F, \\
& x^{-f} & \in & \{0,1\}^E, & \text{for each } f \in F, \\
& y & \in & \{0,1\}^E &
\end{array}
\tag{ILP}
$$

The LP-relaxation (LP) is obtained by relaxing all integrality constraints in (ILP). To keep notation short, we let $x \in \left(\mathbf{R}^E\right)^E$ be the vector with parts x^{-f}, $f \in F$. It is straightforward to verify that integer solutions to (ILP) coincide with feasible solutions to the RAP instance. In the following, we will denote, by $\chi^S \in \{0,1\}^E$, the incidence vector of a subset $S \subseteq E$.

Now, let (x, y) be a fractional solution to (LP). We describe hereafter a rounding procedure that yields an approximation for RAP. Consider some edge $f \in F$. Since x^{-f} is contained in $P_G \cap \{x \in \mathbf{R}^E \mid x_f = 0\}$, there exist positive scalars $\lambda_1^{-f}, \cdots, \lambda_k^{-f}$ with $\sum_{i\in[k]} \lambda_i^{-f} = 1$, and perfect matchings $M_1^{-f}, \cdots, M_k^{-f}$ in $G - f$ such that $x^{-f} = \sum_{i\in[k]} \lambda_i^{-f} \chi^{M_i^{-f}}$. By Caratheodory's theorem, there is a decomposition of the latter type with k bounded by $O(m) = O\left(n^2\right)$. Furthermore given x^{-f}, such a decomposition can be computed in polynomial time using polyhedral techniques [20, Thm. 6.5.11].

Our algorithm performs several iterations of randomized rounding based on the latter decomposition of fractional matchings. More precisely, at each iteration, an infeasible set $X \subseteq E$ of edges, that was chosen so far, is augmented with an additional set M of edges chosen randomly as follows. First, an arbitrary edge f is chosen from E among all edges not yet covered by X, i.e. among all $e' \in E$ such that the edge set X selected so far contain no perfect matching that does not include e'. Next, a decomposition of the vector x^{-f} as a convex combination of perfect matchings is computed, as above. This decomposition is then used to select a single perfect matching $\bar{M}$ from $\{M_1^{-f}, \cdots, M_k^{-f}\}$ *randomly*, where M_i^{-f} is chosen with probability λ_i^{-f} for all $i \in [k]$. Finally, the augmenting set $M \subseteq \bar{M}$ is chosen to contain all edges of $\bar{M}$ connecting *distinct connected components* of X. The edges of M

are added to X and the algorithm proceeds to the next iteration. The algorithm terminates when X is a feasible solution. A summary of the algorithm is presented as Algorithm 2.

To prove the correctness of the algorithm we resort again to properties of matching-covered graphs. Concretely, as a main ingredient of the proof of Lemma 12, which states a useful structural property of intermediate solutions in the algorithm, we use the following classic result.

Algorithm 2 : Randomized $O(\log n)$-Approximation for RAP

Require: $G = (R \dot\cup T, E)$ with $|R| = |T|$, and $c \in \mathbf{R}^E_{\geq 0}$.
Ensure: A feasible solution X to RAP on G with $F = E$ and cost vector c.
1: Solve (LP) to obtain an optimal solution (x, y)
2: $X \leftarrow \emptyset$
3: **while** X is infeasible **do**
4: Select an edge $f \in F$ such that $X \setminus \{f\}$ contains no perfect matching
5: Compute a decomposition of x^{-f} as $x^{-f} = \sum_{i=1}^{k} \lambda_i^{-f} \chi^{M_i^{-f}}$ and select one matching $\bar{M} \in \{M_i^{-f} \mid i \in [k]\}$ with $\Pr\left[\bar{M} = M_i^{-f}\right] = \lambda_i^{-f}$ for all $i \in [k]$
6: Add to X all edges from $\bar{M}$ that connect distinct connected components in $(R \dot\cup T, X)$
7: **end while**
8: **return** X

▶ **Theorem 11** ([28, Thm. 4.1.1., p. 122]). *A connected bipartite graph $H = (U \dot\cup W, E)$ with $|U \dot\cup W| \geq 4$ is matching-covered if and only if for any $u \in U$ and $w \in W$ the graph $H - \{u\} - \{w\}$ has a perfect matching.*

▶ **Lemma 12.** *Let X be a non-empty set of edges already selected in an arbitrary iteration of Algorithm 2. Then, the graph $G[X] := (R \dot\cup T, X)$ is matching-covered.*

Proof. As X is assumed to be non-empty, X contains at least one perfect matching of G. Thus, $G[X]$ does not have isolated nodes.

Now, let $S \subseteq R \dot\cup T$ be the nodes of some connected component of $G[X]$. It suffices to prove that the graph $(S, X[S])$, with $X[S] := \{e \in X \mid e = \{s_1, s_2\}, \text{ for some } s_1, s_2 \in S\}$, is matching-covered. For $|S| = 2$, $X[S]$ contains exactly one edge that belongs to a perfect matching in X. Thus, the claim is proved.

Next, assume that $|S| > 2$. To prove that $(S, X[S])$ is matching-covered, we proceed by induction on the number of iterations in Algorithm 2. In the first iteration, a perfect matching is added to X in Step 6, thus the claim holds in that case.

Now, let $X' \subseteq X$ be the set of edges selected until the beginning of the iteration preceding the current iteration. By the induction hypothesis, we can assume that every connected component of $(R \dot\cup T, X')$ is matching-covered.

To prove the claim we need to show that every edge $e \in X[S]$ is contained in some perfect matching of S. If $e \in X'$, this claim holds by the inductive hypothesis, and due to $X' \subseteq X$. In case that $e \notin X'$, we have that $e \in \bar{M}$, where $\bar{M}$ is selected in Step 5 in the current iteration. This means that e connects nodes from two distinct connected components of $(R \dot\cup T, X')$.

Now, pick any cycle $C \subseteq X$ in $G[X]$ containing e with a minimum number of edges from $\bar{M}$. Let $D_1, \cdots, D_l \subseteq R \dot\cup T$ be the components in $(R \dot\cup T, X')$ that have edges in C. From minimality of $|C \cap \bar{M}|$ it follows that C is a simple cycle (i.e. each node is contained in at most two of its edges) and that each component D_j, $j = 1, \cdots, l$ contains exactly two nodes incident to the cycle. This cycle can now be used to demonstrate the existence of the desired

perfect matching M' as follows. First, include in M' all edges in $C \cap \bar{M}$. Then, in every component D_j for $j = 1, \cdots, l$ pick a matching covering all nodes, except the two nodes incident to the cycle C. Due to Theorem 11, such a matching exists since each component D_j is matching-covered. The matching chosen so far covers exactly the nodes in $D_1 \cup \cdots \cup D_l$. Finally, pick any matching covering all other components of $(R \dot\cup T, X')$ that are not incident to C. This matching exists, since again, $(R \dot\cup T, X')$ is matching-covered. The result is a perfect matching in $G[X]$ containing e, which completes the proof. ◀

Lemma 12 guarantees that at every stage in the algorithm, the only edges not yet covered by the current solution X are the isolated edges of $G[X]$. Now, since at an iteration where an uncovered edge f is chosen in Step 4, the set M must contain two edges distinct from f, that are incident to the endpoints of f, the edge f is guaranteed to be covered in the end of this iteration. This immediately implies that the algorithm terminates with a feasible solution after at most $|E|$ iterations. It hence remains to bound the expected cost of the solution returned by Algorithm 2.

▶ **Theorem 13.** *The expected cost of the solution returned by Algorithm 2 is* $O(\log n) \cdot \mathrm{OPT}$, *where* OPT *is the optimal solution value for the* RAP *instance.*

Proof. The feasibility of the obtained solution and the bound on the running time are guaranteed by Lemma 12.

For a set $Q \subseteq E$ of edges we denote by $c_{\mathrm{LP}}(Q)$ the contribution of the edges in Q to the LP cost, i.e. $c_{\mathrm{LP}}(Q) = \sum_{e \in Q} c_e y_e$. For a node $v \in R \dot\cup T$, we denote by $\delta(v) \subseteq E$ the set of edges incident to v. To bound the approximation guarantee we bound the expectation of the ratio $c(X)/c_{\mathrm{LP}}(E)$. Since the LP is a relaxation of the problem we have $c_{\mathrm{LP}}(E) \leq \mathrm{OPT}$. Thus, this ratio is a valid bound on the approximation guarantee.

To obtain the bound we design a scheme that charges every selected edge in any stage of the algorithm to one of its endpoints. We then show that the expected cost charged to any node $v \in V$ is bounded by $O(\log n)$ times the *fractional cost* $c_{\mathrm{LP}}(\delta(v))$ associated with the node. This then implies that the expected cost of all edges added by the algorithm is at most

$$O(\log n) \cdot \sum_{v \in R \dot\cup T} c_{\mathrm{LP}}(\delta(v)) \leq O(\log n) \cdot \mathrm{OPT},$$

where the last inequality follows from linearity of expectation, $c_{\mathrm{LP}}(E) \leq \mathrm{OPT}$ and $c_{\mathrm{LP}}(E) = \frac{1}{2} \sum_{v \in R \dot\cup T} c_{\mathrm{LP}}(\delta(v))$.

We describe next how the costs of the selected edges are charged to the nodes of the graph. Let $\bar{X} \subseteq E$ be the set of edges returned by the algorithm. Formally, with each node $v \in R \dot\cup T$ we associate a collection of edges $R_v \subseteq \bar{X}$ such that $\bigcup_{v \in R \dot\cup T} R_v = \bar{X}$ and such that $c(R_v)$ is bounded by $O(\log n)$ times the fractional load at v in expectation.

The sets R_v are constructed as follows. In the beginning $R_v = \emptyset$ for all $v \in R \dot\cup T$. Let X be the set of edges selected so far by the algorithm and let $M \subseteq E \setminus X$ be the set of edges selected to be added to X in Step 6 of the current iteration. At this stage, the sets R_v might already contain some edges. We describe how these sets change as a result of the selection of M. Consider an edge $f = \{r, t\} \in M$. Recall that the algorithm only includes edges in the solution if they connect different connected components in $(R \dot\cup T, X)$. Thus, r and t lie in different connected components. Let D_r and D_t be the node sets of the connected components to which r and t belong, respectively, and assume without loss of generality that $|D_r| \leq |D_t|$. Then, f is charged to r, i.e. f is included in R_r. In other words, an edge added by the algorithm in any iteration is charged to the node contained in the *smaller connected component*, with ties broken arbitrarily.

It is obvious that the latter scheme charges all edges in $\bar{X}$ to some nodes, such that $\bigcup_{v \in V} R_v = \bar{X}$ holds in the end of the last iteration. It remains to analyze the quantity $c(R_v)$ for a single node $v \in R \dot{\cup} T$. The bound on $c(\bar{X})$ will then follow from linearity of expectation and the previous discussion. To arrive at the desired bound it suffices to make the following two observations.

First, at any time, if an edge is charged to v, its expected cost is at most $c_{\text{LP}}(\delta(v))$. Indeed, recall that the edges in M come from a perfect matching chosen at random from the decomposition of some fractional perfect matching x^{-f} in the graph (this x^{-f} corresponds to the edge f chosen in Step 4 in the current iteration). Let this decomposition be

$$x^{-f} = \sum_{i \in [k]} \lambda_i^{-f} \chi_{M_i^{-f}}.$$

The distribution over the integral matchings defining x^{-f} induces a distribution over the edges incident to v: each edge $e \in \delta(v)$ is contained in the perfect matching with a probability $p_e \in [0,1]$ given by

$$p_e = \sum_{i \in [k] \,:\, e \in M_i^{-f}} \lambda_i^{-f} = x_e^{-f}.$$

Since $x_e^{-f} \leq y_e$ for all $e \in E$ we have that the expected cost of the edge charged to v is at most $\sum_{e \in \delta(v)} c_e x_e^{-f} \leq c_{\text{LP}}(\delta(v))$, proving the first property.

The second observation concerns the number of times the node v is charged in the course of the algorithm. Consider any iteration in which some edge was charged to v, and let D_v be the nodes in the component of v in the beginning of the iteration. Since we always charge an edge to the node in the smaller component, and since charged edges always merge connected components, the size of the connected component containing v in the end of the iteration is *at least* $2|D_v|$. Since the graph only contains n nodes, this doubling can only happen at most $\log n$ times.

We conclude that $c(R_v)$ is, in expectation, indeed at most $O(\log n) c_{LP}(\delta(v))$, which concludes the proof of the theorem. ◀

Lemma 12 and Theorem 13 imply the correctness of Theorem 8 for the uniform case. The generalization to the non-uniform case is explained in the proof of Theorem 8, which we bring next.

Proof of Theorem 8. It remains to show how to treat the case $F \neq E$. For this, we provide a transformation to reduce such an instance to a uniform instance by losing only a factor of 2 in the approximation guarantee.

The transformation first adds to the graph one parallel edge $\bar{e}$ for every $e \notin F$. Let G' be the obtained graph. The new set of vulnerable edges is set to $F' = E[G']$. Solutions for the two RAP instances are in obvious correspondence: A solution $X \subseteq E[G]$ to the original instance can be transformed to a solution for the new instance of at most double the cost by taking $X' = X \cup \{\bar{e} \mid e \in X \setminus F\}$. Conversely, a solution X' for the new instance can be transformed to a solution for the new instance with the same, or better cost, by choosing $X = X' \cap E[G]$.

Let OPT' denote the optimal solution value of the transformed uniform instance. Our $O(\log n)$-approximation algorithm for the general case proceeds by first transforming the instance to a uniform instance of RAP, as above, then invoking Algorithm 2 to obtain the set X', having expected cost at most $O(\log n)\text{OPT}' = O(\log n)\text{OPT}$ and then returning $X = X' \cap E[G]$. ◀

We conclude this section by arguing why simpler randomized rounding techniques, for instance, ones that lead to logarithmic approximation to many covering problems, are unlikely to lead to a similar result for RAP. The reason for this is that there does not seem to be a simple way to obtain a compact set cover-type representation of RAP without losing a super-logarithmic factor in the approximation guarantee. One natural attempt could be to consider every vulnerable edge $f \in F$ as an *element* that needs to be covered, and every possible perfect matching $M \subseteq E$ that does not contain f, a *covering set* that covers the edge f (and all other edges in $F \setminus M$). The cost of the covering set is simply the sum of the costs of edges in the corresponding perfect matching. Unfortunately, it is easy to come up with examples in which the optimal solution value in the latter set covering model has cost $\Omega(n)\text{OPT}$. Such instances can be constructed, for example by choosing an instance, such that any feasible solution must have some nodes with very high degree, while an optimal solution has cost $O(n)$.

4 Conclusion and Future Work

This paper studies a novel practically relevant robust variant of the assignment problem (RAP). We showed tight connections between RAP and classical notions in matching theory, including matching-covered graphs and ear decompositions, and used these connections to obtain asymptotically tight approximation results for RAP. In our approximation algorithm for the general variant of RAP we combined classical results for matching-covered graphs with LP randomized rounding techniques.

Some ongoing and future work includes the following lines of research. Study a version of RAP with node failures, or with a combination of node and edge failures. This problem has many potential applications beyond the ones listed here. Study the variant of RAP where each scenario consists of at most k edges, for some input parameter $k > 1$. This paper treats the case $k = 1$. Besides, it is interesting to study the complexity of RAP in general graphs.

Abstract

Makespan scheduling on identical machines is one of the most basic and fundamental packing problem studied in the discrete optimization literature. It asks for an assignment of n jobs to a set of m identical machines that minimizes the makespan. The problem is strongly NP-hard, and thus we do not expect a $(1+\varepsilon)$-approximation algorithm with a running time that depends polynomially on $1/\varepsilon$. Furthermore, Chen et al. [3] recently showed that a running time of $2^{(1/\varepsilon)^{1-\delta}} + \text{poly}(n)$ for any $\delta > 0$ would imply that the Exponential Time Hypothesis (ETH) fails. A long sequence of algorithms have been developed that try to obtain low dependencies on $1/\varepsilon$, the better of which achieves a running time of $2^{\tilde{O}(1/\varepsilon^2)} + O(n \log n)$ [10]. In this paper we obtain an algorithm with a running time of $2^{\tilde{O}(1/\varepsilon)} + O(n \log n)$, which is tight under ETH up to logarithmic factors on the exponent.

Our main technical contribution is a new structural result on the *configuration-IP*. More precisely, we show the existence of a highly symmetric and sparse optimal solution, in which all but a constant number of machines are assigned a configuration with small support. This structure can then be exploited by integer programming techniques and enumeration. We believe that our structural result is of independent interest and should find applications to other settings. In particular, we show how the structure can be applied to the minimum makespan problem on related machines and to a larger class of objective functions on parallel machines. For all these cases we obtain an efficient PTAS with running time $2^{\tilde{O}(1/\varepsilon)} + \text{poly}(n)$.

1 Introduction

Minimum makespan scheduling is one of the foundational problems in the literature on approximation algorithms [6, 7]. In the *identical machine* setting the problem asks for an assignment of a set of n jobs $\mathcal{J}$ to a set of m identical machines $\mathcal{M}$. Each job $j \in \mathcal{J}$ is

characterized by a non-negative processing time $p_j \in \mathbb{Z}_{>0}$. The load of a machine is the total processing time of jobs assigned to it, and our objective is to minimize the *makespan*, that is, the maximum machine load. This problem is usually denoted $P||C_{\max}$. It is well known to admit a *polynomial time approximation scheme* (PTAS) [9], and there has been many subsequent works improving the running time or deriving PTAS's for more general settings. The fastest PTAS for $P||C_{\max}$ achieves a running time of $2^{O(1/\varepsilon^2)\log^3(1/\varepsilon))} + O(n \log n)$ for $(1+\varepsilon)$-approximate solutions [10]. Very recently, Chen et al. [3] showed that, assuming the *exponential time hypothesis* (ETH), there is no PTAS that yields $(1+\varepsilon)$-approximate solutions for $\varepsilon > 0$ with running time $2^{(1/\varepsilon)^{1-\delta}} + \text{poly}(n)$ for any $\delta > 0$ [3].

Given a guess $T \in \mathbb{N}$ on the optimal makespan, which can be found with binary search, the problem reduces to deciding the existence of a packing of the jobs to m machines (or bins) of capacity T. If we aim for a $(1+\varepsilon)$-approximate solution, for some $\varepsilon > 0$, we can assume that all processing times are integral and T is a constant number, namely $T \in O(1/\varepsilon^2)$. This can be achieved with well known rounding and scaling techniques [1, 2, 8] which will be specified later. Let $\pi_1 < \pi_2 < \ldots < \pi_d$ be the job sizes appearing in the instance after rounding, and let b_k denote the number of jobs of size π_k. The mentioned rounding procedure implies that the number of different job sizes is $d = O((1/\varepsilon)\log(1/\varepsilon))$. Hence, for large n we obtain a highly symmetric problem where several jobs will have the same processing time. Consider the *knapsack polytope* $\mathcal{P} = \{c \in \mathbb{R}^d_{\geq 0} : \pi \cdot c \leq T\}$. A packing on one machine can be expressed as a vector $c \in Q = \mathbb{Z}^d \cap \mathcal{P}$, where c_k denotes the number of jobs of size π_k assigned to the machine. Elements in $Q = \mathbb{Z}^d \cap \mathcal{P}$ are called *configurations*. Considering a variable $x_c \in \mathbb{Z}_{\geq 0}$ that decides the multiplicity of configuration c in the solution, our problem reduces to solving the following linear integer program (ILP):

$$\text{[conf-IP]} \quad \sum_{c \in Q} c \cdot x_c = b, \tag{1}$$

$$\sum_{c \in Q} x_c = m, \tag{2}$$

$$x_c \in \mathbb{Z}_{\geq 0} \qquad \text{for all } c \in Q. \tag{3}$$

In this article we derive new insights on this ILP that help us to design faster algorithms for $P||C_{\max}$ and other more general problems. These including makespan scheduling on *related machines* $Q||C_{\max}$, and a more general class of objective functions on parallel machines. We show that all these problems admit a PTAS with running time $2^{O((1/\varepsilon)\log^4(1/\varepsilon))} + \text{poly}(n)$. Hence, our algorithm is best possible up to polylogarithmic factors in the exponent assuming ETH [3].

1.1 Literature Review

There is an old chain of approximation algorithms for $P||C_{\max}$, starting from the seminal work by Graham [6, 7]. The first PTAS was given by Hochbaum and Shmoys [9] and had a running time of $(n/\varepsilon)^{O((1/\varepsilon)^2)} = n^{O((1/\varepsilon)^2 \log(1/\varepsilon))}$. This was improved to $n^{O((1/\varepsilon)\log^2(1/\varepsilon))}$ by Leung [14]. Subsequent articles improve further the running time. In particular Hochbaum and Shmoys (see [8]) and Alon et al. [1, 2] obtain an *efficient PTAS*[1] (EPTAS) with running time $2^{(1/\varepsilon)^{\text{poly}(1/\varepsilon)}} + O(n \log n)$. Alon et al. [1, 2] consider general techniques that work for

[1] That is, a PTAS whose running time is $f(1/\varepsilon)\text{poly}(|I|)$ where $|I|$ is the encoding size of the input and f is some function.

several objective functions, including all L_p-norm of the loads and maximizing the minimum machine load.

The previously fastest PTAS for $P||C_{\max}$ achieves a running time of $2^{O((1/\varepsilon)^2 \log^3(1/\varepsilon))} + O(n \log n)$ [10]. More generally, this work gives an EPTAS for the case of related (uniform) machines, where each machine $i \in \mathcal{M}$ has a speed s_i and assigning to i job j implies a processing time of p_j/s_i. For this more general case the running time is $2^{O((1/\varepsilon)^2 \log^3(1/\varepsilon))} + \text{poly}(n)$. For the simpler case of $P||C_{\max}$, the ILP can be solved directly since the number of variables is a constant. This can be done with Lentras' algorithm [13], or even with Kannan's algorithm [12] that gives an improved running time. This technique yields a running time that is doubly exponential in $1/\varepsilon$. This was, in essence, the approach by Alon et al. [1, 2] and Hochbaum and Shmoys [8]. To lower the dependency on $1/\varepsilon$, Jansen [10] uses a result by Eisenbrand and Shmonin [4] that implies the existence of a solution x with support of size at most $O(d \log(dT)) = O((1/\varepsilon) \log^2(1/\varepsilon))$. First guessing the support and then solving the ILP with $O((1/\varepsilon) \log^2(1/\varepsilon))$ integer variables and using Kannan's algorithm yields the desired running time of $2^{O((1/\varepsilon)^2 \log^3(1/\varepsilon))} + O(n \log n)$.

The configuration ILP has recently been studied in the context of the (1-dimensional) cutting stock problem. In this case, the dimension d is constant, $T = 1$, and π is a rational vector. Moreover, π and b are part of the input. Goemans and Rothvoß [5] obtain an optimal solution in time $\log(\Delta)^{2^{O(d)}}$, where Δ is the largest number appearing in the denominator of π_k or the multiplicities b_k. This is achieved by first showing that there exists a pre-computable set $\tilde{Q} \subseteq Q$ with polynomial many elements, such that there exists a solution x that gives all but constant (depending only on d) amount of weight to $\tilde{Q}$. We remark that applying this result to a rounded instance of $P||C_{\max}$ yields a running time that is doubly exponential on $1/\varepsilon$.

1.2 Our Contributions

Our main contribution is a new insight on the structure of the solutions of [conf-IP]. These properties are specially tailored to problems in which T is bounded by a constant, which in the case of $P||C_{\max}$ can be guaranteed by rounding and scaling. The same holds for $Q||C_{\max}$ with a more complex rounding and case analysis.

We first classify configurations by their support. We say that a configuration is *simple* if its support is of size at most $\log(T+1)$, otherwise it is *complex*. Our main structural result[2] states that there exists a solution x in which all but $O(d \log(dT))$ weight is given to simple configurations, the support is bounded by $O(d \log(dT))$ (as implied by Eisenbrand and Shmonin [4]) and no complex configuration has weight larger than 1.

▶ **Theorem 1** (Thin solutions). *Assume that [conf-IP] is feasible. Then there exists a feasible solution x to [conf-IP] such that:*

1. *if $x_c > 1$ then the configuration c is simple,*
2. *the support of x satisfies $|\text{supp}(x)| \leq 4(d+1)\log(4(d+1)T)$, and*
3. *$\sum_{c \in Q_c} x_c \leq 2(d+1)\log(4(d+1)T)$, where Q_c denotes the set of complex configurations.*

[2] We remark the resemblance of this structure to the result by Goemans and Rothvoß [5]. Indeed, similarly to their result, we can precompute a subset of configurations such that all but a constant amount of weight of the solution is given to such set. In their case the set is of cardinality polynomial on the input and is constructed by covering the integral solutions of the knapsack polytope by parallelepipeds. In our case, all but $O(d \log dT)$ weight is given to simple configurations.

We call a solution satisfying the properties of the theorem *thin*. The theorem can be shown by iteratively applying a sparsification lemma that shows that if a solution gives a weight of two or more to a complex configuration, then we can replace this partial solution by two configurations with smaller support. The sparsification lemma is shown by a simple application of the pigeonhole principle. The theorem can be shown by mixing this technique with the theorem of Eisenbrand and Shmonin [4] and a potential function argument.

As an application to our main structural theorem, we derive a PTAS for $P||C_{\max}$ by first guessing the jobs assigned to complex configurations. An optimal solution for this subinstance can be derived by a dynamic program. For the remaining instance we know the existence of a solution using only simple configurations. Then we can guess the support of such solution and solve the corresponding [conf-IP] restricted to the guessed variables. The main use of having simple configurations is that we can guess the support of the solution much faster, as the number of simple configuration is (asymptotically) smaller than the total number of configurations. The complete procedure takes time $2^{O((1/\varepsilon)\log^4(1/\varepsilon))} + O(n \log n)$. Moreover, using the rounding and case analysis of Jansen [10], we derive an mixed integer linear program that can be suitably decomposed in order to apply our structural result iteratively. This yields a PTAS with a running time of $2^{O((1/\varepsilon)\log^4(1/\varepsilon))} + \text{poly}(n)$ for $Q||C_{\max}$.

Similarly, we can extend our results to derive PTAS's for a larger family of objective functions as considered by Alon et al. [1, 2]. Let ℓ_i denote the load of machine i, that is, the total processing time of jobs assigned to machine i for a given solution. Our techniques then gives a PTAS with the same running time for the problem of minimizing the L_p-norms of the loads (for fixed p), and maximizing $\min_{i \in M} \ell_i$, among others. To solve this problem, we can round the instance and state an IP analogous to [conf-IP] but considering an objective function. However, the objective function prevents us to use the main theorem as it is stated. To get over this issue, we study several ILPs. In each ILP we consider x_c to be a variable only if c has a given load, and fix the rest to be some optimal solution. Applying to each such ILP Theorem 1, plus some extra ideas, yields an analogous structural theorem. Afterwards, an algorithm similar to the one for makespan minimization yields the desired PTAS.

From an structural point of view, our sparsification lemma has other consequences on the structure of the knapsack polytope and the LP-relaxation of the [conf-IP]. More precisely, we can show that any vertex of the convex hull of Q must be simple. This, for example, helps us to upper bound the number of vertices by $2^{O(\log^2(T)+\log^2(d))}$. Moreover, we can show that the configuration-LP, obtained by replacing the integrality restriction in [conf-IP] by $x \geq 0$, if it is feasible then admits a solution whose support consist purely of simple configurations. Due to space limitations we leave many details and proofs to the full version.

2 Preliminaries

We will use the following notation throughout the paper. By default $\log(\cdot) = \log_2(\cdot)$, unless stated otherwise. Given two sets A, I, we will denote by A^I the set of all vectors indexed by I with entries in A, that is, $A^I = \{(a_i)_{i \in I} : a_i \in A \text{ for all } i \in I\}$. Moreover, for $A \subseteq \mathbb{R}$, we denote the support of a vector $a \in A^I$ as $\text{supp}(a) = \{i \in I : a_i \neq 0\}$.

We consider an arbitrary knapsack polytope $\mathcal{P} = \{c \in \mathbb{R}^d_{\geq 0} : \pi \cdot c \leq T\}$ where $\pi \in \mathbb{Z}^d_{>0}$ is a non-negative integral (row) vector and T is a positive integer. We assume without loss of generality that each coordinate π_k of π is upper bounded by T (otherwise $c_k = 0$ for all $c \in \mathbb{Z}^d \cap \mathcal{P}$). We focus on the set of integral vectors in $\mathcal{P}$ which we denote by $Q = \mathbb{Z}^d \cap \mathcal{P}$. We call an element $c \in Q$ a *configuration*. Given $b \in \mathbb{R}^d$, consider the problem of decomposing b as a conic integral combination of m configurations. That is, our aim is to find a feasible solution to [conf-IP], defined above.

A crucial property of the [conf-IP] is that there is always a solution with a support of small cardinality. This follows from a Caratheodory-type bound obtained by Eisenbrand and Shmonin [4]. Since we will need the argument later, we state the result applied to our case and revise its (very elegant) proof. We split the proof in two lemmas.

For a given subset $A \subseteq Q$, let us denote by x^A the indicator vector of A, that is $x^A_c = 1$ if $c \in A$, and 0 otherwise. Let us also denote by M the $(d+1) \times |Q|$ matrix that defines the system of equalities (1) and (2).

▶ **Lemma 2** (Eisenbrand and Shmonin [4]). *Let $x \in \mathbb{Z}^Q_{\geq 0}$ be a vector such that $|\operatorname{supp}(x)| > 2(d+1)\log(4(d+1)T)$. Then there exist two disjoint sets A, B with $\emptyset \neq A, B \subseteq \operatorname{supp}(x)$ such that $Mx^A = Mx^B$.*

▶ **Lemma 3** (Eisenbrand and Shmonin [4]). *If [conf-IP] is feasible, then there exists a feasible solution x such that $|\operatorname{supp}(x)| \leq 2(d+1)\log(4(d+1)T)$.*

Proof. Let x be a solution to [conf-IP] that minimizes $|\operatorname{supp}(x)| = s$. Assume by contradiction that $s > 2(d+1)\log(4(d+1)T)$. We show that we can find another solution x' to [conf-IP] with $|\operatorname{supp}(x')| < |\operatorname{supp}(x)|$, contradicting the minimality of $|\operatorname{supp}(x)|$. By Lemma 2, there exist two disjoint subsets $A, B \in \operatorname{supp}(x)$ such that $Mx^A = Mx^B$. Moreover, let $\lambda = \min\{x_c : c \in A\}$. Vector $x' := x - \lambda x^A + \lambda x^B$ is also a solution to [conf-IP] and has a strictly smaller support since a configuration $c^* \in \arg\min\{x_c : c \in A\}$ satisfies $x'_{c^*} = 0$. ◀

3 Structural Results

Recall that we call a configuration c simple if $|\operatorname{supp}(c)| \leq \log(T+1)$ and complex otherwise. An important observation to show Theorem 1 is that if c is a complex configuration, then $2c$ can be written as the sum of two configurations of smaller support. This is shown by the following Sparsification Lemma.

▶ **Lemma 4** (Sparsification Lemma). *Let $c \in Q$ be a complex configuration. Then there exist two configurations $c_1, c_2 \in Q$ such that*

1. $\pi \cdot c_1 = \pi \cdot c_2 = \pi \cdot c$,
2. $2c = c_1 + c_2$,
3. $\operatorname{supp}(c_1) \subsetneq \operatorname{supp}(c)$ *and* $\operatorname{supp}(c_2) \subsetneq \operatorname{supp}(c)$.

Proof. Consider for each subset $S \subseteq \operatorname{supp}(c)$, a configuration $c^S \in Q$ such that $c^S_i = c_i$ if $i \in S$ and $c^S = 0$ otherwise. As the number of subsets of $\operatorname{supp}(c)$ is $2^{|\operatorname{supp}(c)|}$, and $c^R \neq c^S$ if and only if $R \neq S$, the collection of vectors $V := \{c^S : S \subseteq \operatorname{supp}(c)\}$ has cardinality $|V| = 2^{|\operatorname{supp}(c)|}$.

On the other hand, for any vector $c^S \in V$ it holds that $\pi \cdot c^S \leq \pi \cdot c \leq T$. Hence, $\pi \cdot c^S \in \{0, 1 \ldots, T\}$ can take only $T+1$ different values. Using that c is a complex configuration and hence $2^{|\operatorname{supp}(c)|} > 2^{\log(T+1)} = T+1$, the pigeonhole principle ensures that there are two different non-empty configurations $c^S, c^R \subseteq V$ with $\pi \cdot c^S = \pi \cdot c^R$. By removing the intersection, we can assume w.l.o.g. that S and R have no intersection. We define $c_1 = c - c^S + c^R$ and $c_2 = c - c^R + c^S$, which satisfy the properties of the lemma as

$$\pi \cdot c_1 = \pi \cdot c - \pi \cdot c^S + \pi \cdot c^R = \pi \cdot c \quad \text{and}$$
$$2c = c - c^S + c^R + c - c^R + c^S = c_1 + c_2.$$

Since $\operatorname{supp}(c_1) \subseteq \operatorname{supp}(c) \setminus S$ and $\operatorname{supp}(c_2) \subseteq \operatorname{supp}(c) \setminus R$, property 3 is satisfied. ◀

With Lemma 4 we are ready to show Theorem 1. For the proof it is tempting to apply the lemma iteratively, replacing any complex configuration that is used twice by two configurations with smaller support. This can be repeated until there is no complex configuration taken multiple times. Then we can apply the technique of Lemma 3 to the obtained solution to bound the cardinality of the support. However, the last step might break the structure obtained if the solution implied by Lemma 3 uses a complex configuration more than once. In order to avoid this issue we consider a potential function. We show that a vector minimizing the chosen potential uses each complex configuration at most once, and that the number of complex configurations in the support is bounded. Finally, we apply the techniques from Lemma 3 restricted to variables corresponding to simple configurations.

Proof of Theorem 1. Consider the following potential function of a solution $x \in \mathbb{Z}^Q_{\geq 0}$ of [conf-IP],

$$\Phi(x) = \sum_{\text{complex config. } c} x_c |\operatorname{supp}(c)|.$$

Let x be a solution of [conf-IP] with minimum potential $\Phi(x)$, which is well defined since the set of feasible solutions has finite cardinality. We show two properties of x.

P1: *$x_c \leq 1$ for each complex configuration $c \in Q$.*

Assume otherwise. Consider the two configurations c_1 and c_2 implied by the previous lemma. We define a new solution $x'_e = x_e$ for $e \notin \{c, c_1, c_2\}$, $x'_{c_1} = x_{c_1} + 1$, $x'_{c_2} = x_{c_2} + 1$ and $x'_c = x_c - 2$. Since $|\operatorname{supp}(c_1)| < |\operatorname{supp}(c)|$ and $|\operatorname{supp}(c_2)| < |\operatorname{supp}(c)|$, we obtain that $\Phi(x') < \Phi(x)$ which contradicts the minimality of $\Phi(x)$.

P2: *The number of complex configurations in* $\operatorname{supp}(x)$ *is at most* $2(d+1)\log(4(d+1)T)$.

Let $\tilde{x}$ be the vector defined as $\tilde{x}_c = x_c$ if $c \in Q$ is complex, and $\tilde{x} = 0$ if $c \in Q$ is simple. Then Lemma 2 implies that there are exist two disjoint subsets $A, B \subseteq \operatorname{supp}(\tilde{x})$ of complex configurations such that $Mx^A = Mx^B$. Thus, the solution $x' = x - x^A + x^B$ and the solution $x'' = x - x^B + x^A$ are feasible for [config-IP]. By linearity, the potential function on the new solutions are $\Phi(x') = \Phi(x) - \Phi(x^A) + \Phi(x^B)$ or respectively $\Phi(x'') = \Phi(x) - \Phi(x^B) + \Phi(x^A)$. If $\Phi(x^A) > \Phi(x^B)$ or $\Phi(x^B) > \Phi(x^A)$ then we have constructed a new solution with smaller potential, contradicting our assumption on the minimality of $\Phi(x)$. We conclude that $\Phi(x^B) = \Phi(x^A)$ and thus $\Phi(x) = \Phi(x')$. By construction of x', we obtain that $x'_c > x_c \geq 1$ for any complex configuration $c \in B$. Having multiplicity ≥ 2 for a complex configuration c, we can proceed as in Case 1 to find a new solution with decreased potential, which yields a contradiction.

Given these two properties, to conclude the theorem it suffices to upper bound the number of simple configurations by $2(d+1)\log(4(d+1)T)$. Suppose this property is violated, then we find two sets $A, B \subseteq \operatorname{supp}(x)$ of simple configurations (see Lemma 2) with $Mx^A = Mx^B$ and proceed as in Lemma 3. Since Lemma 3 is only applied to simple configurations, properties P1 and P2 continue to hold and the theorem follows. ◀

Our techniques, in particular our Sparsification Lemma, imply two corollaries on the structure of the knapsack polytope and the LP-relaxation implied by the [conf-IP].

▶ **Corollary 5.** *Every vertex of conv.hull(Q) is a simple configuration. Moreover, the total number of simple configurations in Q is upper bounded by $2^{O(\log^2(T)+\log^2(d))}$ and thus the same expression upper bounds the number of vertices of conv.hull(Q).*

The following corollary follows as each complex configuration can be represented by a convex combination of simple configurations.

▶ **Corollary 6.** *Let [conf-LP] be the LP relaxation of [conf-IP], obtained by changing each constraint $x_c \in \mathbb{Z}_{\geq 0}$ to $x_c \geq 0$ for all $c \in Q$. If the LP is feasible then there exists a solution x such that each configuration $c \in \operatorname{supp}(x)$ is simple.*

4 Applications to Scheduling on Parallel Machines

In what follows we show how to exploit the structural insights of the previous section to derive faster algorithms for parallel machines scheduling problems. We start by considering $P||C_{\max}$, where we seek to assign a set of jobs $\mathcal{J}$ with processing times $p_j \in \mathbb{Z}_{>0}$ to a set $\mathcal{M}$ of m machines. For a given assignment $a : \mathcal{J} \mapsto \mathcal{M}$, we define the load of a machine i as $\sum_{j:a(j)=i} p_j$ and the *makespan* as the maximum load of jobs over all machines, which is the minimum time needed to complete the execution of all jobs on the processors. The goal is to find an assignment $\mathcal{J} \mapsto \mathcal{M}$ that minimizes the makespan.

We first follow well known rounding techniques [1, 2, 9, 8]. Consider an error tolerance $0 < \varepsilon < 1/3$ such that $1/\varepsilon^2$ is an integer. To get an estimation of the optimal makespan, we follow the standard dual approximation approach. First, we can use, e.g., the 2-approximation algorithm by Graham [6] to get an initial guess of the optimal makespan. Using binary search, we can then estimate the optimal makespan within a factor of $(1+\varepsilon)$ in $O(\log(1/\varepsilon))$ iterations. Therefore, it remains to give an algorithm that decides for a given makespan T, if there exists an assignment with makespan $(1+O(\varepsilon))T$ or reports that there exists no assignment with makespan $\leq T$.

For a given makespan T we define the set of big jobs $\mathcal{J}_{\text{big}} = \{j \in \mathcal{J} : p_j \geq \varepsilon T\}$ and the set of small jobs $\mathcal{J}_{\text{small}} = \mathcal{J} \setminus \mathcal{J}_{\text{big}}$. The following lemma shows that small jobs can be replaced from the instance by adding big jobs, each of size εT, as placeholders. Let S be the sum of processing times of jobs in $\mathcal{J}_{\text{small}}$ and let S^* denote the next value of S rounded up to the next multiple of εT, that is, $S^* = \varepsilon T \cdot \lceil S/(\varepsilon T) \rceil$. We define a new instance containing only big jobs by $\mathcal{J}^* = \mathcal{J}_{\text{big}} \cup \mathcal{J}_{\text{new}}$, where $\mathcal{J}_{\text{new}}$ contains $S^*/(\varepsilon T) \in \mathbb{N}$ jobs of size εT. The proof of the next lemma and the rest of the missing proofs of this section can be found in the full version.

▶ **Lemma 7.** *Given a feasible assignment $a : \mathcal{J} \mapsto \mathcal{M}$ of jobs with makespan T. Then there exists a feasible assignment $a_B : \mathcal{J}^* \mapsto \mathcal{M}$ of makespan $T^* \leq (1+\varepsilon)T$. Similarly, an assignment of jobs in $\mathcal{J}^*$ of makespan T^* can be transformed to an assignment of $\mathcal{J}$ of makespan at most $(1+\varepsilon)T^*$.*

By scaling the processing times of jobs in $\mathcal{J}^*$, we can assume that the makespan T has value $1/\varepsilon^2$. Also notice that we can assume that $p_j \leq T$ for all j, otherwise we cannot pack all jobs within makespan T. This implies that each job $j \in \mathcal{J}^*$ has a processing time of $1/\varepsilon \leq p_j \leq 1/\varepsilon^2$. In the following we give a transformation of big jobs in $\mathcal{J}^*$ by rounding their processing times. We first round the jobs to the next power of $1+\varepsilon$ as $p'_j = (1+\varepsilon)^{\lceil \log_{(1+\varepsilon)} p_j \rceil}$, and thus all rounded processing times belong to $\Pi' = \{(1+\varepsilon)^k : 1/\varepsilon \leq (1+\varepsilon)^k \leq (1+\varepsilon)/\varepsilon^2 \text{ and } k \in \mathbb{N}\}$. We further round processing times p'_j to the next integer $\bar{p}_j = \lceil p'_j \rceil$ and define a new set $\Pi = \{\lceil p \rceil : p \in \Pi'\}$. Notice that Π only contains integers and $|\Pi| \leq |\Pi'| \in O((1/\varepsilon)\log(1/\varepsilon))$.

▶ **Lemma 8.** *If there is a feasible schedule of jobs $\mathcal{J}^*$ with processing times p_j onto m machines with makespan $T^* \leq (1+\varepsilon)T$, then there is also a feasible schedule of jobs $\mathcal{J}^*$ with*

rounded processing $\bar{p}_j$ with a makespan of at most $(1+5\varepsilon)T$. Furthermore, the number of different processing times is at most $|\Pi| \in O((1/\varepsilon)\log(1/\varepsilon))$.

In what follows we give an algorithm that decides in polynomial time the existence of a solution for instance $\mathcal{J}^*$ with processing times $\bar{p}_j$ and makespan $\bar{T} = \lfloor (1+5\varepsilon)T \rfloor$. We call numbers in Π by $\pi_1, \ldots, \pi_d$ and define the vector $\pi = (\pi_1, \pi_2, \ldots, \pi_d) \in \mathbb{N}^d$ of rounded processing times. We consider *configurations* to be vectors in $Q = \mathcal{P} \cap \mathbb{Z}^d$, where $\mathcal{P} = \{c \in \mathbb{R}^d_{\geq 0} : \pi \cdot c \leq \bar{T}\}$ is a knapsack polytope (see Section 3). As before, we say that a configuration is simple if $|\operatorname{supp}(c)| \leq \log(\bar{T}+1)$, and complex otherwise. For a given assignment of jobs to machines, we say that a machine follows a configuration c if c_k is the number of jobs of size π_k assigned to the machine. We denote by $Q_c \subseteq Q$ the set of complex configurations and by $Q_s \subseteq Q$ the set of simple configurations.

Let b_k be the number of jobs of size π_k in the instance $\mathcal{J}^*$ (with processing times $\bar{p}$). Consider an ILP with integer variables x_c for each $c \in Q$, which denote the number of machines that follow configuration c. With these parameters the problem of scheduling all jobs in a solution of makespan $\bar{T}$ is equivalent to finding a solution to [conf-IP]. To solve the ILP we use, among other techniques, Kannan's algorithm [12] which is an improvement on the algorithm by Lenstra [13]. The algorithm has a running time of $2^{O(N \log N)} s$ where N is the number of variables and s is number of bits used to encode the input of the ILP in binary.

By Theorem 1, if [conf-IP] is feasible then there exists a thin solution. In particular if one configuration c is used by more than one machine then c is simple, and the total number of used configurations is $4(d+1)\log(4(d+1)\bar{T}) \in O((1/\varepsilon)\log^2(1/\varepsilon))$. Additionally, the number of machines following a complex configurations is at most $2(d+1)\log(4(d+1)\bar{T}) \in O((1/\varepsilon)\log^2(1/\varepsilon))$. We consider the following strategy to decide the existence of a schedule of makespan $\bar{T}$.

▶ Algorithm 9.

1. For each processing time π_k, guess the number $b^c_k \leq b_k$ of jobs covered by complex configurations.
2. Find a minimum number of machines m^c to schedule jobs b^c with makespan $\bar{T}$.
3. Guess the support of simple configurations $\bar{Q}_s \subseteq Q_s$ used by a thin solution, with $|\bar{Q}_s| \leq 4(d+1)\log(4(d+1)\bar{T}) \in O((1/\varepsilon)\log^2(1/\varepsilon))$.
4. Solve the ILP restricted to configurations in $\bar{Q}_s$:

$$\sum_{c \in \bar{Q}_s} c \cdot x_c = b - b^c,$$
$$\sum_{c \in \bar{Q}_s} x_c = m - m^c,$$
$$x_c \in \mathbb{Z}_{\geq 0} \qquad \text{for all } c \in \bar{Q}_s.$$

One of the key observations to prove the running time of the algorithm is that the number of simple configurations $|Q_s|$ is bounded by a quasi polynomial term:

$$|Q_s| \leq 2^{O(\log^2(1/\varepsilon))}.$$

This follows easily by Corollary 5, using that $|\bar{T}| \in O(1/\varepsilon^2)$ and $d = |\Pi| \in O((1/\varepsilon)\log(1/\varepsilon))$.

▶ **Lemma 10.** *Algorithm 9 can be implemented with a running time of $2^{O((1/\varepsilon)\log^4(1/\varepsilon))}\log(n)$.*

Proof. In step 1, the algorithm guesses which jobs are processed on machines following a complex configurations. Since each configuration contains at most $O(1/\varepsilon)$ jobs, there are at most $O(m^c/\varepsilon) = O((1/\varepsilon^2)\log^2(1/\varepsilon))$ jobs assigned to such machines. For each size $\pi_k \in \Pi$, we guess the number b_k^c of jobs of size π_k assigned to such machines. Hence, we can enumerate all possibilities for jobs assigned to complex machines in time $2^{O((1/\varepsilon)\log^2(1/\varepsilon))}$. After guessing the jobs, we can assign them to a minimum number of machines in step 2 (with makespan $\bar{T}$) with a simple dynamic program that stores vectors $(\ell, z_1, \ldots, z_d)$ with $z_k \leq b_k^c$ being the number of jobs of size π_k used in the first $\ell \leq m^c$ processors [11]. The size of the dynamic programming table is $O(m^c \prod_{k=1}^{d}(b_k^c+1))$. For any vector $(\ell, z_1, \ldots, z_d)$, determining whether it corresponds to a feasible solution can be done by checking all vectors of the type $(\ell-1, z_1', \ldots, z_d')$ for $z_k' \leq z_k$. Thus, the running time of the dynamic program is $O(m^c[\prod_{k=1}^{d}(b_k^c+1)]^2)$. Since $b_k^c \in O((1/\varepsilon^2)\log^2(1/\varepsilon))$ for each k, recalling that $m^c \in O((1/\varepsilon)\log^2(1/\varepsilon))$, and that $d = |\Pi| \in O((1/\varepsilon)\log(1/\varepsilon))$, we obtain that step 2 can be implemented with $2^{O((1/\varepsilon)\log^2(1/\varepsilon))}$ running time.

In step 3, our algorithm guesses the support of a thin solution x. Recall that if x is thin then $|\operatorname{supp}(x)| \leq 4(d+1)\log(4(d+1)\bar{T}) = O((1/\varepsilon)\log^2(1/\varepsilon))$. Let $D = 4(d+1)\log(4(d+1)\bar{T})$. Then this guess can be done in time

$$\sum_{i=0}^{D} \binom{|Q_s|}{i} \leq (D+1)|Q_s|^D \leq 2^{O((1/\varepsilon)\log^4(1/\varepsilon))}.$$

We remark that for this step is that thin solutions are particularly useful. Indeed, guessing the support on the original ILP takes time $2^{O((1/\varepsilon)^2\log^3(1/\varepsilon))}$.

In step 4, the restricted ILP with $4(d+1)\log(4(d+1)\bar{T}) = O((1/\varepsilon)\log^2(1/\varepsilon))$ variables is solved. Moreover, the size of the input can be bounded by $O((1/\varepsilon^2)\log^3(1/\varepsilon)\log(n))$. Running Kannan's algorithm [12] to solve the ILP takes time $2^{O((1/\varepsilon)\log^3(1/\varepsilon))}\log(n)$. Hence, the total running time of our algorithm can be bounded by $2^{O((1/\varepsilon)\log^4(1/\varepsilon))}\log(n)$. ◀

Putting all pieces together, we conclude with the following theorem.

▶ **Theorem 11.** *The minimum makespan problem on parallel machines $P||C_{\max}$ admits an EPTAS with running time $2^{O((1/\varepsilon)\log^4(1/\varepsilon))} + O(n\log n)$.*

4.1 Extension to other objectives

We now consider a more general family of objective functions defined by Alon et al. [1, 2]. For a fixed function $f : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$, we consider the following two objective functions: (I) $\min \sum_{i\in\mathcal{M}} f(\ell_i)$, and (II) $\min \max_{i\in\mathcal{M}} f(\ell_i)$, where ℓ_i denotes the load of machine i. Analogously, we study maximization versions of the problems: (I') $\max \sum_{i\in\mathcal{M}} f(\ell_i)$ and (II') $\max \min_{i\in\mathcal{M}} f(\ell_i)$.

For the minimization versions of the problem we assume that f is convex, while for (I') and (II') we assume it is concave. Moreover, we will need that the function satisfies the following sensitivity condition.

▶ **Condition 12.** *For all $\varepsilon > 0$ there exists $\delta = \delta(\varepsilon) > 0$ such that for all $x, y \in \mathbb{R}_{\geq 0}$,*

$$(1-\delta)y \leq x \leq (1+\delta)y \quad \Rightarrow \quad (1-\varepsilon)f(y) \leq f(x) \leq (1+\varepsilon)f(y).$$

Alon et al. showed that each problem in that family admits a PTAS with running time $h(\varepsilon)+O(n\log n)$, where $h(\varepsilon)$ is a constant term that depends only on ε. Moreover, if $\delta(\varepsilon)$ in the condition further satisfies that $1/(\delta(\varepsilon)) \in O(1/\varepsilon)$, the running time is $2^{(1/\varepsilon)^{\mathrm{poly}(1/\varepsilon)}} + O(n\log n)$.

In what follows we show how to improve this dependency if we have the additional condition that function f is non-decreasing, i.e., for all $0 \leq x \leq y$ we have that $f(x) \leq f(y)$. Since $1/(\delta(\varepsilon)) \in O(1/\varepsilon)$, we know that, for small enough ε, there exists a constant γ (independent of ε and δ) such that $1/\delta \leq \gamma/\varepsilon$. Moreover, we can assume w.l.o.g. that $\delta \leq \varepsilon$, and thus $\delta \leq \varepsilon \leq \gamma\delta$.

It is worth noticing that many interesting functions belong to this family. In particular (II) with $f(x) = x$ corresponds to the minimum makespan problem, (I) with $f(x) = x^p$, for constant p, corresponds to a problem that is equivalent to minimizing the L_p-norm of the vector of loads. Similarly, (II') with $f(x) = x$ corresponds to maximizing the minimum machine load. Notice that for all those objectives we have that $1/\delta = O(1/\varepsilon)$.

The techniques of Alon et al. are based on a rounding method and then solving an ILP. We based our results in the same rounding techniques and extend them further. We show that to obtain a PTAS in time $2^{O((1/\varepsilon)\log^4(1/\varepsilon))} + O(n \log n)$ it suffices to obtain a $(1 + O(\varepsilon))$-approximate solution to the rounded instance in the same running time. The details of the rounding are given in the full version.

Let $L = \sum_j p_j/m$ be the average machine load (of the original instance). After our rounding we obtain an instance I' with job set $\mathcal{J}'$ and processing times $\bar{p}_j$ for $j \in \mathcal{J}'$. Moreover, the $\bar{p}_j$ are multiples of L/λ^2, where $\lambda \geq 1/\delta$ is an integer such that $\lambda = O(1/\delta)$, and also $\bar{p}_j \geq L/\lambda$. It holds that there exists an optimal solution of the rounded instance with makespan at most $4L$ (see full version). Let $\Pi = \{\pi_1, \ldots, \pi_d\}$ be the distinct values that the processing times $\bar{p}_j$ can take. Our rounding guarantees that $d = |\Pi| = O((1/\delta)\log(1/\delta))$. We consider the knapsack polytope with capacity $\bar{T} := 4L$, that is $\mathcal{P} = \{c \in \mathbb{R}^d_{\geq 0} : \pi \cdot c \leq \bar{T}\}$. Notice that π and $\bar{T}$ are integer multiples of L/λ^2, and that $\mathcal{P}$ can also be written as $\{c \in \mathbb{R}^d_{\geq 0} : \pi/(L/\lambda^2) \cdot c \leq \bar{T}/(L/\lambda^2)\}$.

As before, we say that a configuration is simple if $|\operatorname{supp}(c)| \leq \log(\bar{T} + 1)$, and complex otherwise. We denote by $Q_c \subseteq Q$ the set of complex configurations and by $Q_s \subseteq Q$ the set of simple configurations. In what follows we focus on objective function (I).

We set an ILP for the problem as before. Notice that each configuration c incurs a cost of $f_c := f(\pi \cdot c)$. Moreover, we round and scale the values f_c by defining $\bar{f}_c = \lceil f_c/(\varepsilon f_{\min})\rceil$, where $f_{\min} = \min_{c \in Q} f_c$. It is not hard to see that solving a problem with those coefficients yields a $(1 + \varepsilon)$-approximate solution to the optimal solution of I' with processing times $\bar{p}_j$. Let also b_k be the number of jobs j of processing time $\bar{p}_j = \pi_k$ in $\mathcal{J}'$. Consider the ILP obtained by adding to [conf-IP] the objective function $\min \sum_{c \in Q} \bar{f}_c \cdot x_c$. We call this ILP [cost-conf-IP]. With our previous discussion, it suffices to solve this ILP optimally. To solve this problem, we first notice that the largest coefficient in the objective can be bounded as follows.

▶ **Lemma 13.** *If f satisfies Condition 12 and it is non-decreasing, then the largest value $\max_{c \in Q} \bar{f}_c$ is upper bounded by $1/\delta^{O(1)}$.*

As we now must consider the objective function, we cannot simply apply Theorem 1 to [cost-conf-ILP]. However, we can prove a slightly weaker version by decomposing the ILP in several smaller ones and applying the theorem to each of them.

▶ **Theorem 14.** *If* [cost-conf-IP] *is feasible, then there exists an optimal solution x satisfying:*

1. $\sum_{c \in Q_c} x_c \in O((1/\delta^3)\log^2(1/\delta))$, *and*
2. $|\operatorname{supp}(x) \cap Q_s| \in O((1/\delta)\log^2(1/\delta))$.

Proof. Notice that the load of each configuration $\pi \cdot c$ is a multiple of L/λ^2, and thus $\pi \cdot c \in \{L/\lambda, L/\lambda + L/(\lambda^2), \ldots, 4L\}$. We classify the configurations according to their loads,

$Q^\ell := \{c \in Q : \pi \cdot c = L/\lambda + \ell \cdot L/(\lambda^2)\}$, for $\ell \in \{0, \dots, 4\lambda^2 - \lambda\}$. Let x^* be an optimal solution of [cost-conf-IP]. Then we can considered an ILP for each load value ℓ:

$$[\text{conf-IP}]_\ell \quad \sum_{c \in Q^\ell} c \cdot x_c = \sum_{c \in Q^\ell} c \cdot x^*_c, \tag{4}$$

$$\sum_{c \in Q^\ell} x_c = \sum_{c \in Q^\ell} x^*_c, \tag{5}$$

$$x_c \in \mathbb{Z}_{\geq 0} \qquad \text{for all } c \in Q^\ell. \tag{6}$$

Scaling π by multiplying it by λ^2/L we obtain an integral vector (since π is an integer multiple of $L/(\lambda^2)$), we can apply Theorem 1 to each ILP $[\text{conf-IP}]_\ell$, which yields that there exists a thin solution x^ℓ. In particular the number of complex configurations in x^ℓ is $\sum_{c \in Q_c \cap Q^\ell} x^\ell_c \in O((1/\delta)\log^2(1/\delta))$. Since $\bar{f}_c$ depends only on the load of c, concatenating these solutions yields a solution $x' := (x^\ell)_\ell$ that is optimal for [cost-conf-IP], such that $\sum_{c \in Q_c} x'_c \in O((\lambda^2) \cdot (1/\delta)\log^2(1/\delta)) = O((1/\delta^3)\log^2(1/\delta))$. It remains to bound the number of simple configurations in the support. To this end, we consider the ILP restricted to simple configurations as follows:

$$[\text{cost-conf-IP}]_s \quad \min \sum_{c \in Q_s} \bar{f}_c \cdot x_c$$

$$\sum_{c \in Q_s} c \cdot x_c = b - \sum_{c \in Q_c} c \cdot x'_c, \tag{7}$$

$$\sum_{c \in Q_s} x_c = m - \sum_{c \in Q_c} x'_c, \tag{8}$$

$$x_c \in \mathbb{Z}_{\geq 0} \qquad \text{for all } c \in Q_s. \tag{9}$$

We apply the result of Eisenbrand and Shmonin [4] to this ILP. In its more general form, this result ensures the existence of a solution x'' with support of size $O(N(\log(N)+\Delta))$, where N is the number of restrictions and Δ is the encoding size of the largest coefficient appearing in the cost vector and restriction matrix. In our case $N = d + 1 = O((1/\delta)\log(1/\delta))$, and $\Delta = O(\log(\max\{1/\delta, \max_{c \in Q} \bar{f}_c)\}) = O(\log(1/\delta))$ (Lemma 13). Thus $O(N(\log(N) + \Delta)) = O((1/\delta)\log^2(1/\delta))$. The theorem follows by concatenating $(x''_c)_{c \in Q_s}$ with $(x'_c)_{c \in Q_c}$. ◀

Finally, we use the structure given by the theorem to solve this ILP optimally. The idea is similar to Algorithm 9 and thus we defer the details to the full version.

▶ **Theorem 15.** *Consider the scheduling problem on parallel machines with objective functions* (I), (II) *for f convex (respectively* (I') *and* (II') *for f concave). If f satisfies Condition 12 for $1/\delta = O(1/\varepsilon)$ and it is non-decreasing, then the problem admits an EPTAS with running time $2^{O((1/\varepsilon)\log^4(1/\varepsilon))} + O(n \log n)$.*

5 Minimum makespan scheduling on uniform machines

In this section we generalize our result for $P||C_{\max}$ to uniform machines. Consider a set of jobs $\mathcal{J}$ with processing times p_j and a set of m non-identical machines $\mathcal{M}$ where machine $i \in \mathcal{M}$ runs at speed s_i. If job j is executed on machine i the machine needs p_j/s_i time units to complete the job. The problem is to find an assignment $a : \mathcal{J} \to \mathcal{M}$ for the jobs to the machines that minimizes the makespan; $\max_i \sum_{j:a(j)=i} p_j/s_i$. The problem is denoted by $Q||C_{max}$. We suppose that $s_1 \geq s_2 \geq \ldots \geq s_m$. Jansen [10] found an efficient polynomial

time approximation scheme (EPTAS) for this scheduling problem which has a running time of $2^{O(1/\varepsilon^2 \log^3(1/\varepsilon))} + \text{poly}(n)$. Here we show how to improve the running time and prove the main result of this section.

▶ **Theorem 16.** *There is an EPTAS (a family of algorithms $\{A_\varepsilon : \varepsilon > 0\}$) which, given an instance I of $Q||C_{max}$ with n jobs and m machines and a positive number $\varepsilon > 0$, produces a schedule of makespan $A_\varepsilon(I) \leq (1+\varepsilon)\textsc{Opt}(I)$. The running time of A_ε is $2^{O(1/\varepsilon \log^4(1/\varepsilon))} + \text{poly}(n)$.*

Let $0 < \delta < \varepsilon$. We follow the approach by Jansen [10], transforming the scheduling problem into a bin packing problem with different bin capacities, rounding the processing times and bin capacities, and dividing the bins into at most three groups $\mathcal{B}_1, \mathcal{B}_2$ and $\mathcal{B}_3$ depending on the bin capacities.

Here, we focus on a special case which contains the main difficulty of the problem. The full exposition can be found in the full version. In group $\mathcal{B}_2$, the bins can have a capacity of value $\bar{c}(1) > \ldots > \bar{c}(L)$ for some $L \in O(1/\delta \log(1/\delta))$. We call B_ℓ the set of bins in $\mathcal{B}_2$ with capacity $\bar{c}(\ell)$. Our rounded instance contains jobs of sizes $\pi_1, \ldots, \pi_d$ for $d \in O(1/\delta \log(1/\delta))$. For each B_ℓ we consider configurations $\bar{C}_1^{(\ell)}, \ldots, \bar{C}_{\bar{h}_\ell}^{(\ell)}$. The configurations are defined using job of size at least $\delta\bar{c}(\ell)$ which are rounded up to multiples of $\delta^2\bar{c}(\ell)$. Thus, regarding these configurations (and only these configurations), jobs have sizes of the form $q(k,\ell)\delta^2\bar{c}(\ell)$ with $q(k,\ell) \in \mathbb{Z}^+$ and $k \in \{1,\ldots,d\}$. We denote by $a(k, \bar{C}_i^{(\ell)})$ the multiplicity of jobs of size $q(k,\ell)\delta^2\bar{c}(\ell)$ in configuration $\bar{C}_i^{(\ell)}$. The rounding implies also that the rounded size $size(\bar{C}_i^{(\ell)})$ of a configuration is a multiple of $\delta^2\bar{c}(\ell)$. Each such configuration corresponds to an integral point inside the knapsack polytope $\mathcal{P}_\ell = \{C = (a(k,C))_k : \sum_k q(k,\ell)\delta^2\bar{c}(\ell)a(k,C) \leq (1+\delta)\bar{c}(\ell)\}$.

Let $\bar{m}_\ell = |B_\ell|$ be the number of machines of capacity $\bar{c}(\ell)$. Consider a given solution to our scheduling problem. For this case we say that a bin in B_ℓ follows a configuration $\bar{C}_i^{(\ell)}$ if it has $a(k, \bar{C}_i^{(\ell)})$ jobs whose size, rounded to the next multiple of $\delta^2\bar{c}(\ell)$, equals to $q(k,\ell)\delta^2\bar{c}(\ell)$. Let $\bar{x}_i^{(\ell)}$ be the number of bins in B_ℓ that follows configuration $\bar{C}_i^{(\ell)}$. Notice that the configurations do not consider jobs of size smaller than $\delta\bar{c}(\ell)$ that might be assigned to a bin in B_ℓ. Consider the following ILP, which we denote by $[\text{conf-IP}]_Q$:

$$\sum_i x_i^{(\ell)} = \bar{m}_\ell \qquad \text{for } \ell = 1,\ldots,L,$$

$$\sum_{\ell,i} a(k, \bar{C}_i^{(\ell)}) x_i^{(\ell)} = \sum_{\ell,i} a(k, \bar{C}_i^{(\ell)}) \bar{x}_i^{(\ell)} \qquad \text{for } k = 1\ldots,d,$$

$$\sum_i \frac{size(\bar{C}_i^{(\ell)})}{\delta^2\bar{c}(\ell)} x_i^{(\ell)} = \sum_i \frac{size(\bar{C}_i^{(\ell)})}{\delta^2\bar{c}(\ell)} \bar{x}_i^{(\ell)},$$

$$x_i^{(\ell)} \geq 0 \,\text{integral} \qquad \text{for } i = 1,\ldots,\bar{h}_\ell, \ell = 1,\ldots,L.$$

The second equality of the ILP ensures that the solution constructed maintains the same subset of jobs larger than $\delta\bar{c}(\ell)$ to bins in B_ℓ as solution $\bar{x}$. The third equality ensures that we are leaving enough space for jobs not covered by a configuration (i.e., a job that is assigned within B_ℓ but whose size is less than $\delta\bar{c}(\ell)$). As in previous sections, a configuration $\bar{C}_i^{(\ell)}$ is called simple if $|\operatorname{supp}(\bar{C}_i^{(\ell)})| \leq \log(\bar{c}(\ell)(1+\delta)/(\delta^2\bar{c}(\ell)) + 1) = \log(1/\delta^2 + 1/\delta + 1)$ (here we are scaling the capacity of a configuration by $\delta^2\bar{c}(\ell)$, since all rounded job sizes are multiples of $\delta^2\bar{c}(\ell)$). Otherwise, we call a configuration $\bar{C}_i^{(\ell)}$ complex. Crucially, the ILP above satisfies that all coefficients are at most $\text{poly}(1/\delta)$. This allows us to generalize our result in Theorem 1 to our ILP above, with a similar proof technique as Theorem 14, which yields the following lemma. Using this lemma, we can define an algorithm similar to

the algorithm for the case of identical machines, to obtain an improved running time for $Q||C_{max}$ and prove Theorem 16.

▶ **Lemma 17.** *Assume that the ILP [conf-IP]$_Q$ is feasible and let S denote the set of all simple configurations. Then there exists a feasible solution x' such that:* (1) *If $x'^{(\ell)}_i > 1$ then the configuration $\bar{C}^{(\ell)}_i$ is simple,* (2) *the support of x' satisfies $|\operatorname{supp}(x') \cap S| \in O(1/\delta \log^2(1/\delta))$, and* (3) *the support of x' satisfies $|\operatorname{supp}(x') \setminus S| \in O(1/\delta^2 \log^3(1/\delta))$.*

Abstract

We study the Capacitated k-Median problem for which existing constant-factor approximation algorithms are all pseudo-approximations that violate either the capacities or the upper bound k on the number of open facilities. Using the natural LP relaxation for the problem, one can only hope to get the violation factor down to 2. Li [SODA'16] introduced a novel LP to go beyond the limit of 2 and gave a constant-factor approximation algorithm that opens $(1+\epsilon)k$ facilities.

We use the configuration LP of Li [SODA'16] to give a constant-factor approximation for the Capacitated k-Median problem in a seemingly harder configuration: we violate only the capacities by $1+\epsilon$. This result settles the problem as far as pseudo-approximation algorithms are concerned.

1 Introduction

In the capacitated k-median problem (CKM), we are given a set F of facilities together with their capacities $u_i \in \mathbb{Z}_{>0}$ for $i \in F$, a set C of clients, a metric d on $F \cup C$, and a number k. We are asked to open some of these facilities $F' \subseteq F$ and give an assignment $\sigma : C \to F'$ connecting each client to one of the open facilities so that the number of open facilities is not bigger than k, i.e. $|F'| \leq k$ (*cardinality constraint*), and each facility $i \in F'$ is connected to at most u_i clients, i.e. $\left|\sigma^{-1}(i)\right| \leq u_i$ (*capacity constraint*). The goal is to minimize the sum of the connection costs, i.e. $\sum_{j \in C} d(\sigma(j), j)$.

Without the capacity constraint, i.e. $u_i = \infty$ for all $i \in F$, this is the famous k-median problem (KM). The first constant-factor approximation algorithm for KM is given by Charikar et al. [9], guaranteeing a solution within $6\frac{2}{3}$ times the cost of the optimal solution. Then the approximation ratio has been improved by a series of papers [13, 8, 3, 12, 17, 5]. The current best ratio for KM is $2.675 + \epsilon$ due to Byrka et al. [5], which was obtained by improving a part of the algorithm given by Li and Svensson [17].

On the other hand, we don't have a true constant approximation for CKM. All known constant-factor results are pseudo-approximations which violate either the cardinality or the

capacity constraint. Aardal et al. [1] gave an algorithm which finds a $(7+\epsilon)$-approximate solution to CKM by opening at most $2k$ facilities, i.e. violating the cardinality constraint by a factor of 2. Guha [11] gave an algorithm with approximation ratio 16 for the more relaxed *uniform* CKM, where all capacities are the same, by connecting at most $4u$ clients to each facility, thus violating the capacity constraint by 4. Li [14] gave a constant-factor algorithm for uniform CKM with capacity violation of only $2+\epsilon$ by improving the algorithm in [9]. For non-uniform capacities, Chuzhoy and Rabani [10] gave a 40-approximation for CKM by violating the capacities by a factor of 50 using a mixture of primal-dual schema and lagrangian relaxations. Their algorithm is for a slightly relaxed version of the problem called *soft* CKM where one is allowed to open multiple collocated copies of a facility in F. The CKM definition we gave above is sometimes referred to as *hard* CKM as opposed to this version. Recently, Byrka et al. [4] gave a constant-factor algorithm for hard CKM by keeping capacity violation factor under $3+\epsilon$.

All these algorithms for CKM use the basic LP relaxation for the problem which is known to have an unbounded integrality gap even when we are allowed to violate either the capacity or the cardinality constraint by $2-\epsilon$. In this sense, results of [1] and [14] can be considered as reaching the limits of the basic LP relaxation in terms of restricting the violation factor. In order to go beyond these limits, Li [15] introduced a novel LP called the *rectangle* LP and presented a constant-factor approximation algorithm for soft uniform CKM by opening $(1+\epsilon)k$ facilities. This was later generalized by the same author to non-uniform CKM [16], where he introduced an even stronger LP relaxation called the *configuration* LP. Very recently, independently of the work in this paper, Byrka et al. [6] used this configuration LP to give a similar algorithm for uniform CKM violating the capacities by $1+\epsilon$.

1.1 Our Result

In this paper, we use the configuration LP of [16] to give an $O(1/\epsilon^5)$-approximation algorithm for non-uniform hard CKM which respects the cardinality constraint and connects at most $(1+\epsilon)u_i$ clients to any open facility $i \in F$. The running time of our algorithm is $n^{O(1/\epsilon)}$. Thus, with this result, we now have settled the CKM problem from the view of pseudo-approximation algorithms: either $(1+\epsilon)$-cardinality violation or $(1+\epsilon)$-capacity violation is sufficient for a constant approximation for CKM.

The known results for the CKM problem have suggested that designing algorithms with capacity violation (satisfying the cardinality constraint) is harder than designing algorithms with cardinality violation. Note, for example, that the best known cardinality violation factor for non-uniform CKM among algorithms using only the basic LP relaxation (a factor of 2 in [1]) matches the smallest possible cardinality violation factor dictated by the gap instance. In contrast, the best capacity-violation factor is $3+\epsilon$ due to [4], but the gap instance for the basic LP with the largest known gap eliminates only the algorithms with capacity violation smaller than 2. Furthermore, we can argue that, for algorithms based on the basic LP and the configuration LP, a β-capacity violation can be converted to a β-cardinality violation, suggesting that allowing capacity violation is more restrictive than allowing cardinality violation. We leave the detail to the full version of the paper.

Our Techniques. Our algorithm uses the configuration LP introduced in [16] and the framework of [16] that creates a two-level clustering of facilities. [16] considered the $(1+\epsilon)$-cardinality violation setting, which is more flexible in the sense that one has the much freedom to distribute the ϵk extra facilities. In our $(1+\epsilon)$-capacity violation setting, each facility i can provide an extra ϵu_i capacity; however, these extra capacities are restricted by the

locations of the facilities. In particular, we need one more level of clustering to form so-called "groups" so that each group contains $\Omega(1/\epsilon)$ fractional open facility. Only with groups of $\Omega(1/\epsilon)$ facilities, we can benefit from the extra capacities given by the $(1+\epsilon)$-capacity scaling. Our algorithm then constructs distributions of local solutions. Using a dependent rounding procedure we can select a local solution from each distribution such that the solution formed by the concatenation of local solutions has a small cost. This initial solution may contain more than k facilities. We then remove some already-open facilities, and bound the cost incurred due to the removal of open facilities. When we remove a facility, we are guaranteed that there is a close group containing $\Omega(1/\epsilon)$ open facilities and the extra capacities provided by these facilities can compensate for the capacity of the removed facility.

Organization. The remaining part of the paper is organized as follows. In Sections 2 and 3, we describe the configuration LP introduced in [16] and our three-level clustering procedure respectively. In Section 4, we show how to construct the distributions of local solutions. Then finally in Section 5, we show how to obtain our final solution by combining the distributions we constructed. Due to the page limit, some proofs are omitted and they can be found in the full version of the paper.

2 The Basic LP and the Configuration LP

In this section, we give the configuration LP of [16] for CKM. We start with the following basic LP relaxation:

$$\min \quad \sum_{i\in F, j\in C} d(i,j)x_{i,j} \quad \text{s.t.} \qquad \text{(Basic LP)}$$

$$\sum_{i\in F} y_i \le k; \qquad (1)$$

$$\sum_{i\in F} x_{i,j} = 1, \qquad \forall j \in C; \qquad (2)$$

$$x_{i,j} \le y_i, \qquad \forall i \in F, j \in C; \qquad (3)$$

$$\sum_{j\in C} x_{i,j} \le u_i y_i, \qquad \forall i \in F; \qquad (4)$$

$$0 \le x_{i,j}, y_i \le 1, \qquad \forall i \in F, j \in C. \qquad (5)$$

In the LP, y_i indicates whether a facility $i \in F$ is open, and $x_{i,j}$ indicates whether client $j \in C$ is connected to facility $i \in F$. Constraint (1) is the cardinality constraint assuring that the number of open facilities is no more than k. Constraint (2) says that every client must be fully connected to facilities. Constraint (3) requires a facility to be open in order to connect clients. Constraint (4) is the capacity constraint.

It is well known that the basic LP has unbounded integrality gap, even if we are allowed to violate the cardinality constraint or the capacity constraint by a factor of $2-\epsilon$. The description of the instance can be found in the full version of the paper. In order to overcome the gap in the cardinality-violation setting, Li [16] introduced a novel LP for CKM called the configuration LP, which we formally state below. Let us fix a set $B \subseteq F$ of facilities. Let $\ell = \Theta(1/\epsilon)$ and $\ell_1 = \Theta(\ell)$ be sufficiently large integers. Let $\mathcal{S} = \{S \subseteq B : |S| \le \ell_1\}$ and $\widetilde{\mathcal{S}} = \mathcal{S} \cup \{\perp\}$, where $\perp$ stands for "any subset of B with size more than ℓ_1"; for convenience, we also treat $\perp$ as a set such that $i \in \perp$ holds for every $i \in B$. For $S \in \mathcal{S}$, let z_S^B indicate the event that the set of open facilities in B is exactly S and $z_\perp^B$ indicate the event that the number of open facilities in B is more than ℓ_1.

For every $S \in \widetilde{\mathcal{S}}$ and $i \in S$, $z_{S,i}^B$ indicates the event that $z_S^B = 1$ and i is open. (If $i \in B$ but $i \notin S$, then the event will not happen.) Notice that when $i \in S \ne \perp$, we always have

$z^B_{S,i} = z^B_S$; we keep both variables for notational purposes. For every $S \in \widetilde{\mathcal{S}}, i \in S$ and client $j \in C$, $z^B_{S,i,j}$ indicates the event that $z^B_{S,i} = 1$ and j is connected to i. In an integral solution, all the above variables are $\{0,1\}$ variables. The following constraints are valid. To help understand the constraints, it is good to think of $z^B_{S,i}$ as $z^B_S \cdot y_i$ and $z^B_{S,i,j}$ as $z^B_S \cdot x_{i,j}$.

$$\sum_{S \in \widetilde{\mathcal{S}}} z^B_S = 1; \tag{6}$$

$$\sum_{S \in \widetilde{\mathcal{S}}: i \in S} z^B_{S,i} = y_i, \qquad \forall i \in B; \tag{7}$$

$$\sum_{S \in \widetilde{\mathcal{S}}: i \in S} z^B_{S,i,j} = x_{i,j}, \qquad \forall i \in B, j \in C; \tag{8}$$

$$0 \le z^B_{S,i,j} \le z^B_{S,i} \le z^B_S, \qquad \forall S \in \widetilde{\mathcal{S}}, i \in S, j \in C; \tag{9}$$

$$z^B_{S,i} = z^B_S, \qquad \forall S \in \mathcal{S}, i \in S; \tag{10}$$

$$\sum_{i \in S} z^B_{S,i,j} \le z^B_S, \qquad \forall S \in \widetilde{\mathcal{S}}, j \in C; \tag{11}$$

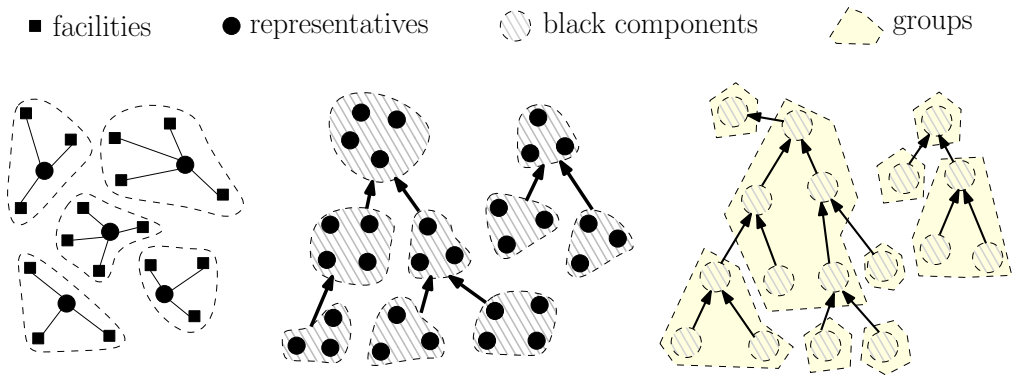
$$\sum_{j \in C} z^B_{S,i,j} \le u_i z^B_{S,i}, \qquad \forall S \in \widetilde{\mathcal{S}}, i \in S; \tag{12}$$

$$\sum_{i \in B} z^B_{\perp,i} \ge \ell_1 z^B_{\perp}. \tag{13}$$

Constraint (6) says that $z^B_S = 1$ for exactly one $S \in \widetilde{\mathcal{S}}$. Constraint (7) says that if i is open then there is exactly one $S \in \widetilde{\mathcal{S}}$ with $z^B_{S,i} = 1$. Constraint (8) says that if j is connected to i then there is exactly one $S \in \widetilde{\mathcal{S}}$ such that $z^B_{S,i,j} = 1$. Constraint (9) is by the definition of variables. Constraint (10) holds as we mentioned earlier. Constraint (11) says that if $z^B_S = 1$ then j can be connected to at most 1 facility in S. Constraint (12) is the capacity constraint. Constraint (13) says that if $z^B_\perp = 1$, there are at least ℓ_1 open facilities in B.

The configuration LP is obtained from the basic LP by adding the z variables and Constraints (6) to (13) for every $B \subseteq F$. Since there are exponentially many subsets $B \subseteq F$, we don't know how to solve this LP efficiently. However, note that there are only polynomially many ($n^{O(\ell_1)}$) z^B variables for a fixed $B \subseteq F$. Given a fractional solution (x, y) to the basic LP relaxation, we can construct the values of z^B variables and check their feasibility for Constraints (6) to (13) in polynomial time as in [16]. Our rounding algorithm either constructs an integral solution with the desired properties, or outputs a set $B \subseteq F$ such that Constraints (6) to (13) are infeasible. In the latter case, we can find a constraint in the configuration LP that (x, y) does not satisfy. Then we can run the ellipsoid method and the rounding algorithm in an iterative way (see, e.g., [7, 2]).

Notations. From now on, we fix a solution $(\{x_{i,j} : i \in F, j \in C\}, \{y_i : i \in F\})$ to the basic LP. We define $d_{\mathsf{av}}(j) := \sum_{i \in F} x_{i,j} d(i,j)$ to be the connection cost of j, for every $j \in C$. Let $D_i := \sum_{j \in C} x_{i,j} (d(i,j) + d_{\mathsf{av}}(j))$ for every $i \in F$, and $D_S := \sum_{i \in S} D_i$ for every $S \subseteq F$. We denote the value of the solution (x, y) by $\mathsf{LP} := \sum_{i \in F, j \in C} x_{i,j} d(i,j) = \sum_{j \in C} d_{\mathsf{av}}(j)$. Note that $D_F = \sum_{i \in F, j \in C} x_{i,j} (d(i,j) + d_{\mathsf{av}}(j)) = \sum_{i \in F, j \in C} x_{i,j} d(i,j) + \sum_{j \in C} d_{\mathsf{av}}(j) \sum_{i \in F} x_{i,j} = 2\mathsf{LP}$. For any set $F' \subseteq F$ of facilities and $C' \subseteq C$ of clients, we shall let $x_{F',C'} := \sum_{i \in F', j \in C'} x_{i,j}$; we simply use $x_{i,C'}$ for $x_{\{i\},C'}$ and $x_{F',j}$ for $x_{F',\{j\}}$. For any $F' \subseteq F$, let $y_{F'} := \sum_{i \in F'} y_i$. Let $d(A,B) := \min_{i \in A, j \in B} d(i,j)$ denote the minimum distance between A and B, for any $A, B \subseteq F \cup C$; we simply use $d(i,B)$ for $d(\{i\}, B)$.



(a). bundles $\{U_v\}_{v\in R}$ (b). black components $\mathcal{J}$ and forest $\Upsilon^*_{\mathcal{J}}$ (c). groups $\mathcal{G}$ and forest $\Upsilon_{\mathcal{G}}$

Figure 1 The three-phase clustering procedure. In the first phase (Figure (a)), we partition F into bundles, centered at the set R of representatives. In the second phase (Figure (b)), we partition R into a family $\mathcal{J}$ of black components and construct a degree-2 rooted forest over $\mathcal{J}$. In the third phase (Figure(c)), we partition $\mathcal{J}$ into a family $\mathcal{G}$ of groups; $\Upsilon_{\mathcal{G}}$ is formed from $\Upsilon^*_{\mathcal{J}}$ by contracting each group into a single node.

Moving of Demands. After the set of open facilities is decided, the optimum connection assignment from clients to facilities can be computed by solving the minimum cost b-matching problem. Due to the integrality of the matching polytope, we may allow the connections to be fractional. That is, if there is a good fractional assignment, then there is a good integral assignment. So we can use the following framework to design and analyze the rounding algorithm. Initially there is one unit of demand at each client $j \in C$. During the course of our algorithm, we move demands fractionally within $F \cup C$; moving α units of demand from i to j incurs a cost of $\alpha d(i,j)$. At the end, all the demands are moved to F and each facility $i \in F$ has at most $(1+O(\frac{1}{\ell}))u_i$ units of demand. We open a facility if it has positive amount of demand. Our goal is to bound the total moving cost by $O(\ell^5)\mathsf{LP}$ and the number of open facilities by k.

3 Representatives, Black Components, and Groups

Our algorithm starts with bundling facilities together with a three-phase process each of which creates bigger and bigger clusters. At the end, we have a nicely formed network of sufficiently big clusters of facilities. See Figure 1 for illustration of the three-phase clustering.

3.1 Representatives, Bundles and Initial Moving of Demands

In the first phase, we use a standard approach to facility location problems ([18, 19, 9, 16]) to partition the facilities into *bundles* $\{U_v\}_{v\in R}$, where each bundle U_v is associated with a center $v \in C$ that is called a *representative* and $R \subseteq C$ is the set of representatives. Each bundle U_v has a total opening at least $1/2$.

Let $R = \emptyset$ initially. Repeat the following process until C becomes empty: we select the client $v \in C$ with the smallest $d_{\mathsf{av}}(v)$ and add it to R; then we remove all clients j such that $d(j,v) \le 4d_{\mathsf{av}}(j)$ from C (thus, v itself is removed). We use v and its variants to index representatives, and j and its variants to index general clients. The family $\{U_v : v \in R\}$ is the Voronoi diagram of F with R being the centers: let $U_v = \emptyset$ for every $v \in R$ initially; for

each location $i \in F$, we add i to U_v for $v \in R$ that is closest to i. For any subset $V \subseteq R$, we use $U(V) := \bigcup_{v \in V} U_v$ to denote the union of Voronoi regions with centers V.

▶ **Lemma 1.** *The following statements hold:*

- **(1a)** *for all $v, v' \in R, v \neq v'$, we have $d(v, v') > 4\max\{d_{\mathsf{av}}(v), d_{\mathsf{av}}(v')\}$*
- **(1b)** *for all $j \in C$, there exists $v \in R$, such that $d_{\mathsf{av}}(v) \leq d_{\mathsf{av}}(j)$ and $d(v, j) \leq 4d_{\mathsf{av}}(j)$;*
- **(1c)** *$y_{U_v} \geq 1/2$ for every $v \in R$;*
- **(1d)** *for any $v \in R$, $i \in U_v$, and $j \in C$, we have $d(i, v) \leq d(i, j) + 4d_{\mathsf{av}}(j)$.*

The next lemma shows that moving demands from facilities to their corresponding representative doesn't cost much.

▶ **Lemma 2.** *For every $v \in R$, we have $\sum_{i \in U_v} x_{i,C} d(i, v) \leq O(1) D_{U_v}$.*

Since $\{U_v : v \in R\}$ forms a partition of F, we get the following corollary.

▶ **Corollary 3.** $\sum_{v \in R, i \in U_v} x_{i,C} d(i, v) \leq O(1)\mathsf{LP}$.

Initial Moving of Demands. With this corollary, we now move all the demands from C to V. First for every $j \in C$ and $i \in F$, we move $x_{i,j}$ units of demand from j to i. The moving cost of this step is exactly LP. After the step, all demands are at F and every $i \in F$ has $x_{i,C}$ units of demand. Then, for every $v \in R$ and $i \in U_v$, we move the $x_{i,C}$ units of demand at i to v. The moving cost for this step is $O(1)\mathsf{LP}$. Thus, after the initial moving, all demands are at the set R of representatives: a representative v has $x_{U_v,C}$ units of demand.

3.2 Black Components

In the second phase, we employ the minimum-spanning-tree construction of [16] to partition the set R of representatives into a family $\mathcal{J}$ of so-called *black components*. There is a degree-2 rooted forest $\Upsilon^*_{\mathcal{J}}$ over $\mathcal{J}$ with many good properties. For example, each non-root black component is not far away from its parent, and each root black component of $\Upsilon^*_{\mathcal{J}}$ contains a total opening of $\Omega(\ell)$. (For simplicity, we say the total opening at a representative $v \in R$ is y_{U_v}, which is the total opening at the bundle U_v.) The forest in [16] can have a large degree, while our algorithm requires the forest to have degree 2. This property is guaranteed by using the left-child-right-sibling representation.

Due to the page limit, we leave the description of the framework of [16] to the full version of the paper, and give its summary in the following lemma:

▶ **Lemma 4.** *There is an efficient algorithm to partition R into a set $\mathcal{J}$ of* black components *(or components, for simplicity) and construct a rooted forest $\Upsilon^*_{\mathcal{J}}$ over $\mathcal{J}$, such that if we let $L(J) = d(J, R \setminus J)$ for every black component $J \in \mathcal{J}$, then the following properties hold:*

- **(4a)** *for every $J \in \mathcal{J}$, there is a spanning tree over the representatives in J such that for every edge (v, v') in the spanning tree we have $d(v, v') \leq L(J)$;*
- **(4b)** *every root component $J \in \mathcal{J}$ of $\Upsilon^*_{\mathcal{J}}$ has $y_{U(J)} \geq \ell$ and every non-root component $J \in \mathcal{J}$ has $y_{U(J)} < \ell$;*
- **(4c)** *every root component $J \in \mathcal{J}$ of $\Upsilon^*_{\mathcal{J}}$ has either $y_{U(J)} < 2\ell$ or $|J| = 1$;*
- **(4d)** *for any non-root component J and its parent J', we have $L(J) \geq L(J')$;*
- **(4e)** *for any non-root component J and its parent J', we have $d(J, J') \leq O(\ell)L(J)$;*
- **(4f)** *every component J has at most two children.*

3.3 Groups

In the third phase, we apply a simple greedy algorithm to the forest $\Upsilon^*_{\mathcal{J}}$ to partition the set $\mathcal{J}$ of black components into a family $\mathcal{G}$ of *groups*, where each group $G \in \mathcal{G}$ contains many black components that are connected in $\Upsilon^*_{\mathcal{J}}$. By contracting each group $G \in \mathcal{G}$, the forest $\Upsilon^*_{\mathcal{J}}$ over the set $\mathcal{J}$ of black components becomes a forest $\Upsilon_{\mathcal{G}}$ over the set $\mathcal{G}$ of groups. Each group has a total opening of $\Omega(\ell)$, unless it is a leaf-group in $\Upsilon_{\mathcal{G}}$.

We partition the set $\mathcal{J}$ into groups using a technique similar to [4, 6]. For each rooted tree $T = (\mathcal{J}_T, E_T)$ in $\Upsilon^*_{\mathcal{J}}$, we construct a group G of black components as follows. Initially, let G contain the root component of T. While $\sum_{J \in G} y_{U(J)} < \ell$ and $G \neq \mathcal{J}_T$, repeat the following procedure. Choose the component $J \in \mathcal{J}_T \setminus G$ that is adjacent to G in T, with the smallest L-value, and add J to G.

Thus, by the construction G is connected in T. After we have constructed the group G, we add G to $\mathcal{G}$. We remove all black components in G from T. Then, each T is broken into many rooted trees; we apply the above procedure recursively for each rooted tree.

So, we have constructed a partition $\mathcal{G}$ for the set $\mathcal{J}$ of components. If for every $G \in \mathcal{G}$, we contract all components in G into a single node, then the rooted forest $\Upsilon^*_{\mathcal{J}}$ over $\mathcal{J}$ becomes a rooted forest $\Upsilon_{\mathcal{G}}$ over the set $\mathcal{G}$ of groups. $\Upsilon_{\mathcal{G}}$ naturally defines a parent-child relationship over $\mathcal{G}$. The following lemma uses Properties **(4a)** to **(4f)** of $\mathcal{J}$ and the way we construct $\mathcal{G}$.

▶ **Lemma 5.** *The following statements hold for the set $\mathcal{G}$ of groups and the rooted forest $\Upsilon_{\mathcal{G}}$ over $\mathcal{G}$:*

- **(5a)** *any root group $G \in \mathcal{G}$ contains a single root component $J \in \mathcal{J}$;*
- **(5b)** *if $G \in \mathcal{G}$ is not a root group, then $\sum_{J \in G} y_{U(J)} < 2\ell$;*
- **(5c)** *if $G \in \mathcal{G}$ is a non-leaf group, then $\sum_{J \in G} y_{U(J)} \geq \ell$;*
- **(5d)** *let $G \in \mathcal{G}, G' \in \mathcal{G}$ be the parent of G, $J \in G$ and $v \in J$, then the distance between v and any representative in $\bigcup_{J' \in G'} J'$ is at most $O(\ell^2)L(J)$;*
- **(5e)** *any group G has at most $O(\ell)$ children.*

4 Constructing Local Solutions

In this section, we shall construct a local solution, or a distribution of local solutions, for a given set $V \subseteq R$ which is the union of some black components. A local solution for V contains a pair $(S \subseteq U(V), \beta \in \mathbb{R}_{\geq 0}^{U(V)})$, where S is the facilities we open in $U(V)$ and β_i for each $i \in U(V)$ is the amount of supply at i: the demand that can be satisfied by i. Thus $\beta_i = 0$ if $i \in U(V) \setminus S$. We shall use the supplies at $U(V)$ to satisfy the $x_{U(V),C}$ demands at V after the initial moving of demands; thus, we require $\sum_{i \in U(V)} \beta_i = x_{U(V),C}$. There are two other main properties we need the distribution to satisfy: (a) the expected size of S from the distribution is not too big, and (b) the cost of matching the demands at V and the supplies at $U(V)$ is small.

We distinguish between *concentrated* black components and *non-concentrated* black components. Roughly speaking, a component $J \in \mathcal{J}$ is concentrated if in the fractional solution (x, y), for most clients $j \in C$, j is either almost fully served by facilities in $U(J)$, or almost fully served by facilities in $F \setminus U(J)$. We shall construct a distribution of local solutions for each concentrated component J. We require Constraints (6) to (13) to be satisfied for $B = U(J)$ (if not, we return the set $U(J)$ to the separation oracle) and let z^B be the vector satisfying the constraints. Roughly speaking, the z^B-vector defines a distribution of local solutions for V. A local solution (S, β) is good if S is not too big and the total demand $\sum_{i \in S} \beta_i$ satisfied by S is not too small. Then, our algorithm randomly selects (S, β)

from the distribution defined by z^B, under the condition that (S, β) is good. The fact that J is concentrated guarantees that the total mass of good local solutions in the distribution is large; therefore the factors we lose due to the conditioning are small.

For non-concentrated components, we construct a single local solution (S, β), instead of a distribution of local solutions. Moreover, the construction is for the union V of some non-concentrated components, instead of an individual component. The components that comprise V are close to each other; by the fact that they are non-concentrated, we can move demands arbitrarily within V, without incurring too much cost. Thus we can essentially treat the distances between representatives in V as 0. Then we are only concerned with two parameters for each facility $i \in U(V)$: the distance from i to V and the capacity u_i. Using a simple argument, the optimum fractional local solution (that minimizes the cost of matching the demands and supplies) is almost integral: it contains at most 2 fractionally open facilities. By fully opening the two fractional facilities, we find an integral local solution with small number of open facilities.

The remaining part of this section is organized as follows. We first formally define concentrated black components, and explain the importance of the definition. We then define the earth-mover-distance, which will be used to measure the cost of satisfying demands using supplies. The construction of local solutions for concentrated components and non-concentrated components will be stated in Theorem 9 and Lemma 10 respectively. Due to the page limit, their proofs will only appear in the full version of the paper.

Concentrated Black Components. The definition of concentrated black component is the same as that of [16], except that we choose the parameter ℓ_2 differently.

▶ **Definition 6.** Define $\pi_J = \sum_{j \in C} x_{U(J),j}(1 - x_{U(J),j})$, for every black component $J \in \mathcal{J}$. A black component $J \in \mathcal{J}$ is said to be *concentrated* if $\pi_J \le x_{U(J),C}/\ell_2$, and *non-concentrated* otherwise, where $\ell_2 = \Theta(\ell^3)$ is large enough.

We use $\mathcal{J}^{\mathsf{C}}$ to denote the set of concentrated components and $\mathcal{J}^{\mathsf{N}}$ to denote the set of non-concentrated components. The next lemma from [16] shows the importance of π_J.

▶ **Lemma 7.** *For any $J \in \mathcal{J}$, we have $L(J)\pi_J \le O(1)D_{U(J)}$.*

Recall that $L(J) = d(J, R \setminus J)$ and $x_{U(J),C}$ is the total demand in J after the initial moving. Thus, according to Lemma 7, if J is not concentrated, we can use $D_{U(J)}$ to charge the cost for moving all the $x_{U(J),C}$ units of demand out of J, provided that the moving distance is not too big compared to $L(J)$. This gives us freedom for handling non-concentrated components. If J is concentrated, the amount of demand that is moved out of J must be comparable to π_J; this will be guaranteed by the configuration LP.

Earth Mover Distance. In order to measure the moving cost of satisfying demands using supplies, we define the earth mover distance:

▶ **Definition 8** (Earth Mover Distance)**.** Given a set $V \subseteq R$ with $B = U(V)$, a demand vector $\alpha \in \mathbb{R}^V_{\ge 0}$ and a supply vector $\beta \in \mathbb{R}^B_{\ge 0}$ such that $\sum_{v \in V} \alpha_v \le \sum_{i \in B} \beta_i$, the earth mover distance from α to β is defined as $\mathrm{EMD}_V(\alpha, \beta) := \inf_f \sum_{v \in V, i \in B} f(v,i)d(v,i)$, where f is over all functions from $V \times B$ to $\mathbb{R}_{\ge 0}$ such that

- $\sum_{i \in B} f(v,i) = \alpha_v$ for every $v \in V$;
- $\sum_{v \in V} f(v,i) \le \beta_i$ for every $i \in B$.

For some technical reason, we allow some fraction of a supply to be unmatched. From now on, we shall use $\alpha_v = x_{U_v,C}$ to denote the amount of demand at v after the initial moving. For any set $V \subseteq R$ of representatives, we use $\alpha|_V$ to denote the vector α restricted to the coordinates in V.

We now summarize our constructions of local solutions for concentrated and non-concentrated black components, respectively.

▶ **Theorem 9.** *Let $J \in \mathcal{J}^{\mathsf{C}}$ and let $B = U(J)$. Assume Constraints (6) to (13) are satisfied for B. Then, we can find a distribution $(\phi_{S,\beta})_{S\subseteq B,\beta\in\mathbb{R}^B_{\geq 0}}$ of pairs (S,β), such that*

(9a) *$s_\phi := \mathbb{E}_{(S,\beta)\sim\phi}|S| \in [y_B, y_B(1+2\ell\pi_J/x_{B,C})]$, and $s_\phi = y_B$ if $y_B > 2\ell$,*

and for every (S,β) in the support of ϕ, we have

(9b) *$|S| \in \{\lfloor s_\phi \rfloor, \lceil s_\phi \rceil\}$;*
(9c) *$\beta_i \leq (1+O(1/\ell))u_i$ if $i \in S$ and $\beta_i = 0$ if $i \in B \setminus S$;*
(9d) *$\sum_{i\in S}\beta_i = x_{B,C} = \sum_{v\in J}\alpha_v$.*

Moreover, the distribution ϕ satisfies

(9e) *the support of ϕ has size at most $n^{O(\ell)}$;*
(9f) *$\mathbb{E}_{(S,\beta)\sim\phi}\mathrm{EMD}_J(\alpha|_J,\beta) \leq O(\ell^4)D_B$.*

▶ **Lemma 10.** *Let $\mathcal{J}' \subseteq \mathcal{J}^{\mathsf{N}}$ be a set of non-concentrated black components, $V = \bigcup_{J\in\mathcal{J}'} J$ and $B = U(V)$. Assume there exists $v^* \in R$ such that $d(v,v^*) \leq O(\ell^2)L(J)$ for every $J \in \mathcal{J}'$ and $v \in J$. Then, we can find a pair $(S \subseteq B, \beta \subseteq \mathbb{R}^B_{\geq 0})$ such that*

(10a) *$|S| \in \{\lceil y_B \rceil, \lceil y_B \rceil + 1\}$;*
(10b) *$\beta_i \leq u_i$ if $i \in S$ and $\beta_i = 0$ if $i \in B \setminus S$;*
(10c) *$\sum_{i\in S}\beta_i = x_{B,C} = \sum_{v\in V}\alpha_v$;*
(10d) *$\mathrm{EMD}_V(\alpha|_V,\beta) \leq O(\ell^2\ell_2)D_B$.*

5 Rounding Algorithm

In this section we describe our rounding algorithm. We start by giving the intuition behind the algorithm. For each concentrated component $J \in \mathcal{J}$, we construct a distribution of local solutions using Theorem 9. We shall construct a partition $\mathcal{V}^{\mathsf{N}}$ of the representatives in $\bigcup_{J\in\mathcal{J}^{\mathsf{N}}} J$ so that each $V \in \mathcal{V}^{\mathsf{N}}$ is the union of some nearby components in $\mathcal{J}^{\mathsf{N}}$. For each set $V \in \mathcal{V}^{\mathsf{N}}$, we apply Lemma 10 to construct a local solution. If we independently and randomly choose a local solution from every distribution we constructed, then we can move all the demands to the open facilities at a small cost, by Property **(9f)** and Property **(10d)**.

However, we may open more than k facilities, even in expectation. Noticing that the fractional solution opens y_B facilities in a set B, the extra number of facilities come from two places. In Property **(9a)** of Theorem 9, we may open in expectation $y_B \cdot 2\ell\pi_J/x_{B,C}$ more facilities in B than y_B. Then in Property **(10a)** of Lemma 10, we may open $\lceil y_B \rceil$ or $\lceil y_B \rceil + 1$ facilities in B. To reduce the number of open facilities to k, we shall shut down (or remove) some already-open facilities and move the demands satisfied by these facilities to the survived open facilities: a concentrated component $J \in \mathcal{J}^{\mathsf{C}}$ is responsible for removing $y_B \cdot 2\ell\pi_J/x_{B,C} < 1$ facilities in expectation; a set $V \in \mathcal{V}^{\mathsf{N}}$ is responsible for removing up to 2 facilities. Lemma 7 allows us to bound the cost of moving demands caused by the removal, provided that the moving distance is not too big. To respect the capacity constraint up to a factor of $1+\epsilon$, we are only allowed to scale the supplies of the survived open facilities by a factor of $1+O(1/\ell)$. Both requirements will be satisfied by the forest structure over groups and the fact that each non-leaf group contains $\Omega(\ell)$ fractional opening (Property **(5c)**). Due

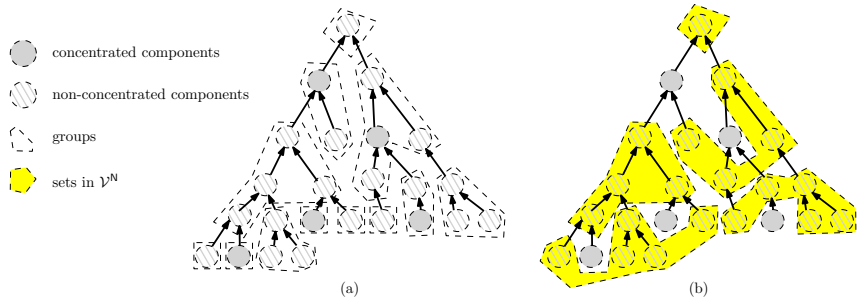


Figure 2 Figure (a) gives the forest $\Upsilon^*_{\mathcal{J}}$ over $\mathcal{J}$ and the set $\mathcal{G}$ of groups (denoted by empty polygons). Figure (b) gives $\mathcal{V}^{\mathsf{N}}$: each set $V \in \mathcal{V}^{\mathsf{N}}$ is the union of components in a solid polygon.

to the forest structure and Property **(5c)**, we always have enough open facilities locally that can support the removing of facilities.

In order to guarantee that we always open k facilities, we need to use a dependent rounding procedure for opening and removing facilities. As in many of previous algorithms, we incorporate the randomized rounding procedure into random selections of vertex points of polytopes respecting marginal probabilities. In many cases, a randomized selection procedure can be derandomized since there is an explicit linear objective we shall optimize.

We now formally describe our rounding algorithm. For every group $G \in \mathcal{G}$, we use Λ_G to denote the set of child-groups of G. We construct a partition $\mathbb{J}^{\mathsf{C}}$ of $\mathcal{J}^{\mathsf{C}}$ as follows. For each root group $G \in \mathcal{G}$, we add $G \cap \mathcal{J}^{\mathsf{C}}$ to $\mathbb{J}^{\mathsf{C}}$ if it is not empty. For each non-leaf group $G \in \mathcal{G}$, we add $\bigcup_{G' \in \Lambda_G}(G' \cap \mathcal{J}^{\mathsf{C}})$ to $\mathbb{J}^{\mathsf{C}}$, if it is not empty. We construct the partition $\mathbb{J}^{\mathsf{N}}$ for $\mathcal{J}^{\mathsf{N}}$ in the same way, except that we consider components in $\mathcal{J}^{\mathsf{N}}$. We also define a set $\mathcal{V}^{\mathsf{N}}$ as follows: for every $\mathcal{J}' \in \mathbb{J}^{\mathsf{N}}$, we add $\bigcup_{J \in \mathcal{J}'} J$ to $\mathcal{V}^{\mathsf{N}}$; thus, $\mathcal{V}^{\mathsf{N}}$ forms a partition for $\bigcup_{J \in \mathcal{J}^{\mathsf{N}}} J$. See Figure 2 for the definition of $\mathcal{V}^{\mathsf{N}}$.

In Section 5.1, we describe the procedure for opening a set S^* of facilities, whose cardinality may be larger than k. Then in Section 5.2, we define the procedure remove, which removes one open facility. We wrap up the algorithm in Section 5.3.

5.1 Constructing Initial Set S^* of Open Facilities

In this section, we open a set S^* of facilities, whose cardinality may be larger than k, and construct a supply vector $\beta^* \in \mathbb{R}^F_{\geq 0}$ such that $\beta^*_i = 0$ if $i \notin S^*$. (S^*, β^*) will be the concatenation of all local solutions we constructed.

It is easy to construct local solutions for non-concentrated components. For each set $\mathcal{J}' \in \mathbb{J}^{\mathsf{N}}$ of components and its correspondent $V = \bigcup_{J \in \mathcal{J}'} J \in \mathbb{J}^{\mathsf{N}}$, we apply Lemma 10 to obtain a local solution $\left(S \subseteq U(V), \beta \in \mathbb{R}^{U(V)}_{\geq 0}\right)$. Then, we add S to S^* and let $\beta^*_i = \beta_i$ for every $i \in U(V)$. Notice that $\mathcal{J}'$ either contains a single root black component J, or contains all the non-concentrated black components in the child-groups of some group G. In the former case, the diameter of J is at most $O(\ell)L(J)$ by Property **(4a)**; in the latter case, we let v^* be an arbitrary representative in $\bigcup_{J' \in G} J'$ and then any representative $v \in J, J \in \mathcal{J}'$ has $d(v, v^*) \leq O(\ell^2)L(J)$ by Property **(5d)**. Thus, all the properties in Lemma 10 are satisfied.

For concentrated components, we only obtain distributions of local solutions by applying Theorem 9. For every $J \in \mathcal{J}^{\mathsf{C}}$, we check if Constraints (6) to (13) are satisfied for $B = U(J)$. If not, we return a separation plane for the fractional solution; otherwise we apply Theorem 9 to each component J to obtain a distribution $\left(\phi^J_{S,\beta}\right)_{S \subseteq U(J), \beta \in \mathbb{R}^{U(J)}_{\geq 0}}$. To produce local solutions for concentrated components, we shall use a dependent rounding procedure that respects the

marginal probabilities. As mentioned earlier, we shall define a polytope and the procedure randomly selects a vertex point of the polytope.

We let $s_J := s_{\phi_J} := \mathbb{E}_{(S,\beta)\sim\phi^J}|S|$ be the expectation of $|S|$ according to distribution ϕ^J. For notational convenience, we shall use $a \approx b$ to denote $a \in \left[\lfloor b \rfloor, \lceil b \rceil\right]$. Consider the following polytope $\mathcal{P}$ defined by variables $\{\psi^J_{S,\beta}\}_{J\in\mathcal{J}^{\mathsf{C}},S,\beta}$ and $\{q_J\}_{J\in\mathcal{J}^{\mathsf{C}}}$.[1]

$$\psi^J_{S,\beta}, p_J \in [0,1] \qquad \forall J \in \mathcal{J}^{\mathsf{C}}, S, \beta; \tag{14}$$

$$\sum_{S,\beta} \psi^J_{S,\beta} = 1, \qquad \forall J \in \mathcal{J}^{\mathsf{C}}; \tag{15}$$

$$\sum_{J\in\mathcal{J}'} q_J \le 1, \qquad \forall \mathcal{J}' \in \mathbb{J}^{\mathsf{C}}; \tag{16}$$

$$\sum_{S,\beta} \psi^J_{S,\beta}|S| - q_J \approx y_{U(J)}, \qquad \forall J \in \mathcal{J}^{\mathsf{C}}; \tag{17}$$

$$\sum_{J\in\mathcal{J}'} \left(\sum_{S,\beta} \psi^J_{S,\beta}|S| - q_J\right) \approx \sum_{J\in\mathcal{J}'} y_{U(J)}, \quad \forall \mathcal{J}' \in \mathbb{J}^{\mathsf{C}}; \tag{18}$$

$$\sum_{J\in\mathcal{J}^{\mathsf{C}}} \left(\sum_{S,\beta} \psi^J_{S,\beta}|S| - q_J\right) \approx \sum_{J\in\mathcal{J}^{\mathsf{C}}} y_{U(J)}. \tag{19}$$

In the above LP, ψ^J is the indicator vector for local solutions for J and q_J indicates whether J is responsible for removing one facility; if $q_J = 1$, we shall call $\mathsf{remove}(J)$ later. Up to changing of variables, any vertex point of $\mathcal{P}$ is defined by two laminar families of tight constraints and thus $\mathcal{P}$ is integral:

▶ **Lemma 11.** *$\mathcal{P}$ is integral.*

We set $\psi^{*J}_{S,\beta} = \phi^J_{S,\beta}$ and $q^*_J = s_J - y_{U(J)}$ for every $J \in \mathcal{J}^{\mathsf{C}}$ and (S,β). Then,

▶ **Lemma 12.** *(ψ^*, q^*) is a point in polytope $\mathcal{P}$.*

We randomly select a vertex point (ψ, q) of $\mathcal{P}$ such that $\mathbb{E}[\psi^J_{S,\beta}] = \psi^{*J}_{S,\beta} = \phi^J_{S,\beta}$ for every $J \in \mathcal{J}^{\mathsf{C}}, (S,\beta)$, and $\mathbb{E}[q_J] = q^*_J = s_J - y_{U(J)}$ for every $J \in \mathcal{J}^{\mathsf{C}}$. Since ψ is integral, for every $J \in \mathcal{J}$, there is a unique local solution $\left(S \subseteq U(J), \beta \in \mathbb{R}^{U(J)}_{\ge 0}\right)$ such that $\psi^J_{S,\beta} = 1$; we add S to S^* and let $\beta^*_i = \beta_i$ for every $i \in U(J)$.

This finishes the definition of the initial S^* and β^*. Let $\alpha^* = \alpha$ (recall that $\alpha_v = x_{U_v,C}$ is the demand at v after the initial moving, for every $v \in R$) be the initial demand vector. Later we shall remove facilities from S^* and update α^* and β^*. S^*, α^*, β^* satisfy the following properties, which will be maintained as the rounding algorithm proceeds.

(13a) $\sum_{v\in V} \alpha^*_v = \sum_{v\in V} \beta^*_v$ for every $V \in \mathcal{J}^{\mathsf{C}} \cup \mathcal{V}^{\mathsf{N}}$;
(13b) $\sum_{v\in R} \alpha^*_v = |C|$.

Property **(13a)** is due to Properties **(9d)** and **(10c)**. Property **(13b)** holds since $\sum_{v\in R} \alpha^*_v = \sum_{v\in R} x_{U_v,C} = x_{F,C} = |C|$.

5.2 The remove procedure

In this section, we define the procedure remove that removes facilities from S^* and updates α^* and β^*. The procedure takes a set $V \in \mathcal{J}^{\mathsf{C}} \cup \mathcal{V}^{\mathsf{N}}$ as input. If V is a root black component,

[1] For every $J \in \mathcal{J}^{\mathsf{C}}$, we only consider the pairs (S,β) in the support of ϕ^J; thus the total number of variables is $n^{O(\ell)}$.

then we let $G = \{V\}$ be the root group containing V; if V is a non-root concentrated component, let G be the parent group of the group containing V; otherwise V is the union of non-concentrated components in all child-groups of some group, and we let G be this group. Let $V' = \bigcup_{J' \in G} J'$. Before calling $\mathsf{remove}(V)$, we require the following properties to hold:

- **(14a)** $|S^* \cap U(V)| \geq 1$;
- **(14b)** $\left|S^* \cap U(V')\right| \geq \ell - 6$.

While maintaining Properties **(13a)** and **(13b)**, the procedure $\mathsf{remove}(V)$ will

- **(15a)** remove from S^* exactly one open facility, which is in $U(V \cup V')$,
- **(15b)** not change $\alpha^*|_{R\setminus(V\cup V')}$ and $\beta^*|_{F\setminus U(V\cup V')}$,
- **(15c)** increase α^*_v by at most a factor of $1 + O(1/\ell)$ for every $v \in V \cup V'$ and increase β^*_i by at most a factor of $1 + O(1/\ell)$ for every $i \in U(V \cup V')$.

Moreover,

- **(15d)** the moving cost for converting the old α^* to the new α^* is at most $O(\ell^2)\beta^*_{i^*} L(J)$ for some black component $J \subseteq V$ and facility $i^* \in U(J)$;
- **(15e)** for every $V'' \in \mathcal{J}^{\mathsf{C}} \cup \mathcal{V}^{\mathsf{N}}$, $\mathrm{EMD}_{V''}\big(\alpha^*|_{V''}, \beta^*|_{U(V'')}\big)$ will be increased by at most a factor of $1 + O(1/\ell)$.

Due to the page limit, we only highlight the key ideas used to implement $\mathsf{remove}(V)$ and leave the formal description to the full version of the paper. Assume V is not a root component. We choose an arbitrary facility $i \in S^* \cap U(V)$. Notice that there are $\Omega(\ell)$ facilities in $S^* \cap U(V')$. If the $\beta^*_i \leq \sum_{v' \in V'} \alpha^*_{v'}/\ell$, then we can shut down i and send the demands that should be sent to i to V'. We only need to increase the supplies in $U(V')$ by a factor of $1 + O(1/\ell)$. Otherwise, we shall shut down the facility $i' \in S^* \cap U(V')$ with the smallest $\beta^*_{i'}$ value. Since there are at least $\Omega(\ell)$ facilities in $U(V')$, we can satisfy the $\beta^*_{i'}$ units of unsatisfied demands using other facilities in $S^* \cap U(V')$. For this i', we have $\beta^*_{i'} \leq O(1)\beta^*_i$. Thus, the total amount of demands that will be moved is comparable to β^*_i. In either case, the cost of redistributing the demands is not too big. When V is a root component, we shall shut down the facility $i' \in S^* \cap U(V)$ with the smallest $\beta^*_{i'}$ value.

5.3 Obtaining the Final Solution

To obtain our final set S^* of facilities, we call the remove procedures in some order. We consider each group G using the top-to-bottom order. That is, before we consider a group G, we have already considered its parent group. If G is a root group, then it contains a single root component J. If $J \in \mathcal{J}^{\mathsf{N}}$, repeat the the following procedure twice: if there is some facility in $S^* \cap U(J)$ then we call $\mathsf{remove}(J)$. If $J \in \mathcal{J}^{\mathsf{C}}$ and $q_J = 1$ then we call $\mathsf{remove}(J)$. Now if G is a non-leaf group, then do the following. Let $V = \bigcup_{G' \in \Lambda_G, J \in G' \cap \mathcal{J}^{\mathsf{N}}} J$. Repeat the following procedure twice: if there is some facility in $S^* \cap U(V)$ then we call $\mathsf{remove}(V)$. For every $G' \in \Lambda_G$ and $J \in G' \cap \mathcal{J}^{\mathsf{C}}$ such that $q_J = 1$ we call $\mathsf{remove}(J)$.

▶ **Lemma 16.** *After the above procedure, we have $|S^*| \leq y_F \leq k$.*

By Properties **(15b)** and **(15c)**, and Constraint (16), our final β^*_i is at most $1 + O(1/\ell)$ times the initial β^*_i for every $i \in V$. Finally we have $\beta^*_i \leq (1 + O(1/\ell))u_i$ for every $i \in F$. Thus, the capacity constraint is violated by a factor of $1 + \epsilon$ if we set ℓ to be large enough.

It remains to bound the expected cost of the solution S^*; this is done by bounding the cost for transferring the original α^* to the final α^*, as well as the cost for matching our final α^* and β^*.

We first focus on the transferring cost. By Property **(15e)**, when we call $\mathsf{remove}(V)$, the transferring cost is at most $O(\ell^2)\beta^*_{i^*} L(J)$ for some black component $J \subseteq V$ and i^*. Notice that

$\beta^*_{i^*}$ is scaled by at most a factor of $(1 + O(1/\ell))$, we always have $\beta^*_{i^*} \leq (1 + O(1/\ell))\alpha_{U(J),C}$. So, the cost is at most $O(\ell^2)x_{U(J),C}L(J)$. If V is the union of some non-concentrated components, then this quantity is at most $O(\ell^2)\ell_2\pi_J L(J) \leq O(\ell^2\ell_2)D_{U(J)} \leq O(\ell^2\ell_2)D_{U(V)}$. We call $\mathsf{remove}(V)$ at most twice, thus the contribution of V to the transferring cost is at most $O(\ell^2\ell_2)D_{U(V)}$. If V is a concentrated component J, then the quantity might be large. However, the probability we call $\mathsf{remove}(J)$ is $\mathbb{E}[q_J] = q^*_J = s_J - y_{U(J)} \leq 2\ell y_{U(J)}\pi_J/x_{U(J),C}$ if $y_{U(J)} \leq 2\ell$ and it is 0 otherwise (by Property **(9a)**). So, the expected contribution of this V to the transferring cost is at most $O(\ell^2)x_{U(J),C}L(J) \times 2\ell y_{U(J)}\pi_J/x_{U(J),C} \leq O(\ell^4)\pi_J L(J) \leq O(\ell^4)D_{U(J)}$ by Lemma 7. Thus, overall, the expected transferring cost is at most $O(\ell^5)D_F = O(\ell^5)\mathsf{LP}$.

Then we consider the matching cost. Since we maintained Property **(13a)**, the matching cost is bounded by $\sum_{V\in\mathcal{J}^{\mathsf{C}}\cup\mathcal{V}^{\mathsf{N}}} \mathrm{EMD}_V(\alpha^*|_V, \beta^*|_{U(V)})$. Due to Property **(15e)**, this quantity has only increased by a factor of $1 + O(1/\ell)$ during the course of removing facilities. For the initial α^* and β^*, the expectation of this quantity is at most $\sum_{J\in\mathcal{J}^{\mathsf{C}}} O(\ell^4)D_{U(J)} + \sum_{V\in\mathcal{V}^{\mathsf{N}}} O(\ell^2\ell_2)D_{U(V)}$ due to Properties **(9f)** and **(10d)**. This is at most $O(\ell^5)D_F = O(\ell^5)\mathsf{LP}$.

We have found a set S^* of at most k facilities and a vector $\beta^* \in \mathbb{R}^F_{\geq 0}$ such that $\beta^*_i = 0$ for every $i \notin S^*$ and $\beta^*_i \leq (1 + O(1/\ell))u_i$. If we set $\ell = \Theta(1/\epsilon)$ to be large enough, then $\beta^*_i \leq (1 + \epsilon)u_i$. The cost for matching the α-demand vector and the β^* vector is at most $O(\ell^5)\mathsf{LP} = O(1/\epsilon^5)\mathsf{LP}$. Thus, we obtained a $O(1/\epsilon^5)$-approximation for CKM with $(1 + \epsilon)$-capacity violation.

Approximating Directed Steiner Problems via Tree Embedding

Abstract

Directed Steiner problems are fundamental problems in Combinatorial Optimization and Theoretical Computer Science. An important problem in this genre is the *k-edge connected directed Steiner tree* (k-DST) problem. In this problem, we are given a directed graph G on n vertices with edge-costs, a root vertex r, a set of h terminals T and an integer k. The goal is to find a min-cost subgraph $H \subseteq G$ that connects r to each terminal $t \in T$ by k edge-disjoint r,t-paths. This problem includes as special cases the well-known *directed Steiner tree* (DST) problem (the case $k = 1$) and the *group Steiner tree* (GST) problem. Despite having been studied and mentioned many times in literature, e.g., by Feldman et al. [SODA'09, JCSS'12], by Cheriyan et al. [SODA'12, TALG'14], by Laekhanukit [SODA'14] and in a survey by Kortsarz and Nutov [Handbook of Approximation Algorithms and Metaheuristics], there was no known non-trivial approximation algorithm for k-DST for $k \geq 2$ even in a special case that an input graph is directed acyclic and has a constant number of layers. If an input graph is not acyclic, the complexity status of k-DST is not known even for a very strict special case that $k = 2$ and $h = 2$.

In this paper, we make a progress toward developing a non-trivial approximation algorithm for k-DST. We present an $O(D \cdot k^{D-1} \cdot \log n)$-approximation algorithm for k-DST on directed acyclic graphs (DAGs) with D layers, which can be extended to a special case of k-DST on "general graphs" when an instance has a *D-shallow* optimal solution, i.e., there exist k edge-disjoint r,t-paths, each of length at most D, for every terminal $t \in T$. For the case $k = 1$ (DST), our algorithm yields an approximation ratio of $O(D \log h)$, thus implying an $O(\log^3 h)$-approximation algorithm for DST that runs in quasi-polynomial-time (due to the height-reduction of Zelikovsky [Algorithmica'97]). Our algorithm is based on an LP-formulation that allows us to embed a solution to a tree-instance of GST, which does not preserve connectivity. We show, however, that one can randomly extract a solution of k-DST from the tree-instance of GST.

Our algorithm is almost tight when k and D are constants since the case that $k = 1$ and $D = 3$ is NP-hard to approximate to within a factor of $O(\log h)$, and our algorithm archives the same approximation ratio for this special case. We also remark that the $k^{1/4-\epsilon}$-hardness instance of k-DST is a DAG with 6 layers, and our algorithm gives $O(k^5 \log n)$-approximation for this special case. Consequently, as our algorithm works for general graphs, we obtain an $O(D \cdot k^{D-1} \cdot \log n)$-approximation algorithm for a D-shallow instance of the *k edge-connected directed Steiner subgraph* problem, where we wish to connect every pair of terminals by k edge-disjoint paths.

1 Introduction

Network design is an important class of problems in Combinatorial Optimization and Theoretical Computer Science as it formulates scenarios that appear in practical settings. In particular, we might wish to design an overlay network that connects a server to clients, and this can be formulated as the *Steiner tree* problem. In a more general setting, we might have an additional constraint that the network must be able to function after link or node failures, leading to the formulation of the *survivable network design* problem. These problems are well-studied in symmetric case where a network can be represented by an undirected graph. However, in many practical settings, links in networks are not symmetric. For example, we might have different upload and download bandwidths in each connection, and sometimes, transmissions are only allowed in one direction. This motivates the study of network design problems in directed graphs, in particular, *directed Steiner* problems.

One of the most well-known directed network design problem is the *directed Steiner tree* problem (DST), which asks to find a minimum-cost subgraph that connects a given root vertex to each terminal. DST is a notorious problem as there is no known polynomial-time algorithm that gives an approximation ratio better than polynomial. A polylogarithmic approximation can be obtained only when an algorithm is allowed to run in quasi-polynomial-time [2, 13, 6]. A natural generalization of DST, namely, the k *edge-connected directed Steiner tree* (k-DST) problem, where we wish to connect a root vertex to each terminal by k edge-disjoint paths, is even more mysterious as there is no known non-trivial approximation algorithm, despite having been studied and mentioned many times in literature, e.g., by Feldman et al. [5], by Cheriyan et al. [3] and by Laekhanukit [10]. The problem is also mentioned in a survey by Kortsarz and Nutov [9] and in a later update by Nutov [12].

The focus of this paper is in studying the approximability of k-DST. Let us formally describe k-DST. In k-DST, we are given a directed graph G with edge-costs $\{c_e\}_{e\in E(G)}$, a root vertex r and a set of terminals $T \subseteq V(G)$. The goal is to find a min-cost subgraph $H \subseteq G$ such that H has a k edge-disjoint directed r,t-paths from the root r to each terminal $t \in T$. Thus, removing any $k-1$ edges from H leaves at least one path from the root r to each terminal $t \in T$, and DST is the case when $k = 1$ (i.e., we need only one path). The complexity status of k-DST tends to be negative. It was shown by Cheriyan et al. [3] that the problem is at least as hard as the *label cover* problem. Specifically, k-DST admits no $2^{\log^{1-\epsilon} n}$-approximation, for any $\epsilon > 0$, unless NP $\subseteq$ DTIME$(2^{\text{polylog}(n)})$. Laekhanukit [10], subsequently, showed that k-DST admits no $k^{1/4-\epsilon}$-approximation unless NP = ZPP. The integrality gap of a natural LP-relaxation for k-DST is $\Omega(k/\log k)$ which holds even for a special case of *connectivity-augmentation* where we wish to increase a connectivity of a graph by one. All the lower bound results are based on the same construction which are directed acyclic graphs (DAGs) with diameter 5, i.e., any path in an input graph has length (number of edges) at most 5 (we may also say that it has 6 *layers*). Even for a very simple variant of k-DST, namely $(1,2)$-DST, where we have two terminals, one terminal requires one path from the root and another terminal requires 2 edge-disjoint paths, it was not known whether the problem is NP-hard or polynomial-time solvable. To date, the only known positive result for k-DST is an $O(n^{kh})$-time (exact) algorithm for k-DST on DAGs [3], which thus runs in polynomial-time when kh is constant, and a folk-lore h-approximation algorithm, which can be obtained by computing min-cost k-flow for h times, one from the root r to each terminal t and then returning the union as a solution. We emphasize that there was no known non-trivial approximation algorithm even when an input graph is "directed acyclic" and has "constant number of layers". Also, in contrast to DST in which an $O(2^h \text{poly}(n))$-time (exact)

algorithm exists for general graphs, it is not known whether k-DST for $k = 2$ and $h = 2$ is polynomial-time solvable if an input graph is not acyclic. This leaves challenging questions whether ones can design a non-trivial approximation algorithm for k-DST on DAGs with at most D layers, and whether ones can design a non-trivial approximation algorithm when an input graph is not acyclic.

In this paper, we make a progress toward developing a non-trivial approximation algorithm for k-DST. We present the first "non-trivial" approximation algorithm for k-DST on DAGs with D layers that achieves an approximation ratio of $O(D \cdot k^{D-1} \cdot \log n)$. Our algorithm can be extended to a special case of k-DST on "general graphs" where an instance has a *D-shallow* optimal solution, i.e., there exist k edge-disjoint r, t-paths, each of length at most D, for every terminal $t \in T$. Consequently, as our algorithm works for a general graph, we obtain an $O(D \cdot k^{D-1} \cdot \log n)$-approximation algorithm for a D-shallow instance of the *k edge-connected directed Steiner subgraph* problem, where we wish to connect every pair of terminals by k edge-disjoint paths, i.e., the set of terminals T is required to be k-edge connected in the solution subgraph (there is no root vertex in this problem).

Our algorithm is almost tight when k and D are constants because the case that $k = 1$ and $D = 3$ is essentially the *set cover* problem, which is NP-hard to approximate to within a factor of $O(\log h)$ [11, 4], and our algorithm achieves the same approximation ratio. We also remark that the $k^{1/4-\epsilon}$-hardness instance of k-DST is a DAG with 6 layers, and our algorithm gives $O(k^5 \log n)$-approximation for this special case. For $k = 1$, we obtain a slightly better bound of $O(D \log h)$, thus giving an LP-based $O(\log^3 h)$-approximation algorithm for DST as a by product.

The key idea of our algorithm is to formulate an LP-relaxation with a special property that a fractional solution can be embedded into a tree instance of the *group Steiner tree* problem (GST). Thus, we can apply the GKR Rounding algorithm in [7] for GST on trees to round the fractional solution. However, embedding of an LP-solution to a tree instance of GST does not preserve connectivity. Also, it does not lead to a reduction from k-DST to the k edge-connected variant of GST, namely, k-GST. Hence, our algorithm is, although simple, not straightforward.

1.1 Our Results

Our main result is an $O(D \cdot k^{D-1} \cdot \log n)$-approximation algorithm for k-DST on a D-shallow instance, which includes a special case that an input graph is directed acyclic and has at most D layers.

▶ **Theorem 1.** *Consider the k edge-connected directed Steiner tree problem. Suppose an input instance has an optimal solution H^* in which, for every terminal $t \in T$, H^* has k edge-disjoint r, t-paths such that each path has length at most D. Then there exists an $O(D \cdot k^{D-1} \cdot \log n)$-approximation algorithm. In particular, there is an $O(D \cdot k^{D-1} \cdot \log n)$-approximation algorithm for k-DST on a directed acyclic graph with D layers.*

For the case $k = 1$, our algorithm yields a slightly better guarantee of $O(D \log h)$. Thus, we have as by product an LP-based approximation algorithm for DST. Applying Zelikovsky's height-reduction theorem [14, 8], this implies an LP-based quasi-polynomial-time $O(\log^3 h)$-approximation algorithm for DST. (The algorithm runs in time $O(\text{poly}(n^D)$ and has approximation ratio $O(h^{1/D} \cdot D^2 \log h)$.)

Theorem 1 also implies an algorithm of the same (asymptotic) approximation ratio for a D-shallow instance of the k edge-connected directed Steiner subgraph problem, where we wish to find a subgraph H such that the set of terminals T is k-edge-connected in H. To

see this, we invoke the algorithm in Theorem 1 as follows. Take any terminal $t^* \in T$ as a root vertex of a k-DST instance. Then we apply the algorithm for k-DST to find a subgraph H^{out} such that every terminal is k edge-connected from t^*. We apply the algorithm again to find a subgraph H^{in} such that every terminal is k edge-connected to t^*. Then the set of terminals T is k-edge connected in the graph $H^{out} \cup H^{in}$ by transitivity of edge-connectivity. The cost incurred by this algorithm is at most twice that of the algorithm in Theorem 1. Thus, we have the following theorem as a corollary of Theorem 1

▶ **Theorem 2.** *Consider the k edge-connected directed Steiner subgraph problem. Suppose an input instance has an optimal solution H^* in which, for every pair of terminals $s, t \in T$, H^* has k edge-disjoint s,t-paths such that each path has length at most D. Then there exists an $O(D \cdot k^{D-1} \cdot \log n)$-approximation algorithm.*

1.1.0.1 Overview of our algorithm

The key idea of our algorithm is to embed an LP solution for k-DST to a standard LP of GST on a tree. (We emphasize that we embed the LP solution of k-DST to that of GST not k-GST.) At first glance, a reduction from k-DST to GST on trees is unlikely to exist because any such reduction would destroy all the connectivity information. We show, however, that such tree-embedding exists, but we have to sacrifice running-time and cost to obtain such embedding.

The reduction is indeed the same as a folk-lore reduction from DST to GST on trees. That is, we list all rooted-paths (paths that start from the root vertex) of length at most D in an input graph and form a suffix tree. In the case of DST, if there is an optimal solution which is a tree of height D, then it gives an approximation preserving reduction from GST to DST which blows up the size (and thus the running time) of the instance to $O(n^D)$. Unfortunately, for the case of k-DST with $k > 1$, this reduction does not give an equivalent reduction from k-DST to k-GST on trees. The reduction is valid in one direction, i.e., any feasible solution to k-DST has a corresponding feasible solution to the tree-instance of k-GST. However, the converse is not true as a feasible solution to the tree-instance of k-GST might not give a feasible solution to k-DST. Thus, our reduction is indeed an "invalid" reduction from k-DST to a tree instance of "GST" (the case $k = 1$).

To circumvent this problem, we formulate an LP that provides a connection between an LP solution on an input k-DST instance and an LP solution of a tree-instance of GST. Thus, we can embed an LP solution to an LP-solution of GST on a (very large) tree. We then round the LP solution using the GKR Rounding algorithm for GST on trees [7]. This algorithm, again, does not give a feasible solution to k-DST as each integral solution we obtain only has "connectivity one" and thus is only feasible to DST. We cope with this issue by using a technique developed by Chalermsook et al. in [1]. Specifically, we sample a sufficiently large number of DST solutions and show that the union of all these solutions is feasible to k-DST using cut-arguments.

Each step of our algorithm and the proofs are mostly standard, but ones need to be careful in combining each step. Otherwise, the resulting graph would not be feasible to k-DST.

Organization. We provide definitions and notations in Section 2. We start our discussion by presenting a reduction from DST to GST in Section 3. Then we discuss properties of minimal solutions for k-DST in Section 4. We present standard LPs for k-DST and GST in

Section 5 and formulate a stronger LP-relaxation for k-DST in Section 6. Then we proceed to present our algorithm in Section 7. Finally, we provide some discussions in Section 8.

2 Preliminaries

We use standard graph terminologies. We refer to a directed edge (u, v), shortly, by uv (i.e., u and v are head and tail of uv, respectively), and we refer to an undirected edge by $\{u, v\}$. For a (directed or undirected) graph G, we denote by $V(G)$ and $E(G)$ the sets of vertices and edges of G, respectively. If a graph G is associated with edge-costs $\{c_e\}_{e\in E(G)}$, then we denote the cost of any subgraph $H \subseteq G$ by $\mathsf{cost}(H) = \sum_{e\in E(H)} c_e$. For any path P, we use *length* to mean the number of edges in a path P and use *cost* to mean the total costs of edges in P.

In the *directed Steiner tree* problem (DST), we are given a directed graph G with edge-costs $\{c_e\}_{e\in E(G)}$, a root vertex r and a set of terminals $T \subseteq V(G)$. The goal is to find a min-cost subgraph $H \subseteq G$ such that H has a directed path from the root r to each terminal $t \in T$. A generalization of DST is the k *edge-connected directed Steiner tree* problem (k-DST). In k-DST, we are given the same input as in DST plus an integer k. The goal is to find a min-cost subgraph H that has k edge-disjoint paths from the root r to each terminal $t \in T$. The k *edge-connected directed Steiner subgraph* problem is a variant of k-DST, where there is no root vertex, and the goal is to find a min-cost subgraph H such that the set of terminals T is k edge-connected in H.

The problems on undirected graphs that are closely related to of DST and k-DST are the *group Steiner tree* problem (GST) and the k *edge-connected group Steiner tree* problem (k-GST). In GST, we are given an undirected graph $\mathcal{G}$ with edge-costs $\{c_e\}_{e\in E(G)}$, a root vertex r and a collection of subset of vertices $\{\mathcal{T}_i\}_{i=1}^h$ called groups. The goal is to find a a min-cost subgraph $\mathcal{H}$ that connects r to each group $\mathcal{T}_i$. In k-GST, the input consists of an additional integer k, and the goal is to find a min-cost subgraph H with k edge-disjoint $r, \mathcal{T}_i$-paths for every group T_i.

Consider an instance of DST (resp., k-DST). We denote by Q the set of all paths in G that start from the root r. The set of paths in Q that end with a particular pattern, say $\sigma = (v_1, \ldots, v_q)$, is denoted by $Q(\sigma)$. This pattern σ can be a vertex v, an edge e or a path $\sigma = (v_1, \ldots, v_q)$ in G. For example, $Q(u, v, w)$ consists of paths P of the form $P = (r, \ldots, u, v, w)$. We say that a path P ends in a vertex v (resp., an edge e) if v (resp., e) is the last vertex (resp., edge) of P.

We may consider only paths with particular length, say D. We denote by Q_D the set of paths that start at r and has length at most D. The notation for Q_D is analogous to Q, e.g., $Q_D(uv) \subseteq Q_D$ is the set of paths in Q_D that end in an edge uv. A concatenation of a path p with an edge e or a vertex v are denoted by $p + e$ and $p + v$, respectively. For example, $(u_1, \ldots, u_\ell) + vw = (u_1, \ldots, u_\ell, v, w)$.

Given a subset of vertices S, the set of edges entering S is denoted by

$$\delta^-(S) = \{uv \in E : u \in S, v \notin S\}$$

The indegree of S is denoted by $\mathsf{indeg}(S) = |\delta^-(S)|$. Analogously, we use $\delta^+(S)$ and $\mathsf{outdeg}(S)$ for the set of edges leaving S. For undirected graphs, we simply use the notations $\delta(S)$ and $\mathsf{deg}(S)$.

We say that a feasible solution H to k-DST is D-*shallow* if, for every terminal $t \in T$, there exists a set of k edge-disjoint r, t-paths in H such that every path has length at most D. An instance of k-DST that has an optimal D-shallow solution is called a D-shallow instance.

We also use the term D-shallow analogously for k-GST and the k edge-connected Steiner subgraph problem.

To distinguish between the input of k-DST (which is a directed graph) and k-GST (which is an undirected graph), we use script fonts, e.g., $\mathcal{G}$, to denote the input of k-GST. Also, we use $\mathcal{Q}$ to denote the set of all paths from the root r to any vertex v in the graph $\mathcal{G}$. The cost of a set of edges F (or a graph) is defined by a function $\mathsf{cost}(F) = \sum_{e \in F} c_e$. At each point, we consider only one instance of k-DST (respectively, k-GST). So, we denote the cost of the optimal solution to k-DST by opt_{kDST} (respectively, opt_{kGST}).

3 Reduction from Directed Steiner Tree to Group Steiner Tree

In this section, we describe a reduction $\mathcal{R}$ from DST to GST. We recall that Q denotes all the r, v-paths in a DST instance G. The reduction is by simply listing paths in the directed graph G as vertices in a tree $\mathcal{G} = \mathcal{R}(G)$ and joining each path p to $p + e$ if $p + e$ is a path in G. In fact, $\mathcal{R}(G)$ is a *suffix tree* of paths in Q. To be precise,

$$V(\mathcal{G}) = \{p : p \text{ is an } r, v\text{-path in } G\}$$
$$E(\mathcal{G}) = \{\{p, p + e\} : \text{both } p \text{ and } p + e \text{ are paths in } G \text{ starting at } r\}$$

We set the cost of edges of $\mathcal{G}$ to be $c_{\{p,p+e\}} = c_e$. Since the root r has no incoming edges in G, r maps to a unique vertex $(r) \in \mathcal{G}$, and we define (r) as the root vertex of the GST instance. We will abuse r to mean both the root of DST and its corresponding vertex of GST. For each terminal $t_i \in T$, define a group of the GST instance as

$$\mathcal{T}_i := Q(t_i) = \{p \subseteq G : p \text{ is an } r, t_i\text{-path in } G\}$$

It is easy to see that the reduction $\mathcal{R}$ produces a tree, and there is a one-to-one mapping between a path in the tree $\mathcal{G} = \mathcal{R}(G)$ and a path in the original graph G. Thus, any tree in G corresponds to a subtree of $\mathcal{R}(G)$ (but not vice versa), which implies that the reduction $\mathcal{R}$ is approximation-preserving (i.e., $\mathsf{opt}_{DST} = \mathsf{opt}_{GST}$). Note, however, that the size of the instance blows up from $O(n + m)$ to $O(n^D)$, where D is the length of the longest path in G. The reduction holds for general graphs, but it is approximation-preserving only if the DST instance is D-shallow, i.e., it has an optimal solution H^* such that any r, t_i-path in H^* has length at most D, for all terminals $t_i \in T$. However, Zelikovsky [14, 8] showed that the *metric completion* of G always contains a D-shallow solution with cost at most $D|V(G)|^{1/D}$ of an optimal solution to DST. (This is now known as Zelikovsky's height reduction theorem.) Thus, we may list only paths of length at most D from the metric completion. We denote the reduction that lists only paths of length at most D by $\mathcal{R}_D$.

4 Properties of Minimal Solutions to k-DST

In this section, we provide structural lemmas which are building blocks in formulating a strong LP-relaxation for k-DST. These lemmas characterize properties of a minimal solution to k-DST.

▶ **Lemma 3.** *Let H be any minimal solution to k-DST. Then H has at most k edge-disjoint r, v-paths, for any vertex $v \in V(H)$.*

Proof. Suppose to a contrary that H has $k + 1$ edge-disjoint r, v-paths, for some vertex $v \in V(H)$. Then v must have indegree at least $k + 1$ in H. We take one of the $k - 1$ edges

entering v, namely, uv. By minimality of H, removing uv results in a graph $H' = H - uv$ that has less than k edge-disjoint r, t_i-paths for some terminal $t_i \in T$. Thus, by Menger's theorem, there must be a subset of vertices $S \subseteq V$ such that $t_i \in S$, $r \in V - S$ and $\mathsf{indeg}_{H'}(S) \leq k-1$. Observe that we must have uv in $\delta^-_H(S)$ because H is a feasible solution to k-DST, which means that $v \in S$. Since we remove only one edge uv from H, the graph H' must have k edge-disjoint r, v-paths. But, this implies that $\mathsf{indeg}_{H'}(S) \geq k$, a contradiction. ◀

▶ **Lemma 4.** *Let H be any minimal solution to k-DST. Any vertex $v \in V(H)$ has indegree exactly $\lambda(v)$, where $\lambda(v)$ is the maximum number of edge-disjoint r, v-paths in H.*

Proof. The proof follows a standard uncrossing argument. Assume a contradiction that v has indegree at least $\lambda(v)+1$ in H. By Menger's theorem, there is a subset of vertices $U \subseteq V$ such that $\mathsf{indeg}_H(U) = \lambda(v)$, $v \in U$ and $r \notin U$ that separates v from r. We assume that U is a minimum such set. Since $\mathsf{indeg}_H(v) > \lambda(v)$, there is an edge $uv \in E(H)$ that is not contained in $\delta^-_H(U)$, i.e., $u, v \in U$.

By minimality of H, removing uv results in the graph $H' = H - uv$ such that H' has less than k edge-disjoint r, t_i-paths for some terminal $t_i \in T$. Thus, by Menger's theorem, there is a subset of vertices W such that $t_i \in W$, $r \notin W$, $uv \in \delta^-_H(W)$ and $\mathsf{indeg}_H(W) = k$. (The latter is because H is a feasible solution to k-DST.)

Now we apply an uncrossing argument to U and W. By submodularity of indeg_H, we have $\mathsf{indeg}_H(U) + \mathsf{indeg}_H(W) \geq \mathsf{deg}_H(U \cap W) + \mathsf{deg}_H(U \cup W)$. Observe that $v \in U \cap W$, $t \in U \cup W$ and $r \notin S \cup S'$. So, by the edge-connectivity of v and t,

$$\mathsf{indeg}_H(U \cap W) \geq \lambda(v) \quad \text{and} \quad \mathsf{indeg}_H(U \cup W) \geq k \tag{1}$$

The sum of the left-hand side of Eq (1) is $\mathsf{indeg}_H(U) + \mathsf{indeg}_H(W) = k + \lambda(v)$. So, we conclude that $\mathsf{indeg}_H(U \cap W) = \lambda(v)$ and $\mathsf{indeg}_H(U \cup W) = k$. Consequently, we have the set $U' = U \cap W$ such that $\mathsf{indeg}_H(U') = \lambda(v)$, $v \in U'$ and $r \notin U'$ that separates v from r. Since $u \notin W$, we know that U' is strictly smaller than U. This contradicts to the minimality of U. ◀

The following is a corollary of Lemma 3 and Lemma 4

▶ **Corollary 5.** *Let H be a minimal solution to k-DST. Then any vertex $v \in V(H)$ has indegree at most k.*

The next lemma follows from Corollary 5.

▶ **Lemma 6.** *Consider any minimal solution H to k-DST (which is a simple graph). For any edge $e \in E(H)$ and $\ell \geq 2$, there are at most $k^{\ell-2}$ paths in H with length at most ℓ that start at the root r and ends in e. That is, $|Q^H_\ell(e)| \leq k^{\ell-2}$ for all $e \in E(H)$, where $Q^H_\ell(e)$ is the set of r, v-paths of length ℓ in H.*

Proof. We prove by induction. The base case $\ell = 2$ is trivial because any rooted path of length at most 2 cannot have a common edge.

Assume, inductively, that $|Q^H_{\ell-1}(e)| \leq k^{\ell-3}$ for some $\ell \geq 3$. Consider any edge $vw \in E(H)$. By Corollary 5, v has indegree at most k. Thus, there are at most k edges entering v, namely, $u_1 v, \ldots, u_d v$, where $d = \mathsf{indeg}(v)$. By the induction hypothesis, each edge is the last edge of at most $k^{\ell-3}$ paths in $Q^H_{\ell-1}$. Thus, we have at most $d \cdot k^{\ell-3} \leq k^{\ell-2}$ paths that end in uv. That is,

$$|Q^H_\ell(vw)| \leq \sum_{i=1}^{d} |Q^H_{\ell-1}(u_d v)| \leq \sum_{i=1}^{d} k^{\ell-3} = d \cdot k^{\ell-3} \leq k^{\ell-2}.$$

◀

5 Standard LPs for k-DST and GST

In this section, we describe standard LPs for k-DST and GST. Each LP consists of two sets of variables, a variable x_e on each edge e and a variable f_p^i on each path p and a terminal t_i. The variable x_e indicates whether we choose an edge e in a solution. The variable f_p^i is a flow-variable on each path and thus can be written in a compact form using a standard flow formulation.

$$\text{LP-k-DST} \begin{cases} \min & \sum_{e\in E(G)} c_e x_e & & \\ \text{s.t.} & \sum_{p\in Q(t_i):e\in E(p)} f_p^i & \le x_e & \forall e \in E(G), \forall t_i \in T \\ & \sum_{p\in Q(t_i)} f_p^i & \ge k & \forall t_i \in T \\ & x_e & \le 1 & \forall e \in E(G) \\ & x_e & \ge 0 & \forall e \in E(G) \\ & f_p^i & \ge 0 & \forall p \in Q(t_i), \forall t_i \in T. \end{cases}$$

The standard LP for GST is similar to LP-k-DST.

$$\text{LP-GST} \begin{cases} \min & \sum_{e\in E(\mathcal{G})} c_e x_e & & \\ \text{s.t.} & \sum_{v\in\mathcal{T}_i}\sum_{p\in\mathcal{Q}(v):e\in E(p)} f_p^i & \le x_e & \forall e \in E(\mathcal{G}), \forall i = 1,2,\ldots,h \\ & \sum_{v\in\mathcal{T}_i}\sum_{p\in\mathcal{Q}(v)} f_p^i & \ge 1 & \forall i = 1,2,\ldots,h \\ & x_e & \le 1 & \forall e \in E(\mathcal{G}) \\ & x_e & \ge 0 & \forall e \in E(\mathcal{G}) \\ & f_p^i & \ge 0 & \forall p \in \mathcal{Q}, \forall i = 1,2,\ldots,h \end{cases}$$

6 A Strong LP-relaxation for for k-DST

In this section, we formulate a strong LP-relaxation for k-DST that allows us to embed a fractional solution into an LP solution of LP-GST on a tree.

$$\text{LP-k-DST*} \begin{cases} \min & \sum_{e\in E} c_e x_e & & \\ \text{s.t.} & \sum_{p\in Q(t_i):e\in E(p)} f_p^i & \le x_e & \forall e \in E(G), \forall t_i \in T \\ & \sum_{p\in Q(t_i)} f_p^i & \ge k & \forall t_i \in T \\ & \sum_{p\in Q(t_i):q\subseteq p} f_p^i & \le y_q & \forall q \in Q, \forall t_i \in T \\ & & & \text{(Subflow Capacity)} \\ & \sum_{p\in Q_\ell(e)} y_p & \le \max\{1, k^{\ell-2}\}\cdot x_e & \forall e \in E, \forall \ell \ge 1 \\ & & & \text{(Aggregating } k\text{-Flow)} \\ & x_e & \le 1 & \forall e \in E(G) \\ & x_e & \ge 0 & \forall e \in E(G) \\ & f_p^i & \ge 0 & \forall p \in Q(t_i), \forall t_i \in T \\ & y_p & \ge 0 & \forall p \in Q \end{cases}$$

For D-shallow instances of k-DST, we replace Q by Q_D to restrict length of paths to be at most D. The next lemma shows that LP-k-DST* is an LP-relaxation for k-DST.

▶ **Lemma 7.** *LP-k-DST* is an LP-relaxation for k-DST. Moreover, replacing Q by Q_D gives an LP-relaxation for k-DST on D-shallow instances.*

Proof. LP-k-DST* is, in fact, obtained from LP-k-DST (which is a standard LP) by adding a new variable y_p and two constraints.

1. **Subflow-Capacity:** $\sum_{p\in Q(t_i):q\subseteq p} f_p^i \le y_q, \forall q \in Q, \forall t_i \in T.$

2. **Aggregating k-Flow:** $\sum_{p \in Q_\ell(e)} y_p \leq \max\{1, k^{\ell-2}\} \cdot x_e, \forall e \in E, \forall \ell \geq 1.$

To show that these two constraints are valid for k-DST, we take a minimal feasible (D-shallow) solution H of k-DST. We define a solution (x, f, y) to LP-k-DST as below.

$$x_e = \begin{cases} 1 & \text{if } e \in E(H) \\ 0 & \text{otherwise} \end{cases} \qquad y_p = \begin{cases} 1 & \text{if } p \subseteq H \wedge p \in Q \\ 0 & \text{otherwise} \end{cases}$$
$$f_p^i = \begin{cases} 1 & \text{if } p \subseteq H \wedge p \in Q(t_i) \\ 0 & \text{otherwise} \end{cases}$$

By construction, $f_p^i = 1$ implies that $y_p = 1$. Thus, (x, f, y) satisfies the Subflow-Capacity constraint. By minimality of H, Corollary 6 implies that even if we list all the paths of length $\ell \geq 2$ in H, at most $k^{\ell-2}$ of them end in the same edge, and we know that rooted paths of length one share no edge (given that H is a simple graph). Thus, (x, f, y) satisfies the Aggregating k-Flow constraint. Consequently, these two constraints are valid for k-DST.

On the other hand, any integral solution that is not feasible to k-DST could not satisfy the constraints of LP-k-DST* simply because LP-k-DST* contains the constraints of LP-k-DST, which is a standard LP for k-DST. Thus, LP-k-DST* is an LP-relaxation for k-DST.

The proof for the case of D-shallow instances is the same as above except that we take H as a minimal D-shallow solution and replace Q by Q_D. ◀

7 An Approximation Algorithm for k-DST

In this section, we present an approximation algorithm for k-DST on a D-shallow instance. Our algorithm is simple. We solve LP-k-DST* on an input graph G and then embed an optimal fractional solution (x, f, y) to an LP-solution $(\hat{x}, \hat{f})$ of LP-GST on the tree $\mathcal{R}(G)$. We lose a factor of $O(k^{D-2})$ in this process. As we now have a tree-embedding of an LP-solution, we can invoke the GKR Rounding algorithm [7] to round an LP-solution on the tree $\mathcal{R}(G)$. Our embedding guarantees that any edge-set of size $k-1$ in the original graph G never maps to an edge-set in the tree $\mathcal{G} = \mathcal{R}(G)$ that separates r and $\mathcal{T}_i = Q(t_i)$ in $\mathcal{G}$. So, the rounding algorithm still outputs a feasible solution to GST with constant probability even if we remove edges in the tree $\mathcal{G}$ that correspond to a subset of $k-1$ edges in G. Consequently, we only need to run the algorithm for $O(D \cdot k \cdot \log n)$ times to boost the probability of success so that, for any subset of $k-1$ edges and any terminal $t_i \in T$, we have at least one solution that contains an r, t_i-path using none of these $k-1$ edges. In other words, the union of all the solutions satisfies the connectivity requirement. Our algorithm is described in Algorithm 1.

Algorithm 1 Algorithm for k-DST

Solve LP-k-DST* and obtain an optimal solution (x, f, y).
Map (x, f, y) to a solution $(\hat{x}, \hat{f})$ to LP-GST on $\mathcal{G} = \mathcal{R}(G)$.
for $i = 1$ **to** $2Dk \log_2 n$ **do**
  Run GKR Rounding on $(\hat{x}, \hat{f})$ to get a solution $\mathcal{Z}_i$.
  Map $\mathcal{Z}_i$ back to a subgraph Z_i of G.
end for
return $H = \bigcup_i Z_i$ as a solution to k-DST.

We map a solution (x, f, y) of LP-k-DST* on G to a solution $(\hat{x}, \hat{f})$ of LP-GST on the tree $\mathcal{G} = \mathcal{R}(G)$ as below. Note that there is a one-to-one mapping between a path in G and

a path in the tree $\mathcal{G}$.

$$\begin{aligned} \hat{x}_{\{p,p+e\}} &:= y_{p+e} && \text{for all } p+e \in Q \\ \hat{f}^i_p &:= f^i_p && \text{for all } p \in Q \text{ and for all } t_i \in T \end{aligned}$$

7.1 Cost Analysis

We show that $\mathsf{cost}(\hat{x}, \hat{f}) \le k^{D-2} \cdot \mathsf{cost}(x, f, y)$.

▶ **Lemma 8.** *Consider a solution $(\hat{x}, \hat{f})$ to LP-GST, which is mapped from a solution (x, f) of LP-k-DST* when an input k-DST instance is D-shallow, for $D \ge 2$. The cost of $(\hat{x}, \hat{f})$ is at most $\mathsf{cost}(\hat{x}, \hat{f}) \le k^{D-2} \cdot \mathsf{cost}(x, f)$.*

Proof. By the constraint $\sum_{p \in Q_\ell(e)} f_p \le \max\{1, k^{\ell-2}\} \cdot x_e$, we have that

$$\begin{aligned} \mathsf{cost}(\hat{x}, \hat{f}) &= \textstyle\sum_{e' \in E(\mathcal{G})} c_{e'} \hat{x}_{e'} && = \textstyle\sum_{e \in E(G)} \sum_{\{p,p+e\} \in E(\mathcal{G})} c_e \hat{x}_{\{p,p+e\}} \\ &= \textstyle\sum_{e \in E(G)} \sum_{p+e \in Q} c_e f_{p+e} && = \textstyle\sum_{e \in E(G)} \sum_{p \in Q(e)} c_e f_p \\ &= \textstyle\sum_{e \in E(G)} \left(c_e \cdot \sum_{p \in Q(e)} f_p \right) && \le \textstyle\sum_{e \in E(G)} c_e \cdot k^{D-2} \cdot x_e \\ &= k^{D-2} \cdot \mathsf{cost}(x, f). \end{aligned}$$

◀

It can be seen from Algorithm 1 and Lemma 8 that the algorithm outputs a solution H with cost at most $O(Dk^{D-1} \log n) \cdot \mathsf{cost}(x, f)$. Thus, H is an $O(Dk^{D-1} \log n)$-approximate solution. It remains to show that H is feasible to k-DST.

7.2 Feasibility Analysis

Now we show that H is feasible to k-DST with high probability. To be formal, consider any subset $F \subseteq E(G)$ of $k-1$ edges. We map F to their corresponding edges $\mathcal{F}$ in the tree $\mathcal{G}$. Thus, $\mathcal{F} := \{\{P, P+e\} : P + e \in Q \wedge e \in F\}$.

Observe that no vertices in $\mathcal{G} - \mathcal{F}$ correspond to paths that contain an edge in F. Thus, we can define an LP solution (y^F, z^F) for LP-GST on the graph $\mathcal{G} - \mathcal{F}$ as follows.

$$y^F_e = \begin{cases} \hat{x}_e & \text{if } e \notin \mathcal{F} \\ 0 & \text{otherwise} \end{cases} \qquad z^{F,i}_p = \begin{cases} \hat{f}^i_p & \text{if } E(p) \cap \mathcal{F} = \emptyset \\ 0 & \text{otherwise} \end{cases}$$

We show that (y^F, z^F) is feasible to LP-GST on $\mathcal{G} - \mathcal{F}$.

▶ **Lemma 9.** *For any subset of edges $F \subseteq E(G)$, define (y^F, z^F) from $(\hat{x}, \hat{f})$ as above. Then (y^F, z^F) is feasible to LP-GST on $\mathcal{G} - \mathcal{F}$.*

Proof. First, observe that $z^{F,i}_p > 0$ only if a path p contains no edges in $\mathcal{F}$. So, by construction, (y^F, z^F) satisfies $z^{F,i}_p = \hat{f}^i_p \le \hat{x}_e = y^F_e$ for all $e \in E(p)$. Hence, (y^F, z^F) satisfies the capacity constraint.

Next we show that (y^F, z^F) satisfies the connectivity constraint. Consider the solution (x, f, y) to LP-k-DST*. By the feasibility of (x, f, y) and the Max-Flow-Min-Cut theorem, the graph $G - F$ with capacities $\{x_e\}_{e \in G-F}$ can support a flow of value one from r to any terminal t_i. This implies that $\sum_{p \in Q(t_i) : E(p) \cap F = \emptyset} f^i_p \ge 1$. Consequently, we have

$$\begin{aligned} \textstyle\sum_{p \in Q(t_i) : E(p) \cap F = \emptyset} f^i_p &= \textstyle\sum_{p \in \mathcal{T}_i : E(p) \cap F = \emptyset} \sum_{p' \in \mathcal{Q}(v)} \hat{f}^i_{p'} \\ &= \textstyle\sum_{v \in \mathcal{T}_i} \sum_{p' \in \mathcal{Q}(v) : E(p') \cap \mathcal{F} = \emptyset} \hat{f}^i_{p'} \\ &= \textstyle\sum_{v \in \mathcal{T}_i} \sum_{p' \in \mathcal{Q}(v) : E(p') \cap \mathcal{F} = \emptyset} z^{F,i}_{p'} \\ &= \textstyle\sum_{v \in \mathcal{T}_i} \sum_{p' \in \mathcal{Q}(v)} z^{F,i}_{p'} \\ &\ge 1. \end{aligned}$$

All the other constraints are satisfied because (y^F, z^F) is constructed from $(\hat{x}, \hat{f})$. Thus, (y^F, z^F) is feasible to LP-GST on $\mathcal{G} - \mathcal{F}$. ◀

Lemma 9 implies that we can run the GKR Rounding algorithm on (y^F, z^F). The following is the property of GKR Rounding.

▶ **Lemma 10** ([7]). *There exists a randomized algorithm such that, given a solution $(\hat{x}, \hat{f})$ to LP-GST on a tree $\mathcal{G}$ with height D, the algorithm outputs a subgraph $\mathcal{H} \subseteq \mathcal{G}$ so that the probability that any subset of vertices $U \subseteq V(\mathcal{G})$ is connected to the root is at least*

$$\Pr[\mathcal{H} \text{ has an } r, U\text{-path.}] \geq \frac{\sum_{v \in U} \sum_{p \in \mathcal{Q}(v)} \hat{f}_p^i}{O(D)}$$

Moreover, the probability that each edge is chosen is at most $\hat{x}_e$. That is, $\mathbb{E}[\mathsf{cost}(\mathcal{H})] = \mathsf{cost}(\hat{x}, \hat{f})$. The running time of the algorithm is $O(|E(\mathcal{G})| + |V(\mathcal{G})|)$.

Since $(y^F, z^F) \leq (\hat{x}, \hat{f})$ (coordinate-wise), we can show that running GKR Rounding on $(\hat{x}, \hat{f})$ simulates the runs on (y^F, z^F) for all $F \subseteq E(G)$ with $|F| \leq k - 1$, simultaneously.

▶ **Lemma 11.** *Let $\mathcal{H}$ be a subgraph of $\mathcal{G}$ obtained by running GKR Rounding on $(\hat{x}, \hat{f})$, and let H be a subgraph of G corresponding to $\mathcal{H}$. Then, for any subset of edges $F \subseteq E(G)$ with $|F| \leq k - 1$ and for any terminal $t_i \in T$,*

$$\Pr[H - F \text{ has an } r, t_i\text{-path}] \geq \frac{1}{O(D)}.$$

Proof. Let us briefly describe the work of GKR Rounding. The algorithm marks each edge e in the tree with probability $x_e / x_{\varrho(e)}$, where $\varrho(e)$ is the parent of an edge e in $\mathcal{G}$, which is unique. Then the algorithm picks an edge e if all of its ancestors are marked. Clearly, removing any set of edges $\mathcal{F}$ from $\mathcal{G}$ only affects paths that contain an edge in $\mathcal{F}$.

Let (y^F, z^F) be defined from $(\hat{x}, \hat{f})$ as above. This LP solution is defined on a graph $\mathcal{G} - \mathcal{F}$. Thus, the probability of success is not affected by removing $\mathcal{F}$ from the graph. By Lemma 9, we can run GKR Rounding on (y^F, z^F) and obtain a subgraph $\mathcal{H}^F$ of $\mathcal{G} - \mathcal{F}$. Since $z_p^F \leq \hat{f}_p$ for all paths $p \in \mathcal{Q}$ and $z_p^F = 0$ for all $p \in \mathcal{Q} : E(p) \cap \mathcal{F} \neq \emptyset$, we have from Lemma 10 and Lemma 9 that

$$\begin{aligned}
\Pr[H - F \text{ has an } r, t_i\text{-path}] &= \Pr[\mathcal{H} - \mathcal{F} \text{ has an } r, \mathcal{T}_i\text{-path}] \\
&\geq \Pr[\mathcal{H}^F \text{ has an } r, \mathcal{T}_i\text{-path}] \\
&\geq \frac{\sum_{v \in \mathcal{T}_i} \sum_{p \in \mathcal{Q}(v)} z_p^F}{O(D)} \\
&\geq \tfrac{1}{O(D)}.
\end{aligned}$$

◀

Finally, we recall that Algorithm 1 employs GKR Rounding on $(\hat{x}, \hat{f})$ for $2Dk \log_2 n$ times. So, for any subset of $k - 1$ edges $F \subseteq E(G)$ and for any terminal $t_i \in T$, there exists one subgraph that has an r, t_i-path that contains no edge in F with large probability. In particular, the union is a feasible solution to k-DST with high probability.

▶ **Lemma 12.** *Consider the run of Algorithm 1. The solution subgraph $H = \bigcup_i Z_i$ is a feasible solution to k-DST with probability at least $1/n$.*

Proof. For $i = 1, 2, \ldots, 2Dk \log_2 n$, let Z_i be a subgraph of G obtained by running GKR Rounding on $(\hat{x}, \hat{f})$ and mapping the solution back to a subgraph of G as in Algorithm 1.

By Lemma 11, $Z_i - F$ has an r, t_i-path with probability $\Omega(1/D)$. Since each Z_i is sampled independently, we have

$$\Pr[\forall i\, Z_i - F \text{ has no } r, t_i\text{-path}] \leq \left(1 - \frac{1}{O(D)}\right)^{2Dk \log_2 n} \leq \left(\frac{1}{e}\right)^{2k \log_2 n} \leq n^{-2k}.$$

We have at most $|E(G)|^{k-1} \leq n^{2(k-1)}$ such sets F and at most $h \leq n$ terminals. So, there are at most n^{2k-1} bad events where there exists an edge-set of size $k-1$ that separates the root r and some terminal $t_i \in T$. Therefore, by union bound, $H = \bigcup_i Z_i$ is a feasible solution to k-DST with probability at least $1/n$. ◀

This completes the proof of Theorem 1. Note that, for the case of DST ($k = 1$), we only need to run GKR Rounding for $O(D \log h)$ times, thus implying an approximation ratio of $O(D \log h)$.

8 Conclusion and Discussion

We presented the first non-trivial approximation algorithm for k-DST in a special case of a D-shallow instance, which exploits the reduction from DST to GST. We hope that our techniques will shed some light in designing an approximation algorithm for k-DST in general case and perhaps lead to a bi-criteria approximation algorithm in the same manner as in [1].

One obstruction in designing an approximation algorithm in directed graphs is that there is no "true" (perhaps, probabilistic) tree-embedding for directed graphs. Both devising a tree-embedding for directed graphs and designing an approximation algorithm for k-DST with $k \geq 2$ are big open problems in the area. Another open problem, which is considered as the most challenging one by many experts, is whether there exists a polynomial-time algorithm for DST that yields a sub-polynomial approximation ratio.

Acknowledgements. Our work was inspired by the works of Rothvoß [13] and Friggstad et al. [6] and by discussions with Joseph Cheriyan and Lap Chi Lau. We also thank Zachary Friggstad for useful discussions and anonymous referees for valuable comments.

Abstract

Budgeted Red-Blue Median is a generalization of classic k-Median in that there are two sets of facilities, say $\mathcal{R}$ and $\mathcal{B}$, that can be used to serve clients located in some metric space. The goal is to open k_r facilities in $\mathcal{R}$ and k_b facilities in $\mathcal{B}$ for some given bounds k_r, k_b and connect each client to their nearest open facility in a way that minimizes the total connection cost.

We extend work by Hajiaghayi, Khandekar, and Kortsarz [2012] and show that a *multiple-swap* local search heuristic can be used to obtain a $(5+\epsilon)$-approximation for Budgeted Red-Blue Median for any constant $\epsilon > 0$. This is an improvement over their single swap analysis and beats the previous best approximation guarantee of 8 by Swamy [2014].

We also present a matching lower bound showing that for every $p \geq 1$, there are instances of Budgeted Red-Blue Median with local optimum solutions for the p-swap heuristic whose cost is $5 + \Omega\left(\frac{1}{p}\right)$ times the optimum solution cost. Thus, our analysis is tight up to the lower order terms. In particular, for any $\epsilon > 0$ we show the single-swap heuristic admits local optima whose cost can be as bad as $7 - \epsilon$ times the optimum solution cost.

1 Introduction

Facility location problems crop up in many areas of computing science and operations research. A typical problem involves a set of clients and possible facility locations located in a metric space. The goal is to open some facilities and connect each client to some open facility as cheaply as possible. These problems become difficult when there are costs associated with opening facilities or additional constraints that ensure we cannot open too many facilities.

We study Budgeted Red-Blue Median, one particular instance of this type of problem. Here we are given a set of clients C, a set of *red* facilities $\mathcal{R}$, and a set of *blue* facilities $\mathcal{B}$. These are located in some metric space with metric distances $d(i,j) \geq 0$ for any two $i, j \in C \cup \mathcal{R} \cup \mathcal{B}$. Additionally, we are given two integer bounds $k_r \leq |\mathcal{R}|$ and $k_b \leq |\mathcal{B}|$. The

goal is to select/open k_r red facilities R and k_b blue facilities B to minimize

$$\text{cost}(R \cup B) := \sum_{j \in C} \min_{i \in R \cup B} d(i,j)\,.$$

The classic NP-hard k-Median problem appears as a special case when, say, $\mathcal{R} = \emptyset$. Thus, Budgeted Red-Blue Median is NP-hard. In this paper, we focus on approximation algorithms for Budgeted Red-Blue Median, in particular on local search techniques.

1.1 Previous Work

The study of Budgeted Red-Blue Median from the perspective of approximation algorithms was initiated by Hajiaghayi, Khandekar, and Kortsarz [9], where they obtain a constant-factor approximation by a local search algorithm that iteratively tries to swap one red and/or one blue facility in the given solution. The do not specify the constant in their analysis, but it looks to be greater than 8. Citing [9] as inspiration, Krishnaswamy et al. studied a generalization of Budgeted Red-Blue Median known as Matroid Median [10]. Here, a matroid structure is given over the set of facilities and we can only open a set of facilities if they form an independent set in the matroid. They obtain a constant-factor approximation for Matroid Median through rounding an LP relaxation. This was later refined to an 8-approximation by Swamy [15].

The special case of k-Median is a classic optimization problem and has received a lot of attention from both theoretical and practical communities. The best approximation guarantee known so far is 2.675 by Byrka et al. [5], who build heavily on the breakthrough work of Li and Svensson for the problem [11].

While local search techniques have been used somewhat infrequently in the design of approximation algorithms in general, it may be fair to say that they have seen the most success in facility location problems. For almost 10 years, the best approximation for k-Median was based on a local search algorithm. Arya et al. [3] show that a multiple-swap heuristic leads to a $(3+\epsilon)$-approximation for k-Median for any constant $\epsilon > 0$. This analysis was simplified in [8], which inspires much of our analysis.

Another textbook application of local search is a $(1+\sqrt{2})$-approximation for Uncapacitated Facility Location [3, 6]. Local search has been very helpful in approximating Capacitated Facility Location, the first constant-factor approximation was by Pál, Tardos, and Wexler [13] and the current best approximation is a $(5+\epsilon)$-approximation by Bansal, Garg, and Gupta [4]. In the special case when all capacities are uniform, Aggarwal et al. [1] obtain a 3-approximation. Even more examples of local search applied to other facility location variants can be found in [2, 7, 8, 12, 14].

1.2 Our Results and Techniques

We show that a multiswap generalization of the local search algorithm considered in [9] is a $(5+\epsilon)$-approximation for Budgeted Red-Blue Median. That is, for a value p say the p-swap heuristic is the algorithm that, upon given an initial feasible solution, tries to swap up to p facilities of each colour. If no such swap produces a cheaper solution, it terminates. Otherwise, it iterates with the now cheaper solution. Algorithm 1 in Section 2 gives the formal description of our algorithm.

Say that a solution is locally optimum for the p-swap heuristic if no cheaper solution can be found by swapping up to p facilities of each colour. Let OPT denote the cost of an optimum solution. Our main result is the following.

▶ **Theorem 1.** *Any locally optimum solution for the p-swap heuristic has cost at most* $(5 + O(1/\sqrt{p})) \cdot OPT$.

Using standard techniques (briefly mentioned in Section 2), this readily leads to a polynomoial-time approximation algorithm. By choosing $p = \theta(1/\epsilon^2)$ we have the following.

▶ **Theorem 2.** *For any constant* $\epsilon > 0$, Budgeted Red-Blue Median *admits a polynomial-time* $(5 + \epsilon)$*-approximation.*

This improves over the 8-approximation for Budgeted Red-Blue Median in [15].

We emphasize the approximation guarantee from Theorem 1 result is for Budgeted Red-Blue Median only, the 8-approximation in [15] is still the best approximation for the general Matroid Median problem. Indeed, [10] show that Matroid Median cannot be approximated within any constant factor using any constant number of swaps even in the generalization of Budgeted Red-Blue Median where there can be a super-constant number facility colours.

We also present a lower bound that matches our analysis up the lower order terms.

▶ **Theorem 3.** *For any integers* p, ℓ *with* $1 \leq p \leq \ell/2$*, there is an instance of* Budgeted Red-Blue Median *that has a locally-optimum solution for the p-swap heuristic with cost at least* $\left(5 + \frac{2}{p} - \frac{10p}{\ell+1}\right) \cdot OPT$.

By letting $\ell \to \infty$ but keeping p fixed, we see that the p-swap heuristic cannot guarantee a ratio better than $5 + \frac{2}{p}$. So, Theorem 1 is tight up to lower order terms. Also, for $p = 1$ we see that the single-swap heuristic analyzed in [9] is not better than a 7-approximation.

Local search techniques are typically analyzed by constructing a set of candidate *test swaps* where some facilities in the optimum solution are swapped in and some from the local optimum are swapped out in order to generate a useful inequality. One of the main features of the k-Median analysis in [3] and [8] is that such swaps can be considered that ensure each facility in the global optimum is swapped in once and, by averaging some swaps, each facility in the local optimum is swapped out to the extent of at most $1 + O(\epsilon)$ times. Each time a facility in the local optimum is swapped out, they pay an additional 2 times the global optimum cost for some clients to reassign them.

We obtain only a $5 + \epsilon$ approximation because we end up swapping out some facilities in the local optimum solution to the extent of $2 + O(\epsilon)$, thereby paying an additional $2 + O(\epsilon)$ more than in the k-Median analysis. Ultimately, this is because some of our initial swaps generate inequalities that depend *positively* on client assignment costs in the local optimum. So we consider additional swaps that do not introduce any more positive dependence on the local optimum to cancel them out.

This issue was also encountered in the analysis in [9]. In some sense, we are showing that this is the only added difficulty over the standard k-Median analysis. However, the averaging arguments we use are a bit more sophisticated than the analysis for k-Median.

1.3 Organization

Section 2 presents the algorithm and describes some useful notation. In particular, it presents a way to decompose the global and local optimum solution into structured groups that are examined in the analysis. Section 3 analyzes the quality of locally optimum solutions to prove Theorem 1. Section 4 proves Theorem 3 with an explicit construction of a bad example. We conclude with some remarks in Section 5.

2 Notation and Preliminaries

Say that a *feasible solution* is a pair (R, B) of subsets $R \subseteq \mathcal{R}$ and $B \subseteq \mathcal{B}$ with $|R| = k_r$ and $|B| = k_b$. Algorithm 1 describes the local search algorithm.

Algorithm 1 The p-Swap Heuristic for Budgeted Red-Blue Median

Let (R, B) be an arbitrary feasible solution.
while there is some feasible solution (R', B') with $|R - R'| \leq p$
and $|B - B'| \leq p$ and $\text{cost}(R' \cup B') < \text{cost}(R \cup B)$ **do**
$(R, B) \leftarrow (R', B')$
end while
return (R, B)

While a single iteration of Algorithm 1 can be executed in $n^{O(p)}$ (where n is the total number of locations in the problem), it may be that the number of iterations is not polynomially bounded. We can employ a well-known trick to ensure it does terminate in a polynomial number of steps while losing only another ϵ in our analysis. The idea is to perform the update only if $\text{cost}(R' \cup B') \leq (1 - \epsilon/\Delta) \cdot \text{cost}(R \cup B)$ where Δ is some quantity that is polynomial in the input size. Our analysis is compatible with this approach; one can check that the total weight of all inequalities we consider is polynomially bounded. For example, see [3] for details. We do not focus any further on this issue, and instead work toward analyzing the cost of the solutions produced by Algorithm 1 as it is stated.

From now on, let $S = R \cup B$ with $R \subseteq \mathcal{R}, B \subseteq \mathcal{B}$ denote an arbitrary local optimum solution. That is, there is no cheaper solution (R', B') with $|R - R'| \leq p$ and $|B - B'| \leq p$. Also fix a global optimum solution $O = R^* \cup B^*$ where $R^* \subseteq \mathcal{B}$ and $B^* \subseteq \mathcal{B}$. We assume that $S \cap O = \emptyset$. This is without loss of generality, as we can duplicate each facility location in the input and say that S use the first copies and O use the second copies. It is easy to verify that S is still a local optimum solution.

To help analyze the cost, we will introduce some notation. For any client $j \in \mathcal{C}$, let $s_j \in S$ denote the local optimum facility is closest to j and $o_j \in O$ denote the global optimum facility that is closest to j, breaking ties arbitrarily. For brevity, let $c_j = d(j, s_j)$ be the cost of assigning j in the local optimum and $c^*_j = d(j, o_j)$ the cost of assigning j in the global optimum. Thus, $\text{cost}(S) = \sum_{j \in C} c_j$ and $\text{cost}(O) = \sum_{j \in C} c^*_j$. For any facility $i^* \in O$ we let $N^*(i^*) = \{j \in C : o_j = i^*\}$ and for any $i \in S$ we let $N(i) = \{j \in C : s_j = i\}$.

Let $\phi : O \to S$ map each facility in O to its nearest facility in S, breaking ties arbitrarily. For $i \in S$, let $\deg(i) = |\phi^{-1}(i)|$. If $\deg(i) \neq 0$, let $\text{cent}(i)$ be the facility in $\phi^{-1}(i)$ that is closest to i, again breaking ties arbitrarily.

We also borrow some additional notation from [9].

▶ **Definition 4** (very good, good, bad facility)**.** A facility $i \in S$ is *very good* if $\deg(i) = 0$, *good* if no $i^* \in \phi^{-1}(i)$ has the same colour as i, and *bad* otherwise.

The analysis in [9] divides $S \cup O$ into *blocks* that satisfy certain properties. We require slightly stronger properties than their blocks guarantee. We also use a slightly different notion of what it means for some $i \in S$ to be a *leader*. The required properties are summarized in the following lemma, which also serves as our definition of a block. The proof can be found in the full version of our work.

▶ **Lemma 5.** *We can partition $S \cup O$ into* blocks T *satisfying the following properties.*
- $|T \cap R| = |T \cap R^*|$ *and* $|T \cap B| = |T \cap B^*|$.

- *For every $i \in S \cap T$, we also have $\phi^{-1}(i) \subseteq T$. For every $i^* \in O \cap T$, we have $\phi(i^*) \in T$.*
- *There is some facility $\hat{i} \in T \cap S$ with $\deg(\hat{i}) > 0$ designated as the* leader *that has the following properties. Every other $i \in T \cap S - \{\hat{i}\}$ is either good or very good and all good $i \in T \cap S - \{\hat{i}\}$ have the same colour.*

We will focus on analyzing one block at a time to prove the approximation guarantee. This provides us with a cleaner way to describe the test swaps and the additional structure will help handle the inevitable cases where we have to swap out some $i \in S$ but cannot swap in all of $\phi^{-1}(i)$. For example, this can happen if all blue facilities $i \in B$ have $\deg(i)$ being very large (so all $\deg(i') = 0$ facilities are red). We will still need to close some of them in order to open facilities in B^* when generating bounds via test swaps.

Before delving into the analysis we note the following two bounds. The first has been used extensively in local search analysis and was first proven in [3] and the second was proven in [9].

▶ **Lemma 6.** *For any $j \in C$, $d(j, \phi(o_j)) - c_j \leq 2c_j^*$.*

▶ **Lemma 7.** *For any $j \in C$, $d(j, \text{cent}(\phi(o_j))) - c_j \leq 3c_j^* + c_j$.*

Finally, we often consider operations that add or remove a single item from a set (usually to exclude the leader $\hat{i}$ of a block from some parts of the analysis). To keep the notation cleaner we let $A + i$ and $A - i$ refer to $A \cup \{i\}$ and $A - \{i\}$, respectively, for sets of facilities A and a single facility i.

3 Multiswap Analysis

Recall that we are assuming $S = R \cup B$ is a locally optimum solution with respect to the heuristic that swaps at most p facilities of each colour and that $O = R^* \cup B^*$ is some globally optimum solution. We assume $p = t^2 + 1$ for some sufficiently large integer t.

Focus on a single block T. For brevity, let $T_R^* = T \cap R^*$ and $T_B^* = T \cap B^*$ denote the red and blue facilities from the optimum solution in T. Similarly let $T_R = T \cap R$ and $T_B = T \cap B$ denote the red and blue facilities from the local optimum solution in T. The main goal of this section is to demonstrate the following inequality for group T.

▶ **Theorem 8.** *For some absolute constant γ that is independent of t, we have*

$$0 \leq \sum_{j \in N^*(T_R^* \cup T_B^*)} \left[\left(1 + \frac{\gamma}{t}\right) c_j^* - c_j \right] + \sum_{j \in N(T_R \cup T_B)} \left[\left(4 + \frac{\gamma}{t}\right) \cdot c_j^* + \frac{\gamma}{t} \cdot c_j \right].$$

Theorem 1 follows by summing over all associated inequalities for the various blocks.

The analysis breaks into a number of cases based on whether T_R^* and/or T_B^* are large. In each of the cases, we use the following notation and assumptions. Let $\hat{i}$ denote the leader in T. Without loss of generality, assume all other $i \in T_B \cup T_R$ with $\deg(i) > 0$ are blue facilities. Let $\overline{B} = \{i \in T_B - \hat{i} : \deg(i) > 0\}$, so $\text{cent}(\overline{B})$ denotes $\{i^* \in T_B^* \cup T_R^* : \text{cent}(\phi(i^*)) = i^*\}$. Figure 1 illustrates this notation.

The swaps we consider in these cases are quite varied, but we always ensure we swap in $\text{cent}(i)$ whenever some $i \in S \cap T$ with $\deg(i) > 0$ is swapped out. This way, we can always bound the reassignment cost of each client j by using either Lemma 6 or Lemma 7.

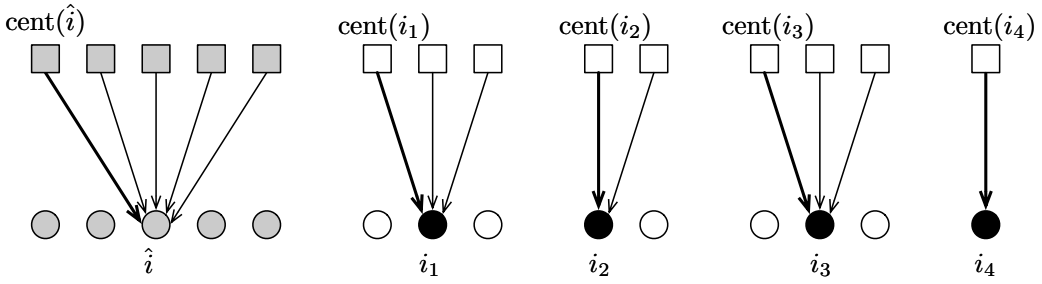

Figure 1 Illustration of a block T. The facilities on the top are in $T \cap O$ and the facilities on the bottom are in $T \cap S$. The directed edges depict ϕ, and the thick edges connect cent(i) to i. The facilities coloured black lie in $\mathcal{B}$, the facilities coloured white lie in $\mathcal{R}$, and the facilities coloured grey could either lie in $\mathcal{B}$ or $\mathcal{R}$. Note that $\overline{B} = \{i_1, i_2, i_3, i_4\}$ and cent($\overline{B}$) = {cent(i_1), cent(i_2), cent(i_3), cent(i_4)}. The layout of the figure is suggestive of how the block was constructed by adding "good" groups to the initial bad group in the procedure of generating blocks. The details of this procedure can be found in the full version of our work.

3.1 Case $|T_R^*| \leq t^2, |T_B^*| \leq t$

In this case, we simply swap out all of $T_R \cup T_B$ and swap in all of $T_R^* \cup T_B^*$. Because $R \cup B$ is a locally optimum solution and because this swaps at most t^2 facilities of each colour, we have:

$$0 \leq \text{cost}(S \cup (T_R^* \cup T_B^*) - (T_R \cup T_B)) - \text{cost}(S)\,.$$

Of course, after the swap each client will move to its nearest open facility. As is typical in local search analysis, we explicitly describe a (possibly suboptimal) reassignment of clients to facilities to upper bound this cost change.

Each $j \in N^*(T_R^* \cup T_B^*)$ is moved from s_j to o_j which incurs an assignment cost change of exactly $c_j^* - c_j$. Each $j \in N(T_R \cup T_B) - N^*(T_R^* \cup T_B^*)$ is moved to $\phi(o_j)$. Note that $\phi(o_j) \notin T$ so it remains open after the swap. By Lemma 6, the assignment cost change is bounded by $2c_j^*$. Every other client j that has not already been reassigned remains at s_j and incurs no assignment cost change. Thus,

$$0 \leq \sum_{j \in N^*(T_R^* \cup T_B^*)} (c_j^* - c_j) + \sum_{j \in N(T_R \cup T_B)} 2c_j^*$$

which is even better than what we are required to show for Theorem 8.

We note that the analysis Section 3.4 could be extended to subsume this analysis (with a worse constant), but we have included it here anyway to provide a gentle introduction to some of the simpler aspects of our approach.

3.2 Case $|T_R^*| \geq t^2 + 1, |T_B^*| \geq t + 1$

We start by briefly discussing some challenges in this case. In the worst case, all of the $i_b \in T_B$ have deg(i) being very large. The issue here is that we need to swap in each $i_b^* \in T_B^*$ in order to generate terms of the form $c_j^* - c_j$ for j with $o_j = i_b^*$. But this requires us to swap out some i_b. Since we cannot swap in all of $\phi^{-1}(i_b)$, we resort to only swapping in cent(i_b).

Any client j with s_j being closed and $o_j \in \phi^{-1}(i_b) - \text{cent}(i_b)$ cannot be reassigned to $\phi(o_j)$, so we send it to cent($\phi(o_j)$) and use Lemma 7 to bound the reassignment cost. This

leaves a term of the form $+c_j$, so we have to consider additional swaps involving $-c_j$ in their bound to cancel this out. These additional swaps cause us to lose a factor of roughly 5 instead of 3.

Another smaller challenge is that we do not want to swap out the leader $\hat{i} \in T \cap S$ for a variety of technical reasons. However, since $|T_R^*|$ and $|T_B^*|$ are both big, this is not much of a problem. When we swap in some $i^* \in T \cap O$, we will just swap out a randomly chosen facility in $T \cap S - \hat{i}$ of the same colour. The probability any particular facility is swapped in this way is very small. Ultimately, each facility in $T \cap S - \hat{i}$ will be swapped out at most $2 + O(1/t)$ times in expectation.

To be precise, we partition the set of clients in $N(T_R \cup T_B)$ into two groups:

$$C_{bad} := N(\overline{B}) \cap N^*(T_R^* - \text{cent}(\overline{B})) \quad \text{and} \quad C_{ok} := N(T_R \cup T_B - \hat{i}) - C_{bad}.$$

We have omitted $N(\hat{i})$ from C_{ok} because we will not close $\hat{i}$.

The first group is dubbed *bad* because there may be a swap where both s_j and $\phi(o_j)$ are closed yet o_j is not opened so we can only use Lemma 7 to bound their reassignment cost. In fact, some clients $j \in C_{good}$ may also be involved in such a swap, but we are able to use an averaging argument for these clients to show that the resulting $+s_j$ term from using Lemma 7 appears with negligible weight and does not need to be cancelled.

We consider the following two types of swaps to generate our initial inequality.

- For each $i_b^* \in T_B^*$, choose a random $i_b \in T_B - \hat{i}$. If $i_b \notin \overline{B}$ (i.e. $\deg(i_b) = 0$) then simply swap out i_b and swap in i_b^*. If $i_b \in \overline{B}$ then swap out i_b and a random $i_r \in T_R - \hat{i}$ and swap in i_b^* and $\text{cent}(i_b)$.
- For each $i_r^* \in T_R^* - \text{cent}(\overline{B})$, swap in i_r^* and swap out a randomly chosen $i_r \in T_R - \hat{i}$.

By choosing facilities at "random", we mean uniformly at random from the given set and this should be done independently for each invokation of the swap.

▶ **Lemma 9.**

$$0 \le \sum_{j \in N^*(T_B^* \cup T_R^*)} \left(\frac{t+1}{t} \cdot c_j^* - c_j \right) + \sum_{j \in C_{ok}} \left[\left(2 + \frac{5}{t} \right) c_j^* + \frac{1}{t} c_j \right] + \frac{t+1}{t} \sum_{j \in C_{bad}} (3c_j^* + c_j) \,.$$

Proof. For brevity, we will let $\beta_R = \frac{|T_R|}{|T_R - \hat{i}|}$ and $\beta_B = \frac{|T_B|}{|T_B - \hat{i}|}$. Note that $\beta_R, \beta_B \le \frac{t+1}{t}$ and that either $\beta_R = 1$ or $\beta_B = 1$.

First consider a swap of the first type that swaps in $\{i_b^*, \text{cent}(i_b)\}$ and swaps out $\{i_b, i_r\}$ for some i_b with $\deg(i_b) > 0$. Because $R \cup B$ is a local optimum the cost of the solution does not decrease after performing this swap. We provide an upper bound on the reassignment cost.

Each $j \in N^*(\{i_b^*, \text{cent}(i_b)\})$ is reassigned from s_j to o_j and incurs an assignment cost change of $c_j^* - c_j$. Every client $j \in N(\{i_b, i_r\})$ that has not yet been reassigned is first moved to $\phi(o_j)$. If this $\phi(o_j)$ remains open, assign j to it. By Lemma 6, the assignment cost for j increases by at most $2c_j^*$. If $\phi(o_j)$ is not open then $\phi(o_j) = i_b$ (because $\deg(i_r) = 0$) so we instead move j to $\text{cent}(\phi(o_j)) = \text{cent}(i_b)$. Lemma 7 shows the assignment cost increases by at most $3c_j^* + c_j$. This can only happen if $s_j \in \{i_r, i_b\}$ and $\phi(o_j) = i_b$.

Combining these observations and using slight overestimates, we see

$$0 \le \sum_{j \in N^*(\{i_b^*, \text{cent}(i_b)\})} (c_j^* - c_j) + \sum_{\substack{j \in N(\{i_b, i_r\}) \\ \phi(o_j) \ne i_b}} 2c_j^* + \sum_{\substack{j \in N(\{i_b, i_r\}) \\ \phi(o_j) = i_b}} (3c_j^* + c_j). \tag{1}$$

Now, if the random choice for i_b in the swap has $\deg(i_b) = 0$, then swapping $\{i_b\}$ out and $\{i_b^*\}$ in generates an even simpler inequality:

$$0 \leq \sum_{j \in N^*(i_b^*)} (c_j^* - c_j) + \sum_{j \in N(i_b)} 2c_j^*. \tag{2}$$

To see this, just reassign each $j \in N^*(i_b^*)$ from s_j to o_j and reassign the remaining $j \in N(i_b)$ from s_j to $\phi(o_j)$ (which remains open because $\deg(i_b) = 0$) and use Lemma 6.

Consider the expected inequality that is generated for this fixed i_b^*. We start with some useful facts that follow straight from the definitions and the swap we just performed.

- Any $j \in N^*(\text{cent}(\overline{B}))$ has o_j being opened with probability $\frac{1}{|T_B - \hat{i}|}$.
- Any $j \in C_{bad}$ has s_j being closed with probability $\frac{1}{|T_B - \hat{i}|}$.
- Any $j \in C_{ok} - N(T_R)$ has s_j being closed with probability $\frac{1}{|T_B - \hat{i}|}$. When this happens, if o_j is not opened then $\phi(o_j)$ must be open. That is, $s_j \in C_{ok}$ means $o_j \in T_B^* \cup \text{cent}(\overline{B})$.

  Furthermore, if $o_j \in T_B^*$ then $\phi(o_j) = \hat{i}$ (by the structure of block T) which remains open. If $o_j \in \text{cent}(\overline{B})$ then either $\phi(o_j)$ was not closed, or else $\text{cent}(\phi(o_j)) = o_j$ was opened.
- Any $j \in C_{ok} \cap N(T_R)$ has s_j being closed with probability $\frac{|\overline{B}|}{|T_B - \hat{i}|} \cdot \frac{1}{|T_R - \hat{i}|}$. If o_j and $\phi(o_j)$ are closed, then we move j to $\text{cent}(\phi(o_j))$. However, this can only happen with probability $\frac{1}{|T_B - \hat{i}|} \cdot \frac{1}{|T_R - \hat{i}|}$ since it must be that $\phi(o_j)$ is the blue facility that was randomly chosen to be closed.

Averaging (1) over all random choices and using some slight overestimates we see

$$\begin{aligned} 0 \quad \leq \quad & \sum_{j \in N^*(i_b^*)} (c_j^* - c_j) + \frac{1}{|T_B - \hat{i}|} \cdot \sum_{j \in N^*(\text{cent}(\overline{B}))} (c_j^* - c_j) \\ & + \frac{1}{|T_B - \hat{i}|} \left[\sum_{j \in C_{bad}} (3c_j^* + c_j) + \sum_{j \in C_{ok} - N(T_R)} 2c_j^* \right] \\ & + \frac{1}{|T_B - \hat{i}|} \cdot \frac{1}{|T_R - \hat{i}|} \sum_{j \in C_{ok} \cap N(T_R)} (|\overline{B}| 2c_j^* + 3c_j^* + c_j). \end{aligned}$$

Summing over all $i_b^* \in T_B^*$ (i.e. over all swaps of the first type) shows

$$\begin{aligned} 0 \quad \leq \quad & \sum_{j \in N^*(T_B^*)} (c_j^* - c_j) + \beta_B \cdot \sum_{j \in N^*(\text{cent}(\overline{B}))} (c_j^* - c_j) \\ & + \beta_B \cdot \left[\sum_{j \in C_{bad}} (3c_j^* + c_j) + \sum_{j \in C_{ok} - N(T_R)} 2c_j^* \right] \\ & + \frac{\beta_B}{|T_R - \hat{i}|} \cdot \sum_{j \in C_{ok} \cap N(T_R)} ((2|\overline{B}| + 3)c_j^* + c_j). \end{aligned} \tag{3}$$

Next, consider the second type of swap that swaps in some $i_r^* \in T_R^* - \text{cent}(\overline{B})$ and swaps out some randomly chosen $i_r \in T_R - \hat{i}$. Over all such swaps, the expected number of times each $i_r \in T_R - \hat{i}$ is swapped out is $\frac{|T_R^*| - |\overline{B}|}{|T_R - \hat{i}|} = \beta_R - \frac{|\overline{B}|}{|T_R - \hat{i}|}$. In each such swap, we reassign $j \in N^*(i_r^*)$ from s_j to o_j and every other $j \in N(i_r)$ from j to $\phi(o_j)$ which is still open because $\deg(i_r) = 0$. Thus,

$$0 \leq \sum_{j \in N^*(T_R^* - \text{cent}(\overline{B}))} (c_j^* - c_j) + \left(\beta_R - \frac{|\overline{B}|}{|T_R - \hat{i}|} \right) \cdot \sum_{j \in C_{ok} \cap N(T_R)} 2c_j^* \,.$$

Scaling this bound by β_B, adding it to (3), and recalling $|T_R| \geq t^2$ shows

$$\begin{aligned} 0 \quad \leq \quad & \sum_{j \in N^*(T_B^*)} (c_j^* - c_j) + \beta_B \cdot \sum_{j \in N^*(T_R^*)} (c_j^* - c_j) \\ & + \beta_B \cdot \left[\sum_{j \in C_{bad}} (3c_j^* + c_j) + \sum_{j \in C_{ok} - N(T_R)} 2c_j^* + \right] \\ & + \beta_B \cdot \sum_{j \in C_{ok} \cap N(T_R)} \left[\left(2\beta_R + \frac{3}{t^2} \right) \cdot c_j^* + \frac{1}{t^2} \cdot c_j \right]. \end{aligned}$$

Recall that $\beta_B, \beta_R \leq \frac{t+1}{t}$ and also $\beta_B \cdot \beta_R \leq \frac{t+1}{t}$ to complete the proof of Lemma 9. ◀

Our next step is to cancel terms of the form $+c_j$ in the bound from Lemma 9 for $j \in C_{bad}$. To do this, we again perform the second type of swap for each $i \in T_R^* - \text{cent}(\overline{B})$ but reassign clients a bit differently in the analysis.

▶ **Lemma 10.**

$$0 \leq \sum_{j \in C_{bad}} (c_j^* - c_j) + \frac{t+1}{t} \cdot \sum_{j \in C_{ok} \cap N(T_R)} 2c_j^* .$$

Proof. For each $i_r^* \in T_R^* - \text{cent}(\overline{B})$, swap i_r^* in and a randomly chosen $i_r \in T_r - \hat{i}$. Rather than reassigning all $j \in N^*(i_r^*)$ to i_r^*, we only reassign those in $C_{bad} \cap N^*(i_r^*)$. Since $\deg(i_r) = 0$ then any other $j \in N(i_r)$ can be reassigned to $\phi(o_j)$ and which increases the cost by at most $2c_j^*$.

Summing over all i_r^*, observing that $C_{bad} \subseteq T_R^* - \text{cent}(\overline{B})$, and also observing that each $j \in C_{ok}$ has s_j closed at most $\beta_R \leq \frac{t+1}{t}$ times in expectation, we derive the inequality stated in Lemma 10. ◀

Adding the bounds stated in Lemmas 9 and 10 shows that Theorem 8 holds in this case.

3.3 Case $|T_R^*| \geq t^2 + 1, |T_B^*| \leq t$

In this case, we start by swapping in all of T_B^* and swapping out all of T_B (including, perhaps, $\hat{i}$ if it is blue). In the same swap, we also swap in $\text{cent}(T_B)$ and swap out a random subset of the appropriate number of facilities in $T_R - \hat{i}$. This is possible as $|T_R - \hat{i}| \geq t \geq |\text{cent}(T_B)|$. By random subset, we mean among all subsets of $T_r - \hat{i}$ of the necessary size, choose one uniformly at random.

As with Section 3.2, we begin with a definition of bad clients that is specific to this case:

$$C_{bad} := N(T_B) \cap N^*(T_R^* - \text{cent}(T_B)) .$$

Clients $j \in C_{bad}$ have both s_j and $\phi(o_j)$ being closed yet o_j is not opened and we cannot make this negligible with an averaging argument.

▶ **Lemma 11.**

$$0 \quad \leq \quad \sum_{j \in N^*(T_B^* \cup \text{cent}(T_B))} (c_j^* - c_j) + \frac{1}{t} \sum_{j \in N(T_R)} (3c_j^* + c_j) + \sum_{j \in C_{bad}} (3c_j^* + c_j)$$

Proof. After the swap, reassign every $j \in N^*(T_B^* \cup \text{cent}(T_B))$ from s_j to o_j, for a cost change of $c_j^* - c_j$. Every other j that has s_j being closed is first reassigned to $\phi(o_j)$. If this is not open, then further move j to $\text{cent}(o_j)$ which must be open because the only facilities $i \in T_R \cup T_B$ with $\deg(i) > 0$ that were closed lie in T_B and we opened $\text{cent}(T_B)$.

If $j \in N(T_B) - C_{bad}$ then $o_j \in T_B^* \cup \text{cent}(T_B)$ and we have already assigned j to o_j. If $j \in C_{bad}$ then we have moved j to $\text{cent}(\phi(o_j))$ and the cost change is $3c_j^* + c_j$ by Lemma 7.

Finally, if $j \in N(T_R)$ then we either move j to $\phi(o_j)$ or to $\text{cent}(\phi(o_j))$ if $\phi(o_j)$ is not open. The worst-case bound on the reassignment cost is $3c_j^* + c_j$ by Lemmas 6 and 7. However, note that $s_j \in T_R$ is closed with probability at most $1/t$ because we closed a random subset of $T_r - \hat{i}$ of size at most t and $|T_r - \hat{i}| \geq t^2$. ◀

We still need to swap in $T_R^* - \text{cent}(T_B)$. For each such facility i_r^*, swap in i_r^* and swap out a randomly chosen $i_r \in T_R - \hat{i}$. The analysis of these swaps is nearly identical to analysis of the second type of swaps in Section 3.2, so we omit it and merely summarize what we get by combining the resulting inequalities with the inequality from Lemma 11.

▶ **Lemma 12.**

$$0 \leq \sum_{j \in N^*(T_R^* \cup T_B^*)} (c_j^* - c_j) + \sum_{j \in N(T_R)} \left(\frac{t^2+1}{t^2} \cdot 2c_j^* + \frac{1}{t} \cdot (3c_j^* + c_j) \right) + \sum_{j \in C_{bad}} (3c_j^* + c_j) \,.$$

We cancel the $+c_j$ terms for $j \in C_{bad}$ with one further collection of swaps. For each $i_r^* \in T_R^* - \text{cent}(T_B)$ we swap in i_r^* and a randomly chosen $i_r \in T_R - \hat{i}$. The following lemma summarizes a bound we can obtain from these swaps. It is proven in essentially the same way as Lemma 10.

▶ **Lemma 13.**

$$0 \leq \sum_{j \in C_{bad}} (c_j^* - c_j) + \frac{t^2+1}{t^2} \cdot \sum_{j \in N(T_R)} 2c_j^* \,.$$

Adding this to the bound from Lemma 12 and recalling $C_{bad} \subseteq N(T_B)$ shows

$$0 \leq \sum_{j \in N^*(T_R^* \cup T_B^*)} (c_j^* - c_j) + \sum_{j \in N(T_R \cup T_B)} \left(\frac{t^2+3t+1}{t^2} \cdot 4c_j^* + \frac{1}{t} \cdot c_j \right) .$$

3.4 Case $|T_R^*| \leq t^2, |T_B^*| \geq t+1$

Because $\phi^{-1}(i) \subseteq T_R^*$ and $\deg(i) > 0$ for each $i \in \overline{B}$, then $|\overline{B}| \leq t^2$ as well. We will swap all of T_R^* for all of T_R, but we will also swap some blue facilities at the same time. Let $B' = \overline{B}$ and let $\overline{B}'$ be an arbitrary subset of T_B^* of size $|\overline{B}|$.

If $\hat{i} \notin T_R \cup B'$ then add $\hat{i}$ to B'. If $\text{cent}(\hat{i}) \notin T_R^* \cup \overline{B}'$ then add $\text{cent}(\hat{i})$ to $\overline{B}'$. At this point, $\left| |\overline{B}'| - |B'| \right| \leq 1$ Add an arbitrary $i_b^* \in T_B^* - \overline{B}'$ to $\overline{B}'$ or $i_b \in T_B - B'$ to B' to ensure $|\overline{B}'| = |B'|$.

We begin by swapping out $T_R \cup B'$ and swapping in $T_R^* \cup \overline{B}'$. The following list summarizes the important properties of this selection, the first point emphasizes that this swap will not improve the objective function since S is a locally optimum solution for the p-swap heuristic where $p = t^2 + 1$.

- $|B'| = |\overline{B}'| \leq t^2 + 1$ and $|T_R^*| \leq t^2$.
- T_R^* was swapped in and T_R was swapped out.
- For each $i \in T_R \cup T_B$ with $\deg(i) > 0$, i was swapped out and $\text{cent}(i)$ was swapped in.

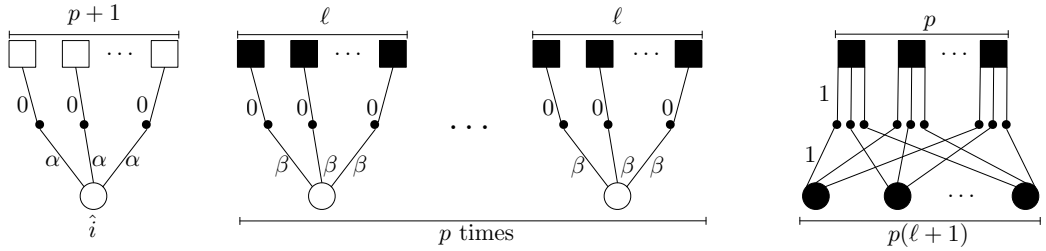

Figure 2 Illustration of the bad locality gap. Blue facilities are depicted with black and red facilities are depicted with white. The top facilities are the global optimum and the bottom are the local optimum (all of $\mathcal{R}$ and $\mathcal{B}$ is depicted in the picture). Each client is represented by a small black dot. There are $p^2 \cdot (\ell + 1)$ clients in the right group, one for each pair of local and global optimum facilities in the group. The metric is the shortest path metric of the presented graph, if two locations are not connected in the picture then their distance is a very large value. Every edge in the right-most group with $p^2(\ell + 1)$ clients has length 1. Recall $\beta = 2p$ and $\alpha = (\ell - p)2p$.

The following describes precisely the clients j that will be moved to $\text{cent}(\phi(o_j))$ in our analysis.

$$C_{bad} := [N(T_R \cup B') - N^*(T_R^* \cup \overline{B}')] \cap \{j : \phi(o_j) \in T_R \cup B'\}.$$

The following bound is generated from swapping out $T_R \cup B'$ and swapping in $T_R^* \cup \overline{B}'$ and follows from the same arguments we have been using throughout the paper.

▶ **Lemma 14.**

$$0 \le \sum_{j \in N^*(T_R^* \cup \overline{B}')} (c_j^* - c_j) + \sum_{j \in N(T_R \cup B') - C_{bad}} 2c_j^* + \sum_{j \in C_{bad}} (3c_j^* + c_j).$$

Next, let $\kappa_B : (T_B^* - \overline{B}') \to (T_B - B')$ be an arbitrary bijection of the remaining blue facilities that were not swapped. For every $i_b^* \in T_B^* - \overline{B}'$, consider the effect of swapping in i_b^* and swapping out $\kappa_B(i_b^*)$. Note that every facility i_b swapped out in this way has $\deg(i_b) = 0$. So we can derive two possible inequalities from such swaps.

$$0 \le \sum_{j \in N^*(i_b^*)} (c_j^* - c_j) + \sum_{j \in N(\kappa_B(i_b^*))} 2c_j^* \quad \text{and} \quad 0 \le \sum_{\mathrm{j} \in \mathrm{N}^*(\mathrm{i}_\mathrm{b}^*) \cap \mathrm{C}_{bad}} (\mathrm{c}_\mathrm{j}^* - \mathrm{c}_\mathrm{j}) + \sum_{\mathrm{j} \in \mathrm{N}(\kappa_\mathrm{B}(\mathrm{i}_\mathrm{b}^*))} 2\mathrm{c}_\mathrm{j}^*. \quad (4)$$

The second inequality follows from only reassigning clients $j \in N^*(i_b^*) \cap C_{bad}$ from s_j to o_j.

Adding the bound in Lemma 14 to the sum of both inequalities over all $i_b^* \in T_B^* - \overline{B}'$ and noting that $\kappa_B(T_B^* - \overline{B}) \cap (T_R \cup B') = \emptyset$, we see

$$0 \le \sum_{j \in N^*(T_R^* \cup T_B^*)} (c_j^* - c_j) + \sum_{j \in N(T_R \cup T_B)} 4c_j^*.$$

4 Locality Gaps

Here we prove Theorem 3. Let p, ℓ be integers satisfying $p \ge 1$ and $\ell \ge 2p$. Consider the instance with $k_r = p + 1$ and $k_b = p(\ell + 1)$ depicted in Figure 2. Here, $\beta = 2p$ and $\alpha = \beta \cdot (\ell - p)$.

The cost of the local optimum solution is $\alpha \cdot (p+1) + \beta \cdot p \cdot \ell + p^2(\ell+1)$ and the cost of the global optimum solution is simply $p^2(\ell+1)$. Through some careful simplification, we see the local optimum solution has cost at least $5 + \frac{2}{p} - \frac{10p}{\ell+1}$ times the global optimum solution.

To complete the proof of Theorem 3, we must verify that the presented local optimum solution indeed cannot be improved by swapping up to p facilities of each colour. The straightforward details appear in the full version of this paper.

5 Conclusion

We have demonstrated that a natural p-swap local search procedure for Budgeted Red-Blue Median is a $(5 + O(1/\sqrt{p}))$-approximation. This guarantees a better approximation ratio than the single-swap heuristic from [9], which we showed may find solutions whose cost is $(7-\epsilon) \cdot OPT$ for arbitrarily small ϵ. Our analysis is essentially tight in that the p-swap heuristic may find solutions whose cost is $(5 + \frac{2}{p} - \epsilon) \cdot OPT$.

More generally, one can ask about the p-swap heuristic for the generalization where there are many different facility colours. If the number of colours is part of the input then any local search procedure that swaps only a constant number of facilities in total cannot provide good approximation guarantees [10]. However, if the number of different colours is bounded by a constant, then perhaps one can get better approximations through multiple-swap heuristics.

However, generalizing the approaches taken with Budgeted Red-Blue Median to this setting seems more difficult; one challenge is that it is not possible to get such nicely structured blocks. It would also be interesting to see what other special cases of Matroid Median admit good local-search based approximations. For example, the Mobile Facility Location problem studied in [2] is another special case of Matroid Median that admits a $(3+\epsilon)$-approximation through local search.

Finally, the locality gap of the p-swap heuristic for k-Median is known to be $3 + \frac{2}{p}$ [3] and we have just shown it is at least $5 + \frac{2}{p}$ for Budgeted Red-Blue Median. Even if the multiple-swap heuristic for the generalization to a constant number of colours can provide a constant-factor approximation, this constant may be worse than the alternative 8-approximation obtained through Swamy's general Matroid Median approximation [15].

Abstract

We present a probabilistic polynomial-time reduction from the lattice Bounded Distance Decoding (BDD) problem with parameter $1/(\sqrt{2}\cdot\gamma)$ to the unique Shortest Vector Problem (uSVP) with parameter γ for any $\gamma > 1$ that is polynomial in the lattice dimension n. It improves the BDD to uSVP reductions of [Lyubashevsky and Micciancio, CRYPTO, 2009] and [Liu, Wang, Xu and Zheng, Inf. Process. Lett., 2014], which rely on Kannan's embedding technique. The main ingredient to the improvement is the use of Khot's lattice sparsification [Khot, FOCS, 2003] before resorting to Kannan's embedding, in order to boost the uSVP parameter.

1 Introduction

A (full-rank) lattice $\mathcal{L}$ in dimension n is the set of all integer linear relations of n linearly independent vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n \in \mathbb{Q}^n$. The minimum $\lambda_1(\mathcal{L})$ quantifies the discreteness of $\mathcal{L}$: the smallest Euclidean distance between two distinct lattice vectors is $\lambda_1(\mathcal{L})$. A standard computational problem on lattices is the so-called Bounded Distance Decoding problem (BDD_α): Given as inputs a basis $\mathbf{B} = (\mathbf{b}_i)_i$ of a lattice $\mathcal{L}$ and a vector $\mathbf{t} \in \mathbb{Q}^n$ (called target vector) within distance $\alpha \cdot \lambda_1(\mathcal{L})$ of $\mathcal{L}$, the goal is to find a vector $\mathbf{b} \in \mathcal{L}$ closest to $\mathbf{t}$. Here $\alpha > 0$ is a problem parameter, which may be a function of the lattice dimension n. The hardness of BDD was initially studied in the context of linear codes by Vardy in [22], and later in the context of lattices by Liu *et al.* in [14].

In communications theory, BDD models the task of decoding in the context of continuous channels with white Gaussian noise [6]. The information to be transmitted is stored in a

lattice vector, and the receiver should recover this vector from a noisy version thereof. The knowledge of the signal-to-noise ratio implies a bound on the distance from the noisy vector to the lattice. Decoding a white Gaussian noise channel can be seen as a version of BDD in which the distance to the lattice follows a prescribed distribution.

In cryptography, BDD is closely related to the Learning With Errors problem (LWE) [19], which serves as a security foundation for numerous cryptographic primitives. When the number of requested LWE samples is bounded (which is most often the case in cryptographic constructions), LWE may be viewed as a variant of BDD in which the offset from $\mathbf{t}$ to $\mathcal{L}$ is Gaussian (like in the decoding context), and $\mathcal{L}$ is randomly sampled.

A common approach to solve BDD is via Kannan's embedding technique [9, Se. 6]. The principle is to map the offset between $\mathbf{t}$ and a closest lattice vector to $\mathbf{t}$, to a shortest non-zero vector in an $(n+1)$-dimensional lattice. Lattice reduction [12, 20] and short lattice vector enumeration [8, 7] may then be used to find shortest non-zero vectors in the $(n+1)$-dimensional lattice. Formally, Kannan's embedding technique is a reduction from BDD to a variant of the Shortest Vector Problem (SVP) in which the pair of shortest non-zero vectors in the lattice under scope are known to be much shorter than any other lattice vector not parallel to them. For a lattice $\mathcal{L}$, we define the second minimum $\lambda_2(\mathcal{L})$ as the minimal radius of a zero-centered ball that contains two or more linearly independent vectors from $\mathcal{L}$. The unique Shortest Vector Problem (uSVP_γ) of parameter $\gamma \geq 1$ consists in finding a shortest non-zero vector in a lattice $\mathcal{L}$ described by an input basis $\mathbf{B} = (\mathbf{b}_i)_i$, under the promise that $\lambda_2(\mathcal{L}) \geq \gamma \cdot \lambda_1(\mathcal{L})$. This reduction was analyzed by Lyubashevsky and Micciancio in [15], who showed that $\text{BDD}_{1/(2\gamma)}$ reduces to uSVP_γ for any $\gamma \geq 1$. Later, Liu *et al.* [13] refined the analysis of Lyubashevsky and Micciancio and proved that BDD_{1/γ_1} reduces to uSVP_γ with $\gamma_1 = \sqrt{3/(4-\gamma^2)}\gamma + 1$, for any $\gamma \in (1, 1.9318)$. It is folklore [3, 17] that the analysis can be tightened even more, resulting in a proof that BDD_{1/γ_1} reduces to uSVP_γ with $\gamma_1 = (2\gamma^2 + 2\lfloor\gamma\rfloor\lfloor\gamma+1\rfloor)/(2\lfloor\gamma\rfloor+1)$, for any $\gamma \geq 1$. For the sake of completeness, we give a proof in Appendix A.1 of the full version. Note that in the case of $\gamma = 1$ (and in fact all integral γ), all three results are identical: $\text{BDD}_{1/2}$ reduces to uSVP_1.

Our result. We give a probabilistic polynomial-time reduction from $\text{BDD}_{1/(\sqrt{2}\gamma)}$ to uSVP_γ, for any $\gamma \geq 1$ that is polynomially bounded as a function of n. As clearly visible in Figure 1, this reduction supersedes all prior results with respect to the BDD problem parameter. In particular, we reduce $\text{BDD}_{1/\sqrt{2}}$ to uSVP_1. Our improvement comes with two weaknesses: the reduction is probabilistic and restricted to polynomially bounded γ. Like prior reductions, the dimension of the uSVP instance is only one more than the dimension of the BDD instance.

Technical overview. We illustrate our improvement with the case of $\text{BDD}_{1/2}$. Given the $\text{BDD}_{1/2}$ instance $(\mathbf{B}, \mathbf{t})$, Kannan's embedding consists in constructing the following uSVP_1 instance:

$$\mathbf{B}' = \begin{pmatrix} \mathbf{B} & \mathbf{t} \\ \mathbf{0} & d \end{pmatrix} \in \mathbb{Q}^{n+1},$$

with $d = \text{dist}(\mathbf{t}, \mathcal{L}) \leq \lambda_1(\mathcal{L})/2$, where $\mathcal{L}$ is the lattice spanned by $\mathbf{B}$ (in fact, the reduction does not know d, but this is a mere technical problem which can be handled easily, as explained in Section 2). If $\mathbf{c}$ denotes a closest vector to $\mathbf{t}$ in $\mathcal{L}$ then it may be proved that the vector $\mathbf{s}' = ((\mathbf{c}-\mathbf{t})^{\mathrm{T}}, -d)^{\mathrm{T}}$ is a shortest non-zero vector of lattice $\mathcal{L}'$ of basis $\mathbf{B}'$. Now, let $\mathbf{s}$ denote a shortest non-zero vector in $\mathcal{L}$ and assume that $\mathbf{t}$ is exactly halfway between $\mathbf{c}$ and $\mathbf{c}+\mathbf{s}$. Then both $\mathbf{s}'$ and $\mathbf{s}' + (\mathbf{s}^{\mathrm{T}}, 0)^{\mathrm{T}}$ in $\mathcal{L}'$ have norm $\sqrt{2} \cdot d$ but are linearly independent.

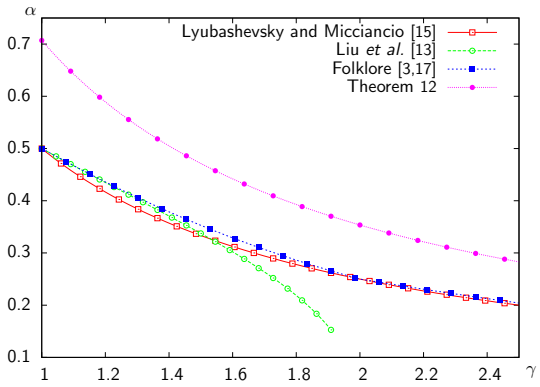

Figure 1 Comparison between prior reductions from BDD_α to uSVP_γ, and ours.

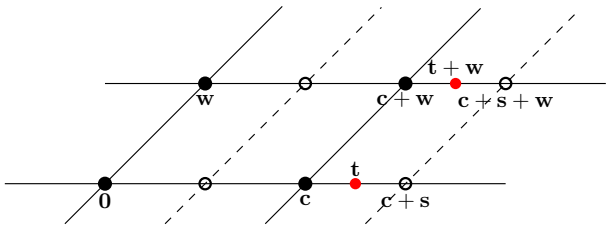

Figure 2 An example of sparsification for $\mathrm{BDD}_{1/2}$ (here $\mathbf{w} \in \mathcal{L}_{p,\mathbf{z}}/\mathcal{L}$).

This shows that we can have $\lambda_2(\mathcal{L}') = \lambda_1(\mathcal{L}')$ and obtain a uSVP_γ instance with $\gamma = 1$. This is a limitation of Kannan's embedding and hence of its analyzes.

We modify the reduction to increase the ratio $\lambda_2(\mathcal{L}')/\lambda_1(\mathcal{L}')$. To achieve this, we use lattice sparsification on $\mathcal{L}$. It provides a full-rank sublattice $\mathcal{L}_{\mathrm{sparse}} \subseteq \mathcal{L}$ that still contains a closest vector $\mathbf{c} \in \mathcal{L}$ to $\mathbf{t}$, but no other close-by vector. We consider the vectors of $\mathcal{L}$ whose coordinates with respect to a basis $\mathbf{B}$ satisfy a linear equation modulo some prime integer p: $\mathcal{L}_{\mathrm{sparse}} = \mathcal{L}_{p,\mathbf{z}} = \{\mathbf{b} \in \mathcal{L} : \langle \mathbf{z}, \mathbf{B}^{-1}\mathbf{b} \rangle = 0 \bmod p\}$, for some vector $\mathbf{z} \in \mathbb{Z}_p^n$. This technique was first introduced by Khot in [10, 11]. To guarantee that vectors in $\mathcal{L}$ remain in the sparsified set with probability close to $1/p$, a uniform coset of $\mathcal{L}_{p,\mathbf{z}}$ (modulo $\mathcal{L}$) was considered in [4, 5]. Technically, we use the formulation from [21] of the latter variant.

The aim of sparsification in our context is to keep a closest vector $\mathbf{c} \in \mathcal{L}$ to $\mathbf{t}$, and remove as many as nearby vectors of $\mathcal{L}$ as possible. After sparsification, vector $\mathbf{c}$ remains in the sparse lattice (with non-negligible probability), and all other remaining vectors are much further away from $\mathbf{t}$. For $\mathrm{BDD}_{1/2}$, a simple example of sparsification is shown in Figure 2: there are two points simultaneously closest to the target point; then sparsification is used to remove one of the closest points (either is fine); in the sparse lattice, the closest vector is much closer than any other lattice vector. In Figure 2, after sparsification, all the lattice vectors labelled with filled dots are kept, e.g., vector $\mathbf{c} + \mathbf{w}$, and other vectors labelled with hollow dots are removed, e.g., vector $\mathbf{c} + \mathbf{s} + \mathbf{w}$.

The probability of keeping a vector of $\mathcal{L}$ in the sparsified set is essentially $1/p$. As we want the probability of keeping $\mathbf{c}$ to be non-negligible, we are hence restricted to taking $p \leq \mathrm{poly}(n)$. As a result, we cannot remove more than polynomially many close-by vectors, because each

one individually is removed with probability $\approx 1 - 1/p$ (a precise statement is given in Lemma 8). To assess the limitation of our reduction, we are hence interested in the largest value of α such that for any lattice $\mathcal{L}$ and any vector $\mathbf{t}$, there are at most $\mathrm{poly}(n)$ vectors within distance $\alpha \cdot \lambda_1(\mathcal{L})$ from $\mathbf{t}$. The quantity $\alpha \cdot \lambda_1(\mathcal{L})$ can be viewed as the worst-case list-decoding radius. Interestingly, this problem was studied by Ajtai [1] and Micciancio [16] in the context of proving hardness of SVP. Proofs of the following two statements may be found in [18, Chap. 5]:

- For any lattice $\mathcal{L}$ and vector $\mathbf{t}$, there are $\leq 2n$ vectors of $\mathcal{L}$ within distance $\lambda_1(\mathcal{L})/\sqrt{2}$ from $\mathbf{t}$.
- For any $\alpha > 1/\sqrt{2}$, there exists $\varepsilon > 0$ such that for any sufficiently large n we can find an n-dimensional lattice $\mathcal{L}$ and a vector $\mathbf{t}$ such that there are $\geq 2^{n^\varepsilon}$ vectors of $\mathcal{L}$ within distance $\alpha \cdot \lambda_1(\mathcal{L})$ from $\mathbf{t}$.

The overall reduction consists in first sparsifying $\mathcal{L}$ to $\mathcal{L}_{p,\mathbf{z}}$ and shifting $\mathbf{t}$ (as we use a coset of $\mathcal{L}_{p,\mathbf{z}}$), and then resorting to Kannan's embedding. To increase the ratio $\lambda_2(\mathcal{L}')/\lambda_1(\mathcal{L}')$, we decrease the bottom-right entry in $\mathbf{B}'$ from d to $k \cdot d$ for some $k < 1$. Geometrically, this has the effect of limiting the contribution of the extra dimension. This idea was already used in [13], but we decrease k even further, to $1/\mathrm{poly}(n)$. An additional difficulty, related to this decrease of k, is that short vectors in $\mathcal{L}'$ may be obtained by using multiples of $\mathbf{t}$. Let $m \geq 2$ and $\mathbf{d} \in \mathcal{L}$ closest to $m\mathbf{t}$. Then, vector $((\mathbf{d} - m\mathbf{t})^{\mathrm{T}}, mkd)^{\mathrm{T}}$ may be very short (if very unlucky, it has norm mkd). We remove such annoying vectors with sparsification.

Open problems. In [15], Lyubashevsky and Micciancio considered the relative hardness of BDD and uSVP. They obtained a reduction from $\mathrm{BDD}_{1/(2\gamma)}$ to uSVP_γ, and a reduction from uSVP_γ to $\mathrm{BDD}_{1/\gamma}$ (for all $\gamma \geq 1$). This led them to conjecture that it may be possibly to show that (i)- $\mathrm{uSVP}_{\gamma/2}$ reduces to $\mathrm{BDD}_{1/\gamma}$, or (ii)- $\mathrm{BDD}_{1/\gamma}$ reduces to uSVP_γ, or (iii)- uSVP_γ reduces to $\mathrm{BDD}_{1/(\sqrt{2}\gamma)}$ and $\mathrm{BDD}_{1/(\sqrt{2}\gamma)}$ reduces to uSVP_γ. By showing the second half of (iii), (i) becomes very unlikely.

Independently, it would be interesting to make our reduction deterministic and let it work even for parameters γ that are not $\leq \mathrm{poly}(n)$.

Notation. For a lattice $\mathcal{L}$, a point $\mathbf{t}$, a radius r, we define $\mathcal{B}(\mathbf{t}, r) = \{\mathbf{x} : \|\mathbf{x} - \mathbf{t}\| \leq r\}$. We let $\mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}))$ denote the distance between $\mathbf{t}$ and lattice $\mathcal{L}(\mathbf{B})$. We always represent the basis of lattice in column form. If S is a finite set, we let $\#S$ denote its cardinality.

2 Reminders

In this section, we recall basic facts on lattices and lattice problems. We then consider lattice sparsification and its use in the context of BDD instances.

2.1 Lattice problems

We refer the reader to [18] for an introduction to the computational aspects of lattices.

▶ **Definition 1** (Lattice). An n-dimensional lattice $\mathcal{L} \subseteq \mathbb{Q}^m$ $(m \geq n)$ is a discrete additive subgroup of $\mathbb{R}^m$. The lattice $\mathcal{L}$ is the set of all integral linear combinations of n linearly independent basis vectors $\mathbf{B} = \{\mathbf{b}_1, \cdots, \mathbf{b}_n\} \subseteq \mathbb{Q}^m$. In other words, we have

$$\mathcal{L}(\mathbf{B}) = \left\{ \sum_{i \in [n]} u_i \mathbf{b}_i : \ \mathbf{u} \in \mathbb{Z}^n \right\}.$$

▶ **Definition 2** (Successive minima)**.** For any lattice $\mathcal{L}$, the i-th minimum $\lambda_i(\mathcal{L})$ is the radius of the smallest ball with center $\mathbf{0}$ and containing i linearly independent lattice vectors:

$$\lambda_i(\mathcal{L}) = \inf\{r : \dim(\mathrm{span}(\mathcal{L} \cap \mathcal{B}(\mathbf{0}, r))) \geq i\}.$$

In this work, we investigate the respective hardness of uSVP_γ and BDD_α defined below, when the lattice dimension n goes to infinity. The problem parameters γ and α can be functions of n.

▶ **Definition 3** (Unique Shortest Vector Problem (uSVP_γ))**.** Let $\gamma \geq 1$. Given as input a lattice basis $\mathbf{B}$ such that $\lambda_2(\mathbf{B}) \geq \gamma \cdot \lambda_1(\mathbf{B})$, the goal is to find a non-zero vector $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ of norm $\lambda_1(\mathcal{L}(\mathbf{B}))$. The Shortest Vector Problem (SVP) corresponds to $\gamma = 1$.

In the literature (in [15], for example), uSVP is sometimes be defined with a strict lower bound on $\lambda_2(\mathbf{B})$. We allow equality (as in [13]), as it is more convenient in our proofs. Note that Lemma 5 below implies that these two variants are equivalent.

▶ **Definition 4** (Bounded Distance Decoding (BDD_α))**.** Let $\alpha > 0$. Given as inputs a lattice basis $\mathbf{B}$ and a vector $\mathbf{t}$ such that $\mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \leq \alpha \cdot \lambda_1(\mathbf{B})$, the goal is to find a lattice vector $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ closest to $\mathbf{t}$.

Note that in some works, the range of α is restricted to $(0, 1/2)$. This is to guarantee that there is exactly one element of $\mathcal{L}$ in the ball of radius $\alpha \cdot \lambda_1(\mathcal{L})$ centered on $\mathbf{t}$. The problem is well-defined even for large α, and in this work we actually consider $\alpha \geq 1/2$.

In the next lemma, it is stated that BDD_α is equivalently hard for any parameter α' that is within a factor $(1 - 1/n)^c$ of α, for any constant c.

▶ **Lemma 5** ([15, Cor. 2])**.** *For any $\alpha > 0$, any constant $c > 0$, there is a polynomial-time reduction from BDD_α to $\mathrm{BDD}_{\alpha(1-1/n)^c}$.*

2.2 Approximation results

Given as input an n-dimensional lattice basis $\mathbf{B} \in \mathbb{Q}^{n \times n}$, it is possible to find a non-zero vector that has norm at most $2^{n/2} \cdot \lambda_1(\mathcal{L}(\mathbf{B}))$ in time polynomial in n and also the bit-sizes of the entries of $\mathbf{B}$, by using the LLL algorithm [12]. Further, by using the Babai round-off algorithm [2] with inputs an n-dimensional lattice basis $\mathbf{B} \in \mathbb{Q}^{n \times n}$ and a target vector $\mathbf{t} \in \mathbb{Q}^n$, one obtains an approximation of the distance between $\mathbf{t}$ and $\mathcal{L}(\mathbf{B})$ within a factor $2^{n/2}$ in time polynomial in n and also the bit-sizes of the entries of $\mathbf{B}$ and $\mathbf{t}$.

▶ **Lemma 6** ([12, Prop. 1.6])**.** *There exists a polynomial-time algorithm that, given as input an n-dimensional lattice basis $\mathbf{B} \in \mathbb{Q}^{n \times n}$, outputs $\ell \in \lambda_1(\mathcal{L}) \cdot [1, 2^{n/2})$.*

▶ **Lemma 7** ([2, Thm. 3.1])**.** *There exists a polynomial-time algorithm that, given as input an n-dimensional lattice basis $\mathbf{B} \in \mathbb{Q}^{n \times n}$ and a target vector $\mathbf{t} \in \mathbb{Q}^n$, outputs $d \in \mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \cdot [1, 2^{n/2})$.*

We will rely on much tighter approximations to $\lambda_1(\mathcal{L}(\mathbf{B}))$ (resp. $\mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}))$) than provided by Lemmata 6 and 7. We explain here why we may assume that we know $\ell \in \lambda_1(\mathcal{L}(\mathbf{B})) \cdot [1, 1/(1 - 1/n))$ (resp. $d \in \mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \in [1, 1/(1 - 1/n))$).

Our reduction is from BDD, whose candidate solutions can be compared in polynomial time. Assume the reduction finds the optimal solution in one case among polynomially many, but that we do not know which one. Then we may call the reduction this polynomially many times, and keep a best solution among the returned ones. Concretely, our reduction will be

proved correct if we know a tight approximation to $\lambda_1(\mathcal{L}(\mathbf{B}))$ and $\mathrm{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}))$, where $(\mathbf{B}, \mathbf{t})$ is the BDD instance. We can assume without loss of generality that we have these tight approximations, as the interval $[1, 2^{n/2})$ may be covered by polynomially many intervals of the form $x \cdot [1, 1/(1-1/n))$ for well-chosen rational x's.

2.3 Lattice sparsification

Our techniques rely on lattice sparsification, and, more concretely, on the following lemma.

▶ **Lemma 8** ([21, Cor. 2.16]). *For any prime p, collection of vectors $\mathbf{v}_1, \cdots, \mathbf{v}_N \in \mathbb{Z}_p^n \setminus \{\mathbf{0}\}$, and $\mathbf{x} \notin \{\mathbf{v}_i\}_{i \le N}$, we have*

$$\frac{1}{p} - \frac{N}{p^2} - \frac{N}{p^{n-1}} \le \Pr_{\mathbf{z},\mathbf{u} \hookleftarrow U(\mathbb{Z}_q^n)} \left[\begin{array}{ll} \forall i, & \langle \mathbf{z}, \mathbf{v}_i + \mathbf{u} \rangle \neq 0 \bmod p \\ & \langle \mathbf{z}, \mathbf{x} + \mathbf{u} \rangle = 0 \bmod p \end{array} \right] \le \frac{1}{p} + \frac{1}{p^n}.$$

The upper bound in Lemma 8 is not used in this work, but we keep it to show that the difference between the upper and lower bound is small, and thus that the lower bounds is almost tight. Lemma 8 leads to the definition of a sublattice that will be used in our reduction from BDD to uSVP. The lemma below explains that we can efficiently compute a basis of the sublattice.

▶ **Lemma 9.** *There exists a polynomial-time algorithm which, given as inputs a basis $\mathbf{B} \in \mathbb{Q}^{n \times n}$ of an n-dimensional lattice $\mathcal{L}$, an integer p and a vector $\mathbf{z} \in \mathbb{Z}_p^n$, outputs a basis $\mathbf{B}_{p,\mathbf{z}}$ of the lattice $\mathcal{L}_{p,\mathbf{z}} = \{\mathbf{x} \in \mathcal{L} \mid \langle \mathbf{z}, \mathbf{B}^{-1}\mathbf{x} \rangle = 0 \bmod p\}$.*

Proof. According to the definition of the lattice $\mathcal{L}_{p,\mathbf{z}}$, we have

$$\langle \mathbf{z}, \mathbf{y} \rangle = 0 \bmod p,$$

where $\mathbf{y} = \mathbf{B}^{-1}\mathbf{x}$ and $\mathbf{x} \in \mathcal{L}_{p,\mathbf{z}}$. We can obtain a basis $\mathbf{S}$ of the kernel $\mathbf{y}$ over $\mathbb{Z}^n$. We compute the column Hermite normal form of $\begin{bmatrix} \mathbf{S} & p\mathbf{I}_n \end{bmatrix} \in \mathbb{Z}^{n \times 2n}$; and obtain the nonzero columns $\mathbf{S}' \in \mathbb{Z}^{n \times n}$. The columns of $\mathbf{S}'$ generate the lattice orthogonal to $\mathbf{z} \pmod p$. In the end, we compute $\mathbf{B}_{p,\mathbf{z}} = \mathbf{B}\mathbf{S}'$, which is a basis for the lattice $\mathcal{L}_{p,\mathbf{z}}$. ◀

Below, we state that for any two lattice vectors in $\mathcal{L}$ with distance smaller than $p \cdot \lambda_1(\mathcal{L})$ where p is an integer, the coordinates of these two lattice vectors differ modulo p.

▶ **Lemma 10.** *For any basis $\mathbf{B}$, any integer p and any pair of lattice vectors $\mathbf{x} \neq \mathbf{v}$ with $\|\mathbf{x} - \mathbf{v}\| < p \cdot \lambda_1(\mathcal{L}(\mathbf{B}))$, we have that $\mathbf{B}^{-1}\mathbf{x} \neq \mathbf{B}^{-1}\mathbf{v} \bmod p$.*

Proof. For all lattice vector $\mathbf{a}$, we let $\widetilde{\mathbf{a}}$ denote its coordinate vector under the basis $\mathbf{B}$. Assume by contradiction that $\widetilde{\mathbf{x}} = \widetilde{\mathbf{v}} \bmod p$. Equivalently, we have $\mathbf{x} - \mathbf{v} \in p \cdot \mathcal{L}(\mathbf{B})$.

Combined with $\mathbf{x} \neq \mathbf{v}$, we have $\|\mathbf{x} - \mathbf{v}\| \ge p \cdot \lambda_1(\mathcal{L})$, which is in contradiction with $\|\mathbf{x} - \mathbf{v}\| < p \cdot \lambda_1(\mathcal{L})$. As a result, we have $\widetilde{\mathbf{x}} \neq \widetilde{\mathbf{v}} \bmod p$. ◀

The proof from [18] of the lemma below is by induction. It goes fast over a subtle counting argument when reducing the problem in dimension $n+1$ to dimension n. We briefly recall the proof and give more explanations on the counting argument in Appendix A.2 of the full version.

▶ **Lemma 11** ([18, Thm. 5.2]). *For any n-dimensional lattice $\mathcal{L}$ and any vector $\mathbf{t} \in \mathbb{Q}^n$, we have $\#\mathcal{L} \cap \mathcal{B}(\mathbf{t}, \lambda_1(\mathcal{L})/\sqrt{2}) \le 2n$.*

We will use the above three lemmas in the following way to tackle BDD. Consider the coordinate vectors (with respect to some arbitrary basis) of all lattice vectors in $\mathcal{B}(\mathbf{t}, r)$ with $r = \lambda_1(\mathcal{L})/\sqrt{2}$ and some arbitrary target vector $\mathbf{t}$. First, according to Lemma 10 with $p > 2\sqrt{2}$, we can obtain that one of the coordinate vectors differs from all the others modulo p. Further, by Lemma 8, a uniformly chosen vector $\mathbf{z}$ over $\mathbb{Z}_p$ is orthogonal to exactly one of the coordinate vectors (shifted by another uniformly chosen vector $\mathbf{u}$) with non-negligible probability. Assume that this orthogonal coordinates vector is the coordinates vector of a closest lattice vector to $\mathbf{t}$: this occurs with non-negligible probability as $\#\mathcal{L} \cap \mathcal{B}(\mathbf{t}, r) \leq 2n$. We can consider the sublattice $\mathcal{L}_{p,\mathbf{z}}$, which contains just this BDD solution and none of the other vectors of $\mathcal{L} \cap \mathcal{B}(\mathbf{t}, r)$. This will help us ensuring a large gap between the first two minima of the uSVP lattice in the BDD to uSVP reduction.

Note that $\mathbf{u}$ is necessary, as otherwise some superfluous vectors (including vector $\mathbf{0}$) could be multiples of the solution vector and hence always stay in $\mathcal{L}_{p,\mathbf{z}}$ if the solution vector does.

3 Reducing $\mathrm{BDD}_{1/(\sqrt{2}\gamma)}$ to u$\mathrm{SVP}_{\gamma(1+\varepsilon)}$

In this section, we use a $\mathrm{uSVP}_{\gamma(1+\varepsilon)}$ solver with $\varepsilon = \Omega(1/n)$ to solve $\mathrm{BDD}_{1/(\sqrt{2}\gamma)}$.

▶ **Theorem 12.** *Let $\gamma(n) \leq \mathrm{poly}(n)$. There is a probabilistic polynomial-time reduction from $\mathrm{BDD}_{1/(\sqrt{2}\gamma)}$ to $\mathrm{uSVP}_{\gamma(1+\varepsilon)}$, where $\varepsilon = \Omega(1/n)$.*

Thanks to Lemma 5, it suffices to reduce $\mathrm{BDD}_{(1-1/n)/(\sqrt{2}\gamma)}$ to $\mathrm{uSVP}_{\gamma(1+\varepsilon)}$. Let us first describe the reduction.

Algorithm 1. The $\mathrm{BDD}_{(1-1/n)/(\sqrt{2}\gamma)}$ to $\mathrm{uSVP}_{\gamma(1+\varepsilon)}$ reduction.

Input: a basis $\mathbf{B} = \{\mathbf{b}_i\}_{i\in[n]}$ of an n-dimensional lattice $\mathcal{L} \subseteq \mathbb{Q}^n$, and a target point $\mathbf{t} \in \mathbb{Q}^n$.

Output: a lattice point $\mathbf{c}$ such that $\|\mathbf{c} - \mathbf{t}\| = \mathrm{dist}(\mathbf{t}, \mathcal{L})$.

0. Guess $d_0 \in [d, d/(1-1/n))$ and $\ell_0 \in [\ell, \ell/(1-1/n))$, where $d = \mathrm{dist}(\mathbf{t}, \mathcal{L})$ and $\ell = \lambda_1(\mathcal{L})$ (see Section 2.2).

1. Compute p the smallest prime greater than $4\gamma n^2$.
Sample $\mathbf{z}, \mathbf{u}$ uniformly and independently in $\mathbb{Z}_p^n$.
Compute $\mathbf{w} = \mathbf{B}\bar{\mathbf{u}} \in \mathcal{L}$, such that $\bar{\mathbf{u}} = \mathbf{u} \bmod p$ and $\|\mathbf{t} + \mathbf{w}\| \geq (n+1)\ell_0/\sqrt{2}$.
Use the algorithm of Lemma 9 to compute a basis $\mathbf{B}_{p,\mathbf{z}}$ of $\mathcal{L}_{p,\mathbf{z}} = \{\mathbf{b} \in \mathcal{L} : \langle \mathbf{z}, \mathbf{B}^{-1}\mathbf{b}\rangle = 0 \bmod p\}$.

2. Set $k = 1/(n-1)$. Define

$$\mathbf{B}' = \begin{pmatrix} \mathbf{B}_{p,\mathbf{z}} & \mathbf{t}+\mathbf{w} \\ \mathbf{0} & kd_0 \end{pmatrix}.$$

3. Run the $\mathrm{uSVP}_{\gamma(1+\varepsilon)}$ solver on input $\mathbf{B}'$. Let $\mathbf{s}' = ((\mathbf{s}'_1)^{\mathrm{T}}, s'_2)^{\mathrm{T}}$ be its output. Output $\mathbf{s}'_1 + \mathbf{t}$.

It may be checked that the above algorithm runs in polynomial time. The rest of the section is devoted to proving its correctness.

In this reduction, we are given a $\mathrm{BDD}_{(1-1/n)/(\sqrt{2}\gamma)}$ instance $(\mathbf{B}, \mathbf{t})$. Let $\mathbf{c} \in \mathcal{L}$ be a closest vector to $\mathbf{t}$. In order to construct a uSVP instance, our strategy is to use lattice sparsification to keep only one closest vector $\mathbf{c} + \mathbf{w}$ for some lattice shift $\mathbf{w}$ closest to $\mathbf{t} + \mathbf{w}$ (the shift vector $\mathbf{w}$ comes from Lemma 8). As the sparsification results in a lattice, we not only keep $\mathbf{c} + \mathbf{w}$, but also the $m \cdot (\mathbf{c} + \mathbf{w})$'s for all $m \leq \gamma n$. Simultaneously, all other vectors inside the balls with centers $\{m \cdot (\mathbf{t} + \mathbf{w})\}_{m\leq\gamma n}$ and radius $\lambda_1(\mathcal{L})/\sqrt{2}$ are regarded

as superfluous vectors and removed through sparsification. For the first γ balls, we have $m \cdot (\mathbf{c}+\mathbf{w}) \in \mathcal{B}(m \cdot (\mathbf{t}+\mathbf{w}), \lambda_1(\mathcal{L})/\sqrt{2})$. We can keep exactly one vector inside every ball with sparsification over these balls. However, for $m > \gamma$, all closest points to $\mathbf{t}$ may fall out of the corresponding ball, but may end up in another relevant ball: vector $i \cdot (\mathbf{c}+\mathbf{w})$ may belong to $\mathcal{B}(j \cdot (\mathbf{t}+\mathbf{w}), \lambda_1(\mathcal{L})/\sqrt{2})$ for some $j \neq i$. As a consequence, there can be more than one lattice vector inside a ball, which may result in no gap between first two minima of the uSVP oracle input lattice. In order to avoid this, we make every two balls far away from each other by choosing $\mathbf{w}$ such that $\mathbf{t}+\mathbf{w}$ is long.

▶ **Lemma 13.** *Consider a basis $\mathbf{B}$ of an n-dimensional lattice $\mathcal{L}$, a vector $\mathbf{c} \in \mathcal{L}$ and a vector $\mathbf{t} \in \mathbb{R}^n$ such that $\|\mathbf{c}-\mathbf{t}\| \leq r = \lambda_1(\mathcal{L})/(\sqrt{2}\gamma)$ for some $\gamma > 0$. Let p prime with $p \geq n+1$. For any $\mathbf{z} \in \mathbb{Z}_p^n$, We have*

$$\Pr_{\mathbf{u},\mathbf{z} \hookleftarrow U(\mathbb{Z}_p^n)} \left[\begin{array}{ccc} \mathbf{c}+\mathbf{w} & \in & \mathcal{L}_{p,\mathbf{z}} \cap \mathcal{B}(\mathbf{t}+\mathbf{w}, \gamma \cdot r) \\ \mathbb{Z} \cdot (\mathbf{c}+\mathbf{w}) & \supseteq & \mathcal{L}_{p,\mathbf{z}} \cap \bigcup\limits_{i \leq \gamma n} \mathcal{B}(i \cdot (\mathbf{t}+\mathbf{w}), \gamma \cdot r) \end{array} \right] \geq \frac{1}{p} - \frac{N}{p^2} - \frac{N}{p^{n-1}},$$

where $\mathbf{w}$ is arbitrary such that $\mathbf{B}^{-1}\mathbf{w} = \mathbf{u} \bmod p$ and $N = \#\mathcal{L} \cap \cup_{i \leq \gamma n} \mathcal{B}(i \cdot (\mathbf{t}+\mathbf{w}), \gamma \cdot r)$.

Further, if $\mathbf{w}$ is chosen such that $\|\mathbf{t}+\mathbf{w}\| > \gamma(n+1)r$, we have, for all $i \in [\gamma n]$,

$$i \cdot (\mathbf{c}+\mathbf{w}) \notin \bigcup_{j \neq i, j \in [\gamma n]} \mathcal{B}\left(j \cdot (\mathbf{t}+\mathbf{w}), \gamma \cdot r\right).$$

Proof. For $i \in [\gamma n]$, we define $N_i = \#\mathcal{L} \cap \mathcal{B}(i \cdot \mathbf{t}, \gamma \cdot r) \setminus \{i \cdot \mathbf{c}\}$ and $\{\mathbf{v}_{ij}\}_{j \in [N_i]} = (\mathcal{L} \cap \mathcal{B}(i \cdot \mathbf{t}, \gamma \cdot r)) \setminus \{i \cdot \mathbf{c}\}$. For any $\mathbf{v} \in \mathcal{L}$, we use $\widetilde{\mathbf{v}}$ to denote the coordinate of $\mathbf{v}$ under the basis $\mathbf{B}$. We claim that, with probability $\geq 1/p - N/p^2 - N/p^{n-1}$, the vector $\mathbf{z}$ is orthogonal (modulo p) to $\widetilde{\mathbf{c}}$, and at the same time not orthogonal to any $\widetilde{\mathbf{v}}_{ij}$ for $i \in [\gamma n]$ and $j \in [N_i]$.

We have, for all $i \in [\gamma n]$ and $j \in [N_i]$,

$$\|i \cdot \mathbf{c} - \mathbf{v}_{ij}\| \leq i \cdot \|\mathbf{c}-\mathbf{t}\| + \|i \cdot \mathbf{t} - \mathbf{v}_{ij}\| \leq (n+1)(\gamma r) = \frac{n+1}{\sqrt{2}} \cdot \lambda_1(\mathcal{L}).$$

By choice of p, this is smaller than $p \cdot \lambda_1(\mathcal{L})$. Thanks to Lemma 10, we have $i \cdot \widetilde{\mathbf{c}} \neq \widetilde{\mathbf{v}}_{ij} \bmod p$. Moreover, as p is prime and $p \geq \gamma n + 1 > i$, we have $\widetilde{\mathbf{c}} \neq \frac{1}{i} \cdot \widetilde{\mathbf{v}}_{ij} \bmod p$.

Now we apply Lemma 8 with $\widetilde{\mathbf{c}}$ and $\{\frac{1}{i} \cdot \widetilde{\mathbf{v}}_{ij}\}_{i \in [\gamma n], j \in [N_i]}$. We have

$$\Pr_{\mathbf{z},\mathbf{u} \hookleftarrow U(\mathbb{Z}_p^n)} \left[\begin{array}{lcl} \forall i,j: & \langle \mathbf{z}, \frac{1}{i} \cdot \widetilde{\mathbf{v}}_{ij} + \mathbf{u} \rangle & \neq 0 \bmod p \\ & \langle \mathbf{z}, \widetilde{\mathbf{c}} + \mathbf{u} \rangle & = 0 \bmod p \end{array} \right] \geq \frac{1}{p} - \frac{N}{p^2} - \frac{N}{p^{n-1}}.$$

As p is prime and sufficiently large, the inequality $\langle \mathbf{z}, \frac{1}{i} \cdot \widetilde{\mathbf{v}}_{ij} + \mathbf{u} \rangle \neq 0 \bmod p$ is equivalent to $\langle \mathbf{z}, \widetilde{\mathbf{v}}_{ij} + i \cdot \mathbf{u} \rangle \neq 0 \bmod p$. Therefore

$$\Pr_{\mathbf{z},\mathbf{u} \hookleftarrow U(\mathbb{Z}_p^n)} \left[\begin{array}{lcl} \forall i,j: & \langle \mathbf{z}, \widetilde{\mathbf{v}}_{ij} + i \cdot \mathbf{u} \rangle & \neq 0 \bmod p \\ & \langle \mathbf{z}, \widetilde{\mathbf{c}} + \mathbf{u} \rangle & = 0 \bmod p \end{array} \right] \geq \frac{1}{p} - \frac{N}{p^2} - \frac{N}{p^{n-1}}.$$

This proves the first claim of the lemma.

Let $i \neq j \leq \gamma n$. Then, by the triangle inequality and the assumption on $\mathbf{w}$, we have:

$$\|i \cdot (\mathbf{c}+\mathbf{w}) - j \cdot (\mathbf{t}+\mathbf{w})\| \geq |j-i| \cdot \|\mathbf{t}+\mathbf{w}\| - i\|\mathbf{c}-\mathbf{t}\| > \gamma(n+1)r - (\gamma n)r = \gamma r.$$

This completes the proof of the lemma. ◀

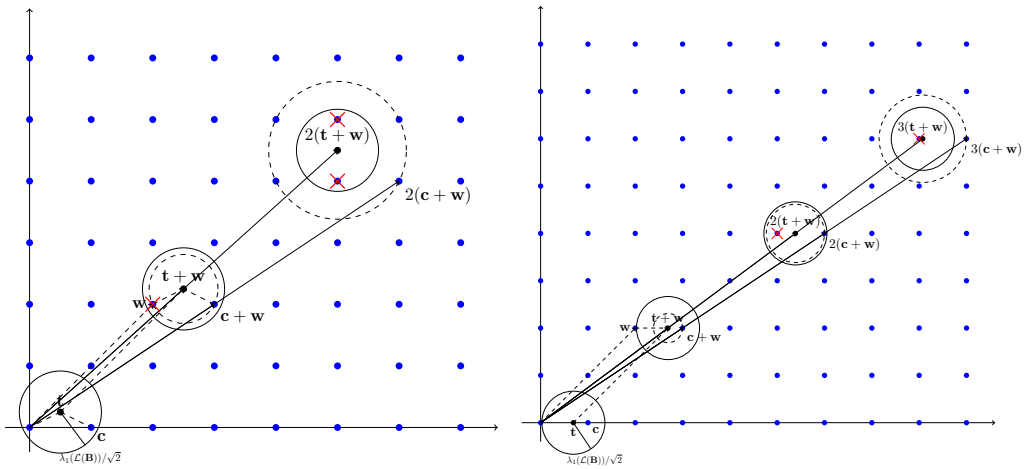

Figure 3 Sparsification for a $\mathrm{BDD}_{1/\sqrt{2}}$ instance (left) and for a $\mathrm{BDD}_{1/(2\sqrt{2})}$ instance (right).

As we have $p > 4\gamma n^2 \geq 2N$ (thanks to Lemma 11), with non-negligible probability, none of the vectors of $\mathcal{L}$ belonging to the γn balls is in the sparser lattice $\mathcal{L}_{p,\mathbf{z}}$, except possibly those in $\{i \cdot (\mathbf{c}+\mathbf{w})\}_{i\in[\gamma n]}$. In the rest of the reduction analysis, we assume that we are in this situation and do not repeatedly state that this occurs with non-negligible probability.

As an illustration of Lemma 13, we include Figure 3. In the case of $\gamma = 1$ (left subfigure), there are several plain balls with radius $\lambda_1(\mathcal{L})$, centered in $\mathbf{t}$, $\mathbf{t}+\mathbf{w}$ and $2(\mathbf{t}+\mathbf{w})$. The dashed balls illustrate the distance between $i \cdot (\mathbf{c}+\mathbf{w})$ and $i \cdot (\mathbf{t}+\mathbf{w})$ for all $i \in [\gamma n]$. We can see that $\mathbf{c}+\mathbf{w}$ (within the dashed ball) is inside the plain ball, and $2 \cdot (\mathbf{c}+\mathbf{w})$ (within the dashed ball) is outside of its corresponding plain ball. Similarly, in the case of $\gamma = 2$ (right subfigure), vector $i \cdot (\mathbf{c}+\mathbf{w})$ is outside of its corresponding plain ball only when $i > 2$. Note in particular that in the case of $\gamma = 2$, vector $\mathbf{0}$ is not the closest point to the target vector, but belongs to the plain ball with center $\mathbf{t}$. Thus vector $\mathbf{0}$ should be removed via sparsification. As it is kept in any sparsified lattice, this is impossible to achieve. This illustrates why center $\mathbf{t}$ is shifted to a new point $\mathbf{t}+\mathbf{w}$ (then the shift $\mathbf{w}$ of $\mathbf{0}$ may be removed via sparsification). In both figures, the red crosses denote the points that are removed from the lattice via sparsification.

In Step 2 of the reduction, we construct a basis $\mathbf{B}'$ of an $(n+1)$-dimensional lattice $\mathcal{L}'$ by using Kannan's embedding technique. In Step 3, we call the $\mathrm{uSVP}_{\gamma(1+\varepsilon)}$ oracle with input basis $\mathbf{B}'$. The correctness of the reduction is provided by Lemmata 14, 15 and 16.

Any vector in lattice $\mathcal{L}'$ can be written as $\mathbf{b}' = ((\mathbf{b}+m(\mathbf{t}+\mathbf{w}))^{\mathrm{T}}, mkd_0)^{\mathrm{T}}$ with $\mathbf{b} \in \mathcal{L}_{p,\mathbf{z}}$ and $m \in \mathbb{Z}$. We claim that the vector $\mathbf{s}' = (((\mathbf{c}+\mathbf{w})-(\mathbf{t}+\mathbf{w}))^{\mathrm{T}}, -kd_0)^{\mathrm{T}} = ((\mathbf{c}-\mathbf{t})^{\mathrm{T}}, -kd_0)^{\mathrm{T}}$ is a shortest non-zero vector in $\mathcal{L}'$ and also that $\lambda_2(\mathcal{L}')/\lambda_1(\mathcal{L}') = \gamma(1+\Omega(1/n))$. Thus $\pm\mathbf{s}'$ will be output by the $\mathrm{uSVP}_{\gamma(1+\varepsilon)}$ oracle. We can then obtain the vector $\mathbf{c} = (\mathbf{c}+\mathbf{w})-(\mathbf{t}+\mathbf{w})+\mathbf{t} \in \mathcal{L}$. In the following, we give lower bounds for the norm of $\mathbf{b}' = ((\mathbf{b}+m(\mathbf{t}+\mathbf{w}))^{\mathrm{T}}, mkd_0)^{\mathrm{T}}$ not parallel to $\mathbf{s}'$, which depend on the value of m. Without loss of generality, we restrict ourselves to $m \geq 0$.

The following lemma is analogous to the '$m = 0$ case' of the Lyubashevsky-Micciancio reduction [15]. Note that the lower bound in the statement is essentially $2\gamma^2$.

▶ **Lemma 14.** *If $m = 0$ and $\mathbf{b}' \neq \mathbf{0}$, then $\|\mathbf{b}'\|^2/\|\mathbf{s}'\|^2 \geq 2\gamma^2/(1+1/(n-1)^2)$.*

Proof. As $m = 0$ and $\mathbf{b}' \neq \mathbf{0}$, we must have $\mathbf{b} \neq \mathbf{0}$. As a result, we have

$$\|\mathbf{b}'\|^2 \;=\; \|\mathbf{b}\|^2 \;\geq\; \lambda_1^2(\mathcal{L}) \;\geq\; \frac{2\gamma^2 d^2}{(1-\frac{1}{n})^2} \;\geq\; 2\gamma^2 d_0^2.$$

Thus, in this case, we have the gap

$$\frac{\|\mathbf{b}'\|^2}{\|\mathbf{s}'\|^2} \geq \frac{2\gamma^2 d_0^2}{d^2 + d_0^2 k^2} \geq \frac{2\gamma^2}{1+k^2} = \frac{2\gamma^2}{1+\frac{1}{(n-1)^2}}.$$

◀

The second lemma bounds the gap for small m's. It is where our improvement over prior reductions stems from. Note that the lower bound in the statement is essentially γ^2.

▶ **Lemma 15.** *If $m \leq \gamma n$ and $\mathbf{b}'$ is linearly independent with $\mathbf{s}'$, then $\|\mathbf{b}'\|^2/\|\mathbf{s}'\|^2 \geq (\gamma^2 + 1/n^2)/((1-1/n)^2 + 1/(n-1)^2)$.*

Proof. By Lemma 13, we have

$$\mathbf{c} + \mathbf{w} \;\in\; \mathcal{L}_{p,\mathbf{z}} \bigcap \bigcup_{i \leq \gamma n} \mathcal{B}\left(i \cdot (\mathbf{t}+\mathbf{w}), \frac{\lambda_1(\mathcal{L})}{\sqrt{2}}\right) \;\subseteq\; \mathbb{Z} \cdot (\mathbf{c}+\mathbf{w}).$$

Thus, as $\mathbf{b} \notin \mathbb{Z} \cdot (\mathbf{c}+\mathbf{w})$ (by assumption), we have

$$\|\mathbf{b}'\|^2 = \|\mathbf{b} - m \cdot (\mathbf{t}+\mathbf{w})\|^2 + m^2 d_0^2 k^2 \geq \frac{\lambda_1^2(\mathcal{L})}{2} + m^2 d_0^2 k^2 \geq \left(\frac{d\gamma}{1-\frac{1}{n}}\right)^2 + m^2 d_0^2 k^2.$$

Thus, in this case, we have the gap

$$\frac{\|\mathbf{b}'\|^2}{\|\mathbf{s}'\|^2} \geq \frac{(\frac{d\gamma}{1-\frac{1}{n}})^2 + m^2 d_0^2 k^2}{d^2 + d_0^2 k^2} \geq \frac{(\frac{d\gamma}{1-\frac{1}{n}})^2 + m^2 d^2 k^2}{d^2 + (\frac{d}{1-\frac{1}{n}})^2 k^2} = \frac{\gamma^2 + \frac{m^2}{n^2}}{(1-\frac{1}{n})^2 + \frac{1}{(n-1)^2}}.$$

The gap is an increasing function in m and hence it suffices to consider $m = 1$. ◀

The third lemma bounds the gap for larger m's. This corresponds to the 'large m case' of the Lyubashevsky-Micciancio reduction. As in the previous case, the lower bound in the statement is essentially γ^2.

▶ **Lemma 16.** *If $m > \gamma n$, then $\|\mathbf{b}'\|^2/\|\mathbf{s}'\|^2 \geq \gamma^2/((1-1/n)^2 + 1/(n-1)^2)$.*

Proof. For any $\mathbf{b} \in \mathcal{L}$, we have $\|\mathbf{b}'\|^2 \geq m^2 k^2 d_0^2$. Thus, in this case, we have the gap

$$\frac{\|\mathbf{b}'\|^2}{\|\mathbf{s}'\|^2} \geq \frac{m^2 k^2 d_0^2}{d^2 + k^2 d_0^2} \geq \frac{m^2 k^2 d^2}{d^2 + (\frac{d}{1-\frac{1}{n}})^2 k^2} = \frac{m^2}{(n-1)^2 + \frac{n}{(n-1)^2}}.$$

The gap is an increasing function in m and hence it suffices to consider the $m = \gamma n$. ◀

Now, we complete the proof of Theorem 12. According to Lemmata 14, 15 and 16, the uSVP gap satisfies, for large enough n

$$\frac{\lambda_2^2(\mathcal{L}')}{\lambda_1^2(\mathcal{L}')} \geq \min\left(\frac{2\gamma^2}{1+\frac{1}{(n-1)^2}}, \frac{\gamma^2+\frac{1}{n^2}}{(1-\frac{1}{n})^2+\frac{1}{(n-1)^2}}, \frac{\gamma^2}{(1-\frac{1}{n})^2+\frac{1}{(n-1)^2}}\right) \geq \gamma^2\left(1 + \Omega\left(\frac{1}{n}\right)\right).$$

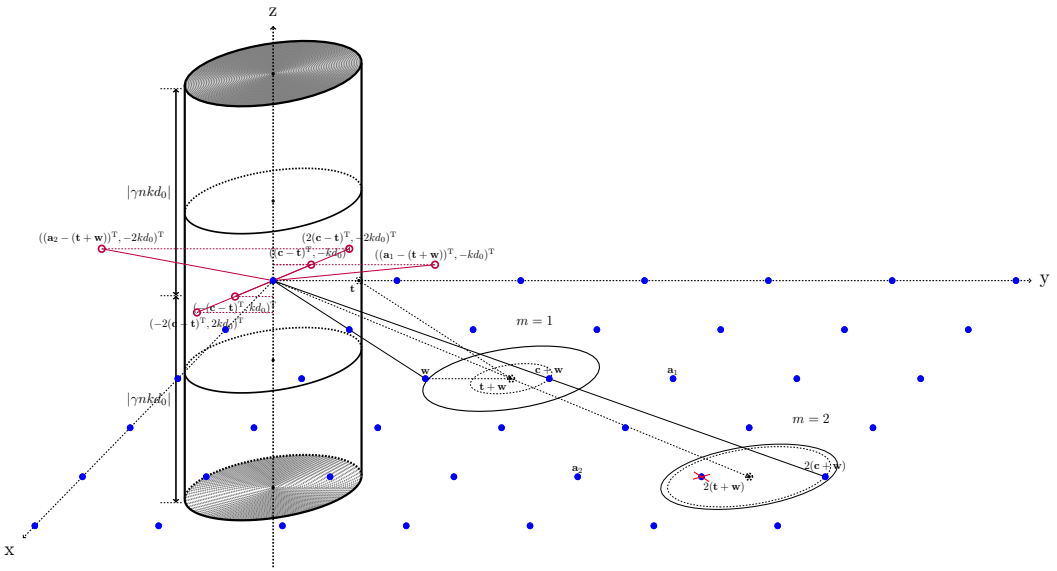

Figure 4 Geometric illustration of the reduction.

We include Figure 4 to geometrically illustrate the overall reduction. For convenience, we take $k = -1/(n-1)$ in the figure. We use filled dots to label points of 2-dimensional lattice $\mathcal{L}$, and hollow dots to label points of 3-dimensional lattice $\mathcal{L}'$ that are not in $\mathcal{L}$ (recall that $\mathcal{L} \subseteq \mathcal{L}'$). With Kannan's embedding technique, the offset between the vectors of $\mathcal{L}$ (e.g., $\mathbf{c}+\mathbf{w}$) and the shifted target $\mathbf{t}+\mathbf{w}$ are mapped to $\mathcal{L}'$ (e.g., $((\mathbf{c}-\mathbf{t})^{\mathrm{T}}, -kd_0)^{\mathrm{T}}$). Thanks to sparsification, all the points of $\mathcal{L}'$ belonging to the drawn cylinder (of height $|2\gamma nkd_0|$) are multiples of the shortest non-zero vector $\mathbf{s}' = ((\mathbf{c}-\mathbf{t})^{\mathrm{T}}, -kd_0)^{\mathrm{T}}$, e.g., $\pm((\mathbf{c}-\mathbf{t})^{\mathrm{T}}, -kd_0)^{\mathrm{T}}$ and $\pm(2(\mathbf{c}-\mathbf{t})^{\mathrm{T}}, -2kd_0)^{\mathrm{T}}$. All other points in $\mathcal{L}'$ that are linearly independent from $\mathbf{s}'$ lie outside of the cylinder, e.g., $((\mathbf{a}_1-(\mathbf{t}+\mathbf{w}))^{\mathrm{T}}, -kd_0)^{\mathrm{T}}$ and $((\mathbf{a}_2-(\mathbf{t}+\mathbf{w}))^{\mathrm{T}}, -2kd_0)^{\mathrm{T}}$. This cylinder forces the second minimum $\lambda_2(\mathcal{L}')$ to be large, and, more concretely, larger than $\gamma\lambda_1(\mathcal{L}')$. This corresponds to Lemma 15 (Lemma 14 handles the points of $\mathcal{L}$ and Lemma 16 handles the points of $\mathcal{L}'$ whose z-component is large).

Acknowledgments. We thank Steven Galbraith, Daniele Micciancio and Jinming Wen for helpful discussions.

A Parallel Repetition Theorem for All Entangled Games*

Henry Yuen†

Massachusetts Institute of Technology, Cambridge, MA, USA
hyuen@mit.edu

Abstract

The behavior of games repeated in parallel, when played with quantumly entangled players, has received much attention in recent years. Quantum analogues of Raz's classical parallel repetition theorem have been proved for many special classes of games. However, for general entangled games no parallel repetition theorem was known.

We prove that the entangled value of a two-player game G repeated n times in parallel is at most $c_G n^{-1/4} \log n$ for a constant c_G depending on G, provided that the entangled value of G is less than 1. In particular, this gives the first proof that the entangled value of a parallel repeated game must converge to 0 for all games whose entangled value is less than 1. Central to our proof is a combination of both classical and quantum correlated sampling.

1 Introduction

A two-player one-round game G is played between a referee and two isolated players (who we will call Alice and Bob), who communicate only with the referee and not between themselves. The referee first samples a question pair (x, y) from some distribution μ and sends x to Alice and y to Bob. Alice and Bob respond with answers a and b respectively, and they win if $V(x, y, a, b) = 1$ for some predicate V.

The maximum winning probability of Alice and Bob in a game G is a quantity that depends on what resources they are allowed to use. If their answers are a deterministic function of their received question (and perhaps some public random string), then we call their maximum winning probability the *classical value* of G, denoted by $\mathrm{val}(G)$. However quantum mechanics allows Alice and Bob to share a resource called *entanglement*, which gives rise to correlations that cannot be reproduced with public randomness only. When Alice and Bob make use of entanglement to play a game G, we call their maximum winning probability the *entangled value* of G, denoted by $\mathrm{val}^*(G)$. For all games, the classical value is at most the entangled value. Cast in the language of games, the famous Bell's Theorem states that there exist games G where those values are different: $\mathrm{val}^*(G) > \mathrm{val}(G)$ [3].

The Parallel Repetition Question is the following natural and basic question: given a game G with value less than 1, what is the value of the game G^n, wherein Alice and Bob

play n independent instances of G played *in parallel*? More formally, in the game G^n, the referee samples n independent question pairs $(x_1, y_1), \ldots, (x_n, y_n)$ from μ, and sends $(x_1, \ldots, x_n)$ to Alice, and sends $(y_1, \ldots, y_n)$ to Bob. Alice responds with answer tuple $(a_1, \ldots, a_n)$, Bob responds with $(b_1, \ldots, b_n)$, and the players win if for all coordinates $i \in [n]$, $V(x_i, y_i, a_i, b_i) = 1$.

The difficulty in relating $\mathrm{val}(G^n)$ with $\mathrm{val}(G)$ and n is that even though each of the n instances of G in G^n are independent, Alice and Bob need not play each instance independently. For example, since Alice receives $(x_1, \ldots, x_n)$ all at once, she can use some question x_j to answer the i'th game, and Bob can do something similar. Because of such strategies, for every k there are games G such that $\mathrm{val}(G^k) = \mathrm{val}(G) < 1$. This shows that the naive expectation that $\mathrm{val}(G^n) = \mathrm{val}(G)^n$ is false.

The naive expectation is not too far from the truth, however: Raz's Parallel Repetition Theorem [19] states that

$$\mathrm{val}(G^n) \leq (1 - (1 - \mathrm{val}(G))^3)^{c_G n},$$

where c_G is a constant depending on G. In particular, as n goes to infinity, the classical success probability goes to 0 exponentially fast in n (provided that $\mathrm{val}(G) < 1$). The proof is highly nontrivial, although it has been simplified and improved upon in recent years [12, 4]. Raz's Parallel Repetition Theorem has heavily influenced complexity theory, most notably in the areas of hardness of approximation [11] and communication complexity [13, 5].

One open question, which we call the Quantum Parallel Repetition Conjecture, asks whether an analogue of Raz's Parallel Repetition Theorem holds in the setting of entangled players. The Quantum Parallel Repetition Conjecture has been resolved for many special cases of games, including free games [6, 14, 7], projection games [9], XOR games [8], unique games [15], anchored games [1], and fortified games [2]. However, the general case has remained elusive. Not only do we not know of a quantum analogue of Raz's Parallel Repetition Theorem, it hasn't even been shown that if $\mathrm{val}^*(G) < 1$, then $\mathrm{val}^*(G^n)$ goes to 0 as n goes to infinity! Could quantum entanglement allow players to counteract the value-decreasing effect of parallel repetition?

In this paper we prove that for all nontrivial entangled games G (i.e. $\mathrm{val}^*(G) < 1$), the entangled value of G^n must converge to 0. This resolves a weaker version of the Quantum Parallel Repetition Conjecture for general games. Quantitatively, our result is the following:

▶ **Theorem 1** (Main Theorem). *Let G be a game involving two entangled players with $\mathrm{val}^*(G) = 1 - \varepsilon$. Then for all integer $n > 0$,*

$$\mathrm{val}^*(G^n) \leq c \cdot \frac{s_G \log n}{\varepsilon^{17} n^{1/4}}$$

where c is a universal constant and s_G is the bit-length of the players' answers in G.

This shows that the entangled value of G^n must decay at a polynomial rate with n. The full Quantum Parallel Repetition Conjecture states that the rate of decay is in fact exponential, and this remains an important open problem.

1.1 Previous work

There has been extensive work on the parallel repetition of entangled games. As stated earlier, past results have applied to various special classes of games, but there was no result that covered *all* games.

The results coming closest to the Quantum Parallel Repetition Conjecture are the work of Kempe and Vidick [16] and Bavarian, Vidick, and Yuen [1, 2]. Rather than proving parallel repetition theorems for general games, these works prove general *gap amplification* theorems, which are closely related. Instead of showing that for games G where $\mathrm{val}^*(G) < 1$ that $\mathrm{val}^*(G^n)$ goes to 0 with n, the game G is first converted to another game H where analyzing $\mathrm{val}^*(H^n)$ is much more tractable. Gap amplification is a technique used in complexity theory and cryptography to amplify the difference between two cases of a problem (usually called the *completeness* and *soundness* cases).

Kempe and Vidick showed that given an arbitrary game G, one can efficiently transform it to another game H with the following properties: if the *classical* value of G is 1 (meaning that there is a perfect deterministic strategy), then $\mathrm{val}(H^n) = 1$ (and thus $\mathrm{val}^*(H^n) = 1$). If the *entangled* value of G is less than 1, then the entangled value of H^n decays at a polynomial rate $n^{-\Omega(1)}$. In this tranformed game H, in addition to playing the game G, the referee will randomly choose to ask "consistency" questions to check that the players give the same answers on the same questions[1]. Thus [16] prove gap amplification for general games – with a caveat. Because of the random consistency checks in the game H, the "quantum completeness" is not preserved: even if $\mathrm{val}^*(G) = 1$, it is not necessarily the case that $\mathrm{val}^*(H) = 1$.

More recently, Bavarian, Vidick, and Yuen [1, 2] gave better gap amplification results for entangled games[2]. They showed that for general games G, one can apply a simple transformation to obtain another game H with the following properties:

1. If $\mathrm{val}^*(G) = 1$, then $\mathrm{val}^*(H^n) = 1$.
2. If $\mathrm{val}^*(G) < 1$, then $\mathrm{val}^*(H^n) \leq \exp(-\Omega(n))$.

Note that the transformation from G to H preserves quantum completeness, and that when $\mathrm{val}^*(G) < 1$, the entangled value of the repeated game decays *exponentially*. Like [16], the transformations of [1, 2] construct H by adding auxiliary questions to the game G. The transformation given in [1] is called *anchoring*, and the trasformation in [2] is called *fortification*. The latter transformation gives a quantum generalization of the fortification technique of [17] for *classical games*. The quantitative aspects of repeated anchored games are different from those of fortified games, but both yield general gap amplification theorems for entangled games.

The results of Bavarian, Vidick and Yuen show that, while we do not know if the Quantum Parallel Repetition Conjecture holds for all games G, we *do* know that it holds for a class of games that effectively captures the general case, in fact with exponential decay similar to Raz's theorem. Since the main application of parallel repetition in complexity theory and quantum information is gap amplification, the results of [1, 2] effectively settle the Quantum Parallel Repetition Conjecture – as far as applications are concerned.

But as a scientific question, the original Quantum Parallel Repetition Conjecture is a fundamental and basic problem about the power of entanglement in games. Prior to this work, one might have wondered whether there exists a game G such that $\mathrm{val}^*(G) < 1$, but there is some constant δ such that for infinitely many n there is a nefarious entangled strategy for G^n with success probability at least δ? Here we prove that this cannot happen.

1.2 Proof overview

Theorem 1 is proved via reduction: if $\mathrm{val}^*(G^n)$ is too large, then from an optimal entangled strategy for G^n we can construct an entangled strategy for the single-shot game G that wins

[1] This transformation is to due to Feige and Kilian [10], who proved a similar result for classical games.
[2] They also obtain general gap amplification results for games with more than two players.

with probability strictly greater than $\mathrm{val}^*(G)$, which would be a contradiction.

In more detail, suppose that $\mathrm{val}^*(G) = 1 - \varepsilon$. If the success probability of the players in G^n is dramatically larger than our target bound (which in our case is $\sim n^{-O(1)}$), then we can identify a set of coordinates $C \subseteq [n]$ that is not too large, but has the property that for a uniformly random coordinate $i \in [n] - C$,

$$\Pr(\text{Win game } i \mid \text{Win games in } C) > 1 - \varepsilon/2 \tag{1}$$

where here the probability is both over the randomness of the questions in G^n, the randomness of the players' entangled strategy, and the randomly chosen index i. Thus it would be advantageous if Alice and Bob could play the single-shot game G by "embedding" it in a randomly chosen ith coordinate of G^n, and playing G^n *conditioned* on the event that the games indexed by C have been won. If they could do this, then by (1), the probability they win the ith coordinate of G^n, and hence the original game G, is at least $1 - \varepsilon/2 > \mathrm{val}^*(G)$, which would be a contradiction.

If the players are classical (i.e. use deterministic strategies), this embedding is performed in the following way. Alice and Bob are first given questions (X_i, Y_i) for the i'th game. Based on their received question, Alice and Bob jointly sample a *dependency-breaking variable* R. The essential features of this dependency-breaking variable are:

1. **Usefulness:**[3] $\mathsf{P}_{A_iB_i|RX_iY_iW_C} = \mathsf{P}_{A_i|RX_iW_C} \cdot \mathsf{P}_{B_i|RY_iW_C}$
2. **Sampleability:** $\mathsf{P}_{R|X_iY_iW} \approx \mathsf{P}_{R|X_iW_C} \approx \mathsf{P}_{R|Y_iW_C}$

where "$\approx$" means closeness in statistical distance. Here, W_C denotes the event that the players win all the games in C. $\mathsf{P}_{A_iB_i|RX_iY_iW_C}$ denotes the probability distribution of Alice's and Bob's answers in the ith coordinate when playing G^n, conditioned on the dependency-breaking variable R, their received questions for the ith game (X_i, Y_i), *and* the event W_C. The "Usefulness property" states that, the players' answers in the ith round are independent of each other, conditioned on R, their own questions, and W_C. Thus, given R distributed according to $\mathsf{P}_{R|X_iY_iW_C}$, Alice can sample A_i on her own, because she possesses R and X_i, and similarly Bob can sample B_i on his own, because he possesses knowledge of R and Y_i. By (1), the probability that $V(X_i, Y_i, A_i, B_i) = 1$ will be strictly greater than $\mathrm{val}^*(G)$, wherein we would arrive at a contradiction.

As the name suggests, the "sampleability property" implies that Alice and Bob can (approximately) jointly sample the variable R. Even though the distribution $\mathsf{P}_{R|X_iY_iW_C}$ may depend on both players' questions, the sampleability property shows R, up to some error, only depends on X_i or Y_i, but not both. Using the *correlated sampling procedure* of [12], Alice and Bob can jointly sample R from $\mathsf{P}_{R|X_iY_iW}$ with high probability.

At a high level, the proof of our quantum parallel repetition theorem is similar. However instead of sampling a dependency-breaking variable R, the players will need to sample a *dependency-breaking state*. It is an entangled state $|\Psi_{x_iy_i}\rangle$ that depends on both Alice's and Bob's questions (x_i, y_i), and satisfies similar Usefulness and Sampleability properties:

1. **Usefulness:** The distribution of measurement outcomes by making local measurements on $|\Psi_{X_iY_i}\rangle$ is equal to $\mathsf{P}_{A_iB_i|X_iY_iW_C}$.
2. **Sampleability:** There exist states $|\Phi_{X_i}\rangle$ and $|\Gamma_{Y_i}\rangle$ such that $|\Psi_{X_iY_i}\rangle \approx |\Phi_{X_i}\rangle \approx |\Gamma_{Y_i}\rangle$

where "$\approx$" means closeness in ℓ_2 distance, and the statements hold on average over X_iY_i.

[3] We will let P denote the probability distribution that describes the joint distribution of the random variables relevant in an execution of the strategy for G^n, including the players' questions $X_1, \ldots, X_n, Y_1, \ldots, Y_n$, the players' answers $A_1, \ldots, A_n, B_1, \ldots, B_n$, and the dependency-breaking variable R.

The Usefulness property states that if on input (x_i, y_i), Alice and Bob were to share the entangled state $|\Psi_{x_i y_i}\rangle$, then they could make local measurements to obtain outcomes distributed according to $\mathsf{P}_{A_i B_i | X_i Y_i W_C}$, which would mean that their success probability would be $\Pr(\text{Win } i \mid \text{Win } C)$, which is greater than $\text{val}^*(G)$, an impossibility.

The Sampleability property implies that on input (x_i, y_i) Alice and Bob are actually able to approximately prepare the state $|\Psi_{x_i y_i}\rangle$. This is because of the *quantum correlated sampling procedure* of Dinur, Steurer, and Vidick, who used it to prove a parallel repetition theorem for entangled projection games [9]. It is entirely analogous to Holenstein's correlated sampling procedure: Alice has a description of a state $|\Phi_{X_i}\rangle$ that's close to $|\Psi_{X_i Y_i}\rangle$, and Bob has a description of a state $|\Gamma_{Y_i}\rangle$ that is also close to $|\Psi_{X_i Y_i}\rangle$. Via local transformations on preshared quantum entanglement, Alice and Bob can generate an approximation of $|\Psi_{X_i Y_i}\rangle$. Combined with the Usefulness property, Alice and Bob are then able to win the ith game with too high probability.

It is not difficult to define states that satisfy the Usefulness property. Consider an execution of the entangled strategy for G^n. In the beginning, the players share some entangled state $|\psi\rangle$, and upon obtaining questions $(x_1, \ldots, x_n)$ and $(y_1, \ldots, y_n)$, the players apply local measurements depending on these questions to $|\psi\rangle$ to obtain answer tuples $(a_1, \ldots, a_n)$ and $(b_1, \ldots, b_n)$. One can define an ensemble of states $\{|\Psi_{x_i, y_i}\rangle\}$ that are, roughly speaking, derived from the post-measurement state of the players *conditioned* on the players having won all the games in C (that is, conditioned on the event W_C), *and* having received a specific question pair (x_i, y_i) in the i'th coordinate. Such an ensemble of states would satisfy the Usefulness property.

However, the primary challenge is achieving Sampleability property, that is, to show the states $|\Psi_{x_i, y_i}\rangle$ only depend on one player's question, but not both. One major obstacle to proving the Sampleability property is the following: in the players' strategy for G^n, Bob (say) may elect to "print" his entire vector of questions $(y_1, \ldots, y_n)$ into the entangled state $|\psi\rangle$. He can do this by applying a local unitary operation controlled on his questions on some ancilla qubits in $|\psi\rangle$. We cannot say he does not do this, because the shared entangled state $|\psi\rangle$ and the players' measurements are completely arbitrary. But this implies that we cannot hope to prove that the post-measurement state is independent of y_i, conditioned on x_i.

Despite such barriers, we are able to define the $|\Psi_{x_i, y_i}\rangle$ in such a way that removes such adversarial dependencies on the players' questions. Assuming (for contradiction) that the players' probability of success is at least $n^{-O(1)}$, then we are able to prove that these states satisfy the Sampleability property. We build upon many previous works: we use the information theoretic framework of [6, 14], carefully combined with the operator analysis techniques from [9]. The definition of the dependency-breaking states $|\Psi_{x_i, y_i}\rangle$ includes the classical dependency-breaking variables of [12] used to prove Raz's parallel repetition theorem. Our final constructed strategy for the single-shot game G uses both classical and quantum correlated sampling procedures.

2 Preliminaries

2.1 Probability distributions

We largely adopt the notational conventions from [12] for probability distributions. We let capital letters denote random variables and lower case letters denote specific samples. We will use subscripted sets to denote tuples, e.g., $X_{[n]} := (X_1, \ldots, X_n)$, $x_{[n]} = (x_1, \ldots, x_n)$, and if $C \subset [n]$ is some subset then X_C will denote the sub-tuple of $X_{[n]}$ indexed by C. We use P_X to denote the probability distribution of random variable X, and $\mathsf{P}_X(x)$ to

denote the probability that $X = x$ for some value x. For multiple random variables, e.g., X, Y, Z, $\mathsf{P}_{XYZ}(x, y, z)$ denotes their joint distribution with respect to some probability space understood from context.

We use $\mathsf{P}_{Y|X=x}(y)$ to denote the conditional distribution $\mathsf{P}_{YX}(y, x)/\mathsf{P}_X(x)$, which is defined when $\mathsf{P}_X(x) > 0$. When conditioning on many variables, we usually use the shorthand $\mathsf{P}_{X|y,z}$ to denote the distribution $\mathsf{P}_{X|Y=y,Z=z}$. For example, we write $\mathsf{P}_{V|\omega_{-i},x_i,y_i}$ to denote $\mathsf{P}_{V|\Omega_{-i}=\omega_{-i},X_i=x_i,Y_i=y_i}$. For an event W we let $\mathsf{P}_{XY|W}$ denote the distribution conditioned on W. We use the notation $\mathbb{E}_X f(x)$ and $\mathbb{E}_{\mathsf{P}_X} f(x)$ to denote the expectation $\sum_x \mathsf{P}_X(x) f(x)$.

Let P_{X_0} be a distribution of $\mathcal{X}$, and for every x in the support of P_{X_0}, let $\mathsf{P}_{Y|X_1=x}$ be a conditional distribution defined over $\mathcal{Y}$. We define the distribution $\mathsf{P}_{X_0}\mathsf{P}_{Y|X_1}$ over $\mathcal{X} \times \mathcal{Y}$ as

$$(\mathsf{P}_{X_0}\mathsf{P}_{Y|X_1})(x, y) := \mathsf{P}_{X_0}(x) \cdot \mathsf{P}_{Y|X_1=x}(y).$$

Additionally, we write $\mathsf{P}_{X_0Z}\mathsf{P}_{Y|X_1}$ to denote the distribution $(\mathsf{P}_{X_0Z}\mathsf{P}_{Y|X_1})(x, z, y) := \mathsf{P}_{X_0Z}(x, z) \cdot \mathsf{P}_{Y|X_1=x}(y)$.

For two random variables X_0 and X_1 over the same set $\mathcal{X}$, we use

$$\|\mathsf{P}_{X_0} - \mathsf{P}_{X_1}\| := \frac{1}{2} \sum_{x \in \mathcal{X}} |\mathsf{P}_{X_0}(x) - \mathsf{P}_{X_1}(x)|,$$

to denote the total variation distance between P_{X_0} and P_{X_1}.

2.2 Quantum information theory

For comprehensive references on quantum information we refer the reader to [18, 21].

For a vector $|\psi\rangle$, we use $\||\psi\rangle\|$ to denote its Euclidean length. For a matrix A, we will use $\|A\|_1$ to denote its *trace norm* $\mathrm{Tr}(\sqrt{AA^\dagger})$, and $\|A\|_F$ to denote its *Frobenius norm* $\sqrt{\mathrm{Tr}(AA^\dagger)}$. A density matrix is a positive semidefinite matrix with trace 1. The *fidelity* between two density matrices ρ and σ is defined as $F(\rho, \sigma) = \|\sqrt{\rho}\sqrt{\sigma}\|_1$. For Hermitian matrices A, B we write $A \preceq B$ to indicate that $A - B$ is positive semidefinite. We use $\mathbb{I}$ to denote the identity matrix. A *positive operator valued measurement* (POVM) with outcome set $\mathcal{A}$ is a set of positive semidefinite matrices $\{E^a\}$ labeled by $a \in \mathcal{A}$ that sum to the identity.

We will use the convention that, when $|\psi\rangle$ is a pure state, ψ refers to the rank-1 density matrix $|\psi\rangle\langle\psi|$. We use subscripts to denote system labels; so ρ_{AB} will denote the density matrix on the systems A and B. A *classical-quantum* state ρ_{XE} is classical on X and quantum on E if it can be written as $\rho_{XE} = \sum_x p(x)|x\rangle\langle x|_X \otimes \rho_{E|X=x}$ for some probability measure $p(\cdot)$. The state $\rho_{E|X=x}$ is by definition the E part of the state ρ_{XE}, conditioned on the classical register $X = x$. We write $\rho_{XE|X=x}$ to denote the state $|x\rangle\langle x|_X \otimes \rho_{E|X=x}$. We often write expressions such as $\rho_{E|x}$ as shorthand for $\rho_{E|X=x}$ when it is clear from context which registers are being conditioned on. This will be useful when there are many classical variables to be conditioned on.

2.3 Classical and quantum correlated sampling

Correlated sampling is a key component of Holenstein's proof of the classical parallel repetition theorem.

▶ **Lemma 2** (Classical correlated sampling [12]). *Let* P *and* Q *be two probability distributions over a universe* $\mathcal{U}$ *such that* $\|\mathsf{P} - \mathsf{Q}\|_1 \leq \varepsilon < 1$*. Then there exists a zero communication two-player protocol using shared randomness where the first player outputs an element* $p \in \mathcal{U}$ *distributed according to* P*, the second player samples an element* $q \in \mathcal{U}$ *distributed according to* Q*, and with probability at least* $1 - O(\varepsilon)$*, the two elements are identical (i.e.* $p = q$*).*

We call the protocol in the Lemma above the *classical correlated sampling procedure*. The next lemma is the quantum extension of the correlated sampling lemma, proved by [9] in order to obtain a parallel repetition theorem for entangled projection games, a class of two-player games. Their lemma is a robust version of the quantum state embezzlement procedure of [20].

▶ **Lemma 3** (Quantum correlated sampling [9]). *Let d be an integer. Then there exists an integer d' and a collection of unitaries V_ψ, W_ψ acting on $\mathbb{C}^{dd'}$ for every state $|\psi\rangle \in \mathbb{C}^d \otimes \mathbb{C}^d$, such that the following holds: for any two states $|\varphi\rangle, |\theta\rangle \in \mathbb{C}^d \otimes \mathbb{C}^d$,*

$$\|\overline{V}_\varphi \otimes W_\theta |E_{dd'}\rangle - |\varphi\rangle|E_{d'}\rangle\| \leq O(\| \, |\varphi\rangle - |\theta\rangle \, \|^{1/6})$$

where $|E_d\rangle \propto \sum_{j=1}^d \frac{1}{\sqrt{j}}|j\rangle|j\rangle$ is the d-dimensional embezzlement state.

We shall call the protocol in the Lemma above the *quantum correlated sampling procedure*.

3 Proof of the Main Theorem

Let G be a two-player one-round game with question distribution μ and referee predicate $V(x, y, a, b)$. Let $\mathcal{A}$ and $\mathcal{B}$ denote the alphabets of Alice's and Bob's answers, respectively. Let $\mathrm{val}^*(G) = 1 - \varepsilon$.

Consider an optimal entangled strategy for G^n, which consists of a shared entangled state $|\psi\rangle^{E_A E_B} \in \mathbb{C}^d \otimes \mathbb{C}^d$ and measurement POVMs for Alice and Bob, $\{A^{a_{[n]}}_{x_{[n]}}\}$ and $\{B^{b_{[n]}}_{y_{[n]}}\}$ respectively. We will assume that $|\psi\rangle$ is symmetric; i.e., $|\psi\rangle = \sum_i \sqrt{\lambda_i}|v_i\rangle|v_i\rangle$ for some orthonormal basis $\{|v_i\rangle\}$. This is without loss of generality, as we can always rotate (say) Bob's basis vectors to match Alice's basis vectors, and fold the unitary rotation into Bob's measurements. For $i \in [n]$, let W_i denote the event that the players win coordinate i using this optimal strategy. Let $W = W_1 \wedge \cdots \wedge W_n$ denote the event that the players win all coordinates. For a set $C \subseteq [n]$, let $W_C = \wedge_{i \in C} W_i$.

▶ **Proposition 4.** *Suppose that $\log 1/\Pr(W) \leq \varepsilon n/16 - \log 4/\varepsilon$. Then there exists a set $C \subseteq [n]$ of size at most $t = \frac{8}{\varepsilon}(\log 4/\varepsilon + \log 1/\Pr(W))$ such that*

$$\Pr_{i \notin C}(W_i|W_C) \geq 1 - \varepsilon/2.$$

where i is chosen uniformly from $[n] - C$.

Proof. Set $\delta = \varepsilon/8$. Let $W_{>1-\delta}$ denote the event that the players won more than $(1-\delta)n$ rounds. To show existence of such a set C, we will show that $\mathbb{E}_C \Pr(\neg W_i|W_C) \leq \varepsilon/2$, where C is a (multi)set of t independently chosen indices in $[n]$. This implies that there exists a particular set C such that $\Pr(\neg W_i|W_C) \leq \varepsilon/2$, which concludes the claim.

First we write, for a fixed C, $\Pr(\neg W_i|W_C) = \Pr(\neg W_i|W_C, W_{>1-\delta}) \Pr(W_{>1-\delta}|W_C) + \Pr(\neg W_i|W_C, \neg W_{>1-\delta}) \Pr(\neg W_{>1-\delta}|W_C)$. Observe that $\Pr(\neg W_i|W_C \wedge W_{>1-\delta})$ is the probability that, conditioned on winning all rounds in C, the randomly selected coordinate $i \in [n]-C$ happens to be one of the (at most) δn lost rounds. This is at most $\delta n/(n-t) \leq \varepsilon/4$, where we use our assumption on t from the Proposition statement. Now observe that

$$\mathop{\mathbb{E}}_C \Pr(\neg W_{>1-\delta}|W_C) \leq \mathop{\mathbb{E}}_C \frac{\Pr(W_C|\neg W_{>1-\delta})}{\Pr(W_C)} \leq \frac{1}{\Pr(W)}(1-\delta)^t \leq \varepsilon/4$$

where in the second line we used the fact that $\Pr(W_C) \geq \Pr(W)$. ◀

For the rest of the proof we will fix a set C given by Proposition 4.

3.1 Dependency-breaking variables

We introduce the random variables that play an important role in the proof of Theorem 1. Let $C \subseteq [n]$ be as given by Proposition 4. We fix $C = \{m+1, m+2, \ldots, n\}$, where $m = n - |C|$, as this will easily be seen to hold without loss of generality. Let $(X_{[n]}, Y_{[n]})$ be distributed according to $\mu_{[n]}$ and $(A_{[n]}, B_{[n]})$ be defined from $X_{[n]}$ and $Y_{[n]}$ as follows:

$$\mathsf{P}_{A_{[n]}B_{[n]}|x_{[n]},y_{[n]}}(a_{[n]}, b_{[n]}) = \langle\psi| A^{a_{[n]}}_{x_{[n]}} \otimes B^{b_{[n]}}_{y_{[n]}} |\psi\rangle.$$

Let (X_C, Y_C) and $\mathrm{Z} = (A_C, B_C)$ be random variables that denote the players' questions and answers respectively associated with the coordinates indexed by C.

We use the random variables Ω and R that are crucially used in Holenstein's proof of Raz's parallel repetition theorem. Let $D_1, \ldots, D_m$ be independent and uniformly distributed in $\{Alice, Bob\}$. Let $M_1, \ldots, M_m$ be independent random variables defined in the following way: for each $i \in [m]$,

$$M_i = \begin{cases} X_i & \text{if } D_i = Alice \\ Y_i & \text{if } D_i = Bob \end{cases}$$

Now for $i \in [m]$, we define $\Omega_i := (D_i, M_i)$. We say that Ω_i *fixes Alice's input* if $D_i = Alice$, and otherwise Ω_i fixes Bob's input. We write Ω to denote the random variable $(\Omega_1, \ldots, \Omega_m, X_C, Y_C)$, where $X_C Y_C$ are Alice and Bob's questions in the coordinates indexed by C. For $i \in [m]$ we write Ω_{-i} to denote the random variable Ω with Ω_i omitted.

▶ **Proposition 5.** *Conditioned on Ω, $X_{[n]}$ and $Y_{[n]}$ are independent.*

Finally, we will define a *dependency-breaking variable* $R := (\Omega, A_C, B_C)$, where A_C and B_C are the players' answers in the coordinates indexed by C. For $i \notin C$, we let $R_{-i} := (\Omega_{-i}, A_C, B_C)$. R_i will refer to Ω_i. We will use lowercase letters to denote instantiations of these random variables: e.g., r_{-i}, x_i, and y_i refer to specific values of R_{-i}, X_i, and Y_i.

Throughout our proofs, all expectations are implicitly over the measure defined by P. For example, the expectation $\mathbb{E}_{\Omega_{-i}Z|x_i,y_i}$ indicates $\sum_{\omega_{-i},a_C,b_C} \mathsf{P}_{\Omega_{-i}A_CB_C|x_i,y_i}(\omega_{-i}, a_C, b_C)$. Given an event such as W (winning all the coordinates) or W_C (winning all the coordinates in C), $\mathsf{P}(W)$ and $\mathsf{P}(W_C)$ will mean the probability of these events with respect to the distribution P.

The following Lemma expresses the idea that, because W_C is an event that occurs with not-too-small probability, conditioning on it cannot skew the distribution of variables corresponding to an average coordinate by too much. This Lemma follows in a straightforward manner from the [12].

▶ **Lemma 6.** *The following statements hold on, average over i chosen uniformly in $[m]$:*
1. $\mathbb{E}_i \left\| \mathsf{P}_{R_i X_i Y_i | W_C} - \mathsf{P}_{R_i X_i Y_i} \right\|_1 \leq O(\sqrt{\delta})$
2. $\mathbb{E}_i \left\| \mathsf{P}_{X_i Y_i R_{-i} | W_C} - \mathsf{P}_{X_i Y_i} \cdot \mathsf{P}_{R_{-i}|X_i W_C} \right\|_1 \leq O(\sqrt{\delta})$
3. $\mathbb{E}_i \left\| \mathsf{P}_{X_i Y_i R_{-i} | W_C} - \mathsf{P}_{X_i Y_i} \cdot \mathsf{P}_{R_{-i}|Y_i W_C} \right\|_1 \leq O(\sqrt{\delta})$

where $\delta := \frac{1}{m}\left(\log 1/\mathsf{P}(W_C) + |C| \log |\mathcal{A}||\mathcal{B}|\right)$.

3.2 Two key Lemmas, and proof of the Main Theorem

For every $i \in [n] - C$, we will construct a collection of bipartite states $\{|\Psi_{r_{-i},x_i,y_i}\rangle\} \subseteq \mathbb{C}^d \otimes \mathbb{C}^d$, which we call dependency-breaking states, that are indexed by the dependency-breaking variable r_{-i} defined above, and questions (x_i, y_i). The following lemmas state the important properties of this collection of states:

▶ **Lemma 7** (Usefulness Lemma). *For all r_{-i}, x_i, y_i, there exist POVMs $\{\widehat{A}^{a_i}_{r_{-i},x_i}\}$ and $\{\widehat{B}^{b_i}_{r_{-i},y_i}\}$ acting on $\mathbb{C}^d$ such that*

$$\mathsf{P}_{A_iB_i|r_{-i},x_i,y_i}(a_i,b_i) = \mathrm{Tr}\left(\widehat{A}^{a_i}_{r_{-i},x_i} \otimes \widehat{B}^{b_i}_{r_{-i},y_i} \Psi_{r_{-i},x_i,y_i}\right).$$

▶ **Lemma 8** (Sampleability Lemma). *There exists an integer $d' \geq d$ such that for every i, r_{-i}, x_i, y_i, there exist local unitaries $U_{r_{-i},x_i}, V_{r_{-i},y_i}$ acting on $\mathbb{C}^{d'}$ such that*

$$\mathop{\mathbb{E}}_{i} \mathop{\mathbb{E}}_{X_iY_i} \left[\mathop{\mathbb{E}}_{R_{-i}|x_i,y_i,W_C} \left\| U_{r_{-i},x_i} \otimes V_{r_{-i},y_i} |E_{dd'}\rangle - |\Psi_{r_{-i},x_i,y_i}\rangle |E_{d'}\rangle \right\| \right] \leq O((\delta^{1/4}/\mathsf{P}(W_C))^{1/12})$$

where $|E_{dd'}\rangle$ and $|E_{d'}\rangle$ are dd' and d'-dimensional embezzlement states, respectively, and δ is defined to be $\frac{1}{m}(\log 1/\mathsf{P}(W_C) + |C| \log |\mathcal{A}||\mathcal{B}|)$.

Lemma 7 shows that the states $|\Psi_{r_{-i},x_i,y_i}\rangle$ are *useful* to have; they allow Alice and Bob to produce answers in the i'th coordinate whose statistics are consistent with the dependency-breaking variable r_{-i} and their inputs (x_i, y_i). Lemma 8 shows that these states are *locally generatable* by Alice and Bob, when given joint access to preshared entanglement, the dependency-breaking variable r_{-i} and their own inputs x_i and y_i respectively.

Using these two Lemmas we can prove the Main Theorem.

Proof of the Main Theorem. Consider the following strategy for the game G. Alice and Bob share beforehand the embezzlement state $|E_{dd'}\rangle$ of dimension dd' given by Lemma 8, and they also have access to shared randomness. Given inputs (x_i, y_i) distributed according to $\mathsf{P}_{X_iY_i} = \mu$:

1. Alice and Bob jointly sample a uniformly random $i \in [n] - C$.
2. Alice and Bob jointly, approximately sample R_{-i} from $\mathsf{P}_{R_{-i}|x_i,y_i,W_C}$ using the classical correlated sampling procedure.
3. Alice applies U_{r_{-i},x_i} to her side of $|E_{dd'}\rangle$
4. Bob applies V_{r_{-i},y_i} to his side of $|E_{dd'}\rangle$
5. Alice measures her side of the entanglement using $\{\widehat{A}^{a_i}_{r_{-i},x_i}\}$ and outputs the outcome a_i
6. Bob measures his side of the entanglement using $\{\widehat{B}^{b_i}_{r_{-i},y_i}\}$ and outputs the outcome b_i

We now analyze the success probability of this strategy. We will use $\widetilde{\mathsf{P}}$ to denote the distribution of variables in the probability space associated with an execution of this strategy. For example, we will write $\widetilde{\mathsf{P}}_{R_{-i}|X_iY_i}$ to denote the distribution of R_{-i} conditioned on X_iY_i that is sampled in Step 1. From Lemma 6 we have that on average over i, $\mathsf{P}_{X_iY_iR_{-i}|W_C} \approx \mathsf{P}_{X_iY_i} \cdot \mathsf{P}_{R_{-i}|X_iW_C} \approx \mathsf{P}_{X_iY_i} \cdot \mathsf{P}_{R_{-i}|Y_iW_C}$, where "$\approx$" means closeness in statistical distance. By invoking the classical correlated sampling procedure of Lemma 2, we get

$$\mathop{\mathbb{E}}_{i} \|\mathsf{P}_{X_iY_i} \cdot \widetilde{\mathsf{P}}_{R_{-i}|X_iY_i} - \mathsf{P}_{X_iY_iR_{-i}|W_C}\|_1 \leq O(\sqrt{\delta}).$$

After Step 3, Alice and Bob will possess a state $|\Lambda_{r_{-i},x_i,y_i}\rangle$ such that

$$\mathop{\mathbb{E}}_{i} \mathop{\mathbb{E}}_{X_iY_i} \left[\mathop{\mathbb{E}}_{R_{-i}|x_i,y_i,W_C} \|\Lambda_{r_{-i},x_i,y_i} - \Psi_{r_{-i},x_i,y_i}\|_1 \right] \leq \eta$$

where $\eta = O((\delta^{1/4}/\mathsf{P}(W_C))^{1/12})$. Consider the measurement process in Steps 4 and 5. Let $\widetilde{\mathsf{P}}_{A_iB_i|r_{-i},x_i,y_i}$ denote the distribution of measurement outcomes in this strategy, conditioned

on their inputs and a sampled value of r_{-i}. By Lemma 7 and the fact that the trace norm is nonincreasing under quantum operations, we have that

$$\mathop{\mathbb{E}}_{i} \mathop{\mathbb{E}}_{X_iY_i} \left[\mathop{\mathbb{E}}_{R_{-i}|x_i,y_i,W_C} \|\widetilde{\mathsf{P}}_{A_iB_i|x_i,y_i,r_{-i}} - \mathsf{P}_{A_iB_i|x_i,y_i,r_{-i}}\|_1 \right] \leq \eta$$

or equivalently

$$\mathop{\mathbb{E}}_{i} \|\mathsf{P}_{X_iY_i} \cdot \widetilde{\mathsf{P}}_{R_{-i}|X_iY_iW_C} \cdot \widetilde{\mathsf{P}}_{A_iB_i|x_i,y_i,r_{-i}} - \mathsf{P}_{X_iY_i} \cdot \mathsf{P}_{R_{-i}|X_iY_iW_C} \cdot \mathsf{P}_{A_iB_iR_{-i}|X_iY_iW_C}\|_1 \leq \eta.$$

By Lemma 6 we have $\mathbb{E}_i \|\mathsf{P}_{X_iY_i|W_C} - \mathsf{P}_{X_iY_i}\| \leq \sqrt{\delta}$. By triangle inequality and that $\widetilde{\mathsf{P}}_{X_iY_i} = \mathsf{P}_{X_iY_i}$, we have

$$\mathop{\mathbb{E}}_{i} \|\widetilde{\mathsf{P}}_{X_iY_iR_{-i}A_iB_i} - \mathsf{P}_{X_iY_iR_{-i}A_iB_i|W_C}\|_1 \leq O(\eta).$$

Note that $\widetilde{\mathsf{P}}_{X_iY_iR_{-i}A_iB_i}$ represents the probability distribution of all the variables present in the strategy above. Let W_i denote the probability the players win the ith coordinate. Thus we get

$$\mathop{\mathbb{E}}_{i} |\widetilde{\mathsf{P}}(W_i) - \mathsf{P}(W_i|W_C)| \leq O(\eta). \tag{2}$$

Assume that

$$\mathsf{P}(W) \geq \frac{cs \log n}{\varepsilon^{17} n^{1/4}}$$

where $c > 0$ is a universal constant, and s is the bit-length of the players' answers. Since $\mathsf{P}(W_C) \geq \mathsf{P}(W)$, and using our bound on $|C|$ (from Proposition 4) and our bound on δ (from Lemma 6), this implies that the right hand side of (2) is at most $\varepsilon/4$ (for an appropriate choice of c). This implies that

$$\mathop{\mathbb{E}}_{i} \widetilde{\mathsf{P}}(W_i) \geq \mathop{\mathbb{E}}_{i} \mathsf{P}(W_i|W_C) - \varepsilon/4 \geq 1 - \varepsilon/2 - \varepsilon/4 > \mathrm{val}^*(G)$$

where in the second line we used the bound from Proposition 4. However, this implies that there exists an i such that $\widetilde{\mathsf{P}}(W_i) > \mathrm{val}^*(G)$, which is a contradiction. Therefore $\mathsf{P}(W) \leq \frac{cs \log n}{\varepsilon^{17} n^{1/4}}$. ◀

Now we turn to defining the states and operators promised in the two key lemmas above, as well as giving an intuition for them.

3.3 Quantum states and operators

In this subsection we define the states $|\Psi_{r_{-i},x_i,y_i}\rangle$ and measurement operators $\{\widehat{A}^{a_i}_{r_{-i},x_i}\}$ and $\{\widehat{B}^{b_i}_{r_{-i},y_i}\}$. Recall that the dependency-breaking variable R consists of the set of fixed questions $\Omega = (X_C, Y_C, \Omega_1, \ldots, \Omega_m)$ and fixed answers $Z = (A_C, B_C)$ for the coordinates in C.

Coarse-grained measurements. We first *coarsen* the measurement POVMs $\{A^{a_{[n]}}_{x_{[n]}}\}$ and $\{B^{b_{[n]}}_{y_{[n]}}\}$ that constitute Alice and Bob's strategy in G^n to construct a set of *intermediate measurements*, which essentially produce answers for the games in set C, conditioned on a setting of Ω.

Fix i, ω, a_C, b_C, x_i, y_i. Define $A^{a_C}_{\omega_{-i},x_i} = \sum_{a_{[n]}|a_C} \mathbb{E}_{X_{[n]}|\omega_{-i},x_i} A^{a_{[n]}}_{x_{[n]}}$, and $B^{b_C}_{\omega_{-i},y_i} = \sum_{b_{[n]}|b_C} \mathbb{E}_{Y_{[n]}|\omega_{-i},y_i} B^{b_{[n]}}_{y_{[n]}}$ where $a_{[n]}|a_C$ (resp. $b_{[n]}|b_C$) indicates summing over all tuples $a_{[n]}$ consistent with the suffix a_C (resp. $b_{[n]}$ consistent with suffix b_C) and recall that $\mathbb{E}_{X_{[n]}|\omega_{-i},x_i}$ is shorthand for $\sum_{x_{[n]}} \mathsf{P}_{X_{[n]}|\Omega_{-i}=\omega_{-i},X_i=x_i}(x_{[n]})$. We also define $A^{a_C}_{\omega} = \mathbb{E}_{X_{[n]}|\omega} A^{a_C}_{x_{[n]}}$ and $B^{b_C}_{\omega} = \mathbb{E}_{Y_{[n]}|\omega} B^{b_C}_{y_{[n]}}$.

Let ρ denote the reduced density matrix of $|\psi\rangle$ on Alice's side. Since we have assumed that $|\psi\rangle$ is symmetric, ρ is also the reduced density matrix on Bob's side. For all i, ω, x_i, y_i, a_C, b_C, let U_{ω_{-i},x_i,a_C}, U_{ω,a_C}, V_{ω_{-i},y_i,b_C}, and V_{ω,b_C} be unitaries such that

$$U_{\omega_{-i},x_i,a_C}(A^{a_C}_{\omega_{-i},x_i})^{1/2}\sqrt{\rho} \qquad V_{\omega_{-i},y_i,b_C}(B^{b_C}_{\omega_{-i},y_i})^{1/2}\sqrt{\rho}$$
$$U_{\omega,a_C}(A^{a_C}_{\omega})^{1/2}\sqrt{\rho} \qquad V_{\omega,b_C}(B^{b_C}_{\omega})^{1/2}\sqrt{\rho}$$

are positive semidefinite. Such unitaries can be found via singular value decompositions. For notational convenience, let

$$S_{\omega_{-i},x_i,a_C} = U_{\omega_{-i},x_i,a_C}(A^{a_C}_{\omega_{-i},x_i})^{1/2} \qquad T_{\omega_{-i},y_i,b_C} = V_{\omega_{-i},y_i,b_C}(B^{b_C}_{\omega_{-i},y_i})^{1/2}$$
$$S_{\omega,a_C} = U_{\omega,a_C}(A^{a_C}_{\omega})^{1/2} \qquad T_{\omega,b_C} = V_{\omega,b_C}(B^{b_C}_{\omega})^{1/2}$$

Fine-grained measurements. Now we can define the *fine-grained measurements* that Alice and Bob can apply to obtain answers for the i'th game. Define

$$\widehat{A}^{a_i}_{r_{-i},x_i} = S^{-1}_{\omega_{-i},x_i,a_C} A^{a_C,a_i}_{\omega_{-i},x_i} S^{-1}_{\omega_{-i},x_i,a_C} \qquad \widehat{B}^{b_i}_{r_{-i},y_i} = T^{-1}_{\omega_{-i},y_i,b_C} B^{b_C,b_i}_{\omega_{-i},y_i} T^{-1}_{\omega_{-i},y_i,b_C}$$

where

$$A^{a_C,a_i}_{\omega_{-i},x_i} = \sum_{a_{[n]}|a_C,a_i} \mathbb{E}_{X_{[n]}|\omega_{-i},x_i} A^{a_{[n]}}_{x_{[n]}} \qquad B^{b_C,b_i}_{\omega_{-i},y_i} = \sum_{b_{[n]}|b_C,b_i} \mathbb{E}_{Y_{[n]}|\omega_{-i},y_i} B^{b_{[n]}}_{y_{[n]}}$$

and $a_{[n]}|a_C,a_i$ (resp. $b_{[n]}|b_C,b_i$) denotes summing over all $a_{[n]}$ consistent with a_C and a_i (resp. all $b_{[n]}$ consistent with b_C and b_i). It is easy to verify that the sets $\{\widehat{A}^{a_i}_{r_{-i},x_i}\}_{a_i\in\mathcal{A}}$ and $\{\widehat{B}^{b_i}_{r_{-i},y_i}\}_{b_i\in\mathcal{B}}$ form POVMs. Here, for a square matrix A, A^{-1} denotes its generalized inverse.

States. Now we are ready to define the states. Fix i, $r_{-i} = (\omega_{-i}, a_C, b_C)$, and x_i, y_i. Then let

$$|\Psi_{r_{-i},x_i,y_i}\rangle = \frac{S_{\omega_{-i},a_C,x_i} \otimes T_{\omega_{-i},b_C,y_i}|\psi\rangle}{\left\|S_{\omega_{-i},a_C,x_i} \otimes T_{\omega_{-i},b_C,y_i}|\psi\rangle\right\|}.$$

Observe that the normalization $\left\|S_{\omega_{-i},a_C,x_i} \otimes T_{\omega_{-i},b_C,y_i}|\psi\rangle\right\|^2$ is equal to $\mathsf{P}_{A_C B_C|\omega_{-i},x_i,y_i}(a_C, b_C)$.

3.4 Proof of Usefulness Lemma (Lemma 7)

This Lemma follows from a simple calculation: for every $x_i, y_i, a_i, b_i, r_{-i}$:

$$\begin{aligned}
&\mathrm{Tr}\left(\widehat{A}^{a_i}_{r_{-i},x_i} \otimes \widehat{B}^{b_i}_{r_{-i},y_i} \Psi_{r_{-i},x_i,y_i}\right) \\
&= \frac{1}{\left\| S_{\omega_{-i},a_C,x_i} \otimes T_{\omega_{-i},b_C,y_i} |\psi\rangle \right\|^2} \mathrm{Tr}\left(A^{a_C,a_i}_{\omega_{-i},x_i} \otimes B^{b_C,b_i}_{\omega_{-i},y_i} |\psi\rangle\langle\psi|\right) \\
&= \frac{1}{\mathsf{P}_{A_C B_C|\omega_{-i},x_i,y_i}(a_C,b_C)} \sum_{a_{[n]}|a_C,a_i} \sum_{b_{[n]}|b_C,b_i} \mathop{\mathbb{E}}_{X_{[n]}Y_{[n]}|\omega_{-i},x_i,y_i} \mathrm{Tr}\left(A^{a_{[n]}}_{x_{[n]}} \otimes B^{b_{[n]}}_{y_{[n]}} |\psi\rangle\langle\psi|\right) \\
&= \frac{\mathsf{P}_{A_i B_i A_C B_C|\omega_{-i},x_i,y_i}(a_i,b_i,a_C,b_C)}{\mathsf{P}_{A_C B_C|\omega_{-i},x_i,y_i}(a_C,b_C)} \\
&= \mathsf{P}_{A_i B_i|r_{-i},x_i,y_i}(a_i,b_i).
\end{aligned}$$

In the second equality we used that conditioned on Ω, $X_{[n]}$ and $Y_{[n]}$ are independent, so therefore $\mathbb{E}_{X_{[n]}|\omega_{-i},x_i} \mathbb{E}_{Y_{[n]}|\omega_{-i},y_i} = \mathbb{E}_{X_{[n]}Y_{[n]}|\omega_{-i},x_i,y_i}$. In the last equality we used that $r_{-i} = (\omega_{-i}, a_C, b_C)$. This concludes the Usefulness Lemma.

3.5 Proof of the Sampleability Lemma (Lemma 8)

Overview. Here we give some intuition. We first analyze an ensemble of states $\{|\Gamma_{x_i,x_C,a_C}\rangle\}$ (for now we omit mention of the dependency-breaking variable R for simplicity). These are indexed by Alice's questions in the i'th coordinate, her questions in the C coordinates, as well as her answers in the C coordinates. The state $|\Gamma_{x_i,x_C,a_C}\rangle$ roughly represents the state of the players where only Alice has applied her measurements – Bob hasn't done anything yet.

Fix a y_i, x_C, a_C. For average x_i, x_i' that are independently sampled from the marginal distribution $\mathsf{P}_{X_i|Y_i=y_i}$, we will show that $\||\Gamma_{x_i,x_C,a_C}\rangle - |\Gamma_{x_i',x_C,a_C}\rangle\| \sim \frac{1}{n}$. To handle issues such as Alice "printing" her input onto the state $|\psi\rangle$ (as discussed in the introduction), the definition of $|\Gamma_{x_i,x_C,a_C}\rangle$ requires local unitaries that "undo" such overt actions of Alice and Bob – this is accomplished by the unitaries U and V defined in Section 3.3.

Then, we consider what happens when we apply Bob's measurement to both states $|\Gamma_{x_i,x_C,a_C}\rangle$ and $|\Gamma_{x_i',x_C,a_C}\rangle$, and condition on obtaining answers b_C for the C coordinates. His measurement will depend on the questions y_i and y_C. The post-measurement states will be precisely $|\Psi_{x_i,y_i,x_C,y_C,a_C,b_C}\rangle$ and $|\Psi_{x_i',y_i,x_C,y_C,a_C,b_C}\rangle$. The distance between these states will be, roughly speaking, the distance between $|\Gamma_{x_i,x_C,a_C}\rangle$ and $|\Gamma_{x_i',x_C,a_C}\rangle$ divided by the probability of Bob obtaining outcome b_C conditioned on Alice obtaining a_C. If we average this distance over all choices of x_C, y_C, a_C, b_C that imply the event W_C, we get that the average distance between $|\Psi_{x_i,y_i,x_C,y_C,a_C,b_C}\rangle$ and $|\Psi_{x_i',y_i,x_C,y_C,a_C,b_C}\rangle$ is approximately $\frac{1}{n\mathsf{P}(W_C)}$. If $\mathsf{P}(W)$ is much greater than $1/n$, then this distance is small. We then invoke quantum correlated sampling (Lemma 3), and that proves the Sampleability Lemma.

Because of space constraints, we omit the proof and refer the reader to the full version at `http://arxiv.org/abs/1604.04340`.

Abstract

We give two results concerning the power of the Sum-Of-Squares(SoS)/Lasserre hierarchy. For binary polynomial optimization problems of degree $2d$ and an odd number of variables n, we prove that $(n+2d-1)/2$ levels of the SoS/Lasserre hierarchy are necessary to provide the exact optimal value. This matches the recent upper bound result by Sakaue, Takeda, Kim and Ito.

Additionally, we study a conjecture by Laurent, who considered the linear representation of a set with no integral points. She showed that the Sherali-Adams hierarchy requires n levels to detect the empty integer hull, and conjectured that the SoS/Lasserre rank for the same problem is $n-1$. We disprove this conjecture and derive lower and upper bounds for the rank.

1 Introduction

In this paper we are concerned with the unconstrained *binary polynomial optimization problems* (BPOP):

$$\min_{x\in\{0,1\}^n} f(x)$$

where $f(x)$ is a multivariate polynomial. Many basic optimization problems are special cases of this general problem. Prominent examples include the MaxCut problem and the boolean Max k-CSP. For these problems the polynomials have at most degree 2 and k, respectively.

The Sum-of-Squares (SoS)/Lasserre hierarchy of semidefinite (SDP) relaxations [14, 21] is one of the most studied solution methods for general polynomial optimization problems (POP) including BPOP. The hierarchy is parameterized by a parameter t called the *relaxation level* and larger levels correspond to tighter relaxations. At level t, the relaxation consists of $n^{O(t)}$ variables and constraints, and it is thus solvable in time $n^{O(t)}$ using for example the ellipsoid method. At level n the SOS hierarchy finds the exact optimal value of an arbitrary constrained BPOP (but not a general POP).

* Supported by the Swiss National Science Foundation project 200020-144491/1 "Approximation Algorithms for Machine Scheduling Through Theory and Experiments".

For *quadratic* BPOP, Laurent [16] conjectured that at level $\lceil \frac{n}{2} \rceil$ the relaxation provides the exact optimal value. She also provided a matching lower bound showing that $\lfloor \frac{n}{2} \rfloor$ levels are not enough for finding the integer cut polytope of the complete graph with n nodes, when n is odd (the result was preceded by a similar lower bound by Grigoriev [9] for the KNAPSACK problem). The conjecture was proved by Fawzi, Saunderson and Parrilo [7] while showing that $\lceil \frac{n}{2} \rceil$ rounds are enough to exactly solve *any* unconstrained BPOP of degree 2. Very recently, Sakaue, Takeda, Kim and Ito [22] extended the result of [7] and showed that the SoS hierarchy requires at most $\lceil (n+r-1)/2 \rceil$ rounds to find the exact optimal value of an unconstrained BPOP of degree r with n variables. Note that the two upper bounds [7, 22] coincide when n is odd and $r = 2$, whereas for even n there is a difference of 1 (although [22] show also that if the optimized polynomial consists of only even degree monomials, the bound reduces to $\lceil (n+r-2)/2 \rceil$, matching the bound of [7] for example for the MAXCUT problem for every n). Furthermore, Sakaue et al. [22] numerically confirmed that for some degrees their bound is tight for certain instances of unconstrained BPOPs with 8 variables.

In a recent breakthrough Lee, Raghavendra and Steurer [17] proved that for the class of MAX-CSPs the SoS relaxation yields the "optimal" SDP approximation, meaning that SDPs of polynomial-size are equivalent in power to those arising from $O(1)$ rounds of the SoS relaxations. This result implies that known lower bound for SoS SDP relaxations translates to corresponding lower bounds on the size of any SDP formulations. With this aim, they build on the work of Grigoriev/Laurent [9, 16] to show that, for odd n, any sum of squares of degree $\lfloor n/2 \rfloor$ polynomials has ℓ_1-error at least $2^{n-2}/\sqrt{n}$ in approximating the following quadratic function

$$f(x) = (\|x\|_1 - \lfloor n/2 \rfloor)(\|x\|_1 - \lfloor n/2 \rfloor - 1) \tag{1}$$

This result is shown to imply lower bounds on the semidefinite extension complexity of the *correlation polytope* (which is isomorphic to the cut polytope and sometimes also called boolean quadric polytope). By reduction, the latter in turn implies exponential lower bounds for the integer cut, TSP and stable set polytopes. In [18] Lee, Prakash, de Wolf and Yuen proved that these lower bounds cannot be improved by showing better ℓ_1-approximations of $f(x)$.

Our Results

In this paper we give two results concerning the power of the SoS hierarchy. Our first result shows that the bound given by Sakaue et al. [22] is tight for polynomials with even degree and an odd number of variables. More precisely, we consider BPOPs of the form $\min_{x \in \{0,1\}^n} f_d(x)$ where $f_d(x)$ is a degree $2d$ (for $d \geq 1$) polynomial defined as follows:

$$f_d(x) = (\|x\|_1 - \lfloor n/2 \rfloor + d - 1)^{\underline{2d}} \tag{2}$$

where $k^{\underline{r}} = k(k-1)\cdots(k-r+1)$ denotes the falling factorial. For $d = 1$ we have $f_1(x) = f(x)$, where $f(x)$ is the polynomial defined in (1) and considered in [17, 18]. We show that for odd $n = 2m+1$, the SoS relaxation allows negative values for polynomial $f_d(x)$ that is non-negative over $\{0,1\}^n$, even at level $\lceil \frac{n+2d-1}{2} \rceil - 1 = m + d - 1$.

Our second result concerns comparing the SoS hierarchy to other lift and project methods. A commonly used benchmark for comparing hierarchies is to find the smallest level at which they find the convex hull of a given set of integral points P,[1] usually given as an intersection

[1] The smallest such level is called the *rank* of P, and it is always smaller or equal to n for the usually studied hierarchies.

of the set $\{0,1\}^n$ and a polytope. Examples of such results include [8, 9, 10, 11, 16, 19, 23]. In [15], Laurent shows that the Sherali-Adams hierarchy detects that the set

$$K = \{0,1\}^n \cap \left\{ x \in [0,1]^n \mid \sum_{r \in R} x_r + \sum_{r \in R \setminus N} (1 - x_r) \geq \frac{1}{2} \text{ for all } R \subseteq N \right\} \tag{3}$$

is empty only after n levels. She then conjectures the SoS rank of K is $n-1$. The polytope K has been used earlier to show that n iterations are needed also for the following procedures: the Lovász-Schrijver N_+ operator (with positive semidefiniteness) [8], the Lovász-Schrijver N_+ operator combined with taking Chvátal cuts [4], and the N_+ operator combined with taking Gomory mixed integer cuts (equivalent to disjunctive cuts) [5]. In this paper we disprove Laurent's conjecture, and show that indeed the SoS rank of K is bounded between $\Omega(\sqrt{n})$ and $n - \Omega(n^{1/3})$.

Interestingly, Au [1] and the authors of this paper [12] independently considered the rank of a variation of the set K where on the right hand side of the inequalities there is an exponentially small constant instead of $\frac{1}{2}$. Both works show that the rank of the modified K is exactly n.

In our proofs we demonstrate the use of a recent theorem of the authors [13] that simplifies the positive semidefiniteness (PSD) condition of the SoS hierarchy when the problem formulation is highly symmetric (as noted in [18], Blekherman [3] has also obtained a similar result that is still in preparation).

Our first result is obtained by showing that a certain conical combination of solutions with non-integral relaxation value to the SoS relaxation for the function (1) gives a negative SoS relaxation value for the polynomials (2) of degree $2d$. Then, for the first and the second result, we apply the theorem in [13] to reduce the PSDness condition into showing that a particular inequality is satisfied for every polynomial with a certain form. Showing that the inequality is satisfied (lower bounds) or cannot be satisfied (upper bounds) then boils down to evaluating or approximating a certain combinatorial sum. Our results also answer the question in [18] regarding the applications of the theorem of [3, 13].

2 The Sum-of-Squares hierarchy

In this paper we consider the SoS hierarchy when applied to (i) unconstrained 0/1 polynomial optimization problems, and (ii) approximating the convex hull of the set

$$P = \{x \in \{0,1\}^n \mid g_\ell(x) \geq 0, \forall \ell \in [p]\} \tag{4}$$

where $g_\ell(x)$ are linear constraints and p a positive integer. The form of the SoS hierarchy we use in this paper is equivalent to the one used in literature (see e.g. [2, 14, 15]) and follows from applying a change of basis to the dual certificate of the refutation of the proof system (see [13] for the details on the change of basis and [20] for discussion on the connection to the proof system). We use this change of basis in order to obtain a useful decomposition of the moment matrices as a sum of rank one matrices of special kind.

For any $I \subseteq N = \{1, \ldots, n\}$, let x_I denote the 0/1 solution obtained by setting $x_i = 1$ for $i \in I$, and $x_i = 0$ for $i \in N \setminus I$. For a function $f : \{0,1\}^n \to \mathbb{R}$, we denote by $f(x_I)$ the value of the function evaluated at x_I. In the SoS hierarchy defined below there is a variable y_I^N that can be interpreted as the "relaxed" indicator variable for the solution x_I. We point out that in this formulation of the hierarchy the number of variables $\{y_I^N : I \subseteq N\}$ is exponential in n, but this is not a problem in our context since we are interested in proving lower and upper bounds rather than solving an optimization problem.

Let $\mathcal{P}_t(N)$ be the collection of subsets of N of size at most $t \in \mathbb{N}$. For every $I \subseteq N$, the q-zeta vector $Z_I \in \mathbb{R}^{\mathcal{P}_q(N)}$ is a 0/1 vector with J-th entry ($|J| \leq q$) equal to 1 if and only if $J \subseteq I$.[2] Note that $Z_I Z_I^\top$ is a rank one matrix and the matrices considered in Definitions 1 and 2 are linear combinations of these rank one matrices.

To simplify the presentation we define the SoS hierarchy separately for polynomial optimization problems and for the integer hull approximation.

▶ **Definition 1.** The t-th round SoS hierarchy relaxation of $\min_{x\in\{0,1\}^n} f(x)$, denoted by $\text{SoS}_t(f)$, is the optimization problem with variables $\{y_I^N \in \mathbb{R} : \forall I \subseteq N\}$ of the form

$$\min_{y^N \in \mathbb{R}^{2^n}} \sum_{I\subseteq N} y_I^N f(x_I) \tag{5}$$

$$\text{s.t.} \sum_{I\subseteq N} y_I^N = 1, \tag{6}$$

$$\sum_{I\subseteq N} y_I^N Z_I Z_I^\top \succeq 0, \text{ where } Z_I \in \mathbb{R}^{\mathcal{P}_t(N)} \tag{7}$$

▶ **Definition 2.** The t-th round SoS hierarchy relaxation for the set P as given in (4), denoted by $\text{SoS}_t(P)$, is the set of variables $\{y_I^N \in \mathbb{R} : \forall I \subseteq N\}$ that satisfy

$$\sum_{I\subseteq N} y_I^N = 1, \tag{8}$$

$$\sum_{I\subseteq N} y_I^N Z_I Z_I^\top \succeq 0, \text{ where } Z_I \in \mathbb{R}^{\mathcal{P}_{t+1}(N)} \tag{9}$$

$$\sum_{I\subseteq N} g_\ell(x_I) y_I^N Z_I Z_I^\top \succeq 0, \ \forall \ell \in [p], \text{ where } Z_I \in \mathbb{R}^{\mathcal{P}_t(N)} \tag{10}$$

It is straightforward to see that the SoS hierarchy formulation given in Definition 2 is a relaxation of the integral polytope. Indeed consider any feasible integral solution $x_I \in P$ and set $y_I^N = 1$ and the other variables to zero. This solution clearly satisfies (8) and (9) because the rank one matrix $Z_I Z_I^\top$ is positive semidefinite (PSD), and (10) since $x_I \in P$.

For a set $Q \subseteq [0,1]^n$, we define the projection from $\text{SoS}_t(Q)$ to $\mathbb{R}^n$ as $x_i = \sum_{i\in I\subseteq N} y_I^N$ for each $i \in \{1, ..., n\}$. The *SoS rank* of Q, $\rho(Q)$, is the smallest t such that $\text{SoS}_t(Q)$ projects exactly to the convex hull of $Q \cap \{0,1\}^n$.

2.1 Using symmetry to simplify the PSDness conditions

In this section we present a theorem given in [13] that can be used to simplify the PSDness conditions (7), (9) and (10) when the problem formulation is very symmetric. More precisely, the theorem can be applied whenever the solutions and constraints are symmetric in the sense that $w_I^N = w_J^N$ whenever $|I| = |J|$ where w_I^N is understood to denote either y_I^N or $g_\ell(x_I) y_I^N$. In what follows we denote by $\mathbb{R}[x]$ the ring of polynomials with real coefficients and by $\mathbb{R}[x]_d$ the polynomials in $\mathbb{R}[x]$ with degree less or equal to d.

[2] In order to keep the notation simple, we do not emphasize the parameter q as the dimension of the vectors should be clear from the context.

▶ **Theorem 3** ([13]). *For any $t \in \{1,\dots,n\}$, let $\mathcal{S}_t$ be the set of univariate polynomials $G_h(k) \in \mathbb{R}[k]$, for $h \in \{0,\dots,t\}$, that satisfy the following conditions:*

$$G_h(k) \in \mathbb{R}[k]_{2t} \tag{11}$$
$$G_h(k) = 0 \qquad \text{for } k \in \{0,\dots,h-1\} \cup \{n-h+1,\dots,n\}, \text{ when } h \geq 1 \tag{12}$$
$$G_h(k) \geq 0 \qquad \text{for } k \in [h-1, n-h+1] \tag{13}$$

For any fixed set of values $\{w_k^N \in \mathbb{R} : k = 0,\dots,n\}$, if the following holds

$$\sum_{k=h}^{n-h} \binom{n}{k} w_k^N G_h(k) \geq 0 \qquad \forall G_h(k) \in \mathcal{S}_t \tag{14}$$

then

$$\sum_{k=0}^{n} w_k^N \sum_{\substack{I \subseteq N \\ |I|=k}} Z_I Z_I^\top \succeq 0$$

where $Z_I \in \mathbb{R}^{\mathcal{P}_t(N)}$.

Note that polynomial $G_h(k)$ in (13) is nonnegative in a *real interval*, and in (12) it is zero over a *set of integers*. Moreover, constraints (14) are trivially satisfied for $h > \lfloor n/2 \rfloor$.

3 Tightness of the SoS upper bounds for unconstrained BPOPs

In [22] it is shown that the SoS hierarchy exactly solves any unconstrained BPOP of degree r with n variables after $\lceil \frac{n+r-1}{2} \rceil$ levels. We show that this bound is tight for certain values of n and r, by giving a polynomial of degree $r = 2d$ for $d \geq 1$ that is non-negative over the hypercube, and show that when $n = 2m+1$, $m \geq d$, the SoS relaxation of the corresponding BPOP attains a negative value at level $t = \lceil \frac{n+2d-1}{2} \rceil - 1 = m + d - 1$.

More precisely, we consider the degree $2d$ polynomial

$$f_d(x) = (\|x\|_1 + d - m - 1)^{\underline{2d}} \tag{15}$$

where $k^{\underline{r}} = k(k-1)\cdots(k-r+1)$ denotes the falling factorial and $\|x\|_1 = \sum_i x_i$. For the sake of convenience, we denote by $f_d(k)$ the univariate polynomial evaluated at any point x with $\sum_i x_i = k$. We obtain the following result

▶ **Theorem 4.** *For odd n, the SoS relaxation of minimizing f_d requires at least $\lceil \frac{n+2d-1}{2} \rceil$ levels to find the exact optimum.*

3.1 Proof of Theorem 4

The case $d = 1$

The polynomial $f_1(x)$ is connected to the MaxCut problem in the complete graph of $n = 2m+1$ vertices in the following way: Let $x \in \{0,1\}^n$ denote any partition of the vertices into two sets in the natural way. Then, the maximal cut is achieved whenever $\sum_i x_i$ is either m or $m+1$, and $m(m+1) - f_1(x)$ counts the edges in the cut. Therefore, the SoS hierarchy is not able to exactly solve the MaxCut problem if it allows for solutions with negative values of the objective function (5).

It is shown in [13] that[3]

$$y_I^N[\alpha] = (n+1)\binom{\alpha}{n+1}\frac{(-1)^{n-|I|}}{\alpha-|I|} \qquad \forall I \subseteq N \tag{16}$$

is a feasible solution to the SoS hierarchy (as given in Definition 1) at level $\lfloor\alpha\rfloor$ for any non-integer $0 < \alpha < \frac{n}{2}$. Since the value of the solution only depends on the size of the set I, we denote by $y_k^N[\alpha]$ any $y_I^N[\alpha]$ with $|I| = k$. As a consequence of the proof in [13] it follows that for any non-integer $0 < \alpha \leq n$, $\sum_{i=0}^n \binom{n}{k} y_k^N[\alpha] = 1$. Furthermore, it is shown that the objective function attains the value $\sum_{k=0}^n \binom{n}{k} y_k^N[\alpha] f_1(k) = f_1(\alpha)$ and that in particular for $\alpha = \frac{n}{2}$, $f_1(\alpha) = -\frac{1}{4}$ at level $t = m$. Next we generalize this approach to $f_d(x)$.

Polynomials of degree $2d$

Consider the following solution

$$z_k^N = (2d-2)!(n+1)\binom{\frac{n}{2}-d+1}{n+1}\frac{(-1)^{n-k}}{(\frac{n}{2}+d-1-k)^{\underline{2d-1}}} \qquad \forall k \in \{0,\ldots,n\} \tag{17}$$

We show that for this solution, the SoS hierarchy objective (5) attains a negative value (see Lemma 10) and (7) is satisfied. For convenience, we do not actually show that (6) is satisfied and in fact it is not. We show, however, that $\sum_{k=0}^n \binom{n}{k} z_k > 0$, which implies that with proper normalization also (6) can be satisfied (see Lemma 7).

First we prove that the solution z_k^N can be written as a conical combination of the solutions $y_k^N[\cdot]$ in (16). We begin with the following lemma about partial fraction decompositions.

▶ **Lemma 5.** *For any $b \in \mathbb{N}_+$ and $a \in \mathbb{R}$ the following identity holds*

$$\frac{1}{(x-a)^{\underline{b}}} = \sum_{i=0}^{b-1} \frac{(-1)^{b-1-i}}{i!(b-1-i)!}\frac{1}{(x-a-i)}\,.$$

Proof. It is known that given two polynomials $P(x)$ and $Q(x) = (x-a_1)(x-a_2)\cdots(x-a_n)$, where the a_i are distinct constants and $\deg P < n$, the rational polynomial $\frac{P(x)}{Q(x)}$ can be decomposed into

$$\frac{P(x)}{Q(x)} = \sum_{i=1}^n \frac{P(a_i)}{Q'(a_i)}\frac{1}{(x-a_i)}$$

where $Q'(x)$ is the derivative of $Q(x)$. In our case, since $P(x) = 1$ and $Q(x) = \prod_{i=0}^{b-1}(x-a-i)$, we get

$$\frac{1}{(x-a)^{\underline{b}}} = \sum_{i=0}^{b-1} \frac{1}{\prod_{j\neq i}(a+i-(a+j))}\frac{1}{(x-a-i)} = \sum_{i=0}^{b-1} \frac{(-1)^{b-1-i}}{i!(b-1-i)!}\frac{1}{(x-a-i)}\,. \qquad \blacktriangleleft$$

Now we can express the solution z_k^N as a conical combination of the solutions $y_k^N[\cdot]$.

[3] The same solution was earlier considered in different basis by [10, 16] for the Knapsack and MaxCut problems respectively to show that the SoS hierarchy does not exactly solve the aforementioned problems at level $\lfloor\frac{n}{2}\rfloor$.

▶ **Lemma 6.** *The solution* (17) *can be decomposed as a conical combination of* $y_k^N[\cdot]$*:*

$$z_k^N = \sum_{j=0}^{2d-2} a_j y_k^N[n/2+d-1-j] \qquad \forall k \in \{0,\dots,n\}$$

for positive

$$a_j = \binom{2d-2}{j} \frac{(\frac{n}{2}+d-1)^{\underline{j}}}{(\frac{n}{2}-d+1+j)^{\underline{j}}}\,.$$

Proof. By Lemma 5 we get that

$$\frac{1}{(\frac{n}{2}+d-1-k)^{\underline{2d-1}}} = \sum_{j=0}^{2d-2} \frac{(-1)^{2d-2-j}}{j!(2d-2-j)!} \cdot \frac{1}{(\frac{n}{2}+d-1-k-j)}$$

and by writing

$$\binom{\frac{n}{2}-d+1}{n+1} = \frac{(-\frac{n}{2}+d-2-j)^{\underline{2d-2-j}}}{(\frac{n}{2}+d-1-j)^{\underline{2d-2-j}}} \binom{\frac{n}{2}+d-1-j}{n+1}$$

and using raising factorial notation, $(-b)^{\underline{a}} = (-1)^a b^{\overline{a}}$, we get that

$$\begin{aligned} z_k^N &= \sum_{j=0}^{2d-2} \frac{(2d-2)!}{j!(2d-2-j)!} \frac{(-\frac{n}{2}+d-2-j)^{\underline{2d-2-j}}}{(\frac{n}{2}+d-1-j)^{\underline{2d-2-j}}} \\ &\quad \cdot (n+1)\binom{\frac{n}{2}+d-1-j}{n+1} \frac{(-1)^{2d-2-j+n-k}}{(\frac{n}{2}+d-1-k-j)} \\ &= \sum_{j=0}^{2d-2} \binom{2d-2}{j} \frac{(\frac{n}{2}-d+2+j)^{\overline{2d-2-j}}}{(\frac{n}{2}+d-1-j)^{\underline{2d-2-j}}} y_k^N\left[\frac{n}{2}+d-1-j\right] \\ &= \sum_{j=0}^{2d-2} \binom{2d-2}{j} \frac{(\frac{n}{2}+d-1)^{\underline{j}}}{(\frac{n}{2}-d+1+j)^{\underline{j}}} y_k^N\left[\frac{n}{2}+d-1-j\right] \end{aligned}$$

◀

▶ **Lemma 7.** *We have* $\sum_{k=0}^n \binom{n}{k} z_k^N > 0$ *for every odd* n*,* $n = 2m+1$*, and* $d \in [m]$*.*

Proof. The proof follows by recalling that for every $\alpha \in [0,n] \setminus \mathbb{Z}$, $\sum_{i=0}^n \binom{n}{k} y_k^N[\alpha] = 1$ and by the fact that all the coefficients in the decomposition in Lemma 6 are positive. ◀

Now we show that the solution (17) is a feasible solution for the SoS hierarchy at level $t = m+d-1$. The solution (17) is symmetric, and so by Theorem 3 (see (14)) is enough to prove that for $t = m+d-1$,

$$\sum_{k=0}^n \binom{n}{k} z_k^N G_h(k) \geq 0 \qquad \forall G_h(k) \in \mathcal{S}_t\,.$$

We first note that the solution (17) attains positive values for every integer $k \in \{m-d+1,\dots,m+d\}$. Indeed, for $k = m-d+1+p$ for $p = \{0,\dots,2d-1\}$, since

$$\left(\frac{n}{2}-d+1\right)^{\underline{n+1}} = \left(\frac{n}{2}-d+1\right)^{\underline{m-d+2}} \left(\frac{1}{2}\right)^{\overline{m+d}} (-1)^{m+d}$$

and for $0 \leq p \leq 2d-1$

$$\left(\frac{n}{2}+d-1-k\right)^{\underline{2d-1}} = \left(2d-\frac{3}{2}-p\right)^{\underline{2d-1-p}} \left(\frac{1}{2}\right)^{\overline{p}} (-1)^p$$

the only, not obviously, non-negative part of z_k^N is

$$\frac{(-1)^{m+d}(-1)^{m+d-p}}{(-1)^p}$$

which is always positive. Thus the above (see (14)) is always satisfied whenever $h \geq m-d+1$ by the definition of the polynomials $G_h \in \mathcal{S}_t$.

It follows that it is enough to prove that the above is satisfied for $h \leq m-d$ which is implied if the following is true

$$\sum_{k=0}^{n} \binom{n}{k} z_k^N P(k) \geq 0$$

for every polynomial $P(x) \in \mathbb{R}[x]_{2t}$ that is nonnegative in the interval $[m-d+1, m+d]$.

▶ **Lemma 8.** *For any polynomial $P(x) \in \mathbb{R}[x]_{2(m+d-1)}$ we have*

$$\sum_{k=0}^{n} \binom{n}{k} z_k^N P(k) = \sum_{j=0}^{2d-2} a_j P\left(\frac{n}{2}+d-1-j\right).$$

Proof. Let $g(k) = (\frac{n}{2}+d-1-k)^{\underline{2d-1}}$ be the polynomial of degree $2d-1$ that corresponds to the denominator in polynomial in z_k^N (see (17)). By the polynomial remainder theorem, $P(k) = g(k)Q(k) + R(k)$, where the $Q(k)$ is the unique polynomial of degree at most $\deg(P) - \deg(g) \leq n-2$, and for the remainder it holds $R(r) = P(r)$ for all the roots r of polynomial $g(k)$. Then

$$\sum_{k=0}^{n} \binom{n}{k} z_k^N P(k) = \sum_{k=0}^{n} \binom{n}{k} z_k^N g(k)Q(k) + \sum_{k=0}^{n} \binom{n}{k} z_k^N R(k).$$

Here $\sum_{k=0}^{n} \binom{n}{k} z_k^N g(k)Q(k) = 0$, as $\sum_{k=0}^{n} (-1)^k \binom{n}{k} k^c = 0$ for every $c \leq n-1$. We remark here that if the level t is greater than $m+d-1$, then the polynomial Q can be of degree n or more and this reasoning fails.

By Lemma 6 we can write the sum with the remainder polynomial $R(k)$ as

$$\sum_{j=0}^{2d-2} a_j \sum_{k=0}^{n} \binom{n}{k} y_k^N \left[\frac{n}{2}+d-1-j\right] R(k)$$

and, again by the polynomial reminder theorem, for every $j \in \{0, \ldots, 2d-2\}$, $R(k) = (\frac{n}{2}+d-1-j-k)S_j(k) + R(\frac{n}{2}+d-1-j)$ and as before, since the degree of R is less or equal to $2d-2$, we have $\sum_{i=0}^{n} (-1)^k \binom{n}{k} S_j(k) = 0$. Thus, since $R(r) = P(r)$ for all the roots r of the polynomial $g(k)$, the above reduces to

$$\sum_{j=0}^{2d-2} a_j \left(R\left(\frac{n}{2}+d-1-j\right) \underbrace{\sum_{k=0}^{n} \binom{n}{k} y_k^N \left[\frac{n}{2}+d-1-j\right]}_{=1} \right)$$

$$= \sum_{j=0}^{2d-2} a_j P\left(\frac{n}{2}+d-1-j\right)$$

◀

By Lemma 8 we immediately obtain the following corollary.

▶ **Corollary 9.** *For any polynomial* $P(x) \in \mathbb{R}[x]_{2(m+d-1)}$ *such that* $P(x) \geq 0$ *for* $x \in [m-d+1, m+d]$ *we have*

$$\sum_{k=0}^{n} \binom{n}{k} z_k^N P(k) \geq 0\,.$$

Proof. By Lemma 8 we have that

$$\sum_{k=0}^{n} \binom{n}{k} z_k^N P(k) = \sum_{j=0}^{2d-2} a_k P\left(\frac{n}{2} + d - 1 - j\right)$$

which is positive since it is a conical combination of points at which polynomial P is positive. ◀

It remains to show that the objective value of the SoS hierarchy (5) attains a negative value.

▶ **Lemma 10.** *The sum* $\sum_{k=0}^{n} \binom{n}{k} z_k^N f_d(k)$ *is negative for every odd* $n = 2m+1$*, for any positive integer* m *and* $d \in \{1, ..., m\}$*.*

Proof. By Lemma 8, the solution z_k^N is such that

$$\sum_{k=0}^{n} \binom{n}{k} z_k^N f_d(k) = \sum_{j=0}^{2d-2} a_j f_d\left(\frac{n}{2} + d - 1 - j\right)\,.$$

Then, the claim is proved by showing that the following function $g(d,n)$ is negative for every odd $n = 2m+1$, for any positive integer m and $d \in [m]$. Formally, that

$$g(d,n) = \sum_{j=0}^{2d-2} \binom{2d-2}{j} \frac{(\frac{n}{2}+d-1)^{\underline{j}}}{(\frac{n}{2}-d+1+j)^{\underline{j}}} (2d-3/2-j)^{\underline{2d}} < 0$$

More precisely we show that the following identity holds (where !! denotes the double factorial).

$$g(d,n) = (2d-3/2)^{\underline{2d}} \cdot \frac{4^{d-1}(2d-2)!(2d-1)!!}{(d-1)!(4d-3)!!} \cdot \frac{(2m-2d+3)!!(m-1)!}{(m-d)!(2m+1)!!} \tag{18}$$

By simple inspection it is easy to see that (18) is negative and the claim follows.

We start by rewriting $g(d,n)$ by using the following (easy to check) identities:

$$\binom{2d-2}{j}\left(\frac{n}{2}+d-1\right)^{\underline{j}} = \frac{(2-2d)^{\overline{j}}\left(1-d-\frac{n}{2}\right)^{\overline{j}}}{j!}$$

$$\left(\frac{n}{2}-d+1+j\right)^{\underline{j}} = \left(2-d+\frac{n}{2}\right)^{\overline{j}}$$

$$(2d-3/2-j)^{\underline{2d}} = (2d-3/2)^{\underline{2d}} \frac{(3/2)^{\overline{j}}}{(3/2-2d)^{\overline{j}}}$$

By the above identities we have that

$$\begin{aligned} g(d,n) &= \sum_{j=0}^{2d-2} \binom{2d-2}{j} \frac{(\frac{n}{2}+d-1)^{\underline{j}}}{(\frac{n}{2}-d+1+j)^{\underline{j}}} (2d-3/2-j)^{\underline{2d}} \\ &= (2d-3/2)^{\underline{2d}} \sum_{j=0}^{2d-2} \frac{(2-2d)^{\overline{j}}\left(1-d-\frac{n}{2}\right)^{\overline{j}}(3/2)^{\overline{j}}}{\left(2-d+\frac{n}{2}\right)^{\overline{j}}(3/2-2d)^{\overline{j}}} \cdot \frac{1}{j!} \\ &= (2d-3/2)^{\underline{2d}} \sum_{j=0}^{\infty} \frac{(2-2d)^{\overline{j}}\left(1-d-\frac{n}{2}\right)^{\overline{j}}(3/2)^{\overline{j}}}{\left(2-d+\frac{n}{2}\right)^{\overline{j}}(3/2-2d)^{\overline{j}}} \cdot \frac{1}{j!} \\ &= (2d-3/2)^{\underline{2d}} \cdot {}_3F_2\left[\begin{matrix} a & b & c \\ 1+a-b & 1+a-c \end{matrix}; 1\right] \end{aligned} \tag{19}$$

where ${}_3F_2\left[\begin{smallmatrix} a & b & c \\ 1+a-b & 1+a-c \end{smallmatrix}; 1\right] = \sum_{j=0}^{\infty} \frac{(a)^{\overline{j}}(b)^{\overline{j}}(c)^{\overline{j}}}{(1+a-b)^{\overline{j}}(1+a-c)^{\overline{j}}} \cdot \frac{1}{j!}$ is the generalized hypergeometric series with $a = 2-2d$, $b = 1-d-n/2$ and $c = 3/2$.

Note that $1+a/2-b-c = \frac{n-1}{2} > 0$ and by using Dixon's identity [6] for the generalized hypergeometric series ${}_3F_2\left[\begin{smallmatrix} a & b & c \\ 1+a-b & 1+a-c \end{smallmatrix}; 1\right]$ (when $\Re(1+a/2-b-c) > 0$) we have

$$\begin{aligned} {}_3F_2\left[\begin{matrix} a & b & c \\ 1+a-b & 1+a-c \end{matrix}; 1\right] &= \frac{\Gamma(1+\frac{1}{2}a)\Gamma(1+a-b)\Gamma(1+a-c)\Gamma(1+\frac{1}{2}a-b-c)}{\Gamma(1+a)\Gamma(1+\frac{1}{2}a-b)\Gamma(1+\frac{1}{2}a-c)\Gamma(1+a-b-c)} \\ &= \frac{\Gamma(2-d)\Gamma(5/2-d+m)\Gamma(3/2-2d)\Gamma(m)}{\Gamma(3-2d)\Gamma(3/2+m)\Gamma(1/2-d)\Gamma(1-d+m)} \end{aligned}$$

Note that $\Gamma(2-d) = (1-d)\Gamma(1-d)$ and $\Gamma(3-2d) = 2(1-d)(1-2d)\Gamma(1-2d)$. By using the Euler's reflection formula we have that $\frac{\sin(\pi d)}{\pi} = \frac{1}{\Gamma(1-d)\Gamma(d)}$ and $\frac{\sin(\pi 2d)}{\pi} = \frac{1}{\Gamma(1-2d)\Gamma(2d)}$, and by the integrality of d we have that

$$\frac{\Gamma(1-d)}{\Gamma(1-2d)} = \frac{\sin(\pi 2d)(2d-1)!}{\sin(\pi d)(d-1)!} = \frac{2\cos(\pi d)(2d-1)!}{(d-1)!} = \frac{2(-1)^d(2d-1)!}{(d-1)!}.$$

Therefore

$$\frac{\Gamma(2-d)}{\Gamma(3-2d)} = (-1)^{d+1}\frac{(2d-2)!}{(d-1)!}.$$

Recall that for nonnegative integer values of x we have $\Gamma(\frac{1}{2}-x) = \frac{(-2)^x}{(2n-1)!!}\sqrt{\pi}$ and $\Gamma(\frac{1}{2}+x) = \frac{(2x-1)!!}{2^x}\sqrt{\pi}$, and the following holds.

$$\begin{aligned} {}_3F_2\left[\begin{matrix} a & b & c \\ 1+a-b & 1+a-c \end{matrix}; 1\right] &= (-1)^{d+1}\frac{(2d-2)!}{(d-1)!}\frac{(m-1)!}{(m-d)!} \cdot \frac{\Gamma(\frac{5}{2}-d+m)\Gamma(\frac{3}{2}-2d)}{\Gamma(\frac{3}{2}+m)\Gamma(\frac{1}{2}-d)} \\ &= \frac{4^{d-1}(2d-2)!(2d-1)!!}{(d-1)!(4d-3)!!}\frac{(2m-2d+3)!!(m-1)!}{(m-d)!(2m+1)!!} \end{aligned}$$

By simple inspection we see that ${}_3F_2\left[\begin{smallmatrix} a & b & c \\ 1+a-b & 1+a-c \end{smallmatrix}; 1\right]$ is always positive and $g(d,n)$, see (19), is negative as claimed. ◀

4 Rank bounds for detecting a particular empty integral hull

In [15] Laurent considers the representation of the empty set as (3) and shows that the Sherali-Adams procedure requires n levels to detect that $K = \emptyset$. She conjectures that the SoS rank of K is $n-1$. In this section we disprove this conjecture and derive a lower and upper bound for the SoS rank of K.

▶ **Theorem 11.** *The SoS rank of K in (3) can be bounded by $\Omega(\sqrt{n}) \leq \rho(K) \leq n - \Omega(n^{\frac{1}{3}})$.*

Proof.

The upper bound

By symmetry, the solution $y_I^N = \frac{1}{2^n}$ for each $I \subseteq N$ is feasible to $\text{SoS}_t(K)$ unless $\text{SoS}_t(K) = \emptyset$. Let us assume that such a solution is feasible and consider the constraint of K corresponding to $R = N$. Then, $g_R(x_I)$ is negative only when $I = \emptyset$.

To analyse the PSDness, we apply Theorem 3. Notice that in this case we can assume that $P(k)$ is of the form $G_0(k)$, since if $h > 0$, the only negative term in the sum (14) corresponding to $k = 0$ is canceled due to $G_h(0) = 0$, and the inequality holds trivially. Therefore, the PSDness condition (10) reduces to

$$\sum_{k=0}^{n} \binom{n}{k} \frac{1}{2^n} \left(k - \frac{1}{2}\right) P^2(k) \geq 0 \tag{20}$$

for every polynomial P of degree t. Importantly, what is not mentioned in the statement of Theorem 3, in this case the PSDness condition actually becomes an if and only if condition (see Theorem 7 in [13]). Therefore, showing that (20) is not satisfied implies that the PSDness condition (10) is not satisfied.

We now fix the polynomial as $P(k) = \prod_{i=1}^{t}(n - k - i + 1)$, i.e., such that P has the roots at $n, n-1, ..., n-t+1$, and argue that such a polynomial can never satisfy (20) when t is large. Indeed, rewriting the condition using this polynomial, removing the redundant factor $\frac{1}{2^n}$ and moving the negative term to the right hand side, we have the necessary requirement for the positive semidefiniteness that

$$\sum_{k=1}^{n-t} \binom{n}{k} \left(k - \frac{1}{2}\right) \prod_{i=1}^{t}(n - k - i + 1)^2 \geq \frac{1}{2} \prod_{i=1}^{t}(n - i + 1)^2 .$$

Notice that now the sum goes up to $n - t$ only, since all the terms $k > n - t$ are 0 by our choice of the polynomial. By dividing both sides by the positive term $\prod_{i=1}^{t}(n - i + 1)^2$ and observing that $\frac{\prod_{i=1}^{t}(n-k-i+1)}{\prod_{i=1}^{t}(n-i+1)} = \frac{(n-t)^{\underline{k}}}{n^{\underline{k}}}$, the condition further simplifies to

$$\sum_{k=1}^{n-t} \binom{n}{k} \left(k - \frac{1}{2}\right) \left(\frac{(n-t)^{\underline{k}}}{n^{\underline{k}}}\right)^2 \geq \frac{1}{2} \tag{21}$$

Next we upper bound the sum on the left hand side of (21) by considering a generic element for any $1 \leq k \leq n - t$. Any element can be bounded by

$$\binom{n}{k} \left(k - \frac{1}{2}\right) \left(\frac{(n-t)^{\underline{k}}}{n^{\underline{k}}}\right)^2 \leq \frac{n^k e^k}{k^k} k \frac{(n-t)^{2k}}{(n-k)^{2k}} \leq \frac{e^k}{k^{k-1}} \left(\frac{n(n-t)^2}{(n-k)^2}\right)^k .$$

Here we use $\frac{e^k}{k^{k-1}} < 3$ for any k and $\frac{1}{n-k} \leq \frac{1}{t}$ for $k \leq n - t$. Then, for $t \geq n - o(\sqrt{n})$, it holds $\frac{n(n-t)^2}{t^2} < 1$ so we can approximate

$$\frac{e^k}{k^{k-1}} \left(\frac{n(n-t)^2}{(n-k)^2}\right)^k \leq 3 \frac{n(n-t)^2}{t^2} .$$

Now, the sum on the left hand side of (21) is upper bounded by $3(n-t)\frac{n(n-t)^2}{t^2}$ and thus the solution is never feasible to $\text{SoS}_t(K)$ if

$$3 \frac{n(n-t)^3}{t^2} < \frac{1}{2} .$$

Setting $t = n - Cn^{\frac{1}{3}}$ satisfies the inequality asymptotically for an appropriate constant C.

The lower bound

We show that the symmetric solution $y_I^N = \frac{1}{2^n}$ is feasible for $\text{SoS}_t(K)$ when t is $\Omega(\sqrt{n})$. Again, by symmetry it is enough to show that the moment matrix of one constraint is PSD, and again we consider the constraint corresponding to $R = N$. Therefore, we need to show that (20) is satisfied for any choice of the polynomial P with degree less or equal to t. Writing the polynomial P in root form with roots $r_i,\ i = 1, ..., t$, we get similarly as in (21) the condition

$$\sum_{k=1}^{n} \binom{n}{k} \left(k - \frac{1}{2}\right) \prod_{i=1}^{t} \left(\frac{k - r_i}{r_i}\right)^2 \geq \frac{1}{2} \tag{22}$$

Now, we seek for a lower bound for the sum on the left hand side and find the condition on t such that the lower bound still exceeds $\frac{1}{2}$.

One can show (see [13]) that the roots r_i can be assumed to be real and to be located in the interval $[0, n]$. Furthermore, we can assume that the polynomial has degree of exactly t. Then, we look for the worst-case assignment for the roots.

No matter how the roots are located, there exist at least one non-zero point $k \in N$ such that $|k - r_i| \geq \frac{n}{2(t+1)}$ for every root r_i and $k \geq \lfloor \frac{n}{2(t+1)} \rfloor$. In the worst case the smallest of such points is $\lfloor \frac{n}{2(t+1)} \rfloor$. Let $u = \lfloor \frac{n}{2(t+1)} \rfloor$ be this point. Then, (22) is satisfied if we can show that

$$\binom{n}{u} \left(u - \frac{1}{2}\right) \frac{\left(\frac{n}{2(t+1)}\right)^{2t}}{\prod_{i=1}^{t} r_i^2} \geq \frac{1}{2}\,.$$

Next, the worst case of the location for the roots in this formulation is $r_i = n$ for every $i = 1, ..., t$, since all the roots can be assumed to be less or equal to n. We can also get rid of the term $u - \frac{1}{2}$, since it is always greater than 1. We then obtain that (22) holds if

$$\binom{n}{u} \frac{\left(\frac{n}{2(t+1)}\right)^{2t}}{n^{2t}} \geq \frac{1}{2}\,.$$

Here we use the inequality $\binom{n}{u} > \frac{n^u}{u^u}$ and the fact that $\frac{1}{2(t+1)} \geq \frac{1}{4t}$ to get that if $\frac{n^u}{u^u}(4t)^{-2t} \geq \frac{1}{2}$ holds, then the solution is feasible for $\text{SoS}_t(K)$. We have that $n \geq tu$, so the above is satisfied if

$$\frac{(tu)^u}{u^u}(4t)^{-2t} \geq \frac{1}{2} \Leftrightarrow t^u(4t)^{-2t} \geq \frac{1}{2}\,.$$

We have that $u \geq \frac{n}{4t}$, so it is enough to satisfy $t^{\frac{n}{4t}}(4t)^{-2t} \geq \frac{1}{2}$, which is equivalent to $4^{-2t}t^{\frac{n}{4t}-2t} \geq \frac{1}{2}$. If here $t = \frac{\sqrt{n}}{4}$ we need to then satisfy $4^{-\sqrt{n}}\sqrt{n}^{\sqrt{n}/2} \geq \frac{1}{2}$, which holds asymptotically in n. ◀

Open question. We note that applying the theorem of [13], it is possible to perform numerical experiments to test the SoS rank of the polytope K with large number of variables. For a fixed number of variables, the upper bound can be experimented by fixing the polynomial P in (20) in some systematic way and by finding the level t (i.e., the number of roots) for which the expression is positive/negative for that polynomial. For the lower bound, the polynomial in (20) can be expressed in the root form and the PSDness can be tested using a numerical solver to minimize the resulting expression, where the roots are the variables to be minimized.

Based on such experiments, we conjecture that the SoS rank of K is "close" to $\frac{n}{2}$ and suggest that our bounds in Theorem 11 are far from being tight. Therefore we leave it as an open question to improve our bounds for the rank.

Abstract

The algebraic dichotomy conjecture of Bulatov, Krokhin and Jeavons yields an elegant characterization of the complexity of constraint satisfaction problems. Roughly speaking, the characterization asserts that a CSP L is tractable if and only if there exist certain non-trivial operations known as polymorphisms to combine solutions to L to create new ones.

In this work, we study the dynamical system associated with repeated applications of a polymorphism to a distribution over assignments. Specifically, we exhibit a correlation decay phenomenon that makes two variables or groups of variables that are not perfectly correlated become independent after repeated applications of a polymorphism.

We show that this correlation decay phenomenon can be utilized in designing algorithms for CSPs by exhibiting two applications:

1. A simple randomized algorithm to solve linear equations over a prime field, whose analysis crucially relies on correlation decay.
2. A sufficient condition for the simple linear programming relaxation for a 2-CSP to be sound (have no integrality gap) on a given instance.

1 Introduction

A vast majority of natural computational problems have been classified to be either polynomial-time solvable or NP-complete. While there is little progress in determining the exact time complexity for fundamental problems like matrix multiplication, it can be argued that a much coarser classification of P vs.~NP-complete has been achieved for a large variety of problems. Notable problems that elude such a classification include factorization or graph isomorphism.

A compelling research direction at this juncture is to understand what causes problems to be easy (in P) or hard (NP-complete). More precisely, for specific classes of problems, does there exist a unifying theory that explains and characterizes why some problems in the class are in P while others are NP-complete? For the sake of concreteness, we will present a few examples.

It is well-known that 2-Sat is polynomial-time solvable, while 3-Sat is NP-complete. However, the traditional proofs of these statements are unrelated to each other and therefore shed little light on what makes 2-Sat easy while 3-Sat NP-complete.

Over the last decade, a theory of tractability has emerged for the class of constraint satisfaction problems (CSP). While this candidate theory remains conjectural for now, it successfully explains all the existing algorithms and hardness results for CSPs. To set the stage for the results of this paper, we begin with a brief survey of the theory for CSPs.

A constraint satisfaction problem (CSP) Λ is specified by a family of predicates over a finite domain $[q] = \{1, 2, \ldots, q\}$. Every instance of the CSP Λ consists of a set of variables $\mathcal{V}$, along with a set of constraints $\mathcal{C}$ on them. Each constraint in $\mathcal{C}$ consists of a predicate from the family Λ applied to a subset of variables. For a CSP Λ, the associated satisfiability problem Λ-Sat is defined as follows.

▶ **Problem 1** (Λ-Sat)**.** *Given an instance $\Im$ of the CSP Λ, determine whether there is an assignment satisfying all the constraints in $\Im$.*

A classic theorem of Schaefer [11] asserts that among all satisfiability problems over the boolean domain ($\{0, 1\}$), only Linear-Equations-Mod-2, 2-Sat, Horn-Sat, Dual-Horn Sat and certain trivial CSPs are solvable in polynomial time. The rest of the boolean CSPs are NP-complete. The dichotomy conjecture of Feder and Vardi [7] asserts that every Λ-Sat is in P or NP-complete. The conjecture has been shown to hold for CSPs over domains of size up to 3 [4].

In this context, it is natural to question as to what makes certain Λ-Sat problems tractable while the others are NP-complete. Bulatov, Jeavons and Krokhin [6] conjectured a beautiful characterization for tractable satisfiability problems. We will present an informal description of this characterization known as the *algebraic dichotomy conjecture*. We refer the reader to the work of Kun & Szegedy [8] for a more formal description.

To motivate this characterization, let us consider a CSP known as the XOR problem. An instance of the XOR problem consists of a system of linear equations over $\mathbb{Z}_2 = \{0, 1\}$. Fix an instance $\Im$ of XOR over n variables. Given three solutions $X^{(1)}, X^{(2)}, X^{(3)} \in \{0, 1\}^n$ to $\Im$, one can create a new solution $Y \in \{0, 1\}^n$:

$$Y_i = X_i^{(1)} \oplus X_i^{(2)} \oplus X_i^{(3)} \qquad \forall i \in [n]\,.$$

It is easy to check that Y is also a feasible solution to the instance $\Im$. Thus the $XOR : \{0, 1\}^3 \to \{0, 1\}$ yields a way to combine three solutions in to a new solution to the same instance. Note that the function XOR was applied to each bit of the solution individually. An operation of this form that preserves the satisfiability of the CSP is known as a *polymorphism*. Formally, a polymorphism of a CSP Λ-Sat is defined as follows:

▶ **Definition 2** (Polymorphisms)**.** A function $p : [q]^R \to [q]$ is said to be *a polymorphism* for the CSP Λ-Sat, if for every instance $\Im$ of Λ, and R assignments $X^{(1)}, X^{(2)}, \ldots, X^{(R)} \in [q]^n$ that satisfy all constraints in $\Im$, the vector $Y \in [q]^n$ defined below is also a feasible solution.

$$Y_i = p(X_i^{(1)}, X_i^{(2)}, X_i^{(3)}, \ldots, X_i^{(R)}) \qquad \forall i \in [n]\,.$$

Note that the dictator functions $p(x^{(1)}, \ldots, x^{(R)}) = x^{(i)}$ are polymorphisms for every CSP Λ-Sat. These will be referred to as *projections* or trivial polymorphisms. All the tractable cases of boolean CSPs in Schaefer's theorem are characterized by existence of non-trivial polymorphisms. Specifically, 2-SAT has the Majority function, Horn-SAT has the OR function, and Dual Horn-SAT has the AND function as a polymorphism. Roughly speaking, Bulatov et al. [6] conjectured that the existence of non-dictator polymorphisms characterizes CSPs that are tractable. Their work showed that the set of polymorphisms Poly(Λ) of a CSP Λ characterizes the complexity of Λ-Sat. There are many equivalent

ways of formalizing what it means for an operation to be *non-trivial* or *non-dictator*. A particularly simple way to formulate the algebraic dichotomy conjecture arises out of the recent work of Barto and Kozik [2]. A polymorphism $p : [q]^k \to [q]$ is called a *cyclic term* if

$$p(x_1, \ldots, x_k) = p(x_2, \ldots, x_k, x_1) = \ldots = p(x_k, x_1, \ldots, x_{k-1}) \quad \forall x_1, \ldots, x_k \in [q] \,.$$

Note that the above condition strictly precludes the operation p from being a dictator.

▶ **Conjecture 3** ([6, 9, 2]). Λ-SAT *is in* P *if* Λ *admits a cyclic term, otherwise* Λ-SAT *is* NP*-complete.*

Surprisingly, one of the implications of the conjecture has already been confirmed.

▶ **Theorem 4** ([6, 9, 2]). Λ-SAT *is* NP*-complete if* Λ *does not admit a cyclic term.*

The algebraic approach to understanding the complexity of CSPs has received much attention, and the algebraic dichotomy conjecture has been verified for several subclasses of CSPs such as conservative CSPs [3], CSPs with no ability to count [1] and CSPs with Maltsev operations [5]. Recently, Kun and Szegedy reformulated the algebraic dichotomy conjecture using analytic notions similar to influences [8].

Despite considerable progress in recent years [2], the algebraic dichotomy conjecture still remains open. Kun & Szegedy suggested the use of analytic techniques towards resolving the conjecture [8], which forms the inspiration for this work. This work demonstrates a phenomenon of correlation decay associated with iterated applications of polymorphisms and then exploits this phenomenon towards designing algorithms for CSPs.

1.1 Correlation Decay

We associate a natural dynamical system with a polymorphism $p : [q]^k \to [q]$ that corresponds to iterated applications of the polymorphism. Towards a formal definition of the dynamical system, let us fix a probability distribution μ over $[q]^n$. It is useful to think of μ as a distribution over assignments to a CSP instance on n variables.

For an operation $p : [q]^k \to [q]$, the distribution $p(\mu)$ over $[q]^n$ is one that is sampled by taking k independent samples from μ and applying the operation p to them. Define the dynamical system $\{\mu_t\}_{t \in \mathbb{N}}$ with $\mu_0 = \mu$,

$$\mu_t \stackrel{\text{def}}{=} p(\mu_{t-1}) \,, \forall t \in \mathbb{N}.$$

Roughly speaking, the key technical insight of this work is that the correlations among the coordinates decay as $t \to \infty$ for a *non-dictator* operation p. For the sake of simplicity, let us restrict our attention to the case of a distribution μ_{XY} on $[q] \times [q]$ (see Section 4 for the general theorem on distributions over $[q]^n$). Let $\mu_{|X}$ and $\mu_{|Y}$ denote the marginals of μ_{XY}. For any distribution Θ, let $\mathrm{supp}(\Theta)$ denote its support. We are ready to state a version of our correlation decay theorem.

▶ **Theorem 5.** *Let* μ_{XY} *be a distribution over* $[q] \times [q]$*. Let* $G_{\mu_{XY}}$ *denote the bipartite graph on vertices* $\mathrm{supp}(\mu_{|X}) \cup \mathrm{supp}(\mu_{|Y})$ *whose edges are given by the support of* μ_{XY}*. For a cyclic term* $p : [q]^k \to [q]$*, consider the dynamical system* $\{\mu_t\}_{t \in \mathbb{N}}$ *defined as* $\mu_0 := \mu_{XY}$*,* $\mu_t := p(\mu_{t-1}) \forall t \in \mathbb{N}$*. If* $G_{\mu_{XY}}$ *is a connected graph then*

$$\lim_{t \to \infty} \|\mu_t - \mu_{t|X} \times \mu_{t|Y}\|_1 = 0 \,.$$

i.e., μ_t *gets closer and closer to a product distribution as* $t \to \infty$*.*

Suppose p is a polymorphism of a CSP Λ and μ_{XY} is a distribution supported over satisfying assignments to an instance of Λ, then for every t, μ_t is also supported over satisfying assignments to Λ. Intuitively, this seems to be at odds with the correlation decay phenomenon: cyclic polymorphisms make variables uncorrelated yet still preserve satisfying assignments.

To resolve this paradox, notice that Theorem 5 requires that the graph $G_{\mu_{XY}}$ be *connected*. Connectivity of $G_{\mu_{XY}}$ corresponds to asserting that there are *no perfect correlations* between X and Y. This lack of perfect correlation can be quantified using the spectrum of the bipartite graph $G_{\mu_{XY}}$. Specifically, one can associate a correlation parameter $\rho(X,Y)$ (see Definition 18) such that $\rho(X,Y) < 1$ if and only if $G_{\mu_{XY}}$ is connected. $\rho(X,Y)$ is closely related to the second-eigenvalue of the adjacency matrix of the bipartite graph $G_{\mu_{XY}}$.

If $G_{\mu_{XY}}$ is disconnected, every connected component of $G_{\mu_{XY}}$ corresponds to a *perfect correlation* between X and Y. If the support of μ consists of all satisfying assignments to a constraint, then the polymorphism p necessarily preserves these *perfect correlations*, i.e., for all $t \in \mathbb{N}$, (X,Y) sampled from μ_t will be such that X and Y belong to the same connected component of $G_{\mu_{XY}}$. Summarizing, our result suggests that a cyclic polymorphism preserves *perfect correlations*, while *imperfect correlations* decay.

Discussion. A brief overview of the correlation decay argument is presented in Section 4. The details of the argument are fairly technical and draw upon various analytic tools such as hypercontractivity, the Berry-Esseen theorem and Fourier analysis (see Section 4). A key bottleneck in the analysis is that the individual marginals change with each iteration thereby changing the fourier spectrum of the operations involved.

Theorem 5 can be thought of as an analytic analogue of a theorem on *absorbing subalgebras* (Theorem 4.11 in [1]), which formed a key ingredient in the breakthrough work of Barto and Kozik [1]. This work of Barto and Kozik showed that a major subclass of CSPs namely *CSPs with no ability to count* can be solved using local consistency. Roughly speaking, *CSPs with no ability to count* are precisely those that don't contain linear equations within them, i.e., these CSPs don't admit gadget reductions from linear equations over a finite field.

Interestingly, we will show that the same correlation decay phenomenon is useful in solving linear equations over prime fields! We will also present an application of correlation decay towards rounding linear programming relaxations for CSPs. We will outline these two applications in the upcoming subsections.

1.2 Solving Linear Systems

The input to the algorithm consists of a linear system $Ax = b$ where $A \in \mathbb{F}_q^{m \times n}$ and $b \in \mathbb{F}_q^n$. Consider the following naive algorithm for solving the linear systems for some $N \in \mathbb{N}$.

1. $\mathcal{S}_0 \leftarrow N$ uniformly random assignments from $\mathbb{F}_q^n$.
2. for $i = 1$ to m do
   - **Selection:** $\mathcal{S}_i \leftarrow \mathcal{S}_{i-1} \cap \{x | \langle A_i, x\rangle = b_i\}$
3. Output an assignment $z \in \mathcal{S}_m$ if $\mathcal{S}_m \neq \emptyset$, else output INFEASIBLE

Clearly, if the algorithm outputs an assignment z then $Az = b$. By definition, the i^{th} *generation* $\mathcal{S}_i$ consists of uniformly random assignments that satisfy the first i equations $\{\langle A_j, x\rangle = b_j | j \leqslant i\}$. Therefore, the $i+1^{st}$ linear function $\langle A_{i+1}, x\rangle$ is either constant over $\mathcal{S}_i$ or takes every value in $\mathbb{F}_q$ with probability roughly $1/q$.

If the linear system $Ax = b$ is satisfiable and is linearly independent, then the expected size of i^{th} generation $\mathcal{S}_i$ is given by $\mathbb{E}\,|\mathcal{S}_i| = \frac{1}{q}\,\mathbb{E}\,|\mathcal{S}_{i-1}|$. Therefore the initial sample size

Input: $A \in \mathbb{F}_q^{m \times n}$, $b \in \mathbb{F}_q^m$

1. $\mathcal{S}_0 \leftarrow N$ uniformly random assignments from $\mathbb{F}_q^n$.
2. for $i = 1$ to m do
   - **Selection:** $\mathcal{T}_i \leftarrow \mathcal{S}_{i-1} \cap \{x | \langle A_i, x \rangle = b_i\}$
   - **Recombination:** Generate $\mathcal{S}_i$ by using the following sampling procedure N times independently.
     - Sample $y^{(1)}, y^{(2)}, y^{(3)}$ i.i.d from $\mathcal{T}_i$ and compute $p(y^{(1)}, y^{(2)}, y^{(3)}) = y^{(1)} - y^{(2)} + y^{(3)}$.
3. Output an assignment $z \in \mathcal{S}_m$ if $\mathcal{S}_m \neq \emptyset$, else output INFEASIBLE

Figure 1 Randomized algorithm for linear equations over $\mathbb{F}_q$.

$|\mathcal{S}_0|$ has to be at least q^m to ensure the correctness of the algorithm, making the runtime exponential.

A natural approach to fix the algorithm is as follows. After each selection step, use the polymorphism associated with linear systems in order to *create* new assignments from the existing sample. For the sake of concreteness, we fix the following polymorphism $p : [q]^3 \to [q]$ for linear systems.

$$p(y^{(1)}, y^{(2)}, y^{(3)}) = y^{(1)} - y^{(2)} + y^{(3)} \, .$$

The details of the algorithm are as shown in Figure 1.

Since p is a polymorphism, the recombination steps don't affect the progress made in the selection steps, i.e., $\mathcal{S}_i$ satisfy the first i equations for each i. While the polymorphism p is useful to maintain the sample size after each selection, the sample size alone is insufficient to ensure the success of the algorithm. We require the sample $\mathcal{S}_i$ to be somewhat similar a uniformly random sample from the set of all solutions to the first i equations.

Here is an alternate take on the issue. A finite sized sample $\mathcal{S}$ of a distribution μ has *spurious correlations* that are absent in μ. For example, in the initial sample $\mathcal{S}_0$, the first two variables $x_1, x_2 \in [q]$ will be close to independent, but there is bound to be some assignment $\alpha, \beta \in [q]^2$ such that $\mathbb{P}_{x \in \mathcal{S}_0}[x_1 = \alpha \wedge x_2 = \beta] \geqslant 1/q^2 + \Omega(1/\sqrt{N})$ due to random deviation. At the i^{th} stage, the sample $\mathcal{S}_i$ has a set of *perfect correlations* induced by the first i equations, but there are additional *spurious correlations* between the variables owing to sample size being bounded.

The magnitudes of spurious correlations in the sample need to be controlled. Otherwise, a spurious correlation could result in $\langle A_i, x \rangle \neq b_i$ for all $x \in \mathcal{S}_{i-1}$ for some i, making $\mathcal{T}_i = \emptyset$ even though the linear system is satisfiable. Each selection step reduces the sample size thereby potentially amplifying the spurious correlations. However, the recombination step exploits the correlation decay phenomena to decrease the spurious correlations. In Section 3, we will show the following.

▶ **Theorem 6.** *For all primes q, the randomized algorithm in Figure 1 with the choice $N = \lceil (150q^4 \ln q) \cdot n \rceil$ satisfies these properties.*

Completeness: *If algorithm returns $z \in \mathbb{F}_q^n$, then z satisfies the linear system $Az = b$.*

Soundness: *If the system $Ax = b$ is feasible, then with probability at least $1 - e^{-n}$ the algorithm will return a solution to the system.*

The algorithm described above is somewhat similar to a deterministic algorithm of Bulatov and Dalmau [5] for CSPs admitting Maltsev polymorphisms in that it maintains a basis for the solution space and updates the basis by including one equation in to the system at each step. We find the randomized algorithm interesting in that it admits a very generic

description that uses little about the structure of the underlying CSP. Moreover, the analysis of the algorithm crucially relies on correlation decay – a phenomenon that seems inherent to all tractable CSPs.

1.3 Rounding Linear Programs via Correlation Decay

Correlation decay can also be used towards rounding linear programming relaxations. For the sake of clarity, let us restrict our attention to 2-CSPs where every constraint has arity two. These results can be generalized to k-CSPs. Further, every CSP can be reduced to a 2-CSP while preserving the existence of cyclic terms.

First, we introduce the BasicLP linear programming relaxation for CSPs of arity two. Let Λ be a CSP of arity two over the alphabet $[q]$, and $\mathcal{I}$ be an instance of Λ. For every variable X in $\mathcal{I}$, the LP associates a probability distribution μ_X over $[q]$. For every constraint $C_i(X,Y)$ in $\mathcal{I}$, the LP associates a probability distribution μ_{XY} over $[q] \times [q]$, supported on satisfying assignments to the constraint C_i. The pairwise distributions μ_{XY} are constrained to be consistent with the marginal distributions μ_X and μ_Y. The BasicLP program for 2-CSPs is described in detail in Section 5.

▶ **Definition 7.** An LP relaxation $\mathcal{L}$ for a CSP is *sound* on an instance $\mathcal{I}$ if the feasibility of the LP relaxation $\mathcal{L}$ on $\mathcal{I}$ implies satisfiability of the instance $\mathcal{I}$.

Typically, one shows the soundness of an LP relaxation by a rounding scheme that extracts an assignment to the CSP from the LP solution. We exhibit a sufficient condition for an LP relaxation to be *sound* on an instance $\mathcal{I}$. For a constraint $C_i(X,Y)$, let $G_{\mu_{XY}}$ denote the bipartite graph whose edges are given by the support of the distribution μ_{XY}.

▶ **Theorem 8.** *Let Λ be a 2-CSP that admits a cyclic polymorphism and let $\mathcal{I}$ be an instance Λ. Suppose there exists a solution to the* BasicLP *relaxation for $\mathcal{I}$ such that all the associated graphs $G_{\mu_{XY}}$ are connected, then the* BasicLP *relaxation is* sound *on the instance $\mathcal{I}$, i.e., $\mathcal{I}$ is satisfiable.*

2 Background

We first introduce some basic notation. Let $[q]$ denote the alphabet $[q] = \{1, \ldots, q\}$. For a probability distribution μ on the finite set $[q]$ we will write μ^k to denote the product distribution on $[q]^k$ given by drawing k independent samples from μ.

If μ is a joint probability distribution on $[q]^n$ we will write $\mu_1, \mu_2, \ldots \mu_n$ for the n marginal distributions of μ. Further we will use $\mu^\times$ to denote the product distribution with the same marginals as μ. That is we define $\mu^\times \stackrel{\text{def}}{=} \mu_1 \times \mu_2 \times \cdots \times \mu_n$.

An operation p of arity k is a map $p : [q]^k \to [q]$. For a set of k assignments $x^{(1)}, \ldots, x^{(k)} \in [q]^n$, we will use $p(x^{(1)}, \ldots, x^{(k)}) \in [q]^n$ to be the assignment obtained by applying the operation p on each coordinate of $x^{(1)}, \ldots, x^{(k)}$ separately. More formally, let $x_j^{(i)}$ be the jth coordinate of x_i. We define

$$p(x^{(1)} \ldots x^{(k)}) = \left(p(x_1^{(1)} \ldots x_1^{(k)}), p(x_2^{(1)} \ldots x_2^{(k)}), \ldots, p(x_n^{(1)} \ldots x_n^{(k)})\right).$$

▶ **Definition 9.** For two operations $p_1 : [q]^{k_1} \to [q]$ and $p_2 : [q]^{k_2} \to [q]$, define an operation $p_1 \otimes p_2 : [q]^{k_1 \times k_2} \to [q]$ as follows:

$$p_1 \otimes p_2(\{x_{ij}\}_{i \in [k_1], j \in [k_2]}) = p_1\left(p_2(x_{11}, x_{12}, \ldots, x_{1k_2}), \ldots, p_2(x_{k_1 1}, x_{k_1 2}, \ldots, x_{k_1 k_2})\right)$$

▶ **Lemma 10** (Hoeffding bound)**.** *Suppose $Z_1, \ldots, Z_N$ are complex-valued random variables such that $|Z_i|$ is always bounded by 1. If $Z = \frac{1}{N}\sum_i Z_i$ then, $\mathbb{P}[|Z - \mathbb{E}[Z]| \geqslant \delta] \leqslant 2e^{-\delta^2 N/4}$.*

3 Solving Linear Systems via Correlation Decay

In this section, we will analyze the randomized algorithm for linear equations in Figure 1 and present a proof of Theorem 6. We begin with setting up some notation dealing with affine subspaces of $\mathbb{F}_q^n$.

▶ **Definition 11.** For an affine subspace $V \subseteq \mathbb{F}_q^n$ and $b \in \mathbb{F}_q$, set $V_b^\perp \stackrel{\text{def}}{=} \{w | \forall x \in V, \langle x, w\rangle = b\}$, and let $V^\perp \stackrel{\text{def}}{=} \cup_{b\in\mathbb{F}_q} V_b$.

In the setting of linear equations, correlations can be measured using Fourier analysis. Therefore, we recall the definition of characters over $\mathbb{F}_q^n$.

▶ **Definition 12.** For every $w \in \mathbb{F}_q^n$, the corresponding character χ_w is a function $\chi_w : \mathbb{F}_q^n \to \mathbb{C}$ given by $\chi_w(x) = \omega^{\langle w,x\rangle}$, where ω is a primitive q^{th} root of unity and $\langle w, x\rangle$ denotes the inner product of w and x over $\mathbb{F}_q$.

We will quantify the *spurious correlations* in our sample using the notion of bias as defined below.

▶ **Definition 13** (Bias)**.** For a vector $w \in \mathbb{F}_q^n$ and a multiset $\mathcal{S} \subseteq \mathbb{F}_q^n$, define the bias of w over $\mathcal{S}$ as,

$$\text{bias}_w(\mathcal{S}) = |\mathop{\mathbb{E}}_{x\in\mathcal{S}}[\chi_w(x)]| = \frac{1}{|\mathcal{S}|}|\sum_{x\in\mathcal{S}} \chi_w(x)|\,.$$

An ε-biased sample from an affine subspace V is one in which all the *spurious correlations* are bounded by ε. Formally,

▶ **Definition 14** (ε-biased sample)**.** For $\varepsilon \in [0, 1]$, a multiset of vectors $\mathcal{S} \in \mathbb{F}_q^n$ is a ε-biased sample of an affine subspace $V \subseteq \mathbb{F}_q^n$ if $\mathcal{S} \subseteq V$ and for all $w \notin V^\perp$, $|\text{bias}_w(\mathcal{S})| \leqslant \varepsilon$.

Effect of Selection on Bias

▶ **Lemma 15.** *Let $\mathcal{S}$ be a ε-biased sample from an affine subspace V. For all $w \notin V^\perp$ and $b \in \mathbb{F}_q$, the following holds:*

1. $\mathbb{P}_{z\in\mathcal{S}}[\langle w, z\rangle = b] \in \left[\frac{1}{q} - \varepsilon, \frac{1}{q} + \varepsilon\right]$.
2. *If $\mathcal{T} = \mathcal{S} \cap \{z | \langle w, z\rangle = b\}$ then $\mathcal{T}$ is a $q\varepsilon/(1-q\varepsilon)$-biased sample from the affine subspace $V \cap \{z \in \mathbb{F}_q^n | \langle w, z\rangle = b\}$.*

Proof. Let $\mathbb{I}_{\langle w,z\rangle=b}$ be the indicator of the event that $\langle w, z\rangle = b$. Using the identity $\mathbb{I}_{\langle w,z\rangle=b} = \frac{1}{q}\sum_{\alpha\in\mathbb{F}_q}(\chi_w(z)\omega^{-b})^\alpha$, we can write

$$\mathop{\mathbb{P}}_{z\in\mathcal{S}}[\langle w, z\rangle = b] = \mathop{\mathbb{E}}_{z\in\mathcal{S}}\left[\frac{1}{q}\sum_{\alpha\in\mathbb{F}_q}(\chi_w(z)\omega^{-b})^\alpha\right]\,.$$

Simplifying the above expression using the identity $\chi_w(z)^\alpha = \chi_{\alpha w}(z)$ we get

$$\mathop{\mathbb{P}}_{z\in\mathcal{S}}[\langle w, z\rangle = b] = \frac{1}{q} + \frac{1}{q}\sum_{\alpha\in\mathbb{F}_q/\{0\}} \omega^{-\alpha b} \mathop{\mathbb{E}}_{z\in\mathcal{S}}[\chi_{\alpha w}(z)]\,.$$

Hence,

$$\left|\mathop{\mathbb{P}}_{z\in\mathcal{S}}[\langle w, z\rangle = b] - \frac{1}{q}\right| \leqslant \frac{1}{q}\sum_{\alpha\in\mathbb{F}_q/\{0\}}\left|\mathop{\mathbb{E}}_{z\in S}[\chi_{\alpha w}(z)]\right| \leqslant \frac{1}{q}\sum_{\alpha\in\mathbb{F}_q/\{0\}}|\text{bias}_{\alpha w}(\mathcal{S})| \leqslant \varepsilon$$

Let V' denote the affine subspace $V' = V \cap \{z \in \mathbb{F}_q^n | \langle w, z\rangle = b\}$. Clearly, $\mathcal{T}$ is a subset of V' if $\mathcal{S}$ is a subset of V. By definition, for every $v \in \mathbb{F}_q^n$ the bias over $\mathcal{T}$ is given by

$$\text{bias}_v(\mathcal{T}) = \mathop{\mathbb{E}}_{z\in\mathcal{T}}[\chi_v(z)] = \mathop{\mathbb{E}}_{z\in\mathcal{S}}[\chi_v(z)|\langle w, z\rangle = b] = \frac{1}{\mathbb{P}[\langle w, z\rangle = b]} \mathop{\mathbb{E}}_{z\in\mathcal{S}}\left[\chi_v(z)\mathbb{I}_{\langle w,z\rangle=b}\right] \quad (3.1)$$

Evaluating the expectation inside,

$$\mathop{\mathbb{E}}_{z\in\mathcal{S}}\left[\chi_v(z)\mathbb{I}_{\langle w,z\rangle=b}\right] = \frac{1}{q}\sum_{\alpha\in\mathbb{F}_q}\mathop{\mathbb{E}}_{z\in\mathcal{S}}\left[\chi_v(z)(\chi_w(z)\omega^{-b})^\alpha\right] = \frac{1}{q}\sum_{\alpha\in\mathbb{F}_q}\omega^{-b\alpha}\text{bias}_{v+\alpha w}(\mathcal{S}) \quad (3.2)$$

For a vector $v \notin (V')^\perp$, we claim that $v + \alpha w \notin V^\perp$ for any $\alpha \in \mathbb{F}_q$. Suppose not, then $v + \alpha w \in V^\perp$ which implies that for some $b' \in \mathbb{F}_q$, we have $\langle v + \alpha w, z\rangle = b'$ for all $z \in V$. This implies that for all $z \in V'$, $\langle v, z\rangle = \langle v + \alpha w, z\rangle - \alpha\langle w, z\rangle = b' - \alpha b$ – a constant, a contradiction to the fact that $v \notin (V')^\perp$.

Since $\mathcal{S}$ is an ε-biased sample from V and $v + \alpha w \notin V^\perp$, we have $\text{bias}_{v+\alpha w}(\mathcal{S}) \leqslant \varepsilon$. Using this bound in (3.2) we get $\mathbb{E}_{z\in S}\left[\chi_v(z)\mathbb{I}_{\langle w,z\rangle=b}\right] \leqslant \varepsilon$ .Substituting in (3.1) and using the fact that $\mathbb{P}[\langle w, z\rangle = b] \geqslant 1/q - \varepsilon$, we conclude that $\text{bias}_v(\mathcal{T}) \leqslant \frac{\varepsilon}{(1/q-\varepsilon)}$ for any $v \in V^\perp$. ◀

Recombination Reduces Bias

▶ **Lemma 16.** *For all $i \in [m]$, if the sample $\mathcal{T}_i \in \mathbb{F}_q^n$ is a ε-biased sample of an affine subspace $V \subseteq \mathbb{F}_q^n$, then for all $\delta > 0$, then the sample $\mathcal{S}_i$ generated by recombination is a $\varepsilon^3 + \delta$-biased sample from V with probability at least $1 - 2q^n e^{-\delta^2 N/4}$.*

Proof. The multiset $\mathcal{S}_i$ consists of N-i.i.d samples from a probability distribution. Fix any $w \in V^\perp$. The expected value of the bias w over U is given by,

$$\mathbb{E}\left[\text{bias}_w(U)\right] = \mathbb{E}\left[\frac{1}{N}\sum_{z\in U}\chi_w(z)\right] = \frac{1}{N}\sum_{z\in U}\mathbb{E}\left[\chi_w(z)\right]$$

For every sample $z = p(y^{(1)}, y^{(2)}, y^{(3)})$ in $\mathcal{S}_i$, the expectation of the bias is given by

$$|\mathop{\mathbb{E}}_{y^{(j)}\in\mathcal{T}_i}[\chi_w(y_1 - y_2 + y_3)]| = |\mathop{\mathbb{E}}_{y^{(j)}\in\mathcal{T}_i}[\chi_w(y^{(1)})\overline{\chi_w(y^{(2)})}\chi_w(y^{(3)})]| = |\prod_{j=1}^{3}\mathop{\mathbb{E}}_{y^{(j)}\in\mathcal{T}_i}[\chi_w(y^{(j)}]|$$

Therefore, the expected value of the bias of w over $\mathcal{S}_i$ is, $\mathbb{E}\left[\text{bias}_w(\mathcal{S}_i)\right] \leqslant \text{bias}_w^3(\mathcal{T}_i)$. Since $\mathcal{T}_i$ is a ε-biased sample from V, for each $w \in V^\perp$ $|\text{bias}_w(\mathcal{T}_i)| \leqslant \varepsilon$. Therefore, we get that

$$\begin{aligned}\mathbb{P}\left[|\text{bias}_w(\mathcal{S}_i)| \geqslant \varepsilon^3 + \delta\right] &\leqslant \mathbb{P}\left[|\text{bias}_w(\mathcal{S}_i) - \mathbb{E}[\text{bias}_w(\mathcal{S}_i)]| \geqslant \delta\right] \\ &\leqslant 2e^{-\delta^2 N/4} \qquad \text{(Lemma 10)}\end{aligned}$$

By a union bound over all q^n characters $w \in \mathbb{F}_q^n$, we get the desired result. ◀

Analysis of the Algorithm

Proof of Theorem 6. Fix $\varepsilon = \frac{1}{2q^2}$ and $\delta = \frac{1}{6q}$. Let V_k denote the affine subspace consisting of solutions to the first k equations $\{A_i x = b_i | 1 \leqslant i \leqslant k\}$. We will show the following claim from which Theorem 6 follows immediately.

▶ **Claim 17.** *If $N = \lceil(150q^4 \ln q) \cdot n\rceil$, then with probability at least $1 - e^{-n}$ the following holds: for all $0 \leqslant k \leqslant m$, $\mathcal{S}_k$ is an ε-biased sample from V_k for $\varepsilon = \frac{1}{4q}$.*

The argument is by induction on k. For $k = 0$, the set S_0 consists of N random vectors from $\mathbb{F}_q^n$ and $V_0 = \mathbb{F}_q^n$. By definition, $V_0^\perp = \mathbb{F}_q^n - \{0\}$. For every $w \in \mathbb{F}_q^n - \{0\}$, the bias of w is given by, $\text{bias}_w(\mathcal{S}_0) = \frac{1}{N}\sum_{i=1}^N \chi_w(z_i)$. In particular, it is easy to see that $\mathbb{E}[\text{bias}_w(\mathcal{S}_0)] = 0$. By applying Lemma 10, we get that

$$\mathbb{P}[|\text{bias}_w(\mathcal{S}_0)| \geqslant \varepsilon] \leqslant 2e^{-\varepsilon^2 N/4}\,.$$

By a simple union bound, $\mathcal{S}_0$ is ε-biased sample with probability at least $1 - q^n 2e^{-\varepsilon^2 N/4} = 1 - q^n 2e^{-N/16q^4}$.

Let us suppose $\mathcal{S}_\ell$ is a ε-biased sample from V_ℓ. By Lemma 15, we get that $\mathcal{T}_{\ell+1}$ is a $q\varepsilon/(1-q\varepsilon)$-biased sample from $V_{\ell+1}$. By Lemma 16, with probability at least $1 - 2q^n e^{-\delta^2 N/4}$, the bias of $\mathcal{S}_{\ell+1}$ obtained by recombination is at most,

$$\text{bias}(\mathcal{S}_{\ell+1}) \leqslant \text{bias}(\mathcal{T}_{\ell+1})^3 + \delta \leqslant (q\varepsilon/(1-q\varepsilon))^3 + \delta = \frac{1}{q^3} + \delta < \varepsilon\,.$$

Applying a union bound over all $\ell \in \{0,\ldots,m\}$, with probability at least $1 - 2mq^n e^{-N/144q^2}$, $\mathcal{S}_\ell$ is an ε-biased sample from V_ℓ for all $\ell \in \{1,\ldots,m\}$. Setting $N = \lceil (150q^4 \ln q)\cdot n\rceil$, the claim follows. ◀

4 Correlation Decay

In this section we state our main theorem regarding the decay of correlation between random variables under repeated applications of cyclic operations. Recall that Theorem 5 states the theorem for two variables. Throughout this section we will use this two variable case as a running example. We begin by defining a quantitative measure of correlation and using it to bound the statistical distance to a product distribution.

4.1 Correlation and Statistical Distance

To gain intuition for our measure of correlation consider the example of two boolean random variables X and Y with joint distribution μ. In this case we will measure correlation by taking the supremum over appropriately normalized test functions $f, g : \{0,1\} \to \mathbb{R}$ and computing $\mathbb{E}[f(X)g(Y)]$.

▶ **Definition 18.** Let X, Y be discrete-valued random variables with joint distribution μ. Let $\Omega_1 = ([q_1], \mu_1)$ and $\Omega_2 = ([q_2], \mu_2)$ denote the probability spaces corresponding to X, Y respectively. The correlation $\rho(X, Y)$ is given by

$$\rho(X,Y) \stackrel{\text{def}}{=} \sup_{f,g} \mathbb{E}[f(X)g(Y)]$$

where the supremum runs over all f, g where $\mathbb{E}[f] = \mathbb{E}[g] = 0$ and $\mathbf{Var}[f] = \mathbf{Var}[g] = 1$. We will interchangeably use the notation $\rho(\mu)$ or $\rho(\Omega_1, \Omega_2)$ to denote the correlation.

To see that this notion of correlation makes intuitive sense, suppose X and Y are independent. In this case correlation is zero because $\mathbb{E}[f(X)g(Y)] = \mathbb{E}[f(X)]\,\mathbb{E}[g(Y)] = 0$. Next suppose that $X = Y = 1$ with probability $\frac{1}{2}$ and $X = Y = 0$ with probability $\frac{1}{2}$. In this case we can set $f(1) = g(1) = 1$ and $f(0) = g(0) = -1$ to obtain $\mathbb{E}[f(X)g(Y)] = 1$. This matches up with the intuition that such an X and Y are perfectly correlated. We now give the general definition for our measure of correlation. Next we show that, as the correlation for a pair of random variables X and Y becomes small, the variables become nearly independent.

▶ **Lemma 19.** *Let X, Y be discrete-valued random variables with joint distribution μ_{XY} and respective marginal distributions μ_X and μ_Y. If X takes values in $[q_1]$ and Y takes values in $[q_2]$, then $\|\mu_{XY} - \mu_X \times \mu_Y\|_1 \leqslant \min(q_1, q_2)\rho(X, Y)$*

It turns out that there is also a simple combinatorial condition that is essentially equivalent to a bound on the correlation. First we define a natural bipartite graph associated to a joint distribution.

▶ **Definition 20.** Let X, Y be jointly distributed according to μ as in Definition 18. Define a bipartite graph G_μ on vertex set $([q_1], [q_2])$ by adding an edge (a, b) whenever $\mathbb{P}_\mu[X = a, Y = b] > 0$.

Now the following lemma from [10] states that $\rho(\mu) < 1$ whenever the graph G_μ is connected.

▶ **Lemma 21** (Lemma 2.9 in [10])**.** *Let μ be a joint distribution where the minimum non-zero probability that μ assigns to any element is α. If G_μ is connected then $\rho(\mu) < 1 - \frac{\alpha^2}{2}$.*

In addition, if G_μ is disconnected, then $\rho(\mu) = 1$. Therefore checking if $\rho(\mu) < 1$ amounts to checking connectivity of G_μ.

4.2 Proof Overview

To begin with, we explain why one should expect correlations to decay under repeated applications of cyclic operations. Consider the simple example of two boolean random variables X and Y with a joint distribution μ. Let the marginal distributions of X and Y be uniform and let us suppose $X = Y$ with probability $\frac{1}{2} + \gamma$ and $X \neq Y$ with the remaining probability. Let $p : \{0,1\}^k \to \{0,1\}$ be the majority operation on k bits.

Next suppose we draw k samples (X_i, Y_i) from μ and evaluate $p(X_1 \dots X_k)$ and $p(Y_1 \dots Y_k)$. Since the marginal distributions of both X and Y are uniform, the same is true for $p(X_1 \dots X_k)$ and $p(Y_1 \dots Y_k)$. However, the probability that $p(X_1 \dots X_k) = p(Y_1 \dots Y_k)$ is strictly less than $\frac{1}{2} + \gamma$. To see why first let $F : \{-1, 1\} \to \{-1, 1\}$ be the majority function where 1 encodes boolean 0 and -1 encodes boolean 1. Note that the probability that $F(X_1 \dots X_k) = F(Y_1 \dots Y_k)$ is given by $\frac{1}{2} + \frac{1}{2}\mathbb{E}[F(X_1 \dots X_k)F(Y_1 \dots Y_k)]$.

Now if we write the Fourier expansion of F the above expectation is

$$\sum_{S,T} \hat{F}_S \hat{F}_T \, \mathbb{E}\left[\prod_{i \in S} X_i \prod_{j \in T} Y_j\right] = \sum_S \hat{F}_S^2 \prod_{i \in S} \mathbb{E}[X_i Y_i] = \sum_S \hat{F}_S^2 (2\gamma)^{|S|}$$

Suppose first that all the non-zero Fourier coefficients $\hat{F}_S$ have $|S| = 1$. In this case the probability that $F(X_1 \dots X_k) = F(Y_1 \dots Y_k)$ stays the same since $\frac{1}{2} + \frac{1}{2}(2\gamma) = \frac{1}{2} + \gamma$. However, in the case of majority, it is well known that $\sum_{|S|=1} \hat{F}_S^2 < 1 - c$ for a constant $c > 0$. Thus, the expectation is in fact given by

$$\mathbb{E}[F(X_1 \dots X_k)F(Y_1 \dots Y_k)] \leqslant (1 - c)(2\gamma) + c(2\gamma)^2 < 2\gamma$$

Thus the probability that $F(X_1 \dots X_k) = F(Y_1 \dots Y_k)$ is strictly less than $\frac{1}{2} + \gamma$. Therefore, if we repeatedly apply the majority operation, we should eventually have that X and Y become very close to independent.

There are two major obstacles to generalizing the above observation to arbitrary cyclic operations. First, for a general operation p, we will not be able to explicitly compute the entire Fourier expansion. Instead, we will have to use the fact that p is cyclic to get a bound

on the total Fourier mass on degree-one terms. Second, unlike in our example, the marginal distributions of X and Y may change after every application of p. This means that the correct Fourier basis to use also changes.

The fact that the marginal distributions change under p causes difficulties even for the simple example of the boolean OR operation on two bits. Consider a highly biased distribution over $0, 1$ given by $X = 1$ with probability ε and $X = 0$ with probability $1 - \varepsilon$. Now consider the function $f(X) = \frac{1}{2}(X_1 + X_2)$. Note that this function agrees with OR except when $X_1 \neq X_2$. Thus, $f(X) = OR(X)$ with probability $1 - 2\varepsilon(1 - \varepsilon) > 1 - 2\varepsilon$. This means that as ε approaches zero, OR approaches a function f with $\sum_{|S|=1} \hat{f}_S^2 = 1$.

Thus, there are distributions for which the correlation decay under the OR operation approaches zero. This means that we cannot hope to prove a universal bound on correlation decay for every marginal distribution, even in this very simple case. The problem for the general case is that as we repeatedly apply some operation p it could be that the marginals converge to some point where p does not result in correlation decay.

It is useful to note that for the OR operation, the probability that $X = 1$ increases under every application. Thus, as long as the initial distribution has a non-negiligible probability that $X = 1$, we will have that correlation does indeed decay in each step. Though this particular observation applies only to the OR operation, our proof in the general case does rely on the fact that, using only properties of the initial distribution of X we can get bounds on correlation decay in every step. In summary, we are able to achieve correlation decay for arbitrary cyclic operations. We now state our main theorem to this effect.

▶ **Theorem 22** (Correlation Decay). *Let μ be a distribution on $[q]^n$. Let $X_1, \ldots, X_n$ be the jointly distributed $[q]$-valued random variables drawn from μ. Further, let $\rho = \max_i \rho((X_1; X_2; \ldots; X_{i-1}), X_i) < 1$ and λ be the minimum probability of an atom in the marginal distributions $\{\mu_i\}_{i\in[n]}$. For any $\eta > 0$ and $r \geqslant \Omega_q\left(\frac{\log \lambda}{\log \rho} \log^2\left(\frac{qn}{\eta}\right)\right)$, if $p_1, \ldots, p_r$ is a sequence of operations each of which are cyclic terms then,*

$$\|p_1 \otimes p_2 \otimes \ldots \otimes p_r(\mu) - p_1 \otimes p_2 \otimes \ldots \otimes p_r(\mu^\times)\|_1 \leqslant \eta\,.$$

We now give a brief outline of the main ideas of the proof. For a cyclic operation p, the degree-one Fourier coefficients with respect to any distribution are all equal. Suppose that for some probability distribution μ, the operation p has nearly all of its Fourier mass on degree one coefficients. Then $p(x)$ is close to a sum of independent random variables. Therefore, a quantitative version of the Central Limit Theorem (in particular a variant of the Berry-Esseen Theorem), implies that $p(x)$ is close to a Gaussian random variable.

Next, since $p(x)$ is an operation on $[q]$ it only takes q different values. This should then give us a contradiction: a random variable taking only q different values cannot be close to a continuous random variable like a Gaussian. Unfortunately there is a problem with this argument. The error term in the Berry-Esseen theorem depends on the L^3-norm of the independent random variables. Thus, we must control the L^3-norms of the Fourier basis for p under the distribution μ in order for the previous argument to work.

Now the problem is that, even in the case of the OR operation, the L^3-norms of vectors in the Fourier basis can become arbitrarily large as μ changes under repeated applications of the operation. So, we are forced to prove that the elements of the Fourier basis that have high L^3-norm somehow have very small contribution to the correlation. The main idea here is that the correlation of a joint distribution μ is determined by the singular values of a certain linear operator T_μ known as the conditional expectation operator.

We establish a trade-off between the L^3-norm of the singular vectors of T_μ and the correlation contributed by their corresponding singular values. In particular we show that,

for any singular vector v of T_μ with large L^3-norm, the corresponding singular value must be small. This in turn implies that we need only look at the elements of the Fourier basis with small L^3-norm, as all the other elements do not contribute to the correlation of μ.

Our proof relating L^3-norms to singular values relies heavily on the fact that the operator T_μ is *hypercontractive*. Briefly, hypercontractivity is a property that allows us to bound $\|T_\mu f\|_3 \leqslant \|f\|_2$ under certain conditions on μ. If f is a singular vector of T_μ with singular value σ and unit L^2-norm, we then have $\sigma\|f\|_3 \leqslant 1$. This is precisely the sort of trade-off between the L^3-norm of f and the corresponding singular value that we use in our proof. We defer the details of the proof of the theorem to the full version.

5 Soundness of a LP relaxation

In this section, we use correlation decay to give a sufficient condition for when linear programming can be used to solve a CSP with a cyclic polymorphism. For clarity we state and prove everything in this section for CSPs where every constraint has arity two. First we introduce the basic LP relaxation for CSPs of arity two.

Let Λ be a CSP of arity two over the alphabet $[q]$, and $\mathcal{I}$ be an instance of Λ. For every variable X in $\mathcal{I}$ and element $a \in [q]$ we introduce an LP variable $\mu_X(a)$, which can be thought of as the probability that X is assigned a. For every constraint $C_i(X,Y)$ in $\mathcal{I}$ and every pair of elements $a, b \in [q]$ we introduce an LP variable $\mu_{XY}(a,b)$, which can be thought of as the probability that the pair of variables (X,Y) are assigned the values (a,b). The basic LP relaxation for instance $\mathcal{I}$ is then given by the following LP feasibility problem.

BasicLP Relaxation

$\sum_{a\in[q]} \mu_X(a) = 1$	$\forall X$ (μ_X is a probability distribution)
$\sum_{a,b\in[q]} \mu_{XY}(a,b) = 1$	$\forall X,Y$ (μ_{XY} is a probability distribution)
$\sum_{b\in[q]} \mu_{XY}(a,b) = \mu_X(a)$	$\forall b, C_i(X,Y)$ (local consistency for X)
$\sum_{a\in[q]} \mu_{XY}(a,b) = \mu_Y(b)$	$\forall b, C_i(X,Y)$ (local consistency for Y)
$\mu_{XY}(a,b) = 0$	$\forall C_i(X,Y), a, b$ s.t. $C_i(a,b) = 0$ (μ_{XY} satisfies $C_i(X,Y)$)

Proof of Theorem 8. Let p be a cyclic polymorphism of Λ. For each constraint $C_i(X,Y)$, since $G_{\mu_{XY}}$ is connected, Theorem 5 implies that as $k \to \infty$,

$$\|p^{\otimes k}(\mu_{XY}) - p^{\otimes k}(\mu_X) \times p^{\otimes k}(\mu_Y)\|_1 \to 0$$

Now independently sample the value of every variable V from the distribution $p^{\otimes k}(\mu_V)$. The joint distribution of values for every pair (X,Y) is precisely the product distribution $p^{\otimes k}(\mu_X) \times p^{\otimes k}(\mu_Y)$. Thus, for every constraint $C_i(X,Y)$, the distribution of the values for (X,Y) can be made arbitrarily close to the distribution $p^{\otimes k}(\mu_{XY})$ by taking k large enough. Since p is a polymorphism of Λ and μ_{XY} is a distribution on satisfying assignments to $C_i(X,Y)$, we have that $p^{\otimes k}(\mu_{XY})$ is a distribution on satisfying assignments.

Therefore, for large enough k, there will be a non-zero probability that every constraint $C_i(X,Y)$ is satisfied. In particular, this implies that the instance $\mathcal{I}$ is satisfiable. ◀

Abstract

The edge-percolation and vertex-percolation random graph models start with an arbitrary graph G, and randomly delete edges or vertices of G with some fixed probability. We study the computational hardness of problems whose inputs are obtained by applying percolation to worst-case instances. Specifically, we show that a number of classical $\mathcal{NP}$-hard graph problems remain essentially as hard on percolated instances as they are in the worst-case (assuming $\mathcal{NP} \not\subseteq \mathcal{BPP}$). We also prove hardness results for other $\mathcal{NP}$-hard problems such as Constraint Satisfaction Problems, where random deletions are applied to clauses or variables.

We focus on proving the hardness of the Maximum Independent Set problem and the Graph Coloring problem on percolated instances. To show this we establish the robustness of the corresponding parameters $\alpha(\cdot)$ and $\chi(\cdot)$ to percolation, which may be of independent interest. Given a graph G, let G' be the graph obtained by randomly deleting edges of G. We show that if $\alpha(G)$ is small, then $\alpha(G')$ remains small with probability at least 0.99. Similarly, we show that if $\chi(G)$ is large, then $\chi(G')$ remains large with probability at least 0.99.

1 Introduction

The theory of $\mathcal{NP}$-hardness suggests that we are unlikely to find optimal solutions to $\mathcal{NP}$-hard problems in polynomial time. This theory applies to the worst-case setting where one considers the worst running-time over all inputs of a given length. It is less clear whether these hardness results apply to "real-life" instances. One way to address this question is to examine to what extent known $\mathcal{NP}$-hardness results are stable under random perturbations, as it seems reasonable to assume that a given instance of a problem may be subjected to noise originating from multiple sources.

Recent work has studied the effect of random perturbations of the input on the runtime of algorithms. In their seminal paper Spielman and Teng [28] introduced the idea of *smoothed*

analysis to explain the superior performance of algorithms in practice compared with formal worst-case bounds. Roughly speaking, smoothed analysis studies the running time of an algorithm on a perturbed worst-case instance. In particular, they showed that subjecting the weights of an arbitrary linear program to Gaussian noise yields instances on which the simplex algorithm runs in expected polynomial time, despite the fact that there are pathological linear programs for which the simplex algorithm requires exponential time. Since then smoothed analysis has been applied to a number of other problems [10, 29].

In contrast to smoothed analysis, we study when worst-case instances of problems remain hard under random perturbations. Specifically, we study to what extent $\mathcal{NP}$-hardness results are robust when instances are subjected to random deletions. Previous work is mainly concerned with *Gaussian* perturbations of *weighted* instances. Less work has examined the robustness of hardness results of unweighted instances with respect to discrete noise.

We focus on two forms of percolation on graphs. Given a graph $G = (V, E)$ and a parameter $p \in (0, 1)$, we define $G_{p,e} = (V, E')$ as the probability space of graphs on the same set of vertices, where each edge $e \in E$ is contained in E' independently with probability p. We say that $G_{p,e}$ is obtained from G by *edge percolation*. We define $G_{p,v} = (V', E')$ as the probability space of graphs, in which every vertex $v \in V$ is contained in V' independently with probability p, and $G_{p,v}$ is the subgraph of G induced by the vertices V'. We say that $G_{p,v}$ is obtained from G by *vertex percolation*. We also study appropriately defined random deletions applied to instances of other $\mathcal{NP}$-hard problems, such as 3-SAT and Subset-Sum.

Throughout we refer to instances that are subjected to random deletions as *percolated instances*. Our main question is whether such percolated instances remain hard to solve by polynomial-time algorithms assuming $\mathcal{NP} \nsubseteq BPP$.

1.1 A first example – 3-Coloring

Consider the 3-Coloring problem, where given a graph $G = (V, E)$ we need to decide whether G is 3-colorable. Suppose that given a graph G we sample a random subgraph G' of G, by deleting each edge of G independently with probability $p = \frac{1}{2}$, and ask whether the resulting graph is 3-colorable. Is there a polynomial time algorithm that can decide with high probability whether G' is 3-colorable?

We demonstrate that a polynomial-time algorithm for deciding whether G' is 3-colorable is impossible assuming $\mathcal{NP} \nsubseteq \mathcal{BPP}$. We show this by considering the following polynomial time reduction from the 3-Coloring problem to itself.

Given an n-vertex graph H the reduction outputs a graph G that is an R-blow-up of H for $R = C\sqrt{\log(n)}$, where $C > 0$ is large enough. That is, replace each vertex of H by a cloud of R vertices that form an independent set in G, and for each edge in H place a complete $R \times R$ bipartite graph in G between the corresponding clouds in G. It is easy to see that H is 3-colorable if and only if G is 3-colorable.

In fact, the foregoing reduction satisfies a stronger *robustness* property for random subgraphs G' of G. Namely, if H is 3-colorable, then G is 3-colorable, and hence G' is also 3-colorable with probability 1. On the other hand, if H is not 3-colorable, then G is not 3-colorable, and with high probability G' is not 3-colorable either.

Indeed, for any edge (v_1, v_2) in H let U_1, U_2 be two clouds in G corresponding to v_1 and v_2. Fixing two arbitrary sets $U_1' \subseteq U_1$ and $U_2' \subseteq U_2$ each of size $R/3$, the probability that there is no edge connecting a vertex from U_1 to a vertex in U_2 is $2^{-R^2/9}$. By union bounding over the $|E| \cdot \binom{R}{R/3}^2 \ll 2^{R^2/9}$ choices of U_1', U_2' we get that there is at least one edge between U_1' and U_2' with high probability. When this holds we can decode any 3-coloring of G' to a 3-coloring of H by coloring each vertex v of H with the color that appears the largest number

of times in the coloring of the corresponding cloud in G', breaking ties arbitrarily. Therefore a polynomial time algorithm for deciding the 3-colorability of G implies a polynomial time algorithm for determining the 3-colorability of H with high probability. It follows that unless $\mathcal{NP} \subseteq \text{co}\mathcal{RP}$ there is no polynomial time algorithm that given a 3-colorable graph G finds a 3-coloring of a random subgraph of G.[1]

Toward a stronger notion of robustness

The example above raises the question of whether the blow-up described above is really necessary. Naïvely, one could hope for stronger hardness of the 3-Coloring problem, namely, that for any graph H if H is not 3-colorable, then with high probability a random subgraph H' of H is not 3-colorable either. However, this is not true in general, as H can be a 3-critical graph, i.e., a 3-colorable graph such that deletion of *any* edge of H decreases its chromatic number (consider for example the case of an odd cycle).

Nonetheless, if random deletions do not decrease the chromatic number of a graph by much, then one could use hardness of approximation results for chromatic number to deduce hardness results for coloring percolated graphs. In this paper we show that the chromatic number of a graph is indeed robust to random deletions. We show that if we delete each edge of a graph with probability $\frac{1}{2}$, then (with probability 0.99) the chromatic number does not drop by much.

We also consider the question of robustness for other graph parameters. For independent sets we demonstrate that if the independence number of G is small, then with high probability the independence number of a random subgraph of G is small as well. Similarly, we show that for a k-SAT formula that is sufficiently dense, randomly deleting its clauses does not change the maximum possible fraction of clauses that can be satisfied simultaneously. In particular, this implies that these problems remain essentially as hard on percolated instances as they are on worst-case instances.

▶ Remark. It is worth noting that there are graph parameters for which percolated instances differ significantly from the original instance. For example, standard results in random graph theory imply that for every n-vertex graph G, with high probability the size of the largest clique in the graph G' obtained by edge percolation with $p = \frac{1}{2}$ is $O(\log n)$. In particular, a maximum clique in G' can be found in time $n^{O(\log n)}$, which is significantly faster than the fastest known algorithm for finding a maximum clique in the worst-case.

1.2 Robustness of $\mathcal{NP}$-hard problems under percolation

In proving hardness results for percolated instances we use the concept of *robust reductions* which we explain below. It will be convenient to consider promise problems[2]. We start by introducing the following definition.

▶ **Definition 1.** Let $A = (A_{YES}, A_{NO})$ and $B = (B_{YES}, B_{NO})$ be two promise problems. For each $y \in \{0,1\}^*$ (an instance of the problem B) let $\mathsf{noise}(y)$ be a distribution on $\{0,1\}^*$, that is samplable in time $\text{poly}(|y|)$.

[1] Note that in the foregoing example, if we start with a bounded degree graph H, we can reduce it to a bounded degree graph G by using an $R \times R$ bipartite expander instead of the complete bipartite graph.

[2] Recall, that a promise problem is a generalization of a decision problem, where for the problem L there are two disjoint subsets L_{YES} and L_{NO}, such that an algorithm that solves L must accept all the inputs in L_{YES} and reject all inputs in L_{NO}. If the input does not belong to $L_{YES} \cup L_{NO}$, there is no requirement on the output of the algorithm.

- A polynomial time reduction R from A to B is said to be *noise-robust* if
  1. For all $x \in A_{YES}$ it holds that $\mathsf{R}(x) \in B_{YES}$, and $\Pr[\mathsf{noise}(\mathsf{R}(x)) \in B_{YES}] > 0.99$.
  2. For all $x \in A_{NO}$ it holds that $\mathsf{R}(x) \in B_{NO}$, and $\Pr[\mathsf{noise}(\mathsf{R}(x)) \in B_{NO}] > 0.99$.
- If in the first item we have $\Pr[\mathsf{noise}(\mathsf{R}(x)) \in B_{YES}] = 1$, then we say that R is a noise-robust co$\mathcal{RP}$-reduction. Similarly, if in the second item we have $\Pr[\mathsf{noise}(\mathsf{R}(x)) \in B_{NO}] = 1$, then we say that R is a noise-robust $\mathcal{RP}$-reduction.
- The problem $B = (B_{YES}, B_{NO})$ is said to be *$\mathcal{NP}$-hard under a noise-robust reduction* if there exists a *noise-robust* reduction from an $\mathcal{NP}$-hard problem to B.
- We say that the problem A is *strongly-noise-robust* to B if
  1. For all $x \in A_{YES}$ it holds that $x \in B_{YES}$, and $\Pr[\mathsf{noise}(x) \in B_{YES}] > 0.99$.
  2. For all $x \in A_{NO}$ it holds that $x \in B_{NO}$, and $\Pr[\mathsf{noise}(x) \in B_{NO}] > 0.99$.

Note that in the last item of Definition 1 there is no reduction involved. Instead, we think of the problem A as a relaxation of B with $A_{YES} \subseteq B_{YES}$ and $A_{NO} \subseteq B_{NO}$, and hence any algorithm that solves B in particular solves A. However, it is a relaxed problem in a stronger sense, namely, after applying noise to a YES-instance (resp. NO-instance) of A, it stays a YES-instance (resp. NO-instance) of B with high probability.

We use the term noise-robust to avoid confusion with other notions of robust reductions that have appeared in the literature. In order to ease readability, we will often write robust reductions instead, always referring to noise-robust reductions as defined above.

▶ **Proposition 2.** *Let $L = (L_{YES}, L_{NO})$ be a promise problem, and for each y instance of L, let $\mathsf{noise}(y)$ be a distribution on instances of L that is samplable in time* $\mathrm{poly}(|y|)$.

If L is $\mathcal{NP}$-hard under a noise-robust reduction, then there is no polynomial time algorithm that when given an input y decides with high probability whether $\mathsf{noise}(y) \in L_{YES}$ or $noise(y) \in L_{NO}$, unless $\mathcal{NP} \subseteq \mathcal{BPP}$.

Indeed, the example given in Section 1.1 gives a noise-robust reduction from the 3-Coloring problem to itself, where noise refers to random deletions of the edges in a given graph. Therefore, the 3-Coloring problem is $\mathcal{NP}$-hard under a noise-robust reduction.

1.3 Our results

In this paper we show that a number of $\mathcal{NP}$-hard problems remain hard to solve even after random deletions, i.e., they are $\mathcal{NP}$-hard under noise-robust reductions. Furthermore, we show that some gap $\mathcal{NP}$-hard problems are, in fact, strongly-noise-robust to the same problems with a smaller gap. Specifically, we focus on showing these results for the gap versions of the maximum independent set and chromatic number problems. As technical tools, we prove a number of combinatorial results about the independence number and the chromatic number of percolated graphs that might be of independent interest.

Maximum Independent Set and Percolation

▶ **Theorem 3.** *Let $G = (V, E)$ be an n-vertex graph. Then, with high probability $\alpha(G_{p,e}) \leq O\left(\frac{\alpha(G)}{p}\log(np)\right)$.*

We observe that in general, the upper bound above cannot be improved, as it is well known that the independence number of $G(n,p)$ is $\Omega\left(\frac{\log(np)}{p}\right)$ with high probability (see, e.g., [4]).

In the Coloring-vs-MIS(q,a) problem, given an n-vertex graph G such that $q \cdot a \geq n$, the goal is to distinguish between the YES-case where $\chi(G) \leq q$ and the NO-case where

$\alpha(G) \leq a$. By using Theorem 3 together with the inapproximability results of Feige and Kilian [11] saying that for every $\varepsilon > 0$ it is $\mathcal{NP}$-hard to decide whether a given n-vertex graph G satisfies $\chi(G) \leq n^{\varepsilon}$ or $\alpha(G) \leq n^{\varepsilon}$ we obtain the following hardness result.

▶ **Theorem 4.** *For any q, a the Coloring-vs-MIS(q, a) problem is strongly-noise-robust to Coloring-vs-MIS$\left(q, O\left(\frac{a}{p}\log(np)\right)\right)$, where n denotes the number of vertices in the given graph, and noise is the p-edge-percolation of this graph.*

In particular, for any constant $\varepsilon > 0$, unless $\mathcal{NP} \subseteq \mathcal{BPP}$ there is no polynomial time algorithm that given an n-vertex graph G approximates either $\alpha(G_{p,e})$ or $\chi(G_{p,e})$ within a $\frac{1}{pn^{1-2\varepsilon}}$ (resp. $pn^{1-2\varepsilon}$) factor for any $p > \frac{1}{n^{1-2\varepsilon}}$.

We also prove analogous theorems for vertex percolation.

Graph Coloring and Percolation

Theorem 3 says that it is hard to approximate the chromatic number of a percolated graph within a $n^{1-\varepsilon}$ factor, but says nothing about hardness of coloring percolated graphs with small (constant) chromatic number. We address this question below by proving lower bounds[3] on the chromatic number of percolated graphs. To do this we use results from additive combinatorics and discrete Fourier analysis.

▶ **Theorem 5.** *Let $G = (V, E)$ be an n-vertex graph. Then, for every $\alpha \in (0, 1)$ it holds that $\Pr[\chi(G_{\frac{1}{2},v}) \geq \max\{\chi(G)/3 - O_\alpha(1), \chi(G)/2 - O_\alpha(\sqrt{n})\}] > 1 - \alpha$.*

▶ **Theorem 6.** *Let $G = (V, E)$ be an n-vertex graph with m edges. Then, for every $\alpha \in (0, 1)$ it holds that $\Pr[\chi(G_{\frac{1}{2},e}) \geq \max\{\Omega_\alpha(\chi(G)^{1/3}), \Omega_\alpha(\chi(G)/m^{1/4})\}] > 1 - \alpha$.*

For $G_{\frac{1}{2},v}$ the $\chi(G)/2 - O_\alpha(\sqrt{n})$ lower bound is better when $\chi(G) = \omega(\sqrt{n})$, and the $\chi(G)/3 - O_\alpha(1)$ lower bound is better when $\chi(G) = o(\sqrt{n})$. For $G_{\frac{1}{2},e}$ the $\Omega_\alpha(\chi(G)/m^{1/4})$ lower bound is better when $\chi(G) = \omega(m^{3/8})$, and the $\Omega_\alpha(\chi(G)^{1/3})$ lower bound is better when $\chi(G) = o(m^{3/8})$.

Note that this result also gives lower bounds on the chromatic number of $G_{p,v}, G_{p,e}$ where $p \neq \frac{1}{2}$ by composing the bounds in Theorems 5 and 6 $\lceil \log_2(1/p) \rceil$ times.

▶ Remark. Bukh [7] has considered coloring edge-percolated graphs, and states the question of whether $\mathbf{E}[\chi(G_{\frac{1}{2},e})] = \Omega(\chi(G)/\log(\chi(G)))$ as an "interesting problem." Bukh observed that the chromatic number of $G_{\frac{1}{2},e}$ has the same distribution as the chromatic number of the complement of $G_{\frac{1}{2},e}$, and therefore $\mathbf{E}[\chi(G_{\frac{1}{2},e})] \geq \sqrt{\chi(G)}$. However, it is not clear how to leverage the lower bound on the expectation to obtain a lower bound on $\chi(G_{\frac{1}{2},e})$ *with high probability*, which is required for our noise robust reductions. Moreover, for $k \ll \sqrt{n}$ standard martingale methods do not seem to work for showing high probability estimates.

In the Gap-Coloring(q, Q) problem we are given an n-vertex graph G and the goal is to distinguish between the YES-case where G is q-colorable, and the NO-case where the chromatic number of G is at least Q. There is a large body of work proving hardness results for this problem [14, 20, 18] including stronger results assuming variants of the Unique Games Conjecture [8, 9]. Using the $\mathcal{NP}$-hardness of the Gap-Coloring$(q, \exp(\Omega(q^{1/3})))$ problem of Huang [18] we obtain an analogous hardness result under noise-robust reductions for this problem.

[3] The notation $O_\alpha(f(n))$ means that $O(f(n))$ holds for fixed α.

▶ **Theorem 7.** *For all $q < Q$ the Gap-Coloring(q, Q) problem is strongly-noise-robust to the Gap-Coloring$(q, \Omega(Q^{1/3}))$ problem, where noise is $\frac{1}{2}$-edge-percolation applied to the graph.*

In particular, for any sufficiently large constant q given a q-colorable graph G it is $\mathcal{NP}$-hard to find a $2^{\Omega(q^{1/3})}$-coloring of $G_{\frac{1}{2},e}$.

Satisfiability and Other Problems

We also state a hardness result for approximating the value of a clause-percolated instance of k-SAT. A k-SAT formula Φ is a collection of m clauses on n Boolean variables, where each clause is an OR of k-literals. Given a formula Φ, and an assignment σ to its variables, denote by $val_\sigma(\Phi)$ the fraction of constraints of Φ satisfied by σ. The value of Φ is defined as $val(\Phi) = \max_\sigma val_\sigma(\Phi)$. If $val(\Phi) = 1$ we say that Φ is satisfiable.

Given an instance Φ of k-SAT its *clause percolation* is a random formula Φ^c_p over the same set of variables, obtained from Φ by keeping each clause of Φ independently with probability p.

▶ **Theorem 8.** *Let $\varepsilon, \delta \in (0, 1)$ be fixed constants. Then, unless $\mathcal{NP} \subseteq \text{co}\mathcal{RP}$, there is no polynomial time algorithm that when given a satisfiable instance Φ over n-variables of 3-SAT, finds an assignment σ to Φ^c_p such that $val_\sigma(\Phi^c_p) > 7/8 + \varepsilon$ for all $p > \frac{1}{n^{2-\delta}}$.*

One ingredient of the proof of Theorem 8, that may be of independent interest, is establishing that k-SAT does not admit a non-trivial approximation on dense formulas that contain $n^{k-\eta}$ clauses, where $\eta > 0$ is an arbitrary small positive constant.

We prove analogous theorems also for other CSP's as well as other graph theoretic problems such as Vertex Cover and Directed Hamiltonian Cycle. We also prove hardness results for the percolated Subset Sum problem. The exact statements and complete proofs, including of Theorem 8, appear in the full version of the paper.

1.4 Preliminaries

An *independent set* in a graph $G = (V, E)$ is a set of vertices that spans no edges. The *independence number* $\alpha(G)$ denotes the maximum size of an independent set in G. A *legal coloring* of a graph G is an assignment of colors to vertices such that no two adjacent vertices share the same color. The *chromatic number* $\chi(G)$ denotes the minimum number of colors needed for a legal coloring of G. Note that in a legal coloring of G each color class forms an independent set, and hence $\chi(G) \cdot \alpha(G) \geq n$.

We will always measure the running time of algorithms in terms of the size of the percolated instance. Since G and $G_{p,e}$ have the same number of vertices, this generally does not affect the size of the instance by more than a polynomial factor. On the other hand, $G_{p,v}$ may be much smaller than G for very small values of p. However, in this work we will be only dealing with the case where $p = \frac{1}{n^{1-\Omega(1)}}$, hence with high probability the size of the vertex percolated and original graphs are polynomially related as well.

We will use the following version of the Chernoff bound.

▶ **Lemma 9** (Chernoff bound, Theorem 7.3.2 in [17])**.** *Let $x_1, \ldots, x_n$ be independent Bernoulli trials with $\Pr[x_i = 1] = p$, and let $\mu = \mathbf{E}[\sum_{i=1}^n x_i] = pn$. Let $r \geq e^2$. Then $\Pr[\sum_{i=1}^n x_i > (1 + r)\mu] < \exp(-(\mu r/2) \ln r)$.*

1.5 Related Work

There is a wide body of work on random discrete structures that has produced a wide range of mathematical tools [4, 13, 15, 23]. Randomly subsampling subgraphs by including each

edge independently in the sample with probability p has been studied extensively in works concerned with cuts and flows (e.g., [19]). More recently, sampling subgraphs has been used to find independent sets [12]. The effect of subsampling variables in mathematical relaxations of constraint satisfaction problems on the value of these relaxations was studied in [2].

Edge-percolated graphs have been also used to construct hard instances for specific algorithms. For example, Kučera [21] proved that the well known greedy coloring algorithm performs poorly on the complete r-partite graph in which every edge is removed independently with probability $1/2$ and $r = n^{\varepsilon}$ for $\varepsilon > 0$. Namely, for this graph G, even if vertices are considered in a random order by the greedy algorithm, with high probability $\Omega(\frac{n}{\log n})$ colors are used to color the percolated graph whereas $\chi(G) \leq n^{\varepsilon}$.

Misra [24] studies edge percolated instances of the Max-Cut problem. He proves that in graphs of fixed maximal degree d it is impossible (assuming $\mathcal{NP} \neq \mathcal{BPP}$) to compute the size of the maximum cut in $G_{p,e}$ in polynomial time whenever $p = \frac{1+\varepsilon}{d-1}$. The techniques used in [24] differ from ours and rely on the recent hardness result for counting independent sets in sparse graphs [27].

The chromatic number of Erdős-Rényi random graphs $G(n,p)$ has been studied extensively. Grimmett and McDiarmid [16] showed that for a fixed p with high probability it holds that $\chi(G(n,p)) = \Theta(\log(1/1-p)\frac{n}{\log n})$. Bollobás [3] later determined the right constant, proving that $\chi(G(n,p)) \sim \log(1/(1-p))\frac{n}{2\log(n)}$ for every $p \in (0,1)$. Łuczak [22] further improved the previous result by showing that it holds for subconstant values of p. In this paper we study the independence number and chromatic number of general percolated graphs. A recent paper by Bollobás et al. [5] studied a special case of this, namely the independence number of edge percolated Kneser graphs.

2 Maximum Independent Set and Percolation

In this section we demonstrate the hardness of approximating $\alpha(G)$ and $\chi(G)$ in both edge percolated and vertex percolated graphs. We base our results on a theorem of Feige and Kilian, saying that for every fixed $\varepsilon > 0$ the problem Coloring-vs-MIS$(n^{\varepsilon}, n^{\varepsilon})$ is $\mathcal{NP}$-hard.

▶ **Theorem 10** ([11]). *For every $\varepsilon > 0$ it is $\mathcal{NP}$-hard to decide whether a given n-vertex graph G satisfies $\chi(G) \leq n^{\varepsilon}$ or $\alpha(G) \leq n^{\varepsilon}$.*

Edge percolation

Below we prove Theorem 3. We will use the following lemma, due to Turan (see, e.g. [1]).

▶ **Lemma 11.** *Every graph H with l vertices and e edges contains an independent set of size at least $\frac{l^2}{2e+l}$.*

As a corollary we observe that if a graph contains no large independent sets, then it can also cannot contain large subsets of the vertices that span a small number of edges.

▶ **Corollary 12.** *Let $G = (V,E)$ be an n-vertex graph satisfying $\alpha(G) < k$. Then every set of vertices of size $l \geq k$ spans at least $l(l-k)/2k$ edges.*

Proof. Let H be a subgraph of G induced by l vertices, and suppose that H spans e edges. Then, by Lemma 11 we have $\alpha(H) \geq \frac{l^2}{2e+l}$. On the other hand, $\alpha(H) \leq \alpha(G) \leq k$, and hence $\frac{l^2}{2e+l} \leq k$, as required. ◀

We are now ready to prove Theorem 3 saying that for any n-vertex graph $G = (V,E)$ it holds that with high probability $\alpha(G_{p,e}) \leq O\left(\frac{\alpha(G)}{p}\log(np)\right)$.

Proof of Theorem 3. For a given graph G, let $k = \alpha(G)+1$ and let $C > 0$ be a large enough constant. By Corollary 12, every subset of size $l = C\frac{\alpha(G)}{p}\log(np)$ spans at least $\frac{l(l-k)}{2k}$ edges in G. Hence, by taking union bound over all subsets of size l, the probability there exists a set of size l in $G_{p,e}$ that spans no edge is at most

$$\binom{n}{l}\cdot(1-p)^{\frac{l(l-k)}{2k}} < \left(\frac{en}{l}\right)^{l}\cdot\exp\left(-p\cdot\frac{l(l-k)}{2k}\right) < (np)^{-\Omega(l)},$$

where the last inequality uses the choices of l and k, implying that $\left(\frac{en}{l}\right)^{l} < (np)^{l}$ and $\exp(-p\frac{l(l-k)}{2k}) < \exp(-\Omega(l\cdot\log(np))) = (np)^{-\Omega(l)}$. Therefore, with high probability $\alpha(G_{p,e}) \leq C\frac{\alpha(G)}{p}\log(np)$. ◀

Theorem 4 follows immediately from Theorem 3.

Proof of Theorem 4. Let G be an instance G of the Coloring-vs-MIS(q,a) problem. Note that for the YES-case if $\chi(G) \leq q$, then clearly $\chi(G_{p,e}) < q$. For the NO-case by Theorem 3 if $\alpha(G) \leq a$, then with high probability $\alpha(G_{p,e}) \leq O\left(\frac{a}{p}\log(np)\right)$ which implies the strongly-noise-robust hardness.

The "in particular" part follows immediately from Theorem 10. ◀

▶ Remark. Note that for constant $p > 0$ (e.g., $p = 1/2$) this theorem establishes inapproximability for the independence number of $G_{p,e}$ that matches the inapproximability for the worst case.

▶ Remark. Note also that for $p > \frac{1}{n^{1-\varepsilon}}$ (in fact, for $p > \frac{\log(n)}{n}$) such random percolated graphs have maximal degree at most $O(pn)$ with high probability. Therefore, such graphs $G_{p,e}$ can be colored efficiently using $O(pn)$ colors. In particular, with high probability $G_{p,e}$ contains an independent set of size $\Omega(1/p)$ and hence, the independence number can be approximated within a factor of $1/pn$ on p-percolated instances.

Vertex percolation

Next we handle vertex percolation. We show that approximating $\alpha(G)$ and $\chi(G)$ on percolated instances is essentially as hard as worst-case instances, where the vertices remain with probability $p > \frac{1}{n^{1-\delta}}$, where n is the number of vertices in the graph for any constant $\delta \in (0,1)$. We do it again by relying on the hardness of the gap problem Coloring-vs-MIS for percolated instances.

Note that in the case of vertex percolation, the (in)approximability guarantee should depend on the number of vertices in the percolated graph $G_{p,v}$, and not on the number in the original graph.

▶ **Theorem 13.** *The Coloring-vs-MIS(q,a) problem is strongly-noise-robust to itself, where noise is the vertex percolation with parameter any $p > 0$.*

In particular, for any $\delta, \varepsilon > 0$ unless $\mathcal{NP} \subseteq \mathcal{BPP}$ there is no polynomial time algorithm that approximates either $\alpha(G_{p,v})$ or $\chi(G_{p,v})$ within a factor $m^{1-\varepsilon}$ for constant any $\varepsilon > 0$, where m denotes the number of vertices in $G_{p,v}$, and any $p > \frac{1}{n^{1-\delta}}$.

Proof. The strong robustness of Coloring-vs-MIS(q,a) is clear, since for any graph G if G' is a vertex induced subgraph of G, then $\chi(G') \leq \chi(G)$, and $\alpha(G') \leq \alpha(G)$, which is, in particular, true for $G' = G_{p,v}$.

For the "in particular" part, for a given $p > \frac{1}{n^{1-\delta}}$ let $c = \frac{\log(pn)}{\log(n)} \in (\delta, 1)$ so that $p = \frac{1}{n^{1-c}}$, and let $\eta = \varepsilon \cdot c$.

Let G be an n-vertex graph, let $G_{p,v}$ be it vertex-percolated subgraph, and let m be the number of vertices in $G_{p,v}$. By the Chernoff bound in Lemma [17], with high probability we have $|m - pn| < 0.1pn$, and so, we assume from now on that $n^\eta < 2m^\varepsilon$.

By Theorem 10 it is $\mathcal{NP}$-hard to decide whether a given n-vertex graph G satisfies $\chi(G) \leq n^\eta$ or $\alpha(G) \leq n^\eta$. By the choice of parameters, if $\chi(G) \leq n^\eta$ then $\chi(G_{p,v}) \leq n^\eta < 2m^\varepsilon$, and similarly, if $\alpha(G) \leq n^\eta$ then $\alpha(G_{p,v}) < n^\eta < 2m^\varepsilon$. This completes the proof of the theorem. ◀

3 Graph Coloring and Percolation

We present our results in terms of the *maximum coverage problem* [30], which is a variant of the set cover problem, and show later how graph coloring is related to maximum coverage.

3.1 Maximum Coverage

In the maximum coverage problem we are given a family of sets $\mathcal{F} = \{S_1, \ldots, S_m\}$ with $S_i \subseteq [n]$ and a number c. The goal is to find c sets in $\mathcal{F}$ such the cardinality of the union of these c sets is as large as possible. We will make use of the representation of a set S in terms of its incidence vector $x(S) \in \{0,1\}^n$. In this way, we can reformulate the maximum coverage problem as follows. Given $A \subseteq \mathbb{F}_2^n$, find elements $y_1, \ldots, y_c \in A$ that maximize $\|\vee_{i=1}^c y_i\|_1$, the Hamming weight of the bitwise-OR of the vectors.

We will prove two existential results saying that if A is of constant density $\alpha > 0$, then there exists a good cover using only 2 or 3 vectors.

▶ **Lemma 14.** *Let $A \subseteq \mathbb{F}_2^n$ with $|A| \geq \alpha 2^n$. Then there exist $y_1, y_2, y_3 \in A$ such that $\|y_1 \vee y_2 \vee y_3\|_1 \geq n - 4/\alpha^3$.*

▶ **Lemma 15.** *Let $A \subseteq \mathbb{F}_2^n$ with $|A| \geq \alpha 2^n$. Then there exist $y_1, y_2 \in A$ such that $\|y_1 \vee y_2\|_1 \geq n - (1+r)\sqrt{n}$, where $r = \max\{e^2, 2\ln 1/\alpha\}$.*

3.2 Proof of Lemma 14 using additive combinatorics

Lemma 14 follows almost immediately from a result about sumsets. Recall that the Minkowski sum of two sets A, B is defined as $A + B = \{x + y : x \in A, y \in B\}$.

▶ **Lemma 16** (Corollary 3.5 in [26]). *Let $A \subseteq \mathbb{F}_2^n$ with $|A| \geq \alpha 2^n$. Then $A + A + A$ contains an affine subspace of dimension at least $n - 4/\alpha^3$.*

Because an affine subspace of dimension at least $n - 4/\alpha^3$ must contain an element of Hamming weight at least $n - 4/\alpha^3$, Lemma 14 follows from Lemma 16 and the observation that $\|\sum_{i=1}^c y_i\|_1 \leq \|\bigvee_{i=1}^c y_i\|_1$.

3.3 Proof of Lemma 15 using Fourier analysis

We use an inequality from Fourier analysis to give a proof of Lemma 15 via the probabilistic method.

▶ **Definition 17.** Given $x \in \mathbb{F}_2^n$, define $y \sim N_\rho(x)$ by letting each y_i be equal to x_i with probability $\frac{1+\rho}{2}$, and be equal to $1 - x_i$ with probability $\frac{1-\rho}{2}$.

Let $\mathrm{Uni}(S)$ denote the uniform distribution on a set S, and let U_n denote $\mathrm{Uni}(\mathbb{F}_2^n)$. The following lemma is a corollary of the reverse Bonami-Beckner inequality.

▶ **Lemma 18** (Corollary 3.5 in [25]). *Let $A, B \subseteq \mathbb{F}_2^n$ with $|A| = |B| = \alpha 2^n$. Then*

$$\Pr_{\substack{x \leftarrow Uni(A) \\ y \leftarrow N_\rho(x)}}[y \in B] \geq \alpha^{(1+\rho)/(1-\rho)}.$$

Proof of Lemma 15. Let $A \subseteq \mathbb{F}_2^n$ with $|A| \geq \alpha 2^n$, and let $B = A + \vec{1} = \{x + \vec{1} : x \in A\}$, where $\vec{1}$ is the n-dimensional all 1s vector. Note that to prove Lemma 15 it suffices to show that there exist $x \in A, y \in B$ such that $\|x + y\|_1 = (1 + r) \cdot \sqrt{n}$, since then $y + \vec{1} \in A$ and $\|x + (y + \vec{1})\|_1 = n - (1 + r) \cdot \sqrt{n}$.

Let $\varepsilon = 1/\sqrt{n}$ and let $\rho = 1 - 2\varepsilon$. By Lemma 18,

$$\Pr_{\substack{x \leftarrow U_n \\ y \leftarrow N_\rho(x)}}[x \in A, y \in B] = \Pr_{\substack{x \leftarrow \mathrm{Uni}(A) \\ y \leftarrow N_\rho(x)}}[y \in B] \cdot \Pr_{x \leftarrow U_n}[x \in A] \geq \alpha^{2/(1-\rho)} = \alpha^{\sqrt{n}}. \tag{1}$$

Set $r = \max\{e^2, 2\ln(1/\alpha)\}$. Note that by definition of $y \sim N_\rho(x)$ we have that $\Pr[x_i \neq y_i] = 1/\sqrt{n}$ for each i independently. Therefore, by the Chernoff bound in Lemma 9,

$$\Pr_{\substack{x \leftarrow U_n \\ y \leftarrow N_\rho(x)}}[\|x + y\|_1 \leq (1 + r)\sqrt{n}] \geq 1 - e^{-(r/2 \ln r)\sqrt{n}} \geq 1 - \alpha^{2\sqrt{n}}. \tag{2}$$

Since the sum of the probabilities in Equations (1) and (2) is strictly greater than 1, the corresponding events cannot be disjoint. Hence there exist $x \in A, y \in B$ such that $\|x + y\|_1 \leq (1 + r)\sqrt{n}$. ◀

3.4 Coloring Using Subgraphs

We now show how to apply the results in the previous subsection to the graph coloring problem. Throughout this section we let $G = (V, E)$ with $n = |V|, m = |E|$. We will identify the elements of $[n]$ with vertices V in the vertex percolation case and the elements of $[m]$ with edges E in the edge percolation case. Let $G_{|U}$ denote the subgraph of G induced by $U \subseteq V$.

▶ **Lemma 19.** *Let $G = (V, E)$ and let $V_1, V_2 \subseteq V$ with $V_1 \cup V_2 = V$. If $\chi(G_{|V_1}) \leq k_1$ and $\chi(G_{|V_2}) \leq k_2$ then $\chi(G) \leq k_1 + k_2$.*

Proof. Assume that $V_1 \cap V_2 = \emptyset$ (if not, replace V_1 with $V_1 \setminus V_2$ in the following argument). Color $G_{|V_1}$ with k_1 colors and color $G_{|V_2}$ with k_2 fresh colors. Because $G_{|V_1}$ and $G_{|V_2}$ are colored with separate colors any edges between V_1 and V_2 have endpoints with distinct colors. ◀

▶ **Lemma 20.** *Let $G = (V, E)$, let $E_1, E_2 \subseteq E$ with $E_1 \cup E_2 = E$, and let $G_1 = (V, E_1), G_2 = (V, E_2)$. If $\chi(G_1) \leq k_1$ and $\chi(G_2) \leq k_2$ then $\chi(G) \leq k_1 k_2$.*

Proof. Let c_1 be a coloring of G_1 with k_1 colors, and let c_2 be the coloring of G_2 with k_2 colors. We claim that the coloring as $c(v) = (c_1(v), c_2(v))$ is a legal coloring of G with $k_1 k_2$ colors. Consider an edge $e = (u, v) \in E$. If $e \in E_1$ then $c(u)$ differs from $c(v)$ in the fist coordinate. Otherwise $e \in E_2$ in which case $c(u)$ differs from $c(v)$ in the second coordinate. ◀

3.5 Lower Bounding the Chromatic Number

We now prove lower bounds on the chromatic number of percolated graphs. We will consider both vertex and edge percolation with $p = \frac{1}{2}$. This choice of p is important because $G_{\frac{1}{2},v}$,

$G_{\frac{1}{2},e}$ become the distributions of graphs induced by uniformly random subsets of V and E, respectively. However, we also obtain bounds for $p < \frac{1}{2}$ by composing the bounds for $p = \frac{1}{2}$. When stating bounds based on Lemma 15 we set $r = \max\{e^2, 2\ln(1/\alpha)\}$.

The idea will be to argue that if many subgraphs of a graph G are k-colorable then G is colorable with $f(k)$ colors for relatively small $f(k)$. To see how this idea works, consider the following easy case. Suppose that $\Pr[\chi(G_{\frac{1}{2},v}) \leq k] > \frac{1}{2}$. Then there exists $V' \subseteq V$ such that $G_{|V'}$ and $G_{|\overline{V'}}$ are both k-colorable. It follows that G is $2k$-colorable by Lemma 19. We now consider the case where the density of k colorable subgraphs α is less than $\frac{1}{2}$.

Proof of Theorem 5

We now prove Theorem 5, saying that if G is an n-vertex graph, then for every $\alpha \in (0,1)$ it holds that $\Pr[\chi(G_{\frac{1}{2},v}) \geq \max\{\chi(G)/3 - O_\alpha(1), \chi(G)/2 - O_\alpha(\sqrt{n})\}] > 1 - \alpha$. The proof relies on the following two lemmas.

▶ **Lemma 21.** $\Pr[\chi(G_{\frac{1}{2},v}) \leq k] \geq \alpha \Rightarrow \chi(G) \leq 3k + 4/\alpha^3$.

Proof. Identify subsets of vertices V with vectors in $\mathbb{F}_2^n$. Because $\Pr[\chi(G_{\frac{1}{2},v}) \leq k] \geq \alpha$ by Lemma 14 there exist $V_1, V_2, V_3 \subseteq V$ such that each $G_{|V_i}$ is k-colorable and $|V_1 \cup V_2 \cup V_3| \geq n - 4/\alpha^3$. Using Lemma 19, we can then color $G_{|V_1 \cup V_2 \cup V_3}$ with $3k$ colors. Coloring the remaining $4/\alpha^3$ nodes each with a different, new color implies the lemma. ◀

▶ **Lemma 22.** $\Pr[\chi(G_{\frac{1}{2},v}) \leq k] \geq \alpha \Rightarrow \chi(G) \leq 2k + (1+r)\sqrt{n}$.

Proof. Identify subsets of vertices V with vectors in $\mathbb{F}_2^n$. Because $\Pr[\chi(G_{\frac{1}{2},v}) \leq k] \geq \alpha$ by Lemma 15 there exist $V_1, V_2 \subseteq V$ such that $G_{|V_1}, G_{|V_2}$ are k-colorable and $|V_1 \cup V_2| \geq n - (1+r)\sqrt{n}$. Using Lemma 19, we can then color $G_{|V_1 \cup V_2}$ with $2k$ colors. Coloring the remaining $(1+r)\sqrt{n}$ nodes each with a different, new color implies the lemma. ◀

Lemmas 21 and 22 imply Theorem 5. Taking the contrapositive of Lemma 21 we get

$$\chi(G) > 3k + 4/\alpha^3 \Rightarrow \Pr[\chi(G_{\frac{1}{2},v}) > k] \geq 1 - \alpha,$$

which is equivalent to

$$\chi(G) > \ell \Rightarrow \Pr[\chi(G_{\frac{1}{2},v}) > (\ell - 4/\alpha^3)/3] \geq 1 - \alpha.$$

Similarly, taking the contrapositive of Lemma 22 we get the bound

$$\chi(G) > \ell \Rightarrow \Pr[\chi(G_{\frac{1}{2},v}) > \ell/2 - O_\alpha(\sqrt{n})] \geq 1 - \alpha.$$

Proof of Theorem 6

Next we prove Theorem 6, saying that if G is an n-vertex graph with m edges, then for every $\alpha \in (0,1)$ it holds that $\Pr[\chi(G_{\frac{1}{2},e}) \geq \max\{\Omega_\alpha(\chi(G)^{1/3}), \Omega_\alpha(\chi(G)/m^{1/4})\}] > 1 - \alpha$. The techniques are similar to those used for proving Theorem 5, but with several additional observations we push the techniques further.

▶ **Lemma 23.** $\Pr[\chi(G_{\frac{1}{2},e}) \leq k] \geq \alpha \Rightarrow \chi(G) \leq k^3 + 8/\alpha^3$.

Proof. Identify subsets of edges E with vectors in $\mathbb{F}_2^m$. Because $\Pr[\chi(G_{\frac{1}{2},e}) \leq k] \geq \alpha$ by Lemma 14 there exist $E_1, E_2, E_3 \subseteq E$ such that each $G_i = (V, E_i)$ is k-colorable and $|E_1 \cup E_2 \cup E_3| \geq m - 4/\alpha^3$. Using Lemma 20, we can then color $G(V, E_1 \cup E_2 \cup E_3)$ with k^3 colors. Color the endpoints of the remaining $E \setminus (E_1 \cup E_2 \cup E_3)$ edges using $8/\alpha^3$ new colors to achieve a $(k^3 + 8/\alpha^3)$-coloring of G. ◀

The next lemma gives an unconditional upper bound on chromatic number.

▶ **Lemma 24.** *Let $G = (V, E)$ be a graph with $|E| = m$. Then $\chi(G) \leq 3\sqrt{m} + 1$.*

Proof. Partition V into sets $V_0 = \{v \in V : \deg(v) < \sqrt{m}\}$ and $V_1 = \{v \in V : \deg(v) \geq \sqrt{m}\}$. By Brooks' Theorem [6], $\chi(G_{|V_0}) \leq \max_{v \in V_0} \deg(v) + 1 \leq \sqrt{m} + 1$. Furthermore, because $\sum_{v \in V_1} \deg(v) \leq 2m$, it follows that $|V_1| \leq 2\sqrt{m}$, and in particular $\chi(G_{|V_1}) \leq 2\sqrt{m}$. The result follows by Lemma 19. ◀

We use a variant of the same partitioning trick in the following lemma.

▶ **Lemma 25.** $\Pr[\chi(G_{\frac{1}{2},e}) \leq k] \geq \alpha \Rightarrow \chi(G) \leq (4 + 2r)km^{1/4}$.

Proof. Note first that if $k \geq m^{1/4}$, then the claimed bound holds by Lemma 24. So we assume henceforth that $k < m^{1/4}$.

Identify subsets of edges E with vectors in $\mathbb{F}_2^m$. Because $\Pr[\chi(G_{\frac{1}{2},e}) \leq k] \geq \alpha$ by Lemma 15 there exist $E_1, E_2 \subseteq E$ such that $G_1 = (V, E_1), G_2 = (V, E_2)$ are k-colorable and $|E_1 \cup E_2| \geq m - (1 + r)\sqrt{m}$.

Let $E_3 = E \setminus (E_1 \cup E_2)$ be the set of edges that are not in $E_1 \cup E_2$, and define the graph $G_3 = (V, E_3)$. Define a partition $U, \overline{U}$ of V, where $U = \{v \in V : \deg_{G_3}(v) < m^{1/4}/k\}$ and $\overline{U} = \{v \in V : \deg_{G_3}(v) \geq m^{1/4}/k\}$. We claim (1) that $\chi(G_{|U}) \leq 2km^{1/4}$ and (2) that $\chi(G_{|\overline{U}}) \leq 2(1 + r)km^{1/4}$. By Lemma 19 we then get the upper bound $\chi(G) \leq \chi(G_{|U}) + \chi(G_{|\overline{U}}) \leq (4 + 2r)km^{1/4}$.

To prove (1) note that by Brooks' Theorem [6] we have $\chi((G_3)_{|U}) \leq 2m^{1/4}/k$, and thus by Lemma 20 $\chi(G_{|U}) \leq \chi(G_1) \cdot \chi(G_2) \cdot \chi((G_3)_{|U}) \leq 2km^{1/4}$. For (2) note that $\sum_{v \in \overline{U}} \deg_{G_3}(v) \leq 2(1 + r)\sqrt{m}$, and hence $\chi(G_{|\overline{U}}) \leq \left|\overline{U}\right| \leq 2(1 + r)km^{1/4}$, as required. ◀

Taking the contrapositive of Lemmas 23 and 25 implies Theorem 6.

Proof of Theorem 7

Finally, we use Theorem 6 to prove the strong robustness result for Gap-Coloring. Let G be an instance of the Gap-Coloring(q, Q) problem. We claim the following:

YES-case: If $\chi(G) \leq q$, then $\chi(G_{\frac{1}{2},e}) < q$.

NO-case: If $\chi(G) \geq Q$, then $\chi(G_{\frac{1}{2},e}) \geq \Omega(Q^{1/3})$ with probability at least 0.99.

The YES-case is clear, since removing edges cannot increase the chromatic number. The NO-case follows from Theorem 6. Thus, the Gap-Coloring(q, Q) problem is strongly-noise-robust to the Gap-Coloring$(q, \Omega(Q^{1/3}))$ problem. The "in particular" part of the theorem follows from the result of Huang [18] showing that Gap-Coloring$(q, 2^{\Omega(q^{1/3})})$ is $\mathcal{NP}$-hard.

Acknowledgements. We thank Itai Benjamini, Uri Feige, Sam Hopkins for useful discussions. We are grateful to the anonymous referees for helpful comments and turning our attention to [7]. Part of this work was done during the visit of the second author at NYU. The second author wishes to thank Subhash Khot for his hospitality.

Abstract

Given n weighted points (positive or negative) in d dimensions, what is the axis-aligned box which maximizes the total weight of the points it contains?

The best known algorithm for this problem is based on a reduction to a related problem, the Weighted Depth problem [Chan, FOCS, 2013], and runs in time $O(n^d)$. It was conjectured [Barbay et al., CCCG, 2013] that this runtime is tight up to subpolynomial factors. We answer this conjecture affirmatively by providing a matching conditional lower bound. We also provide conditional lower bounds for the special case when points are arranged in a grid (a well studied problem known as Maximum Subarray problem) as well as for other related problems.

All our lower bounds are based on assumptions that the best known algorithms for the All-Pairs Shortest Paths problem (APSP) and for the Max-Weight k-Clique problem in edge-weighted graphs are essentially optimal.

1 Introduction

Consider a set of points in the plane. Each point is assigned a real weight that can be either positive or negative. The Max-Weight Rectangle problem asks to find an axis parallel rectangle that maximizes the total weight of the points it contains. This problem (and its close variants) is one of the most basic problems in computational geometry and is used as a subroutine in many applications [17, 20, 23, 7, 6]. Despite significant work over the past two decades, the best known algorithm runs in time quadratic in the number of points [16, 14, 9]. It has been conjectured that there is no strongly subquadratic time algorithm[1] for this problem [9].

An important special case of the Max-Weight Rectangle problem is when the points are arranged in a square grid. In this case the input is given as an $n \times n$ matrix filled with

Table 1 Upper bounds and conditional lower bounds for the various problems studied. The bounds shown ignore subpolynomial factors.

Problem	**In 2 dimensions**	**In d dimensions**
Max-Weight Rectangle on N weighted points	$O(N^2)$ [9, 12] $\Omega(N^2)$ **[this work]**	$O(N^d)$ [9, 12] $\Omega(N^d)$ **[this work]**
Maximum Subarray on $n \times \cdots \times n$ arrays	$O(n^3)$ [32, 31] $\Omega(n^3)$ **[this work]**	$O(n^{2d-1})$ [Kadane's algorithm] $\Omega(n^{3d/2})$ **[this work]**
Maximum Square Subarray on $n \times \cdots \times n$ arrays	$O(n^3)$ [trivial] $\Omega(n^3)$ **[this work]**	$O(n^{d+1})$ [trivial] $\Omega(n^{d+1})$ **[this work]**
Weighted Depth on N weighted boxes	$O(N)$ [12] $\Omega(N)$ [trivial]	$O(N^{d/2})$ [12] $\Omega(N^{d/2})$ **[this work]**

real numbers and the objective is to compute a subarray that maximizes the sum of its entries [27, 31, 30, 28, 13]. This problem, known as Maximum Subarray problem, has applications in pattern matching [19], data mining and visualization [20] (see [31] for additional references). The particular structure of the Maximum Subarray problem allows for algorithms that run in $O(n^3)$, i.e. $O(N^{3/2})$ with respect to the input size $N = n^2$, as opposed to $O(N^2)$ which is the best algorithm for the more general Max-Weight Rectangle problem.

One interesting question is if this discrepancy between the runtimes of these two very related problems can be avoided. Is it possible to apply ideas from one to improve the runtimes of the other? Despite considerable effort there has been no significant improvement to their runtime other than by subpolynomial factors since they were originally studied.

In this work, we attempt to explain this apparent barrier for faster runtimes by giving evidence of the inherent hardness of the problems. In particular, we show that a strongly subquadratic algorithm for Max-Weight Rectangle would imply a breakthrough for fundamental graph problems. We show similar consequences for $O(N^{3/2-\varepsilon})$ algorithms for the Maximum Subarray problem. Our lower bounds are based on standard hardness assumptions for the All-Pairs Shortest Paths and the Max-Weight k-Clique problems and generalize to the higher-dimensional versions of the problems.

1.1 Related work on the problems

In one dimension, the Max-Weight Rectangle problem and Maximum Subarray problem are identical. The 1-D problem was first posed by Ulf Grenander for pattern detection in images, and a linear time algorithm was found by Jay Kadane [10].

In two dimensions, Dobkin et al [16, 15, 24] studied the Max-Weight Rectangle problem in the case where weights are $+1$ or -1 for its applications to computer graphics and machine learning. They presented the first $O(N^2 \log N)$ algorithm. More recently, Cortés et al [14] studied the problem with arbitrary weights and they developed an algorithm with the same runtime applicable to many variants of the problem. An even faster algorithm was shown by Barbay et al. [9] that runs in $O(N^2)$ time.

For higher dimensions, Barbay et al [9] show a reduction to the related Weighted Depth problem which allows them to achieve runtime $O(N^d)$. Given N axis-parallel rectangular weighted boxes, the Weighted Depth problem asks to find a point that maximizes the total weight of all boxes that contain it. Compared to the Max-Weight Rectangle where we are given points and we aim to find the best box, in this problem, we are given boxes and the aim is to find the best point. The Weighted Depth problem is also related to Klee's

measure problem[2] which has a long line of research. All known algorithms for one problem can be adjusted to work for the other [12]. The Weighted Depth problem was first solved in $O(N^{d/2} \log n)$ by Overmars and Yap [26] and was improved to $O(N^{d/2})$ by Timothy M. Chan [12] who gave a surprisingly simple divide and conquer algorithm.

A different line of work, studies the Maximum Subarray problem. Kadane's algorithm for the 1-dimensional problem can be generalized in higher dimensions for d-dimensional $n \times \cdots \times n$ arrays giving $O(n^{2d-1})$ which implies an $O(n^3)$ algorithm when the array is a $n \times n$ matrix. Tamaki and Tokuyama [32] gave a reduction of the 2-dimensional version of the problem to the distance product problem implying a $O\left(\frac{n^3}{2^{\Omega(\sqrt{\log n})}}\right)$ algorithm by using the latest algorithm for distance product by Ryan Williams [34]. Tamaki and Tokuyama's reduction was further simplified by Tadao Takaoka [31] who also gave a more practical algorithm whose expected time is close to quadratic for a wide range of random data.

1.2 Our results and techniques

Despite significant work on the Max-Weight Rectangle and Maximum Subarray problems, it seems that there is a barrier in improving the best known algorithms for these problems by polynomial factors. Our results indicate that this barrier is inherent by showing connections to well-studied fundamental graph problems. In particular, our first result states that there is no strongly subquadratic algorithm for the Max-Weight Rectangle problem unless the Max-Weight k-Clique problem can be solved in $O(n^{k-\varepsilon})$ time, i.e. substantially faster than the currently best known algorithm. More precisely, we show the following:

▶ **Theorem 1.** *For any constant $\varepsilon > 0$, an $O(N^{2-\varepsilon})$ algorithm for the* Max-Weight Rectangle *problem on N weighted points in the plane implies an $O(n^{k-\varepsilon})$ algorithm for the* Max-Weight k-Clique *problem on a weighted graph with n vertices where $k = 4 \cdot \lceil \varepsilon^{-1} \rceil$.*

Our conditional lower bound generalizes to higher dimensions. Namely, we show that an $O(N^{d-\varepsilon})$ time algorithm for points in d-dimensions implies an $O(n^{k-\varepsilon})$ time algorithm for the Max-Weight k-Clique problem for $k = d^2\lceil \varepsilon^{-1} \rceil$. This matches the best known algorithm [9, 12] for any dimension up to subpolynomial factors. Therefore, because of our reduction, significant improvements in the runtime of the known upper bounds would imply a breakthrough algorithm for finding a k-clique of maximum weight in a graph.

To show this result, we embed an instance of the Max-Weight k-Clique problem to the Max-Weight Rectangle problem, by treating coordinates of the optimal rectangular box as base-n numbers where digits correspond to nodes in the maximum-weight k-clique. In the construction, we place points with appropriate weights so that the weight of any rectangular box corresponds to the weight of the clique it represents. We show that it is sufficient to use only $O(n^{\frac{k}{d}+1})$ points in d-dimensions to represent all weighted k-cliques which gives us the required bound by choosing an appropriately large k.

We also study the special case of the Max-Weight Rectangle problem in the plane where all points are arranged in a square grid, namely the Maximum Subarray problem. Our second result states that for $n \times n$ matrices, there is no strongly subcubic algorithm for the Maximum Subarray problem unless there exists a strongly subcubic algorithm for the All-Pairs Shortest Paths problem. More precisely, we show that:

[2] Klee's measure problem asks for the total volume of the union of N axis-parallel boxes in d dimensions.

▶ **Theorem 2.** *For any constant $\varepsilon > 0$, an $O(n^{3-\varepsilon})$ time algorithm for the* Maximum Subarray *problem on $n \times n$ matrices implies an $O(n^{3 - \varepsilon/10})$ time algorithm for the* All-Pairs Shortest Paths *problem.*

Combined with the fact that the Maximum Subarray problem reduces to the All-Pairs Shortest Paths problem as shown in [32, 31], our result implies that the two problems are equivalent, in the sense that any strongly subcubic algorithm for one would imply a strongly subcubic algorithm for the other.

To extend our lower bound to higher dimensions, we need to make a stronger hardness assumption based on the Max-Weight k-Clique problem. We show that an $O(n^{3d/2 - \varepsilon})$ time algorithm for the Maximum Subarray problem in d-dimensions implies an $O(n^{k-\varepsilon})$ time algorithm for the Max-Weight k-Clique problem. To prove this result, we introduce the following intermediate problem: Given a graph G find a maximum weight subgraph H that is isomorphic to a clique on $2d$ nodes without the edges of a matching (Max-Weight Clique without Matching problem). This graph H contains a large clique of size $3d/2$ as a minor and we show that this implies that no $O(n^{3d/2 - \varepsilon})$ algorithms exist for the Max-Weight Clique without Matching problem. We complete our proof by reducing the Max-Weight Clique without Matching problem to the Maximum Subarray problem in d dimensions.

We note that the best known algorithm for the Maximum Subarray problem runs in $O(n^{2d-1})$ time and is based on Kadane's algorithm for the 1-dimensional problem. It remains an interesting open question to close this gap. To improve either the lower or upper bound, it is necessary to better understand the computational complexity of the Max-Weight Clique without Matching problem.

Another related problem we consider is the Maximum Square Subarray problem: Given an $n \times n$ matrix find a maximum subarray with sides of equal length. This problem and its higher dimensional generalization can be trivially solved in $O(n^{d+1})$ runtime by enumerating over all possible combinations of the $d + 1$ parameters, i.e. the side-length and the location of the hypercube. We give a matching lower bound based on hardness of the Max-Weight k-Clique problem.

Finally, we adapt the reduction for Klee's measure problem shown by Timothy M Chan [11] to show a lower bound for the Weighted Depth problem.

Our results are summarized in Table 1, where we compare the current best upper bounds with the conditional lower bounds that we show.

The conditional hardness results presented above are for the variants of the problems where weights are arbitrary real numbers. We note that all these bounds can be adapted to work for the case where weights are either $+1$ or -1. In this case, we reduce the (unweighted) k-Clique-Detection problem[3] to each of these problems. The k-Clique-Detection problem can be solved in $O(n^{\omega\lfloor k/3 \rfloor + (k \bmod 3)})$ [25] using fast matrix multiplication, where $\omega < 2.372864$ [35, 22] is the fast matrix multiplication exponent.[4] Without using fast matrix multiplication, it is not known whether a purely combinatorial algorithm exists that runs in $O(n^{k-\varepsilon})$ time for any constant $\varepsilon > 0$ and it is a longstanding graph problem. Our lower bounds can be adapted for the $+1$ / -1 versions of the problems obtaining the same runtime exponents for combinatorial algorithms as in Table 1. Achieving better exponents

[3] Given a graph on n vertices, the k-Clique-Detection problem asks whether a k-clique exists in the graph.

[4] There is a slightly faster algorithm for the case when k is not divisible by 3 [18].

for any of these problems would imply a breakthrough combinatorial algorithm for the k-Clique-Detection problem.

There is a vast collection of problems in computation geometry for which conditional lower bounds are based on the assumption of 3-SUM hardness, i.e. that the best known algorithm for the 3-SUM problem[5] can't be solved in time $O(n^{2-\varepsilon})$. This line of research was initiated by [21] (see [33] for more references). Reducing 3-SUM problem to the problems that we study seems hard if possible at all. Our work contributes to the list of interesting geometry problems for which hardness is shown from different assumptions.

1.3 Hardness assumptions

There is a long list of works showing conditional hardness for various problems based on the All-Pairs Shortest Paths problem hardness assumption [29, 36, 4, 2, 3]. Among other results, [36] showed that deciding whether a weighted graph contains a triangle of negative weight is equivalent to the All-Pairs Shortest Paths problem meaning that a strongly subcubic algorithm for the Negative Triangle problem implies a strongly subcubic algorithm for the All-Pairs Shortest Paths problem and the other way around. It is easy to show that the problem of computing the maximum weight triangle in a graph is equivalent to the Negative Triangle problem (by inverting edge-weights of the graph and doing the binary search over the weight of the max-weight triangle). Computing a max-weight triangle is a special case of the problem of computing a max-weight k-clique in a graph for a fixed integer k. This is a very well studied computational problem and despite serious efforts, the best known algorithm for this problem still runs in time $O(n^{k-o(1)})$, which matches the runtime of the trivial algorithm up to subpolynomial factors. The assumption that there is no $O(n^{k-\varepsilon})$ time algorithm for this problem, has served as a basis for showing conditional hardness results for several problems on sequences [1, 5].

2 Preliminaries

2.1 Problems studied in this work

▶ **Definition 3** (Max-Weight Rectangle problem)**.** Given N weighted points (positive or negative) in $d \geq 2$ dimensions, what is the axis-aligned box which maximizes the total weight of the points it contains?

▶ **Definition 4** (Maximum Subarray problem)**.** Given a d-dimensional array M with n^d real-valued entries, find the d-dimensional subarray of M which maximizes the sum of the elements it contains.

▶ **Definition 5** (Max-Weight Square problem)**.** Given a d-dimensional array M with n^d real-valued entries, find the d-dimensional square (hypercube) subarray of M, i.e. a rectangular box with all sides of equal length, which maximizes the sum of the elements it contains.

▶ **Definition 6** (Weighted Depth problem)**.** Given a set of N weighted axis-parallel boxes in d-dimensional space $\mathbb{R}^d$, find a point $p \in \mathbb{R}^d$ that maximizes the sum of the weights of the boxes containing p.

[5] Given a set of integers, decide if there are 3 integers that sum up to 0.

2.2 Hardness assumptions

We use the hardness assumptions of the following problems. Whenever we refer to a weighted graph, we assume that the graph is *edge-weighted* (as opposed to node-weighted).

▶ **Definition 7** (All-Pairs Shortest Paths problem)**.** Given a weighted undirected graph $G = (V, E)$ such that $|V| = n$, find the shortest path between u and v for every $u, v \in V$.

▶ **Definition 8** (Negative Triangle problem)**.** Given a weighted undirected graph $G = (V, E)$ such that $|V| = n$, output yes if there exists a triangle in the graph with negative total edge weight.

▶ **Definition 9** (Max-Weight k-Clique problem)**.** Given an integer k and a weighted graph $G = (V, E)$ with n vertices, output the maximum total edge-weight of a k-clique in the graph. W.l.o.g. we assume that the graph is complete since otherwise we can set the weight of non-existent edges to be equal to a negative integer with large absolute value.

For any fixed k, the best known algorithm for the Max-Weight k-Clique problem runs in time $O(n^{k-o(1)})$.

In Sections 3 and 5, we use the following variant of the Max-Weight k-Clique problem which can be shown to be equivalent to Definition 9:

▶ **Definition 10** (Max-Weight k-Clique problem for k-partite graphs)**.** Given an integer k and a weighted k-partite graph $G = (V_1 \cup \ldots \cup V_k,\ E)$ with kn vertices such that $|V_i| = n$ for all $i \in [k]$. Choose k vertices $v_i \in V_i$ and consider total edge-weight of the k-clique induced by these vertices. Output the maximum total-edge weight of a clique in the graph.

Notation

For any integer n, we denote the set $\{1, 2, \ldots, n\}$ by $[n]$. For a set S and an integer d, we denote the set $\{(s_1, \ldots, s_d) \mid s_i \in S\}$ by S^d.

3 Hardness of the Max-Weight Rectangle problem

The goal of this section is to show a hardness result for the Max-Weight Rectangle problem making the assumption of Max-Weight k-Clique hardness. We will show the result directly for any constant number of dimensions.

▶ **Theorem 11.** *For any constants $\varepsilon > 0$ and d, an $O(N^{d-\varepsilon})$ time algorithm for the* Max-Weight Rectangle *problem on N weighted points in d-dimensions implies an $O(n^{K-\varepsilon})$ time algorithm for the* Max-Weight K-Clique *problem on a weighted graph with n vertices for $K = d^2\lceil\varepsilon^{-1}\rceil$.*

We set $k = d \cdot \lceil\varepsilon^{-1}\rceil$. To prove the theorem, we will construct an instance of the Max-Weight Rectangle problem whose answer computes a max-weight dk-clique in a $(d \times k)$-partite weighted graph G with n nodes in each of its parts. The Max-Weight dk-Clique problem on general graphs reduces to this case since we can create $d \times k$ copies of the nodes and connect nodes among different parts with edge-weights as in the original graph.

The instance of the Max-Weight Rectangle problem will consist of $N = O(n^{k+1})$ points with integer coordinates $\{-n^k, ..., n^k\}^d$. For such an instance the required runtime

for the Max-Weight Rectangle problem, from the theorem statement, would imply that the maximum weight dk-clique can be computed in

$$O\left(N^{d-\varepsilon}\right) = O\left(n^{(k+1)(d-\varepsilon)}\right) = O\left(n^{dk-\varepsilon+(d-k\varepsilon)}\right) = O\left(n^{dk-\varepsilon}\right)$$

where the last equality follows as $k \geq \frac{d}{\varepsilon}$.

To perform the reduction we introduce the following intermediate problem:

▶ **Definition 12** (Restricted Rectangle problem)**.** Given $N = \Omega(n^k)$ weighted points in an $\{-n^k, ..., n^k\}^d$-grid, compute a rectangular box of a restricted form that maximizes the weight of its enclosed points. The rectangular box $\prod_{i=1}^{d}[-x'_i, x_i]$ must satisfy the following conditions:

1. Both $\vec{x}, \vec{x}' \in \{0, ..., n^k - 1\}^d$, and
2. Treating each coordinate x_i as a k-digit integer $(x_{i1}x_{i2}...x_{ik})_n$ in base n, i.e., $x_i = \sum_{j=1}^{k} x_{ij}n^{k-j}$ and $x_{ij} \in \{0, ..., n-1\}$, we must have $\vec{x}' = (\overline{x_d}, \overline{x_1}, \overline{x_2}, ..., \overline{x_{d-1}})$, where for an integer $z = (z_1z_2...z_k)_n \in \{0, ..., n^k - 1\}$, we denote by $\overline{z} = (z_k...z_2z_1)_n$ the integer that has all the digits reversed.

We show that the Restricted Rectangle problem reduces to the Max-Weight Rectangle problem.

3.1 Restricted Rectangle ⇒ Max-Weight Rectangle

Consider an instance of the Restricted Rectangle problem. We can convert it to an instance of the Max-Weight Rectangle problem by introducing several additional points. Let C be a number greater than twice the sum of absolute values of all weights of the given points. We know that the solution to any rectangular box must have weight in $(-C/2, C/2)$.

The conditions of the Restricted Rectangle require that the rectangular box must contain the origin $\vec{0}$. To satisfy that we introduce a point with weight C at the origin. This forces the optimal rectangle to contain the origin since any rectangle that doesn't include this point gets weight strictly less than C.

The integrality constraint is satisfied since all points in the instance have integer coordinates so without loss of generality the optimal rectangle in the Max-Weight Rectangle problem will also have integer coordinates.

Finally, we can force $x'_2 = \overline{x_1}$, by adding for each $x_1 \in \{0, ..., n^k - 1\}$ the 4 points:

- $(x_1, -\overline{x_1}, 0, 0, .., 0)$ with weight C
- $(x_1 + 1, -\overline{x_1}, 0, 0, .., 0)$ with weight $-C$
- $(x_1, -\overline{x_1} - 1, 0, 0, .., 0)$ with weight $-C$
- $(x_1 + 1, -\overline{x_1} - 1, 0, 0, .., 0)$ with weight C

This creates $4n^k$ points and adds weight C to any rectangle with $x'_2 = \overline{x_1}$ without affecting any of the others. Working similarly for $x_2..., x_d$ we can force that the optimal solution satisfies the constraint that $\vec{x}' = (\overline{x_d}, \overline{x_1}, \overline{x_2}, ..., \overline{x_{d-1}})$.

If x and x' satisfy the conditions of the Restricted Rectangle problem, we collect weight dC for satisfying the constraints on all coordinates and C from including the point at the origin. So the total weight is at least $(d+1)C - \frac{C}{2} = (d + \frac{1}{2})C$ as every rectangle has weight at least $-C/2$ with respect to the original points. On the other hand, if at least one of the conditions is not satisfied, we receive weight strictly less than $(d + \frac{1}{2})C$. Thus, the optimal rectangular box for the Max-Weight Rectangle problem coincides with the optimal rectangular box for the Restricted Rectangle problem. The total number of points is still $O(N)$ since $N = \Omega(n^k)$ and we added $O(n^k)$ points.

3.2 Max-Weight $(d \times k)$-Partite Clique $\Rightarrow$ Restricted Rectangle

Consider a $(d \times k)$-partite weighted graph G. We label each of its parts as P_{ij} for $i \in [d]$ and $j \in [k]$. We associate each dk-clique of the graph G with a corresponding rectangular box in the Restricted Rectangle problem. In particular, for a rectangular box defined by a point $\vec{x} \in \{0, ..., n^k - 1\}^d$, each x_{ij}, i.e. the j-th most significant digit of x_i in the base n representation, corresponds to the index of the node in part P_{ij} (0-indexed).

We now create an instance by adding points so that the total weight of every rectangular box satisfying the conditions of the Restricted Rectangle problem is equal to the weight of its corresponding dk clique. To do that we need to take into account the weights of all the edges. We can easily take care of edges between parts $P_{11}, P_{12}, ..., P_{1k}$ of the graph by adding the following points for each $x_1 \in \{0, ..., n^k - 1\}$.

- $(x_1, 0, 0, 0, .., 0)$ with weight $W(x_1)$ equal to the weight of the k-clique $x_{11}, x_{12}, ..., x_{1k}$ in parts $P_{11}, P_{12}, ..., P_{1k}$
- $(x_1 + 1, 0, 0, 0, .., 0)$ with weight $-W(x_1)$

This creates $2n^k$ points and adds weight $W(x_1)$ to any rectangle whose first coordinate matches x_1 without affecting any of the others. We work similarly for every coordinate i from 2 through d accounting for the weight of all edges between parts P_{ia} and P_{ib} for all $i \in [d]$ and $a \neq b \in [k]$. To take into account the additional edges, we show how to add edges between parts P_{1a} and P_{2b}. For all $x_1 \in n^{k-a}\{0, ..., n^a - 1\}$ and $x_2 \in n^{k-b}\{0, ..., n^b - 1\}$ we add the points:

- $(x_1, x_2, 0, 0, .., 0)$ with weight w equal to the weight of the edge between nodes x_{1a} and x_{2b} in parts P_{1a} and P_{2b}.
- $(x_1 + n^{k-a}, x_2, 0, 0, .., 0)$ with weight $-w$
- $(x_1, x_2 + n^{k-b}, 0, 0, .., 0)$ with weight $-w$
- $(x_1 + n^{k-a}, x_2 + n^{k-b}, 0, 0, .., 0)$ with weight w

This adds weight equal to the weight of the edge between nodes x_{1a} and x_{2b} in parts P_{1a} and P_{2b} for any rectangle with corner $\vec{x}$. This creates $O(n^{a+b})$ points. This number becomes too large if $a + b > k + 1$. However, if this is the case we can instead apply the same construction in the part of the space where the numbers x_1 and x_2 appear reversed, i.e. by working with $x'_2 = \overline{x_1}$ and $x'_3 = \overline{x_2}$. For all $x'_2 \in n^{a-1}\{0, ..., n^{k+1-a} - 1\}$ and $x'_3 \in n^{b-1}\{0, ..., n^{k+1-b} - 1\}$ we add the points:

- $(0, -x'_2, -x'_3, 0, 0, .., 0)$ with weight w equal to the weight of the edge between nodes $x'_{2(k+1-a)}$ and $x'_{3(k+1-b)}$ in parts P_{1a} and P_{2b}.
- $(0, -x'_2 - n^{a-1}, -x'_3, 0, .., 0)$ with weight $-w$
- $(0, -x'_2, -x'_3 - n^{b-1}, 0, .., 0)$ with weight $-w$
- $(0, -x'_2 - n^{a-1}, -x'_3 - n^{b-1}, 0, .., 0)$ with weight w

This produces the identical effect as above creating $O(n^{2k+2-a-b})$ rectangles. If $a + b \geq k + 1$ this adds at most $O(n^{k+1})$ points as desired. We add edges between any other 2 parts $P_{i,\cdot}$ and $P_{i',\cdot}$ by performing a similar construction as above.

The overall number of points in the instance is $O(n^{k+1})$ and this completes the proof of the theorem.

4 Hardness for Maximum Subarray in 2 dimensions

In this section our goal is to show that, if we can solve the Maximum Subarray problem on a matrix of size $n \times n$ in time $O(n^{3-\varepsilon})$, then we can solve the Negative Triangle problem in time $O(n^{3-\varepsilon})$ on n vertex graphs. It is known that a $O(n^{3-\varepsilon})$ time algorithm for the Negative Triangle implies a $O(n^{3 - \varepsilon/10})$ time algorithm for the All-Pairs Shortest

Paths problem [36]. Combining our reduction with the latter one, we obtain Theorem 2 from the introduction, which we restate here:

▶ **Theorem 2.** *For any constant $\varepsilon > 0$, an $O(n^{3-\varepsilon})$ time algorithm for the* Maximum Subarray *problem on $n \times n$ matrices implies an $O(n^{3-\varepsilon/10})$ time algorithm for the* All-Pairs Shortest Paths *problem.*

The generalization of this statement can be found in Section 5. Here we prove 2-dimensional case first because the argument is shorter.

Clearly, the Negative Triangle problem in equivalent to the Positive Triangle problem. In the remainder of this section we therefore reduce the problem of detecting whether a graph has a positive triangle to the Maximum Subarray problem.

We need the following intermediate problem:

▶ **Definition 13** (Maximum 4-Combination)**.** Given a matrix $B \in \mathbb{R}^{m \times m}$, output

$$\max_{i,i',j,j' \in [m] \,:\, i \le i' \text{ and } j \le j'} B[i,j] + B[i',j'] - B[i,j'] - B[i',j].$$

Our reduction consists of two steps:

1. Reduce the Positive Triangle problem on n vertex graph to the Maximum 4-Combination problem on $2n \times 2n$ matrix.
2. Reduce the Maximum 4-Combination problem on $n \times n$ matrix to the Maximum Subarray matrix of size $n \times n$.

4.1 Positive Triangle ⇒ Maximum 4-Combination

Let A be the weighted adjacency matrix of size $n \times n$ of the graph and let M be the largest absolute value of an entry in A. Let $M' := 10M$ and $M'' := 100M$. We define matrix $D \in \mathbb{R}^{n \times n}$:

$$D_{i,j} = \begin{cases} M' + M'' & \text{if } i = j; \\ M'' & \text{otherwise.} \end{cases}$$

We define matrix $B \in \mathbb{R}^{2n \times 2n}$:

$$B := \begin{bmatrix} A & -A^T \\ -A^T & D \end{bmatrix}.$$

The reduction follows from the following lemma.

▶ **Lemma 14.** *Let X be the weight of the max-weight triangle in the graph corresponding to the adjacency matrix A. Let Y be the output of the* Maximum 4-Combination *algorithm when run on matrix B. The following equality holds:*

$$Y = X + M' + M''.$$

Proof. Consider integers i, j, i', j' that achieve a maximum in the Maximum 4-Combination instance as per Definition 13. Our first claim is that $i, j \le n$ and $i', j' \ge n + 1$. If this is not true, we do not collect the weight M'' and the largest output that we can get is $\le 4M' \le 9M''/10$. Note that we can easily achieve a larger output with $i = j = 1$ and $i' = j' = n + 1$.

Our second claim is that $i' = j'$. If this is not so, we do not collect the weight M' and the largest output that we can get is $M'' + 4M \leq M'' + M'/2$. Note that we can easily achieve a larger output with $i = j = 1$ and $i' = j' = n + 1$. Thus, we can denote $i' = j' = k + n$.

Now, by the construction of B, we have

$$B[i,j] + B[i',j'] - B[i,j'] - B[i',j] = A[i,j] + A[j,k] + A[k,i] + M' + M''.$$

We get the equality we need. ◀

4.2 Maximum 4-Combination ⇒ Maximum Subarray

Let $A' \in \mathbb{R}^{(n+1)\times(n+1)}$ be a matrix defined by $A'[i,j] = A[i-1,j-1]$ if $i,j \geq 2$ and $A'[i,j] = 0$ otherwise.

Let $C \in \mathbb{R}^{n\times n}$ be a matrix defined by $C[i,j] = A'[i,j] + A'[i+1,j+1] - A'[i,j+1] - A'[i+1,j]$.

The reduction follows from the claim that the output of the Maximum Subarray on C is equal to the output of the Maximum 4-Combination on A'. The claim follows from the following equality:

$$\sum_{i=i'}^{i''} \sum_{j=j'}^{j''} C[i,j] \;=\; A'[i''+1,j''+1] + A'[i',j'] - A'[i''+1,j'] - A'[i',j''+1].$$

The proofs of the hardness results of the next 3 sections are presented in the Appendix of this paper in the interest of space.

5 Hardness for Maximum Subarray for arbitrary number of dimensions

We state the hardness result we prove for the Maximum Subarray problem on d dimensional arrays.

▶ **Theorem 15.** *For any constant $\varepsilon > 0$, an $O\left(n^{d+\lfloor d/2 \rfloor - \varepsilon}\right)$ time algorithm for the* Maximum Subarray *problem on d-dimensional array, implies an $O\left(n^{d+\lfloor d/2 \rfloor - \varepsilon}\right)$ time algorithm for the* Max-Weight $(d + \lfloor d/2 \rfloor)$-Clique *problem.*

The complete proof of Theorem 15 is given in the full version of the paper [8]. It generalizes the constructions used in the hardness proof of Theorem 2.

6 Hardness for Maximum Square Subarray problem

We state the hardness result we prove for the Maximum Square Subarray problem on d dimensional arrays.

▶ **Theorem 16.** *For any constant $\varepsilon > 0$, an $O\left(n^{d+1-\varepsilon}\right)$ time algorithm for the* Maximum Square Subarray *problem on a d-dimensional array implies an $O\left(n^{d+1-\varepsilon}\right)$ time algorithm for the* Max-Weight $(d+1)$-Clique *problem.*

The proof of Theorem 16 is given in the full version of the paper [8].

7 Hardness for Weighted Depth problem

We state the hardness result we prove for the Weighted Depth problem in d dimensional space.

▶ **Theorem 17.** *For any constant $\varepsilon > 0$, an $O\left(n^{\lfloor d/2 \rfloor - \varepsilon}\right)$ time algorithm for the* Weighted Depth *problem in d dimensional space implies an $O\left(n^{d-2\varepsilon}\right)$ time algorithm for the* Max-Weight (d)-Clique *problem.*

The proof of the above theorem is given in the full version of the paper [8].

The Johnson-Lindenstrauss Lemma Is Optimal for Linear Dimensionality Reduction

Kasper Green Larsen[*1] **and Jelani Nelson**[†2]

Abstract

For any $n > 1$, $0 < \varepsilon < 1/2$, and $N > n^C$ for some constant $C > 0$, we show the existence of an N-point subset X of ℓ_2^n such that any linear map from X to ℓ_2^m with distortion at most $1 + \varepsilon$ must have $m = \Omega(\min\{n, \varepsilon^{-2} \lg N\})$. This improves a lower bound of Alon [Alon, Discre. Mathem., 1999], in the linear setting, by a $\lg(1/\varepsilon)$ factor. Our lower bound matches the upper bounds provided by the identity matrix and the Johnson-Lindenstrauss lemma [Johnson and Lindenstrauss, Contem. Mathem., 1984].

1 Introduction

The Johnson-Lindenstrauss lemma [15] states the following.

▶ **Theorem 1** (JL lemma [15, Lemma 1]). *For any N-point subset X of Euclidean space and any $0 < \varepsilon < 1/2$, there exists a map $f : X \to \ell_2^m$ with $m = O(\varepsilon^{-2} \lg N)$ such that*

$$\forall x, y \in X,\ (1-\varepsilon)\|x-y\|_2^2 \leq \|f(x)-f(y)\|_2^2 \leq (1+\varepsilon)\|x-y\|_2^2. \tag{1}$$

We henceforth refer to f satisfying (1) as *having the ε-JL guarantee for X* (often we drop mention of ε when understood from context). The JL lemma has found applications in computer science, signal processing (e.g. compressed sensing), statistics, and mathematics. The main idea in algorithmic applications is that one can transform a high-dimensional problem into a low-dimensional one such that an optimal solution to the lower dimensional problem can be lifted to a nearly optimal solution to the original problem. Due to the decreased dimension, the lower dimensional problem requires fewer resources (time, memory, etc.) to solve. We refer the reader to [12, 28, 21] for a list of further applications.

All known proofs of the JL lemma with target dimension as stated above in fact provide such a map f which is *linear*. This linearity property is important in several applications. For example in the turnstile model of streaming [22], a vector $x \in \mathbb{R}^n$ receives a stream of coordinate-wise updates each of the form $x_i \leftarrow x_i + \Delta$, where $\Delta \in \mathbb{R}$. The goal is to

process x using $m \ll n$ memory. Thus if one wants to perform dimensionality reduction in a stream, which occurs for example in streaming linear algebra applications [7], this can be achieved with linear f since $f(x + \Delta \cdot e_i) = f(x) + \Delta \cdot f(e_i)$. In compressed sensing, another application where linearity of f is inherent, one wishes to (approximately) recover (approximately) sparse signals using few linear measurements [8, 6]. The map f sending a signal to the vector containing some fixed set of linear measurements of it is known to allow for good signal recovery as long as f satisfies the JL guarantee for the set of all k-sparse vectors [6]. Linear f is also inherent in model-based compressed sensing, which is similar but where one assumes the sparsity pattern cannot be an arbitrary one of $\binom{n}{k}$ sparsity patterns, but rather comes from a smaller, structured set [5].

Given the widespread use of dimensionality reduction across several domains, it is a natural and often-asked question whether the JL lemma is tight: does there exist some X of size N such that any such map f must have $m = \Omega(\min\{n, \varepsilon^{-2} \lg N\})$? The paper [15] introducing the JL lemma provided the first lower bound of $m = \Omega(\lg N)$ when ε is smaller than some constant. This was improved by Alon [3], who showed that if $X = \{0, e_1, \ldots, e_n\} \subset \mathbb{R}^n$ is the simplex (thus $N = n + 1$) and $0 < \varepsilon < 1/2$, then any JL map f must embed into dimension $m = \Omega(\min\{n, \varepsilon^{-2} \lg n / \lg(1/\varepsilon)\})$. Note the first term in the min is achieved by the identity map. Furthermore, the $\lg(1/\varepsilon)$ term cannot be removed for this particular X since one can use Reed-Solomon codes to obtain embeddings with $m = O(1/\varepsilon^2)$ (superior to the JL lemma) once $\varepsilon \leq n^{-\Omega(1)}$ [3] (see [23] for details). Specifically, for this X it is possible to achieve $m = O(\varepsilon^{-2} \min\{\lg N, ((\lg N)/\lg(1/\varepsilon))^2\})$. Note also for this choice of X we can assume that any f is in fact linear. This is because first we can assume $f(0) = 0$ by translation. Then we can form a matrix $A \in \mathbb{R}^{m \times n}$ such that the ith column of A is $f(e_i)$. Then trivially $Ae_i = f(e_i)$ and $A0 = 0 = f(0)$.

The fact that the JL lemma is not optimal for the simplex for small ε begs the question: is the JL lemma suboptimal for all point sets? This is a major open question in the area of dimensionality reduction, and it has been open since the paper of Johnson and Lindenstrauss 30 years ago.

Our Main Contribution: For any $n > 1$, $0 < \varepsilon < 1/2$, and $N > n^C$ for some constant $C > 0$, there is an N-point subset X of ℓ_2^n such that any embedding $f : X \to \ell_2^m$ providing the JL guarantee, and where f *is linear*, must have $m = \Omega(\min\{n, \varepsilon^{-2} \lg N\})$. In other words, the JL lemma is optimal in the case where f must be linear.

Our lower bound is optimal: the identity map achieves the first term in the min, and the JL lemma the second. It carries the restriction of only being against linear embeddings, but we emphasize that since the original JL paper [15] 31 years ago, every known construction achieving the JL guarantee has been linear. Thus, in light of our new contribution, the JL lemma cannot be improved without developing ideas that are radically different from those developed in the last three decades of research on the problem.

It is worth mentioning there have been important works on non-linear embeddings into Euclidean space, such as Sammon's mapping [14], Locally Linear Embeddings [26], ISOMAP [27], and Hessian eigenmaps [9]. None of these methods, however, is relevant to the current task. Sammon's mapping minimizes the *average* squared relative error of the embedded point distances, as opposed to the maximum relative error (see [14, Eqn. 1]). Locally linear embeddings, ISOMAP, and Hessian eigenmaps all assume the data lies on a d-dimensional manifold $\mathcal{M}$ in $\mathbb{R}^n$, $d \ll n$, and try to recover the d-dimensional parametrization given a few points sampled from $\mathcal{M}$. Furthermore, various other assumptions are made about the input, e.g. the analysis of ISOMAP assumes that geodesic distance on $\mathcal{M}$ is isometrically

embeddable into ℓ_2^d. Also, the way error in these works is meausured is again via some form of average squared error and not worst case relative error (e.g. [26, Eqn. 2]). The point in all these works is then not to show the *existence* of a good embedding into low dimensional Euclidean space (in fact these works study promise problems where one is promised to exist), but rather to show that a good embedding can be recovered, in some squared loss sense, if the input data is sampled sufficiently densely from $\mathcal{M}$. There has also been other work outside the manifold setting on providing good worst case distortion via non-linear embeddings in the TCS community [10], but this work (1) provides an embedding for the snowflake metric $\ell_2^{1/2}$ and not ℓ_2, and (2) does not achieve $1+\varepsilon$ distortion. Furthermore, differently from our focus, [10] assumes the input has bounded doubling dimension D, and the goal is to achieve target dimension and distortion being functions of D.

▶ Remark. It is worth noting that the JL lemma is different from the *distributional* JL (DJL) lemma that often appears in the literature, sometimes with the same name (though the lemmas are different!). In the DJL problem, one is given an integer $n > 1$ and $0 < \varepsilon, \delta < 1/2$, and the goal is to provide a distribution $\mathcal{F}$ over maps $f : \ell_2^n \to \ell_2^m$ with m as small as possible such that for any fixed $x \in \mathbb{R}^n$

$$\mathop{\mathbb{P}}_{f \leftarrow \mathcal{F}}(\|f(x)\|_2 \notin [(1-\varepsilon)\|x\|_2, (1+\varepsilon)\|x\|_2]) < \delta.$$

The existence of such $\mathcal{F}$ with small m implies the JL lemma by taking $\delta < 1/\binom{N}{2}$. Then for any $z \in X - X$, a random $f \leftarrow \mathcal{F}$ fails to preserve the norm of z with probability δ. Thus the probability that there exists $z \in X - X$ which f fails to preserve the norm of is at most $\delta \cdot \binom{N}{2} < 1$, by a union bound. In other words, a random map provides the desired JL guarantee with high probability (and in fact this map is chosen completely obliviously of the input vectors).

The optimal m for the DJL lemma when using linear maps is understood. The original paper [15] provided a linear solution to the DJL problem with $m = O(\min\{n, \varepsilon^{-2}\lg(1/\delta)\})$, and this was later shown to be optimal for the full range of $\varepsilon, \delta \in (0, 1/2)$ [13, 16]. Thus when δ is set as above, one obtains the $m = O(\varepsilon^{-2}\lg N)$ guarantee of the JL lemma. However, this does not imply that the JL lemma is tight. Indeed, it is sometimes possible to obtain smaller m by avoiding the DJL lemma, such as the Reed-Solomon based embedding construction for the simplex mentioned above (which involves zero randomness).

It is also worth remarking that DJL is desirable for one-pass streaming algorithms, since no properties of X are known when the map f is chosen at the beginning of the stream, and thus the DJL lower bounds of [13, 16] are relevant in this scenario. However when allowed two passes or more, one could imagine estimating various properties of X in the first pass(es) then choosing some f more efficiently based on these properties to perform dimensionality reduction in the last pass. The approach of using the first pass(es) to estimate characteristics of a stream to then more efficiently select a linear sketch to use in the last pass is in fact a common technique in streaming algorithms. For example, [18] used such an approach to design a nearly optimal two-pass algorithm for L_0-estimation in turnstile streams, which consumes nearly a logarithmic factor less memory than the one-pass lower bound for the same problem. In fact all known turnstile streaming algorithms, even those using multiple passes, maintain *linear* maps applied to the input stream (with linear maps in subsequent passes being functions of data collected from applying linear maps in previous passes). It is even reasonable to conjecture that the most space-efficient algorithm for *any* multi-pass turnstile streaming problem for ℓ_2 dimensionality reduction must be of this form, since the recent works [20, 2] give evidence in this direction: namely that if a multi-pass algorithm is viewed as a sequence of finite automata (one for each pass), where the ith automaton is

generated solely from the output of the $(i-1)$st automaton, then it can be assumed that all automata represent *linear maps* with at most a logarithmic factor loss in space. They give examples where this logarithmic factor loss is necessary, but for many problems we know that no loss is necessary when requiring linear maps [4, 17]. Our new lower bound thus gives evidence that one cannot improve dimensionality reduction in the streaming setting even when given multiple passes.

1.1 Proof overview

For any $n > 1$ and $\varepsilon \in (0, 1/2)$ and $N > poly(n)$, we prove the existence of $X \subset \mathbb{R}^n$, $|X| = N$, s.t. if for $A \in \mathbb{R}^{m\times n}$

$$(1-\varepsilon)\|x\|_2^2 \le \|Ax\|_2^2 \le (1+\varepsilon)\|x\|_2^2 \text{ for all } x \in X, \tag{2}$$

then $m = \Omega(\min\{n, \varepsilon^{-2}\lg N\})$. Providing the JL guarantee on $X \cup \{0\}$ implies satisfying (2), and therefore also requires $m = \Omega(\min\{n, \varepsilon^{-2}\lg N\})$. We show such X exists via the probabilistic method, by letting X be the union of all n standard basis vectors together with several independent gaussian vectors. Gaussian vectors were also the hard case in the DJL lower bound proof of [16], though the details were different. Note we can assume $N < \exp(C\varepsilon^2 n)$ for any $C > 0$ we choose, since for larger N the n in the minimum defining m takes effect.

We now give the idea of the lower bound proof to achieve (2). First, we include in X the vectors $e_1, \ldots, e_n$. Then if $A \in \mathbb{R}^{m\times n}$ for $m \le n$ satisfies (2), this forces every column of A to have roughly unit norm. Then by standard results in covering and packing (see Eqn. (5.7) of [25]), there exists some family of matrices $\mathcal{F} \subset \cup_{t=1}^{n}\mathbb{R}^{t\times n}$, $|\mathcal{F}| = e^{O(n^2\lg n)}$, such that

$$\inf_{\hat{A}\in\mathcal{F}\cap\mathbb{R}^{m\times n}} \|A - \hat{A}\|_F \le \frac{1}{n^C} \tag{3}$$

for $C > 0$ a constant as large as we like, where $\|\cdot\|_F$ denotes Frobenius norm. Also, by a theorem of Latała [19], for any $\hat{A} \in \mathcal{F}$ and for a random gaussian vector g,

$$\mathbb{P}_g(|\|\hat{A}g\|_2^2 - \mathrm{tr}(\hat{A}^T\hat{A})| \ge \Omega(\sqrt{\lg(1/\delta)}\cdot\|\hat{A}^T\hat{A}\|_F)) \ge \delta/2 \tag{4}$$

for any $0 < \delta < 1/2$, where $\mathrm{tr}(\cdot)$ is trace. This is a (weaker version of the) statement that for gaussians, the Hanson-Wright inequality [11] not only provides an upper bound on the tail of degree-two gaussian chaos, but also is a lower bound. (The strong form of the previous sentence, without the parenthetical qualifier, was proven in [19], but we do not need this stronger form for our proof – essentially the difference is that in stronger form, (4) is replaced with a stronger inequality also involving the operator norm $\|\hat{A}^T\hat{A}\|$.)

It also follows by standard results that a random gaussian vector g satisfies

$$\mathbb{P}_g(|\|g\|_2^2 - n| > C\sqrt{n\lg(1/\delta)}) < \delta/2 \tag{5}$$

Thus by a union bound, the events of (4), (5) happen simultaneously with probability $\Omega(\delta)$. Thus if we take N random gaussian vectors, the probability that the events of (4), (5) never happen simultaneously for any of the N gaussians is at most $(1-\Omega(\delta))^N = e^{-\Omega(\delta N)}$. By picking N sufficiently large and $\delta = 1/\mathrm{poly}(n)$, a union bound over $\mathcal{F}$ shows that for every $\hat{A} \in \mathcal{F}$, one of the N gaussians satisfies the events of (4) and (5) simultaneously. Specifically, for $N > n^3$ there exist N vectors $\{v_1, \ldots, v_N\} = V \subset \mathbb{R}^n$ such that

- Every $v \in V$ has $\|v\|_2^2 = n \pm O(\sqrt{n\lg N}) = (1 \pm O(\varepsilon))n$.
- For any $\hat{A} \in \mathcal{F}$ there exists some $v \in V$ such that $|\|\hat{A}v\|_2^2 - \mathrm{tr}(\hat{A}^T\hat{A})| = \Omega(\sqrt{\lg N}\cdot\|\hat{A}^T\hat{A}\|_F)$.

Here $\pm B$ represents a value in $[-B, B]$. The final definition of X is $\{e_1, \ldots, e_n\} \cup V$. Then, using (2) and (3), we show that the second bullet implies

$$\mathrm{tr}(\hat{A}^T\hat{A}) = n \pm O(\varepsilon n), \text{ and } |\|Av\|_2^2 - n| = \Omega(\sqrt{\lg N} \cdot \|\hat{A}^T\hat{A}\|_F) - O(\varepsilon n). \tag{6}$$

But then by the triangle inequality, the first bullet above, and (2),

$$\left|\|Av\|_2^2 - n\right| \leq \left|\|Av\|_2^2 - \|v\|_2^2\right| + \left|\|v\|\|_2^2 - n\right| = O(\varepsilon n). \tag{7}$$

Combining (6) and (7) implies

$$\mathrm{tr}(\hat{A}^T\hat{A}) = \sum_{i=1}^{n} \hat{\lambda}_i \geq (1 - O(\varepsilon))n, \text{ and } \|\hat{A}^T\hat{A}\|_F^2 = \sum_{i=1}^{n} \hat{\lambda}_i^2 = O\left(\frac{\varepsilon^2 n^2}{\lg N}\right)$$

where $(\hat{\lambda}_i)$ are the eigenvalues of $\hat{A}^T\hat{A}$. With bounds on $\sum_i \hat{\lambda}_i$ and $\sum_i \hat{\lambda}_i{}^2$ in hand, a lower bound on $\mathrm{rank}(\hat{A}^T\hat{A}) \leq m$ follows by Cauchy-Schwarz (this last step is also common to the proof of [3]).

▶ Remark. It is not crucial in our proof that N be at least n^3. Our techniques straightforwardly extend to show that N can be any value which is $\Omega(n^{2+\gamma})$ for any constant $\gamma > 0$, or even $\Omega(n^{1+\gamma}/\varepsilon^2)$.

2 Preliminaries

Henceforth a *standard gaussian* random variable $g \in \mathbb{R}$ is a gaussian with mean 0 and variance 1. If we say $g \in \mathbb{R}^n$ is standard gaussian, then we mean that g is a multivariate gaussian with identity covariance matrix (i.e. its entries are independent standard gaussian). Also, the notation $\pm B$ denotes a value in $[-B, B]$. For a real matrix $A = (a_{i,j})$, $\|A\|$ is the $\ell_2 \to \ell_2$ operator norm, and $\|A\|_F = (\sum_{i,j} a_{i,j}^2)^{1/2}$ is Frobenius norm.

In our proof we depend on some previous work. The first theorem is due to Latała [19] and says that, for gaussians, the Hanson-Wright inequality is not only an upper bound but also a lower bound.

▶ **Theorem 2** ([19, Corollary 2]). *There exists universal $c > 0$ such that for $g \in \mathbb{R}^n$ standard gaussian and $A = (a_{i,j})$ an $n \times n$ real symmetric matrix with zero diagonal,*

$$\forall t \geq 1,\ \mathop{\mathbb{P}}_{g}\left(|g^T A g| > c(\sqrt{t} \cdot \|A\|_F + t \cdot \|A\|)\right) \geq \min\{c, e^{-t}\}.$$

Theorem 2 implies the following corollary.

▶ **Corollary 3.** *Let g, A be as in Theorem 2, but where A is no longer restricted to have zero diagonal. Then*

$$\forall t \geq 1,\ \mathop{\mathbb{P}}_{g}\left(|g^T A g - tr(A)| > c(\sqrt{t} \cdot \|A\|_F + t \cdot \|A\|)\right) \geq \min\{c, e^{-t}\}.$$

Proof. Let N be a positive integer. Define $\tilde{g} = (\tilde{g}_{1,1}, \tilde{g}_{1,2}, \ldots, \tilde{g}_{1,N}, \ldots, \tilde{g}_{n,1}, \tilde{g}_{n,2}, \ldots, \tilde{g}_{n,N})$ a standard gaussian vector. Then g_i is equal in distribution to $N^{-1/2}\sum_{j=1}^{N} \tilde{g}_{i,j}$. Define $\tilde{A}_N$ as the $nN \times nN$ matrix formed by converting each entry $a_{i,j}$ of A into an $N \times N$ block with each entry being $a_{i,j}/N$. Then

$$g^T A g - \mathrm{tr}(A) = \sum_{i=1}^{n}\sum_{j=1}^{n} a_{i,j} g_i g_j - \mathrm{tr}(A) \overset{d}{=} \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{r=1}^{N}\sum_{s=1}^{N} \frac{a_{i,j}}{N} \tilde{g}_{i,r}\tilde{g}_{j,s} - \mathrm{tr}(A) \overset{\text{def}}{=} \tilde{g}^T \tilde{A}_N \tilde{g} - \mathrm{tr}(\tilde{A}_N)$$

where $\stackrel{d}{=}$ denotes equality in distribution (note $\mathrm{tr}(A) = \mathrm{tr}(\tilde{A}_N)$). By the weak law of large numbers

$$\forall \lambda > 0,\ \lim_{N\to\infty} \mathbb{P}\left(|\tilde{g}^T \tilde{A}_N \tilde{g} - \mathrm{tr}(\tilde{A}_N)| > \lambda\right) = \lim_{N\to\infty} \mathbb{P}\left(|\tilde{g}^T (\tilde{A}_N - \tilde{D}_N)\tilde{g}| > \lambda\right) \tag{8}$$

where $\tilde{D}_N$ is diagonal containing the diagonal elements of $\tilde{A}_N$. Note $\|\tilde{A}_N\| = \|A\|$. This follows since if we have the singular value decomposition $A = \sum_i \sigma_i u_i v_i^T$ (where the $\{u_i\}$ and $\{v_i\}$ are each orthonormal, $\sigma_i > 0$, and $\|A\|$ is the largest of the σ_i), then $\tilde{A}_N = \sum_i \sigma_i u_i^{(N)} (v_i^{(N)})^T$ where $u_i^{(N)}$ is equal to u_i but where every coordinate is replicated N times and divided by $\sqrt{N}$. This implies $|\|\tilde{A}_N - \tilde{D}_N\| - \|A\|| \le \|\tilde{D}_N\| = \max_i |a_{i,i}|/N = o_N(1)$ by the triangle inequality. Therefore $\lim_{N\to\infty} \|\tilde{A}_N - \tilde{D}_N\| = \|A\|$. Also $\lim_{N\to\infty} \|\tilde{A}_N - \tilde{D}_N\|_F = \|A\|_F$. Our corollary follows by applying Theorem 2 to the right side of (8). ◀

The next lemma follows from gaussian concentration of Lipschitz functions [24, Corollary 2.3]. It also follows from the Hanson-Wright inequality [11] (which is the statement of Corollary 3, but with the inequality reversed). Ultimately we will apply it with $t \in \Theta(\lg n)$, in which case the e^{-t} term will dominate.

▶ **Lemma 4.** *For a universal $c > 0$, and $g \in \mathbb{R}^n$ standard gaussian, $\forall t > 0$ $\mathbb{P}(|\|g\|_2^2 - n| > c\sqrt{nt}) < e^{-t} + e^{-\sqrt{nt}}$.*

The following corollary summarizes the above in a form that will be useful later.

▶ **Corollary 5.** *For $A \in \mathbb{R}^{m\times n}$ let $\lambda_1 \ge \cdots \ge \lambda_n \ge 0$ be the eigenvalues of $A^T A$. Let $g^{(1)}, \ldots, g^{(N)} \in \mathbb{R}^n$ be independent standard gaussian vectors. For some universal constants $c_1, c_2, \delta_0 > 0$ and any $0 < \delta < \delta_0$*

$$\mathbb{P}\left(\nexists j \in [N] : \left\{ \left| \|Ag^{(j)}\|_2^2 - \sum_{i=1}^n \lambda_i \right| \ge c_1 \sqrt{\lg(1/\delta)} \left(\sum_{i=1}^n \lambda_i^2 \right)^{1/2} \right\} \wedge \left\{ |\|g^{(j)}\|_2^2 - n| \le c_2 \sqrt{n \lg(1/\delta)} \right\} \right) \le e^{-N\delta}. \tag{9}$$

Proof. We will show that for any fixed $j \in [N]$ it holds that

$$\mathbb{P}\left(\left\{ \left| \|Ag^{(j)}\|_2^2 - \sum_{i=1}^n \lambda_i \right| \ge c_1 \sqrt{\lg(1/\delta)} \left(\sum_{i=1}^n \lambda_i^2 \right)^{1/2} \right\} \wedge \left\{ \|g^{(j)}\|_2^2 \le n + c_2 \sqrt{n \lg(1/\delta)} \right\} \right) > \delta \tag{10}$$

Then, since the g_j are independent, the left side of (9) is at most $(1-\delta)^N \le e^{-\delta N}$.

Now we must show (10). It suffices to show that

$$\mathbb{P}\left(|\|g^{(j)}\|_2^2 - n| \le c_2 \sqrt{n \lg(1/\delta)} \right) > 1 - \delta/2 \tag{11}$$

and

$$\mathbb{P}\left(\left| \|Ag^{(j)}\|_2^2 - \sum_{i=1}^n \lambda_i \right| \ge c_1 \sqrt{\lg(1/\delta)} \left(\sum_{i=1}^n \lambda_i^2 \right)^{1/2} \right) > \delta/2 \tag{12}$$

since (10) would then follow from a union bound. Eqn. (11) follows immediately from Lemma 4 for c_2 chosen sufficiently large. For Eqn. (12), note $\|Ag^{(j)}\|_2^2 = g^T A^T A g$. Then $\sum_i \lambda_i = \mathrm{tr}(A^T A)$ and $(\sum_i \lambda_i^2)^{1/2} = \|A^T A\|_F$. Then (12) frollows from Corollary 3 for δ smaller than some sufficiently small constant δ_0. ◀

We also need a standard estimate on entropy numbers (covering the unit ℓ_∞^{mn} ball by ℓ_2^{mn} balls).

▶ **Lemma 6.** *For any parameter $0 < \alpha < 1$, there exists a family $\mathcal{F}_\alpha \subseteq \bigcup_{m=1}^n \mathbb{R}^{m\times n}$ of matrices with the following two properties:*

1. *For any matrix $A \in \bigcup_{m=1}^n \mathbb{R}^{m\times n}$ having all entries bounded in absolute value by 2, there is a matrix $\hat{A} \in \mathcal{F}_\alpha$ such that A and $\hat{A}$ have the same number of rows and $B = A - \hat{A}$ satisfies $tr(B^TB) \le \alpha/100$.*
2. *$|\mathcal{F}_\alpha| = e^{O(n^2 \lg(n/\alpha))}$.*

Proof. We construct $\mathcal{F}_\alpha$ as follows: For each integer $1 \le m \le n$, add all $m \times n$ matrices having entries of the form $i\frac{\sqrt{\alpha}}{10n}$ for integers $i \in \{-20n/\sqrt{\alpha}, \ldots, 20n/\sqrt{\alpha}\}$. Then for any matrix $A \in \bigcup_{m=1}^n \mathbb{R}^{m\times n}$ there is a matrix $\hat{A} \in \mathcal{F}_\alpha$ such that A and $\hat{A}$ have the same number of rows and every entry of $B = A - \hat{A}$ is bounded in absolute value by $\frac{\sqrt{\alpha}}{10n}$. This means that every diagonal entry of B^TB is bounded by $n\alpha/(100n^2)$ and thus $\mathrm{tr}(B^TB) \le \alpha/100$. The size of $\mathcal{F}_\alpha$ is bounded by $n(40n/\sqrt{\alpha})^{n^2} = e^{O(n^2 \lg(n/\alpha))}$. ◀

3 Proof of main theorem

▶ **Lemma 7.** *Let $\mathcal{F}_\alpha$ be as in Lemma 6 with $1/\,poly(n) \le \alpha < 1$. Then there for any $N > n^3$ there exists a set of N vectors $v_1, \ldots, v_N$ in $\mathbb{R}^n$ such that for every matrix $A \in \mathcal{F}_\alpha$, there is an index $j \in [N]$ such that*

(i) $|\|Av_j\|_2^2 - \sum_i \lambda_i| = \Omega\left(\sqrt{\lg N \sum_i \lambda_i^2}\right)$.

(ii) $|\|v_j\|_2^2 - n| = O(\sqrt{n \lg N})$.

Proof. Let $g^{(1)}, \ldots, g^{(N)} \in \mathbb{R}^n$ be independent standard gaussian. Let $A \in \mathcal{F}_\alpha$ and apply Corollary 5 with $\delta = N^{-1/12} \le n^{-1/4}$. With probability $1 - e^{-\Omega(n^{3-1/4})}$, one of the $g^{(j)}$ for $j \in [N]$ satisfies (i) and (ii) for A. Since $|\mathcal{F}_\alpha| = e^{O(n^2 \lg(n/\alpha))}$, the claim follows by a union bound over all matrices in $\mathcal{F}_\alpha$. ◀

▶ **Theorem 8.** *For any $0 < \varepsilon < 1/2$, $n > 1$, and $n' > n^3$, there exists a set $X \subset \mathbb{R}^n$, $|X| = N = n' + n$, such that if A is a matrix in $\mathbb{R}^{m\times n}$ satisfying $\|Av_i\|_2^2 \in (1 \pm \varepsilon)\|v_i\|_2^2$ for all $v_i \in X$, then $m = \Omega(\min\{n, \varepsilon^{-2} \lg N\})$.*

Proof. We can assume $\varepsilon > 1/\sqrt{n}$ since otherwise an $m = \Omega(n)$ lower bound already follows from [3]. We also can assume $N < \exp(C\varepsilon^2 n)$, since otherwise $\min\{n, \varepsilon^{-2} \lg N\} = n$. To construct X, we first invoke Lemma 7 with $\alpha = \varepsilon^2/n^2$ to find n' vectors $w_1, \ldots, w_{n'}$ such that for all matrices $\tilde{A} \in \mathcal{F}_{\varepsilon^2/n^2}$, there exists an index $j \in [n']$ for which:

1. $|\|\tilde{A}w_j\|_2^2 - \sum_i \tilde{\lambda}_i| \ge \Omega\left(\sqrt{(\lg N)\sum_i \tilde{\lambda}_i^2}\right)$.
2. $|\|w_j\|_2^2 - n| = O(\sqrt{n \lg N}) = O(\varepsilon n)$.

where $\tilde{\lambda}_1 \ge \cdots \ge \tilde{\lambda}_n \ge 0$ denote the eigenvalues of $\tilde{A}^T\tilde{A}$. We let $X = \{e_1, \ldots, e_n, w_1, \ldots, w_{n'}\}$ and claim this set of $N = n' + n$ vectors satisfies the theorem. Here e_i denotes the i'th standard unit vector.

To prove this, let $A \in \mathbb{R}^{m\times n}$ be a matrix with $m \le n$ satisfying $\|Av\|_2^2 \in (1 \pm \varepsilon)\|v\|_2^2$ for all $v \in X$. Now observe that since $e_1, \ldots, e_n \in X$, A satisfies $\|Ae_i\|_2^2 \in (1 \pm \varepsilon)\|e_i\|_2^2 = (1 \pm \varepsilon)$ for all e_i. Hence all entries $a_{i,j}$ of A must have $a_{i,j}^2 \le (1 + \varepsilon) < 2$ (and in fact, all columns of A have ℓ_2 norm at most $\sqrt{2}$). This implies that there is an $m \times n$ matrix $\hat{A} \in \mathcal{F}_{\varepsilon^2/n^2}$ such

that $B = A - \hat{A} = (b_{i,j})$ satisfies $\operatorname{tr}(B^T B) \leq \varepsilon^2/(100n^2)$. Since $\operatorname{tr}(B^T B) = \|B\|_F^2$, this also implies $\|B\|_F \leq \varepsilon/(10n)$. Then by Cauchy-Schwarz,

$$\begin{aligned}
\sum_{i=1}^{n} \hat{\lambda}_i &= \operatorname{tr}(\hat{A}^T \hat{A}) \\
&= \operatorname{tr}((A-B)^T(A-B)) \\
&= \operatorname{tr}(A^T A) + \operatorname{tr}(B^T B) - \operatorname{tr}(A^T B) - \operatorname{tr}(B^T A) \\
&= \sum_{i=1}^{n} \|Ae_i\|_2^2 + \operatorname{tr}(B^T B) - \operatorname{tr}(A^T B) - \operatorname{tr}(B^T A) \\
&= n \pm (O(\varepsilon n) + 2n \cdot \max_j (\sum_i b_{i,j}^2)^{1/2} \cdot \max_k (\sum_i a_{i,k}^2)^{1/2}) \\
&= n \pm (O(\varepsilon n) + 2n \cdot \|B\|_F \cdot \sqrt{2}) \\
&= n \pm O(\varepsilon n).
\end{aligned}$$

Thus from our choice of X there exists a vector $v^* \in X$ such that

(i) $|\|\hat{A}v^*\|_2^2 - n| \geq \Omega\left(\sqrt{(\lg N)\sum_i \hat{\lambda}_i^2}\right) - O(\varepsilon n)$.

(ii) $|\|v^*\|_2^2 - n| = O(\sqrt{n \lg N}) = O(\varepsilon n)$.

Note $\|B\|^2 \leq \|B\|_F^2 = \operatorname{tr}(B^T B) \leq \varepsilon^2/(100n^2)$ and $\|\hat{A}\|^2 \leq \|\hat{A}\|_F^2 \leq (\|A\|_F + \|B\|_F)^2 = O(n^2)$. Then by (i)

(iii)

$$\begin{aligned}
|\|Av^*\|_2^2 - n| &= |\|\hat{A}v^*\|_2^2 + \|Bv^*\|_2^2 + 2\langle \hat{A}v^*, Bv^*\rangle - n| \\
&\geq \Omega\left(\sqrt{(\lg N)\sum_i \hat{\lambda}_i^2}\right) - \|Bv^*\|_2^2 - 2|\langle \hat{A}v^*, Bv^*\rangle| - O(\varepsilon n) \\
&\geq \Omega\left(\sqrt{(\lg N)\sum_i \hat{\lambda}_i^2}\right) - \|B\|^2 \cdot \|v^*\|_2^2 - 2\|B\| \cdot \|A\| \cdot \|v^*\|_2^2 - O(\varepsilon n) \\
&= \Omega\left(\sqrt{(\lg N)\sum_i \hat{\lambda}_i^2}\right) - O(\varepsilon n).
\end{aligned}$$

We assumed $|\|Av^*\|_2^2 - \|v^*\|_2^2| = O(\varepsilon \|v^*\|_2^2) = O(\varepsilon n)$. Therefore by (ii),

$$\left|\|Av^*\|_2^2 - n\right| \leq \left|\|Av^*\|_2^2 - \|v^*\|_2^2\right| + \left|\|v^*\|_2^2 - n\right| = O(\varepsilon n)$$

which when combined with (iii) implies

$$\sum_{i=1}^{n} \hat{\lambda}_i^2 = O\left(\frac{\varepsilon^2 n^2}{\lg N}\right).$$

To complete the proof, by Cauchy-Schwarz since exactly $\operatorname{rank}(\hat{A}^T \hat{A})$ of the $\hat{\lambda}_i$ are non-zero,

$$\frac{n^2}{2} \leq \left(\sum_{i=1}^{n} \hat{\lambda}_i\right)^2 \leq \operatorname{rank}(\hat{A}^T \hat{A}) \cdot \left(\sum_{i=1}^{n} \hat{\lambda}_i{}^2\right) \leq m \cdot O\left(\frac{\varepsilon^2 n^2}{\lg N}\right).$$

Rearranging gives $m = \Omega(\varepsilon^{-2} \lg N)$. Note we assumed $N < \exp(C\varepsilon^2 n)$. Thus considering N larger, we obtain the lower bound $m = \Omega(\min\{n, \varepsilon^{-2} \lg N\})$ as desired. ◀

4 Discussion

One obvious future goal is to obtain an $m = \Omega(\min\{n, \varepsilon^{-2}\lg N\})$ lower bound that also applies to non-linear maps. Unfortunately, such a lower bound cannot be obtained by using the hard set X from Theorem 8. If X is the union of $\{e_1, \ldots, e_n\}$ with $n^{O(1)}$ independent gaussian vectors normalized to each have squared unit norm in expectation, then it is not hard to show (e.g. via a decoupled Hanson-Wright inequality) that X will be ε-incoherent with high probability for any $\varepsilon \in \Omega(\sqrt{\lg n/n})$, where we say a set X is ε-incoherent if (1) for all $x \in X$, $\|x\|_2 = 1 \pm \varepsilon$, and (2) for all $x \neq y \in X$, $|\langle x, y\rangle| \leq \varepsilon$. It is known that any ε-incoherent set of N vectors can be *non-linearly* embedded into dimension $O(\varepsilon^{-2}(\lg N/(\lg\lg N + \lg(1/\varepsilon)))^2)$ by putting each vector in correspondence with a Reed-Solomon codeword (see [23] for details). This upper bound is $o(\varepsilon^{-2}\lg N)$ for any $\varepsilon \in 2^{-\omega(\sqrt{\lg N})}$. Thus, one cannot prove an $\Omega(\varepsilon^{-2}\lg N)$ lower bound against non-linear maps for our hard set X for the full range of $\varepsilon \in [\sqrt{(\lg n)/n}, 1/2]$.

One potential avenue for generalizing our lower bound to the non-linear setting is to shrink $|X|$. Our hard set X contains $N = O(n^3)$ points in $\mathbb{R}^n$ (though as remarked earlier, our techniques easily imply $N = O(n^{1+\gamma}/\varepsilon^2)$ points suffice). Any embedding f could be assumed linear without loss of generality if the elements of X were linearly independent, at which point one would only need to prove a lower bound against linear embeddings. However, clearly $X \subset \mathbb{R}^n$ cannot be linearly independent if $N > n$, as is the case for our X. Thus a first step toward a lower bound against non-linear embeddings is to obtain a hard X with N as small as possible. Alternatively, one could hope to extend the aforementioned non-linear embedding upper bound for incoherent sets of vectors to arbitrary sets of vectors, though such a result if true seems to require ideas very different from all known constructions of JL transforms to date.

Finally, we mention an alternative but similar proof strategy that leads to the same result as proved above. In [16], the authors proved the following theorem (see their Theorem 9):

▶ **Theorem 9** ([16]). *If $A : \mathbb{R}^n \to \mathbb{R}^m$ is a linear transformation with $n \geq 2m$ and $\varepsilon > 0$ is sufficiently small, then for g a randomly chosen vector in $\mathcal{S}^{n-1}$, $\mathbb{P}(|\|Ag\|_2^2 - 1| > \varepsilon) \geq \exp(-O(m\varepsilon^2 + 1))$.*

With this theorem in mind, we can redo our proof steps, first showing that for a matrix $A \in \mathbb{R}^{m\times n}$ and N randomly chosen vectors $g^{(1)}, \ldots, g^{(N)}$, at least one of them will have $|\|Ag^{(j)}\|_2^2 - 1| > \varepsilon$ with probability $1 - \exp(-N\exp(O(m\varepsilon^2 + 1)))$. If $m = o(\varepsilon^{-2}\lg N)$, we can prove an analog of our Lemma 7, showing that there exists a set $X \subset \mathcal{S}^{n-1}$ of $N > n^3$ vectors $v_1, \ldots, v_N$, such that for every matrix $A \in \mathcal{F}_\alpha$, there is an index $j \in [N]$ with $|\|Av_j\|_2^2 - 1| > \varepsilon$. Finally, we could redo the steps in the proof of Theorem 8, showing that any JL-matrix for $X \cup \{e_1, \ldots, e_n\}$ must be sufficiently "close" to a matrix in $\mathcal{F}_\alpha$ and hence there is a vector v_j in X whose norm is distorted by too much. In summary, their theorem would replace our Corollary 3. The proof of their theorem is slightly more involved than the proof of Corollary 3 (once one assumes Theorem 2), albeit not by much. We believe there is value in knowing both proofs and we hope the underlying ideas may be useful in other applications.

Acknowledgments. We thank Radosław Adamczak for pointing out how to derive Corollary 3 from Theorem 2, and for pointing out the reference [1], which uses a more involved but similar argument. We also thank Yi Li for helpful conversation.

Abstract

Transportation cost metrics, also known as the Wasserstein distances W_p, are a natural choice for defining distances between two pointsets, or distributions, and have been applied in numerous fields. From the computational perspective, there has been an intensive research effort for understanding the W_p metrics over $\mathbb{R}^k$, with work on the W_1 metric (a.k.a *earth mover distance*) being most successful in terms of theoretical guarantees. However, the W_2 metric, also known as the *root-mean square* (RMS) bipartite matching distance, is often a more suitable choice in many application areas, e.g. in graphics. Yet, the geometry of this metric space is currently poorly understood, and efficient algorithms have been elusive. For example, there are no known non-trivial algorithms for nearest-neighbor search or sketching for this metric.

In this paper we take the first step towards explaining the lack of efficient algorithms for the W_2 metric, even over the three-dimensional Euclidean space $\mathbb{R}^3$. We prove that there are no meaningful embeddings of W_2 over $\mathbb{R}^3$ into a wide class of normed spaces, as well as that there are no efficient sketching algorithms for W_2 over $\mathbb{R}^3$ achieving constant approximation. For example, our results imply that: 1) any embedding into L_1 must incur a distortion of $\Omega(\sqrt{\log n})$ for pointsets of size n equipped with the W_2 metric; and 2) any sketching algorithm of size s must incur $\Omega\left(\sqrt{\log n}/\sqrt{s}\right)$ approximation. Our results follow from a more general statement, asserting that W_2 over $\mathbb{R}^3$ contains the 1/2-snowflake of *all* finite metric spaces with a uniformly bounded distortion. These are the first non-embeddability/non-sketchability results for W_2.

well as statistical physics, mathematical economics, automated control, shape optimization, applied probability, partial differential equations, metric geometry and many more, see [44, 39]. These metrics are also known as Wasserstein distance, Kantorovich-Rubinstein distance, Prokhorov distance, or the earth mover distance. We now recall basic notation and terminology from the theory of transportation cost metrics [57]. For a metric space (X, d_X) and $p \in (0, \infty)$, let $\mathcal{P}_p(X)$ denote the space of all (Borel) probability measures μ on X satisfying $\int_X d_X(x, x_0)^p \mathrm{d}\mu(x) < \infty$ for some (hence all) $x_0 \in X$. The *Wasserstein-p distance* between $\mu, \nu \in \mathcal{P}_p(X)$ is then

$$\mathsf{W}_p(\mu, \nu) \stackrel{\text{def}}{=} \inf_{\pi \in \Pi(\mu,\nu)} \left(\iint_{X \times X} d_X(x, y)^p \mathrm{d}\pi(x, y) \right)^{\frac{1}{p}},$$

where $\Pi(\mu, \nu)$ is the set of all couplings (matchings) π between (μ, ν) on X, i.e., probability measures π on $X \times X$ such that $\mu(A) = \pi(A \times X)$ and $\nu(A) = \pi(X \times A)$ for every $A \subseteq X$. W_p on $\mathcal{P}_p(X)$ is a metric whenever $p \geqslant 1$. Here we consider the classic setting of X being $\mathbb{R}^k$, for $k \geqslant 2$, endowed with the standard Euclidean distance.

In computer science, the transportation metrics on $\mathbb{R}^k$ play an important role in computer vision [58, 46, 21, 22, 28, 42, 38, 33], machine learning [20], information retrieval [45], and mechanism design [16], among others. For example, an image can be represented as a set of pixels in a color space $\mathbb{R}^3$; the transportation cost between such sets yields an accurate measure of dissimilarity between color characteristics of the images [47, 25].

These applications motivated a lot of research into the *computational* properties of transportation metrics. In particular, typical problems are to develop efficient algorithms for: computing the distance between two pointsets (finitely-supported measures), nearest neighbor search under these metrics, as well as problems in the streaming and sketching context.

So far, most of the rigorous algorithmic results have been developed for the W_1 metric, often refered to as the Earth Mover Distance (EMD). There is a long line of work on approximation algorithms for computing EMD between two pointsets in $\mathbb{R}^k$ [55, 2, 56, 1, 24, 49], culminating in a near-linear time algorithm achieving a $(1 + \varepsilon)$-approximation [50, 3, 7]. Nearest neighbor search algorithms all proceed via either embedding EMD into L_1 or sketching. Understanding the embeddability of EMD over $\mathbb{R}^k$ into L_1 is a well-known open problem [30], and the best distortion is currently known [14, 25, 26, 37, 5] to be between $O(k \log n)$ and $\Omega(k + \sqrt{\log n})$ for pointsets in $[n]^k = \{1, 2, \dots n\}^k$. Similarly, designing sketching algorithms for EMD over $\mathbb{R}^k$ is also a well-known open problem [40, 41]. Some of the sketching bounds for W_1 follow from the aforementioned L_1 embeddings, and some others are proved directly [4, 6].

Yet, in a number of applications the Wasserstein-2 distance W_2 is a *more natural* distance than Wasserstein-1 (EMD), and indeed other communities have paid more attention to W_2 [53]. Specifically, W_2 (a.k.a., *root-mean square bipartite matching distance*) corresponds to the "ℓ_2 error" between two pointsets, in contrast to the "ℓ_1 error" measured by W_1; as such they have better regularity properties and also have a differential interpretation [53]. See [34, 18] for a further discussion of why using W_2 gives results of a better quality than W_1. W_2 is used in graphics [51, 52, 54, 53], for shape interpolation [12], for barycenter computation [15, 11], shape reconstruction [19], blue noise generation [18], triangulations [34], among others.

Surprisingly, the algorithmic results for W_2 have been much more elusive. The best algorithms for computing W_2 distance between two pointsets follow from [43, 3], who obtain $\tilde{O}(n^2)$ time for exact and $\tilde{O}(n^{3/2})$ for approximate computation (in contrast to the near-linear

time algorithms for W_1). Beyond these results, there are no known non-trivial algorithms for embedding, nearest neighbor search, or sketching for W_2! This discrepancy raises the question of why there has been such a dire lack of progress on algorithms for W_2.

Here we address this question by proving the first explicit lower bounds for W_2 over $\mathbb{R}^3$, establishing that it is a very rich space that cannot be represented faithfully even with weak guarantees in a large class of normed spaces (that includes all L_q spaces for finite q, and much more). In particular, focusing on W_2 on measures over $\mathbb{R}^3$ supported on at most n points, we show that $\Omega(\sqrt{\log n})$ distortion is required for either: 1) embedding of W_2 into L_1, and 2) constant-size sketching. To contrast these results to those known for W_1 over the same set of measures, while W_1 has a similar non-embeddability into L_1 [37], it does not translate into *sketching* lower bounds. In fact, it was only recently established [6] that the approximation for sketching W_1 must be super-constant (without giving an explicit bound). Besides stronger sketching lower bounds, our results for W_2 are stronger than any known W_1 non-embeddability results since they apply to a larger class of Banach space targets (nontrivial type), and also rule out embeddings that are much weaker than bi-Lipschitz, like coarse embeddings. Finally, our results also apply to W_p space for $p \in (1,2)$, yielding a $\Omega((\log n)^{1/p})$ distortion lower bound, which is asymptotically stronger than the distortion lower bound known for embedding W_1 into L_1.

Our results apply to measures over $\mathbb{R}^3$ only, and the validity of analogous results for measures over $\mathbb{R}^2$ remains an open question. The only progress has been obtained in the forthcoming work [8], where the authors establish the first lower bound for embedding $\mathsf{W}_2(\mathbb{R}^2)$ into L_1, showing that the distortion goes to infinity (without an explicit bound). However, [8] does not yield the full strength of our results in terms of ruling out embeddings into spaces with nontrivial type, as well as, say, coarse embeddings.

1.1 Main Results

We now present our results on non-existence of good embedding and sketching methods for W_2 over $\mathbb{R}^3$. We then show that these results follow from a more general principle: that W_2 over $\mathbb{R}^3$ is snowflake-universal, and hence, say, we can embed the square-root of a shortest path metric on an expander graph into it with distortion arbitrarily close to 1. Our results apply to all W_p for $p > 1$, but not to W_1.

Non-embeddability results. We now introduce the standard notion of embeddings.

▶ **Definition 1.** Fix two metric spaces (X, d_X) and (Y, d_Y), and $D \in [1, \infty]$. A mapping $f : X \to Y$ is an embedding with distortion at most D if there exists $s \in (0, \infty)$ such that every $x, y \in X$ satisfy $s \cdot d_X(x, y) \leqslant d_Y(f(x), f(y)) \leqslant Ds \cdot d_X(x, y)$. The infimum over those $D \in [1, \infty]$ for which this holds true is called the distortion of f and is denoted $\mathbf{dist}(f)$. If there exists a mapping $f : X \to Y$ with distortion at most D then we say that (X, d_X) embeds with distortion D into (Y, d_Y). The infimum of $\mathbf{dist}(f)$ over all $f : X \to Y$ is denoted $c_{(Y,d_Y)}(X, d_X)$, or $c_Y(X)$ if the metrics are clear from the context.

We prove the following theorem.

▶ **Theorem 2.** *For any fixed $p \in (1, \infty)$ and $n \in \mathbb{N}$, consider the metric space X consisting of all the measures on $\mathbb{R}^3$ that are supported on at most n points, equipped with the W_p metric. Then any embedding of X into L_1 must incur distortion $\Omega(((p-1)\log n)^{1/p})$.*

Theorem 2 implies a $\Omega(\sqrt{\log n})$ approximation for any algorithmic approach proceeding via embedding W_2 over measures on $\mathbb{R}^3$ whose support is of size at most n into L_1. While

embedding into L_1 is a common algorithmic technique for high-dimensional metric spaces, it is not the only one. In particular, despite non-embeddability into L_1, a metric could admit a better embedding into, say, $L_{1/2}$, which would imply efficient sketches and nearest neighbor search algorithms. We rule out such weaker embeddings as well.

In fact, our work actually yields impossibility results that are much stronger than the bi-Lipschitz nonembeddability statement that corresponds to Theorem 2. Our most general results are contained in the full version of this paper, but here is one illustrative example. Let X be either L_1 or a Banach space of nontrivial type.[1] Then for $p \in (1, \infty)$ there do not exist any nondecreasing functions $\alpha, \beta : [0, \infty) \to [0, \infty)$ with $\lim_{t\to\infty} \alpha(t) = \infty$ for which there is a mapping $f : \mathcal{P}_p(\mathbb{R}^3) \to X$ that satisfies

$$\forall\, \mu, \nu \in \mathcal{P}_p(\mathbb{R}^3), \qquad \alpha(\mathsf{W}_p(\mu, \nu)) \leqslant \|f(\mu) - f(\nu)\|_X \leqslant \beta(\mathsf{W}_p(\mu, \nu)).$$

Theorem 2 corresponds to the special case when the function α, β are linear and X is L_1. In common metric geometry jargon, the above statement asserts that $\mathcal{P}_p(\mathbb{R}^3)$ fails to admit a coarse embedding into any normed space of nontrivial type.

Sketching. We can also state our results using the language of the sketching algorithms. The notion of sketching is defined as follows [48].

▶ **Definition 3.** Fix a metric (X, d_X), and approximation $D \geqslant 1$. We say (X, d_X) has sketching complexity $s \geqslant 1$ if, for any threshold $r > 0$, there exists a distribution over sketching maps $\mathrm{sk} : X \to \{0,1\}^s$ and reconstruction algorithms $R : \{0,1\}^s \times \{0,1\}^s \to \{\text{close}, \text{far}\}$, satisfying the following. For any $x, y \in X$, with at least $2/3$ probability of success:

- if $d_X(x, y) \leqslant r$, then $R(\mathrm{sk}(x), \mathrm{sk}(y)) = \text{close}$;
- if $d_X(x, y) > Dr$, then $R(\mathrm{sk}(x), \mathrm{sk}(y)) = \text{far}$.

We are now ready to state our sketching lower bound for W_p for $p > 1$.

▶ **Theorem 4.** *Fix $p \in (1, \infty)$ and let $n, s \in \mathbb{N}$. Consider the metric space X consisting of all the measures on $\mathbb{R}^3$ that are supported on at most n points, equipped with the W_p metric. Then any sketching algorithm for X with sketching complexity s must have an approximation guarantee of $D = \Omega\left(\left(\frac{(p-1)\log n}{s}\right)^{1/p}\right)$.*

We note that, for comparison, standard ℓ_1, ℓ_2 metrics have constant sketching complexity [27, 48, 9]. Also, for W_1 over $\mathbb{R}^3$ (or $\mathbb{R}^2$), the only known lower bound is that $Ds = \omega(1)$, shown recently in [6], based on [37].

Snowflake universality. Our results follow from a more general phenomenon, captured by the following theorem.

▶ **Theorem 5.** *If $p \in (1, \infty)$ then for every finite metric space (X, d_X) we have*

$$c_{(\mathcal{P}_p(\mathbb{R}^3), \mathsf{W}_p)}\left(X, d_X^{\frac{1}{p}}\right) = 1.$$

[1] The correct class of Banach spaces here could even be all those Banach spaces that do not contain *every* finite metric space with distortion arbitrarily close to 1, but currently this stronger version of the ensuing statement holds true conditionally on a well-known open question in metric geometry; see the full version of this paper for more details.

For a metric space (X, d_X) and $\theta \in (0,1]$, the metric space (X, d_X^θ) is commonly called the *θ-snowflake* of (X, d_X); see e.g. [17]. Thus Theorem 5 asserts that the θ-snowflake of any finite metric space (X, d_X) embeds with distortion $1+\varepsilon$ into $\mathcal{P}_p(\mathbb{R}^3)$ for every $\varepsilon \in (0,\infty)$ and $\theta \in (0, 1/p]$.[2] Our techniques fall short of proving a longstanding conjecture of Bourgain [13], who asked whether $(\mathcal{P}_1(\mathbb{R}^2), \mathsf{W}_1)$ is not universal (i.e., does not contain all finite metrics).[3] Bourgain proved in [13] that $(\mathcal{P}_1(\ell_1), \mathsf{W}_1)$ is universal (despite the fact that ℓ_1 is not universal), but it remains an intriguing open question to determine whether or not $(\mathcal{P}_1(\mathbb{R}^k), \mathsf{W}_1)$ is universal for any finite $k \in \mathbb{N}$, the case $k = 2$ being most challenging.

Theorem 6 below implies that Theorem 5 is sharp if $p \in (1,2]$, and yields a nontrivial, though probably non-sharp, restriction on the embeddability of snowflakes into $\mathcal{P}_p(\mathbb{R}^3)$ also for $p \in (2,\infty)$.

▶ **Theorem 6.** *For arbitrarily large $n \in \mathbb{N}$ there exists an n-point metric space (X_n, d_{X_n}) such that for every $\alpha \in (0,1]$ we have*

$$c_{(\mathcal{P}_p(\mathbb{R}^3), \mathsf{W}_p)}(X_n, d_{X_n}^\alpha) \gtrsim \begin{cases} (\log n)^{\alpha - \frac{1}{p}} & \text{if } p \in (1,2], \\ (\log n)^{\alpha + \frac{1}{p} - 1} & \text{if } p \in (2,\infty). \end{cases}$$

Here, and in what follows, we use standard asymptotic notation, i.e., for $a, b \in [0,\infty)$ the notation $a \gtrsim b$ (respectively $a \lesssim b$) stands for $a \geqslant cb$ (respectively $a \leqslant cb$) for some universal constant $c \in (0,\infty)$. The notation $a \asymp b$ stands for $(a \lesssim b) \wedge (b \lesssim a)$.

The rest of the paper is organized as follows. We give the proof of Theorem 5 in Section 2, and its consequences, Theorem 2 and 4, in Section 2.1. We then present some future research directions suggested by our results in Section 3. We defer the proof of Theorem 6 to the full version.

2 Proof of Theorem 5

To establish the theorem, we will construct an explicit embedding of an n-point metric into $\mathsf{W}_2(\mathbb{R}^3)$. In what follows fix $n \in \mathbb{N}$ and an n-point metric space (X, d_X).

We start by presenting the intuition behind the construction. In particular, let us demonstrate a fundamental difference between W_1 and W_p for $p > 1$ for a simple transportation instance. We will exploit this construction in our embedding. Fix a positive integer k, and consider the optimal transport between the sets $A = \{0, \frac{1}{k}, \frac{2}{k}, \ldots, \frac{k-1}{k}\}$ and $B = \{\frac{1}{k}, \frac{2}{k}, \ldots, 1\}$. While under the W_1 metric the optimal cost is simply 1, under W_p the optimal transport would send every $x \in A$ to $x + \frac{1}{k} \in B$, which incurs a cost of $\left(\sum_{i=1}^k \left(\frac{1}{k}\right)^p\right)^{1/p} = k^{1/p-1} \xrightarrow[k\to\infty]{} 0$. Note that for any $0 \leqslant \varepsilon < 1$, we can increase the transport cost to ε by introducing a "gap" of size εk. E.g., for some i, define $A = \{0, \frac{1}{k}, \ldots, \frac{i}{k}, \frac{i+\varepsilon k}{k}, \frac{i+\varepsilon k+1}{k}, \ldots, \frac{k-1}{k}\}$ and $B = A \setminus \{0\} \cup \{1\}$. Then the optimal transport cost under W_p would be

$$\left(\left(\frac{\varepsilon k}{k}\right)^p + \sum_{i=1}^{k-\varepsilon k}\left(\frac{1}{k}\right)^p\right)^{1/p} \xrightarrow[k\to\infty]{} \varepsilon\,.$$

[2] Formally, Theorem 5 makes this assertion when $\theta = 1/p$, but for general $\theta \in (0, 1/p]$ one can then apply Theorem 5 to the metric space $(X, d_X^{\theta p})$ to deduce the seemingly more general statement.

[3] Bourgain actually formulated this question as asking whether a certain Banach space (namely, the dual of the Lipschitz functions on the square $[0,1]^2$) has finite Rademacher cotype, but this is equivalent to the above formulation.

We shall use the fact that any graph, in particular the complete graph, can be realized in $\mathbb{R}^3$, so that if every edge is represented by a wire, there are no wire crossings (except at vertices). Imagine that each wire is replaced by a set of points with distances $1/k$ between neighboring points. We then introduce a gap of length proportional to $d_X(u,v)^{1/p}$ on the wire connecting u and v. The embedding of $u \in X$ will be into a uniform measure over the point realizing u, and all the points in all the wires. Then the transport from u to v must move the mass at u to the mass of v. By the simple example above, this can be done at cost proportional to $d_X(u,v)^{1/p}$, when k is sufficiently large. The trickier part is showing no better transport exist. To this end, we require that all the wires are sufficiently far apart, so any transport plan that does not move along the wires will have a huge cost. Finally, the triangle inequality ensures that the cost of a plan using the wires between the points $u = u_0, u_1, \ldots, u_q = v$ is at least $d_X(u,v)^{1/p}$ (this is the reason why we make the gaps proportional to the p-th roots).

We now proceed with the formal proof of the theorem. Write $X = \{x_1, \ldots, x_n\}$ and fix $\phi : \{1,\ldots,n\} \times \{1,\ldots,n\} \to \{1,\ldots,n^2\}$ to be an arbitrary bijection between $\{1,\ldots,n\} \times \{1,\ldots,n\}$ and $\{1,\ldots,n^2\}$. Below it will be convenient to use the following notation.

$$m \stackrel{\text{def}}{=} \min_{\substack{x,y\in X\\ x\neq y}} d_X(x,y)^{\frac{1}{p}} \qquad \text{and} \qquad M \stackrel{\text{def}}{=} \max_{x,y\in X} d_X(x,y)^{\frac{1}{p}}. \tag{1}$$

Fix $K \in \mathbb{N}$. Denoting the standard basis of $\mathbb{R}^3$ by $e_1 = (1,0,0)$, $e_2 = (0,1,0)$, $e_3 = (0,0,1)$, for every $i,j \in \{1,\ldots,n\}$ with $i < j$ define five families of points in $\mathbb{R}^3$ by setting for $s \in \{0,\ldots,K\}$,

$$Q^1_s(i,j) \stackrel{\text{def}}{=} \frac{Mi}{m}e_1 + \frac{M\phi(i,j)s}{mK}e_2, \tag{2}$$

$$Q^2_s(i,j) \stackrel{\text{def}}{=} \frac{Mi}{m}e_1 + \frac{M\phi(i,j)}{m}e_2 + \frac{Ms}{mK}e_3, \tag{3}$$

$$Q^3_s(i,j) \stackrel{\text{def}}{=} \frac{M(s(j-i)+Ki) + (K-s)d_X(x_i,x_j)^{\frac{1}{p}}}{mK}e_1 + \frac{M\phi(i,j)}{m}e_2 + \frac{M}{m}e_3, \tag{4}$$

$$Q^4_s(i,j) \stackrel{\text{def}}{=} \frac{Mj}{m}e_1 + \frac{M\phi(i,j)}{m}e_2 + \frac{M(K-s)}{mK}e_3, \tag{5}$$

$$Q^5_s(i,j) \stackrel{\text{def}}{=} \frac{Mj}{m}e_1 + \frac{M(K-s)\phi(i,j)}{mK}e_2. \tag{6}$$

Then $Q^1_K(i,j) = Q^2_0(i,j)$, $Q^3_K(i,j) = Q^4_0(i,j)$ and $Q^4_K(i,j) = Q^5_0(i,j)$, so the total number of points thus obtained equals $5(K+1) - 3 = 5K + 2$.

Define $\mathcal{B} \subseteq \mathbb{R}^3$ by setting

$$\mathcal{B} \stackrel{\text{def}}{=} \bigcup_{\substack{i,j\in\{1,\ldots,n\}\\ i<j}} \mathcal{B}_{ij}, \tag{7}$$

where for every $i,j \in \{1,\ldots,n\}$ with $i < j$ we write

$$\mathcal{B}_{ij} \stackrel{\text{def}}{=} \bigcup_{s=0}^{K} \left\{Q^1_s(i,j), Q^2_s(i,j), Q^3_s(i,j), Q^4_s(i,j), Q^5_s(i,j)\right\}. \tag{8}$$

Hence $|\mathcal{B}_{ij}| = 5K + 2$. We also define $\mathcal{C} \subseteq \mathbb{R}^3$ by

$$\mathcal{C} \stackrel{\text{def}}{=} \mathcal{B} \setminus \left\{\frac{Mi}{m}e_1 :\ i \in \{1,\ldots,n\}\right\}. \tag{9}$$

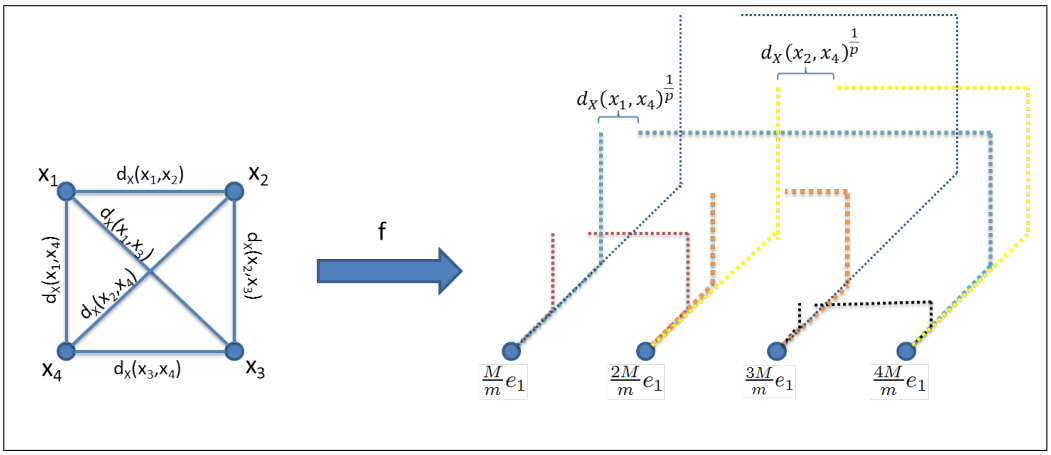

Figure 1 A schematic depiction of the embedding $f : X \to \mathcal{P}_p(\mathbb{R}^3)$ for a four-point metric space $(X, d_X) = (\{x_1, x_2, x_3, x_4\}, d_X)$. Here the x-axis is the horizontal direction, the z-axis is the vertical direction and the y-axis is perpendicular to the page plane. Recall that m and M are defined in (1).

Note that by (2) we have $(Mi/m)e_1 = Q_0^1(i,j)$ if $i, j \in \{1, \ldots, n\}$ satisfy $i < j$, and by (6) we have $(Mi/m)e_1 = Q_K^5(\ell, i)$ if $\ell, i \in \{1, \ldots, n\}$ satisfy $\ell < i$. Thus $\mathcal{C}$ corresponds to removing from $\mathcal{B}$ those points that lie on the x-axis. In what follows, we denote $N = |\mathcal{C}| + 1$. Finally, for every $i \in \{1, \ldots, n\}$ we define $\mathcal{C}_i \subseteq \mathbb{R}^3$ by

$$\mathcal{C}_i \stackrel{\text{def}}{=} \mathcal{C} \cup \left\{ \frac{Mi}{m} e_1 \right\}. \tag{10}$$

Hence $|\mathcal{C}_i| = N$. Our embedding $f : X \to \mathcal{P}_p(\mathbb{R}^3)$ will be given by

$$\forall\, j \in \{1, \ldots, n\}, \qquad f(x_j) \stackrel{\text{def}}{=} \frac{1}{N} \sum_{u \in \mathcal{C}_j} \delta_u, \tag{11}$$

where, as usual, δ_u is the point mass at u. Thus $f(x_j)$ is the uniform probability measure over $\mathcal{C}_j$. A schematic depiction of the above construction appears in Figure 1 below.

Lemma 7 below estimates the distortion of f, proving Theorem 5.

▶ **Lemma 7.** *Fix $\varepsilon \in (0,1)$ and $p \in (1, \infty)$. Let $f : X \to \mathcal{P}_p(\mathbb{R}^3)$ be the mapping appearing in (11), considered as a mapping from the snowflaked metric space $(X, d_X^{1/p})$ to the metric space $(\mathcal{P}_p(\mathbb{R}^3), \mathsf{W}_p)$. Then, recalling the definitions of m and M in (1), we have*

$$K \geqslant \left(\frac{5M^p n^{2p}}{pm^p \varepsilon} \right)^{\frac{1}{p-1}} \implies \mathbf{dist}(f) \leqslant 1 + \varepsilon. \tag{12}$$

Proof. We shall show that under the assumption on K that appears in (12) we have

$$\forall\, i, j \in \{1, \ldots, n\}, \qquad \left(\frac{d_X(x_i, x_j)}{m^p N} \right)^{\frac{1}{p}} \leqslant \mathsf{W}_p(f(x_i), f(x_j)) \leqslant (1+\varepsilon) \left(\frac{d_X(x_i, x_j)}{m^p N} \right)^{\frac{1}{p}}, \tag{13}$$

where we recall that we defined N to be equal to $|\mathcal{C}| + 1$ for $\mathcal{C}$ given in (9). Clearly (13) implies that $\mathbf{dist}(f) \leqslant 1 + \varepsilon$, as required.

To prove the right hand inequality in (13), suppose that $i, j \in \{1, \ldots, n\}$ satisfy $i < j$ and consider the coupling $\pi \in \Pi(f(x_i), f(x_j))$ given by

$$\pi \stackrel{\text{def}}{=} \frac{1}{N} \left(\sum_{t=1}^{5} \sum_{s=0}^{K-1} \delta_{\left(Q_s^t(i,j), Q_{s+1}^t(i,j)\right)} + \delta_{\left(Q_K^2(i,j), Q_0^3(i,j)\right)} + \sum_{u \in \mathcal{C} \setminus \mathcal{B}_{ij}} \delta_{(u,u)} \right), \tag{14}$$

where for (14) recall (8) and (9). The meaning of (14) is simple: the supports of $f(x_i)$ and $f(x_j)$ equal $\mathcal{C}_i$ and $\mathcal{C}_j$, respectively, where we recall (10). Note that $\mathcal{C}_i \setminus \mathcal{C}_j = \{Q_0^1(i,j)\}$ and $\mathcal{C}_j \setminus \mathcal{C}_i = \{Q_K^5(i,j)\}$, where we recall (2) and (6). So, the coupling π in (14) corresponds to shifting the points in $\mathcal{B}_{ij}$ from the support of $f(x_i)$ to the support of $f(x_j)$ while keeping the points in $\mathcal{C} \setminus \mathcal{B}_{ij}$ unchanged.

Now, recalling the definitions (2), (3), (4), (5) and (6),

$$\begin{aligned}\mathsf{W}_p(f(x_i),f(x_j))^p &\leqslant \iint_{\mathbb{R}^3\times\mathbb{R}^3} \|x-y\|_2^p \mathrm{d}\pi(x,y)\\ &= \frac{1}{N}\sum_{t=1}^{5}\sum_{s=0}^{K-1} \left\|Q_s^t(i,j)-Q_{s+1}^t(i,j)\right\|_2^p + \frac{\|Q_K^2(i,j)-Q_0^3(i,j)\|_2^p}{N}. \end{aligned} \tag{15}$$

Note that if $s \in \{0,\ldots,K-1\}$ then by (2), (3), (5), (6) we have

$$\begin{aligned} &t \in \{1,5\} \implies \left\|Q_s^t(i,j)-Q_{s+1}^t(i,j)\right\|_2 = \frac{M\phi(i,j)}{mK} \leqslant \frac{Mn^2}{mK},\\ &t \in \{2,4\} \implies \left\|Q_s^t(i,j)-Q_{s+1}^t(i,j)\right\|_2 = \frac{M}{mK}. \end{aligned} \tag{16}$$

Also, by (3) and (4) we have

$$\left\|Q_K^2(i,j)-Q_0^3(i,j)\right\|_2 = \frac{d_X(x_i,x_j)^{\frac{1}{p}}}{m}. \tag{17}$$

Finally, by (4) for every $s \in \{0,\ldots,K-1\}$ we have

$$\left\|Q_s^3(i,j)-Q_{s+1}^3(i,j)\right\|_2 = \frac{M(j-i)}{mK} - \frac{d_X(x_i,x_j)^{\frac{1}{p}}}{mK} \leqslant \frac{Mn}{mK}, \tag{18}$$

where we used the fact that $M(j-i)-d_X(x_i,x_j)^{1/p} \geqslant 0$, which holds true by the definition of M in (1) because $j-i \geqslant 1$. A substitution of (16), (17) and (18) into (15) yields the estimate

$$\begin{aligned}\mathsf{W}_p(f(x_i),f(x_j))^p &\leqslant \frac{d_X(x_i,x_j)}{m^pN} + \frac{5K}{N}\left(\frac{Mn^2}{mK}\right)^p\\ &= \left(1+\frac{5M^pn^{2p}}{K^{p-1}d_X(x_i,x_j)}\right)\frac{d_X(x_i,x_j)}{m^pN} \leqslant (1+p\varepsilon)\frac{d_X(x_i,x_j)}{m^pN},\end{aligned}$$

where we used the fact that by the definition of m in (1) we have $m^p \leqslant d_X(x_i,x_j)$, and the lower bound on K that is assumed in (12). This implies the right hand inequality in (13) because $1+p\varepsilon \leqslant (1+\varepsilon)^p$.

Passing now to the proof of the left hand inequality in (13), we need to prove that for every $i,j \in \{1,\ldots,n\}$ with $i<j$ we have

$$\forall\, \pi \in \Pi(f(x_i),f(x_j)), \qquad \iint_{\mathbb{R}^3\times\mathbb{R}^3} \|x-y\|_2^p \mathrm{d}\pi(x,y) \geqslant \frac{d_X(x_i,x_j)}{m^pN}. \tag{19}$$

Note that we still did not use the triangle inequality for d_X, but this will be used in the proof of (19). Also, the reason why we are dealing with $\mathcal{P}_p(\mathbb{R}^3)$ rather than $\mathcal{P}_p(\mathbb{R}^2)$ will become clear in the ensuing argument.

Recall that the measures $f(x_i)$ and $f(x_j)$ are uniformly distributed over sets of the same size, and their supports $\mathcal{C}_i$ and $\mathcal{C}_j$ (respectively) satisfy $\mathcal{C}_i \triangle \mathcal{C}_j = \{(Mi/m)e_1, (Mj/m)e_1\}$.

Since the set of all doubly stochastic matrices is the convex hull of the permutation matrices, and every permutation is a product of disjoint cycles, it follows that it suffices to establish the validity of (19) when $\pi = \frac{1}{N}\sum_{\ell=1}^{L}\delta_{(u_{\ell-1},u_\ell)}$ for some $L \in \{1,\ldots,n\}$ and $u_1,\ldots u_{L-1} \in \mathcal{C}$, where we set $u_0 = (Mi/m)e_1$ and $u_L = (Mj/m)e_1$. With this notation, our goal is to show that

$$\frac{1}{N}\sum_{\ell=1}^{L}\|u_\ell - u_{\ell-1}\|_2^p \geqslant \frac{d_X(x_i,x_j)}{m^p N}. \tag{20}$$

For every $a \in \{1,\ldots,n\}$ define $\mathcal{S}_a \subseteq \mathbb{R}^3$ by $\mathcal{S}_a \stackrel{\text{def}}{=} \mathcal{S}_a^1 \cup \mathcal{S}_a^2$, where

$$\mathcal{S}_a^1 \stackrel{\text{def}}{=} \bigcup_{b=a+1}^{n}\bigcup_{s=0}^{K}\left\{Q_s^1(a,b), Q_s^2(a,b)\right\}, \tag{21}$$

and

$$\mathcal{S}_a^2 \stackrel{\text{def}}{=} \bigcup_{c=1}^{a-1}\bigcup_{s=0}^{K}\left\{Q_s^3(c,a), Q_s^4(c,a), Q_s^5(c,a)\right\}. \tag{22}$$

Thus, recalling (7), the sets $\mathcal{S}_1,\ldots,\mathcal{S}_n$ form a partition of $\mathcal{B}$ and $a \in \mathcal{S}_a$ for every $a \in \{1,\ldots,n\}$. For every $\ell \in \{0,\ldots,L\}$ let $a(\ell)$ be the unique element of $\{1,\ldots,n\}$ for which $u_\ell \in \mathcal{S}_{a(\ell)}$. Then $a(0) = i$ and $a(L) = j$. The left hand side of (20) can be bounded from below as follows

$$\frac{1}{N}\sum_{\ell=1}^{L}\|u_\ell - u_{\ell-1}\|_2^p \geqslant \frac{1}{N}\sum_{\ell=1}^{L}\min_{\substack{u\in\mathcal{S}_{a(\ell-1)}\\ v\in\mathcal{S}_{a(\ell)}}}\|u-v\|_2^p. \tag{23}$$

We shall show that

$$\forall\, a,b \in \{1,\ldots,n\},\ \forall (u,v) \in \mathcal{S}_a \times \mathcal{S}_b, \qquad \|u-v\|_2^p \geqslant \frac{d_X(x_a,x_b)}{m^p}. \tag{24}$$

The validity of (24) implies the required estimate (20) because, by (23), it follows from (24) and the triangle inequality for d_X that

$$\frac{1}{N}\sum_{\ell=1}^{L}\|u_\ell - u_{\ell-1}\|_2^p \geqslant \frac{1}{N}\sum_{\ell=1}^{L}\frac{d_X\left(x_{a(\ell-1)},x_{a(\ell)}\right)}{m^p} \geqslant \frac{d_X(x_i,x_j)}{m^p N}.$$

It remains to justify (24). Suppose that $a,b \in \{1,\ldots,n\}$ satisfy $a < b$ and $(u,v) \in \mathcal{S}_a \times \mathcal{S}_b$. Write $u = Q_s^t(c,d)$ and $v = Q_\sigma^\tau(\gamma,\delta)$ for some $s,\sigma \in \{0,\ldots,K\}$, $t,\tau \in \{1,\ldots,5\}$ and $c,d,\gamma,\delta \in \{1,\ldots,n\}$.

We shall check below, via a direct case analysis, that the absolute value of one of the three coordinates of $u-v$ is either at least M/m or at least $d_X(x_a,x_b)^{1/p}/m$. Since by the definition of M in (1) we have $M \geqslant d_X(x_a,x_b)^{1/p}$, this assertion will imply (24).

Suppose first that $t,\tau \in \{1,2,4,5\}$. By comparing (21), (22) with (2), (3), (4), (5) we see that $\langle u,e_1\rangle = Ma/m$ and $\langle v,e_1\rangle = Mb/m$. Since $b-a \geqslant 1$, this implies that $\langle u-v,e_1\rangle \geqslant M/m$, as required.

If $t = \tau = 3$ then by (22) we necessarily have $d = a$ and $\delta = b$. Hence $(c,d) \neq (\gamma,\delta)$ and therefore $|\phi(c,d) - \phi(\gamma,\delta)| \geqslant 1$, since ϕ is a bijection between $\{1,\ldots,n\}\times\{1,\ldots,n\}$ and $\{1,\ldots,n^2\}$. By (4) we therefore have $|\langle u-v,e_2\rangle| \geqslant M/m$, as required.

It remains to treat the case $t \neq \tau$ and $3 \in \{t, \tau\}$. If $\{t, \tau\} \subseteq \{1, 3, 5\}$ then by contrasting (4) with (2) and (6) we see that the third coordinate of one of the vectors u, v vanishes while the third coordinate of the other vector equals M/m. Therefore $|\langle u - v, e_3\rangle| \geqslant M/m$, as required. The only remaining case is $\{t, \tau\} \subseteq \{2, 3, 4\}$. In this case $|\langle u-v, e_2\rangle| = M|\phi(c, d)-\phi(\gamma, \delta)|/m$, by (4), (3), (5). So, if $(c, d) \neq (\gamma, \delta)$ then $|\phi(c, d) - \phi(\gamma, \delta)| \geqslant 1$, and we are done. We may therefore assume that $c = \gamma$ and $d = \delta$. Observe that by (22) if $\{t, \tau\} = \{3, 4\}$ then $\{d, \delta\} = \{a, b\}$, which contradicts $d = \delta$. So, we also necessarily have $\{t, \tau\} = \{2, 3\}$, in which case, since $a < b$, by (21) and (22) we see that $c = \gamma = a$ and $d = \delta = b$. By interchanging the labels s and σ if necessary, we may assume that $u = Q^2_\sigma(a, b)$ and $v = Q^3_s(a, b)$. By (3) and (4) we therefore have

$$\begin{aligned}\langle v - u, e_1\rangle &= \frac{M(s(b-a)+Ka)}{mK} + \frac{(K-s)d_X(x_a,x_b)^{\frac{1}{p}}}{mK} - \frac{Ma}{m} \\ &= \frac{d_X(x_a,x_b)^{\frac{1}{p}}}{m} + \frac{sM(b-a) - sd_X(x_a,x_b)^{\frac{1}{p}}}{mK} \geqslant \frac{d_X(x_a,x_b)^{\frac{1}{p}}}{m},\end{aligned}$$

where we used the fact that by (1) we have $M \geqslant d_X(x_a, x_b)^{1/p}$, and that $b - a \geqslant 1$. This concludes the verification of the remaining case of (24), and hence the proof of Lemma 7 is complete. ◀

2.1 Implications: Theorems 2 and 4

Theorem 2 follows from the fact that the shortest path metric on an expander graph on N nodes has $\Omega(\log N)$ distortion lower bound for embedding it into L_1 [29]. Note that in the proof above we obtain measures supported on n points where $n \leqslant N^{O(1)} \cdot \left(\frac{5M^pN^{2p}}{pm^p}\right)^{\frac{1}{p-1}}$ for a $1 + \varepsilon = 2$ approximation. Hence, any embedding of W_p on $\mathbb{R}^3$ pointsets of size n into L_1 has a distortion lower bound of $\Omega((\log N)^{1/p}) = \Omega(((p-1)\log n)^{1/p})$.

Similarly, Theorem 4 follows by considering X to be the N-point subset of $(\mathcal{P}_1(\{0,1\}^{O(\log N)}), \mathsf{W}_1)$ introduced in [26, Section 3]. Any sketching algorithm for this metric X requires $\Omega(\frac{\log N}{s})$ approximation for sketching complexity s [5, Theorem 4.1]. Since we can embed X into the square of W_2 with constant distortion, we obtain a $\Omega\left(\left(\frac{(p-1)\log n}{s}\right)^{1/p}\right)$ approximation lower bound for any W_p sketch with sketching complexity s.

3 Future Directions

As discussed in the Introduction, it seems plausible that Theorem 5 and Theorem 6 are not sharp when $p \in (2, \infty)$. Specifically, we conjecture that there exist $D_p \in [1, \infty)$ such that for every finite metric space (X, d_X) we have

$$c_{\mathcal{P}_p(\mathbb{R}^3)}\left(X, \sqrt{d_X}\right) \leqslant D_p. \tag{25}$$

Perhaps (25) even holds true with $D_p = 1$. Since L_2 admits an isometric embedding into L_p (see e.g. [59]), the perceived analogy between Wasserstein p spaces and L_p spaces makes it natural to ask whether or not $(\mathcal{P}_2(\mathbb{R}^3), \mathsf{W}_2)$ admits a bi-Lipschitz embedding into $(\mathcal{P}_p(\mathbb{R}^3), \mathsf{W}_p)$. If the answer to this question were positive then (25) would hold true by virtue of the case $p = 2$ of Theorem 5. We also conjecture that the lower bound of Theorem 6 could be improved when $p > 2$ to state that for arbitrarily large $n \in \mathbb{N}$ there exists an n-point metric space (Y, d_Y) such that for every $\alpha \in (1/2, 1]$,

$$c_{(\mathcal{P}_p(\mathbb{R}^3), \mathsf{W}_p)}(Y, d_Y^\alpha) \gtrsim_p (\log n)^{\alpha - \frac{1}{2}}. \tag{26}$$

It was shown in [36] that L_p has Markov type 2 for every $p \in (2,\infty)$. We therefore ask whether or not $(\mathcal{P}_p(\mathbb{R}^3), \mathsf{W}_p)$ has Markov type 2 for every $p \in (2,\infty)$. A positive answer to this question would imply that the lower bound (26) is indeed achievable. For this purpose it would also suffice to show that for every $p \in (2,\infty)$ and $k \in \mathbb{N}$ we have

$$M_p((\mathcal{P}_p(\mathbb{R}^3), \mathsf{W}_p); 2^k) \lesssim_p 2^{k\left(\frac{1}{2}-\frac{1}{p}\right)}. \tag{27}$$

Proving (27) may be easier than proving that $M_2(\mathcal{P}_p(\mathbb{R}^3), \mathsf{W}_p) < \infty$, since the former involves arguing about the pth powers of Wasserstein p distances while the latter involves arguing about Wasserstein p distances squared. Note that $M_p(L_p; m) \lesssim \sqrt{p} m^{1/2-1/p}$ by [36] (see also [35, Theorem 4.3]), so the L_p-version of (27) is indeed valid.

Another natural direction to pursue concerns with the distortion of embedding finite metric spaces into Wasserstein spaces.

▶ **Question 1.** *Is it true that for $p \in (1,2]$ and $n \in \mathbb{N}$ every n-point metric space (X, d_X) satisfies*

$$c_{\mathcal{P}_p(\mathbb{R}^3)}(X) \lesssim_p (\log n)^{1-\frac{1}{p}}?$$

A positive answer to Question (1) would resolve the *metric cotype dichotomy problem* [31] (see the full version for more details). We believe that Question 1 is an especially intriguing challenge in embedding theory (for a concrete and natural target space) because a positive answer would require an interesting new construction, and a negative answer would require devising a new bi-Lipschitz invariant that would serve as an obstruction for embeddings into Wasserstein spaces.

Focusing for concreteness on the case $p = 2$, Question 1 asks whether $c_{\mathcal{P}_2(\mathbb{R}^3)}(X) \lesssim \sqrt{\log n}$ for every n-point metric space (X, d_X). Note that Theorem 5 implies that (X, d_X) embeds into $\mathcal{P}_2(X)$ with distortion at most the square root of the *aspect ratio* of (X, d_X), i.e.,

$$c_{(\mathcal{P}_2(\mathbb{R}^3), \mathsf{W}_2)}(X, d_X) \leqslant \sqrt{\frac{\operatorname{diam}(X, d_X)}{\min_{\substack{x,y\in X\\ x\neq y}} d_X(x,y)}}, \tag{28}$$

but we are asking here for the largest possible growth rate of the distortion of X into $\mathcal{P}_2(X)$ in terms of the cardinality of X. While for certain embedding results there are standard methods (see e.g. [10, 23, 32]) for replacing the dependence on the aspect ratio of a finite metric space by a dependence on its cardinality, these methods do not seem to apply to our embedding in (28). See the full version for further discussion.

yinyt@nju.edu.cn

Abstract

We prove an $\Omega(d/\log\frac{sw}{nd})$ lower bound for the average-case cell-probe complexity of deterministic or Las Vegas randomized algorithms solving approximate near-neighbor (ANN) problem in d-dimensional Hamming space in the cell-probe model with w-bit cells, using a table of size s. This lower bound matches the highest known worst-case cell-probe lower bounds for any static data structure problems.

This average-case cell-probe lower bound is proved in a general framework which relates the cell-probe complexity of ANN to isoperimetric inequalities in the underlying metric space. A tighter connection between ANN lower bounds and isoperimetric inequalities is established by a stronger richness lemma proved by cell-sampling techniques.

1 Introduction

The nearest neighbor search (NNS) problem is a fundamental problem in Computer Science. In this problem, a database $y = (y_1, y_2, \ldots, y_n)$ of n points from a metric space (X, dist) is preprocessed to a data structure, and at the query time given a query point x from the same metric space, we are asked to find the point y_i in the database which is closest to x according to the metric.

In this paper, we consider a decision and approximate version of NNS, the approximate near-neighbor (ANN) problem, where the algorithm is asked to distinguish between the two cases: (1) there is a point in the databases that is λ-close to the query point for some radius λ, or (2) all points in the database are $\gamma\lambda$-far away from the query point, where $\gamma \geq 1$ is the approximation ratio.

The complexity of nearest neighbor search has been extensively studied in the cell-probe model, a classic model for data structures. In this model, the database is encoded to a table consisting of memory cells. Upon each query, a cell-probing algorithm answers the query by making adaptive cell-probes to the table. The complexity of the problem is measured by the tradeoff between the time cost (in terms of number of cell-probes to answer a query) and the space cost (in terms of sizes of the table and cells). There is a substantial body of work on the cell-probe complexity of NNS for various metric space [6, 7, 5, 11, 8, 14, 3, 2, 16, 17, 12, 20].

It is widely believed that NNS suffers from the "curse of dimensionality" [10]: The problem may become intractable to solve when the dimension of the metric space becomes very high. Consider the most important example, d-dimensional Hamming space $\{0,1\}^d$ with $d \geq C \log n$ for a sufficiently large constant C. The conjecture is that NNS in this metric remains hard to solve when either approximation or randomization is allowed individually.

In a series of pioneering works [6, 5, 11, 14, 3], by a rectangle-based technique of asymmetric communication complexity known as the richness lemma [15], cell-probe lower bounds in form of $\Omega(d/\log s)$, where s stands for the number of cells in the table, were proved for deterministic approximate near-neighbor (due to Liu [14]) and randomized exact near-neighbor (due to Barkol and Rabani [5]). Such lower bound is the highest possible lower bound one can prove in the communication model. This fundamental barrier was overcome by an elegant self-reduction technique introduced in the seminal work of Pătraşcu and Thorup [18], in which the cell-probe lower bounds for deterministic ANN and randomized exact near-neighbor were improved to $\Omega(d/\log \frac{sw}{n})$, where w represents the number of bits in a cell. More recently, in a previous work of us [20], by applying the technique of Pătraşcu and Thorup to the certificates in data structures, the lower bound for deterministic ANN was further improved to $\Omega(d/\log \frac{sw}{nd})$. This last lower bound behaves differently for the polynomial space where $sw = \text{poly}(n)$, near-linear space where $sw = n \cdot \text{polylog}(n)$, and linear space where $sw = O(nd)$. In particular, the bound becomes $\Omega(d)$ when the space cost is strictly linear in the entropy of the database, i.e. when $sw = O(nd)$.

When both randomization and approximation are allowed, the complexity of NNS is substantially reduced. With polynomial-size tables, a $\Theta(\log\log d/\log\log\log d)$ tight bound was proved for randomized approximate NNS in d-dimensional Hamming space [7, 8]. If we only consider the decision version, the randomized ANN can be solved with $O(1)$ cell-probes on a table of polynomial size [8]. For tables of near-linear size, a technique called cell-sampling was introduced by Panigrahy *et al.* [16, 17] to prove $\Omega(\log n/\log \frac{sw}{n})$ lower bounds for randomized ANN. This was later extended to general asymmetric metrics [1].

Among these lower bounds, the randomized ANN lower bounds of Panigrahy *et al.* [16, 17] were proved explicitly for *average-case* cell-probe complexity. The significance of average-case complexity for NNS was discussed in their papers. A recent breakthrough in upper bounds [4] also attributes to solving the problem on a random database. Retrospectively, the randomized exact near-neighbor lower bounds due to the density version of richness lemma [6, 5, 11] also hold for random inputs. All these average-case lower bounds hold for Monte Carlo randomized algorithms with fixed worst-case cell-probe complexity. This leaves open an important case: the average-case cell-probe complexity for the deterministic or Las Vegas randomized algorithms for ANN, where the number of cell-probes may vary for different inputs.

1.1 Our contributions

We study the average-case cell-probe complexity of deterministic or Las Vegas randomized algorithms for the approximate near-neighbor (ANN) problem, where the number of cell-probes to answer a query may vary for different query-database pairs and the average is taken with respect to the distribution over input queries and databases.

For ANN in Hamming space $\{0,1\}^n$, the hard distribution over inputs is very natural: Every point y_i in the database $y = (y_1, y_2, \ldots, y_n)$ is sampled uniformly and independently from the Hamming space $\{0,1\}^d$, and the query point x is also a point sampled uniformly and independently from $\{0,1\}^d$. According to earlier average-case lower bounds [16, 17] and the recent data-dependent LSH algorithm [4], this input distribution seems to capture the

hardest case for nearest neighbor search and is also a central obstacle to overcome for efficient algorithms.

By a simple proof, we show the following lower bound for the average-case cell-probe complexity of ANN in Hamming space with this very natural input distribution.

▶ **Theorem 1.** *For $d \geq 32 \log n$ and $d < n^{o(1)}$, any deterministic or Las Vegas randomized algorithm solving (γ, λ)-approximate near-neighbor problem in d-dimensional Hamming space in the cell-probe model with w-bit cells for $w < n^{o(1)}$, using a table of size $s < 2^d$, must have expected cell-probe complexity $t = \Omega\left(\frac{d}{\gamma^2 \log \frac{sw\gamma^2}{nd}}\right)$, where the expectation is taken over both the uniform and independent input database and query and the random bits of the algorithm.*

This lower bound matches the highest known worst-case cell-probe lower bounds for *any* static data structure problems. Such lower bound was only known for polynomial evaluation [19, 13] and also worst-case deterministic ANN due to our previous work [20].

We also prove an average-case cell-probe lower bound for ANN under ℓ_∞-distance. The lower bound matches the highest known worst-case lower bound for the problem [2].

In fact, we prove these lower bounds in a unified framework that relates the average-case cell-probe complexity of ANN to isoperimetric inequalities regarding an expansion property of the metric space.

Inspired by the notions of metric expansion defined in [17], we define the following notion of expansion for metric space. Let (X, dist) be a metric space. The λ-neighborhood of a point $x \in X$, denoted as $N_\lambda(x)$ is the set of all points in X within distance λ from x. Consider a distribution μ over X. We say the λ-neighborhoods are **weakly independent** under distribution μ, if for any point $x \in X$, the measure of the λ-neighborhood $\mu(N_\lambda(x)) < \frac{\beta}{n}$ for a constant $\beta < 1$. We say the λ-neighborhoods are (Φ, Ψ)**-expanding** under distribution μ, if for any point set $A \subseteq X$ with $\mu(A) \geq \frac{1}{\Phi}$, we have $\mu(N_\lambda(A)) \geq 1 - \frac{1}{\Psi}$, where $N_\lambda(A)$ denotes the set of all points within distance λ from some point in A.

Consider the database $y = (y_1, y_2, \ldots, y_n) \in X^n$ with every point y_i sampled independently from μ, and the query $x \in X$ sampled independently from μ. We denote this input distribution as $\mu \times \mu^n$. We prove the following lower bound.

▶ **Theorem 2.** *For a metric space (X, dist), assume the followings:*

- *the $\gamma\lambda$-neighborhoods are weakly independent under distribution μ;*
- *the λ-neighborhoods are (Φ, Ψ)-expanding under distribution μ.*

Then any deterministic or Las Vegas randomized algorithm solving (γ, λ)-approximate near-neighbor problem in (X, dist) in the cell-probe model with w-bit cells, using a table of size s, must have expected cell-probe complexity

$$t = \Omega\left(\frac{\log \Phi}{\log \frac{sw}{n \log \Psi}}\right) \quad \text{or} \quad t = \Omega\left(\frac{n \log \Psi}{w + \log s}\right)$$

under input distribution $\mu \times \mu^n$.

The key step to prove such a theorem is a stronger version of the richness lemma that we prove in Section 3. The proof of this stronger richness lemma uses an idea called "cell-sampling" introduced by Panigrahy *et al.* [17] and later refined by Larsen [13]. This new richness lemma as well as this connection between the rectangle-based techniques (such as the richness lemma) and information-theory-based techniques (such as cell-sampling) are of interests by themselves.

2 Preliminary

Let (X, dist) be a metric space. Let $\gamma \geq 1$ and $\lambda \geq 0$. The **(γ, λ)-approximate near-neighbor problem** (γ, λ)-ANN_X^n is defined as follows: A database $y = (y_1, y_2, \ldots, y_n) \in X^n$ of n points from X is preprocessed and stored as a data structure. Upon each query $x \in X$, by accessing the data structure we want to distinguish between the following two cases: (1) there is a point y_i in the database such that $\mathrm{dist}(x, z) \leq \lambda$; (2) for all points y_i in the database we have $\mathrm{dist}(x, z) > \gamma\lambda$. For all other cases the answer can be arbitrary.

More abstractly, given a universe X of queries and a universe Y of all databases, a **data structure problem** is a function $f : X \times Y \to Z$ that maps every pair of **query** $x \in X$ and **database** $y \in Y$ to an answer $f(x, y) \in Z$. In our example of (γ, λ)-ANN_X^n, the query universe is the metric space X, the database universe is the set $Y = X^n$ of all tuples of n points from X, and f maps each query $x \in X$ and database $y \in Y$ to an Boolean answer: $f(x, y) = 0$ if there is a λ-near neighbor of x in the database y; $f(x, y) = 1$ if no points in the database y is a $\gamma\lambda$-near neighbor of x; and $f(x, y)$ can be arbitrary if otherwise. Note that due to a technical reason, we usually use 1 to indicate the "no near-neighbor" case.

Given a data structure problem $f : X \times Y \to Z$, a code $T : Y \to \Sigma^s$ with alphabet $\Sigma = \{0, 1\}^w$ encodes every database $y \in Y$ to a **table** T_y of s **cells** with each cell storing a word of w bits. We use $[s] = \{1, 2, \ldots, s\}$ to denote the set of indices of cells. For each $i \in [s]$, we use $T_y[i]$ to denote the content of the i-th cell of table T_y; and for $S \subseteq [s]$, we write $T_y[S] = (T_y[i])_{i \in S}$ for the tuple of the contents of the cells in S. Upon each query $x \in X$, a **cell-probing algorithm** adaptive retrieves the contents of the cells in the table T_y (which is called **cell-probes**) and outputs the answer $f(x, y)$ at last. Being adaptive means that the cell-probing algorithm is actually a decision tree: In each round of cell-probing the address of the cell to probe next is determined by the query x as well as the contents of the cells probed in previous rounds. Together, this pair of code and decision tree is called a **cell-probing scheme**.

For randomized cell-probing schemes, the cell-probing algorithm takes a sequence of random bits as its internal random coin. In this paper we consider only deterministic or Las Vegas randomized cell-probing algorithms, therefore the algorithm is guaranteed to output a correct answer when it terminates.

When a cell-probing scheme is fixed, the size s of the table as well as the length w of each cell are fixed. These two parameters together give the space complexity. And the number of cell-probes may vary for each pair of inputs (x, y) or may be a random variable if the algorithm is randomized. Given a distribution $\mathcal{D}$ over $X \times Y$, the **average-case cell-probe complexity** for the cell-probing scheme is given by the expected number of cell-probes to answer $f(\boldsymbol{x}, \boldsymbol{y})$ for a $(\boldsymbol{x}, \boldsymbol{y})$ sampled from $\mathcal{D}$, where the expectation is taken over both the input distribution $\mathcal{D}$ and the internal random bits of the cell-probing algorithm.

3 A richness lemma for average-case cell-probe complexity

The richness lemma (or the rectangle method) introduced in [15] is a classic tool for proving cell-probe lower bounds. A data structure problem $f : X \times Y \to \{0, 1\}$ is a natural communication problem, and a cell-probing scheme can be interpreted as a communication protocol between the cell-probing algorithm and the table, with cell-probes as communications.

Given a distribution $\mathcal{D}$ over $X \times Y$, a data structure problem $f : X \times Y \to \{0, 1\}$ is **α-dense** under distribution $\mathcal{D}$ if $\mathbb{E}_{\mathcal{D}}[f(\boldsymbol{x}, \boldsymbol{y})] \geq \alpha$. A combinatorial rectangle $A \times B$ for $A \subseteq X$ and $B \subseteq Y$ is a monochromatic 1-rectangle in f if $f(x, y) = 1$ for all $(x, y) \in A \times B$.

The richness lemma states that if a problem f is dense enough (i.e. being rich in 1's) and is easy to solve by communication, then f contains large monochromatic 1-rectangles. Specifically, if an α-dense problem f can be solved by Alice sending a bits and Bob sending b bits in total, then f contains a monochromatic 1-rectangle of size $\alpha \cdot 2^{-O(a)} \times \alpha \cdot 2^{-O(a+b)}$ in the uniform measure. In the cell-probe model with w-bit cells, tables of size s and cell-probe complexity t, it means the monochromatic 1-rectangle is of size $\alpha \cdot 2^{-O(t \log s)} \times \alpha \cdot 2^{-O(t \log s + tw)}$. The cell-probe lower bounds can then be proved by refuting such large 1-rectangles for specific data structure problems f.

We prove the following richness lemma for average-case cell-probe complexity.

▶ **Lemma 3.** *Let μ, ν be distributions over X and Y respectively, and let $f : X \times Y \to \{0,1\}$ be α-dense under the product distribution $\mu \times \nu$. If there is a deterministic or randomized Las Vegas cell-probing scheme solving f on a table of s cells, each cell containing w bits, with expected t cell-probes under input distribution $\mu \times \nu$, then for any $\Delta \in \left[32t/\alpha^2, s\right]$, there is a monochromatic 1-rectangle $A \times B \subseteq X \times Y$ in f such that $\mu(A) \geq \alpha \cdot \left(\frac{\Delta}{s}\right)^{O(t/\alpha^2)}$ and $\nu(B) \geq \alpha \cdot 2^{-O(\Delta \ln \frac{s}{\Delta} + \Delta w)}$.*

Compared to the classic richness lemma, this new lemma has the following advantages:

- It holds for average-case cell-probe complexity.
- It gives stronger result even restricted to worst-case complexity. The newly introduced parameter Δ should not be confused as an overhead caused by the average-case complexity argument, rather, it strengthens the result even for the worst-case lower bounds. When $\Delta = t$ it gives the bound in the classic richness lemma.
- The lemma claims the existence of a *family* of rectangles parameterized by Δ, therefore to prove a cell-probe lower bound it is enough to refute any one rectangle from this family. As we will see, this gives us a power to prove the highest lower bounds (even for the worst case) known to any static data structure problems.

The proof of this lemma uses an argument called "cell-sampling" introduced by Panigrahy *et al.* [16, 17] for approximate nearest neighbor search and later refined by Larsen [13] for polynomial evaluation. Our proof is greatly influenced by Larsen's approach.

The rest of this section is dedicated to the proof of this lemma.

3.1 Proof of the average-case richness lemma (Lemma 3)

By fixing random bits, it is sufficient to consider only deterministic cell-probing algorithms.

The high level idea of the proof is simple. Fix a table T_y. A procedure called the "cell-sampling procedure" chooses the subset Γ of Δ many cells that resolve the maximum amount of positive queries. This associates each database y to a string $\omega = (\Gamma, T_y[\Gamma])$, which we call a **certificate**, where $T_y[\Gamma] = (T_y[i])_{i \in \Gamma}$ represent the contents of the cells in Γ. Due to the nature of the cell-probing algorithm, once the certificate is fixed, the set of queries it can resolve is fixed. We also observe that if the density of 1's in the problem f is $\Omega(1)$, then there is a $\Omega(1)$-fraction of good databases y such that amount of positive queries resolved by the certificate ω constructed by the cell-sampling procedure is at least an $(\frac{\Delta}{s})^{O(t)}$-fraction of all queries. On the other hand, since $\omega \in \binom{[s]}{\Delta} \times \{0,1\}^{\Delta w}$ there are at most $\binom{s}{\Delta} 2^{\Delta w} = 2^{O(\Delta \ln \frac{s}{\Delta} + \Delta w)}$ many certificates ω. Therefore, at least $2^{-O(\Delta \ln \frac{s}{\Delta} + \Delta w)}$-fraction of good databases (which is at least $2^{-O(\Delta \ln \frac{s}{\Delta} + \Delta w)}$-fraction of all databases) are associated with the same ω. Pick this popular certificate ω, the positive queries that ω resolves together with the good databases that ω is associated with form the large monochromatic 1-rectangle.

Now we proceed to the formal parts of the proof. Given a database $y \in Y$, let $X_y^+ = \{x \in X \mid f(x,y) = 1\}$ denote the set of positive queries on y. We use $\mu_y^+ = \mu_{X_y^+}$ to denote the distribution induced by μ on X_y^+.

Let $P_{xy} \subseteq [s]$ denote the set of cells probed by the algorithm to resolve query x on database y. Fix a database $y \in Y$. Let $\Gamma \subseteq [s]$ be a subset of cells. We say a query $x \in X$ is resolved by Γ if x can be resolved by probing only cells in Γ on the table storing database y, i.e. if $P_{xy} \subseteq \Gamma$. We denote by

$$X_y^+(\Gamma) = \{x \in X_y^+ \mid P_{xy} \subseteq \Gamma\}$$

the set of positive queries resolved by Γ on database y. Assume two databases y and y' are *indistinguishable* over Γ: meaning that for the tables T_y and $T_{y'}$ storing y and y' respectively, the cell contents $T_y[i] = T_{y'}[i]$ for all $i \in \Gamma$. Then due to the determinism of the cell-probing algorithm, we have $X_y^+(\Gamma) = X_{y'}^+(\Gamma)$, i.e. Γ resolve the same set of positive queries on both databases.

The cell-sampling procedure

Fix a database $y \in Y$ and any $\Delta \in \left[32t/\alpha^2, s\right]$. Suppose we have a *cell-sampling procedure* which does the following: The procedure deterministically[1] chooses a unique $\Gamma \subseteq [s]$ such that $|\Gamma| = \Delta$ and the measure $\mu(X_y^+(\Gamma))$ of positive queries resolved by Γ is maximized (and if there are more than one such Γ, the procedure chooses an arbitrary one of them). We use Γ_y^* to denote this set of cells chosen by the cell-sampling procedure. We also denote by $X_y^* = X_y^+(\Gamma_y^*)$ the set of positive queries resolved by this chosen set of cells.

On each database y, the cell-sampling procedure chooses for us the most informative set Γ of cells of size $|\Gamma| = \Delta$ that resolve the maximum amount of positive queries. We use $\omega_y = (\Gamma_y^*, T_y[\Gamma_y^*])$ to denote the contents (along with addresses) of the cells chosen by the cell-sampling procedure for database y. We call such ω_y a **certificate** chosen by the cell-sampling procedure for y.

Let y and y' be two databases. A simple observation is that if two databases y and y' have the same certificate $\omega_y = \omega_{y'}$ chosen by the cell-sampling procedure, then the respective sets $X_y^*, X_{y'}^*$ of positive queries resolved on the certificate are going to be the same as well.

▶ **Proposition 4.** *For any databases $y, y' \in Y$, if $\omega_y = \omega_{y'}$ then $X_y^* = X_{y'}^*$.*

Let $\tau(x,y) = |P(x,y)|$ denote the number of cell-probes to resolve query x on database y. By the assumption of the lemma, $\mathbb{E}_{\mu\times\nu}[\tau(\boldsymbol{x},\boldsymbol{y})] \le t$ for the inputs $(\boldsymbol{x},\boldsymbol{y})$ sampled from the product distribution $\mu \times \nu$. We claim that there are many "good" columns (databases) with high density of 1's and low average cell-probe costs.

▶ **Claim 5.** *There is a collection $Y_{\mathsf{good}} \subseteq Y$ of substantial amount of good databases, such that $\nu(Y_{\mathsf{good}}) \ge \frac{\alpha}{4}$ and for every $y \in Y_{\mathsf{good}}$, the followings are true:*

- *the amount of positive queries is large: $\mu(X_y^+) \ge \frac{\alpha}{2}$;*
- *the average cell-probe complexity* among positive queries *is bounded:*

$$\mathbb{E}_{\boldsymbol{x}\sim\mu_y^+}[\tau(\boldsymbol{x},y)] \le \frac{8t}{\alpha^2}.$$

[1] Being deterministic here means that the chosen set Γ_y^* is a function of y.

Proof. The claim is proved by a series of averaging principles. First consider $Y_{\mathsf{dense}} = \{y \in Y \mid \mu(X_y^+) \geq \frac{\alpha}{2}\}$ the set of databases with at least $\frac{\alpha}{2}$-density of positive queries. By the averaging principle, we have $\nu(Y_{\mathsf{dense}}) \geq \alpha/2$. Since $\mathbb{E}[\tau(\boldsymbol{x}, \boldsymbol{y})] \geq \nu(Y_{\mathsf{dense}})\mathbb{E}[\tau(\boldsymbol{x}, \boldsymbol{y}) \mid y \in Y_{\mathsf{dense}}]$, we have $\mathbb{E}_{\mu \times \nu_{\mathsf{dense}}}[\tau(\boldsymbol{x}, \boldsymbol{y})] \leq \frac{2t}{\alpha}$, where $\nu_{\mathsf{dense}} = \nu_{Y_{\mathsf{dense}}}$ is the distribution induced by ν on Y_{dense}. We then construct $Y_{\mathsf{good}} \subseteq Y_{\mathsf{dense}}$ as the set of $y \in Y_{\mathsf{dense}}$ with average cell-probe complexity bounded as $\mathbb{E}_{\boldsymbol{x} \sim \mu}[\tau(\boldsymbol{x}, y)] \leq \frac{4t}{\alpha}$. By Markov inequality $\nu_{\mathsf{dense}}(Y_{\mathsf{good}}) \geq \frac{1}{2}$ and hence $\nu(Y_{\mathsf{good}}) \geq \frac{\alpha}{4}$. Note that $\mathbb{E}_{\boldsymbol{x} \sim \mu}[\tau(\boldsymbol{x}, y)] \geq \mathbb{E}_{\boldsymbol{x} \sim \mu_y^+}[\tau(\boldsymbol{x}, y)]\mu(X_y^+)$. We have $\mathbb{E}_{\boldsymbol{x} \sim \mu_y^+}[\tau(\boldsymbol{x}, y)] \leq \mathbb{E}_{\boldsymbol{x} \sim \mu}[\tau(\boldsymbol{x}, y)]/\mu(X_y^+) \leq \frac{8t}{\alpha^2}$ for all $y \in Y_{\mathsf{good}}$. ◀

For the rest, we consider only these good databases. Fix any $\Delta \in \left[32t/\alpha^2, s\right]$. We claim that for every good database $y \in Y_{\mathsf{good}}$, the cell-sampling procedure always picks a subset $\Gamma_y^* \subseteq [s]$ of Δ many cells, which can resolve a substantial amount of positive queries:

▶ **Claim 6.** *For every $y \in Y_{\mathsf{good}}$, it holds that $\mu(X_y^*) \geq \frac{\alpha}{4}\left(\frac{\Delta}{2s}\right)^{8t/\alpha^2}$.*

Proof. Fix any good database $y \in Y_{\mathsf{good}}$. We only need to prove there exists a $\Gamma \subseteq [s]$ with $|\Gamma| = \Delta$ that resolve positive queries $\mu(X_y^+(\Gamma)) \geq \frac{\alpha}{4}\left(\frac{\Delta}{2s}\right)^{8t/\alpha^2}$. The claims follows immediately.

We construct a hypergraph $\mathcal{H} \subseteq 2^{[s]}$ with vertex set $[s]$ as $\mathcal{H} = \{P_{xy} \mid x \in X_y^+\}$, so that each positive queries $x \in X_y^+$ on database y is associated (many-to-one) to a hyperedge $e \in \mathcal{H}$ such that $e = P_{xy}$ is precisely the set of cells probed by the cell-probing algorithm to resolve query x on database y.

We also define a measure $\tilde{\mu}$ over hyperedges $e \in \mathcal{H}$ as the total measure (in μ_y^+) of the positive queries x associated to e. Formally, for every $e \in \mathcal{H}$,

$$\tilde{\mu}(e) = \sum_{x \in X_y^+ : P_{xy} = e} \mu_y^+(x).$$

Since $\sum_{e \in \mathcal{H}} \tilde{\mu}(e) = \sum_{x \in X_y^+} \mu_y^+(x) = 1$, this $\tilde{\mu}$ is a well-defined probability distribution over hyperedges in $\mathcal{H}$. Moreover, recalling that $\tau(x, y) = |P_{xy}|$, the the average size of hyperedges

$$\mathbb{E}_{\boldsymbol{e} \sim \tilde{\mu}}[|\boldsymbol{e}|] = \mathbb{E}_{\boldsymbol{x} \sim \mu_y^+}[\tau(\boldsymbol{x}, y)] \leq \frac{8t}{\alpha^2}.$$

By the probabilistic method (whose proof is in the full paper [21]), there must exist a $\Gamma \subseteq [s]$ of size $|\Gamma| = \Delta$, such that the sub-hypergraph $\mathcal{H}_\Gamma$ induced by Γ has

$$\tilde{\mu}(\mathcal{H}_\Gamma) \geq \frac{1}{2}\left(\frac{\Delta}{2s}\right)^{8t/\alpha^2}.$$

By our construction of $\mathcal{H}$, the positive queries associated (many-to-one) to the hyperedges in the induced sub-hypergraph $\mathcal{H}_\Gamma = \{P_{xy} \mid x \in X_y^+ \wedge P_{xy} \subseteq \Gamma\}$ are precisely those positive queries in $X_y^+(\Gamma) = \{x \in X_y^+ \mid P_{xy} \subseteq \Gamma\}$. Therefore,

$$\mu_y^+(X_y^+(\Gamma)) = \sum_{x \in X_y^+, P_{xy} \subseteq \Gamma} \mu_y^+(x) = \tilde{\mu}(\mathcal{H}_\Gamma) \geq \frac{1}{2}\left(\frac{\Delta}{2s}\right)^{8t/\alpha^2}.$$

Recall that $\mu(X_y^+) \geq \frac{\alpha}{2}$ for every $y \in Y_{\mathsf{good}}$. And since $X_y^+(\Gamma) \subseteq X_y^+$, we have

$$\mu(X_y^+(\Gamma)) = \mu_y^+(X_y^+(\Gamma))\mu(X_y^+) \geq \frac{\alpha}{4}\left(\frac{\Delta}{2s}\right)^{8t/\alpha^2}.$$

The claim is proved. ◀

Recall that the certificate $\omega_y = (\Gamma_y^*, T_y[\Gamma_y^*])$ is constructed by the cell-sampling procedure for database y. For every possible assignment $\omega \in \binom{[s]}{\Delta} \times \{0,1\}^{\Delta w}$ of certificate, let Y_ω denote the set of good databases $y \in Y_{\mathsf{good}}$ with this certificate $\omega_y = \omega$. Due to the determinism of the cell-sampling procedure, this classifies the Y_{good} into at most $\binom{s}{\Delta}2^{\Delta w}$ many disjointed subclasses Y_ω. Recall that $\nu(Y_{\mathsf{good}}) \geq \frac{\alpha}{4}$. By the averaging principle, the following proposition is natural.

▶ **Proposition 7.** *There exists a certificate $\omega \in \binom{[s]}{\Delta} \times \{0,1\}^{\Delta w}$, denoted as ω^*, such that*

$$\nu(Y_{\omega^*}) \geq \frac{\alpha}{4\binom{s}{\Delta}2^{\Delta w}}.$$

On the other hand, fixed any ω, since all databases $y \in Y_\omega$ have the same ω_y^*, by Proposition 4 they must have the same X_y^*. We can abuse the notation and write $X_\omega = X_y^*$ for all $y \in Y_\omega$.

Now we let $A = X_{\omega^*}$ and $B = Y_{\omega^*}$, where ω^* satisfies Proposition 7. Due to Claim 6 and Proposition 7, we have

$$\mu(A) \geq \frac{\alpha}{4}\left(\frac{\Delta}{2s}\right)^{8t/\alpha^2} = \alpha \cdot \left(\frac{\Delta}{s}\right)^{O(t/\alpha^2)} \quad \text{and} \quad \nu(B) \geq \frac{\alpha}{4\binom{s}{\Delta}2^{\Delta w}} = \alpha \cdot 2^{-O\left(\Delta \ln \frac{s}{\Delta} + \Delta w\right)}.$$
