Contents

43rd International Colloquium on Automata, Languages, and Programming (ICALP 2016).
Editors: Ioannis Chatzigiannakis, Michael Mitzenmacher, Yuval Rabani, and Davide Sangiorgi
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Track B: Logic, Semantics, Automata and Theory of Programming

Track C: Foundations of Networked Computation: Models, Algorithms and Information Management

Preface

ICALP 2016, the 43rd edition of the International Colloquium on Automata, Languages and Programming, was held in Rome, Italy during July 12–15, 2016. ICALP is a series of annual conferences of the European Association for Theoretical Computer Science (EATCS), which first took place in 1972. This year, the ICALP program consisted of the established track A (focusing on algorithms, automata, complexity, and games) and track B (focusing on logic, semantics, and theory of programming), and of the recently introduced track C (focusing on foundations of networking). In response to the call for papers, the Program Committee received 515 submissions, the highest ever: 319 for track A, 121 for track B, and 75 for track C. Out of these, 146 papers were selected for inclusion in the scientific program: 89 papers for Track A, 36 for Track B, and 21 for Track C. The selection was made by the Program Committees based on originality, quality, and relevance to theoretical computer science. The quality of the manuscripts was very high indeed, and many deserving papers could not be selected.

The EATCS sponsored awards for both a best paper and a best student paper for each of the three tracks, selected by the Program Committees. The best paper awards were given to the following papers:

- Track A: Andreas Galanis, Andreas Göbel, Leslie Ann Goldberg, John Lapinskas and David Richerby. "Amplifiers for the Moran Process".
- Track A: Neeraj Kayal, Chandan Saha and Sébastien Tavenas. "An almost Cubic Lower Bound for Depth Three Arithmetic Circuits".
- Track B: Olivier Bournez, Daniel Graça and Amaury Pouly. "Polynomial Time corresponds to Solutions of Polynomial Ordinary Differential Equations of Polynomial Length".

The best student paper awards, for papers that are solely authored by students, were given to the following papers:

- Track A: Samuel Hetterich. "Analysing Survey Propagation Guided Decimation on Random Formulas".
- Track C: Keerti Choudhary. "An Optimal Dual Fault Tolerant Reachability Oracle".

Apart from the contributed talks, ICALP 2016 included invited presentations by Devavrat Shah, Xavier Leroy, Subhash Khot and Marta Z. Kwiatkowska. Abstracts of their talks are included in these proceedings as well. The program of ICALP 2016 also included presentation of the EATCS Award 2016 to Dexter Kozen, the Gödel Prize 2016 to Steve Brookes and Peter O'Hearn, and the Presburger Award 2016 to Mark Braverman.

This volume of the proceedings contains all contributed papers presented at the conference together with the papers and abstracts of the invited speakers.

We wish to thank all authors who submitted extended abstracts for consideration, the Program Committees for their scholarly effort, and all referees who assisted the Program Committees in the evaluation process. We thank the sponsors (Microsoft; Microsoft Research; AICA, Facebook; Department of Informatics, Sapienza University of Rome; and Austrian) for their support. We are also grateful to Tiziana Calamoneri, Irene Finocchi, Nicola Galesi and Daniele Gorla for organizing ICALP 2016 and all the support staff of the Organizing Committee.

Thanks to Andrei Voronkov for writing the conference management system EasyChair, which was used in handling the submissions and the electronic Program Committee meeting,

as well as in assisting in the assembly of the proceedings. Last but not least, we would like to thank Luca Aceto, the president of EATCS, for his generous advice on the organization of the conference and Efi Chita and the secretary office of EATCS for their support in the preparation of the proceedings.

July 2016

Davide Sangiorgi

Organization

Program Committee

Track A

Yuval Rabani	The Hebrew University of Jerusalem, Israel, Chair
Susanne Albers	TU Munchen, Germany
Andris Ambainis	University of Latvia, Latvia
Per Austrin	KTH Royal Institute of Technology, Sweden
Harry Buhrman	Centrum Wiskunde & Informatica, Netherlands
Elisa Celis	EPFL, Switzerland
Nicolò Cesa-Bianchi	University of Milano, Italy
Marek Cygan	University of Warsaw, Poland
Ilias Diakonikolas	University of Southern California, USA
Josep Diaz	University Polytechnica de Catalunya, Spain
Benjamin Doerr	Ecole Polytechnique, France
Dimitris Fotakis	NTUA, Greece
Anna Gal	University of Texas at Austin, USA
Cyril Gavoille	University of Bordeaux, France
Fabrizio Grandoni	IDSIA, Switzerland
Iftach Haitner	Tel Aviv University, Israel
Monika Henzinger	University of Vienna, Austria
Rahul Jain	National University of Singapore, Singapore
Ken-Ichi Kawarabayashi	National Institute of Informatics, Japan
Piotr Krysta	University of Liverpool, UK
François Le Gall	University of Tokyo, Japan
Stefano Leonardi	University of Roma 1, Italy
Jian Li	Tsinghua University, China
Nutan Limaye	Indian Institute of Technology, India
Satya Lokam	Microsoft Research, India
Raghu Meka	UCLA, USA
Lorenzo Orecchia	Boston University, USA
Rotem Oshman	Tel Aviv University, Israel
Giuseppe Persiano	University of Salerno, Italy
Nikhil Srivastava	University of California, Berkeley, USA
Mikkel Thorup	University of Copenhagen, Denmark
Dominique Unruh	University of Tartu, Estonia
Justin Ward	EPFL, Switzerland

Track B

Davide Sangiorgi	Bologna, Italy, Chair
Parosh Aziz Abdulla	University Uppsala
Tomás Brázdil	Brno, Czech Republic
Arnaud Carayol	CNRS, Marne-La-Vallee, France

43rd International Colloquium on Automata, Languages, and Programming (ICALP 2016).
Editors: Ioannis Chatzigiannakis, Michael Mitzenmacher, Yuval Rabani, and Davide Sangiorgi
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Taolue Chen	Oxford, UK
Silvia Crafa	Padova, Italy
Loris D'Antoni	University of Pennsylvania, USA
Pedro D'Argenio	Córdoba, Argentina
Yuxin Deng	Shanghai, China
Maribel Fernández	King's College London, UK
Matthew Hague	University of London, UK
Anna Ingólfsdóttir	Reykjavik, Iceland
Jarkko Kari	University of Turku, Finland
Joost-Pieter Katoen	Aachen University, Germany
Barbara Konig	University Duisburg-Essen, Germany
Bartek Klin	University of Warsaw, Poland
Parthasarathy Madhusudan	University of Illinois, USA
Massimo Merro	Verona, Italy
Stephan Merz	Inria Nancy, France
Madhavan Mukund	Chennai Mathematical Institute, India
Filip Murlak	University of Warsaw, Poland
Aleksandar Nanevski	Madrid Institute of Advanced Studies, Spain
C.-H. Luke Ong	University of Oxford, UK
J. Perez	Groningen, Netherlands
Damien Pous	Lyon, France
Jakob Rehof	Dortmund, Germany
Tachio Terauchi	Jaist, Japan

Track C

Michael Mitzenmacher	Harvard University, USA, Chair
Luca Becchetti	Sapienza University of Rome, Italy
Shuchi Chawla	USA
Krishnendu Chatterjee	IST Austria
Lap Chi Lau	Chinese University Hong Kong/Waterloo
Flavio Chierichetti	Italy
Graham Cormode	University of Warwick, UK
Edith Elkind	UK
Keren-Censor Hillel	Israel
Martin Hoefer	Germany
Valerie King	Canada
Marc LeLarge	INRIA

Compute Choice

Devavrat Shah

MIT, Cambridge, USA
devavrat@mit.edu

Abstract

In this talk, we shall discuss the question of learning distribution over permutations of n choices based on partial observations. This is central to capturing the so called "choice" in a variety of contexts: understanding preferences of consumers over a collection of products based on purchasing and browsing data in the setting of retail and e-commerce, learning public opinion amongst a collection of socio-economic issues based on sparse polling data, and deciding a ranking of teams or players based on outcomes of games. The talk will primarily discuss the relationship between the ability to learn, nature of partial information and number of available observations. Connections to the classical theory of social choice and behavioral psychology, as well as modern literature in Statistics, learning theory and operations research will be discussed.

Formally Verifying a Compiler: What Does It Mean, Exactly?

Xavier Leroy

INRIA, Paris, France
xavier.leroy@inria.fr

Abstract

Compilers, and especially optimizing compilers, are complicated programs. Bugs in compilers happen, and can lead to miscompilation: the production of wrong executable code from a correct source program. Miscompilation is documented in the literature and a concern for high-assurance software, as it endangers the guarantees obtained by source-level formal verification of programs.

Compiler verification is a radical solution to the miscompilation problem: by applying program proof to the compiler itself, we can obtain mathematically strong guarantees that the generated executable code is faithful to the semantics of the source program. The state of the art in this line of research is arguably the CompCert verified compiler. This talk will give an overview of this optimizing C compiler and of its formal verification, conducted with the Coq proof assistant.

A formal verification is as good as the specifications it uses. In other words, verification reduces the problem of trusting a large implementation to that of ensuring that its formal specification enforce the intended correctness properties. In the case of CompCert, the correctness statement that is proved is rather complex, as it involves large operational semantics (for the C language and for the assembly languages of the target architectures) and simulations between these semantics that support both choice refinement and behavior refinement. The talk will review and discuss these elements of the specification, along with some of the accompanying proof principles.

Model Checking and Strategy Synthesis for Stochastic Games: From Theory to Practice*

Marta Z. Kwiatkowska

University of Oxford, Oxford, UK
marta.kwiatkowska@cs.ox.ac.uk

Abstract

Probabilistic model checking is an automatic procedure for establishing if a desired property holds in a probabilistic model, aimed at verifying quantitative probabilistic specifications such as the probability of a critical failure occurring or expected time to termination.

Much progress has been made in recent years in algorithms, tools and applications of probabilistic model checking, as exemplified by the probabilistic model checker PRISM (http://www.prismmodelchecker.org). However, the unstoppable rise of autonomous systems, from robotic assistants to self-driving cars, is placing greater and greater demands on quantitative modelling and verification technologies. To address the challenges of autonomy we need to consider collaborative, competitive and adversarial behaviour, which is naturally modelled using game-theoretic abstractions, enhanced with stochasticity arising from randomisation and uncertainty. This paper gives an overview of quantitative verification and strategy synthesis techniques developed for turn-based stochastic multi-player games, summarising recent advances concerning multi-objective properties and compositional strategy synthesis. The techniques have been implemented in the PRISM-games model checker built as an extension of PRISM.

1 Introduction

Probability is pervasive: it is used to quantify component failures, unreliable communication media and sensor imprecision, in randomised schemes to ensure efficiency of distributed coordination and resource management mechanisms, when dealing with environmental uncertainty, and to model performance and biological systems. Probabilistic model checking [48], also referred to as quantitative probabilistic verification, is an automated technique for verifying quantitative temporal logic properties of probabilistic models, which typically arise as extensions of Markov chains or Markov decision processes, additionally annotated with quantitative information such as time, energy or cost. The properties capture a variety of quantitative correctness, reliability or performance properties, and provide formal guarantees for properties such as "the maximum probability of the airbag failing to deploy within 0.02

seconds is at most 10^{-10}". Probabilistic model checking involves conventional model checking techniques, for example symbolic and automata-theoretic methods, in combination with numerical or statistical analysis. For models that allow nondeterministic choices, it also enables strategy synthesis from temporal logic specifications to automate decision-making in applications such as robotics and security, where it can be employed to generate controllers or counter-attacks. This is similar to motion planning and optimal control, except that temporal logics are used to rigorously specify high-level goals, yielding controllers that are guaranteed to be correct.

Quantitative verification has been the focus of much interest in recent years, resulting in the adoption of tools such as the real-time model checker UPPAAL [3] and the probabilistic model checker PRISM [51] in several application domains. While UPPAAL is based on the theory of timed automata developed in the 1990s [2], the algorithms underlying PRISM have been known since the mid-1980s [69, 31], but have not entered the mainstream until around year 2000, enabled by symbolic techniques [7, 33, 50, 60] implemented in PRISM's first release [49]. Since then several new models and features have been added, including continuous-time Markov chains and probabilistic timed automata. PRISM has been successfully used to verify quantitative properties of a wide variety of real-life systems, automatically discovering design flaws in some of them. These include anonymity protocols [65], randomised distributed algorithms [53], wireless communication protocols [37], security [8], nanotechnology designs [59], probabilistic software [47], self-adaptive systems [15], molecular signalling pathways [45] and computational DNA circuits [57, 32].

Despite much success of probabilistic model checking, the accelerating technological advances in autonomous systems, to mention robotic assistants, self-driving cars and closed-loop medical devices, place greater and greater demands on quantitative verification technologies. Increasingly, we wish to delegate day-to-day tasks to autonomous, wirelessly connected, Internet-enabled and software-controlled devices, whose aim is to achieve certain objectives, such as safe and fuel efficient autonomous driving on a motorway. This incurs the need to consider cooperative, competitive and adversarial behaviour due to conflicting goals, e.g., safety versus fuel efficiency, while also taking into account their (possibly adversarial) interaction with environment, e.g., other cars. We also need to consider communities comprising digital and human agents, able to represent typical interactions and relationships present in scenarios such as semi-autonomous driving scenarios or collaborating with robotic assistants. Game-theoretic approaches, which explicitly represent the moves and countermoves of players and adversaries, are a natural model to represent and analyse such behaviours through the study of winning strategies. Strategy synthesis from quantitative specifications, in particular, can be viewed as constructing a strategy that is winning against all adversarial players. In these data-rich dynamic environments, stochasticity is needed not only to quantify aspects such as failure, safety and sensor uncertainty, but also to facilitate model derivation through inference from data, for example GPS sensor data.

In this paper we summarise recent progress made towards development of algorithmic techniques, tool implementation and real-life applications for turn-based stochastic multi-player games, implemented in an extension of the PRISM model checker called PRISM-games [25, 54]. Game theory is widely studied in areas such as economics and mechanism design, though is less well established as a modelling abstraction for autonomy. In the verification community, the majority of current research activity is focused on the study of algorithmic techniques and their computational complexity. In contrast, we report on ongoing effort towards the "theory to practice" transfer of quantitative verification and synthesis techniques to the challenging application domain of mobile autonomy. The overview

will cover verification and strategy synthesis from quantitative temporal logic specifications, with a focus on zero-sum, complete observation stochastic games, and will include both single- and multi-objective properties, together with a wide range of quantitative objectives (expected total reward, longrun average and ratio objectives) and compositional assume-guarantee strategy synthesis. We will also briefly describe a number of real-life examples from autonomous systems and lessons learnt through applying PRISM-games in these scenarios. We conclude the paper with a discussion of work in progress and future research in this area.

2 Stochastic Multi-Player Games

Stochastic multi-player games (SMGs) [64, 30] are a generalisation of Markov decision processes, where we distinguish between several types of nondeterministic choices, each corresponding to a different player. SMGs thus allow us to reason about strategic decisions of multiple players competing or collaborating to achieve the same objective. Several stochastic game models exist, which include concurrent games [64, 22] and partial-observation games [18, 20]. Here we focus on *turn-based* games as studied in [30], in which a single player controls the choices made in a given state. The presentation is based on [23, 24, 26, 11, 10, 9, 67], where we refer the reader for further details.

Let $\mathcal{D}(X)$ denote the family of all probability distributions over a set X.

▶ **Definition 1** (Stochastic multi-player game (SMG)). A *stochastic multi-player game* (SMG) is a tuple $\mathcal{G} = (\Pi, S, (S_\Pi, S_p), s_{\text{init}}, \Delta, \mathrm{A}, L)$, where Π is a finite set of players; S is a finite nonempty set of states partitioned into player states $S_\Pi = \bigcup S_{i\in\Pi}$ and probabilistic states S_p; $s_{\text{init}} \in S_\Pi$ is an initial state; $\Delta\colon S \times S \to [0,1]$ is a probabilistic transition function such that for all player states $s, t \in S_\Pi$ and probabilistic states $s' \in S_p$ we have $\Delta(s,t) = 0$, $\Delta(s,s') \in \{0,1\}$ and $\sum_{t\in S_\Pi} \Delta(s',t) = 1$; A is a finite nonempty set of actions; and $L : S_p \to \mathrm{A}$ is an action labelling function.

Note that each state of an SMG is controlled by a single player. The game proceeds as follows. It starts in the initial player state s_{init} and, when in a player $i \in \Pi$ state s, the player chooses the next state s' such that $\Delta(s,s') = 1$, and when in a probabilistic state $s \in S_p$ the next state is sampled according to the probability distribution $\Delta(s',\cdot)$.

Stochastic games can be equivalently defined, see e.g. [24], by partitioning the state space into player states S_Π only, and associating with each such state $s \in S_\Pi$ a set of action-distribution pairs (a,μ) called *moves*, where $a = L(s')$ for some $s' \in S_p$ such that $\Delta(s,s') = 1$ and the distribution μ, defined by $\mu(t) = \Delta(s',t)$ for all $t \in S$, gives the probability of moving to a successor state. If the sets of all players but one are empty, then a stochastic turn-based game is a probabilistic automaton in the sense of Segala [63], a mild generalisation of a Markov decision process (MDP).

We unfold an SMG $\mathcal{G}$ into *paths*, namely possibly infinite sequences $\lambda = s_0 s_1 s_2 \ldots$ such that $\Delta(s_i, s_{i+1}) > 0$ for all $i \geq 0$. Note that player states and probabilistic states alternate in a path. For a finite path $\lambda = s_0 s_1 \ldots s_k$ we use $|\lambda| = k+1$ to denote the length of the path and $\text{last}(\lambda) = x_k$ denotes its last element. A *trace* of λ is the sequence of actions that label the probabilistic states within λ. We use $\text{Path}_{\mathcal{G},s}$ to denote the set of all infinite paths originating in a state $s \in S$ and $\text{Path}_{\mathcal{G}} = \bigcup_{s\in S} \text{Path}_{\mathcal{G},s}$. The sets $\text{FPath}_{\mathcal{G},s}, \text{FPath}_{\mathcal{G}}$ of finite paths are defined analogously.

SMGs can be annotated with rewards, which allows us to formulate a variety of quantitative analyses that assign reward values to paths. We consider cumulative, longrun average and ratio rewards. The analysis typically involves ensuring that the game achieves a certain reward bound or optimising these values in the game.

▶ **Definition 2** (Reward structure)**.** Given a game $\mathcal{G} = (\Pi, S, (S_\Pi, S_p), s_{\text{init}}, \Delta, \mathrm{A}, L)$, a *reward structure* for $\mathcal{G}$ is a function $r : S \to \mathbb{R}$.

To resolve the nondeterminism in an SMG, similarly to MDPs we use strategies, except we now have a strategy for each player $i \in \Pi$. We work with an explicit memory representation of strategies due to [14].

▶ **Definition 3** (Strategy)**.** For an SMG $\mathcal{G} = (\Pi, S, (S_\Pi, S_p), s_{\text{init}}, \Delta, \mathrm{A}, L)$, a *strategy* σ_i for player i of $\mathcal{G}$ is a tuple $\sigma_i = (M, \sigma_i^u, \sigma_i^n, \sigma_i^{\mathsf{init}})$, where M is a countable set of memory elements, $\sigma_i^u \colon M \times S \to \mathcal{D}(M)$ is a memory update function, $\sigma_i^n \colon M \times S_i \to \mathcal{D}(S)$ is a next move function such that $\sigma_i^n(m, s)(s') > 0$ only if $\Delta(s, s') > 0$, and $\sigma_i^{\mathsf{init}} \colon S \to \mathcal{D}(M)$ is an initial memory element function. If the memory update function maps to point distributions, i.e. is of type $\sigma_i^u \colon M \times S \to M$, the strategy σ_i is *deterministic memory update*, and otherwise it is *stochastic memory update*. The set of all strategies for player $i \in \Pi$ is denoted by $\Sigma_{\mathcal{G}}^i$. A *strategy profile* $\sigma = \sigma_1, ...\sigma_{|\Pi|}$ comprises a strategy for every player in $\mathcal{G}$.

For a given strategy σ_i of player i, the game proceeds as follows. It starts in a player state with memory sampled according to the initial distribution function σ_i^{init}. Then, in every step of the game, player i updates the current memory element based on the current state of the game using the memory update function σ_i^u. Moreover, if the game is in a player i state, player i chooses the next state of the game using the next move action σ_i^n.

Strategies can be classified according to the use of randomisation or memory. A given strategy σ_i of player i is *deterministic* (pure) if the next move action σ_i^n is of type $\sigma_i^n \colon M \times S_i \to S$, and otherwise it is *randomised*. Similarly, σ_i is *memoryless* if M is a singleton, *finite memory* if M is finite, and *infinite memory* otherwise. An alternative, standard representation of a deterministic player i strategy is as a function from finite paths terminating in a player i state to distributions over the available moves (a, μ) in the given state. Deterministic memoryless strategies can be simply represented as functions $\sigma_i^n \colon S_i \to S$.

Stochastic memory update strategies have the same power as deterministic memory update but are exponentially more succinct than deterministic memory update [66]. Stochastic memory update strategies can be determinised if their memory is not restricted [10, 9]; in fact, a finite stochastic memory update strategy can result in a finite or infinite deterministic update strategy. Memory elements of the determinised strategies are probability distributions over memory elements, which can be interpreted as the belief that the player has about the memory element, knowing only the history and rules to update them, while the actual memory based on sampling is kept secret.

For a given strategy profile $\sigma = \sigma_1, ...\sigma_{|\Pi|}$, the behaviour of an SMG $\mathcal{G}$ is fully probabilistic and we use $\mathrm{Path}_{\mathcal{G},s}^\sigma$, $\mathrm{Path}_{\mathcal{G}}^\sigma$, $\mathrm{FPath}_{\mathcal{G},s}^\sigma$ and $\mathrm{FPath}_{\mathcal{G}}^\sigma$, respectively, to denote paths obtained under the strategy profile σ. Following standard methods [13], we can define a probability measure $\Pr_{\mathcal{G},s}^\sigma$ over the set of infinite paths $\mathrm{Path}_{\mathcal{G},s}^\sigma$. Given a random variable ρ over this probability space, the expected value of ρ is defined as $\mathbb{E}_{\mathcal{G},s}^\sigma(\rho) = \int_{\mathrm{Path}_{\mathcal{G},s}^\sigma} \rho \, \mathrm{d}\Pr_{\mathcal{G},s}^\sigma$.

We will sometimes require restrictions on SMGs. One such restriction to so called *stopping games* was introduced to avoid infinite accumulation of rewards.

▶ **Definition 4** (Stopping game)**.** A state $s_f \in S$ of a stochastic multi-player game $\mathcal{G} = (\Pi, S, (S_\Pi, S_p), s_{\text{init}}, \Delta, \mathrm{A}, L)$ is called terminal if and only if $\Delta(s_f, s_f) = 1$ and $\Delta(s_f, s') = 0$ for all $s' \neq s_f, s' \in S$. A game is called *stopping* if it has at least one terminal state and if it holds that, for every strategy profile $\sigma = \sigma_1, ...\sigma_{|\Pi|}$ and starting from the initial state, with probability 1 the game eventually stops, *i.e.,* a terminal state is reached.

3 Property Specification

We now introduce a notation for specifying temporal and reward-based properties of stochastic games. The presentation employs a variant of the probabilistic temporal logic called RPATL, based on Probabilistic Computation Tree Logic (PCTL) [12] with rewards [41], enhanced with the coalition operator from Alternating Temporal Logic (ATL) [1]. We discuss both single and multi-objective properties. The full logics RPATL and RPATL* are studied in [23, 29].

▶ **Definition 5** (RPATL property). A *single-objective*, respectively *multi-objective*, RPATL property is a formula ϕ, respectively Φ, in the following grammar:

$$\phi ::= \langle\langle C\rangle\rangle \mathtt{P}_{\bowtie p}[\psi] \mid \langle\langle C\rangle\rangle \mathtt{R}^{r}_{\bowtie x}[\rho] \mid \langle\langle C\rangle\rangle \mathtt{R}^{r/c}_{\bowtie x}[\mathtt{S}]$$

$$\Phi ::= \langle\langle C\rangle\rangle \Big(\bigwedge_{i=1}^{n} \mathtt{P}_{\bowtie p_i}[\psi_i]\Big) \mid \langle\langle C\rangle\rangle \Big(\bigwedge_{j=1}^{m} \mathtt{R}^{r_j}_{\bowtie x_j}[\rho_j]\Big) \mid \langle\langle C\rangle\rangle \Big(\bigwedge_{j=1}^{m} \mathtt{R}^{r_j/c_j}_{\bowtie x_j}[\mathtt{S}]\Big)$$

$$\psi ::= \mathtt{F}\, a$$

$$\rho ::= \mathtt{C} \mid \mathtt{S}$$

where $a \in \mathrm{AP}$ is an atomic proposition, $C \subseteq \Pi$ is a coalition of players, $\bowtie \in \{\leq, \geq\}$, $p \in [0,1]$, r, c are reward structures, and $x \in \mathbb{R}$.

The operator $\mathtt{P}_{\bowtie p}[\psi]$ is the PCTL probabilistic operator, where ψ is a CTL path formula. To simplify the presentation we only consider the reachability path formulas $\mathtt{F}\ a$. The operators $\mathtt{R}^{r}_{\bowtie x}[\mathtt{C}]$ and $\mathtt{R}^{r}_{\bowtie x}[\mathtt{S}]$ respectively denote the expected *total reward* and *longrun average reward* (mean payoff), whereas $\mathtt{R}^{r/c}_{\bowtie x}[\mathtt{S}]$ is a *longrun average ratio* reward. We combine these operators with the coalition operator $\langle\langle\cdot\rangle\rangle$ of ATL as follows. Intuitively, $\langle\langle C\rangle\rangle \mathtt{P}_{\bowtie p}[\psi]$ means that the players in coalition C can collectively ensure that $\mathtt{P}_{\bowtie p}[\psi]$ is satisfied, no matter what the players outside the coalition do. For example, in a game with players 1, 2 and 3, the property $\langle\langle\{1,3\}\rangle\rangle \mathtt{P}_{\geq 1}[\mathtt{F\ end}]$ states that players 1 and 3 have a strategy to ensure that the game reaches an `end`-state almost surely, irrespective of what player 2 does. $\langle\langle C\rangle\rangle \mathtt{R}^{r}_{\bowtie x}[\mathtt{C}]$ means that the players in coalition C can collectively ensure that the expected total reward is in relation $\bowtie$ to x. $\langle\langle C\rangle\rangle \mathtt{R}^{r}_{\bowtie x}[\mathtt{S}]$ and $\langle\langle C\rangle\rangle \mathtt{R}^{r/c}_{\bowtie x}[\mathtt{S}]$ are defined similarly, except that they respectively concern expected average rewards cumulated over infinite paths and expected ratio rewards. Both probabilistic and reward properties can be interpreted in *quantitative* fashion, e.g. $\langle\langle C\rangle\rangle \mathtt{P}_{\max=?}[\mathtt{F}\ a]$, meaning the maximum probability of reaching an a-state that players in C can ensure, regardless of the other players, and similarly for the minimum.

We also allow for *multi-objective* properties Φ defined as conjunctions of coalition properties of the same type, with the interpretation that all conjuncts are required to be satisfied simultaneously; see [26, 10] for a more general definition of multi-objective properties as Boolean combinations. Intuitively, the property $\langle\langle C\rangle\rangle(\bigwedge_{i=1}^{n} \mathtt{P}_{\bowtie p_i}[\psi_i])$ means that players in coalition C have a *collective* strategy to ensure that, for all $i = 1, \ldots, n$, we have that $\mathtt{P}_{\bowtie p_i}[\psi_i]$ holds, no matter what the other players do. $\langle\langle C\rangle\rangle(\bigwedge_{j=1}^{m} \mathtt{R}^{r_j}_{\bowtie x_j}[\rho_j])$ is defined similarly, so, for example, $\langle\langle\{4,5\}\rangle\rangle(\mathtt{R}^{\mathtt{profit}}_{\geq 5}[\mathtt{S}] \wedge \mathtt{R}^{\mathtt{fuel}}_{\leq 10}[\mathtt{S}])$ states that players 4 and 5 have a collective strategy to ensure that expected longrun average profit is at least 5 *and* expected longrun average fuel usage is at most 10, no matter what the other players do. Property $\langle\langle C\rangle\rangle(\bigwedge_{j=1}^{m} \mathtt{R}^{r_j/c_j}_{\geq x_j}[\rho_j])$ is a ratio reward, so for example $\langle\langle\{1,2\}\rangle\rangle(\mathtt{R}^{\mathtt{fuel/time}}_{\leq 10}[\mathtt{S}] \wedge \mathtt{R}^{\mathtt{visit/time}}_{\geq 20}[\mathtt{S}])$ states that players 1 and 2 have a collective strategy to ensure that expected longrun fuel consumption per time unit is at most 10 and expected longrun number of visits is at least 20, no matter what the other players do.

In order to define the semantics of the coalition and multi-objective properties, we require the notion of a coalition game based on the analogous notion for ATL.

▶ **Definition 6** (Coalition game). Given an SMG $\mathcal{G} = (\Pi, S, (S_\Pi, S_p), s_{\text{init}}, \Delta, \mathrm{A}, L)$ and coalition of players $C \subseteq \Pi$, the *coalition game* of $\mathcal{G}$ induced by C is the two-player stochastic game $\mathcal{G}_C = (\Pi, S, (S'_1, S'_2), s_{\text{init}}, \Delta, \mathrm{A}, L)$, where $S'_1 = \bigcup_{i \in C} S_i$ and $S'_2 = \bigcup_{i \in \Pi/C} S_i$. The sets of strategies of player 1 and 2 in the coalition game are respectively denoted $\Sigma^1_{\mathcal{G}_C}$ and $\Sigma^2_{\mathcal{G}_C}$.

▶ **Definition 7** (RPATL semantics). Let $\mathcal{G} = (\Pi, S, (S_\Pi, S_p), s_{\text{init}}, \Delta, \mathrm{A}, L)$ be an SMG whose states are labelled with atomic propositions $a \in AP$. We identify a proposition a with the set of states $S_a = \{s \in S \mid s \models a\}$ satisfying a, also denoted a. The satisfaction relation $\models$ is defined as follows, where formulas ϕ and Φ are interpreted over states of the game, whereas temporal formulas ψ and reward functions ρ are interpreted over paths:

$$\begin{aligned}
\mathcal{G}, \lambda \models \mathtt{F}\, a \quad &\iff \quad \exists i \geq 0 : (\lambda_i \lambda_{i+1} \ldots \models a) \\
\mathcal{G}, s \models \langle\!\langle C \rangle\!\rangle \mathtt{P}_{\bowtie p}[\psi] \quad &\Leftrightarrow \quad \exists\, \sigma_1 \in \Sigma^1_{\mathcal{G}_C} \text{ s.t. } \forall\, \sigma_2 \in \Sigma^2_{\mathcal{G}_C}. \\
&\qquad \Pr^{\sigma_1,\sigma_2}_{\mathcal{G}_C,s}\{\lambda \in \mathrm{Path}_{\mathcal{G}_C,s} \mid \mathcal{G}_C, \lambda \models \psi\} \bowtie p \\
\mathcal{G}, s \models \langle\!\langle C \rangle\!\rangle \mathtt{R}^r_{\bowtie x} \rho \quad &\Leftrightarrow \quad \exists\, \sigma_1 \in \Sigma^1_{\mathcal{G}_C} \text{ s.t. } \forall\, \sigma_2 \in \Sigma^2_{\mathcal{G}_C}. \\
&\qquad \mathbb{E}^{\sigma_1,\sigma_2}_{\mathcal{G}_C,s}(rew(r,\rho)) \bowtie x \\
\mathcal{G}, s \models \langle\!\langle C \rangle\!\rangle \mathtt{R}^{r/c}_{\bowtie x} \mathtt{S} \quad &\Leftrightarrow \quad \exists\, \sigma_1 \in \Sigma^1_{\mathcal{G}_C} \text{ s.t. } \forall\, \sigma_2 \in \Sigma^2_{\mathcal{G}_C}. \\

\mathcal{G}, s \models \langle\!\langle C \rangle\!\rangle (\textstyle\bigwedge_{j=1}^m \mathtt{R}^{r_j/c_j}_{\bowtie x_j}[\mathtt{S}]) \quad &\Leftrightarrow \quad \exists\, \sigma_1 \in \Sigma^1_{\mathcal{G}_C} \text{ s.t. } \forall\, \sigma_2 \in \Sigma^2_{\mathcal{G}_C},\, 1 \leq j \leq m. \\
&\qquad \mathbb{E}^{\sigma_1,\sigma_2}_{\mathcal{G}_C,s}(rew(r/c,\mathtt{S})) \bowtie x_j
\end{aligned}$$

where $\mathcal{G}_C{=}(\Pi, S, (S'_1, S'_2), s_{\text{init}}, \Delta, \mathrm{A}, L)$ is the coalition game of $\mathcal{G}$ induced by C, r is a reward structure for $\mathcal{G}c$, c is a nonnegative reward structure for $\mathcal{G}_C$ s.t. the probability of its mean payoff under any strategy profile is at least some constant value, and

$$\begin{aligned}
rew^k(r)(\lambda) &= \textstyle\sum_{i=0}^k r(\lambda_i) \\
rew(r,\mathtt{C})(\lambda) &= \liminf_{k\to\infty} rew^k(r)(\lambda) \\
rew(r,\mathtt{S})(\lambda) &= \liminf_{k\to\infty} \tfrac{rew^k(r)(\lambda)}{k+1} \\
rew(r/c,\mathtt{S})(\lambda) &= \liminf_{k\to\infty} \tfrac{rew^k(r)(\lambda)}{1+rew^k(c)(\lambda)}
\end{aligned}$$

The properties defined above can be employed for verification as well as strategy synthesis for stochastic multi-player games.

4 Single-objective Properties

Model checking and strategy synthesis for single-objective RPATL properties in stochastic games reduces to checking the existence of, respectively finding (if it exists), a winning strategy in two-player stochastic games, and specifically coalition games. Formally, given a stochastic multi-player game $\mathcal{G}$ and a single-objective RPATL property ϕ, e.g., $\phi = \langle\!\langle C \rangle\!\rangle \mathtt{P}_{\bowtie p}[\psi]$ or

$\phi = \langle\langle C \rangle\rangle \mathtt{R}_{\bowtie x}[\rho]$, the model checking problem is to establish whether $s_{\text{init}} \models \phi$ in the coalition game $\mathcal{G}_C$. The strategy synthesis problem, on the other hand, for a stochastic game $\mathcal{G}$ and a property ϕ as above is to construct a strategy σ_1 for player 1 in the coalition game $\mathcal{G}_C$ (if it exists) that is a witness to the satisfaction $s_{\text{init}} \models \phi$.

Similarly to MDPs, deciding the verification and strategy synthesis problems involves computing the *optimal values* of path formulas ψ and reward functions ρ defined for the minimum in the coalition game $\mathcal{G}_C$ as follows:

$$\begin{aligned} \Pr^{\min}_{\mathcal{G}_C,s}(\psi) &= \inf_{\sigma_1 \in \Sigma^1_{\mathcal{G}_C}} \sup_{\sigma_2 \in \Sigma^2_{\mathcal{G}_C}} \Pr^{\sigma_1,\sigma_2}_{\mathcal{G}_C,s}(\psi), \\ \mathbb{E}^{\min}_{\mathcal{G}_C,s}(rew(r,\rho)) &= \inf_{\sigma_1 \in \Sigma^1_{\mathcal{G}_C}} \sup_{\sigma_2 \in \Sigma^2_{\mathcal{G}_C}} \mathbb{E}^{\sigma_1,\sigma_2}_{\mathcal{G}_C,s}(rew(r,\rho)), \end{aligned} \tag{1}$$

where we swap infimum and supremum to compute the maximum value. A strategy $\sigma_1 \in \Sigma^1_{\mathcal{G}_C}$ of player 1 starting from state s is called *optimal* if it achieves the optimal value, *e.g.,* $\sup_{\sigma_2 \in \Sigma^2_{\mathcal{G}_C}} \Pr^{\sigma_1,\sigma_2}_{\mathcal{G}_C,s}(\psi) = \Pr^{\min}_{\mathcal{G}_C,s}(\psi)$. Similarly, the strategy is called ε-*optimal*, for $\varepsilon > 0$, if it achieves a value deviating by at most ε from the optimum, *e.g.,* $\sup_{\sigma_2 \in \Sigma^2_{\mathcal{G}_C}} \Pr^{\sigma_1,\sigma_2}_{\mathcal{G}_C,s}(\psi) \geq \Pr^{\min}_{\mathcal{G}_C,s}(\psi) + \varepsilon$.

The optimal values and strategies can be used to solve the RPATL single-objective model checking problem in the following way. For example, to establish the verification problem for $\mathcal{G}, s$ and property $\langle\langle C \rangle\rangle \mathtt{P}_{\geq p}[\psi]$, it suffices to verify that in the coalition game $\mathcal{G}_C$ player 1 can ensure $\Pr^{\max}_{\mathcal{G}_C,s}(\psi) \geq p$. The remaining single-objective properties can be addressed in a similar fashion. To solve the strategy synthesis problem, we compute an optimal or a suitable ε-optimal strategy for the coalition, that is, for player 1. Since the games are zero-sum, for every single-objective RPATL property ϕ there exists a winning strategy for one of the players.

The problems of computing the optimal values and strategies for the variant of RPATL discussed here are in NP $\cap$ coNP [26, 9]. No polynomial-time algorithm is known, and the method used in practice to compute optimal values is a *value iteration* algorithm [30]. For probabilistic reachability properties, given the quantitative probabilistic reachability property $\langle\langle C \rangle\rangle \mathtt{P}_{\max=?}[\mathtt{F}\, a]$, the value iteration algorithm [30] computes the optimal values for player 1 states $s \in S_1$ in the coalition game as

$$\Pr^{\max}_{\mathcal{G}_C,s}(\psi) = v^*(s) = \lim_{n \to \infty} v^*_n(s), \tag{2}$$

where $v^*_n(s)$ is computed iteratively as indicated in Fig. 1, with the computation terminated when a suitable precision threshold α is reached, i.e. the maximum difference between $v^*_n(s)$ and $v^*_{n+1}(s)$, for $s \in S$, is not more than α. The computation of minimum values proceeds analogously.

It has been shown that for single-objective probabilistic reachability properties both players have optimal strategies and memoryless deterministic strategies suffice, and an optimal player 1 strategy can be constructed from the optimal values in time linear in the size of the game [4]. For more complex RPATL* properties not discussed here, where ψ is an LTL formula, pure finite-memory strategies may be required, see [4, 21, 23] and references therein. LTL properties ψ involve converting the formula to a Rabin or parity automaton, building the product of the automaton with the coalition game, and computing optimal values for a probabilistic reachability property on the product.

For single-objective cumulative reward properties $\rho = \mathtt{C}$, if a game is non-stopping then the set of states that receive infinite total reward can be computed by solving the game with

$$v_n^*(s) = \begin{cases} 1 & \text{if } s \models a \\ 0 & \text{if } s \not\models a \text{ and } n = 0, \\ \max\{v_{n-1}^*(s), v_n'(s)\} & \text{if } n > 0, \end{cases}$$

$$v_n'(s) = \begin{cases} \max_{s' \in S}\{\Delta(s,s') \cdot v_{n-1}^*(s')\} & \text{if } s \not\models a \text{ and } s \in S_1, \\ \min_{s' \in S}\{\Delta(s,s') \cdot v_{n-1}^*(s')\} & \text{if } s \not\models a \text{ and } s \in S_2, \\ \sum_{s' \in S} \Delta(s,s') \cdot v_{n-1}^*(s') & \text{if } s \not\models a \text{ and } s \in S_p. \end{cases}$$

Figure 1 Value iteration algorithm for the quantitative probabilistic reachability property $\langle\langle C \rangle\rangle \mathtt{P}_{\max=?}[\mathtt{F}\, a]$ computed on the coalition game $\mathcal{G}_C$.

respect to a parity condition [66]. After removing these states, value iteration algorithm similar to that for probabilistic reachability can be applied to compute the (bounded) optimal values for the remaining states. An optimal (memoryless deterministic) player 1 strategy for a stopping game can be constructed from the optimal values in time linear in the size of the game [4].

Longrun average reward properties $\rho = \mathtt{S}$ are more involved since average reward disregards all transient behaviour. Nevertheless, memoryless deterministic strategies still suffice for both players to win [43, 58] and an optimal strategy can be constructed by reduction to the discounted reward problem. An alternative, more practical, method, which also extends to expected and almost sure ratio rewards, was formulated for multi-objective properties [10, 9] under certain restriction on the models. The method employs stochastic memory update strategies and reduction to expected energy objectives, and is discussed in the next section.

5 Multi-objective Properties

In this section, we discuss the problem of multi-objective verification and strategy synthesis for stochastic multi-player games, previously also studied for MDPs [38, 42], where the goal is to simultaneously satisfy a certain combination of properties. Recall that we defined a multi-objective RPATL property Φ as a conjunction of properties of the same type, e.g. $\langle\langle C \rangle\rangle(\bigwedge_{i=1}^{n} \mathtt{P}_{\bowtie p_i}[\psi_i])$ or $\langle\langle C \rangle\rangle(\bigwedge_{j=1}^{m} \mathtt{R}^{r_j}_{\bowtie x_j}[\rho_j])$ (note that in [26] any positive Boolean combinations are allowed). As for single-objective properties, for a given coalition C we reduce the analysis of a multi-player stochastic game $\mathcal{G}$ to the coalition game $\mathcal{G}_C$, and thus it suffices to consider two-player stochastic games.

Let Φ_C be a multi-objective property for coalition C involving m probabilistic or reward properties and $\mathcal{G}_C$ be the induced two-player coalition game. Let $\mathbf{r} = (r_1, \ldots, r_m)$ denote the vector of reward structures and $\mathbf{r}(s) = (r_1(s), \ldots, r_m(s))$, for every $s \in S$. Similarly, $\mathbf{p} = (p_1, \ldots, p_m)$ and $\mathbf{x} = (x_1, \ldots, x_m)$ denote the vectors of probability and reward bounds. We say that the vector of bounds $(\mathbf{p}, \mathbf{x})$ for Φ_C, denoted $\Phi_C(\mathbf{p}, \mathbf{x})$, is *achievable* if and only if there exists a winning strategy for player 1 that guarantees all properties in Φ_C with bounds $\mathbf{p}, \mathbf{x}$. The optimal achievable vectors of bounds are called Pareto vectors.

▶ **Definition 8** (Pareto set)**.** Let Φ_C be a multi-objective property for coalition C involving n probabilistic or reward properties. A vector $(\mathbf{p}, \mathbf{x}) \in \mathbb{R}^m$ is called a *Pareto vector* if the property $\Phi_C(\mathbf{p} - \varepsilon, \mathbf{x} - \varepsilon)$ is achievable in $\mathcal{G}_C$ for every $\varepsilon > 0$ and $\Phi_C(\mathbf{p} + \varepsilon, \mathbf{x} + \varepsilon)$ is not achievable for any $\varepsilon > 0$. The set P of all Pareto vectors for Φ_C is called a *Pareto set*.

$$V_n^*(s) = \begin{cases} \{\mathbf{x} \in \mathbb{R}^m_{\geq 0} \mid \mathbf{x} \leq \mathbf{r}(s)\} & \text{if } n = 0, \\ \mathsf{dwc}(\mathbf{r}(s) + \mathsf{conv}(\bigcup_{\Delta(s,s')=1} V_{n-1}^*(s'))) & \text{if } n > 0 \text{ and } s \in S_1, \\ \mathsf{dwc}(\mathbf{r}(s) + \bigcap_{\Delta(s,s')=1} V_{n-1}^*(s')) & \text{if } n > 0 \text{ and } s \in S_2, \\ \mathsf{dwc}(\mathbf{r}(s) + \sum_{\Delta(s,s')>0} \Delta(s,s') \cdot V_{n-1}^*(s')) & \text{if } n > 0 \text{ and } s \in S_p, \end{cases}$$

$$x \cdot X = \{x \cdot \mathbf{x} \mid \mathbf{x} \in X\},$$

$$\mathbf{x} + X = \{\mathbf{x} + \mathbf{x}' \mid \mathbf{x}' \in X\},$$

$$\mathsf{dwc}(X) = \{\mathbf{y} \mid \exists \mathbf{x} \in X : \mathbf{y} \leq \mathbf{x}\},$$

$$\mathsf{conv}(X) = \{\mathbf{y} \mid \exists \mathbf{x}, \mathbf{x}' \in X, \alpha \in [0,1] : \mathbf{y} = \alpha\mathbf{x} + (1-\alpha)\mathbf{x}'\}.$$

Figure 2 Iterative computation of an ε-approximation of the Pareto set for a multi-objective expected total reward property in a two-player stochastic game. Here, $x \in \mathbb{R}_{\geq 0}$ is a real number, $\mathbf{x} \in \mathbb{R}^m_{\geq 0}$ is a vector, $X \subseteq \mathbb{R}^m_{\geq 0}$ is a set, $\leq$ is the componentwise partial order on $\mathbb{R}^m_{\geq 0}$, $\mathsf{dwc}(X)$ is the downward closure of the set X, and $\mathsf{conv}(X)$ is the convex closure of X. Given a two-player stopping game $\mathcal{G}$ with multiple reward structures $\mathbf{r}$ and a multi-objective total reward property $\Phi(\mathbf{x})$, the approximation is computed for every state $s \in S$ in $k = |S| + \lceil |S| \cdot \frac{\ln(\varepsilon \cdot (n \cdot M)^{-1})}{\ln(1-\delta)} \rceil$ iterations, where $M = |S| \cdot \frac{\max_{i, s \in S} r_i(s)}{\delta}$, $\delta = \Delta_{\min}^{|S|}$, and $\Delta_{\min}$ is the smallest positive probability in $\mathcal{G}$.

The problems of multi-objective verification and strategy synthesis are formulated similarly to the single-objective case discussed in the previous section. However, unlike in the single-objective case, optimal strategies might not exist, as shown in [27] for conjunctions. Further, an infinite-memory strategy may be required, even for stopping games with reachability objectives [26]. Existing solutions therefore compute ε-approximations of Pareto sets and the corresponding ε-optimal strategies.

▶ **Definition 9** (Pareto set approximation)**.** For $\varepsilon > 0$, an ε-approximation of the Pareto set is a set of vectors Q such that for every $(\mathbf{q}, \mathbf{y}) \in Q$ there exists a Pareto vector $(\mathbf{p}, \mathbf{x}) \in P$ with $\|(\mathbf{q}, \mathbf{y}) - (\mathbf{p}, \mathbf{x})\| \leq \varepsilon$, and vice versa, for every Pareto vector $(\mathbf{p}, \mathbf{x}) \in P$ there exists a vector $(\mathbf{q}, \mathbf{y}) \in Q$ with $\|(\mathbf{q}, \mathbf{y}) - (\mathbf{p}, \mathbf{x})\| \leq \varepsilon$, where $\|\cdot\|$ is the Manhattan distance defined as the sum of componentwise differences.

The ε-approximation of the Pareto set for a stopping coalition game $\mathcal{G}_C$ and a multi-objective property $\Phi_C(\mathbf{x})$ can be computed using the iteration algorithm in Fig. 2. The algorithm successively computes, for each state $s \in S$, the sets $V_n^*(s)$, where the nth such set is the downward closure of vectors of bounds achievable by the coalition (player 1), from s, in up to n steps. Since player 1 can randomise between its successor states, the set $V_n^*(s)$ for $s \in S_1$ is computed as a downward, convex closure of the union of $V_{n-1}^*(s')$, for all s' such that $\Delta(s, s') = 1$. For $s \in S_2$, the bounds must be achievable for all successor states, and hence we take the intersection. Finally, for probabilistic states $s \in S_p$, we consider the sum weighted by the corresponding probabilistic distribution.

Once an ε-approximation of the Pareto set has been computed, the corresponding ε-optimal player 1 strategy can be constructed [29, 26, 70], where the stochastic memory update, $\sigma_1 = (M, \sigma_1^u, \sigma_1^n, \sigma_1^{\mathsf{init}})$, representation is employed. In the construction, the vertices of approximation sets $V_n^*(s), s \in S$, act as memory elements M and represent the vector of reward bounds that the strategy currently aims to achieve. The distributions in functions σ_1^u and σ_1^{init} are constructed so that the expected value of the next memory element is an ε-approximation of the target reward bounds $\mathbf{x}$. Employing stochastic memory update

representation enables a reduction in the memory required from up to infinite to finite for stopping games [26].

Since probabilistic reachability properties can be reduced to total reward properties, the iterative algorithm in Fig. 2 can be adapted to compute ε-approximations of Pareto sets for any stopping stochastic game with a multi-objective property that involves only probabilistic reachability properties. This can be extended, for stopping games, to probabilistic LTL properties [29] by employing reduction to Rabin automata and building a synchronous product of all the automata and the original SMG $\mathcal{G}$, with a new terminal state which is entered after $\mathcal{G}$ enters any of its terminal states. However, the strategy synthesis problem for multi-objective probabilistic LTL properties in general stochastic games remains open.

Unfortunately, this method cannot be used for multi-objective strategy synthesis for longrun average reward properties. This is because the algorithm in Fig. 2 approximates the Pareto set in a finite number of iterations by combining the achievable values of successive states, but expected average reward disregard all transient behaviour. Nevertheless, for the special case of almost sure average reward properties [10], strategy synthesis for multi-objective properties of this type reduces to synthesis for multi-objective expected energy properties. The corresponding decision problem is in co-NP, as shown in [9] and [19]. In addition, [9] also formulate an algorithm to construct a strategy, if it exists, where stochastically updated memory strategies are generated, which can yield exponentially more compact representations than deterministically updated strategies used in [19]. Further, [9] identify a general class of games for which the synthesis algorithm can be extended to arbitrary Boolean combinations of expected mean-payoff objectives.

Finally, in [10, 9] a method to handle multi-objective ratio reward properties is provided. To solve the strategy synthesis problem for a single-objective ratio reward property in a coalition game, it suffices to solve the problem for an almost sure average reward property, and this can be extended to (conjunctive) multi-objective properties using vectors.

6 Compositional Strategy Synthesis

One difficulty with multi-objective strategy synthesis, in view of high computational complexity [26], is its scalability. To deal with this problem, [11, 70] formulate a *compositional* framework for strategy synthesis, which allows one to derive a strategy for the composed system by synthesising only for the (smaller) individual components. Firstly, recall that probabilistic automata of [63] correspond to coalition games with only one player present. In verification, the nondeterminism that is present in the probabilistic automaton models an adverse, uncontrollable, environment. By applying a coalition strategy to a game to resolve the controllable nondeterminism, we are left with a probabilistic automaton where only uncontrollable nondeterminism for the remaining players remains. This observation allows us to reuse rules for compositional verification of probabilistic automata, such as those in [56], to derive strategy synthesis rules for SMGs.

The compositional framework of [11, 9, 70] is based on a parallel composition operation for stochastic games, which is closely related to that of probabilistic automata [63], except that the identity of the player is preserved through composition. When composed, the component SMGs $\mathcal{G} = (\Pi, S, (S_\Pi, S_p), s_{\text{init}}, \Delta, \mathrm{A}, L)$ and $\mathcal{G}' = (\Pi', S', (S'_\Pi, S'_p), s'_{\text{init}}, \Delta', \mathrm{A}', L')$ synchronise on shared actions $A \cup A'$, yielding the composed game $\mathcal{G}'' = \mathcal{G} \parallel \mathcal{G}'$. Properties of the component SMGs, as well as the composed game, are then defined on traces, that is, sequences of actions that label the probabilistic states in the path, rather than over paths. Under the assumption that the component games are compatible, *i.e.,* all actions of player 1

in each composite game are enabled and fully controlled by player 1, the player 1 strategy $\sigma_1'' = \sigma_1 \parallel \sigma_1'$ for $\mathcal{G}''$ that is a composition of player 1 strategies for component games preserves all properties. More precisely, if strategies σ_1 and σ_1' guarantee (possibly multi-objective) properties Φ, Φ' in component games, then the composed strategy σ_1'' guarantees property Φ'' in $\mathcal{G}''$, where Φ'' is *any* property for the composed game that can be derived from Φ and Φ' using, for example, assume-guarantee rules in [56]. In particular, player 1 of different component games can cooperate to achieve a common goal: if in one component game player 1 guarantees a property Φ_2 under some assumption Φ_1 on the environment, *i.e.*, $\Phi_1 \Rightarrow \Phi_2$, and player 1 in a different component game ensures Φ_1, then the composition satisfies property Φ_2. A broad range of such assume-guarantee contracts can be supported for both probabilistic and reward multi-objective properties.

The method for compositional strategy synthesis [11] first computes an under-approximation Q of the Pareto set for Φ'' based on ε-approximations Q, Q' of Pareto sets for Φ, Φ'. For a chosen achievable vector of bounds $(\mathbf{p}, \mathbf{x})$ for Φ'', player 1 strategies σ_1, σ_i' are synthesised for component games that achieve $\Phi(\mathbf{p}, \mathbf{x})$, $\Phi'(\mathbf{p}', \mathbf{x}')$, where $(\mathbf{p}, \mathbf{x})$, $(\mathbf{p}', \mathbf{x}')$ are the respective bounds obtained by projecting $(\mathbf{p}, \mathbf{x})$ from Q'' to Q, Q'. The composed strategy $\sigma_1'' = \sigma_1 \parallel \sigma_1'$ then achieves $\Phi''(\mathbf{p}'', \mathbf{x}'')$. Note that, since assume-guarantee contracts may involve implication, to be able to apply this framework and, in particular, to take full advantage of assume-guarantee rules, we would need to be able to synthesise strategies for arbitrary Boolean combinations of properties, which is possible [9, 70] under certain restrictions on models and properties.

7 Tool Implementation and Applications

All techniques overviewed in this paper, including single- and multi-objective, as well as compositional, strategy synthesis problems for turn-based stochastic multi-player games, have been implemented in the open-source tool called PRISM-games [25, 54], developed as an extension of the probabilistic model checker PRISM [52]. PRISM-games can be used to model, verify, solve and simulate stochastic multi-player games with complex properties. As a modelling notation, PRISM-games uses an extension of PRISM's modelling language based on reactive modules. The specification notation is based on RPATL [23], and includes support for the coalition operator; single-objective properties, namely probabilistic reachability, total reward properties for stopping games, average reward and ratio properties for a special class of games called controllable multichain games (for details, see [70]), and almost sure average reward and ratio properties; and multi-objective properties, and specifically Boolean combinations of the same type of reward properties, except for the almost sure average and ratio reward properties for which only conjunctions are supported.

Currently, PRISM-games is an explicit state model checker, which extends the Java-based engine of PRISM, and relies on the Parma Polyhedra Library [6] for symbolic manipulation of convex sets during ε-approximate computation of Pareto sets, see [66, 70].

Below we report on a variety of case studies of autonomous systems that employed stochastic game models and were analysed using PRISM-games. For more information, see [66, 70, 68, 67] and the PRISM-games website [61].

Microgrid demand-side management [66]. The example models a decentralised energy management protocol for smart grids that draw energy from a variety of sources. The system consists of a set of households, where each household follows a simple probabilistic protocol to execute a load if the current energy cost is below a pre-agreed limit, and otherwise it only

executes the load with a pre-agreed probability. The energy cost to execute a load for a single time unit is the number of loads currently being executed in the grid. The analysis of the protocol with respect to the expected load per cost unit for a household, formulated as a single-objective total reward property, exposed a protocol weakness. The weakness was then corrected by disincentivising non-cooperative behaviour.

Human-in-the-loop UAV mission planning [40]. This case study concerns autonomous unmanned aerial vehicles (UAV) performing road network surveillance and reacting to inputs from a human operator. The UAV performs most of the piloting functions, such as selecting the waypoints and flying the route. The operator primarily performs sensor tasks at waypoints but may also pick a road for the UAV at waypoints. The optimal UAV piloting strategy depends on mission objectives, *e.g.,* safety, reachability, coverage, and operator characteristics, *i.e.,* workload, proficiency, and fatigue. The main focus of the case study is on studying a multi-objective property to analyse the trade-off between the mission completion time and the number of visits to restricted operating zones, which have been investigated by computing Pareto sets.

Autonomous urban driving [29]. A stochastic game model of an autonomous car is developed, which considers the car driving through an urban environment and reacting to hazards such as pedestrians, obstacles, and traffic jams. The car does not only decide on the reactions to hazards, which are adversarial, but also chooses the roads to take in order to reach a target location. The presence and probability of hazards is based on statistical information for the road. Through multi-objective strategy synthesis, strategies with optimal trade-off between the probability of reaching the target location, the probability of avoiding accidents and the overall quality of roads on the route are identified.

Aircraft power distribution [10]. An aircraft electrical power network is considered, where power is to be routed from generators to buses through controllable switches. The generators can exhibit failures and switches have delays. The system consists of several components, each containing buses and generators, and the components can deliver power to each other. The network is modelled as a composition of stochastic games, one for each component. These components are physically separated for reliability, and hence allow limited interaction and communication. Compositional strategy synthesis is applied to find strategies with good trade-off between uptime of buses and failure rate. By employing stochasticity, we can faithfully encode the reliability specifications in quantitative fashion, thus improving over previous results. The property is modelled as a conjunction of ratio reward properties.

Self-adaptive software architectures [44, 16]. Self-adaptive software automatically adapts its structure and behaviour according to changing requirements and quantitative goals. Several self-adaptive software architectures, such as adaptive industrial middleware used to monitor and manage sensor networks in renewable energy production plants, have been modelled as stochastic games and analysed. Both single- and multi-objective verification of multi-player stochastic games has been applied to to evaluate their resilience properties and synthesise pro-active adaptation policies.

DNS Bandwidth Amplification Attack [35]. The Domain Name System (DNS) is an Internet-wide hierarchical naming system for assigning IP addresses to domain names, and any disruption of the service can lead to serious consequences. A notable threat to DNS,

namely the bandwidth amplification attack, where an attacker attempts to flood a victim DNS server with malicious traffic, is modelled as a stochastic game. Verification and strategy synthesis is used to analyse and generate counter-measures to defend against the attack.

Attack-defence scenarios in RFID goods management system [5]. This case study considers complex attack-defence scenarios, such as an RFID goods management system, translating attack-defence trees to two-player stochastic games. Probabilistic verification is then employed to check security properties of the attack-defence scenarios and to synthesise strategies for attackers or defenders which guarantee or optimise some quantitative property. The properties considered include single-objective properties such as the probability of a successful attack or the incurred cost, as well as their multi-objective combinations.

8 Challenges

Clearly, there has been much progress towards quantitative verification and aspects of quantitative synthesis for autonomy, with a wide variety of relevant case studies serving as proof of concept. However, a number of significant challenges have yet to be overcome. We briefly review a selection of these below.

Partial information. Practical quantitative verification, as exemplified by PRISM, has so far mostly been limited to complete information systems. This restriction is not applicable to many autonomous scenarios, where agents in the system only have partial information. Partial observability [18, 20] raises a number of algorithmic challenges that need to be tackled.

Modelling social interactions. Autonomous systems are increasingly often employed to assist and interact with humans, and operator models have to be taken into account. Though some progress has been made, for example in the context of UAVs [40], models that incorporate cognitive processes and social interactions, such as those based on trust [39, 46], and the corresponding verification techniques are needed.

Model learning and adaptation from data. Quantitative verification has so far mainly focused on modelling system dynamics, but the behaviour of many autonomous and semi-autonomous systems, such as those involving perception, is data-driven [62]. Techniques that integrate model learning from data in order to inform adaptation in real-time and programming with uncertain data within quantitative verification methodologies are needed.

Model synthesis from specifications. Though correct-by-construction synthesis of strategies has been tackled in a range of models, model synthesis from quantitative specifications requires further study. A possible approach is combining template-based and parameter synthesis methods already developed for Markov chains and MDPs [34, 28, 17] and via discretisation for timed and hybrid automata [36, 55], but more effort is required to tackle autonomous systems.

Scalability, efficiency and precision. Existing model checking and strategy synthesis tools for stochastic games are in early stages of development and substantial effort is necessary to ensure their effectiveness in industrial applications. Compositional approaches, symbolic techniques and methodologies based on induction, deduction and machine learning, as well as their judicious combinations, have great potential.

9 Conclusion

As autonomous systems are becoming an integral part of our society, their failure carries potentially unacceptable and life-endangering risks. Rigorous model-based verification technologies incorporated within the design process can improve their safety and reliability and reduce development costs. This paper has briefly summarised quantitative verification and strategy synthesis techniques developed for autonomous systems modelled as turn-based stochastic multi-player games as implemented in the tool PRISM-games and outlined future research challenges in this challenging yet exciting field.

Abstract

We analyze two classic variants of the Traveling Salesman Problem using the toolkit of fine-grained complexity.

Our first set of results is motivated by the Bitonic tsp problem: given a set of n points in the plane, compute a shortest tour consisting of two monotone chains. It is a classic dynamic-programming exercise to solve this problem in $\mathcal{O}(n^2)$ time. While the near-quadratic dependency of similar dynamic programs for Longest Common Subsequence and Discrete Fréchet Distance has recently been proven to be essentially optimal under the Strong Exponential Time Hypothesis, we show that bitonic tours can be found in subquadratic time. More precisely, we present an algorithm that solves bitonic tsp in $\mathcal{O}(n \log^2 n)$ time and its bottleneck version in $\mathcal{O}(n \log^3 n)$ time. In the more general pyramidal tsp problem, the points to be visited are labeled $1, \ldots, n$ and the sequence of labels in the solution is required to have at most one local maximum. Our algorithms for the bitonic (bottleneck) tsp problem also work for the pyramidal tsp problem in the plane.

Our second set of results concerns the popular k-opt heuristic for tsp in the graph setting. More precisely, we study the k-opt decision problem, which asks whether a given tour can be improved by a k-opt move that replaces k edges in the tour by k new edges. A simple algorithm solves k-opt in $\mathcal{O}(n^k)$ time for fixed k. For 2-opt, this is easily seen to be optimal. For $k = 3$ we prove that an algorithm with a runtime of the form $\widetilde{\mathcal{O}}(n^{3-\varepsilon})$ exists if and only if All-Pairs Shortest Paths in weighted digraphs has such an algorithm. For general k-opt, it is known that a runtime of $f(k) \cdot n^{o(k/\log k)}$ would contradict the Exponential Time Hypothesis. The results for $k = 2, 3$ may suggest that the actual time complexity of k-opt is $\Theta(n^k)$. We show that this is not the case, by presenting an algorithm that finds the best k-move in $\mathcal{O}(n^{\lfloor 2k/3 \rfloor + 1})$ time for fixed $k \geq 3$. This implies that 4-opt can be solved in $\mathcal{O}(n^3)$ time, matching the best-known algorithm for 3-opt. Finally, we show how to beat the quadratic barrier for $k = 2$ in two important settings, namely for points in the plane and when we want to solve 2-opt repeatedly.

1 Introduction

1.1 Motivation

We analyze two classic variants of the Traveling Salesman Problem (TSP) by applying the modern toolkit of fine-grained complexity analysis. The first TSP variant can for instance be found in Chapter 15 of the well-known textbook *"Introduction to Algorithms"* by Cormen, Leiserson, Rivest, and Stein [15]. The chapter discusses dynamic programming, and its problem section poses the following classic exercise:

> ***15-3 Bitonic euclidean traveling-salesman problem***
> In the ***euclidean traveling-salesman problem***, we are given a set of n points in the plane, and we wish to find the shortest closed tour that connects all n points. The general problem is NP-complete, and its solution is therefore believed to require more than polynomial time. J. L. Bentley has suggested that we simplify the problem by restricting our attention to ***bitonic tours***, that is, tours that start at the leftmost point, go strictly rightward to the rightmost point, and then go strictly leftward back to the starting point. In this case, a polynomial-time algorithm is possible. Describe an $\mathcal{O}(n^2)$-time algorithm for determining an optimal bitonic tour.

This exercise already showed up in the very first edition of the book in 1991. Since then, thousands of students pondered about it and (hopefully) found the solution. One might wonder whether $\mathcal{O}(n^2)$ runtime is best possible for this problem. As one of our main contributions, we will show that in fact it is not.

The second TSP variant concerns k-OPT, a popular local search heuristic that attempts to improve a suboptimal solution by a k-OPT *move* (or: *k-move* for short), which is an operation that removes k edges from the current tour and reconnects the resulting pieces into a new tour by inserting k new edges. The cases $k = 2$ [16] and $k = 3$ have been studied extensively with respect to various aspects such as experimental performance [7, 24, 27], (smoothed) approximation ratio [13, 26], rate of convergence [13, 17], and algorithm engineering [19, 21, 29, 30]. The decision problem associated with k-OPT asks, given a tour in an edge-weighted graph, whether it is possible to obtain a tour of smaller weight by replacing k edges. There are $\Theta(n^k)$ possibilities to choose k edges that leave the current tour, and for each choice the number of ways to reconnect the resulting pieces back into a tour is constant (for fixed k). As the weight change for each reconnection pattern can be evaluated in $\mathcal{O}(k)$ time, this simple algorithm finds the best k-OPT improvement in time $\mathcal{O}(n^k)$ for each fixed k. The survey chapter [25] by Johnson and McGeoch extensively discusses k-OPT. On page 233 they write:

> To complete our discussion of running times, we need to consider the time per move as well as the number of moves. This includes the time needed to *find* an improving move (or verify that none exists), together with the time needed to *perform* the move. In the worst case, 2-opt and 3-opt require $\Omega(n^2)$ and $\Omega(n^3)$ time respectively to verify local optimality, assuming all possible moves must be considered.

The two lower bounds in the last sentence are stated without further justification. It is clear that finding an improving k-move takes $\Omega(n^k)$ time, if we require that all possible moves must be enumerated *explicitly*. However, one might wonder whether there are other,

faster algorithmic approaches that proceed without enumerating all moves. As one of our main contributions, we will show that such faster approaches do not exist for $k = 3$ (under the All-Pairs Shortest Paths conjecture), but do exist for all $k \geq 4$.

1.2 Our contributions

We investigate whether the long-standing runtimes of $\mathcal{O}(n^2)$ for bitonic tours and $\mathcal{O}(n^k)$ for finding k-opt improvements are optimal. Such optimality investigations usually involve two ingredients: fast algorithms and runtime lower bounds. While proving unconditional lower bounds is far out of reach, in recent years there has been an influx of techniques for establishing lower bounds on the running time of a given problem, based on a hypothesis about the best-possible running time for another problem. Recent results in this direction consider the problems of computing the Longest Common Subsequence [1, 10] of two length-n strings, the Edit Distance [5, 10] from one length-n string to another, or the Discrete Fréchet Distance [9] between two polygonal n-vertex curves in the plane. If one of these problems allows an algorithm with running time $\mathcal{O}(n^{2-\varepsilon})$, then this would yield an algorithm to test the satisfiability of an n-variable CNF formula ϕ in time $(2-\varepsilon)^n \cdot |\phi|^{\mathcal{O}(1)}$. As decades of research have not led to algorithms with such a running time for cnf-sat, this gives evidence that the classic $\mathcal{O}(n^2)$-time algorithms for these problems are optimal up to $n^{o(1)}$ factors.

Pyramidal tours in the plane. Consider a symmetric tsp instance that is defined by an edge-weighted complete graph. For a linear ordering $1, \ldots, n$ of the vertices in the graph, a *pyramidal* tour has the form $(1, i_1, \ldots, i_r, n, j_1, \ldots, j_{n-r-2})$, where $i_1 < i_2 < \ldots < i_r$ and $j_1 > j_2 > \ldots > j_{n-r-2}$. A *bitonic* tour for a Euclidean tsp instance is pyramidal with respect to the left-to-right order on the points in the plane. Bitonic and pyramidal tours play an important role in the combinatorial optimization literature on the tsp; see [6, 11, 20]. They form an exponentially large set of tours over which we can optimize efficiently, and they lead to well-solvable special cases of the tsp. Combined with a procedure for generating suitable permutations of the vertices, heuristic solutions to tsp can be obtained by computing optimal pyramidal tours with respect to the generated orders [12].

We will show that the classic $\mathcal{O}(n^2)$ dynamic program for finding bitonic tours in the Euclidean plane is far from optimal: by an appropriate use of dynamic geometric data structures, the running time can be reduced to $\mathcal{O}(n \log^2 n)$. To the best of our knowledge, this presents the first improvement in finding bitonic tours since the problem was popularized in *Introduction to Algorithms* [15] in 1991. In fact, we prove the stronger result that an optimal *pyramidal* tour among n points in the plane can be computed in $\mathcal{O}(n \log^2 n)$ time with respect to any given linear order on the points. Our techniques extend to the related Bottleneck Pyramidal tsp problem in the plane, where the goal is to find a pyramidal tour among the cities that minimizes the length of the longest edge. We prove that the underlying decision problem (given a linearly ordered set of points and a bottleneck value B, is there a pyramidal tour of the points whose longest edge has length at most B?) can be solved in $\mathcal{O}(n \log n)$ time, while the underlying optimization version (given a linearly ordered set of points, compute a bitonic tour that minimizes the length of the longest edge) can be solved in $\mathcal{O}(n \log^3 n)$ time. For the decision version of the bottleneck problem, we prove a matching $\Omega(n \log n)$ time lower bound in the algebraic computation tree model by a reduction from Set Disjointness with integer inputs [34]; this reduction even applies to the bitonic setting where the points are ordered from left to right.

***k*-OPT in the graph setting.** The complexity of k-OPT has been analyzed using the framework of parameterized complexity theory. Marx [28] proved that deciding whether there is a k-move that improves a given tour is W[1]-hard parameterized by k, giving evidence that there is no algorithm with runtime $f(k) \cdot n^{\mathcal{O}(1)}$. Guo *et al.* [22] refined this result and proved that, under the *Exponential Time Hypothesis* [23], there is no algorithm that determines whether a tour in a weighted complete graph can be improved by a k-move in time $f(k) \cdot n^{o(k/\log k)}$ for any function f. This lower bound shows that the exponent of n in the runtime of any k-OPT algorithm must grow almost linearly with k. The next question that we settle in this paper is: can one do better than $\mathcal{O}(n^k)$ for finding a k-OPT improvement? The answer turns out to depend on the value of k. For 2-OPT, an easy adversarial argument shows that any deterministic algorithm must inspect all the edge weights. This gives a trivial lower bound of $\Omega(n^2)$, matching the upper bound. For larger values of k, the question becomes more interesting.

The 3-OPT DETECTION problem asks whether the weight of a given tour can be reduced by some 3-move. We show that it is unlikely that 3-OPT DETECTION with weights in the range $[-M, \ldots, M]$ allows an algorithm with a *truly subcubic* runtime of $\mathcal{O}(n^{3-\varepsilon} \operatorname{polylog}(M))$ for $\varepsilon > 0$. We prove that the NEGATIVE EDGE-WEIGHTED TRIANGLE problem (given an edge-weighted graph, is there a triangle of negative weight?) reduces to 3-OPT DETECTION by a reduction that takes $\mathcal{O}(n^2)$ time and increases the size of the graph by only a constant factor. As NEGATIVE EDGE-WEIGHTED TRIANGLE is equivalent to ALL-PAIRS SHORTEST PATHS in weighted digraphs (APSP) with respect to having truly subcubic algorithms [33], a truly subcubic algorithm for 3-OPT DETECTION would contradict the APSP conjecture [2, 3] which states that APSP cannot be solved in truly subcubic time. We also give a reduction in the other direction: finding a 3-OPT improvement reduces to finding a negative edge-weighted triangle. Consequently, 3-OPT DETECTION is *equivalent* to NEGATIVE EDGE-WEIGHTED TRIANGLE and APSP with respect to truly subcubic runtimes. This adds yet another classic problem to the growing list of such equivalent problems [2, 33].

As a final result in this direction, we design an algorithm that finds the best k-OPT improvement in weighted n-vertex complete graphs in $\mathcal{O}(n^{\lfloor 2k/3 \rfloor + 1})$ time for each fixed value of k. For $k = 2$ and $k = 3$, this expression simply boils down to the straightforward time complexities of $\mathcal{O}(n^2)$ and $\mathcal{O}(n^3)$ for 2-OPT and 3-OPT respectively. For $k \geq 4$, however, our result yields a substantial improvement over the trivial $\mathcal{O}(n^k)$ time bound. For example, 4-OPT can be solved in $\Theta(n^3)$ time, matching the best-known algorithm for 3-OPT. The algorithm mixes enumeration of partial solutions with a simple dynamic program.

Faster 2-OPT in the repeated setting and in the planar setting. For the 2-OPT problem in graphs, the runtime for finding a single tour improvement cannot be improved below the trivial $\Theta(n^2)$. However, in the context of local search we are often interested in *repeatedly* finding tour improvements. It is therefore natural to consider whether speedups can be obtained when repeatedly finding improving tours on the same TSP instance. We prove that this is indeed the case: after $\mathcal{O}(n^2)$ preprocessing time, one can repeatedly find the best 2-OPT improvement in $\mathcal{O}(n \log n)$ time per iteration.

The quadratic lower bound for 2-OPT applies only in the graph setting. This raises the question: can we solve 2-OPT faster for points in the plane? We show the answer is yes, by giving an algorithm for 2-OPT DETECTION with runtime $\mathcal{O}(n^{8/5+\varepsilon})$ for all $\varepsilon > 0$. Similarly, 3-OPT DETECTION can be solved in expected time $\mathcal{O}(n^{80/31+\varepsilon})$.

2 Faster pyramidal TSP

In this section we show that the pyramidal TSP and the bottleneck pyramidal TSP problem in the plane can be solved in subquadratic time. For simplicity we only show how to compute the value of an optimal solution; the actual tour can be computed in the standard manner.

Let P be the ordered input set of n points with distinct x-coordinates in the plane. Our algorithm will consider the points in P in order, and maintain a collection of partial solutions that are locally optimal. To make this precise, define $P_i := \{p_1, \ldots, p_i\}$ to be the first i points in P. A *partial solution* for P_i, for some $1 \leq i \leq n$, is a pair P', P'' of monotone paths (w.r.t. the order on P) that together visit all the points in P_i and that only share p_1. We call a partial solution for P_i an (i,j)*-partial tour*, for some $1 \leq j < i$, if one of the paths ends at p_i – this is necessarily the case in a partial solution for P_i – and the other path ends at p_j.

Our starting point is the standard dynamic-programming solution. It uses a 2-dimensional table[1] $A[1..n, 1..n]$, where $A[i,j]$, for $1 \leq j < i \leq n$, is defined as the minimum length of an (i,j)-partial tour; for $i \leq j \leq n$ the entries $A[i,j]$ are undefined. We can compute the entries in the table row by row, using the recursive formula

$$A[i+1,j] = \begin{cases} A[i,j] + |p_i p_{i+1}| & \text{if } 1 \leq j < i \\ \min_{1 \leq k < i} \left(A[i,k] + |p_k p_{i+1}|\right) & \text{if } j = i \end{cases} \tag{1}$$

where $A[2,1] = |p_1 p_2|$. Let us briefly verify this recurrence. For $(i+1,j)$-partial tours with $j < i$, the path P' that visits p_{i+1} must also visit p_i: the other path P'' ends at index $j < i$ and the monotonicity requirement ensures P'' cannot visit i and go back to j. So for $j < i$ any $(i+1,j)$-partial tour consists of an (i,j)-partial tour together with the segment $p_i p_{i+1}$. For $(i+1,i)$-partial tours, the predecessor of p_{i+1} cannot be p_i, since a path ends at p_i. Hence an $(i+1,i)$-partial tour consists of an (i,k)-partial tour for some $1 \leq k < i$ together with the segment $p_k p_{i+1}$. The cheapest combination yields the best partial tour.

After computing the last row of A, the minimum length of a pyramidal tour can be found by computing $\min_{1 \leq k < n} \left(A[n,k] + |p_k p_n|\right)$. There are $\mathcal{O}(n^2)$ entries in A of the first type that each take constant time to evaluate. There are $\mathcal{O}(n)$ entries of the second type that need time $\Theta(n)$. Hence the dynamic program can be evaluated in $\mathcal{O}(n^2)$ time.

Our subquadratic algorithm is based on the following two observations. First, any two subsequent rows $A[i, 1..n]$ and $A[i+1, 1..n]$ are quite similar: the entries $A[i+1,j]$, for $j < i$, can all be obtained from $A[i,j]$ by adding the same value, namely $|p_i p_{i+1}|$. Second, the computation of $A[i+1,i]$ can be sped up using appropriate geometric data structures. Thus our algorithm will maintain a data structure that implicitly represents the current row and allows for fast queries and so-called bulk updates (see below).

Recall that $P_i := \{p_1, \ldots, p_i\}$. The point that defines $\min_{1 \leq k < i} \left(A[i,k] + |p_k p_{i+1}|\right)$ is the point $p_k \in P_{i-1}$ closest to the query point $q := p_{i+1}$ if we use the additively weighted distance function

$$\text{dist}(p_k, q) := w_k + |p_k q|, \tag{2}$$

where $w_k := A[i,k]$ is the weight of p_k. Thus we need a data structure for storing a weighted point set that supports the following operations:

[1] Some of our results can also be obtained from an alternative DP with n states. As we need the 2-dimensional approach for Theorem 4, we present all our results in this setting.

- perform a *nearest-neighbor query* with a query point q, which reports the point p_k closest to q according to the additively weighted distance function,
- perform a *bulk update* of the weights, which adds a given value Δ to the weights of all the points currently stored in the data structure;
- *insert* a new point with a given weight into the data structure.

Answering nearest-neighbor queries for the weighted point set P can be done by performing point location in the *additively weighted Voronoi diagram* [18] of P augmented by a point location data structure [32]. This (static) data structure has size $\mathcal{O}(n)$, can be computed in $\mathcal{O}(n \log n)$ time, and allows for $\mathcal{O}(\log n)$-time queries. To allow for insertions we use the logarithmic method [8]. The logarithmic method makes a data structure semi-dynamic by storing $\mathcal{O}(\log n)$ static data structures of increasing size (resulting in an additional log-factor in the query time). The main observation is that we can handle bulk updates by storing a correction term for the weights with each of the static additively weighted Voronoi diagrams. The additively-weighted nearest neighbor structure does not change when adding the same constant to each point weight, which means we do not have to update the Voronoi diagrams when performing bulk updates. This leads to an implementation that supports each operation in $\mathcal{O}(\log^2 n)$ amortized time. The details are deferred to the full version. Using the data structure we obtain the following theorem.

▶ **Theorem 1.** *Let P be an ordered set of n points in the plane. Then we can compute a minimum-length pyramidal tour for P in $\mathcal{O}(n \log^2 n)$ time and using $\mathcal{O}(n)$ storage.*

Proof. We aim to speed up the classic dynamic-programming algorithm using the data structure described above. Instead of computing the entire dynamic programming table A explicitly, we maintain an implicit representation of one row of the table and compute the rows one by one. The i-th row of A has $i-1$ well-defined entries. We define an implicit representation of row i to be an instance of the data structure storing the weighted point set $P_{i-1} = \{p_1, \ldots, p_{i-1}\}$ such that $w(p_j) = A[i,j]$. The first nontrivial row in A is the second row, $A[2, 1..n]$. An implicit representation for that row consists of the point p_1 of weight $A[2,1] = |p_1 p_2|$.

If we have an implicit representation of row i, we can efficiently obtain an implicit representation of row $i+1$, as we describe next. By our choice of implicit representation, the value of $A[i+1, i]$ according to (1) is exactly the distance from p_{i+1} to its closest neighbor in the data structure under the additively weighted distance function. Hence, the value of k that minimizes the lower expression in (1) can be found by a nearest neighbor query with p_{i+1}. We can therefore transform a representation of row i into a representation for row $i+1$ as follows:

1. Query with point p_{i+1} to find the value $A[i+1, i]$ and remember this value.
2. Perform a bulk update to increase the weight of the points $p_1, \ldots, p_{i-1}$ that are already in the structure by $\Delta := |p_i p_{i+1}|$. Recall that for cells j with $1 \leq j < i$ their value in row $i+1$ is obtained from their value in row i by adding $|p_i p_{i+1}|$.
3. Insert point p_i of weight $A[i+1, i]$ into the structure.[2]

It is easy to verify that this yields an implicit representation of row $i+1$. Since a representation of the first nontrivial row can be found in constant time, and each successive row can be computed from the previous using three data structure operations that take $\mathcal{O}(\log^2 n)$

[2] We could also insert p_i with weight $A[i+1, i] - \Delta$. This way we would not have to subtract Δ from the weights of $p_1, \ldots, p_{i-1}$ in Step 2, and the bulk updates are not needed. As they are trivial in our data structure, we prefer the version that keeps the correspondence between weights and $A[i,j]$ values.

amortized time each, it follows that an implicit representation of the final row can be computed in $\mathcal{O}(n \log^2 n)$ time. The minimum cost of a pyramidal tour is $\min_{1 \leq k < n} (A[n,k] + |p_k p_n|)$, which can be found by querying the representation of the final row with point p_n. ◀

Bottleneck pyramidal TSP. Using a similar global approach but different supporting data structures we can also solve the bottleneck version of the problem – here the goal is to minimize the length of the longest edge in the tour – in subquadratic time. For the decision version of the problem we need the following result.

▶ **Theorem 2.** *We can maintain a collection $\mathcal{D}$ of n congruent disks in a data structure such that we can decide in $\mathcal{O}(\log n)$ time if a query point q lies in* Union($\mathcal{D}$). *The data structure uses $\mathcal{O}(n)$ storage and a new disk can be inserted into $\mathcal{D}$ in $\mathcal{O}(\log n)$ amortized time.*

This result is obtained as follows. Assume the disks have radius $\sqrt{2}$ and consider the integer grid. Let $\mathcal{D}(C) \subseteq \mathcal{D}$ be the set of disks whose centers lie inside a grid cell C. To decide if $q \in$ Union($\mathcal{D}$) we need to test if $q \in$ Union($\mathcal{D}(C)$) for $O(1)$ grid cells C that are sufficiently close to q. Now consider a cell C with $\mathcal{D}(C) \neq \emptyset$. Obviously C itself is completely covered by Union($\mathcal{D}(C)$). Let $\ell_{\text{top}}(C)$ be the line containing the top edge of C. Then the part of Union($\mathcal{D}(C)$) above $\ell_{\text{top}}(C)$ – the other parts are handled similarly – is x-monotone. Moreover, we can show that each disk $D_i \in \mathcal{D}(C)$ contributes at most one arc to the boundary of Union($\mathcal{D}(C)$) above $\ell_{\text{top}}(C)$, and the left-to-right order of the contributed arcs is consistent with the left-to-right order of the corresponding disk centers. Using this fact, we can do point locations and insertions in $O(\log n)$ time. Details can be found in the full version.

Combining the global technique of the previous section with Theorem 2 we obtain the following theorem.

▶ **Theorem 3.** *Let P be an ordered set of n points in the plane, and let $B > 0$ be a given parameter. Then we can decide in $\mathcal{O}(n \log n)$ time and using $\mathcal{O}(n)$ storage if P admits a pyramidal tour whose longest edge has length at most B. This problem requires $\Omega(n \log n)$ time in the algebraic computation tree model of computation.*

The algorithm for the decision version does not easily extend to solve the minimization version of the problem. We therefore design a specialized data structure – a tree storing unions of disks and (regular) Voronoi diagrams – that allows us to obtain the following result.

▶ **Theorem 4.** *Let P be an ordered set of n points in the plane. Then we can compute a pyramidal tour whose bottleneck edge has minimum length in $O(n \log^3 n)$ time and using $\mathcal{O}(n \log n)$ storage.*

3 The k-OPT problem in general graphs

In this section we change the perspective from Euclidean problems to the TSP in general graphs. A *tour* of an undirected graph G is a Hamiltonian cycle in the graph. Depending on the context, we may treat a tour as a permutation of the vertex set or as a set of edges. We consider undirected, weighted complete graphs to model symmetric TSP inputs. The weight of a tour is simply the sum of the weights of its edges. Recall that a *k-move* of a tour T is an operation that replaces a set of k edges in T by another set of k edges from G in such a way that the result is a valid tour. In degenerate cases, such an operation may delete and reinsert the same edge. The associated decision problem is defined as follows.

k-opt Detection
Input: A complete undirected graph G along with a (symmetric) distance function $d\colon E(G) \to \mathbb{N}$, an integer k, and a tour $T \subseteq E(G)$.
Question: Is there a k-move that strictly improves the cost of T?

The optimization problem k-opt Optimization is to compute, given a tour in a graph, a k-move that gives the largest cost improvement, or report that no improving k-move exists.

3.1 On truly subcubic algorithms for 3-OPT

We say that an algorithm for n-vertex graphs with integer edge weights in the range $[-M, \ldots, M]$ runs in *truly subcubic time* if its runtime is bounded by $\mathcal{O}(n^{3-\varepsilon}\,\mathrm{polylog}(M))$ for some constant $\varepsilon > 0$. Vassilevska-Williams and Williams [33] introduced a framework for relating the truly subcubic solvability of several classic problems to each other. We use it to show that the existence of a truly subcubic algorithm for 3-opt is unlikely. Their framework uses a notion of subcubic reducibility based on Turing reducibility [33, §IV] that solves one instance of problem A by repeatedly solving inputs of problem B. For our applications, simple reductions suffice that transform one input of problem A into one input of problem B of roughly the same size, in $\mathcal{O}(n^2)$ time.[3] Such reductions preserve the existence of truly subcubic algorithms, so we take this simpler viewpoint. The following problem is the starting point for our reductions.

Negative Edge-Weighted Triangle
Input: An undirected, complete graph G and a weight function $w\colon E(G) \to \mathbb{Z}$.
Question: Does G contain a triangle whose total edge-weight is negative?

Vassilevska-Williams and Williams [33, Thm. 1.1] proved that Negative Edge-Weighted Triangle has a truly subcubic algorithm if and only if the All-Pairs Shortest Paths problem on digraphs with non-negative integral edge weights has a truly subcubic algorithm.

▶ **Lemma 5.** Negative Edge-Weighted Triangle *can be reduced to* 3-opt Detection *in time* $\mathcal{O}(n^2)$*, increasing the size of the graph and the largest weight by a constant factor.*

Proof. Consider an instance (G, w) of Negative Edge-Weighted Triangle, and let $v_1, \ldots, v_n$ be an enumeration of the vertices of G. Let M be the largest absolute value of an edge weight. We introduce an instance of 3-opt Detection that consists of $2n$ vertices $a_1, \ldots, a_n$ and $b_1, \ldots, b_n$, where the starting tour T uses the ordering $a_1, b_1, a_2, b_2, \ldots, a_n, b_n$. The (symmetric) distances $d(\cdot, \cdot)$ between these vertices are defined as follows:

- $d(a_i, b_i) = 0$ for $1 \leq i \leq n$;
- $d(b_n, a_1) = -3M$, and $d(b_i, a_{i+1}) = -3M$ for $1 \leq i \leq n-1$;
- $d(a_i, b_j) = w(\{v_i, v_j\})$ for $1 \leq i < j \leq n$;
- $d(b_i, a_j) = w(\{v_i, v_j\})$ for $1 \leq i < j - 1 \leq n - 1$;
- $d(a_i, a_j) = d(b_i, b_j) = 3M$ for $1 \leq i \neq j \leq n$.

(For convenience, we allow distances to be negative in this construction. One easily moves to non-negative distances by adding the constant $4M$ to all distances.)

▶ **Claim 6.** *The constructed instance of* 3-opt Detection *allows an improving* 3-opt *move, if and only if the graph G contains a triangle of negative edge-weight.*

[3] We assume that simple arithmetic on weights can be done in constant time. The $\mathrm{polylog}(M)$ factors used in the framework originate from repeated executions to perform binary search on weight values.

Proof. ($\Leftarrow$) Assume that the vertices v_i, v_j, v_k span a triangle of negative edge-weight in G for $i < j < k$. We remove the three edges $\{a_i, b_i\}$, $\{a_j, b_j\}$, and $\{a_k, b_k\}$ from tour T, and we reconnect the resulting pieces by the three edges $\{a_i, b_j\}$, $\{a_j, b_k\}$, and $\{a_k, b_i\}$. The three removed edges have total length 0, while the three inserted edges have negative total length.

($\Rightarrow$) Now assume that there exists an improving 3-move for tour T. This improving move cannot remove any edge $\{b_i, a_{i+1}\}$ or $\{b_n, a_1\}$, as these edges have length $-3M$ while all newly inserted edges have non-negative length. Consequently, the three removed edges will be $\{a_i, b_i\}$, $\{a_j, b_j\}$, and $\{a_k, b_k\}$ for some $i < j < k$. As these three edges have total length 0, the total length of the three inserted edges must be strictly negative. The edges $\{a_x, a_y\}$ and $\{b_x, b_y\}$ all have length $3M$, while the edges $\{a_x, b_y\}$ all have length between $-M$ and M. This implies that every inserted edge is either of the type $\{a_x, b_y\}$, or coincides with one of the removed edges. Suppose for the sake of contradiction that one of the inserted edges coincides with a removed edge $\{a_k, b_k\}$, so that we are actually dealing with a 2-move. Then the two inserted edges in the 2-move must be $\{a_i, a_j\}$ and $\{b_i, b_j\}$, so that the new tour is by $6M$ *longer* than the old tour T. This contradiction leaves only two possibilities for the three inserted edges: either $\{a_i, b_j\}$, $\{a_j, b_k\}$, $\{a_k, b_i\}$, or $\{a_i, b_k\}$, $\{a_k, b_j\}$, $\{a_j, b_i\}$ (of which the latter is actually not a valid 3-move). Since the total length of the three inserted edges is strictly negative, the three vertices v_i, v_j, v_k form a triangle of strictly negative weight in G. ◀

The claim shows the correctness of the reduction. It is easy to perform in $\mathcal{O}(n^2)$ time. ◀

There is an analogous reduction in the other direction, which can be found in the full version. Together, these lemmata show the equivalence of finding negative-weight triangles and detecting improving 3-OPT moves. From our reductions and the results of Vassilevska-Williams and Williams [33, Thm. 1.1], we obtain the following theorem.

▶ **Theorem 7.** *There is a truly subcubic algorithm for* 3-OPT DETECTION *if and only if there is such an algorithm for* ALL-PAIRS SHORTEST PATHS *on weighted digraphs.*

3.2 A fast k-OPT algorithm

We will prove that the k-OPT OPTIMIZATION problem can be solved significantly faster than $\Theta(n^k)$ when $k \geq 4$. To this end, we first analyze the structure of k-OPT moves. Consider a k-move for a given tour $T \subseteq E(G)$, and let $e_1, \ldots, e_k$ be the removed edges with $e_i = \{v_{2i-1}, v_{2i}\}$. We assume throughout that these vertices (and edges) are indexed in such a way that T traverses the vertices v_i in order of increasing index. We assume furthermore that the vertices $v_1, \ldots, v_{2n}$ are pairwise distinct; all our arguments also go through without this assumption, but the notation becomes more complicated in the equality case. The k edges that are then inserted into T are denoted $f_1, \ldots, f_k$. The *signature* of this k-move is a permutation π of $\{1, \ldots, 2k\}$, such that v_j and $v_{\pi(j)}$ form the endpoints of one of the edges $f_1, \ldots, f_k$; see Fig. 1.

Note that the removed edges $e_1, \ldots, e_k$ together with the signature π fully determine the k-move (and in particular determine the inserted edges $f_1, \ldots, f_k$).

Note furthermore that not every permutation π yields a feasible signature that corresponds to some k-move: First, in a feasible signature $\pi(i) = j$ always implies $\pi(j) = i$, and we will always have $\pi(i) \neq i$. Secondly, in a feasible signature the edge set that results from T by removing $e_1, \ldots, e_k$ and by inserting $f_1, \ldots, f_k$ must form a single Hamiltonian cycle – it must never form a collection of two or more cycles. It is easy to check whether a given permutation π constitutes a feasible signature, and to enumerate all feasible signatures.

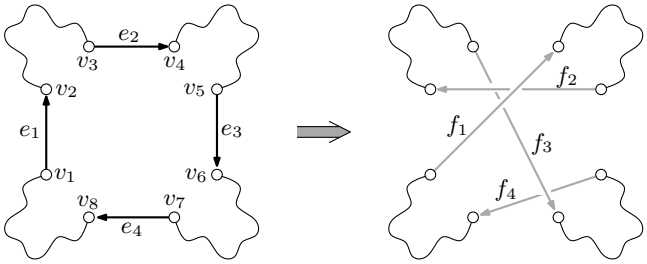

Figure 1 A 4-change with signature 4,5,7,1,2,8,3,6. Edges e_1 and e_4 are non-interfering. As we work on symmetric TSP, the graph and distance function are undirected; the arc directions merely indicate the traversal direction with respect to an arbitrary orientation of the tour.

We say that two of the removed edges e_i and e_j *interfere* with each other in a k-move, if there exists an inserted edge f that connects one of the endpoints of e_i to an endpoint of e_j.

▶ **Lemma 8.** *For any signature π, we can find a subset $E_\pi \subseteq \{e_1, \ldots, e_k\}$ of at least $\lceil k/3 \rceil$ removed edges that are pairwise non-interfering.*

Proof. The $2k$ edges $e_1, \ldots, e_k$ and $f_1, \ldots, f_k$ induce a set of cycles on the vertices $v_1, \ldots, v_{2k}$. If such a cycle contains an even number of removed edges, say 2ℓ, we put every other removed edge along this cycle into E_π; this yields ℓ out of 2ℓ edges for E_π. If the cycle contains only a single removed edge, we put this single edge into E_π; this yields one out of one edge for E_π. If the cycle contains an odd number of removed edges, say $2\ell + 1 \geq 3$, we ignore the first removed edge and then put every other removed edge along the cycle into E_π; this yields ℓ out of $2\ell + 1$ edges for E_π. The weakest contribution to E_π comes from cycles with three removed edges, which yield only one out of three edges for E_π. The claimed bound $\lceil k/3 \rceil$ follows. ◀

▶ **Theorem 9.** *For every fixed $k \geq 3$, the k-opt Optimization problem on an n-vertex graph can be solved in $\mathcal{O}(n^{\lfloor 2k/3 \rfloor + 1})$ time.*

Proof. For computing the best k-move for tour T, it is sufficient to compute for every feasible signature π – for fixed k there are only $\mathcal{O}(1)$ such signatures – the best k-move for tour T with that particular signature. This is done as follows. We first determine a set E_π of pairwise non-interfering edges according to the above lemma. Then we enumerate and handle all possible cases for the locations of the $\lfloor 2k/3 \rfloor$ removed edges not in E_π along T. This yields $\mathcal{O}(n^{\lfloor 2k/3 \rfloor})$ cases to handle, and every such case will be handled in $\mathcal{O}(n)$ time; note that this yields the claimed complexity. In handling a case, the positions of the removed edges not in E_π are frozen, while the edges in E_π have to be embedded into T. The cost of a k-move with signature π decomposes into two parts:

- The first part consists of the total weight of all frozen edges (which is subtracted) and the total weight of inserted edges between frozen edges (which is added).
- The second part consists of the individual contributions of the edges in E_π. For an edge $e \in E_\pi$ and an edge $e' \in T$, the cost of embedding e into e' equals the weight of the two inserted edges adjacent to e minus the weight of e'. As the edges in E_π are pairwise non-interfering, their individual cost contributions do not interact with each other.

As the cost of the first part is fixed in every considered case, our goal is to minimize the total cost of the second part. The frozen edges subdivide the tour T into a number of tour pieces, and we have to find the cheapest way of embedding the corresponding edges from E_π

into such a tour piece. The following paragraph sketches a straightforward dynamic program for finding the optimal embedding for each tour piece in time proportional to the length of the piece. As the length of all tour pieces combined is $\mathcal{O}(n)$, every case is indeed handled in time $\mathcal{O}(n)$.

We are essentially dealing with the following optimization problem. There are r locations $L_1, \ldots, L_r$ (the edges along tour T between two consecutive frozen edges) and s objects $O_1, \ldots, O_s$ (the edges in E_π that should be embedded between the two considered frozen edges). The objects are to be embedded into the locations, so that the location of object O_i always precedes the location of object O_{i+1}. The cost of embedding object O_i into location L_j is denoted $c(i, j)$. For $1 \leq x \leq s$ and $1 \leq y \leq r$, let $V(x, y)$ denote the smallest possible cost incurred by embedding the first x objects $O_1, \ldots, O_x$ into the first y locations $L_1, \ldots, L_y$. As $V(x, y)$ equals the minimum of $V(x, y-1)$ and $V(x-1, y-1) + c(x, y)$, all these values $V(x, y)$ can easily be computed in $\mathcal{O}(rs)$ time. In our situation, r is the length of the considered tour piece and $s \leq k$ is a constant that does not depend on the input; hence the complexity is indeed proportional to the length of the considered tour piece. ◀

4 Faster 2-OPT

In this section we show that it is possible to beat the quadratic barrier for 2-OPT in two important settings, namely when we want to apply 2-moves repeatedly, and in the Euclidean setting in the plane.

Repeated 2-OPT. In the repeated 2-OPT problem, we apply 2-OPT repeatedly (e.g. until no further improvements are possible). One can considerably speed up the 2-OPT computations at each of the iterations, except the first one. The following theorem gives our improvement for the 2-OPT OPTIMIZATION problem, where the goal is to find the best 2-move (rather than any 2-move that improves the tour).

▶ **Theorem 10.** *After $\mathcal{O}(n^2)$ preprocessing and using $\mathcal{O}(n^2)$ storage we can repeatedly solve the* 2-OPT OPTIMIZATION *problem in $\mathcal{O}(n \log n)$ time per iteration.*

The speedup claimed in the theorem relies on a tour representation that supports efficient 2-moves. To apply a 2-move that removes two edges e and e' and replaces them by the appropriate diagonal connections, one effectively has to reverse the part of the tour between e and e', or the part between e' and e. It can therefore take $\Omega(n)$ time to apply a 2-move to a tour represented as a sequence of vertices in an array. Chrobak *et al.* [14] give a speedup by storing the cities on the tour in an ordered balanced binary search tree. Each node in the tree stores a bit indicating whether the tour order is given by an in-order traversal of the subtree rooted there, or by the *reverse* of the in-order traversal. This allows a 2-move to be applied in $\mathcal{O}(\log n)$ time by manipulating reversal bits.

Our approach for repeated 2-OPT OPTIMIZATION is based on a similar data structure that represents tours in balanced search trees. However, instead of having only one tree that stores the current tour, we have n trees; one for each edge $e_1, \ldots, e_n$ in the current tour. A query in the tree $\mathcal{T}(e_i)$ corresponding to edge e_i can be used to determine which edge e_j yields the most profitable 2-move together with e_i. After initializing these n trees, which takes $\mathcal{O}(n^2)$ time, an iteration of 2-OPT OPTIMIZATION can be performed as follows. For each e_i on the current tour, we query in tree $\mathcal{T}(e_i)$ to find the best 2-move that removes e_i and some unknown edge e_j in $\mathcal{O}(\log n)$ time. In this way we find the best overall 2-move which removes, say, edges e_i and e_j. We can update all trees $\mathcal{T}(e_\ell)$ for $\ell \neq i, j$ by deleting e_i

and e_j, and inserting the appropriate replacement edges. Using the reversal bits this can be done in $O(\log n)$ time. Trees $\mathcal{T}(e_i)$ and $\mathcal{T}(e_j)$ are destroyed; we build two new trees from scratch for the two new edges $e_{i'}$ and $e_{j'}$ that enter the tour. This gives $\mathcal{O}(n \log n)$ time per iteration.

It is likely that these techniques can be extended to speed up repeated 3-OPT as well. As the technical details become substantially more cumbersome, we do not pursue this direction.

The planar case. For points in the plane (and under the Euclidean metric) we can speed up 2-OPT computations by using suitable geometric data structures for semi-algebraic range searching; the details had to be omitted from this extended abstract. (Note that we do not consider the repeated version of the problem, but the single-shot version.) A similar approach can be used to speed up 3-OPT in the Euclidean setting in the plane. This leads to the following theorem.

▶ **Theorem 11.** *For any fixed $\varepsilon > 0$,* 2-OPT DETECTION *in the plane can be solved in $\mathcal{O}(n^{8/5+\varepsilon})$ time, and* 3-OPT DETECTION *in the plane can be solved in $\mathcal{O}(n^{80/31+\varepsilon})$ expected time.*

5 Conclusion

Revisiting the worst-case complexity of k-OPT and pyramidal TSP led to a number of new results on these classic problems. Some, such as the equivalence between 3-OPT and APSP with respect to having truly subcubic algorithms, rely on very recent work. Other results, such as the near-linear time algorithm for finding bitonic tours, and the k-OPT algorithm that beats the trivial $\mathcal{O}(n^k)$ upper bound, are obtained using classic techniques. In this respect, it is surprising that these results were not found earlier. These examples show that the availability of new lower bound machinery can inspire new algorithms.

Our findings suggest several directions for further research, both theoretical and applied. An interesting open problem regarding k-OPT DETECTION is whether the problem is fixed-parameter tractable when improving a given tour in an edge-weighted planar graph. This question was also asked by Marx [28] and Guo et al. [22]. Similarly, it is open whether the problem is fixed-parameter tractable when improving a given tour among points in the Euclidean plane. It would be interesting to settle the exact complexity of k-OPT in general weighted graphs. Is $\Theta(n^{\lfloor \frac{2k}{3} \rfloor + 1})$ the optimal running time for k-OPT DETECTION? When all weights lie in the range $[-M, \ldots, M]$, one can detect a negative triangle in an edge-weighted graph in time $\mathcal{O}(M \cdot n^\omega)$ using fast matrix multiplication [4, 31, 35]. By our reduction, this gives an algorithm for 3-OPT DETECTION with weights $[-M, \ldots, M]$ in time $\mathcal{O}(M \cdot n^\omega)$. Can similar speedups be obtained for k-OPT for larger k?

Given the great industrial interest in TSP, establishing the practical applicability of these theoretical results is an important follow-up step. Several of our results rely on data structures that are efficient in theory, but which are currently impractical. These include the additively-weighted Voronoi diagram used for pyramidal tours on points in the plane, and the semi-algebraic range searching data structures used to speed up 2-OPT DETECTION. In contrast, the $\mathcal{O}(n^{\lfloor 2k/3 \rfloor + 1})$ algorithm for finding the best k-move improvement is self-contained, easy to implement, and may have practical potential.

Acknowledgments. We are grateful to Hans L. Bodlaender, Karl Bringmann, and Jesper Nederlof for insightful discussions, an anonymous referee for the observation in Footnote 1, and Christian Knauer for the observation in Footnote 2.

Abstract

We study the following basic problem called Bi-Covering. Given a graph $G(V, E)$, find two (not necessarily disjoint) sets $A \subseteq V$ and $B \subseteq V$ such that $A \cup B = V$ and that every edge e belongs to either the graph induced by A or to the graph induced by B. The goal is to minimize $\max\{|A|, |B|\}$. This is the most simple case of the Channel Allocation problem [Gandhi et. al, Networks, 2006]. A solution that outputs $V, \emptyset$ gives ratio at most 2. We show that under the similar *Strong* Unique Game Conjecture by [Bansal-Khot, FOCS, 2009] there is no $2 - \epsilon$ ratio algorithm for the problem, for any constant $\epsilon > 0$.

Given a bipartite graph, Max-bi-clique is a problem of finding largest $k \times k$ complete bipartite sub graph. For Max-bi-clique problem, a constant factor hardness was known under random 3-SAT hypothesis of Feige [Feige, STOC, 2002] and also under the assumption that NP $\not\subseteq \cap_{\epsilon>0} \mathsf{BPTIME}(2^{n^\epsilon})$ [Khot, SIAM J. on Comp., 2011]. It was an open problem in [Ambühl et. al., SIAM J. on Comp., 2011] to prove inapproximability of Max-bi-clique assuming weaker conjecture. Our result implies similar hardness result assuming the Strong Unique Games Conjecture.

On the algorithmic side, we also give better than 2 approximation for Bi-Covering on numerous special graph classes. In particular, we get 1.876 approximation for Chordal graphs, exact algorithm for Interval Graphs, $1 + o(1)$ for Minor Free Graph, $2 - 4\delta/3$ for graphs with minimum degree δn, $2/(1 + \delta^2/8)$ for δ-vertex expander, $8/5$ for Split Graphs, $2 - (6/5) \cdot 1/d$ for graphs with minimum constant degree d etc. Our algorithmic results are quite non-trivial. In achieving these results, we use various known structural results about the graphs, combined with the techniques that we develop tailored to getting better than 2 approximation.

1 Introduction

We study the Bi-Covering problem - Given a graph $G(V, E)$, find two (not necessarily disjoint) sets $A, B \subseteq V$ such that $A \cup B = V$ and that every edge $e \in E$ belongs to either the graph induced by A or to the graph induced by B. The goal is to minimize $\max\{|A|, |B|\}$.

The problem we study is closely related to the problem of *Channel Allocation* which was studied in [10]. The Channel Allocation Problem can be described as follows: there is a universe of topics, a fixed number of channels and a set of requests where each request is a subset of topics. The task is to send a subset of topics through each channel such that each request is satisfied by set of topics from one of the channel i.e. for every request there must exists at least one channel such that the set of topics present in that channel is a superset of the set of topics from the request. Of course, one can achieve this task trivially by sending all topics through one channel. But, the optimization version of Channel Allocation Problem asks for a way to satisfy all the request by minimizing the maximum number of topics sent through a channel.

Any *connected* undirected graph $G(V, E)$ on n vertices and m edges along with an integer k can be viewed as a special case of channel allocation problem - The set of topics is a set of n vertices, each edge represents a request, where the requested set of topics corresponding to an edge is a pair of its endpoints and the number of channels is k. If we fix the number of channels to $k = 2$ then the optimization problem exactly corresponds to the Bi-Covering problem. Specifically, the optimization problem asks for two subsets A and B of V minimizing $\max\{|A|, |B|\}$ such that $A \cup B = V$ and every edge is totally contained in a graph induced by either A or B.

2 Our Results

Getting 2 approximation for Bi-Covering problem is trivial (by setting A = B = V). We show that Bi-Covering problem is hard to approximate within any factor strictly less than 2 assuming a strong Unique Games Conjecture (UGC) similar to the one in [5] (see Conjecture 12).

▶ **Theorem 1.** *Let $\epsilon > 0$ be any small constant. Assuming a strong Unique Games Conjecture (Conjecture 12), given a graph $G(V, E)$, it is* NP*-hard to distinguish between following two cases:*
1. *G has* Bi-Covering *of size at most $(1/2 + \epsilon)|V|$.*
2. *Any* Bi-Covering *of G has size at least $(1 - \epsilon)|V|$.*
In particular, it is NP-hard (assuming strong UGC) to approximate Bi-Covering *within a factor $2 - \epsilon$ for every $\epsilon > 0$.*

Given this structural hardness result, we get a $\frac{3}{2} - \epsilon$ hardness of Bi-Covering restricted to bipartite graphs by transforming a hard instance from Theorem 1 into a bipartite graph in a natural way (getting a $\frac{3}{2}$-approximation is easy - given a bipartite graph on X and Y with $|X| \geq |Y|$, one can take arbitrary partition X into two equal sized parts X_1 and X_2 and set the Bi-Covering to be $X_1 \cup Y$ and $X_2 \cup Y$).

▶ **Theorem 2.** *Assuming the strong Unique Games Conjecture, for every $\epsilon > 0$,* Bi-Covering *is* NP*-hard to approximate within a factor $\frac{3}{2} - \epsilon$ for bi-partite graphs.*

Our Theorem 1 implies hardness result for the following well known problem:

Max-Bi-Clique problem is as follows:

Input: A bipartite graph $G(X, Y, E)$ with $|X| = |Y| = n$.
Output: Find largest k such that there exists two subsets $A \subseteq X, B \subseteq Y$ of size k and the graph induced on (A, B) is a complete bipartite graph.

Inapproximability of Max-Bi-Clique problem has been studied extensively [1, 6, 8, 13]. Feige[8] showed that using an assumption of average case hardness of 3SAT instance, Max-Bi-Clique cannot be approximated within any constant factor in polynomial time (and hence within n^δ for some $\delta > 0$ using known amplification technique [1, 6]). Feige-Kogan [9] showed that assuming $SAT \notin DTIME(2^{n^{3/4+\epsilon}})$ there is no $2^{(\log n)^\delta}$ approximation for Max-Bi-Clique. They also showed that it is NP-hard to approximate Max-Bi-Clique within any constant factor assuming Max−Clique (finding a maximum sized clique in a graph) does not have a $n/2^{c\sqrt{\log n}}$-approximation. Khot [13] later proved a similar inapproximability result but assuming NP $\nsubseteq \cap_{\epsilon>0}$ BPTIME(2^{n^ϵ}) using a *quasi-random* PCP. It is an important open problem to extend similar hardness results based on weaker complexity assumptions [2]. In particular, it is still not known if UGC implies a constant factor hardness for Max-Bi-Clique. A straightforward corollary from Theorem 1 (see 4.2.2) implies that we get similar hardness results for Max-Bi-Clique based on Conjecture 12.

▶ **Corollary 3.** *Assuming strong Unique Games Conjecture, it is* NP*-hard to approximate* Max-Bi-Clique *within any constant factor.*

As mentioned above, the hardness factor can be boosted to n^δ for some $\delta > 0$ using known techniques. (such as described in [1, 6])

UGC and strong UGC

Unique games conjecture so far helped in understanding the tight inapproximability factors of many problems including, but not limited to, Vertex Cover [14], optimal algorithm for every Max-CSP[16], Ordering CSPs[11], characterizing strong approximation resistance of CSPs[15] etc. The inherent difficulty in showing hardness results assuming Unique Games Conjecture for the problems that we study is that we need some kind of expansion property on the unique games instance which it lacks. It is shown that Unique Games are easy when the constraint graph is an expander[4]. In general, in [3] it is shown that Unique Games are easy when a normalized adjacency matrix of a constraint graph has very few eigenvalues close to 1. So the natural direction is to modify the unique games instance to get some expansion property but weak enough so that it is not tractable by the techniques of [4], [3]. A similar Strong Unique Games Conjecture, which has a *weak expansion property*, has been used earlier in [5] and [17] to show inapproximability results for minimizing weighted completion time on a single machine with precedence constraints and minimizing makespan in precedence constrained scheduling on identical machines respectively. Our result adds another interesting implication of Unique Games Conjecture with weak expansion property, namely inapproximability of Max-Bi-Clique and Bi-Covering. We hope that our results will help motivate study of Strong Unique Games Conjecture and ultimately answering the question about its equivalence to the Unique Games Conjecture.

Algorithmic Results

We give better than 2 approximation for Bi-Covering on numerous special graph classes.

Graph types. A *δ-vertex expander* is a graph so that for every S of size $|S| \leq n/2$, $N_1(S) \geq \delta n$, where $N_1(S)$ is the set of neighbors of S not in S. A *chordal graph* is a graph

that does not contain a cycle of size at least 4 as an induced subgraph. A *split graph* is a graph whose vertex set is a union of a Clique and and independent set, with arbitrarily connections between the clique and the independent set.

A minor of a graph is any subgraph G' that can be derived from G by contracting and removing edges. A *minor free graph* is a graph that does not contain some constant size graph H as a minor.

An *interval graph* is the intersection graph of a family of intervals on the real line. It has one vertex for each interval in the family, and an edge between every pair of vertices corresponding to intervals that intersect.

The algorithmic results can be summarized in the following theorem.

▶ **Theorem 4.** *The* Bi-Covering *problem admits polynomial time algorithms that attain the following ratios (Graph type: approximation ratio):*

1. *Chordal graphs :* 1.876.
2. *Interval Graphs: exact* $O(n^5)$ *time algorithm.*
3. *Minor Free Graph:* $1 + o(1)$.
4. *Graph with minimum degree* δn*:* $2 - 4\delta/3$.
5. δ*-vertex expander Graph:* $2/(1 + \delta^2/8)$.
6. *Split Graphs :* $8/5$.
7. *Graphs with minimum degree* d*:* $2 - (6/5) \cdot 1/d$.

Our algorithms are quite non-trivial. Most of our algorithmic results relies on the fact that if we can find two disjoint sets each of size at least ϵn with no edges in between, then this itself gives $2 - \epsilon$ approximation. To get better bound on ϵ in some special cases we use known theorems related to the structural results of graphs, size of separator, lower bound on independent set size etc. In some of the cases, we create a bipartite graph from a given graph instance and show that the vertex cover in the bipartite graph is small. We then use the bound on the size of vertex cover to find a better bi-covering of the edges in a graph.

3 Organization

In Section 4, we prove the main inapproximability of Bi-Covering and related problems. We refer to the full version of the paper for algorithmic results.

4 Inapproximability of Bi-Covering

The Bi-Covering problem is:

Input: A graph $G(V, E)$
Output: Two subsets $A, B \subseteq V$ such that $A \cup B = V$ and every edge $(u, v) \in E$ either $\{u, v\} \subseteq A$ or $\{u, v\} \subseteq B$. Minimize $\max\{|A|, |B|\}$.

The optimal value of a Bi-Covering on instance $G(V, E)$ is always at least $|V|/2$ and hence getting a 2-approximation for this problem is *trivial* by setting $A = V$ and $B = \emptyset$. In order to beat 2-approximation, one should be able to solve the following weaker problem.

Problem

For small enough $\epsilon > 0$, given an undirected graph $G(V, E)$, distinguish between the following two cases:

1. There exists two disjoint sets $A, B \subseteq V$, $|A|, |B| \geq (1/2 - \epsilon)|V|$ such that there are no edges between A and B.
2. There exists no two disjoint sets $A, B \subseteq V$ $|A|, |B| \geq \epsilon|V|$ such that there are no edges between A and B.

In this section, we show that it is UG-Hard to distinguish between (1) and (2) for any constant $\epsilon > 0$ proving Theorem 1.

4.1 Preliminaries

Let q be any prime for convenience. We are interested in space of functions from $\mathbb{F}_q^n$ to $\mathbb{R}$. Define inner product on this space as $\langle f, g \rangle = \frac{1}{q^n} \sum_{x \in \mathbb{F}_q^n} f(x)g(x)$. Let ω_q be the q^{th} root of unity. For a vector $\alpha \in \mathbb{F}_q^n$, we will denote α_i the i^{th} coordinate of vector α. The *Fourier decomposition* of a function $f : \mathbb{F}_q^n \to \mathbb{R}$ is given as

$$f(x) = \sum_{\alpha \in \mathbb{F}_q^n} \hat{f}(\alpha)\chi_\alpha(x)$$

where $\chi_\alpha(x) := \omega_q^{\langle \alpha, x \rangle}$ and a *Fourier coefficient* $\hat{f}(\alpha) := \langle f, \chi_\alpha \rangle$.

▶ **Definition 5** (Symmetric Markov Operator)**.** Symmetric Markov operator on $\mathbb{F}_q$ can be thought of as a random walk on an undirected graph with the vertex set $\mathbb{F}_q$. It can be represented as a $q \times q$ matrix T where (i, j) th entry is the probability of moving to vertex j from i.

▶ **Definition 6.** For a symmetric Markov operator T, let $1 = \lambda_0 \geq \lambda_1 \geq \lambda_2 \ldots \geq \lambda_{q-1}$ be the eigenvalues of T in a non-increasing order. The spectral radius of T, denoted by $r(T)$, is defined as:

$$r(T) = \max\{|\lambda_1|, |\lambda_{q-1}|\}.$$

For a Markov operator T the condition $r(T) < 1$ is equivalent to saying that the induced regular graph (self-loop allowed) on $\mathbb{F}_q$ is non-bipartite and connected.

For T as above, we also define a Markov operator $T^{\otimes n}$ on $[q]^n$ in a natural way i.e applying a Markov operator $T^{\otimes n}$ to $x \in [q]^n$ is same as applying the Markov operator T on each x_i independently. Note that if T is symmetric then $T^{\otimes n}$ is also symmetric and $r(T^{\otimes n}) = r(T)$.

▶ **Definition 7** (Influence)**.** Let $f : \mathbb{F}_q^n \to \mathbb{R}$ be a function. the influence of the $i'th$ variable on f, denoted by $\mathbf{Inf}_i(f)$ is defines as:

$$\mathbf{Inf}_i(f) = \mathbb{E}[\mathbf{Var}_{x_i}[f(x)|x_1, x_2, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n]]$$

where $x_1, \ldots, x_n$ are uniformly distributed. In terms of Fourier coefficients, it has the following formula:

$$\mathbf{Inf}_i(f) = \sum_{\alpha_i \neq 0} \hat{f}(\alpha)^2.$$

The low-level (level k) influence of $i'th$ variable is defined as:

$$\mathbf{Inf}_i^{\leq k}(f) = \sum_{\alpha_i \neq 0, |\alpha| \leq k} \hat{f}(\alpha)^2.$$

where $|\alpha|$ is the number of non-zero co-ordinates in α.

We will need the following Gaussian stability measure in our analysis:

▶ **Definition 8.** Let $\phi : \mathbb{R} \to [0,1]$ be the cumulative distribution function of the standard Gaussian random variable. For a parameter $\rho, \mu, \nu \in [0,1]$, we define the following two quantities:

$$\underline{\Gamma}_\rho(\mu,\nu) = \Pr[X \leq \phi^{-1}(\mu), Y \geq \phi^{-1}(1-\nu)]$$

$$\overline{\Gamma}_\rho(\mu,\nu) = \Pr[X \leq \phi^{-1}(\mu), Y \leq \phi^{-1}(\nu)]$$

where X and Y are two standard Gaussian variables with covariance ρ.

We are now ready to state the invariance principle from [7] that we need for our reduction.

▶ **Theorem 9** ([7]). *Let T be a symmetric Markov operator on $\mathbb{F}_q$ such that $\rho = r(T) < 1$. Then for any $\tau > 0$ there exists $\delta > 0$ and $k \in \mathbb{N}$ such that if $f, g : \mathbb{F}_q^n \to [0,1]$ are two functions satisfying*

$$\min(\mathbf{Inf}_i^{\leq k}(f), \mathbf{Inf}_i^{\leq k}(g)) \leq \delta$$

for all $i \in [n]$, then it holds that

$$\langle f, T^{\otimes n} g \rangle \geq \underline{\Gamma}_\rho(\mu,\nu) - \tau$$

where $\mu = \mathbb{E}[f]$, $\nu = \mathbb{E}[g]$.

Our hardness result is based on a variant of Unique Games conjecture. First, we define what the Unique game is:

▶ **Definition 10** (Unique Game). An instance $G = (U, V, E, [L], \{\pi_e\}_{e \in E})$ of the Unique Game constraint satisfaction problem consists of a bi-regular bipartite graph (U, V, E), a set of alphabets $[L]$ and a permutation map $\pi_e : [L] \to [L]$ for every edge $e \in E$. Given a labeling $\ell : U \cup V \to [L]$, , an edge $e = (u, v)$ is said to be satisfied by ℓ if $\pi_e(\ell(v)) = \ell(u)$.

G is said to be *at most δ-satisfiable* if every labeling satisfies at most a δ fraction of the edges.

The following is a conjecture by Khot [12] which has been used to prove many *tight* inapproximability results.

▶ **Conjecture 11** (Unique Games Conjecture [12]). *For every sufficiently small $\delta > 0$ there exists $L \in \mathbb{N}$ such that the following holds. Given a an instance $\mathcal{G} = (U, V, E, [L], \{\pi_e\}_{e \in E})$ of* Unique Game *it is NP-hard to distinguish between the following two cases:*

- *YES case: There exist an assignment that satisfies at least $(1-\delta)$ fraction of the edges.*
- *NO case: Every assignment satisfies at most δ fraction of the edge constraints.*

Our hardness results are based on the following stronger conjecture which is similar to the one in Bansal-Khot [5]. We refer readers to [5] for more discussion on comparison between these two conjectures.

▶ **Conjecture 12** (Strong Unique Games Conjecture). *For every sufficiently small $\delta, \gamma, \eta > 0$ there exists $L \in \mathbb{N}$ such that the following holds: Given an instance $\mathcal{G} = (U, V, E, [L], \{\pi_e\}_{e \in E})$ of* Unique Game *which is bi-regular, it is* NP*-hard to distinguish between the following two cases:*

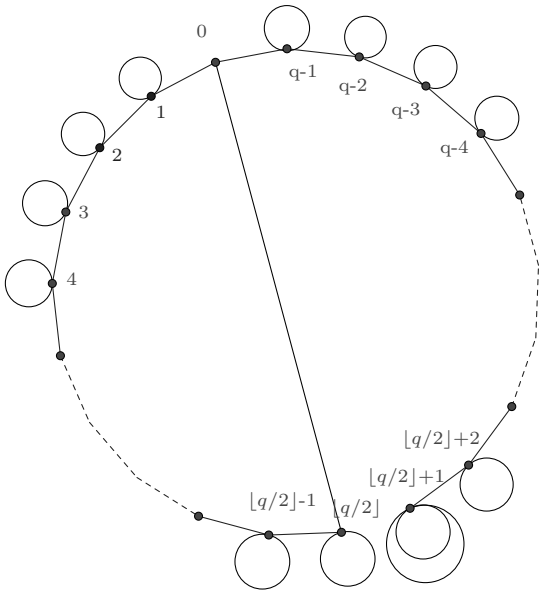

Figure 1 Gadget.

- *YES case: There exist sets $V' \subseteq V$ such that $|V'| \geq (1-\eta)|V|$ and an assignment that satisfies all edges connected to V'.*
- *NO case: Every assignment satisfies at most γ fraction of the edge constraints. Moreover, the instance satisfies the following expansion property. For every set $S \subseteq V$, $|S| = \delta|V|$, we have $|\Gamma(S)| \geq (1-\delta)|U|$, where $\Gamma(S) := \{u \in U \mid \exists v \in S \mathtt{s.t.} (u,v) \in E\}$.*

▶ Remark. We would like to point out that the above conjecture differs from the one in [5] in the completeness case. In [5], the Yes instance has a guarantee that there exists sets $V' \subseteq V, U' \subseteq U$ with $|V'| \geq (1-\eta)|V|, |U'| \geq (1-\eta)|U|$ such that all edges between V' and U' are satisfied.

4.2 $(2-\epsilon)$-inapproximability

In order to prove the $(2-\epsilon)$ hardness, we first start with a *dictatorship test* that we will use as a gadget in the actual reduction.

4.2.1 Dictatorship Test

We design a dictatorship test for the problem Bi-Covering. We are interested in functions $f : \mathbb{F}_q^n \to \mathbb{R}$. f is called a dictator if it is of the form $f(x_1, x_2, \ldots, x_n) = x_i$ for some $i \in [n]$.

4.2.1.1 Dictatorship gadget

For convenience, we will let $q > 2$ be any prime number for the description of the dictatorship gadget. Let $G(\mathbb{F}_q, \mathcal{E})$ be a 3-regular graph on $\mathbb{F}_q$ (where we identify the elements of $\mathbb{F}_q$ by $\{0, 1, \ldots, q-1\}$) with self loops as shown in figure 1:

It is constructed as follows : Take a cycle on $0, 1, 2, \ldots, q-1, 0$, then add a self loop to every vertex except to the vertex 0. Remove the edge $(\lfloor q/2 \rfloor, \lfloor q/2 \rfloor + 1)$, add an edge

$(0, \lfloor q/2 \rfloor)$. Finally, to make it 3-regular, add a self loop to the vertex $\lfloor q/2 \rfloor + 1$. This completes the description of graph G. Since the graph G is connected and non-bipartite, the symmetric Markov operator T defined by the random walk in G has $r(T) < 1$. One crucial thing about G is that it has two large disjoint subsets of vertices, namely $\{1, 2, \ldots, \lfloor q/2 \rfloor\}$ and $\{\lfloor q/2 \rfloor + 1 . \lfloor q/2 \rfloor + 2, \ldots, q-1\}$, with no edges in between.

Consider the vertex set $V = \mathbb{F}_q^R$ for some constant R. We will construct a graph H on V as follows : $(x, y) \in (\mathbb{F}_q^R)^2$ forms an edge in H iff they satisfy the following condition:

$$\forall i \in [R], (x_i, y_i) \in \mathcal{E},$$

x is adjacent to y iff $T^{\otimes R}(x \leftrightarrow y) \neq 0$.

4.2.1.2 Completeness

Let $f : \mathbb{F}_q^R \to \mathbb{R}$ be any dictator, say i^{th} dictator i.e. $f(x) = x_i$. By letting set A to be $f^{-1}(0) \cup f^{-1}(1) \cup \ldots \cup f^{-1}(\lfloor q/2 \rfloor)$ and set B to be $f^{-1}(0) \cup f^{-1}(\lfloor q/2 \rfloor + 1) \cup f^{-1}(\lfloor q/2 \rfloor + 2) \cup \ldots \cup f^{-1}(q-1)$, it can be seen easily that there is no edge between sets $A \setminus B$ and $B \setminus A$. More precisely,

$$\begin{aligned} A \setminus B &= \{x \in \mathbb{F}_q^R \quad | \quad x_i \in \{1, 2, \ldots, \lfloor q/2 \rfloor\}\} \\ B \setminus A &= \{y \in \mathbb{F}_q^R \quad | \quad y_i \in \{\lfloor q/2 \rfloor + 1, \lfloor q/2 \rfloor + 2, \ldots, q-1\}\} \end{aligned}$$

By the property of Markov operator $T^{\otimes R}$, (x, y) are not adjacent if $(x_i, y_i) \notin \mathcal{E}$ for some $i \in [R]$. Hence, there are no edges between $A \setminus B$ and $B \setminus A$. Thus, the optimal value is at most

$$\frac{1}{|V|} \cdot \max\{|A|, |B|\} = \frac{1}{2} + \frac{1}{2q}.$$

4.2.1.3 Soundness

Let $A, B \subseteq V$ such that $A \cup B = V$ and $f, g : \mathbb{F}_q^R \to \{0, 1\}$ be the indicator functions of sets $A \setminus B$ and $B \setminus A$ respectively. Suppose $|A \setminus B| = \epsilon |V|$ and $|B \setminus A| = \epsilon |V|$ for some $\epsilon > 0$ and that there are no edges in between $A \setminus B$ and $B \setminus A$. We will show that in this case, f and g must have a common influential co-ordinate. Since, there are no edges between these sets, we have

$$\mathop{\mathbb{E}}_{\substack{x \sim \mathbb{F}_q^R, \\ y \sim T^{\otimes R}(x)}} [f(x) g(y)] = \langle f, T^{\otimes R} g \rangle = 0 \,.$$

For the application of Invariance principle, Theorem 9, in our case we have $\mathbb{E}[f] = \mathbb{E}[g] = \epsilon > 0$ and $\rho = r(T) < 1$. Thus, for small enough $\tau := \tau(\rho, \epsilon) > 0$,

$$\underline{\Gamma}_\rho(\epsilon, \epsilon) - \tau > 0.$$

We can now apply Theorem 9 to conclude that there exists $i \in [R]$ and $k \in \mathbb{N}$ independent of R such that

$$\min(\mathbf{Inf}_i^{\leq k}(f), \mathbf{Inf}_i^{\leq k}(g)) \geq \delta,$$

for some $\delta(\tau) > 0$. Hence, unless f and g have a common influential co-ordinate, $\frac{1}{|V|} \cdot \max\{|A|, |B|\} \geq 1 - \epsilon$. Thus, the optimum value is at least $1 - \epsilon$

4.2.2 Actual Reduction

The above dictatorship test for large enough q can be composed with the Unique Games instance having some stronger guarantee (Conjecture 12) in a straightforward way that gives $(2-\epsilon)$ hardness for every constant $\epsilon > 0$ assuming UGC. Details as follows:

Let $\mathcal{G} = (U, V, E, [L], \{\pi_e\}_{e\in E})$ be the given instance of Unique Game with parameters $\delta < \frac{\epsilon}{4}, \gamma, \eta > 0$ from Conjecture 12 . We replace each vertex $v \in V$ by a block of q^L vertices, namely by a hypercube $[q]^L$. We will denote this block by $[v]$. As defined in the dictatorship test, let G be the graph on $\mathbb{F}_q$ and T be the induced symmetric Markov operator. For every pair of edges $e_1(u, v_1)$ and $e_2(u, v_2)$ in $\mathcal{G}$, we will add the following edges between $[v_1]$ and $[v_2]$: Let π_1 and π_2 be the permutation constraint associated with e_1 and e_2 respectively. $x \in [v_1]$ and $y \in [v_2]$ are connected by an edge iff $T^{\otimes L}((x \circ \pi_1^{-1}) \leftrightarrow (y \circ \pi_2^{-1})) \neq 0$ (where $(x \circ \pi^{-1})_i = x_{\pi^{-1}(i)}$ for all $i \in [L]$) i.e. for every $i \in [L]$, $x_{\pi_1^{-1}(i)}$ and $y_{\pi_2^{-1}(i)}$ are connected by an edge in graph G. This completes the description of a graph. Let's denote this graph by H.

▶ **Lemma 13** (Completeness). *If there exists an assignment to vertices in $\mathcal{G}$ that satisfies all edges connected to $(1-\eta)$ fraction of vertices in V then H has a* Bi-Covering *of size at most $(1-\eta)(1/2 + 1/2q) + \eta$.*

Proof. Fix a labeling ℓ such that for at least $(1-\eta)$ fraction of vertices in V in $\mathcal{G}$, all edges attached to them are satisfied. Suppose X be the set of remaining η fraction of vertices of V in $\mathcal{G}$. For every vertex $v \in V$, consider the following two partitions of $[v]$:

$$A_v = \{x \in [q]^L : x_{\ell(v)} \in \{1, \ldots, \lfloor q/2 \rfloor\}\}$$
$$B_v = \{x \in [q]^L : x_{\ell(v)} \in \{\lfloor q/2 \rfloor\} + 1, \lfloor q/2 \rfloor\} + 2, \ldots, q\}\}$$
$$C_v = \{x \in [q]^L : x_{\ell(v)} = 0\}$$

Let $A = \cup_{v\in V}(A_v \cup C_v) \cup_{z\in X} [z]$ and $B = \cup_{v\in V}(B_v \cup C_v) \cup_{z\in X} [z]$. The claim is that this is the required edge separating sets. To see this, consider any vertex pair (a, b) such that $a \in A \setminus B$ and $b \in B \setminus A$. We need to show that (a, b) must not be adjacent in H. Suppose $a \in [v_1]$ and $b \in [v_2]$. If v_1 and v_2 don't have a common neighbor then clearly, there is no edge between a and b. Suppose they have a common neighbor u and let $e_1 = (u, v_1)$ and $e_2 = (u, v_2)$ be the edges and π_1 and π_2 be the associated permutation constraints. Since $X \subseteq A \cap B$, $v_1, v_2 \notin X$. Hence ℓ satisfies all constraints associated with v_1 and v_2. In particular, $\pi_1(\ell(v_1)) = \pi_2(\ell(v_2)) =: j$ for some $j \in [L]$. Since $a \in A_{v_1}$, we have $a_{\pi_1^{-1}(j)} = a_{\ell(v_1)} \in \{1, \ldots, \lfloor q/2 \rfloor\}\}$. Similarly, $b_{\pi_2^{-1}(j)} \in \{\lfloor q/2 \rfloor\} + 1, \lfloor q/2 \rfloor\} + 2, \ldots, q\}$. By the construction of edges in H, a and b are not adjacent.

For any v, $|A_v \cup C_v| = |B_v \cup C_v| = (\frac{1}{2} + \frac{1}{2q})q^L$. Thus,

$$|A| = |B| \leq \left(\eta + (1-\eta)\left(\frac{1}{2} + \frac{1}{2q}\right)\right)|V|q^L\,. \qquad \blacktriangleleft$$

▶ **Lemma 14** (Soundness). *For every constant $\epsilon > 0$, there exists a constant γ such that, if $\mathcal{G}$ is at most γ-satisfiable then H has* Bi-Covering *of size at least $1-\epsilon$.*

Proof. Suppose for contradiction, there exists an Bi-Covering of size at most $(1-\epsilon)$. This means there exists two disjoint sets X, Y of size at least ϵ fraction of vertices in H such that there are no edges in between X and Y. Let X^* be the set of vertices in $v \in V$ such that $[v] \cap X \geq \frac{\epsilon}{2}|[v]|$. Similarly, Y^* be the set of vertices in $v \in V$ such that $[v] \cap Y \geq \frac{\epsilon}{2}|[v]|$. By simple averaging argument, $|X^*| \geq \frac{\epsilon}{2}|V|$ and $|Y^*| \geq \frac{\epsilon}{2}|V|$.

▶ **Lemma 15.** *The total fraction of edges connected to X^* whose other end point is in $\Gamma(X^*) \cap \Gamma(Y^*)$ is at least $\frac{1}{2}$.*

Proof. Let $\mathcal{G}$ has left-degree d_1 and right-degree d_2. We have $d_1 = \frac{d_2|V|}{|U|}$. Suppose the claim is not true, then at least $\frac{1}{2}$ fraction of edges have there endpoint in $U \setminus \Gamma(Y^*)$. As, $|U \setminus \Gamma(Y^*)| \leq \delta|U|$, the average degree of a vertex in $U \setminus \Gamma(Y^*)$ is at least $\frac{(1/2)d_2|X^*|}{\delta|U|} \geq \frac{(d_2/2)\cdot(\epsilon/2)|V|}{\delta|U|}$ which is greater than d_1 as $\epsilon > 4\delta$. ◀

For $v \in X^* \cup Y^*$, let $f_v : [q]^L \to \{0,1\}$ be the indicator function of a set $[v] \cap (X \cup Y)$. Define the following label set for $v \in X^* \cup Y^*$ for some $\tau' > 0$ and $k \in \mathbb{N}$:

$$\mathcal{F}(v) := \{i \in [L] \mid \mathbf{Inf}_i^{\leq k}(f_v) \geq \tau'\}.$$

We have $|\mathcal{F}(v)| \leq \frac{\tau'}{k}$ as $\sum_i \mathbf{Inf}_i^{\leq k}(f_v) \leq k$.

▶ **Lemma 16.** *There exists a constant $\tau' := \tau'(q,\epsilon)$ and $k := k(q,\epsilon)$ such that for every $u \in U$ and edges $e_1(u,v), e_2(u,w)$ such that $v \in X^*$ and $w \in Y^*$, we have*

$$\pi_{e_1}(\mathcal{F}(v)) \cap \pi_{e_2}(\mathcal{F}(w)) \neq \emptyset.$$

Proof. As there are no edges between X and Y, we have

$$\mathop{\mathbb{E}}_{\substack{(x\circ\pi_{e_1}^{-1})\sim\mathbb{F}_q^L,\\ (y\circ\pi_{e_2}^{-1})\sim T^{\otimes L}(x\circ\pi_{e_1}^{-1})}} [f_v(x\circ\pi_{e_1}^{-1}) f_w(y\circ\pi_{e_2}^{-1})] = 0.$$

By the soundness analysis of the dictatorship test, it follows that there exists $i \in [L]$ such that

$$\min(\mathbf{Inf}^{\leq k}_{\pi_{e_1}^{-1}(i)}(f_v), \mathbf{Inf}^{\leq k}_{\pi_{e_2}^{-1}(i)}(f_w)) \geq \tau',$$

for some τ', k as a function of q and ϵ. Thus, $i \in \pi_{e_1}(\mathcal{F}(v))$ and $i \in \pi_{e_2}(\mathcal{F}(w))$. ◀

◀

4.2.2.1 Labeling

Fix τ' and k from Lemma 16. We now define a labeling ℓ to vertices in $X^* \subseteq V$ and in $\Gamma(X^*) \cap \Gamma(Y^*) \subseteq U$ as follows: For a vertex $v \in X^*$ set $\ell(v)$ to be an uniformly random label from $\mathcal{F}(v)$. For $u \in \Gamma(X^*) \cap \Gamma(Y^*)$, select an arbitrary neighbor w of u in Y^* and set $\ell(u)$ to be an uniformly random label from the set $\pi_{(u,w)}(\mathcal{F}(w))$ of size at most $\frac{k}{\tau'}$. Fix an edge (u,v) such that $u \in \Gamma(X^*) \cap \Gamma(Y^*)$ and $v \in X^*$. By Lemma 16, for any $w \in Y^*$ since $\pi_{(u,w)}(\mathcal{F}(w)) \cap \pi_{(u,v)}(\mathcal{F}(v)) \neq \emptyset$, The probability that the edge is satisfied by the randomized labeling is at least $\left(\frac{\tau'}{k}\right)^2$. Thus in expectation, at least $\left(\frac{\tau'}{k}\right)^2$ fraction of edges between X^* and $\Gamma(X^*) \cap \Gamma(Y^*)$ are satisfied. By Lemma 15, at least $\frac{1}{2}$ fraction of edges connected to X^* are in between X^* and $\Gamma(X^*) \cap \Gamma(Y^*)$. Finally using bi-regularity, this labeling satisfies at least $\frac{1}{2}\frac{\epsilon}{2}\left(\frac{\tau'}{k}\right)^2$ fraction of edges in $\mathcal{G}$. Setting $\gamma < \frac{1}{2}\frac{\epsilon}{2}\left(\frac{\tau'}{k}\right)^2$ completes the proof. ◀

Proof of Theorem 1

The proof follows from Lemma 13, Lemma 14 and Conjecture 12.

Proof of Theorem 2

Given an input as a bipartite graph, there is a trivial 3/2 approximation for Bi-Covering - Take set A to be the union of a smaller part and half of the larger bi partition and B to be union of smaller part and remaining half of the larger part. It is easy to see these two sets A and B satisfy the property of being a Bi-Covering. As $\max\{|A|, |B|\} \leq \frac{3}{4}|V|$, this is a $\frac{3}{2}$ approximation as OPT is at least $\frac{|V|}{2}$.

The $\frac{3}{2} + \epsilon$ inapproximability follows easily from the above $(2 - \epsilon)$ inapproximability for the general case. The reduction is as follows: Let $G(V, E)$ be the given instance of a Bi-Covering. Construct a natural bipartite graph G' between $V \times V$ where (i, j) forms an edge if $(i, j) \in E$ (or $(j, i) \in E$). Fix a small enough constant $\epsilon > 0$. It is easy to see that if G has a solution of fractional size $1/2 + \epsilon$ then so does G'. Next, if there are sets A' and B' where $\frac{1}{2|V|}\max\{|A'|, |B'|\} \leq \frac{3}{4} - \epsilon$ which satisfy the Bi-Covering property, we have $\frac{1}{2|V|}|A' \setminus B'| = \frac{1}{2|V|}(2|V| - |B'|) \geq 1 - (\frac{3}{4} - \epsilon) = \frac{1}{4} + \epsilon$ and similarly $\frac{1}{2|V|}|B' \setminus A'| \geq \frac{1}{4} + \epsilon$. Note that $A' \setminus B'$ and $B' \setminus A'$ are two disjoint sets whose size of union is at least $(1 + 2\epsilon)|V|$. Thus, we can find two sets, say X' and Y' (namely X' is intersection of $A' \setminus B'$ with left part of the bipartite graph and Y' is the intersection of $B' \setminus A'$ with right part) of size at least $\epsilon|V|$ each, where X' is from left side and Y' is from right side with no edges in between. We now think of X' and Y' as a subset of V. Let $Z = X' \cap Y'$. Partition Z into Z_1 and Z_2 of equal sizes. Take $X = Z_1 \cup (X' \setminus Y')$ and $Y = Z_2 \cup (Y' \setminus X')$. It is now easy to verify that there are no edges in between X and Y in G and $\frac{1}{|V|}\min\{|X|, |Y|\} \geq \frac{\epsilon}{2}$. Hence, if we can find a solution of fractional cost $\frac{3}{4} - \epsilon$ in G' in polynomial time then we can also find a solution of fractional cost $1 - \frac{\epsilon}{2}$ in G in polynomial time and this gives a polynomial time algorithm with approximation factor $2 - \frac{\epsilon}{2}$ for small enough constant $\epsilon > 0$. As Bi-Covering is UG hard to approximate within $(2 - \epsilon)$ for all $\epsilon > 0$ for general graph, this gives a $\frac{3}{2} + \epsilon$ hardness for Bi-Covering in bipartite graph.

Proof of Corollary 3

We prove it by giving reduction from Bi-Covering. Let $G(V, E)$ be the given instance of Bi-Covering. Construct a bipartite graph H between $V \times V$ where (i, j) forms an edge if $(i, j) \notin E$. Fix a small enough constant $\epsilon > 0$. In one direction, if G has a Bi-Covering of fractional size at most $(1/2 + \epsilon)$ then H' contains a $(1/2 - \epsilon)|V| \times (1/2 - \epsilon)|V|$ bipartite clique. In other direction, if H' has a bipartite clique of size $2\epsilon|V| \times 2\epsilon|V|$ then let X' and Y' be the subset of vertices from left and right side of bipartite clique. As before, let $Z = X' \cap Y'$ and Z_1 and Z_2 be the partition of Z of equal size. Let $X = (X' \setminus Y') \cup Z_1$ and $Y = (Y' \setminus X') \cup Z_2$. It follows that $|X|, |Y|$ is at least $\epsilon|V|$ and are disjoint viewed as a subset of V. Also, there are no edges between X and Y. Therefore, $V \setminus X$ and $V \setminus Y$ each of size at most $(1 - \epsilon)|V|$ gives a Bi-Covering of G. Thus, Theorem 1 implies that it is hard to distinguish between Bi−Clique of size $(1/2 - \epsilon)|V|$ and $\epsilon|V|$ which completes the proof of corollary.

Abstract

We study the problem of routing symmetric demand pairs in planar digraphs. The input consists of a directed planar graph $G = (V, E)$ and a collection of k source-destination pairs $\mathcal{M} = \{s_1t_1, \ldots, s_kt_k\}$. The goal is to maximize the number of pairs that are routed along disjoint paths. A pair s_it_i is routed in the symmetric setting if there is a directed path connecting s_i to t_i *and* a directed path connecting t_i to s_i. In this paper we obtain a randomized poly-logarithmic approximation with constant congestion for this problem in planar digraphs. The main technical contribution is to show that a planar digraph with directed treewidth h contains a constant congestion crossbar of size $\Omega(h/\text{polylog}(h))$.

1 Introduction

Disjoint path problems are well-studied routing problems with several applications and fundamental connections to algorithmic and structural results in combinatorial optimization and graph theory. Canonical problems here are the edge-disjoint paths problem (EDP) and the node-disjoint paths problem (NDP) in undirected graphs. In both these problems the input consists of an undirected graph $G = (V, E)$ and k node-pairs $\{s_1t_1, \ldots, s_kt_k\}$. In EDP the goal is to connect the pairs by edge-disjoint paths and in NDP the goal is to connect the pairs by node-disjoint paths. The decision versions of these problems are NP-Complete when k is part of the input. The seminal work of Robertson and Seymour showed that both these problems are fixed parameter tractable when parameterized by k, the number of pairs. In this paper we are concerned with an optimization version of the problems where the goal is to maximize the number of input pairs that can be routed via edge or node-disjoint

paths. To avoid notational overload we will henceforth use EDP and NDP to refer to these maximization versions.

The approximability of EDP and NDP has been extensively studied but our understanding is still limited. The best known approximation for both these problems is $O(\sqrt{n})$ [9, 31] (here n is number of nodes in G) while current hardness of approximation results only rule out an $O(\log^{1/2-\varepsilon} n)$ approximation [2]. Even in planar graphs the best approximation up to very recently was $O(\sqrt{n})$, with a slight improvement just announced [16]. One of the reasons for this state of affairs is that the natural multicommodity flow relaxation has an integrality gap of $\Theta(\sqrt{n})$. On the other hand, two closely related relaxations of these problems have seen significant progress in the last decade. ANF is the relaxation of the disjoint paths problem where a subset of the input pairs $\mathcal{M}'$ is routed if there is a feasible multicommodity flow in the graph that routes one unit of flow for each pair in $\mathcal{M}'$. A second relaxation is to allow some small constant congestion c, i.e., instead of the pairs being routed on disjoint paths we allow up to c paths to use a given edge or node. ANF admits a poly-logarithmic approximation [11, 8]. A series of breakthroughs [33, 1, 13] culminated in a poly-logarithmic approximation for EDP with congestion 2 by Chuzhoy and Li [17]. These ideas have been extended to NDP as well [6, 4]. These results have been made possible by a number of non-trivial ideas and techniques at the intersection of algorithms, combinatorial optimization and graph theory. In particular, the results have been enabled by and contributed to a deeper understanding of the structure of undirected graphs via the notion of treewidth. Treewidth is a well-known graph parameter that plays a fundamental role in the graph-minor theory of Robertson and Seymour; see [3, 4, 5, 14] for some of the recent results.

It is natural to study disjoint paths problems also in *directed* graphs. Here the graph G is directed and the input pairs $\mathcal{M} = \{(s_1, t_1), \ldots, (s_k, t_k)\}$ are ordered and we seek to find a maximum cardinality subset of $\mathcal{M}$ that can be connected by disjoint paths[1]. Unfortunately, it has been shown that disjoint paths problems are highly intractable in directed graphs. It is known that even the simpler case of ANF and with congestion c allowed is hard to approximate to within a factor of $n^{\Omega(1/c)}$ [15]; moreover this holds in acyclic graphs.

A recent paper by a subset of the authors [7] initiated the study of maximum throughput routing problems in directed graphs where the demand pairs are *symmetric*. Here the graph G is directed but the input pairs are unordered as in the undirected setting. Routing a pair s_it_i requires finding a path that connects s_i to t_i *and* a path connecting t_i to s_i. We use Sym-Dir-EDP, Sym-Dir-NDP and Sym-Dir-ANF to denote the analogues of EDP, NDP and ANF respectively in this setting. A detailed motivation for the study of this model is given in [7]. Here we briefly outline some of the key points.

The model is motivated by both theoretical and practical considerations. On the theoretical side the model generalizes (modulo constant congestion) the edge and node disjoint paths problems in undirected graphs. Moreover, flow-cut gaps in this model have been studied in the past and have close connections to various problems including feedback edge/vertex set problems [30, 37, 21, 10]. From the more practical side there are several scenarios where the communication between users is symmetric while the underlying network that supports the communication may be asymmetric (hence modeled as a directed graph); see [26, 25] for instance.

Unlike the case of directed graph routing problems, the symmetric model exhibits tractability. In particular, the well-linked decomposition framework for undirected graphs extends to a large extent to this model [7].

[1] Although edge and node disjoint paths problems are equivalent in general directed graphs, this is not necessarily the case in restricted graph classes such as planar graphs.

To resolve the complexity of disjoint path problems in the symmetric model one needs to understand the structure of directed graphs as a function of their *directed treewidth* [23, 34], that we denote by $\mathrm{dtw}(G)$. As we mentioned, the interplay between algorithmic questions and graph structure theory for undirected graphs has been very successful in the recent past. There has been recent significant progress on the graph theoretic side on directed treewidth; in particular Kawarabayashi and Kreutzer recently established the excluded grid theorem in directed graphs [27, 28].

The main technical contribution of [7] is to generalize the well-linked decomposition framework of [8] to the symmetric demands setting in directed graphs. As a consequence, [7] obtained a poly-logarithmic approximation with constant congestion for Sym-Dir-ANF. The central open question they raised is the following: *Is there a poly-logarithmic approximation for* Sym-Dir-NDP *with constant congestion in general directed graphs?* It was shown in [7] that this can be answered in the positive by addressing the following question which is the analogue that was raised in [8] for undirected graphs: *If a directed graph G has directed treewidth h, does it have a constant congestion routing structure (crossbar) of size $\Omega(h/\mathrm{polylog}(h))$?* Note that grid-minor theorems establish such a connection between treewidth and routing structures, however, the quantitative relationship between the treewidth and the size of the grid is too weak to prove any meaningful approximation for the routing problem. On the other hand, the routing problem has the flexibility of allowing a large constant congestion which enables one to prove the existence of routing structures that are not as rigid as a grid; this relaxation has been the key to algorithmic success on routing. We also note that it is NP-Complete to decide whether a single pair can be routed without congestion in the symmetric setting [22]; thus a congestion of at least 2 is necessary for a non-trivial approximation ratio.

In this paper we take a step towards the general problem by addressing the important special case of planar graphs. Our main algorithmic result is the following.

▶ **Theorem 1.** *There is a randomized poly-logarithmic approximation for* Sym-Dir-NDP *in planar directed graphs with congestion* 5.

The approximation algorithm in the preceding theorem is derived via a natural multicommodity flow relaxation for the problem. The main new technical ingredient is a graph theoretic result that shows that if a planar digraph has directed treewidth h then it has a constant congestion crossbar of size $\Omega(h/\mathrm{polylog}(h))$. We remark that an undirected planar graph with treewidth h has a grid-minor (which is a congestion 2 crossbar) of size $\Omega(h)$. In contrast the known relationship between treewidth and grid-minors in directed planar graphs is much weaker; recent work [27, 28] only shows that there is a directed-grid of size $f(h)$ for some weakly growing function of h. We hope that our crossbar result could be used as a starting point to improve the quantitative bound on the grid-minor theorem for planar digraphs.

1.1 Overview of the Algorithm and Technical Contributions

Here we give a brief outline of the high-level details of the algorithm and some of our technical contributions. Let $(G, \mathcal{M})$ be an instance of Sym-Dir-NDP, where $G = (V, E)$ is a directed planar graph with unit node capacities, and $\mathcal{M} = \{s_1t_1, \ldots, s_kt_k\}$ is a collection of source-destination pairs. We refer to the nodes participating in $\mathcal{M}$ as terminals, and we use $\mathcal{T}$ to denote the set of terminals. It is convenient to assume that the pairs $\mathcal{M}$ form a matching on $\mathcal{T}$.

Well-linked sets: A key notion that we make use of is well-linkedness. Given a directed graph $G = (V, E)$ a subset of nodes $X \subseteq V$ is said to be well-linked if for any two disjoint subsets Y and Z of X of equal size, there exist $|Y|$ node-disjoint paths from Y to Z; note that the definition is symmetric since we can swap Y and Z. We need a relaxation of well-linkedness. For some parameter $\beta \in [0, 1]$, X is β-well-linked if for all disjoint $Y, Z \subset X$ of equal size there are $|Y|$ paths from Y to Z such that no node is in more than $\lceil 1/\beta \rceil$ of these paths; in other words, the node-congestion caused by the paths is at most $\lceil 1/\beta \rceil$. The case $\beta = 1$ corresponds to well-linkedness. It is well-known that in both directed and undirected graphs well-linkedness is closely connected to treewidth. More precisely, a graph has treewidth k iff it has a well-linked set of size $\Theta(k)$; see [34]. Moreover, if X is β-well-linked in G then the treewidth of G is $\Omega(\beta|X|)$.

Algorithm: Here we outline the high-level steps of our algorithm.

1. Solve a multicommodity flow based LP relaxation that routes each pair $s_i t_i$ fractionally to an amount $x_i \in [0, 1]$ to maximize $\sum_{i=1}^{k} x_i$. See Fig. 2 and the description in Section 2.
2. Use the LP relaxation and the well-linked decomposition framework from [7] to reduce the problem, at the loss of a poly-logarithmic factor in the approximation, to instances in which the terminals $\mathcal{T}$ are α-well-linked for some *fixed* constant α.
3. Assuming that $\mathcal{T}$ is α-well-linked in G we have $\mathrm{dtw}(G) = \Omega(k)$ where $k = |\mathcal{T}|$. Using this fact show that G has a large routing structure and use this structure to route a large number of terminal pairs. Use the following steps.
   a. From G obtain an *Eulerian multigraph* $H = (V, E_H)$ whose support is a subgraph of G such that (i) $\mathcal{T}$ is α'-well-linked in H for $\alpha' = \Omega(\frac{1}{\mathrm{polylog}(k)})$ and (ii) $\Delta(H)$, the maximum degree in H, is $\mathrm{polylog}(k)$.
   b. Using the fact that H is Eulerian, has treewidth $\Omega(k/\mathrm{polylog}(k))$, and has maximum degree $\mathrm{polylog}(k)$, show that it has a cylinder-like routing structure of size $\Omega(k/\mathrm{polylog}(k))$. See Fig. 1.
   c. Route terminals to the routing structure and use it to connect a large number of input pairs.

The preceding algorithm follows the general framework that has been very successful in the undirected graph setting in the recent past. The first two steps follows the well-linked decomposition framework from [8] that has been extended to the symmetric demand instances in directed graphs by [7]. This framework allows one to reduce, via the LP relaxation, general instances to instances in which the terminals are well-linked. This incurs a poly-logarithmic factor loss in the approximation. With this reduction in place we have the following property for our instance. The graph G has a terminal set $\mathcal{T}$ of size h and since $\mathcal{T}$ is α-well-linked for some fixed constant α, G has directed treewidth $\Omega(h)$. Now, the remaining task is to show a graph-theoretic result that any directed graph with treewidth h has a constant congestion *crossbar* routing structure of size $\Omega(h/\mathrm{polylog}(h))$. By crossbar we mean a directed graph H with an *interface* $I \subset V(H)$ with the following property: *any* matching on I can be routed in a symmetric fashion in H with constant congestion. The idea then is to route the terminals to the interface of the crossbar and use it to route the desired matching on the terminals.

In undirected planar graphs if G has treewidth h then it has grid-minor of size $\Omega(h)$ [36], and this grid-minor can be used as a crossbar to route $\Omega(h)$ input pairs (see [8] for instance). What about directed graphs? Johnson *et al.* [23], who introduced the notion of directed treewith, conjectured that any directed graph with sufficiently large treewidth contains a cylindrical grid (see Fig. 1) as a butterfly minor. The cylindrical grid can be used as a

crossbar. In an unpublished manuscript, Johnson *et al.* [24] outlined a proof for the case of planar graphs. Kawarabayashi and Kreutzer [27] recently gave a different proof for the planar and minor-free case, and very recently gave a proof for all graphs [28]. However, as we already mentioned, the quantitative relationship between the size of the cylindrical grid and treewidth is very weak. Hence, these results would not yield any meaningful results for our routing problem. Here, we build on the high-level ideas in the work of Johnson *et al.* [24] to establish our main result which gives a constant congestion crossbar of size $\Omega(h/\text{polylog}(h))$ where h is the treewidth of G; our result applies only to planar graphs and establishing a similar result for general graphs is a challenging open problem. Due to space constraints we only mention the key steps.

A key insight from [24] is that given directed graph G one can create an Eulerian multigraph H of bounded degree whose support is a subgraph of G such that $\text{dtw}(H) \geq f(\text{dtw}(G))$ for some function f. Eulerianness as well as small degree are critical for further manipulations. Our first contribution is to show that H can be chosen such that (i) $\text{dtw}(H) = \text{dtw}(G)/\text{polylog}(\text{dtw}(G))$ and (ii) the maximum degree in H, $\Delta(H) = O(\log^2 \text{dtw}(G))$. For this purpose we use Louis's extension of the cut-matching game of Khandekar, Rao and Vazirani [29] to directed graphs [32], combined with the well-linked decomposition framework of [7, 8].

▶ **Theorem 2.** *Suppose that there is a polynomial time algorithm for $\Omega(1)$-node-well-linked instances of* Sym-Dir-NDP *in planar directed Eulerian graphs of maximum degree Δ that achieves a $\beta(\Delta)$-approximation with congestion c. Then there is a polynomial time randomized algorithm that, with high probability, achieves a $\beta(O(\log^2 k)) \cdot O(\log^6 k)$ approximation with congestion c for arbitrary instances of* Sym-Dir-NDP *in planar directed graphs, where k is the number of pairs in the instance.*

Another key insight from [24] is to consider the undirected version of G, denoted by G^{UN}, to obtain a large undirected grid-minor using the fact that $\text{tw}(G^{\text{UN}}) = \Omega(\text{dtw}(G))$. In particular this allows the construction of several disjoint concentric directed cycles in G by exploiting the structure of the grid, Eulerianness, and planarity. We follow their ideas and show that the entire construction can be done in polynomial time to yield $\Omega(\text{dtw}(H)/\Delta(H))$ concentric disjoint cycles.

The final step is to find many disjoint paths that cross the concentric cycles from the inner cycle to the outer cycle and many disjoint paths from the outer cycle to the inner cycle. We show that we can find such paths via some ideas in [24] but with the additional property that these paths originate at the terminals. The collection of concentric cycles with these crossing paths is our desired crossbar and we also obtain the required property that the terminals are linked to this crossbar. We note that [24] have to do considerable work to obtain the cylindrical grid while we are satisfied with the constant congestion properties of the cycles plus paths (see Fig.1).

In the end, we arrive at the following statement whose proof is presented in Section 3.

▶ **Theorem 3.** *Given a plane directed Eulerian graph G of maximum in-degree at most Δ and an α-node-well-linked set X in G with $|X| = \Omega(\Delta^2/\alpha)$, one can in polynomial time find a set of $\Omega(\alpha|X|/\Delta)$ concentric cycles going in the same direction (i.e., all clockwise or all counter-clockwise), sets $Y^+, Y^- \subseteq X$ of size $|Y^+| = |Y^-| = \Omega(\alpha^2|X|/\Delta^2)$ each, and families $\mathcal{P}^+$ and $\mathcal{P}^-$ of node-disjoint paths, such that either*

1. *none of the cycles enclose any vertex of $Y^+ \cup Y^-$, the family $\mathcal{P}^+$ consists of $|Y^+|$ node-disjoint paths from Y^+ to the innermost cycle, and the family $\mathcal{P}^-$ consists of $|Y^-|$ node-disjoint paths from the innermost cycle to Y^-; or*

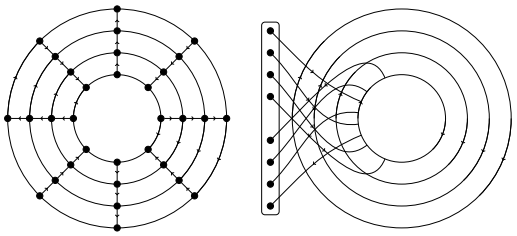

Figure 1 A cylinder (left) and a crossbar we obtain in our proof (right); the vertices in the rounded rectangle is a set of α-well-linked terminals.

$$\max \sum_{i=1}^{k} x_i$$

$$\sum_{p \in \mathcal{P}(s_i,t_i)} f(p) = x_i \qquad i \in [k]$$

$$\sum_{p \in \mathcal{P}(t_i,s_i)} f(p) = x_i \qquad i \in [k]$$

$$\sum_{p:\ v \in p} f(p) \leq 1 \qquad v \in V(G)$$

$$f(p) \geq 0 \qquad p \in \mathcal{P}$$

$$x_i \in [0,1] \qquad i \in [k]$$

2. *all cycles enclose $Y^+ \cup Y^-$, the family $\mathcal{P}^+$ consists of $|Y^+|$ node-disjoint paths from Y^+ to the outermost cycle, and the family $\mathcal{P}^-$ consists of $|Y^-|$ node-disjoint paths from the outermost cycle to Y^-.*

Although we are inspired by [24], in the proof of Theorem 3 we use different methodology based on well-linked sets. We also point out that there are significant technical hurdles in working with directed graphs and treewidth. For instance, one can prove that if an undirected graph has treewidth k then it has $\Omega(k/\log k)$ disjoint cycles. This is closely related to the well-known Erdos-Posa theorem [20]. Relating treewidth and disjoint cycles in directed graphs is significantly harder and was resolved in [35] (and also via the more recent result [28]) but the quantitative relationship is weak and far from the known lower bounds.

Using Theorem 3, we show the following statement, which in turn, together with Theorem 2, immediately yields Theorem 1.

▶ **Theorem 4.** *There is an $\mathcal{O}(\Delta^2/\alpha^3)$ approximation with congestion 5 for* Sym-Dir-NDP *in instances for which the input digraph is planar and Eulerian with maximum degree Δ, and the terminals are α-node-well-linked for some $\alpha \leq 1$.*

In this extended abstract, we focus on proving Theorem 3 on constructing the crossbar in Section 3, and we defer the remaining details and proofs to a longer version of this paper.

2 Preliminaries on LP Relaxation and plane Eulerian digraphs

LP relaxation. Our algorithm uses a standard multicommodity flow relaxation for the problem given in Figure 2. We use $\mathcal{P}(u,v)$ to denote the set of all paths in G from u to v, for each ordered pair (u,v) of nodes. Our assumption that the pairs $\mathcal{M}$ form a matching ensures that the sets $\mathcal{P}(s_i,t_i)$, $\mathcal{P}(t_i,s_i)$, $\mathcal{P}(s_j,t_j)$ and $\mathcal{P}(t_j,s_j)$ are pairwise disjoint. Let $\mathcal{P} = \bigcup_{i=1}^{k}(\mathcal{P}(s_i,t_i) \cup \mathcal{P}(t_i,s_i))$. The LP has a variable $f(p)$ for each path $p \in \mathcal{P}$ representing the amount of flow on p. For each (unordered) pair $s_it_i \in \mathcal{M}$, the LP has a variable x_i denoting the total amount of flow routed for the pair (in the corresponding IP, x_i denotes whether the pair is routed or not). The LP imposes the symmetry constraint that there is a flow from s_i to t_i of value x_i *and* a flow from t_i to s_i of value x_i. Additionally, the LP has

capacity constraints that ensure that the total amount of flow on paths using a given node is at most one.[2]

It is convenient to assume that the pairs $\mathcal{M}$ form a matching on $\mathcal{T}$ and each terminal is a leaf of G, i.e., it is attached to a single neighbor using an edge in each direction. As shown in [7], these properties can be ensured as follows. Given an instance $(G, \mathcal{M})$ with terminal $\mathcal{T}$, we create a new instance $(G', \mathcal{M}')$ by attaching a new leaf neighbor t' to every $t \in \mathcal{T}$ with arcs (t, t') and (t', t), and move the terminal t to t'. Given a solution to the LP relaxation on $(G, \mathcal{M})$, we can easily find a solution of at least half of the value by extending the flow along arcs (t, t') and (t', t); the loss of the flow is due to potential capacity violation at vertex t that is now counted twice along the flow paths. If we obtain an integral solution in $(G', \mathcal{M}')$ (i.e., a routing of some pairs from $\mathcal{M}'$) with congestion $c > 1$, by shortening the paths we obtain a routing with the same congestion in $(G, \mathcal{M})$.

Plane Eulerian Digraphs: First, let us recall the following lemma that encapsulates the main property of Eulerian digraphs that make them similar to undirected graphs.

▶ **Lemma 5.** *Let G be an Eulerian digraph of maximum in-degree Δ, let $A, B \subseteq V(G)$, and let ℓ be an integer. If there exist $(\Delta+1)\ell+1$ undirected vertex-disjoint paths from A to B in G, then there exist $\ell+1$ directed ones as well.*

We also need some notation with respect to planar embeddings. Let Π denote the euclidean plane. For a closed Jordan curve γ and a point $p \in \Pi \setminus \gamma$, by $\zeta_p(\gamma) \in \mathbb{Z}$ we denote the element of the fundamental group of $\Pi \setminus \{p\}$ where γ belongs (with the convention that a clockwise cycle around p is the $+1$ element). A Jordan curve γ is in *general position* with respect to the plane graph G if it has finite number of intersections with G, its starting point and ending point do not belong to G, and whenever a point p lies both on γ and in the interior of an edge $e \in E(G)$, then γ traverses the edge e at this point. *A face-edge curve* in a plane digraph G is a Jordan curve in general position that does not traverse any vertex of G.

For a curve γ in general position with respect to G, we introduce the following notions. Assume γ intersects an edge e while going from a face f to a face f'. If e has the face f on the right and the face f' on the left, then we say that e *crosses γ from left to right* and, otherwise, if e has the face f on the left and the face f' on the right, then we say that e *crosses γ from right to left*. By $\mathrm{cross}^{L\to R}(\gamma)$ and $\mathrm{cross}^{R\to L}(\gamma)$ we denote the number of times an edge crosses γ from left to right and from right to left, respectively; note that in these numbers we may count one edge multiple times, one for each moment γ crosses the edge.

For a vertex v in a digraph G, an *imbalance* of v is the number $\mathrm{imb}_G(v) := \mathrm{indeg}_G(v) - \mathrm{outdeg}_G(v)$. A graph is *balanced* if $\mathrm{imb}_G(v) = 0$ for every $v \in V(G)$, and *Eulerian* if it is additionally weakly connected. Furthermore, let the *imbalance* of a curve γ in a general position with respect to G be $\mathrm{imb}(\gamma) = \mathrm{cross}^{L\to R}(\gamma) - \mathrm{cross}^{R\to L}(\gamma)$. A standard argument shows the following:

[2] There is a subtle issue here with regards to the capacity usage at the endpoints of a path. In the integral solution, a pair of paths, one from s_i to t_i and one from t_i to s_i, is regarded as using the vertex s_i only once and using the vertex t_i only once; in other words, such a pair can be seen as a simple cycle passing through s_i and t_i. To simulate it in the LP relaxation, we consider that the starting vertex belongs to a flow path, but the ending vertex does not belong to it. Alternatively, we can assume that a flow path uses only half of the capacities at its endpoints; these interpretations are equivalent due to the symmetry of the demands.

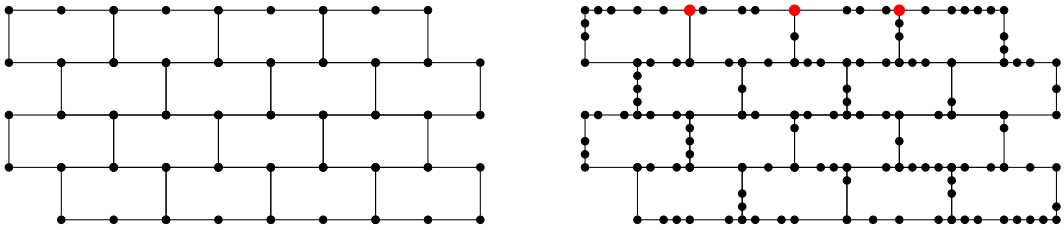

Figure 3 A wall (left) and a subdivided wall (right). The red vertices denote the interface of the wall.

▶ **Lemma 6.** *Let γ be a closed face-edge curve in a plane digraph G. Then*

$$\mathrm{imb}(\gamma) = \sum_{v \in V(G)} \zeta_v(\gamma) \cdot \mathrm{imb}_G(v).$$

We also need the following flow/cut duality.

▶ **Lemma 7.** *Given a plane digraph G, two distinguished faces f^{in} and f^{out}, and an integer k, one can in linear time find either:*

1. *a family of directed vertex-disjoint cycles $C_1, C_2, \ldots, C_k$, all having f^{in} to the right and f^{out} to the left;*
2. *a curve γ in general position with respect to G, that starts in f^{in}, ends in f^{out}, intersects at most k vertices, and satisfies $\mathrm{cross}^{L \to R}(\gamma) = 0$.*

3 The crossbar construction for Eulerian graphs

We first remark that the two outcomes of Theorem 3 are the same if one considers embeddings on the sphere, while on the plane they differ only by the choice of the outer face of the embedding. Furthermore, note that all paths in $\mathcal{P}^+$ and in $\mathcal{P}^-$ intersect every constructed concentric cycle due to planarity.

In the proof of Theorem 3, without loss of generality we assume that every vertex of X is incident to one outgoing arc and one incoming arc, and these two arcs have the same second endpoint: We can achieve it by creating a pendant vertex x' for every $x \in X$, connected to x with arcs (x, x') and (x', x); note that the well-linkedness of X may drop to $\alpha/(\alpha+1)$ in this manner. Consequently, every cycle and path has no vertices in X (except for possibly some endpoints); henceforth we will implicitly use this property multiple times.

Obtaining an undirected grid. We start by applying the construction for *undirected* planar graphs from [8]. Let G^{UN} be the underlying undirected graph of G. Clearly, X is α-node-well-linked in G^{UN} and thus G^{UN} has (undirected) treewidth $\Omega(\alpha|X|)$. Hence we can obtain a large grid minor linked to the terminals X using the following theorem of [8]. In what follows, it is notationally more convenient to work with *subdivided walls as subgraphs*, instead of minors. A $t \times t$ wall and a subdivided wall are shown in Figure 3. The $(t-1)$ vertices of degree three in the top row of a $t \times t$ wall Γ are called the *interface* of the wall, denoted I_Γ.

▶ **Theorem 8** (Theorem 4.5 of [8]). *For every constant $\alpha \leq 1$, given an undirected planar graph H and an α-node-well-linked set X in H, one can in polynomial time find an integer $t = \Omega(\alpha|X|)$, a subdivided $t \times t$ wall Γ in H, and a family of t node-disjoint paths connecting X and the interface of Γ.*

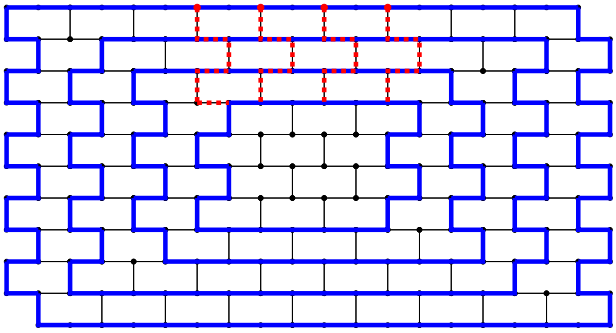

Figure 4 Illustration of Corollary 9. The cycles are blue, while the paths are dashed red.

In our construction we do not need the entire structure of a subdivided wall, but only part of it, as in the following immediate corollary (see Fig. 4).

▶ **Corollary 9.** *One can in polynomial time find an integer $r = \Omega(\alpha|X|)$ and a sequence of node-disjoint concentric undirected cycles $C_1, C_2, \ldots, C_r$ in G^{UN}, with C_1 being the outermost and C_r being the innermost cycle, with the additional property that for every $1 \leq i \leq r$ there exists r vertex-disjoint paths in G^{UN} from X to $V(C_i)$.*

Isles S^{out} and S^{in}. Let us fix a choice of r and cycles $C_1, C_2, \ldots, C_r$ stemming from Corollary 9. For a while, we work only with the undirected graph G^{UN}. Our goal is to strengthen the requirement of the existence of many undirected paths between X and the innermost and outermost cycles by getting more properties about their endpoints, so that we can use an argument similar to the one of [24] to reason about the existence of *directed* concentric cycles with similar connectivity towards X.

To this end, we identify two small connected parts of G^{UN}, S^{out} and S^{in}, one around C_1 and one around C_r. The parts will be large enough so that there is a substantial number of vertex-disjoint directed paths between them and X, but small enough so that they are placed very locally in the graph, and their boundary is small. This last property ensures that after deletion of these parts, the graph is close to Eulerian, and we can make use of Lemma 6.

For a vertex set $Q \subseteq V(G^{\mathrm{UN}})$, a vertex $v \notin Q$, and an integer $\ell \geq 2\Delta$, we say that a vertex set S is a (v, Q, ℓ)-*isle* if $v \in S$, $G^{\mathrm{UN}}[S]$ is connected, $S \cap Q = \emptyset$, and $|N_{G^{\mathrm{UN}}}(S)| \leq \ell$.[3] We will rely on the following greedy procedure, that is inspired by the enumeration algorithm for important separators in parameterized complexity (cf. [12] and [18, Chapter 8]).

▶ **Lemma 10.** *Given a set $Q \subseteq V(G^{\mathrm{UN}})$, a vertex $v \notin Q$, and an integer $\ell \geq 2\Delta$, one can in $O(\ell^3 n)$ time find an inclusion-wise maximal (v, Q, ℓ)-isle.*

Proof. We perform the following iterative procedure. Start with $S = \{v\}$; clearly, S is a (v, Q, ℓ)-isle, as $v \notin Q$ by assumption and the maximum in-degree of G is Δ. In an iterative step, we assume that S is a (v, Q, ℓ)-isle, and our goal is to check if S is an inclusion-wise maximal one, or produce a (v, Q, ℓ)-isle S' with $S \subsetneq S'$.

[3] We use the following notation with respect to neighborhoods. Let G be an undirected graph, $x \in V(G)$, and $S \subseteq V(G)$. Then $N_G(x)$ is the set of neighbors of x in G, $N_G[x] = \{x\} \cup N_G(x)$, $N_G[S] = \bigcup_{x \in S} N_G[x]$, $N_G(S) = N_G[S] \setminus S$, $N^2_G[S] = N_G[N_G[S]]$, and $N^2_G(S) = N_G(N_G[S])$.

To this end, consider every $w \in N_{G^{\text{UN}}}(S) \setminus Q$; note that, by the connectivity of S' and S, there exists such $w \in S' \setminus S$ for every isle S' we are looking for. Collapse in G^{UN} the set $S \cup \{w\}$ into a single vertex s and add a super-source vertex t adjacent to all vertices of Q. Let G' be the resultingg (undirected) graph. Find a minimum $s-t$ vertex cut Z in G', or conclude that such a minimum cut is of size larger than ℓ; this can be done using $\mathcal{O}(\ell)$ rounds of the Ford-Fulkerson algorithm, taking total time $\mathcal{O}(\ell n)$. Moreover, within this time we can find the minimum cut *closest to* t, that is, the unique one with inclusion-wise maximal set of vertices remaining in the connected component with the vertex s (cf. [18]).

If such a cut is found, let S' be the subset of vertices of G corresponding to the connected component of $G' \setminus Z$ containing the vertex s. Clearly, $N_{G^{\text{UN}}}(S') = Z$, and S' is a (v, Q, ℓ)-isle containing S and w. Otherwise, we conclude that no (v, Q, ℓ)-isle containing both S and w exists, since for every such isle S', the set $N_{G^{\text{UN}}}(S')$ is an $s-t$ cut in G' of size at most ℓ.

The computation for fixed S and w takes $\mathcal{O}(\ell n)$ time. Since S is an (v, Q, ℓ)-isle, there are at most ℓ vertices w to try. Due to the fact that we always take the $s-t$ cut closest to t, the size of the set $N_{G^{\text{UN}}}(S)$ strictly grows at every iteration (possibly except the first one, when $S = \{v\}$). Consequently, they are at most $\ell + 1$ iterations of the procedure, and the running time bound follows. ◀

We pick an arbitrary vertex v^{out} on C_1 and an arbitrary vertex v^{in} on C_r, and use Lemma 10 for both these vertices, the set $Q := X$, and threshold $\ell := \lfloor r/(4\Delta + 2) \rfloor$; recall that $|X| = \Omega(\Delta^2/\alpha)$ by the assumptions of Theorem 3 thus we may assume $\ell \geq 2\Delta$. Let S^{out} and S^{in} be the two isles obtained. Since $\ell < r$, and every cycle C_i is connected with r vertex-disjoint paths to X, no cycle C_i is contained in either S^{out} or S^{in}. Since an isle is connected, we obtain the following.

▶ **Lemma 11.** *The isle S^{out} does not contain any vertex that is enclosed by $C_{\ell+1}$, and the isle S^{in} does not contain any vertex that is not strictly enclosed by $C_{r-\ell}$.*

Proof. The proofs for S^{in} and S^{out} are symmetrical, so we just focus here on the case of S^{out}. Assume to the contrary that S^{out} contains a vertex enclosed by $C_{\ell+1}$. Since $v^{\text{out}} \in S^{\text{out}}$ and by the connectity of S^{out}, S^{out} contains a vertex from every cycle C_i, $1 \leq i \leq \ell + 1$. Since $|N_{G^{\text{UN}}}(S^{\text{out}})| \leq \ell$, for some $1 \leq i \leq \ell + 1$ we have that $V(C_i)$ is completely contained in S^{out}. However, recall that there are $r > \ell$ vertex-disjoint paths in G^{UN} connecting C_i with X. This contradicts the facts that $S^{\text{out}} \cap X = \emptyset$ and $|N_{G^{\text{UN}}}(S^{\text{out}})| \leq \ell$. ◀

By Lemma 11, the isles S^{out} and S^{in} are somewhat local in the graph: they do not go too deep into the set of cycles $C_1, C_2, \ldots, C_r$. On the other hand, recall that they are *inclusion-wise maximal* isles; by the next lemma, this ensures that they are connected by a large number of vertex-disjoint undirected paths to the set X. Let $W^{\text{out}} = N^2_{G^{\text{UN}}}[S^{\text{out}}]$ and $W^{\text{in}} = N^2_{G^{\text{UN}}}[S^{\text{in}}]$.

▶ **Lemma 12.** *In G^{UN}, there are $\ell + 1$ node-disjoint undirected paths connecting W^{out} and X and $\ell + 1$ node-disjoint undirected paths connecting W^{in} and X.*

Proof. By symmetry, we can focus on the case of W^{out}. The intuition is as follows: if there does not exist a sufficient amount of desired node-disjoint paths, then the corresponding cut would allow us to construct a strictly larger isle, a contradiction to the maximality of S^{out}. In some sense, $N_{G^{\text{UN}}}(S^{\text{out}})$ is the "last bottleneck" of size at most ℓ between v^{out} and X, and, after passing it, we should have more than ℓ paths between X and $N^2_{G^{\text{UN}}}[S^{\text{out}}] = W^{\text{out}}$.

Formally, assume the contrary of the lemma statement; by Menger's theorem, there exist vertex sets $A, B \subseteq V(G^{\text{UN}})$ such that $A \cup B = V(G^{\text{UN}})$, $|A \cap B| \leq \ell$, $W^{\text{out}} \subseteq A$, $X \subseteq B$, and no edge of G^{UN} has one endpoint in $A \setminus B$ and the second endpoint in $B \setminus A$.

Recall that $S^{\text{out}} \cap X = \emptyset$ by the definition of an isle, while $N^2_{G^{\text{UN}}}[S^{\text{out}}] = W^{\text{out}} \subseteq A$. Hence we may assume that $(N_{G^{\text{UN}}}[S^{\text{out}}] \setminus X) \subseteq (A \setminus B)$, as removing all vertices of $N_{G^{\text{UN}}}[S^{\text{out}}] \setminus X$ from B would not invalidate any of the properties of the pair (A, B). Recall also that $G^{\text{UN}}[S^{\text{out}}]$ is connected; let S_A be the vertex set of the connected component of $G^{\text{UN}} \setminus (A \cap B)$ containing S^{out}. Clearly, $S_A \subseteq A \setminus B$, so $S_A \cap X = \emptyset$. Furthermore, $N_{G^{\text{UN}}}(S_A) \subseteq A \cap B$, so $|N_{G^{\text{UN}}}(S_A)| \leq \ell$. As $S^{\text{out}} \subseteq S_A$, by the maximality of S^{out}, we infer that $S_A = S^{\text{out}}$. Since $N_{G^{\text{UN}}}[S^{\text{out}}] \setminus X \subseteq S_A$, we infer that $N_{G^{\text{UN}}}(S^{\text{out}}) \subseteq X$. However, this is a contradiction, as G^{UN} is connected and $S^{\text{out}} \subsetneq V(G^{\text{UN}}) \setminus X$. ◀

Finding directed concentric cycles. We now use the undirected cycles $C_1, C_2, \ldots, C_r$ to find a large number of node-disjoint *directed* concentric cycles separating S^{in} and S^{out}. Recall that $\ell := \lfloor r/(4\Delta + 2) \rfloor$.

▶ **Lemma 13.** *One can in polynomial time find $\lceil \ell/2 \rceil$ node-disjoint directed concentric cycles, all going in the same direction (all clockwise or all counter-clockwise), such that all vertices of S^{in} are strictly enclosed by the innermost cycle, and all vertices of S^{out} are not enclosed by the outermost cycle, or vice versa, with the roles of S^{in} and S^{out} swapped.*

Proof. Denote $G' = G \setminus (N_{G^{\text{UN}}}[S^{\text{out}}] \cup N_{G^{\text{UN}}}[S^{\text{in}}])$. Let f^{out} and f^{in} be the faces of G' that contain S^{out} and S^{in}, respectively; by Lemma 11, the cycle $C_{\lceil r/2 \rceil}$ remains in G' and $f^{\text{out}} \neq f^{\text{in}}$. Furthermore, the vertices of $N^2_{G^{\text{UN}}}(S^{\text{out}})$ lie on the face f^{out} of G', and the vertices of $N^2_{G^{\text{UN}}}(S^{\text{in}})$ lie on the face f^{in}. We apply Lemma 7 twice to the graph G' and the requirement of ℓ cycles, once for the pair of faces $(f^{\text{out}}, f^{\text{in}})$ and once for the pair $(f^{\text{in}}, f^{\text{out}})$. If at least one of the applications returns a family of cycles, then we are done, as every cycle encloses either S^{in} or S^{out}. Thus, we are left with the case when both the applications return a curve; let us denote these curves γ_1 and γ_2, respectively.

Before we proceed to the formal calculations leading to a contradiction, let us give some intuition. The curves γ_1 and γ_2 are very skewed in terms of the directions of edges crossing it: only edges in one direction are allowed, while in the second direction only ℓ vertices are allowed, and every vertex is of maximum in-degree Δ. The locality of isles S^{out} and S^{in} (Lemma 11) implies that γ_1 and γ_2 cross most of the cycles C_i; consequently, they need to cross much more than $\ell\Delta$ arcs in one direction. However, the graph G' is very close to an Eulerian one, as we have a bound of ℓ on the size of the boundary of S^{out} and S^{in}. This leads to a contradiction with Lemma 6 for a closed curve being essentially a concatenation of γ_1 and γ_2.

Formally, let us first modify the curve γ_1 to obtain a face-edge curve γ_1' as follows: whenever γ_1 crosses a vertex v, we move it slightly to avoid v, at the cost of intersecting some of the arcs incident to v. Since the maximum in-degree and out-degree of G (and thus G') is at most Δ, we have that $\text{cross}^{L \to R}(\gamma_1') \leq \Delta(\ell - 1)$. Similarly, we obtain a curve γ_2' with $\text{cross}^{L \to R}(\gamma_2') \leq \Delta(\ell - 1)$. Since γ_1' starts in f^{out} and ends in f^{in}, while γ_2' starts in f^{in} and ends in f^{out}, we can concatenate these curves (without introducing any new intersection with G') and obtain a closed face-edge curve γ'. This curve γ' visits both f^{out} and f^{in}, and satisfies

$$\text{cross}^{L \to R}(\gamma') \leq 2\Delta(\ell - 1). \tag{1}$$

By Lemma 11, the undirected cycles $C_{\ell+2}, C_{\ell+3}, \ldots, C_{r-\ell-1}$ remain in G', and both γ_1' and γ_2' need to cross at least one edge of each of these cycles. Consequently,

$$\text{cross}^{L \to R}(\gamma') + \text{cross}^{R \to L}(\gamma') \geq 2(r - 2\ell - 2). \tag{2}$$

By merging (1) and (2), and by the choice of ℓ, we obtain that:

$$-\operatorname{imb}(\gamma') = \operatorname{cross}^{R\to L}(\gamma') - \operatorname{cross}^{L\to R}(\gamma') \geq 2(r - 2\ell - 2 - 2\Delta(\ell-1)) > 4\Delta\ell. \tag{3}$$

On the other hand, note that every vertex of G' with a non-zero imbalance is a former neighbor of a vertex of $N_{G^{\text{UN}}}(S^{\text{out}} \cup S^{\text{in}})$. As there are at most 2ℓ vertices in $N_{G^{\text{UN}}}(S^{\text{out}} \cup S^{\text{in}})$, and every such vertex has in-degree and out-degree bounded by Δ, we have

$$\sum_{v \in V(G')} |\operatorname{imb}_{G'}(v)| \leq \sum_{u \in N_{G^{\text{UN}}}(S^{\text{out}} \cup S^{\text{in}})} \operatorname{indeg}_G(u) + \operatorname{outdeg}_G(u) \leq 4\Delta\ell. \tag{4}$$

Equations (3) and (4) stand in contradiction with Lemma 6. ◀

Finishing the crossbar construction. Let $C'_1, \ldots, C'_{\lceil \ell/2 \rceil}$ be the concentric directed cycles found by Lemma 13; by symmetry, assume they all enclose S^{in}. Let $q := \lceil \ell/4 \rceil$. We consider two cases, depending on whether at least half of the vertices of X are enclosed by C'_q or not. The two cases correspond to the two symmetric outcomes of Theorem 3. In what follows, we describe only the first case, when at least half of the vertices of X are enclosed by C'_q, and we use cycles $C'_1, C'_2, \ldots, C'_q$ and vertex-disjoint paths from X to W^{out}; the second case is completely symmetric, but uses cycles $C'_{q+1}, C'_{q+2}, \ldots, C'_\ell$ and paths from X to W^{in}.

Consider the set of $\ell + 1$ paths in G^{UN} connecting W^{out} and X, whose existence is promised by Lemma 12, and let X^{out} be the set of the endpoints of the paths. The vertices in X^{out} may not be enclosed by C'_q. Our goal is to find a different set of vertices that are enclosed by C'_q such that they have disjoint paths to W^{out}; we use well-linkedness of X for this purpose. As $\ell + 1 \leq |X|/2$ and the set X is α node-well-linked, for every set $X' \subseteq X$ of $\ell + 1$ vertices enclosed by C'_q, there exist $\alpha(\ell + 1)$ node-disjoint paths connecting X^{out} and X'. By combining these paths with the paths connecting W^{out} and X^{out}, we obtain a flow that sends $\alpha(\ell + 1)/2$ amount of flow in G^{UN} with unit node capacities from X' to W^{out}, with $1/2$ originating in every vertex in X'. Consequently, there exists a set $Y \subseteq X$ of size at least $\alpha(\ell + 1)/2$, whose vertices are all enclosed by C'_q, and such that there exist $|Y|$ node-disjoint paths in G^{UN} connecting Y and W^{out}.

By Lemma 5, there exist at least $(\alpha\ell - 2)/(2(\Delta + 1))$ node-disjoint directed paths from Y to W^{out} (we let $Y^+ \subset Y$ denote the end points of these paths) and the same amount of node-disjoint directed paths from W^{out} to Y (we let $Y^- \subset Y$ denote the end points of these paths). Recall that $\ell = \Theta(\alpha|X|/\Delta)$, thus $(\alpha\ell - 2)/(2(\Delta + 1)) = \Theta(\alpha^2|X|/\Delta^2)$. As no vertex of W^{out} is strictly enclosed by C'_1, these paths, together with the cycles $C'_1, C'_2, \ldots, C'_q$, form the desired structure. This concludes the proof of Theorem 3.

4 Concluding Remarks

Our main technical contribution in this paper is to show that a planar directed graph has a constant congestion routing structure of size $\Omega(h/\text{polylog}(h))$, where $h = \text{dtw}(G)$. This structural result was motivated by the algorithmic problem of routing symmetric demands in directed graphs. Recent results, in the undirected graph setting, have demonstrated effectively the inherent synergy between approximation algorithms for routing problems and structural results in graph theory related to treewidth. The work in [7] and here are steps towards extending this synergy to directed graphs. The directed graph setting is significantly more challenging, however, and progress in this direction could yield several new benefits. We raise some open problems below.

- Does a planar directed graph with treewidth h have a constant congestion crossbar of size $\Omega(h)$. This would strengthen our result. In particular, is there a cylindrical grid minor of size $\Omega(h)$?
- The techniques in this paper could likely be extended to directed graphs that can be embedded on a bounded genus surface, and more generally to directed graphs whose undirected support graph is from a proper minor-closed family. The ideas of well-linked decomposition and degree-reduction do not rely on planarity. Moreover, there is a linear relationship between treewidth and the size of a grid-minor in undirected graphs from a proper minor-closed family [19].
- Does a general directed graph with treewidth h have a constant congestion crossbar of size $\Omega(h/\text{polylog}(h))$? Is there a cylindrical grid minor of size $\Omega(h^\delta)$ for some fixed $\delta > 0$?

Quasi-4-Connected Components

Martin Grohe

RWTH Aachen University, Aachen, Germany
grohe@informatik.rwth-aachen.de

Abstract

We introduce a new decomposition of a graphs into *quasi-4-connected components*, where we call a graph *quasi-4-connected* if it is 3-connected and it only has separations of order 3 that separate a single vertex from the rest of the graph. Moreover, we give a cubic time algorithm computing the decomposition of a given graph.

Our decomposition into quasi-4-connected components refines the well-known decompositions of graphs into biconnected and triconnected components. We relate our decomposition to Robertson and Seymour's theory of tangles by establishing a correspondence between the quasi-4-connected components of a graph and its tangles of order 4.

1 Introduction

Decompositions of graphs into their connected, biconnected and triconnected components are fundamental in structural graph theory, and they also belong to the basic toolbox of algorithmic graph theory. The existence of such decompositions goes back to work of MacLane [12] from the 1930s (also see Tutte [21]). In the 1970s, Hopcroft and Tarjan [10, 20] showed that the decompositions can be computed in linear time.

In modern terms, the decompositions into biconnected and triconnected components are best described as tree decompositions. To state the decomposition theorems and also our main result, a few technical definitions are unavoidable. Recall that a *tree decomposition* of a graph G is a pair (T, β), where T is a tree and β a mapping that associates a set $\beta(t) \subseteq V(G)$, called the *bag* at t, with every node t of the tree T (subject to certain conditions; see Section 2). The *adhesion* of the decomposition is the maximum of the sizes $|\beta(t) \cap \beta(u)|$ for tree edges tu, which intuitively is the order of the separations of the decomposition. Now the decomposition into biconnected components can be phrased as follows: every graph G has a tree decomposition (T, β) of adhesion at most 1 such that for all tree nodes t the induced subgraph $G[\beta(t)]$ is either 2-connected or a complete graph of order at most 2. The decomposition into triconnected components is more complicated, mainly because the triconnected components of a graph are no longer induced subgraphs, but just topological subgraphs. We say that the *torso* of a set $X \subseteq V(G)$ of vertices of a graph G is the graph $G[\![X]\!]$ obtained from the induced subgraph $G[X]$ by adding edges vw for all distinct $v, w \in X$ such that there is a connected component C of $G \setminus X$ with $v, w \in N(C)$, the neighbourhood of C in G. For example, the torso of the set $X = \{x_1, \dots, x_4\}$ in the graph G shown in Figure 1(a) is the complete graph on X. Now the decomposition into triconnected components can be phrased as follows: every graph G has a tree decomposition (T, β) of adhesion at most 2 such that for all tree nodes t the torso $G[\![\beta(t)]\!]$ is a topological subgraph of G that is either 3-connected or a complete graph of order at most 3.

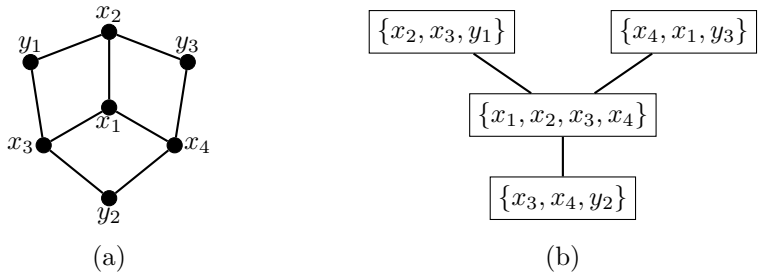

Figure 1 A graph and its decomposition into triconnected components.

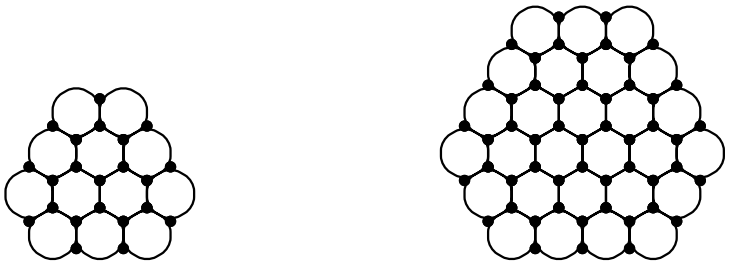

Figure 2 Hexagonal grids of radius 2 and 3.

How about decompositions into 4-connected components, or k-connected components for $k \geq 4$? At least in the clean form of the above decomposition theorems, they simply do not exist. Consider, for example, a hexagonal grid (see Figure 2). Even though the grid is not 4-connected, and it does not even have a nontrivial 4-connected subgraph, there is no good way of decomposing it in a tree-like fashion by separations of order 3. In fact, the only separations of the grid of order 3 are those splitting off a single vertex. If we ignore such separations, we may view the whole grid as one highly connected region. Let us call a graph G *quasi-4-connected* if it is 3-connected and for all separations (Y, S, Z) of order 3 (that is, $|S| = 3$ and Y, S, Z form a partition of $V(G)$ and there are no edges between Y and Z), either $|Y| \leq 1$ or $|Z| \leq 1$. Surprisingly, with this mild relaxation of 4-connectivity we get a nice decomposition theorem along the lines of the decompositions into biconnected and triconnected components.

▶ **Theorem 1** (Decomposition Theorem). *Every graph G has a tree decomposition (T, β) of adhesion at most 3 such that for all tree nodes t the torso $G[\![\beta(t)]\!]$ is a minor of G that is either quasi-4-connected or a complete graph of order at most 4.*

Furthermore, this decomposition can be computed in cubic time.

The decomposition is not unique, but the isomorphism types of the *quasi-4-connected components* into which we decompose are.

There have been earlier generalisations of the decomposition of graphs into triconnected components. The most prominent of these are Robertson and Seymour's tangles [17], which play an important role in the structure theory for graphs with excluded minors [16]. Intuitively, a tangle of order k describes a "k-connected region" in a graph by "pointing to it", that is, by assigning a direction to each separation of order less than k in such a way that "most" of the region described by the tangle is on the side the separation is directed towards. It is known that the tangles of orders 1, 2, 3 are in one-to-one correspondence to the connected, biconnected and triconnected components of a graph [17, 8]. We establish a

similar correspondence between the tangles of order 4 and the quasi-4-connected components. This is our second main theorem, which I think is interesting in its own right, but which is also essential for the proof of Theorem 1. We defer the precise technical statement of this Correspondence Theorem to Section 4 (Theorem 4).

This paper grew out of my work on descriptive complexity theory for graph classes with excluded minors [6, 5], and this may also serve as an illustration of potential applications of our Decomposition Theorem. Separations of order 3 play a special, but somewhat annoying role in the main structure theorems for graph classes with excluded minors such as the "Flat Grid Theorem" of [18] and the structure theorem of [19], and the theorems simplify for quasi-4-connected graphs. In [5] I exploited some of the main ideas underlying our Decomposition Theorem to obtain such simplifications in the context of logical definability, and I believe the Decomposition Theorem proved here may turn out to be similarly useful in an algorithmic context.[1]

Due to space limitations, I had to omit many proof details, examples, and remarks from this conference version of the paper. They can be found in the full version [7] (available on arXiv).

1.1 Related work

It was shown in [17, 1] that for every k, every graph admits a canonical decomposition into its tangles of order k. Related to this is the decomposition into so-called $(k-1)$-blocks due to [3]. An important difference between these results and ours, or rather an additional feature of our decomposition, is that the pieces of our decomposition are quasi-4-connected graphs in their own right and can be dealt with separately (for example in an algorithmic context), whereas tangles of order 4 or 3-blocks are only defined relative to the surrounding graph.

In [15, 14], a notion of k-edge connected component is considered. It is similar to the $(k-1)$-blocks, but with respect to edge connectivity.

On the algorithmic side, it was shown in [9] that the decomposition of a graph into its tangles of order k can be computed in time $n^{O(k)}$. I believe that our techniques can be used to improve this to cubic time for $k = 4$.

There is a different line of work on "k-connected components" that, as far as I can see, is unrelated to ours. There, k-connected components are simply defined as maximal k-connected subgraphs (see, for example, [13]). This leads to completely different decompositions. For example, a graph of maximum degree 3 will only have trivial 4-connected components in this framework. However, what I see as the crucial difference between our form of decomposition and this line of work is that we get *tree* decompositions. This is important for typical dynamic-programming or divide-and-conquer algorithms on the decomposition.

2 Preliminaries

We assume basic knowledge of graph theory and refer the reader to [4] for background. Our notation is standard, let us just review the most important and frequently used notations.

[1] Let me clarify the relation of this work to Chapter 10 of the forthcoming monograph [5]. The basic ideas are the same, and actually my original motivation for the present paper was to make these ideas accessible to readers not interested in logic. However, when I started to work on this paper I noticed the connection to tangles, and it is this connection that provides the right framework and also makes the decomposition much simpler. On the other hand, the main goal of [5] is to obtain a decomposition that is definable in fixed-point logic with counting, and the decomposition we obtain here is not. So, except for some of the basic lemmas underlying the proof of the Correspondence Theorem, the results are incomparable.

All graphs considered in this paper are finite and simple. The vertex set and edge set of a graph G are denoted by $V(G)$ and $E(G)$, respectively. The *order* of G is $|G| := |V(G)|$. For a set $W \subseteq V(G)$, we denote the induced subgraph of G with vertex set W by $G[W]$ and the induced subgraph with vertex set $V(G) \setminus W$ by $G \setminus W$. For a vertex v, we denote the set of neighbours of v in G by $N^G(v)$. In this and similar notations, we omit the index ^{G} if G is clear from the context. For a set $W \subseteq V(G)$, we define $N(W) := \left(\bigcup_{v \in W} N(v)\right) \setminus W$, and for a subgraph $H \subseteq G$ we let $N^G(H) := N^G(V(H))$.

A *tree decomposition* of a graph G is a pair (T, β), where T is a tree and $\beta : V(T) \to 2^{V(G)}$ such that for all $v \in V(G)$ the set $\{t \in V(T) \mid v \in \beta(t)\}$ is connected in T and for all $vw \in E(G)$ there is a $t \in V(T)$ such that $v, w \in \beta(t)$.

A *minor* of G is a graph obtained from G by deleting vertices and edges and contracting edges. A *model* of H in G consists of a family $(M_w)_{w \in V(H)}$ of mutually disjoint connected subsets of $V(G)$ and a family $(e_f)_{f \in E(H)}$ of edges of G such that for every edge $f = ww'$ of H the edge e_f has one endvertex in M_w and one endvertex in $M_{w'}$. Then H is a *minor* of G if and only if there is a model of H in G. We call the sets M_w, for $w \in V(H)$, the *branch sets* of the model $\mathcal{M}$. When reasoning about a model, it is often enough to know the branch sets.

A *faithful model* of H in G is a model $\big((M_w)_{w \in V(H)}, (e_f)_{f \in E(H)}\big)$ such that $w \in M_w$ for all $w \in V(H)$. We say that H is a *faithful minor* of G if $V(H) \subseteq V(G)$ and there is a faithful model of H in G.

Separations of a graph G are usually defined as pairs of subgraphs. However, in this paper it will be more convenient to view them as partitions of the vertex set. We say that a *separation* of G is a triple (Y, S, Z) of (possibly empty) mutually disjoint subsets of $V(G)$ such that $Y \cup S \cup Z = V(G)$ and there is no edge $vw \in E(G)$ such that $v \in Y$ and $w \in Z$. The order of the separation (Y, S, Z) is $|S|$, and the separation is *proper* if both Y and Z are nonempty. The set of all separations of G is denoted by $\mathrm{Sep}(G)$, and the subset of all separations of order less than k (at most k, exactly k) by $\mathrm{Sep}_{<k}(G)$ (resp. $\mathrm{Sep}_{\leq k}(G)$, $\mathrm{Sep}_{=k}(G)$).

A set $S \subseteq V(G)$ is a *separator* of G of *order* $k := |S|$, or a *k-separator*, if there are two vertices $v, w \in V(G) \setminus S$ such that there is a path from v to w in G, but no path from v to w in $G \setminus S$. Note that if G is connected then S is a separator if and only if there is a proper separation (Y, S, Z) of G.

A graph G is *k-connected* if $|G| > k$ and G has no proper $(k-1)$-separation.

A subset $X \subseteq V(G)$ of the vertex set of a graph G is *k-inseparable* if $|X| > k$ and there is no separation (Y, S, Z) of G of order at most k such that $X \cap Y \neq \emptyset$ and $X \cap Z \neq \emptyset$.

3 Tangles

Let G be a graph. Deviating from Robertson and Seymour's [17] original definition, we define tangles as families of separations of the vertex set (as we defined them in Section 2) rather than separations viewed as pairs of graphs or partitions of the edge set. (We show that the two notions are equivalent in the full version [7].) A *G-tangle* of order k is a family $\mathcal{T} \subseteq \mathrm{Sep}_{<k}(G)$ of separations of G of order less than k satisfying the following conditions.

(T.1) For all separations $(Y, S, Z) \in \mathrm{Sep}_{<k}(G)$ either $(Y, S, Z) \in \mathcal{T}$ or $(Z, S, Y) \in \mathcal{T}$.

(T.2) If $(Y_1, S_1, Z_1), (Y_2, S_2, Z_2), (Y_3, S_3, Z_3) \in \mathcal{T}$ then either $Z_1 \cap Z_2 \cap Z_3 \neq \emptyset$ or there is an edge $e \in E(G)$ that has an endvertex in each Z_i.

(T.3) If $(Y, S, Z) \in \mathcal{T}$ then $Z \neq \emptyset$.

For background on tangles and examples, I refer the reader to [17, 8].

Let G be a graph. We define a partial order $\preceq$ on $\mathrm{Sep}(G)$ by letting

$$(Y,S,Z) \preceq (Y',S',Z') \;:\Longleftrightarrow\; S \cup Z \subset S' \cup Z' \text{ or } \big(S \cup Z = S' \cup Z' \text{ and } S \subseteq S'\big). \tag{1}$$

For a G-tangle $\mathcal{T}$, we let $\mathcal{T}_{\min}$ be the set of minimal elements of $\mathcal{T}$ with respect to the partial order $\preceq$. The minimal elements of a tangle will play an important role later. It can be shown that if $(Y,S,Z) \in \mathcal{T}_{\min}$ then Z is connected in G and $S = N(Z)$.

It is shown in [17, 8] that the tangles of order at most 3 are in one-to-one correspondence to the connected, biconnected, and triconnected components of a graph. The following characterisation of the triconnected components motivates our definition of quasi-4-connected regions in the next section.

▶ **Proposition 2.** *Let G be a graph and $R \subseteq V(G)$. The the following are equivalent.*

1. *R is an inclusionwise maximal subset of G such that $G[\![R]\!]$ is 3-connected and a topological subgraph of G.*
2. *$G[\![R]\!]$ is 3-connected and a topological subgraph of G, and for every connected component C of $G \setminus R$ we have $|N(C)| \leq 2$.*

We call sets R satisfying the conditions of this proposition the *triconnected regions* of a graph and the graphs $G[\![R]\!]$ the *triconnected components*.

We can "lift" a tangle from a minor of a graph to the original graph. Let G be a graph, H a minor of G, and $\mathcal{M}$ a model of H in G, say, with branch sets $(M_w)_{w \in V(H)}$. For a separation $(Y,S,Z) \in \mathrm{Sep}(G)$, the *$\mathcal{M}$-projection* of (Y,S,Z) to H is the triple $\pi_{\mathcal{M}}(Y,S,Z) = (Y',S',Z')$ of subsets of $V(H)$ defined by $Y' := \big\{w \in V(H) \;\big|\; V(M_w) \subseteq Y\big\}$, $S' := \big\{w \in V(H) \;\big|\; V(M_w) \cap S \neq \emptyset\big\}$, $Z' := \big\{w \in V(H) \;\big|\; V(M_w) \subseteq Z\big\}$. It is easy to see that (Y',S',Z') is a separation of H of order $|S'| \leq |S|$.

▶ **Lemma 3** ([17])**.** *Let G be a graph, H a minor of G, and $\mathcal{M}$ a model of H in G. Let $\mathcal{T}'$ be an H-tangle of order k. Then the set $\mathcal{T}$ of all separations $(Y,S,Z) \in \mathrm{Sep}_{<k}(G)$ such that $\pi_{\mathcal{M}}(Y,S,Z) \in \mathcal{T}'$ is a G-tangle of order k.*

We call $\mathcal{T}$ be the *lifting* of $\mathcal{T}'$ to G with respect to the model $\mathcal{M}$. Clearly, the lifting may depend on the model. This is even the case if we only consider faithful minors and models.

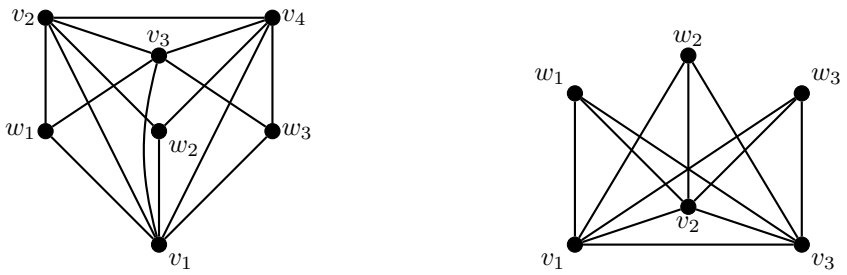
4 Tangles of Order 4

Let us now look at tangles of order 4. We restrict our attention to 3-connected graphs. This is natural; in the full version of the paper we also give a formal justification that we can do this without loss of generality. *For the rest of this section, we assume that G is a 3-connected graph.*

The main result of this section is a correspondence between tangles of order 4 and what we will call *quasi-4-connected regions* of a graph. This correspondence holds for all but a small number of *exceptional* regions, which we shall completely characterise. We first state the theorem; the necessary definitions follow.

▶ **Theorem 4** (Correspondence Theorem)**.** *With every non-exceptional quasi-4-connected region R of G we can associate a G-tangle $\mathcal{T}_R$ of order 4 and with every G-tangle $\mathcal{T}$ of order 4 a non-exceptional quasi-4-connected region $R_{\mathcal{T}}$ such that $\mathcal{T} = \mathcal{T}_{R_{\mathcal{T}}}$.*

We shall call the torsos $G[\![R_{\mathcal{T}}]\!]$ for the G-tangles of order 4 the *quasi-4-connected components* of G.



(a) the graph TH_{+3} (b) the graph TR_{+3}

Figure 3 The exceptional quasi-4-connected graphs.

In general, the mapping $R \mapsto \mathcal{T}_R$ is not injective; the mapping $\mathcal{T} \mapsto R_\mathcal{T}$ is (otherwise the theorem could not hold). The mapping $R \mapsto \mathcal{T}_R$ is *canonical* (or *isomorphism invariant*). This means that for any two graphs G, G' and regions R, R', if f is an isomorphism from G to G' that maps R to R' then f also maps $\mathcal{T}_R$ to $\mathcal{T}_{R'}$. The mapping $\mathcal{T} \mapsto R_\mathcal{T}$ is not canonical. However, the mapping from $\mathcal{T}$ to the quasi-4-connected component $G[\![R_\mathcal{T}]\!]$, viewed as an abstract graph, is.

We can only give a very high-level outline of the proof of the Correspondence Theorem.

4.1 Quasi-4-Connected Graphs and Regions

Recall from the introduction that a graph G is *quasi-4-connected* if G is 3-connected and for all separations $(Y, S, Z) \in \mathrm{Sep}_{=3}(G)$, either $|Y| \leq 1$ or $|Z| \leq 1$. A quasi-4-connected graph G is *exceptional* if it is isomorphic to a subgraph of one of the graphs TH_{+3} or TR_{+3} shown in Figure 3.

▶ **Theorem 5.** *Let G be a quasi-4-connected graph. Then G has a tangle of order 4 if and only if it is not exceptional. Furthermore, if G has a tangle of order 4, it has exactly one such tangle, which consists of all separations $(Y, S, Z) \in \mathrm{Sep}_{<4}(G)$ such that $|Y| < |Z|$.*

A *quasi-4-connected region* of G is a subset $R \subseteq V(G)$ satisfying the following conditions.

(Q.1) $G[\![R]\!]$ is a faithful minor of G.

(Q.2) $G[\![R]\!]$ is quasi-4-connected.

(Q.3) For every connected component C of $G \setminus R$ it holds that $N(C) = 3$.

While conditions (Q.1) and (Q.2) are, to some extent, natural, condition (Q.3) may seem less so. It is a (weak) maximality condition: if $R' \supset R$ such that $G[\![R']\!]$ is quasi-4-connected, then $R' \setminus R$ contains at most one vertex of every connected component C of $G \setminus R$ (unless $|R| = 4$); otherwise $N(C)$ would be separator of $G[\![R']\!]$ witnessing that it is not quasi-4-connected. Conditions (Q.1)–(Q.3) are motivated by the characterisation of the triconnected components given in Proposition 2(2). The reason for choosing these conditions instead of adding some maximality condition is simply that they work best in combination with tangles and for the Decomposition Theorem; it is condition (Q.3) which guarantees that our decomposition will have adhesion 3.

Let R be a quasi-4-connected region of G. If $G[\![R]\!]$ is a non-exceptional quasi-4-connected graph, then it has a unique tangle of order 4, and using Lemma 3, we can lift this tangle to a

G-tangle of order 4. It can be proved that the lifted tangle does not depend on the model of $G[\![R]\!]$ in G, as long as it is faithful. In this case we let $\mathcal{T}_R$ (of the Correspondence Theorem) be this lifted tangle.

However, sometimes we can even associate a tangle with a quasi-4-connected region R if $G[\![R]\!]$ is exceptional. A *non-exceptional extension* of R is a graph $\widehat{H}$ satisfying the following conditions.

(X.1) $\widehat{H}$ is a faithful minor of G.

(X.2) $\widehat{H}$ is non-exceptional quasi-4-connected.

(X.3) $R \subseteq V(\widehat{H})$, and for each connected component C of $G \setminus R$ we have $|V(\widehat{H}) \cap V(C)| \leq 1$.

(X.4) Subject to (X.1)–(X.3), $V(\widehat{H})$ is inclusionwise minimal.

We call the region R *non-exceptional* if it has a non-exceptional extension. Note that if $G[\![R]\!]$ is a non-exceptional quasi-4-connected graph, then $G[\![R]\!]$ is a non-exceptional extension of R.

If $G[\![R]\!]$ is exceptional and $\widehat{H}$ is a non-exceptional extension of R, then there is a unique $\widehat{H}$-tangle $\widehat{\mathcal{T}}$ of order 4. Let $\mathcal{I}$ be a faithful image of $\widehat{H}$ in G. Using Lemma 3, we can lift this tangle to a G-tangle $\mathcal{T}(\widehat{H}, \mathcal{I})$ of order 4. It turns out that this tangle neither depends on the choice of $\widehat{H}$ nor on the choice of $\mathcal{I}$. We let $\mathcal{T}_R := \mathcal{T}(\widehat{H}, \mathcal{I})$.

4.2 The Region of a Tangle

The goal of this section is to define the mapping $\mathcal{T} \mapsto R_{\mathcal{T}}$ from G-tangles of order 4 to quasi-4-connected regions. This is much more difficult than defining the mapping $R \mapsto \mathcal{T}_R$; technically it is clearly the most difficult part of the paper. We can only give the basic idea here. *We fix a G-tangle $\mathcal{T}$ of order 4 for the rest of the section.*

We call two separations $(Y_1, S_1, Z_1), (Y_2, S_2, Z_2) \in \mathrm{Sep}(G)$ *orthogonal* if $(Y_1 \cup S_1) \cap (Y_2 \cup S_2) \subseteq S_1 \cap S_2$. It is not hard to show that the minimal separations of a tangle of order 3 in a graph are mutually orthogonal. The minimal separations of a tangle of order 4 are not necessarily orthogonal, but the next lemma shows that they can only "cross" in a very restricted way.

▶ **Lemma 6** (Crossing Lemma). *Let $(Y_1, S_1, Z_1), (Y_2, S_2, Z_2) \in \mathcal{T}_{\min}$ be distinct. Then either (Y_1, S_1, Z_1) and (Y_2, S_2, Z_2) are orthogonal or $Y_1 \cap Y_2 = \emptyset$ and $S_1 \cap S_2 = \emptyset$ and there is an edge $s_1 s_2 \in E(G)$ such that for $i = 1, 2$ we have $S_i \cap Y_{3-i} = \{s_i\}$.*

In the latter case, we call the edge $s_1 s_2$ the crossedge *of (Y_1, S_1, Z_1) and (Y_2, S_2, Z_2).*

We call a proper separation $(Y, S, Z) \in \mathrm{Sep}_{=3}(G)$ *degenerate* if $|Y| = 1$ and S is an independent set of G. It can be shown that if (Y, S, Z) is non-degenerate then $G[\![Z]\!]$ is a faithful minor of G. We call a crossedge e of separations $(Y_1, S_1, Z_1), (Y_2, S_2, Z_2) \in \mathcal{T}_{\min}$ *non-degenerate* if the two separations are non-degenerate. The key to our proof is the following lemma (which is actually easy to prove).

▶ **Lemma 7** (Crossedge Independence Lemma[2]). *The set of non-degenerate crossedges is a matching of G.*

Let $e^1, \ldots, e^m$ be the non-degenerate crossedges of $\mathcal{T}$, and suppose that $e^i = s_1^i s_2^i$. We contract all these edges to their endvertex s_1^i. The order of the contractions is irrelevant

[2] Actually, this is only a corollary to what we call the "Crossedge Independence Lemma" in the full version [7].

because the edges form a matching. Up to isomorphism, it is also irrelevant whether we contract e^i to s_1^i or s_2^i. Let $G^{(m)}$ be the resulting graph. We show that $G^{(m)}$ is still 3-connected and has a tangle $\mathcal{T}^{(m)}$ of order 4 such that $\mathcal{T}$ is the lifting of $\mathcal{T}^{(m)}$ to G. Furthermore, $\mathcal{T}^{(m)}$ has no non-degenerate crossedges. Hence the non-degenerate separations in $\mathcal{T}^{(m)}_{\min}$ are mutually orthogonal. We let

$$R_{\mathcal{T}} := V(G^{(m)}) \setminus \bigcup_{\substack{(Y,S,Z)\in\mathcal{T}^{(m)}_{\min}\\ \text{non-degenerate}}} Y. \tag{2}$$

We show that $R_{\mathcal{T}}$ is a non-exceptional quasi-4-connected region of G and that $\mathcal{T} = \mathcal{T}_{R_{\mathcal{T}}}$.

5 Decomposition into Quasi-4-Connected Components

With the Correspondence Theorem at hand, it is now relatively easy to prove the Decomposition Theorem 1.

▶ **Theorem 8.** *Let G be a 3-connected graph. Then G has a tree decomposition (T, β) of adhesion at most 3 such that for all $t \in V(T)$, the torso $G[\![\beta(t)]\!]$ is either a complete graph K_3 or K_4 or a quasi-4-connected component of G.*

Furthermore, such a decomposition can be computed in time $O(n^2(n+m))$.

Here, and throughout this section, we denote the numbers of vertices and edges of the input graph G of our algorithms by n and m, respectively.

The Decomposition Theorem 1 follows by combining the decomposition of Theorem 8 with the standard decomposition of a graph into its triconnected components.

The proof of Theorem 8 requires some preparation. For the rest of this section, we assume that G is a 3-connected graph. Let $(Y, S, Z) \in \mathrm{Sep}_{=3}(G)$ be non-degenerate. A *split vertex* of (Y, S, Z) is a vertex $z \in Z$ such that for every connected component C of $G \setminus (S \cup \{z\})$ it holds that $|N(C)| = 3$.

▶ **Lemma 9.** *Let $(Y_0, S_0, Z_0) \in \mathrm{Sep}_{=3}(G)$ be a non-degenerate proper separation such that Z_0 is connected and (Y_0, S_0, Z_0) has no split vertex. Then the set $\mathcal{T}(Y_0, S_0, Z_0)$ of all separations $(Y, S, Z) \in \mathrm{Sep}_{<4}(G)$ such that either $Z_0 \subseteq Z$ or $|Z \cap S_0| > |Y \cap S_0|$ is a G-tangle of order 4.*

Proof. Let $\mathcal{T} := \mathcal{T}(Y_0, S_0, Z_0)$. To see that $\mathcal{T}$ satisfies (T.1), let $(Y, S, Z) \in \mathrm{Sep}_{<4}(G)$. If $S \subseteq Y_0 \cup S_0$, then the connected set Z_0 is either a subset of Z or of Y, and thus either $(Y, S, Z) \in \mathcal{T}$ or $(Z, S, Y) \in \mathcal{T}$. Suppose next that $|S \cap Z_0| = 1$. Let z be the unique vertex in $S \cap Z_0$. Then z is not a split vertex of (Y_0, S_0, Z_0), and hence there is a connected component C of $G \setminus (S_0 \cup \{z\})$ such that $N(C) = S_0 \cup \{z\}$. Then $V(C) \subseteq Z_0$, because $z \in Z_0$, and thus $V(C) \cap S = \emptyset$. It follows that either $V(C) \subseteq Y$ or $V(C) \subseteq Z$. Without loss of generality we may assume that $V(C) \subseteq Z$. As $S_0 \subseteq N(C)$, this implies $S_0 \setminus S \subseteq Z$. As $S_0 \setminus S \neq \emptyset$, it follows that $(Y, S, Z) \in \mathcal{T}$. Finally, suppose that $|S \cap Z_0| \geq 2$. If $S \cap S_0 = \emptyset$, then either $|Z \cap S_0| \geq 2$ or $|Y \cap S_0| \geq 2$, and thus either $(Y, S, Z) \in \mathcal{T}$ or $(Z, S, Y) \in \mathcal{T}$. If $|S \cap S_0| = 1$, then $S \cap Y_0 = \emptyset$, and as G is 3-connected and $Y_0 \neq \emptyset$, the vertices in $S_0 \setminus S$ belong to the same connected component of $G \setminus S$. Hence either both are in Z or both are in Y, and again it follows that either $(Y, S, Z) \in \mathcal{T}$ or $(Z, S, Y) \in \mathcal{T}$.

Observe next that $|V(G)| \geq 6$, because $|Y_0| \geq 1$ and $|S_0| = 3$ and $|Z_0| \geq 2$ (otherwise the unique vertex in Z_0 would be a split vertex).

▶ **Claim 10.** *For all $(Y, S, Z) \in \mathcal{T}$ we have $|S \cup Z| \geq 4$.*

Proof. It follows from the definition of $\mathcal{T}$ that $Z \neq \emptyset$. If $Y = \emptyset$, then $|S \cup Z| = |V(G)| \geq 6$. Otherwise, (Y, S, Z) is a proper separation and thus $|S| = 3$, which implies $|S \cup Z| \geq 4$. ◀

The claim implies that $\mathcal{T}$ satisfies (T.3).

To prove that $\mathcal{T}$ satisfies (T.2), let $(Y_i, S_i, Z_i) \in \mathcal{T}$ for $i = 1, 2, 3$. Suppose for contradiction $Z_1 \cap Z_2 \cap Z_3 = \emptyset$ and that there is no edge that has an endvertex in each Z_i.

▶ **Claim 11.** *For distinct $i, j, k \in [3]$ and $x \in V(G)$, if $x \in Z_i \cap Z_j$ then $x \in Y_k$.*

Proof. We have $x \notin Z_k$, because $Z_i \cap Z_j \cap Z_k = \emptyset$. Suppose that $x \in S_k$, and let $z \in N(x) \cap Z_k$. Such a z exists, because $Z_k \neq \emptyset$ and $N(Z_k) \subseteq S_k$, and as $|S_k| \leq 3$ and G is 3-connected, this implies $N(Z_k) = S_k$. But the edge xz has an endvertex in every Z_i, which contradicts our assumption that no such edge exists. ◀

Case 1: There is an $i \in [3]$ such that $S_i \subseteq Y_0 \cup S_0$. Without loss of generality, we may assume that $i = 1$ and $(Y_1, S_1, Z_1) = (Y_0, S_0, Z_0)$. We may further assume that $S_i \not\subseteq Y_0 \cup S_0$ for $i = 2, 3$. Then $|Z_i \cap S_0| > |Y_i \cap S_0|$.

By Claim 11 we have $Z_2 \cap Z_3 \cap S_0 = Z_2 \cap Z_3 \cap S_1 = \emptyset$. Thus for some $i \in \{2, 3\}$ $|Z_i \cap S_0| < 2$. Without loss of generality we assume $|Z_2 \cap S_0| < 2$. Then $|Y_2 \cap S_0| = \emptyset$ and thus $|S_2 \cap S_0| = 2$. Since $S_2 \not\subseteq Y_0 \cup S_0$, we have $|S_2 \cap Z_0| = 1$. As the vertex in $S_2 \cap Z_0$ is not a split vertex, there is a connected component C of $G \setminus (S_0 \cup S_2)$ such that $N(C) = S_0 \cup S_2$. Then $V(C) \subseteq Z_0 \cap Z_2 = Z_1 \cap Z_2$. Now let $v \in Z_3 \cap S_0$, and let $w \in V(C)$ be adjacent to v. Then the edge vw has an endvertex in each Z_i.

Case 2: $|S_i \cap Z_0| \neq \emptyset$ for all $i \in [3]$. Then $|Z_i \cap S_0| > |Y_i \cap S_0|$. If $|Z_i \cap Z_j \cap S_0| = \emptyset$ for all $i \neq j$, then $|Z_i \cap S_0| = 1$ and thus $|Y_i \cap S_0| = 0$ for all i. Thus $|S_i \cap S_0| = 2$ and $|S_i \cap Y_0| = \emptyset$, because $S_i \not\subseteq S_0 \cup Y_0$. But this implies $Y_0 \subseteq Z_1 \cap Z_2 \cap Z_3$, which is a contradiction.

Hence without loss of generality we may assume that $Z_1 \cap Z_2 \cap S_0 \neq \emptyset$. Let $s \in Z_1 \cap Z_2 \cap S_0$. Then by Claim 11, $s \in Y_3$. Then $|Y_3 \cap S_0| \geq 1$, and this implies $|Z_3 \cap S_0| \geq 2$. Let $s', s'' \in Z_3 \cap S_0$. Then $S_0 = \{s, s', s''\}$.

If $|S_3 \cap Z_0| \leq 1$, there is a connected component C of $G \setminus (S_0 \cup S_3)$ such that $N(C) = S_0 \cup S_3$. But then there is a path from $s \in Y_3$ to $s' \in Z_3$ in $G \setminus S_3$, which is impossible. Hence $|S_3 \cap Z_0| \geq 2$.

Thus $|S_3 \cap Y_0| \leq 1$. Since G is a 3-connected and $Y_0 \neq \emptyset$, there is a path from s to $\{s', s''\}$ with all internal vertices in Y_0. Hence $|Y_0 \cap S_3| = 1$, and the unique vertex $y \in Y_0 \cap S_3$ separates $s \in Y_3$ from $\{s', s''\} \subseteq Z_3$ in the graph $G[Y_0 \cup S_0]$. Then $ss', ss'' \notin E(G)$. Furthermore, $sy \in E(G)$ and y is the only neighbour of s in $Y_0 \cup S_0$, because otherwise $\{y, s\}$ would be separator of G. By Claim 11 and because $y \in S_3$, we have $y \notin Z_1 \cap Z_2$. Say, $y \notin Z_2$. Then $y \in S_2$, because y is adjacent to $s \in Z_2$. As $S_2 \not\subseteq Y_0 \cup S_0$, it now follows that s' and s'' are not both in S_2. As $|Z_2 \cap S_0| > |Y_2 \cap S_2|$, one of these vertices, say, s' is in Z_2.

By Claim 11, $s' \in Z_2 \cap Z_3$ implies $s' \in Y_1$. Arguing as above with (Y_1, S_1, Z_1) instead of (Y_3, S_3, Z_3), we see that $Z_1 \cap S_0 = \{s, s''\}$ and $|S_1 \cap Z_0| = 2$ and $|S_1 \cap Y_0| = 1$, and the unique vertex $y' \in S_1 \cap Y_0$ separates s' from s, s'' in G. Furthermore, $s's, s's'' \notin E(G)$, and $s'y' \in E(G)$ and y' is the only neighbour of s' in $Y_0 \cup S_0$.

Now we have $s'' \in Z_1 \cap Z_3$, and again by the same argument we see that $s'' \in Y_2$ and $Z_2 \cap S_0 = \{s, s'\}$ and $|S_2 \cap Z_0| = 2$ and $|S_2 \cap Y_0| = 1$ and the unique vertex $y'' \in S_1 \cap Y_0$ separates s' from s, s'' in G. Furthermore, $s''s, s''s' \notin E(G)$, and $s''y'' \in E(G)$ and y'' is the only neighbour of s'' in $Y_0 \cup S_0$.

Let us rename the vertices s, s', s'' to s_{12}, s_{23}, s_{13} and the vertices y, y', y'' to y_{12}, y_{23}, y_{13}. Then for distinct i, j, k we have $s_{ij} \in S_0 \cap Z_i \cap Z_j \cap Y_k$ and $S_k \cap Y_0 = \{y_{ij}\}$ and $N(s_{ij}) \cap$

$(Y_0 \cup S_0) = \{y_{ij}\}$. Note that this implies that $S_0 = \{s_{12}, s_{13}, s_{23}\}$ is an independent set. Moreover, $Y_0 \setminus \{y_{ij}\} \subseteq Z_k$, because all $y \in Y_0 \setminus \{y_{ij}\}$ are reachable in $G[Y_0 \cup S_0] \setminus \{y_{ij}\}$ by a path from $\{s_{ik}, s_{jk}\} \subseteq Z_k$.

As the separation (Y_0, S_0, Z_0) is non-degenerate and S_0 is an independent set, we have $|Y_0| > 1$. Since $N(S_0) = \{y_{12}, y_{23}, y_{13}\}$ and $N(y_{ij}) \cap S_0 = \{s_{ij}\}$ and G is 3-connected, it is easy to see that this implies that the vertices y_{ij} are mutually distinct. Now let $e = vw$ be an arbitrary edge of $G[Y_0]$. Such an edge exists, and it has an endvertex in each Z_k. Again, this is a contradiction. ◀

Let $W, X \subseteq V(G)$. Then a (W, X)-*separation* is a separation (Y, S, Z) such that $W \subseteq Y \cup S$ and $X \subseteq Z \cup S$. It is *proper* if $W \cap Y \neq \emptyset$ and $X \cap Z \neq \emptyset$. A (proper) (W, X)-separation (Y, S, Z) is *minimum* if its order is minimal, that is, there is no (proper) (W, X)-separation (Y', S', Z') such that $|S'| < |S|$. It is *leftmost minimum* if it is minimum and, subject to this condition, Y is inclusionwise minimal. It can be shown by a standard submodularity argument that there always is a unique leftmost minimum (W, X)-separation. There is not necessarily a unique leftmost minimum proper (W, X)-separation, but the number of such separations is (polynomially) bounded in terms of k.

▶ **Lemma 12.** *Let $k \geq 1$. Then there is a linear time algorithm that, given a graph G and sets $W, X \subseteq V(G)$, decides if there is a proper (W, X)-separation of order at most k, and if there is computes the set of all leftmost minimum proper (W, X)-separations.*

Let us say that a separation $(Y_0, S_0, Z_0) \in \mathrm{Sep}_{=3}(G)$ *defines* a tangle if (Y_0, S_0, Z_0) is non-degenerate and Z_0 is connected in G and (Y_0, S_0, Z_0) has no split vertex. Then the tangle *defined by* (Y_0, S_0, Z_0) is $\mathcal{T}(Y_0, S_0, Z_0)$ (of Lemma 9).

▶ **Lemma 13.** *There is an algorithm that, given a 3-connected graph G and a separation (Y_0, S_0, Z_0) of G of order 3 defining the tangle $\mathcal{T} = \mathcal{T}(Y_0, S_0, Z_0)$, computes the set of all non-degenerate separations in $\mathcal{T}_{\min}$ and the set of all non-degenerate crossedges of $\mathcal{T}$ in time $O(n(n+m))$.*

Proof. We show how to compute the set $\mathcal{T}_{\min}$; then we can easily filter out the non-degenerate separations.

Let $x \in Z_0$. Observe that if (Z, S, Y) is a proper $(S_0, \{x\})$-separation of order at most 3, then $(Y, S, Z) \in \mathcal{T}$. This follows immediately from the definition of $\mathcal{T}$. It implies the following equivalence for every separation (Y, S, Z) of G of order 3.

1. $(Y, S, Z) \in \mathcal{T}_{\min}$ and (Y, S, Z) does not cross (Y_0, S_0, Z_0).
2. There is an $x \in Z_0$ such that (Z, S, Y) is a leftmost minimum proper $(S_0, \{x\})$-separation.

We can use this equivalence to compute the set of all $(Y, S, Z) \in \mathcal{T}_{\min}$ such that (Y, S, Z) does not cross (Y_0, S_0, Z_0) (repeatedly applying the algorithm of Lemma 12 to all $x \in Z_0$). Note that the equivalence also gives us a linear bound on the number of such (Y, S, Z).

It remains to deal with the $(Y, S, Z) \in \mathcal{T}_{\min}$ crossing (Y_0, S_0, Z_0). For each $s \in S_0$ that has a unique neighbour $y \in Y_0 \cup S_0$, the edge sy may be a crossedge. This gives us at most three potential crossedges, and we deal with them separately. So let $s \in S$ and $y \in Y_0$ such that $N(s) \cap (Y_0 \cap S_0) = \{y\}$. Then for every separation $(Y, S, Z) \in \mathrm{Sep}_{=3}(G)$ the following are equivalent.

3. $y \in S$ and $\big(Z \cap (S_0 \cup Z_0), S \cap (S_0 \cup Z_0), Y \cap (S_0 \cup Z_0)\big)$ is a leftmost minimum proper $(S \setminus \{s\}, \{s\})$-separation in the graph $G[S_0 \cup Z_0]$.
4. $(Y, S, Z) \in \mathcal{T}_{\min}$ and (Y, S, Z) crosses (Y_0, S_0, Z_0) with crossedge ys.

To see this, note that (3) implies that $|S \cap Z_0| = 2$, because (Y_0, S_0, Z_0) has no split vertex. The equivalence between (3) and (4) allows us to compute the remaining separations in $\mathcal{T}_{\min}$.

As we have an overall linear bound on the number of separations in $\mathcal{T}_{\min}$, we can easily compute the set of non-degenerate crossedges. ◀

Let us a call a 3-separator S of G *degenerate* if there is a connected component C of $G \setminus S$ such that the separation $(G \setminus (S \cup V(C)), S, V(C))$ is degenerate. It is easy to see that this is the case if and only if S is an independent set and $G \setminus S$ has exactly two connected components, one of which has order 1.

▶ **Lemma 14.** *There is an a algorithm that, given a 3-connected graph G, decides if G has a non-degenerate 3-separator and computes one if there is in time $O(n^2(n+m))$.*

Proof. We first test if there is an $S \subseteq V(G)$ such that $|S| = 3$ and all connected components of $G \setminus S$ have order 1. In this case, S is a non-degenerate 3-separator if $|G| \geq 6$ or if $|G| \geq 5$ and S is not an independent set.

In the following, we assume that for every $S \subseteq V(G)$ such that $|S| = 3$ there is at least one connected components C of $G \setminus S$ such that $|C| \geq 2$. Now suppose that S is a non-degenerate 3-separator of G. Let Y be the vertex set of a connected component of G of size $|Y| \geq 2$, and let $Z := V(G) \setminus (S \cup Y)$. Let $y \in Y$ and $z \in Z$.

Then there is a leftmost minimum proper $(\{y\}, \{z\})$-separation (Y', S', Z') with $Y' \cup S' \subseteq Y \cup S$, because (Y, S, Z) is a minimum proper $(\{y\}, \{z\})$-separation. The separator S' is non-degenerate unless $Y' = \{y\}$ and S' is an independent set. Then $S' = N(y)$. However, in this case there is a leftmost minimum proper $(S', \{z\})$ separation (Y'', S'', Z'') such that S'' is non-degenerate. To see this, let $y' \in N(y) \cap Y$. Then there is a proper leftmost minimum $(S', \{z\})$ separation (Y'', S'', Z'') with $y, y' \in Y''$ and $Y'' \cup S'' \subseteq Y \cup S$, because (Y, S, Z) is a minimum proper $(S', \{z\})$ separation with $y, y' \in Y$. The set S'' is a non-degenerate 3-separator.

Thus we can find a non-degenerate 3-separator as follows. For all pairs y, z of distinct vertices, we compute all leftmost minimum proper $(\{y\}, \{z\})$-separations (Y', S', Z') and check if there is one such that S' is a non-degenerate 3-separator. If y has degree 3 and $S' := N(y)$ is an independent set, we also compute all leftmost minimum proper $(S', \{z\})$ separations (Y'', S'', Z'') and check if S'' is a non-degenerate 3-separator. ◀

Proof of Theorem 8. If G has no non-degenerate 3-separator, then G is quasi-4-connected, and we return the trivial tree decomposition with a one-node tree. In the following, we assume that G has at least one non-degenerate 3-separator.

We view the tree T in the tree decomposition as directed with all edges pointing away from the root, and we denote the descendant order in the tree by $\trianglelefteq$. With each (directed) edge $e = (s, t)$ of the tree we associate a separation $\mathrm{sep}(s, t) = (Y, S, Z)$ of order 3 such that Z is connected in G and $S = \beta(t) \cap \beta(s)$ and $S \cup Z = \bigcup_{u \geq t} \beta(u)$.

We build the tree decomposition iteratively starting from the root r of the tree. We pick an arbitrary non-degenerate 3-separator S_r of G and let $\beta(r) := S_r$. For every connected component C of $G \setminus S_r$ we create a child t of r, and we let $\mathrm{sep}(r, t) := (V(G) \setminus (S_r \cup V(C)), S_r, V(C))$.

At every step of the construction, we pick a leaf t of the current tree such that $\beta(t)$ is not yet defined. Let s be the parent of t and $\mathrm{sep}(s, t) = (Y_0, S_0, Z_0)$.

Case 1: $|Z_0| \leq 1$. Then $|S_0 \cup Z_0| \leq 4$, and we let $\beta(t) := S_0 \cup Z_0$. The node t will remain a leaf of the final tree.

Case 2: $|Z_0| > 1$ and (Y_0, S_0, Z_0) has a split vertex $z_0 \in Z_0$. Then we let $\beta(t) := S_0 \cup \{z_0\}$. For every connected component C of $G \setminus (S_0 \cup \{z_0\})$ with $V(C) \subseteq Z_0$ we create a child u of t and let $\mathrm{sep}(t,u) := (V(G) \setminus (N(C) \cup V(C)), N(C), V(C))$.

Case 3: $|Z_0| > 1$ and (Y_0, S_0, Z_0) has no split vertex. Let $\mathcal{T} = \mathcal{T}(Y_0, S_0, Z_0)$ be the G-tangle of Lemma 9. Note that $(Y_0, S_0, Z_0) \in \mathcal{T}_{\min}$. Let $R_{\mathcal{T}}$ be the quasi-4-connected region associated with $\mathcal{T}$. When contracting the non-degenerate crossedges that involve S_0, we make sure that we contract them to their endvertices in S_0. Then $S_0 \subseteq R_{\mathcal{T}}$ and $Y_0 \cap R_{\mathcal{T}} = \emptyset$. We let $\beta(t) := R_{\mathcal{T}}$.

For every connected component C of $G \setminus R_{\mathcal{T}}$ we create a child u of t and let $\mathrm{sep}(t,u) := (V(G) \setminus (N(C) \cup V(C)), N(C), V(C))$.

The completes the description of our construction. We need to describe a time $O(n^2(n+m))$-algorithm implementing it. By Lemma 14, we can compute a non-degenerate 3-separator S_r (for the root r) within this time if there is one.

Now we show that we can handle every step of the construction in time $O(n(n+m))$. So let t be a leaf of the current tree, s its parent, and $(Y_0, S_0, Z_0) := \mathrm{sep}(s,t)$. Case 1 is easy. For Case 2, we need to compute all connected components of $G \setminus (S_0 \cup \{z\})$ for all $z \in Z_0$, which we can do in time $O(n(n+m))$. For Case 3, we need to compute $\mathcal{T}_{\min}$ and $R_{\mathcal{T}}$ for the tangle $\mathcal{T} = \mathcal{T}(Y_0, S_0, Z_0)$, and Lemma 13 allows us to do this. ◀

Note that the results of Section 4, in particular the Correspondence Theorem 4, are used in Case 3 of the proof of Theorem 8 (and this is the only place in the proof where they are used).

▶ Remark. Let (T, β) be tree decomposition of G into quasi-4-connected components. The G-tangles of order 4 are associated with all nodes t such that either $|\beta(t)| \geq 5$ or $|\beta(t)| = 4$ and for each subset $S \subseteq \beta(t)$ of size $|S| = 3$ there is a neighbour u of t such that $\beta(u) \cap \beta(t) = S$. In the second case, the neighbours of t allow us to find a non-exceptional extension of the quasi-4-connected region $\beta(t)$.

6 Conclusions

Relaxing 4-connectedness, we introduce the notion of quasi-4-connectedness of graphs and prove that every graph has a decomposition into quasi-4-connected components. We show that the quasi-4-connected components correspond to the tangles of order 4, putting our result in the context of recent work on tangles and decompositions [1, 2, 3, 9, 11, 17]. Furthermore, we prove that our decomposition can be computed in cubic time. Although we do not explore this in the present paper, I believe that the decomposition may turn out to be a useful algorithmic tool, just like the decomposition into 3-connected components (though maybe not quite as broadly applicable).

The most obvious question is whether our result has a generalisation to "quasi-k-connected components", whatever they may be, for $k \geq 5$. I am skeptical, because we exploit many special properties of separators of order 3 here, most importantly the limited way in which they can cross. However, our decomposition is not a straightforward generalisation of the decomposition into 3-connected components either, and it may well be that new ideas lead to perfectly nice decompositions of higher order.

Finally, in particular when thinking of applications, it would be desirable to have a decomposition algorithm working in quadratic or even in linear time. I see no fundamental obstructions to the existence of such an algorithm.

Abstract

We establish the complexity of several graph embedding problems: Subgraph Isomorphism, Graph Minor, Induced Subgraph and Induced Minor, when restricted to H-minor free graphs. In each of these problems, we are given a pattern graph P and a host graph G, and want to determine whether P is a subgraph (minor, induced subgraph or induced minor) of G. We show that, for any fixed graph H and $\epsilon > 0$, if P is H-Minor Free and G has treewidth tw, (induced) subgraph can be solved $2^{O(k^\epsilon tw + k/\log k)} n^{O(1)}$ time and (induced) minor can be solved in $2^{O(k^\epsilon tw + tw \log tw + k/\log k)} n^{O(1)}$ time, where $k = |V(P)|$.

We also show that this is optimal, in the sense that the existence of an algorithm for one of these problems running in $2^{o(n/\log n)}$ time would contradict the Exponential Time Hypothesis. This solves an open problem on the complexity of Subgraph Isomorphism for planar graphs.

The key algorithmic insight is that dynamic programming approaches can be sped up by identifying isomorphic connected components in the pattern graph. This technique seems widely applicable, and it appears that there is a relatively unexplored class of problems that share a similar upper and lower bound.

1 Introduction

We study several problems related to recognizing a pattern graph P as substructure of a host graph G: Subgraph Isomorphism, Induced Subgraph, Graph Minor and Induced Minor. We consider the case in which P excludes a specific minor H, $\epsilon > 0$ is a constant and give algorithms parameterized by the treewidth tw of G and the number of vertices k of

P. Specifically, we show that for any $\epsilon > 0$ and graph H, if P is H-minor free and G has treewidth tw, (induced) subgraph can be solved $2^{O(k^\epsilon tw + k/\log k)} n^{O(1)}$ time and (induced) minor can be solved in $2^{O(k^\epsilon tw + tw \log tw + k/\log k)} n^{O(1)}$ time.

The $k/\log k$ dependence in the exponent is optimal: we present lower bounds based on the Exponential Time Hypothesis, showing that all these problems can not be solved in time $2^{o(n/\log n)}$, even when P is a tree and G is connected and series-parallel (and thus planar). Our lower bound answers a question of Marx [24] negatively: assuming the ETH, there is no $2^{O(\sqrt{k})} n^{O(1)}$ algorithm for subgraph isomorphism on planar graphs. This result is surprising, since for many problems on planar graphs a square root does appear in the exponent.

As an important special case of our result, we show that subgraph isomorphism can be solved in time $2^{O(k^\epsilon \sqrt{n} + k/\log k)}$ on H-Minor Free graphs (which includes planar, bounded-treewidth and bounded-genus graphs). Our result can be combined with a recent result of Fomin et al. [17] to show that subgraph isomorphism can be solved in $2^{O(k/\log k)} n^{O(1)}$ if P is connected and G is apex-minor free, which our lower bound shows is optimal (under ETH).

Subgraph isomorphism has received considerable attention in the literature. Results include polynomially solvable cases, such as recognizing a fixed pattern in planar graphs [13, 15], biconnected outerplanar graphs [22], graphs of log-bounded fragmentation [20] and graphs of bounded genus [10] and certain subclasses of graphs of bounded treewidth [26], exact algorithms [30], lower bounds [19, 11, 28] and results on parameterized complexity [25].

For a pattern graph P of treewidth t, subgraph isomorphism is solvable in $2^{O(k)} n^{O(t)}$ time using the color-coding technique [3]. If the host graph is planar, subgraph isomorphism can be solved in $2^{O(k)} n$ time [13]. In general graphs, subgraph isomorphism can be solved in $2^{O(n \log n)}$ time and, assuming the ETH, this is tight [16].

Graph minor problems are also of interest, especially in the light of Robertson and Seymour's seminal work on graph minor theory (see e.g. [29]) and the recent development of bidimensionality theory [12]. Many graph properties can be tested by checking for the inclusion of some minor. Testing whether a graph G contains a fixed minor P can be done in $O(n^3)$ time [27], this was recently improved to $O(n^2)$ [21]. However, the dependence on n is superexponential in a strong sense. Testing whether a graph P is a minor of a planar graph G can be done in $2^{O(k)} n^{O(1)}$ time [1], which is only single-exponential. Our lower bound shows this running time can not be improved to $2^{o(k/\log k)}$, assuming ETH. Our algorithms are subexponential in k, but (in contrast to [1, 21]) superpolynomial in n. This is to our knowledge the first subexponential minor testing algorithm (for a non-trivial class of graphs).

Our algorithms are based on dynamic programming on tree decompositions. In particular, we use dynamic programming on the host graph and store correspondences to vertices in the pattern graph. The key algorithmic insight is that this correspondence may or may not use certain connected components of the pattern graph (that remain after removing some separator vertices). Instead of storing for each component whether it is used or not, we identify isomorphic connected components and store only the number of times each is used.

In [20], the authors give an algorithm for subgraph isomorphism, which runs in polynomial time for a host graph of bounded treewidth and a pattern graph of log-bounded fragmentation (i.e. removing a separator decomposes the graph into at most logarithmically many connected components). This is achieved using a similar dynamic programming technique, which (in general) uses time exponential in the number of connected components that remain after removing a separator. By assuming the number of connected components (fragmentation) is logarithmic, the authors obtain a polynomial time algorithm. In contrast, we consider a graph class where fragmentation is unbounded, but the number of non-isomorphic connected components is small. This leads to subexponential algorithms.

This paper builds on techniques due to Bodlaender, Nederlof and van Rooij [7, 9]. They give a $2^{O(n/\log n)}$-time algorithm for finding tree decompositions with few bags and a matching lower bound (based on the Exponential Time Hypothesis), and a $2^{O(n/\log n)}$ algorithm for determining whether a given k-colored graph is a subgraph of a properly colored interval graph. These earlier papers, coupled with our results, suggest that this technique may have many more applications, and that there exists a larger class of problems sharing this upper and lower bound.

2 Preliminaries

Graphs. Given a graph G, we let $V(G)$ denote its vertex set and $E(G)$ its edge set. Given $X \subseteq V(G)$, let $G[X]$ denote the subgraph of G induced by X and use shorthand $E(X) = E(G[X])$. Let $Nb(v)$ denote the neighbourhood of v, that is, the vertices adjacent to v. For a set of vertices S, let $Nb(S) = \cup_{v \in S} Nb(v) \setminus S$. Let $CC(G)$ denote the set of the connected components of G. Given $X \subseteq V(G)$, we write as shorthand $CC(X) = CC(G[X])$.

Functions. Given a function $f : A \to B$, we let $f^{-1}(b) = \{a \in A \mid f(a) = b\}$. Depending on the context, we may also let $f^{-1}(b)$ denote (if it exists) the unique $a \in A$ so that $f(a) = b$. We say $g : A \to B$ is a *restriction* of $f : A' \to B'$ if $A \subseteq A'$ and $B \subseteq B'$ and for all $a \in A$, $g(a) = f(a)$. We say g is an *extension* of f if f is a restriction of g.

Isomorphism. We say a graph P is isomorphic to a graph G if there is a bijection $f : V(P) \to V(G)$ so that $(u, v) \in E(P) \iff (f(u), f(v)) \in E(G)$. We say a graph P is a subgraph of G if we can obtain a graph isomorphic to P by deleting edges and or vertices from G, and we say P is an induced subgraph if we can obtain it by deleting only vertices.

Contractions, minors. We say a graph G' is obtained from G by contracting edge (u, v), if G' is obtained from G by replacing vertices u, v with a new vertex w which is made adjacent to all vertices in $Nb(u) \cup Nb(v)$. A graph G' is a minor of G if a graph isomorphic to G' can be obtained from G by contractions and deleting vertices and/or edges. G' is an induced minor if we can obtain it by contractions and deleting vertices (but not edges).

Tree decompositions. A tree decomposition of a graph G is a rooted tree T with for every vertex $i \in V(T)$ a bag $X_i \subseteq V(G)$, such that $\cup_{i \in V(T)} X_i = V(G)$, for all $(u, v) \in E(G)$ there is an $i \in V(T)$ so that $\{u, v\} \subseteq X_i$ and for all $v \in V(G)$, $T[\{i \in V(T) \mid v \in X_i\}]$ is connected. The *width* of a tree decomposition is $\max_{i \in V(T)} |X_i| - 1$ and the *treewidth* of a graph G is the minimum width over all tree decompositions of G. For a node $t \in T$, we let $G[t]$ denote the subgraph of G induced by the vertices contained in the bags of the subtree of T rooted at t.

To simplify our algorithms, we assume that a tree decomposition is given in *nice* form, where each node is of one of four types:

- **Leaf**: A leaf node is a leaf $i \in T$, and $|X_i| = 1$.
- **Introduce**: An introduce node is a node $i \in T$ that has exactly one child $j \in T$, and X_i differs from X_j only by the inclusion of one additional vertex.
- **Forget**: An introduce node is a node $i \in T$ that has exactly one child $j \in T$, and X_i differs from X_j only by the removal of one vertex.
- **Join**: A join node is a node $i \in T$ with exactly two children $j, k \in T$, so that $X_i = X_j = X_k$.

A tree decomposition can be converted to a nice tree decomposition of the same width and of linear size in linear time [5].

3 Algorithmic Results

We begin by describing our algorithm for subgraph isomorphism, which is based on dynamic programming on a tree decomposition T of the host graph G. The algorithm is somewhat similar to that of Hajiaghayi et al. [20] for subgraph isomorphism on log-bounded fragmentation graphs, and we use similar notions of (extensible) partial solutions and characteristic of a partial solution (Section 3.1). Our main contribution is the canonization technique (Section 3.2) and its analysis (Section 3.3), which gives the subexponential running time.

3.1 An algorithm for Subgraph Isomorphism

▶ **Definition 1** ((Extensible) Partial Solution)**.** For a given node $t \in T$ of the tree decomposition of G, a *partial solution (relative to t)* is a triple (G', P', ϕ) where G' is a subgraph of $G[t]$, P' is an induced subgraph of P and $\phi : V(G') \to V(P')$ is an isomorphism from G' to P'.

Say that a partial solution (G', P', ϕ) relative to t is *extensible* if there exists an extension of ϕ, $\psi : V(G'') \to V(P)$ which is an isomorphism from a subgraph G'' of G to P where $V(G'') \cap V(G[t]) = V(G')$.

To facilitate dynamic programming, at node t of the tree decomposition we only consider partial solutions (G', P', ϕ) which *might* be extensible (i.e. we attempt to rule out non-extensible solutions). Note that in a partial solution we have already decided on how the vertices in $G[t]$ are used, and the extension only makes decisions about vertices not in $G[t]$. Instead of dealing with partial solutions directly, our algorithm works with characteristics of partial solutions:

▶ **Definition 2** (Characteristic of a Partial Solution)**.** The characteristic (f, S) of a partial solution (G', P', ϕ) relative to a node $t \in T$ is a function $f : X_t \to V(P) \cup \{\square\}$, together with a subset $S \subseteq V(P) \setminus f(X_t)$, so that:

- for all $v \in V(G') \cap X_t$, $f(v) = \phi(v)$ and $f(v) = \square$ otherwise,
- f is injective, except that it may map multiple elements to $\square$,
- $S = V(P') \setminus \phi(X_t)$.

The following easy observation justifies restricting our attention to characteristics of partial solutions:

▶ **Lemma 3** (Equivalent to Lemma 10, [20])**.** *If two partial solutions have the same characteristic, either both are extensible or neither is extensible.*

▶ **Lemma 4.** *If (f, S) is the characteristic of an extensible partial solution (G', P', ϕ) relative to a node $t \in T$, then S is a union of connected components of $P[V(P) \setminus f(X_t)]$.*

Proof (due to Hajiaghayi et al. [20]). Suppose there exist adjacent vertices $v_1, v_2 \in V(P) \setminus \phi(X_t)$ and $v_1 \in V(P')$, $v_2 \notin V(P')$. Then it is never possible to find a preimage u for v_2 in an extension of (G', P', ϕ): we require that $u \notin V(G[t])$, but all vertices adjacent to $\phi^{-1}(v_1)$ are contained in $V(G[t])$. ◀

The latter fact will be key to achieving the subexponential running time. The requirement that S is a union of connected components also appears in the definition of 'good pair' in Bodlaender et al. [7]. We show how to compute the characteristics of partial solutions in

Procedure 1 Leaf case: computes the partial solution characteristics for a leaf bag $t \in T$, with $X_t = \{v\}$.

let $R = \emptyset$
for each $u \in V(P) \cup \{\square\}$ **do**
    let $f : X_t \to V(P) \cup \{\square\}$ be the function so that $f(v) = u$
    let $R = R \cup \{(f, \emptyset)\}$
end for
filter R
return R

Procedure 2 Introduce case: introduces a vertex v into a bag X_t.

let R be the set of partial solution characteristics for t
let $R' = \emptyset$
for each $(f, S) \in R$ and each $u \in V(P) \setminus (f(X_t) \cup S) \cup \{\square\}$ **do**
    if $u = \square$ **or** for all $w \in Nb(u) \cap f(X_t), (v, f^{-1}(w)) \in E(G)$ **then**
        let $f' : X_t \cup \{v\} \to V(P) \cup \{\square\}$ be the extension of f so that $f(v) = u$
        let $R' = R' \cup \{(f', S)\}$
    end if
end for
filter R'
return R'

Procedure 3 Forget case: forgets a vertex v from a bag X_t.

let R be the set of partial solution characteristics for t
let $R' = \emptyset$
for each $(f, S) \in R$ **do**
    let f' be the restriction of f to $X_t \setminus \{v\}$
    if $f(v) = \square$ **or** $f(v)$ is not adjacent to any vertex of $V(P) \setminus (f(X_t) \cup S)$ **then**
        let $R' = R' \cup \{(f', S \cup \{f(v)\} \setminus \{\square\})\}$
    end if
end for
filter R'
return R'

Procedure 4 Join case: combines the partial solution characteristics for two bags $X_s = X_t$.

let R be the set of partial solution characteristics for s
let T be the set of partial solution characteristics for t
let $R' = \emptyset$
for each $(f, S) \in R$ and each $(g, Q) \in T$ **do**
    if $f = g$ **and** $S \cap Q = \emptyset$ **then**
        let $R' = R' \cup \{(f, S \cup Q)\}$
    end if
end for
filter R'
return R'

a bottom-up fashion, so that we can tell whether G has a subgraph isomorphic to P by examining the characteristics of the root bag. We proceed by giving pseudocode for the leaf, introduce, forget and join cases and argue for their correctness.

The correctness of Procedure 1 is self-evident, as we simply enumerate all the possibilities for f (which means guessing a vertex in P to map v to). We will give details of the *filter* procedure in the next section, for now it suffices to treat the pseudocode as if this call were not present.

Procedure 2 extends existing partial solutions by choosing a vertex to map v to. To ensure we obtain valid characteristics of partial solutions, we check that for any edge incident to v in $P[S \cup f(X_t)]$ there is a corresponding edge in G. Because S is a union of connected components of $G[V(P) \setminus f(X_t)]$, $f(v)$ can not be adjacent to any vertex in S, and thus it suffices to check adjacency only against vertices in $f(X_t)$. Then S remains a union of connected components since the removal of a vertex can only further disconnect S. Note that u is chosen so that f remains injective.

Procedure 3 discards any solutions that would result in S not remaining the union of connected components that we require after forgetting a vertex (note that this means we keep only partial solutions were we have already chosen preimages for all of the neighbours of the image of the vertex being forgotten).

Finally, consider Procedure 4. Because (as a basic property of nice tree decompositions) $V(H[i]) \cap V(H[j]) = X_i$, we obtain an injective function if and only if $S \cap R = \emptyset$. We can therefore merge two partial solutions if they map the vertices of $X_t = X_s$ in the same way and $S \cap R = \emptyset$. Note that we do indeed create all possible partial solutions in this way: given a partial solution, we can split it into partial solutions for the left and right subtrees since (as there are no edges between the internal vertices of the left and right subtrees) a connected component of S must be covered entirely by either the left or right subtree.

These procedures, applied bottom-up on the tree decomposition, give an algorithm that decides subgraph isomorphism. Note that if one exists, a solution can be reconstructed from the characteristics.

3.2 Reducing the number of partial solutions using isomorphism tests

In this section, we show how adapt the algorithm from the previous section to achieve the claimed running time bound. This involves a careful analysis of the number of characteristics, and using isomorphism tests to reduce this number. Currently, if the connected components of S are small (e.g., $O(1)$ vertices each) then their number is large (e.g., $\Omega(n)$ components) and thus in the worst case we have $2^{\Omega(n)}$ partial solutions. However, if there are many small connected components many will necessarily be isomorphic to each other (since there are only few isomorphism classes of small connected components) and we can thus reduce the number of characteristics by identifying isomorphic connected components:

▶ **Definition 5** (Partial Solution Characteristic Isomorphism)**.** Given a bag $t \in T$, two characteristics of partial solutions $(f, S), (g, R)$ for t are *isomorphic* if:

- $f = g$,
- there is a bijection $h : CC(S) \to CC(R)$,
- for all connected components $c \in CC(S)$, c and $h(c)$ are isomorphic when all vertices $v \in c$ vertices are labelled with $Nb(v) \cap f(X_t)$ (i.e. the set of vertices of $f(X_t)$ to which v is adjacent).

Clearly, the algorithm given in the previous section remains correct even if after each procedure we remove duplicate isomorphic characteristics. To this end, we modify the join

Procedure 5 Connected Component Canonization: Computes a canonical representation for a union of connected components $S \subseteq V(P) \setminus f(X_t)$

1: let S' be the union of the large connected components of S
2: let $Q = \emptyset$
3: **for** each small connected component s of S **do**
4: compute the canonical representation r of s when each $v \in V(s)$ is labelled with $Nb(v) \cap f(X_t)$
5: let $Q = Q \cup \{r\}$
6: **end for**
7: Sort S' and Q lexicographically
8: **return** (S', Q)

Procedure 7 Filtering Procedure: Filters a set of partial solution characteristics R to remove duplicates

1: compute the canonical representation C_S for every $(f, S) \in R$ using Procedure 5
2: **sort** R first by f, then by C_S in lexicographical order
3: loop over R, removing all but one of each group of isomorphic partial solutions
4: **return** R

case (Procedure 4): the disjointness check $S \cap Q = \emptyset$ should be replaced with a check that if $P[V(P) \setminus f(X_t)]$ contains $N_P(y)$ connected components of isomorphism class y, and $P[S]$ (resp. $P[Q]$) contains $N_S(y)$ (resp. $N_Q(y)$) connected components of isomorphism class y, then $N_S(y) + N_Q(y) \leq N_P(y)$. Similarly, the statement $S \cup Q$ needs to be changed to, if the union is not disjoint, replace connected components that occur more than once with other connected components of the same isomorphism class (so as to make the union disjoint while preserving the total number of components of the same type).

Call a connected component *small* if it has at most $c \log k$ vertices, and large otherwise. We let $c > 0$ be a constant that depends only on $|V(H)|$ and ϵ. We do not state our choice of c explicitly, but in our analysis we will assume it is "small enough".

For a small connected component s, we label each of its vertices by the subset of vertices of $f(X_t)$ to which it is adjacent. We then compute a canonical representation of this labeled component, for example by considering all permutations of its vertices, and choosing the permutation that results in the lexicographically smallest representation. Note that since we only canonize the small connected components using such a trivial canonization algorithm does not affect the running time of our algorithm, as $(c \log k)!$ is only slightly superpolynomial.

Procedure 5 computes a canonical representation of a partial solution. It requires that we have some predefined ordering of the vertices of G. The canonization procedure 5 allows us to define the *filter* procedure (Procedure 6).

Traditionally, a canonization is a function that maps non-isomorphic graphs to distinct strings, and isomorphic graphs to identical strings. We use this term slightly more loosely, as our canonization procedure 5 may map isomorphic graphs to distinct strings since it only canonizes the small connected components. Thus, Procedure 6 may not remove all duplicate isomorphic partial solutions. However, we will show that it removes enough of them.

3.3 Bounding the number of non-isomorphic partial solutions

In this section, we analyse the number of non-isomorphic partial solutions, and show that the algorithm given in the previous section indeed achieves the stated time bound. In the following, let $\epsilon > 0$ and let G be a graph of treewidth at most tw. Furthermore, suppose that P is H-minor free for some fixed graph H.

Recall that a partial solution for a node $t \in T$ of the tree decomposition consists of $f : X_t \to V(P) \cup \{\square\}$ and a subset $S \subseteq V(P) \setminus f(X_t)$, which is a union of connected components of the subgraph induced by $S \subseteq V(P) \setminus f(X_t)$. The number of choices for f is at most $(k+1)^{|X_t|} = 2^{O(tw \log k)}$. We now proceed to bound the number of cases for S.

We distinguish between connected components of $V(P) \setminus f(X_t)$ of which there are "few", and connected components of $V(P) \setminus f(X_t)$ of which there can be "many", but few non-isomorphic ones. For some constant c, we say a component is *small* if it has at most $c \log k$ vertices, and *large* otherwise. The large connected components are amongst the few, since there are at most $k/(c \log k)$ components with at least $c \log k$ vertices. For each of these components, we store explicitly whether or not it is contained in S. They contribute a factor of $2^{O(k/\log k)}$ to the number of cases. For the small connected components, we will show a partition into the "few" (which we treat similarly to the large connected components), and into the "many, but few non-isomorphic" (for which we store, for each isomorphism class, the number of components from that isomorphism class contained in S).

▶ **Claim.** *For a given node t and function $f : X_t \to V(P)$, there are at most $O(k^{\epsilon/2}tw)$ isomorphism classes of small connected components.*

Proof. For a (small) connected component $x \in CC(V(P) \setminus f(X_t))$, its isomorphism class is determined by the isomorphism class of x itself, and the adjacency of vertices $v \in x$ to vertices in $f(X_t)$. Since $|x| \leq c \log k$ and P is H-minor free, there exists a constant $C_H > 1$ so that there are at most $2^{C_H \cdot c \log k}$ cases for the isomorphism class of x itself (see [4]).

What remains is to bound the number of cases for adjacency of x to X_t. In this specific case, $Nb(x)$ denotes the set of vertices of X_t to which x is incident, that is, $v \in Nb(x)$ if and only if $v \in X_t$ and there exists a vertex $u \in x$ so that $(u, v) \in E(P)$. Using the following lemma, we further divide the small connected components into two cases: the components with a large neighbourhood, and the components with a small neighbourhood.

▶ **Lemma 6** (Gajarskỳ et al., special case of Lemma 3 of [18]). *Let H be a fixed graph. Then there exists a constant d (depending on H), so that if $G = (A, B, E)$ is H-minor free and bipartite, there are at most*

- *$O(|A|)$ vertices in B with degree greater than d,*
- *$O(|A|)$ subsets $A' \subseteq A$ such that $A' = Nb(u)$ for some $u \in B$.*

Taking $A = X_t$, deleting the edges between vertices in X_t and contracting every connected component $x \in CC(V(P) \setminus f(X_t))$ to a single vertex in B, the lemma states that there are at most $O(tw)$ components with $|Nb(x)| > d$ and that the components with $|Nb(x)| \leq d$ have at most $O(tw)$ distinct neighbourhoods in X_t.

For the connected components $x \in CC(V(P) \setminus f(X_t))$ with $|Nb(x)| \leq d$, we have $2^{C_H \cdot c \log k}$ cases for the isomorphism class of x, $O(tw)$ cases for $Nb(x)$ and for every vertex of x, at most 2^d cases for incidence to $Nb(x)$. We thus have at most $2^{C_h \cdot c \log k} \cdot O(tw) \cdot (2^d)^{c \log k}$ isomorphism classes for $x \in CC(S)$ with $Nb(x) \leq d$. For sufficiently small $c > 0$, the asymptotic complexity is $O(k^{\epsilon/2}tw)$. ◀

Since of each component there can be most k occurrences in S, the total number of cases for storing the multiplicity of each class of components is $(k+1)^{O(k^{\epsilon/2}tw)} = 2^{O(k^{\epsilon/2}tw \log k)} = 2^{O(k^{\epsilon}tw)}$.

We now have all the results we need to finish the analysis. Storing the multiplicities of the small connected components gives $2^{O(k^{\epsilon}tw)}$ cases, while storing the subset of large connected components explicitly contributes $2^{O(k/\log k)}$ cases. A partial solution is further characterized by f, for which there are only $2^{O(tw \log k)}$ cases. For a given node t of the tree decomposition, there are thus at most $2^{O(k^{\epsilon}tw + k/\log k)}$ partial solutions.

Finally, we can compute a 5-approximate tree-decomposition of G in time exponential in tw [6], perform dynamic programming as described in Procedures 1-6 to obtain:

▶ **Theorem 7.** *For any graph H and $\epsilon > 0$,* Subgraph Isomorphism *can be solved in time $2^{O(k^{\epsilon}tw+k/\log k)}n^{O(1)}$ if the host graph has treewidth tw and the pattern graph is H-minor free.*

3.4 Adaptation to other problems

In this section, we discuss how our algorithm for Subgraph Isomorphism can be adapted to Induced Subgraph and (Induced) Minor. We begin by describing the graph minor case, then give a brief note on how to adapt both algorithms for the induced case. Some details are omitted from this extended abstract.

Note that P is a minor of G if and only if we have a function $f : V(G) \to V(P) \cup \{\square\}$, such that

- for all $v \in V(P)$, $f^{-1}(v)$ is non-empty, and induces a connected subgraph of G,
- for all $(v, w) \in E(P)$, there are $x \in f^{-1}(v)$ and $y \in f^{-1}(w)$ with $(x, y) \in E(G)$.

Vertices that are deleted are mapped to $\square$, otherwise $f(v)$ gives the vertex that v is contracted to. Call such a function a *solution* for the Graph Minor problem.

If we restrict such solutions to a subgraph $G[t]$, we obtain the notion of partial solution:

▶ **Definition 8** (Partial Solution (Graph Minor))**.** Given a node $t \in T$ of the tree decomposition of G, a *partial solution for the* Graph Minor *problem relative to a node t* is a function $f : V(G[t]) \to V(P) \cup \{\square\}$, such that

1. For each $v \in V(P)$, at least one of the following three cases holds:
   a. each connected component of $G[t][f^{-1}(v)]$ contains at least one vertex from X_t,
   b. $G[t][f^{-1}(v)]$ has one connected component,
   c. $f^{-1}(v)$ is empty.
2. For all $(v, w) \in E(P)$, at least one of the following cases holds:
   a. Some vertex of $f^{-1}(v)$ is adjacent to some vertex of $f^{-1}(w)$ in $G[t]$,
   b. $f^{-1}(v) \cap X_t \neq \emptyset$ and $f^{-1}(w) \cap X_t \neq \emptyset$,
   c. $f^{-1}(v) \cap X_t \neq \emptyset$ and $f^{-1}(w) = \emptyset$,
   d. $f^{-1}(w) \cap X_t \neq \emptyset$ and $f^{-1}(v) = \emptyset$.
   e. $f^{-1}(w) = \emptyset$ and $f^{-1}(v) = \emptyset$.

Intuitively, in 1) we require that the preimage of v can still be made connected (a), is already connected (b) or has not been assigned yet (c), and in 2) we require that the edge (v, w) is already covered (a), can still be covered (b,c,d,e).

As before, our dynamic programming algorithm uses characteristics of partial solutions:

▶ **Definition 9** (Characteristic of a partial solution (Graph Minor))**.** Given a node $t \in T$ of the tree decomposition of G and a *partial solution for the* Graph Minor *problem relative to a node t* $f : V(G[t]) \to V(P) \cup \{\square\}$, the *characteristic* of f is a tuple $(f', S, \sim, F)$ such that:

1. f' is the restriction of f to X_t,
2. $S \subseteq V(P)$ with $S = f(V(G[t])) \setminus (f(X_t) \cup \{\square\})$,
3. $\sim$ is an equivalence relation on X_t, with $v \sim w$, if and only if $f(v) = f(w)$ and there exists a path from v to w in $G[t]$ such that for all vertices x on this path $f(x) = f(v)$.
4. $F \subseteq E(P[f(X_t)])$ such that for every $(v, w) \in E(P[f(X_t)])$, it holds that $(v, w) \in F$ if and only if each of the following holds:
   a. $f^{-1}(v) \cap X_t \neq \emptyset$,
   b. $f^{-1}(w) \cap X_t \neq \emptyset$,
   c. There are $x \in f^{-1}(v)$ and $y \in f^{-1}(w)$ with $(x, y) \in E(G[t])$.

As before, it is easy to see the equivalence between the existence of a minor, solution, and partial solution with certain characteristic.

Compared to our approach for subgraph isomorphism, we no longer require f to be injective – $f^{-1}(v)$ corresponds to the vertices that are contracted to form v. We require that $f^{-1}(v)$ eventually becomes connected. This can either be achieved inside the bag, be achieved below the bag (in the tree decomposition), or above the bag. The relation $\sim$ tracks which components are already connected by vertices below the bag. Similarly, edges inside $P[f(X_t)]$ might not have corresponding edges inside $G[X_t]$, but might instead correspond to edges below or above this bag. The set F stores which edges correspond to edges below the current bag.

This lemma is the counterpart of Lemma 3 and shows that we can apply dynamic programming:

▶ **Lemma 10.** *If partial solutions for the* Graph Minor *problem f and g have the same characteristic and are both relative to t, then f can be extended to a solution if and only if g can be extended to a solution.*

The following lemma shows that we can apply our technique of reducing the number of partial solution characteristics by using isomorphisms:

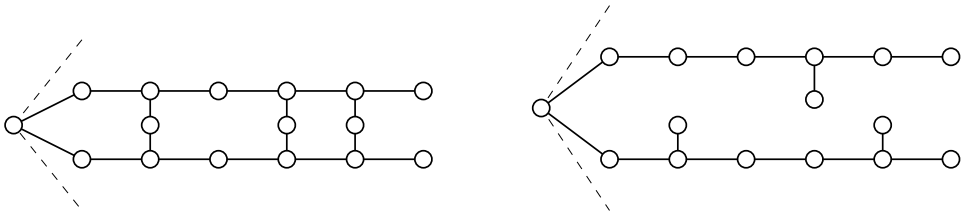
▶ **Lemma 11.** *A partial solution for* Graph Minor *f with characteristic $(f', S, \sim, F)$ can be extended to a solution only if S is a union of connected components of $G[V(P) \setminus f(X_t)]$.*

The analysis of the number of cases of f' and S remains unchanged. There are at most $(tw)^{tw} = 2^{O(tw \log tw)}$ cases for $\sim$, and since P is sparse, at most $2^{O(tw)}$ cases for F.

For the induced cases, only a small modification is needed: it suffices to check in the introduce case that all neighbours (in X_t) of the vertex being introduced are mapped to vertices that are adjacent to the image of the introduced vertex and discard the partial solution otherwise. We thus obtain the following theorem:

▶ **Theorem 12.** *For any graph H and $\epsilon > 0$, if the host graph has treewidth tw and the pattern graph is H-minor free,* Subgraph Isomorphism *and* Induced Subgraph *can be solved in time $2^{O(k^\epsilon tw + k/\log k)} n^{O(1)}$ and* Graph Minor *and* Induced Minor *can be solved in time $2^{O(k^\epsilon tw + tw \log tw + k/\log k)} n^{O(1)}$.*

As a direct corollary, we have that Subgraph Isomorphism, Graph Minor, Induced Subgraph and Induced Minor can be solved in $2^{O(n^{0.5+\epsilon} + k/\log k)}$ time if the host graph is H-minor free for some fixed graph H, as H-minor free graphs have treewidth $O(\sqrt{n})$ [2]. Important special cases include planar graphs, graphs of bounded genus, and graphs of bounded treewidth.



(a) Host graph **(b)** Guest graph

Figure 1 Construction used in the proof of Theorem 14. Host graph (a), representing a string $101001 \in A$ and pattern graph (b), representing strings $000100 \in B$ and $010010 \in C$. The dashed lines represent additional paths attached to vertices u and u'.

4 Hardness Results

Both (Induced) Subgraph and (Induced) Minor are known to be *NP*-complete, even if P is a tree and G is series-parallel (and thus planar), connected and all but one vertex of P and G have degree at most 3, by reduction from Three-Dimensional Matching [26].

We obtain our $2^{o(n/\log n)}$ lower bound by a reduction very similar to the reduction from Three-Dimensional Matching in [26]. We instead reduce from the String 3-Groups problem [7]. In the following, given a string s, we let s_i denote the i^{th} character of s.

String 3-Groups

Instance: Sets $A, B, C \subseteq \{0,1\}^{6\lceil \log n \rceil + 1}$, $|A| = |B| = |C| = n$

Question: Do there exist n triples, so that for each chosen triple $(a, b, c) \in A \times B \times C$ and for all i, $a_i + b_i + c_i \leq 1$ and each element of A, B, C occurs in exactly one triple?

▶ **Theorem 13** ([7], [8]). *Assuming the Exponential Time Hypothesis, there is no algorithm solving* String 3-Groups *in* $2^{o(n)}$ *time.*

▶ **Theorem 14.** *Assuming the Exponential Time Hypothesis, there is no algorithm solving* Subgraph Isomorphism *in* $2^{o(n/\log n)}$ *time, even when the pattern graph is a tree and the host graph is connected and series-parallel and in both the host graph and pattern graph, all vertices but one have maximum degree 3.*

Proof. Let A, B, C be an instance of String 3-Groups. We modify the instance by prepending a 0 to each string in A and B, and a 1 to each string in C. Let $m = 6\lceil \log n \rceil + 2$.

To construct the host graph G, we take a vertex u. For each $a \in A$ we take a path $p_1, \ldots, p_m$ and a path $q_1, \ldots, q_m$. We add edges (p_1, u) and (q_1, u). Whenever $a_i = 0$, we create a vertex r_i and edges $(p_i, r_i), (r_i, q_i)$.

To construct the pattern graph P, we take a vertex u'. For each $b \in B$ (resp. each $c \in C$) we take a path $s_1, \ldots, s_m$. We add an edge (s_1, u'). Whenever $b_i = 1$ (resp. $c_i = 1$), we create a vertex t_i and an edge (s_i, t_i).

A solution to the String 3-Groups problem and this instance of Subgraph Isomorphism correspond as follows: u is mapped to u'. If (a, b, c) is a triple in a solution to String 3-Groups, then the path $s_1, \ldots, s_m$ corresponding to b can be mapped to the path $p_1, \ldots, p_m$ corresponding to a, while the path $s_1, \ldots, s_m$ corresponding to c is mapped to the path $q_1, \ldots, q_m$. Clearly such a mapping is possible if and only if for each i, at most one of a_i, b_i or c_i is 1, since the vertex v_i only exists if $a_i = 0$ and can be used at most once (by either the vertex t_i corresponding to b_i or the vertex t_i corresponding to c_i).

In the reverse direction, note that any subgraph isomorphism must map u to u' by virtue of their degrees. Clearly, the paths in H must correspond one-to-one with paths in G. The correspondence of the paths immediately gives us a partition into triples. The construction enforces that in each such triple, in each position at most one of the strings has a 1, as required. Note that since we modified the instance so that each string $c \in C$ starts with a 1, no triple will contain more than one string from c and consequently, each triple contains exactly one string from each of a, b, c.

Since the graph created in the reduction has $O(n \log n)$ vertices, and assuming the Exponential Time Hypothesis there is no $2^{o(n)}$ algorithm for String 3-Groups, there is no $2^{o(n/\log n)}$ time algorithm for Subgraph Isomorphism, even for the graph classes as claimed in the theorem. ◀

The proof of Theorem 14 can be adapted to Induced Subgraph by subdividing each edge (p_i, r_i) once. Furthermore, the proof also works for (Induced) Graph Minor, since performing a contraction in H is never beneficial.

▶ **Theorem 15.** *Assuming the Exponential Time Hypothesis, there is no algorithm solving* Subgraph Isomorphism, Graph Minor, Induced Subgraph *and* Induced Minor *in* $2^{o(n/\log n)}$ *time, even when the pattern graph is a tree and the host graph is connected and series-parallel and in both the host graph and pattern graph, all vertices but one have maximum degree 3.*

5 Conclusion

We have presented algorithms for (Induced) Subgraph and (Induced) Minor that, by taking advantage of isomorphic structures in the pattern graph, run in subexponential time on H-minor free graphs. These algorithms are essentially optimal since we have shown that the existence of $2^{o(n/\log n)}$ time algorithms would contradict the Exponential Time Hypothesis. We have thus settled the (traditional) complexity of these problems on (general) H-Minor Free graphs.

Our result applies to a wide range of graphs: we require P to be H-Minor Free and G to have truly sublinear treewidth. Some restriction on G is indeed necessary, since if G is an arbitrary graph then Hamiltonian path is a special case (in which P is a path) and a $2^{o(n)}$ algorithm would contradict the ETH [23].

An interesting open question is whether the parameterized complexity can still be improved. Perhaps the dependence of the running time on the treewidth of G can be removed: does there exist an algorithm for subgraph isomorphism on planar graphs running in $2^{O(k/\log k)}n^{O(1)}$? Our result, combined with one due to Fomin et al. [17] implies that the answer to this question is yes if P is connected and G is apex-minor free, but the problem remains open otherwise.

We note that our lower bound proof also works for Immersion [14]. However, our algorithmic technique does not seem to work for immersion. Does the immersion problem also have a $2^{O(n/\log n)}$ algorithm, or is a stronger lower bound possible?

Lemma 6 holds for a more general class of graphs, and we believe it may be possible to extend our result to patterns from a graph class with expansion $O(1)$ or perhaps expansion $O(\sqrt{r})$. We note that for different graph classes, a tradeoff between the size of the small connected components and the factor $k/\log k$ in the exponent is possible: it might be possible to obtain a $2^{O(n/\log\log n)}$-time algorithm for less restrictive graph classes.

Together with the Minimum Size Tree/Path Decomposition problem [7], these problems are amongst the first for which a $2^{\Theta(n/\log n)}$ upper and lower bound is known. Our work shows that the techniques from [7] can be adapted to other problems, and we suspect there may be many more problems for which identifying isomorphic components can speed up dynamic programming algorithms.

Abstract

The thickness of a graph $G = (V, E)$ with n vertices is the minimum number of planar subgraphs of G whose union is G. A polyline drawing of G in $\mathbb{R}^2$ is a drawing Γ of G, where each vertex is mapped to a point and each edge is mapped to a polygonal chain. Bend and layer complexities are two important aesthetics of such a drawing. The bend complexity of Γ is the maximum number of bends per edge in Γ, and the layer complexity of Γ is the minimum integer r such that the set of polygonal chains in Γ can be partitioned into r disjoint sets, where each set corresponds to a planar polyline drawing. Let G be a graph of thickness t. By Fáry's theorem, if $t = 1$, then G can be drawn on a single layer with bend complexity 0. A few extensions to higher thickness are known, e.g., if $t = 2$ (resp., $t > 2$), then G can be drawn on t layers with bend complexity 2 (resp., $3n + O(1)$).

In this paper we present an elegant extension of Fáry's theorem to draw graphs of thickness $t > 2$. We first prove that thickness-t graphs can be drawn on t layers with $2.25n + O(1)$ bends per edge. We then develop another technique to draw thickness-t graphs on t layers with reduced bend complexity for small values of t, e.g., for $t \in \{3, 4\}$, the bend complexity decreases to $O(\sqrt{n})$. Previously, the bend complexity was not known to be sublinear for $t > 2$. Finally, we show that graphs with linear arboricity k can be drawn on k layers with bend complexity $\frac{3(k-1)n}{(4k-2)}$.

1 Introduction

A polyline drawing of a graph $G = (V, E)$ in $\mathbb{R}^2$ maps each vertex of G to a distinct point, and each edge of G to a polygonal chain. Many problems in VLSI layout and software visualization are tackled using algorithms that produce polyline drawings. For a variety of practical purposes, these algorithms often seek to produce drawings that optimize several drawing aesthetics, e.g., minimizing the number of bends, minimizing the number of crossings, etc. In this paper we examine two such parameters: *bend complexity* and *layer complexity*.

The *thickness* of a graph G is the minimum number $\theta(G)$ such that G can be decomposed into $\theta(G)$ planar subgraphs. Let Γ be a polyline drawing of G. Then the *bend complexity*

of Γ is the minimum integer b such that each edge in Γ has at most b bends. A set of edges $E' \subseteq E$ is called a *crossing-free edge set in* Γ, if the corresponding polygonal chains correspond to a *planar polyline drawing*, i.e., no two polylines that correspond to a pair of edges in E' intersect, except possibly at their common endpoints. The *layer complexity* of Γ is the minimum integer t such that the edges of Γ can be partitioned into t crossing-free edge sets. Figure 1(a) illustrates a polyline drawing of K_9 on 3 layers with bend complexity 1. At first glance the layer complexity of Γ may appear to be related to the thickness of G. However, the layer complexity is a property of the drawing Γ, while thickness is a graph property. The layer complexity of Γ can be arbitrarily large even when G is planar, e.g., consider the case when G is a matching and Γ is a straight-line drawing, where each edge crosses all the other edges; see Figure 1(b).

The layer complexity of a thickness-t graph G is at least t, and every n-vertex thickness-t graph admits a drawing on t layers with bend complexity $O(n)$ [20]. The problem of drawing thickness-t graphs on t planar layers is closely related to the *simultaneous embedding* problem, where given a set of planar graphs $G_1, \ldots, G_t$ on a common set of vertices, the task is to compute their planar drawings $D_1, \ldots, D_t$ such that each vertex is mapped to the same point in the plane in each of these drawings. Figure 1(a) can be considered to be a simultaneous embedding of three given planar graphs.

1.1 Related Work

Graphs with low thickness admit polyline drawings on few layers with low bend complexity. If $\theta(G) = 1$, then by Fáry's theorem [16], G admits a drawing on a single layer with bend complexity 0. Every pair of planar graphs can be simultaneously embedded using two bends per edge [15, 17]. Therefore, if $\theta(G) = 2$, then G admits a drawing on two layers with bend complexity 2. The best known lower bound on the bend complexity of such drawings is one [10]. Duncan et al. [9] showed that graphs with maximum degree four can be drawn on two layers with bend complexity 0. Wood [21] showed how to construct drawings on $O(\sqrt{m})$ layers with bend complexity 1, where m is the number of edges in G.

Given an n-vertex planar graph G and a point location for each vertex in $\mathbb{R}^2$, Pach and Wenger [20] showed that G admits a planar polyline drawing with the given vertex locations, where each edge has at most $120n$ bends. They also showed that $\Omega(n)$ bends are sometimes necessary. Badent et al. [1] and Gordon [18] independently improved the bend complexity to $3n + O(1)$. Consequently, for $\theta(G) \geq 3$, these constructions can be used to draw G on $\theta(G)$ layers with at most $3n + O(1)$ bends per edge.

A rich body of literature [3, 4, 12, 13] examines *geometric thickness*, i.e., the maximum number of planar layers necessary to achieve 0 bend complexity. Dujmović and Wood [7] proved that $\lceil k/2 \rceil$ layers suffice for graphs of treewidth k. Duncan [8] proved that $O(\log n)$ layers suffice for graphs with arboricity two or outerthickness two, and $O(\sqrt{n})$ layers suffice for thickness-2 graphs. Dillencourt et al. [6] proved that complete graphs with n vertices require at least $\lceil (n/5.646) + 0.342 \rceil$ and at most $\lceil n/4 \rceil$ layers.

1.2 Our Results

The goal of this paper is to extend our understanding of the interplay between the layer complexity and bend complexity in polyline drawings.

We first show that every n-vertex thickness-t graph admits a polyline drawing on t layers with bend complexity $2.25n + O(1)$, improving the $3n + O(1)$ upper bound derived from [1, 18]. We then give another drawing algorithm to draw thickness-t graphs on t layers, which improves the bend complexity for smaller values of t, e.g., for graphs with $t \in \{3, 4\}$, it reduces the bend complexity to $O(\sqrt{n})$. No such sublinear upper bound on the bend complexity was previously known for $t > 2$. Finally, we show that every n-vertex graph with linear arboricity $k \geq 2$ admits a polyline drawing on k layers with bend complexity $\frac{3(k-1)n}{(4k-2)}$, where the *linear arboricity* of a graph G is the minimum number of linear forests (i.e., each connected component is a path) whose union is G.

The rest of the paper is organized as follows. We start with some preliminary definitions and results (Section 2). In the subsequent section (Section 3) we present two constructions to draw thickness-t graphs on t layers. Section 4 presents the results on drawing graphs of bounded arboricity. Finally, Section 5 concludes the paper pointing out the limitations of our results and suggesting directions for future research.

2 Technical Details

In this section we describe some preliminary definitions, and review some known results.

Let $G = (V, E)$ be a planar graph. A *monotone topological book embedding* of G is a planar drawing Γ of G that satisfies the following properties.

P_1: The vertices of G lie along a horizontal line ℓ in Γ. We refer to ℓ as the *spine* of Γ.

P_2: Each edge $(u, v) \in E$ is an x-monotone polyline in Γ, where (u, v) either lies on one side of ℓ, or crosses ℓ at most once.

P_3: Let (u, v) be an edge that crosses ℓ at point d, where u appears before v on ℓ. Let $u, \ldots, d, \ldots, v$ be the corresponding polyline. Then the polyline $u, \ldots, d$ lies above ℓ, and the polyline $d, \ldots, v$ lies below ℓ.

Figure 1(c) illustrates a monotone topological book embedding of a planar graph. Let $G_1 = (V, E_1)$ and $G_2 = (V, E_2)$ be two graphs on a common set of vertices. A *simultaneous embedding* Γ of G_1 and G_2 consists of their planar drawings D_1 and D_2, where each vertex is mapped to the same point in the plane in both D_1 and D_2. Erten and Kobourov [15] showed that every pair of planar graphs admit a simultaneous embedding with at most three bends per edge. Giacomo and Liotta [17] observed that by using monotone topological book embeddings Erten and Kobourov's [15] construction can achieve a drawing with two bends per edge. Here we briefly recall this drawing algorithm. Without loss of generality assume that both G_1 and G_2 are triangulations. Let π_i, where $1 \leq i \leq 2$, be a vertex ordering that corresponds to a monotone topological book embedding of G_i. Let P_i be the corresponding *spinal path*, i.e., a path that corresponds to π_i. Note that some of the edges of P_i may not

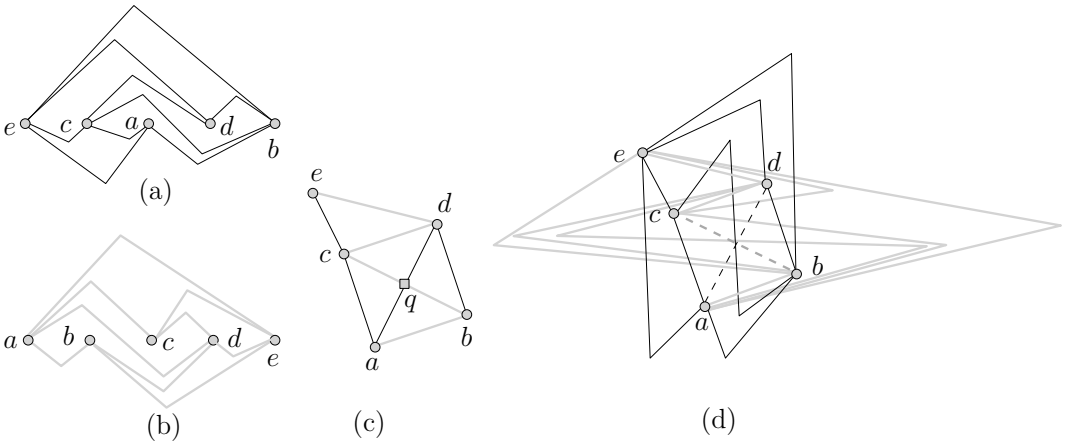

Figure 2 (a)–(b) Monotone topological book embeddings of G_1 and G_2. (c)–(d) Simultaneous embedding of G_1 and G_2, where the deleted edges are shown in dashed lines.

exist in G_i, e.g., edges (a, d) and (b, c) in Figures 2(a) and (b), respectively, and these edges of P_i create edge crossings in G_i. Add a dummy vertex at each such edge crossing. Let $\delta_i(v)$ be the position of vertex v in π_i. Then P_1 and P_2 can be drawn simultaneously on an $O(n) \times O(n)$ grid [5] by placing each vertex at the grid point $(\delta_1(v), \delta_2(v))$; see Figure 2(c). The mapping between the dummy vertices of P_1 and P_2 can be arbitrary, here we map the dummy vertex on (a, d) to the dummy vertex on (b, c). Finally, the edges of G_i that do not belong to P_i are drawn. Let e be such an edge in G_i. If e does not cross the spine, then it is drawn using one bend on one side of P_i according to the book embedding of G_i. Otherwise, let q be a dummy vertex on the edge $e = (u, v)$, which corresponds to the intersection point of e and the spine. The edges (u, q) and (v, q) are drawn on opposite sides of P_i such that the polyline from u to v do not create any bend at q. Since each of (u, q) and (v, q) contains only one bend, e contains only two bends. Finally, the edges of P_i that do not belong to G_i are removed from the drawing; see Figure 2(d).

Let Γ be a planar polyline drawing of a path $P = \{v_1, v_2, \ldots, v_n\}$. We call Γ an *uphill* drawing if for any point q on Γ, the upward ray from q does not intersect the path $v_1, \ldots, q$. Note that q may be a vertex location or an interior point of some edge in Γ. Let a and b be two points in $\mathbb{R}^2$. Then a and b are *r-visible* to each other if and only if their exists a polygonal chain of length r with end points a, b that does not intersect Γ at any point except possibly at a, b. A point p *lies between two other points* v, w, if either the inequality $x(v) < x(p) < x(w)$ or $x(w) < x(p) < x(v)$ holds.

A set of points is *monotone* if the polyline connecting them from left to right is monotone with respect to y-axis. Let S be a set of n points in general position. By the Erdös-Szekeres theorem [14], S can be partitioned into $O(\sqrt{n})$ disjoint monotone subsets, and such a partition can be computed in $O(n^{1.5})$ time [2].

3 Drawing Thickness-t Graphs on t Layers

In this section we give two separate construction techniques to draw thickness-t graphs on t layers. We first present a construction achieving $2.25n + O(1)$ upper bound (Section 3.1), which is simple and intuitive. Although the technique is simple, the idea of the construction will be used frequently in the rest of the paper. Therefore, we explained the construction in reasonable details.

Later, we present a second construction (Section 3.2), which is more involved, and relies on a deep understanding of the geometry of point sets. In this case, the upper bound on the bend complexity will depend on some generalization of Erdös-Szekeres theorem [14], e.g., partitioning a point set into monotone subsequences in higher dimensions (Section 3.2.3).

3.1 A Simple Construction with Bend Complexity $2.25n + O(1)$

Let $G_1, \ldots, G_t$ be the planar subgraphs of the input graph G, and let S be an ordered set of n points on a semicircular arc. Let $V = \{v_1, v_2, \ldots, v_n\}$ be the set of vertices of G. We show that each G_i, where $1 \leq i \leq t$, admits a polyline drawing with bend complexity $2.25n + O(1)$ such that vertex v_j is mapped to the jth point of S. To draw G_i, we will use the vertex ordering of its monotone topological book embedding. The following lemma will be useful to draw the spinal path P_i of G_i.

▶ **Lemma 1.** *Let $S = \{p_0, p_1, \ldots, p_{n+1}\}$ be a set of points lying on an x-monotone semicircular arc (e.g., see Figure 3(a)), and let $P = \{v_1, v_2, \ldots, v_n\}$ be a path of n vertices. Assume that p_0 and p_{n+1} are the leftmost and rightmost points of S, respectively, and the points $p_1, \ldots, p_n$ are equally spaced between them in some arbitrary order. Then P admits an uphill drawing Γ with the vertex v_i assigned to p_i, where $1 \leq i \leq n$, and every point p_i satisfies the following properties:*

(A) *Both the points p_0 and p_{n+1} are $(3n/4)$-visible to p_i.*

(B) *One can draw an x-monotone polygonal chain from p_0 to p_{n+1} with $3n/4$ bends that intersects Γ only at p_i.*

Proof. We prove the lemma by constructing such a drawing Γ for P. The construction assigns a polyline for each edge of P. The resulting drawing may contain edge overlaps, and the bend complexity could be as large as $n - 2$. Later we remove these degeneracies and reduce the bend complexity to obtain Γ.

Drawings of Edges: For each point $p_i \in S$, where $1 \leq i \leq n$, we create an *anchor point* p'_i at $(x(p_i), y(p_i) + \epsilon)$, where $\epsilon > 0$. We choose ϵ small enough such that for any j, where $1 \leq i \neq j \leq n$, all the points of S between p_i and p_j lie above (p'_i, p'_j). Figure 3(a) illustrates this property for the anchor point p'_1.

We first draw the edge (v_1, v_2) using a straight line segment. For each j from 2 to $n - 1$, we now draw the edges (v_j, v_{j+1}) one after another. Assume without loss of generality that $x(p_j) < x(p_{j+1})$. We call a point $p \in S$ between p_j and p_{j+1} a *visited point* if the corresponding vertex v appears in $v_1, \ldots, v_j$, i.e., v has already been placed at p. We draw an x-monotone polygonal chain L that starts at v_j, connects the anchors of the intermediate visited points from left to right, and ends at v_{j+1}. Figure 3(b) illustrates such a construction.

Since the number of bends on L is equal to the number of visited points of S between p_j and p_{j+1}, each edge contains at most α bends, where α is the number of points of S between p_j and p_{j+1}.

Removing Degeneracies: The drawing D_n of the path P constructed above contains edge overlaps, e.g., see the edges (v_3, v_4) and (v_4, v_5) in Figure 3(c). To remove the degeneracies, for each i, we spread the corresponding bend points between p_i and p'_i, in the order they appear on the path, see Figure 3(d). Consequently, we obtain a planar drawing of P. Let the resulting drawing be D'_n. Since each edge (p_j, p_{j+1}) is drawn as an x-monotone polyline above the path $p_1, \ldots, p_j$, D'_n satisfies the uphill property. Note that D'_n may have bend

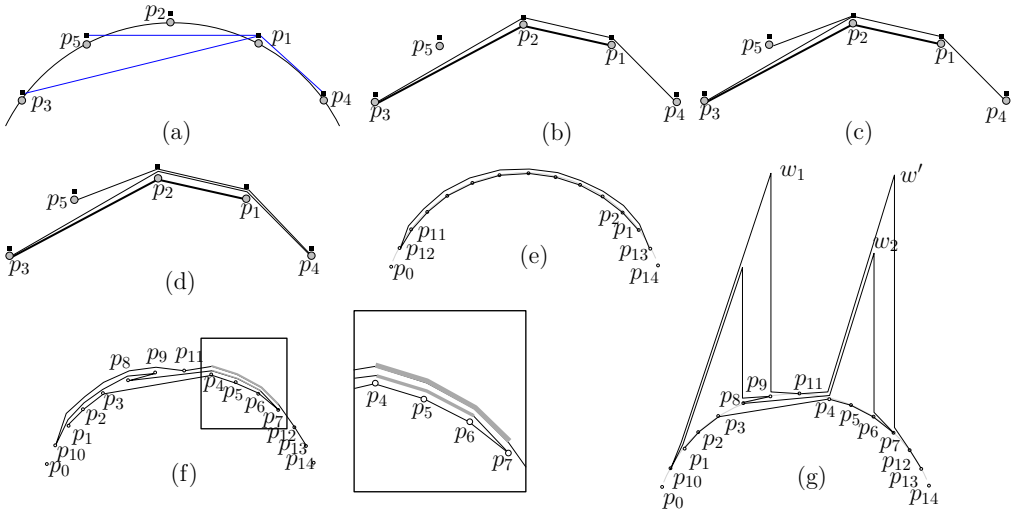

Figure 3 Illustration for the proof of Lemma 1. Anchor points are shown in black squares. For a larger view of this figure, see Appendix A.

complexity $n-2$, e.g., see Figure 3(e). We now show how to reduce the bend complexity and satisfy Properties A–B.

Reducing Bend Complexity: A pair of points in S are *consecutive* if they do not contain any other point of S in between. Let e be any edge of P. Let C_e be the corresponding polygonal chain in D'_n. A pair of bend points on C_e are called *consecutive bends* if their corresponding points in S are also consecutive. A *bend-interval* of C_e is a maximal sequence of consecutive bends in C_e. Note that we can partition the bends on e into disjoint sets of bend-intervals.

For any bend-interval s, let $l(s)$ and $r(s)$ be the x-coordinates of the left and right endpoints of s, respectively. Let s_1 and s_2 be two bend-intervals lying on two distinct edges e_1 and e_2 in D'_n, respectively, where e_2 appears after e_1 in P. We claim that the intervals $[l(s_1), r(s_1)]$ and $[l(s_2), r(s_2)]$ are either disjoint, or $[l(s_1), r(s_1)] \subseteq [l(s_2), r(s_2)]$. We refer to this property as the *balanced parenthesis property of the bend-intervals*. To verify this property assume that for some s_1, s_2, we have $[l(s_1), r(s_1)] \cap [l(s_2), r(s_2)] \neq \phi$. Since e_2 appears after e_1, and since s_2 is a maximal sequence of consecutive bends, the inequalities $l(s_2) \leq l(s_1)$ and $r(s_2) \geq r(s_1)$ hold, i.e., $[l(s_1), r(s_1)] \subseteq [l(s_2), r(s_2)]$. We say that s_1 *is nested by* s_2. Figure 3(f) illustrates such a scenario, where s_1, s_2 are shown in thin and thick gray lines, respectively.

We now consider the edges of P in reverse order, i.e., for each j from n to 2, we modify the drawing of $e = (v_j, v_{j-1})$. For each bend-interval $s = (b_1, b_2 \ldots, b_r)$ of C_e, if s has three or more bends, then we delete the bends $b_2, \ldots, b_{r-1}$, and join b_1 and b_r using a new bend point w. To create w, we consider the two cases of the balanced parenthesis property.

If s is not nested by any other bend-interval in D'_n, then we place w high enough above b_r such that the chain b_1, w, b_r does not introduce any edge crossing, e.g., see the point $w_1(= w)$ in Figure 3(g). On the other hand, if s is nested by some other bend-interval, then let s' be such a bend-interval immediately above s. Since $s' = (b'_1, b'_2, \ldots, b'_r)$ is already processed, it must have been replaced by some chain b'_1, w', b'_r. Therefore, we can find a location for b inside $\angle b'_1 w' b'_r$ such that the chain b_1, w, b_r does not introduce any edge crossing, e.g., see the points w' and $w_2(= w)$ in Figure 3(g). Let the resulting drawing of P be Γ.

We now show that the above modification reduces the bend complexity to $3n/4$. Let e be an edge of P that contains α points from S between its endpoints. Let C_e be the corresponding polygonal chain in D'_n. Recall that any bend-interval of length ℓ in C_e contributes to $\min\{\ell, 3\}$ bends on e in Γ. Therefore, if there are at most $\alpha/4$ bend-intervals on C_e, then e can have at most $3\alpha/4$ bends in Γ. Otherwise, if there are more than $\alpha/4$ bend-intervals, then there are at least $\alpha/4$ points[1] of S that do not contribute to bends on C_e. Therefore, in both cases, C_e can have at most $3\alpha/4$ bends in Γ.

Satisfying Properties A–B: Let p_i be any point of $S \setminus \{p_0, p_{n+1}\}$. We first show that p_0 is $(3n/4)$-visible to p_i. Let D_i, where $1 \leq i \leq n$, be the drawing of the path $v_1, v_2, \ldots, v_i$. Observe that one can insert an edge (p_0, p_i) using an x-monotone polyline L such that the bends on L correspond to the intermediate visited points. Now the drawing of the rest of the path $v_i, v_{i+1}, \ldots, v_n$ can be continued such that it does not cross L. Therefore, if the number of points of S between p_0 and p_i is α, then L has at most α bends. Finally, the process of reducing bend complexity improves the number of bends on L to $3\alpha/4$.

Similarly, we can observe that p_{n+1} is at most $3\alpha'/4$ visible to p_i, where α' is the number of points of S between p_i and p_{n+1}. Since the edges (p_0, p_i) and (p_i, p_{n+1}) are x-monotone, we can draw an x-monotone polygonal chain from p_0 to p_{n+1} with at most $3(\alpha + \alpha')/4 \leq (3n/4)$ bends that intersects Γ only at p_i. ◀

▶ **Theorem 2.** *Every n-vertex graph of t admits a drawing on t layers with bend complexity $2.25n + O(1)$.*

Proof. Let $G_1, \ldots, G_t$ be the planar subgraphs of the input graph G, and let $V = \{v_1, v_2, \ldots, v_n\}$ be the set of vertices of G. Let $S = \{p_0, p_1, \ldots, p_{n+1}\}$ be a set of $n + 2$ points lying on a semicircular arc as defined in Lemma 1. Let P_i be spinal path of the monotone topological book embedding of G_i, where $1 \leq i \leq t$. We first compute an uphill drawing Γ_i of the path P_i. We then draw the edges of G_i that do not belong to P_i. Let $e = (u, v)$ be such an edge, and without loss of generality assume that u appears to the left of v on the spine.

If e lies above (resp., below) the spine, then we draw two x-monotone polygonal chains; one from u to p_0 (resp., p_{n+1}), and the other from v to p_0 (resp., p_{n+1}). By Lemma 1, these polygonal chains do not intersect Γ_i except at u and v, and each contains at most $3n/4$ bends. Hence e contains at most $1.5n$ bends in total.

If e crosses the spine, then it crosses some edge (w, w') of P_i. Draw the edges (u, w) and (w, v) using the polylines $u, \ldots, p_0, \ldots, w$ and $w, \ldots, p_{n+1}, \ldots, v$, respectively. The polylines $u, \ldots, p_0$ and $p_{n+1}, \ldots, v$ are x-monotone, and have at most $3n/4$ bends each. The polyline $C = (p_0, \ldots, w \ldots, p_{n+1})$ is also x-monotone and has at most $3n/4$ bends. Hence the number of bends is $2.25n$ in total. It is straightforward to avoid the degeneracy at w, by adding a constant number of bends on C.

Note that we still have some edge overlaps at p_0 and p_{n+1}. It is straightforward to remove these degeneracies by adding only a constant number of more bends per edge. ◀

3.2 A Construction for Small Values of t

In this section we give another construction to draw thickness-t graphs on t layers. We first show that every thickness-t graph, where $t \in \{3, 4\}$, can be drawn on t layers with bend complexity $O(\sqrt{n})$, and then show how to extend the technique for larger values of t.

[1] Every pair of consecutive bend-intervals contain such a point in between.

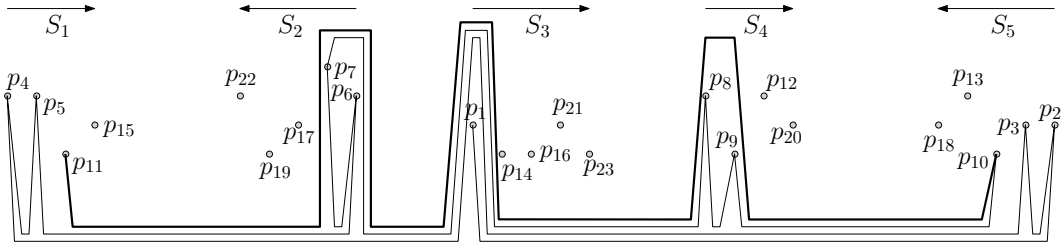

Figure 4 Illustration for the proof of Lemma 3. The edge (p_{10}, p_{11}) is shown in bold. Passing through each intermediate set requires at most 4 bends.

3.2.1 Construction when $t = 3$

Let S be an ordered set of n points, where the ordering is by increasing x-coordinate. A (k, n)-*group* $S_{k,n}$ is a partition of S into k disjoint ordered subsets $\{S_1, \ldots, S_k\}$, each containing contiguous points from S. Label the points of S using a permutation of $p_1, p_2, \ldots, p_n$ such that for each set $S' \in S_{k,n}$, the indices of the points in S' are either increasing or decreasing. If the indices are increasing (resp., decreasing), then we refer S' as a rightward (resp., leftward) set. We will refer to such a labelling as a *smart labelling* of $S_{k,n}$. Figure 4 illustrates a $(5, 23)$-group and a smart labelling of the underlying point set $S_{5,23}$.

Note that for any i, where $1 \leq i \leq n$, deletion of the points $p_1, \ldots, p_i$ removes the points of the rightward (resp., leftward) sets from their left (resp., right). The *necklace* of $S_{k,n}$ is a path obtained from a smart labelling of $S_{k,n}$ by connecting the points p_i, p_{i+1}, where $1 \leq i \leq n-1$. The following lemma constructs an uphill drawing of the necklace using $O(k)$ bends per edge.

▶ **Lemma 3.** *Let S be a set of n points ordered by increasing x-coordinate, and let $S_{k,n} = \{S_1, \ldots, S_k\}$ be a (k, n)-group of S. Label $S_{k,n}$ with a smart labelling. Then the necklace of $S_{k,n}$ admits an uphill drawing with $O(k)$ bends per edge.*

Proof. We construct this uphill drawing incrementally in a similar way as in the proof of Lemma 1. Let D_j, where $1 \leq j \leq n$, be the drawing of the path $p_1, \ldots, p_j$. At each step of the construction, we maintain the invariant that D_j is an uphill drawing.

We first assign v_1 to p_1. Then for each i from 1 to $n-1$, we draw the edge (p_i, p_{i+1}) using an x-monotone polyline L that lies above D_i and below the points $p_{j'}$, where $j' > i+1$. Figure 4 illustrates such a drawing of (p_i, p_{i+1}).

The crux of the construction is that one can draw such a polyline L using at most $O(k)$ bends. Assume that p_i and p_{i+1} belong to the sets $S_l \in S_{k,n}$ and $S_r \in S_{k,n}$, respectively. If S_l and S_r are identical, then p_i and p_{i+1} are consecutive, and hence it suffices to use at most $O(1)$ bends to draw L. On the other hand, if S_l and S_r are distinct, then there can be at most $k-2$ sets of $S_{k,n}$ between them. Let S_m be such a set. While passing through S_m, we need to keep the points that already belong to the path, below L, and the rest of the points above L. By the property of smart labelling, the points that belong to D_i are consecutive in S_m, and lie to the left or right side of S_m depending on whether S_m is rightward or leftward. Therefore, we need only $O(1)$ bends to pass through S_m. Since there are at most $k-2$ sets between S_l and S_r, $O(k)$ bends suffice to construct L. ◀

We are now ready to describe the main construction. Let G be an n-vertex thickness-3 graph, and let G_1, G_2, G_3 be the planar subgraphs of G. Let P_i be the spinal path of the monotone topological book embedding of G_i, where $1 \leq i \leq 3$. We first create a set of n points and assign them to the vertices of G. Later we route the edges of G.

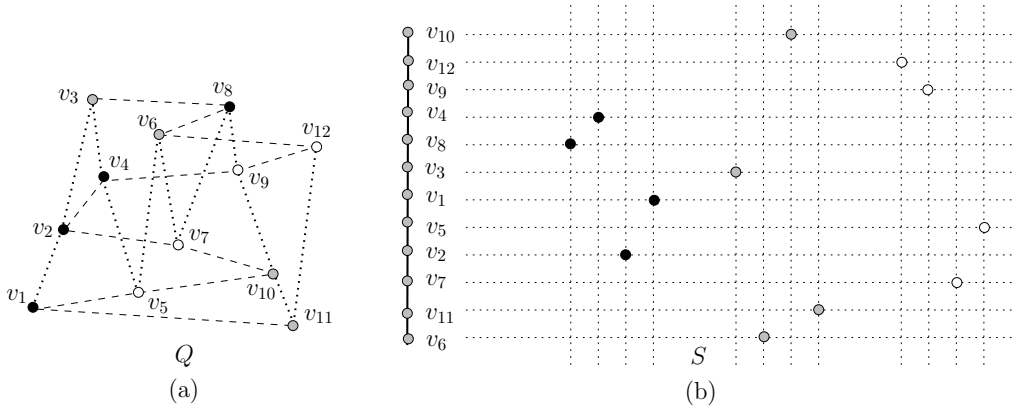

Figure 5 Creating vertex locations for drawing thickness-3 graphs, where P_1, P_2 and P_3 are shown in dotted, dashed and thick solid lines, respectively.

Creating Vertex Locations: Assume without loss of generality that $P_1 = (v_1, \ldots, v_n)$. For each i from 1 to n, we place a point at (i, j) in the plane, where j is the position of v_j in P_2. Let the resulting point set be Q. Recall that Q can be partitioned into disjoint monotone subsets $Q_1, \ldots, Q_k$, where $k \in O(\sqrt{n})$ [2]. Figure 5(a) illustrates such a partition in black, gray and white.

The sets $Q_1, \ldots, Q_k$ are ordered by the x-coordinate, and the indices of the labels of the points at each set is in increasing order. Therefore, if we place the points of the ith set between the lines $x = 2(i-1)n$ and $x = (2i-1)n$, then the resulting point set Q' would be a (k, n)-group, labelled by a smart labelling. Finally, we adjust the y-coordinates of the points according to the position of the corresponding vertices in P_3. Let the resulting point set be S. Figure 5(b) illustrates the vertex locations, where $P_1 = (v_1, v_2, \ldots, v_n)$, $P_2 = (v_{11}, v_1, \ldots, v_3)$, and $P_3 = (v_6, v_{11}, \ldots, v_{10})$.

Edge Routing: It is straightforward to observe that the path P_1 is a necklace for the current labelling of the points of $S_{k,n}$. Therefore, by Lemma 3, we can construct an uphill drawing of P_1 on S. Observe that for every set $S' \in S_{k,n}$, the corresponding points are monotone in Q, i.e., the points of S' are ordered along the x-axis either in increasing or decreasing order of their y-coordinates in Q. Therefore, relabelling the points according to the increasing order of their y-coordinates in Q will produce another smart labelling of S, and the corresponding necklace would be the path P_2. Therefore, we can use Lemma 3 to construct an uphill drawing of P_2 on S. Since the height of the points of S are adjusted according to the vertex ordering on P_3, connecting the points of S from top to bottom with straight line segments yields a y-monotone drawing of P_3.

We now route the edges of G_i that do not belong to P_i, where $1 \leq i \leq 3$. Since P_3 is drawn as a y-monotone polygonal path, we can use the technique of Erten and Kobourov [15] to draw the remaining edges of G_3. To draw the edges of G_2, we insert two points p_0 and p_{n+1} to the left and right of all the points of S, respectively. Then the drawing of the remaining edges of G_1 and G_2 is similar to the edge routing described in the proof of Theorem 2. That is, if the edge $e = (u, v)$ lies above (resp., below) the spine, then we draw it using two x-monotone polygonal chains from p_0 (resp., p_{n+1}). Otherwise, if e crosses the spine, then we draw three x-monotone polygonal chains, one from u to p_0, another from p_0 to p_{n+1}, and the third one from v to p_{n+1}. Since $k \in O(\sqrt{n})$, the number of bends on e is $O(\sqrt{n})$. Finally, we remove the degeneracies, which increases the bends per edge by a small constant.

3.2.2 Construction when $t = 4$

We now show that the technique for drawing thickness-3 graphs can be generalized to draw thickness-4 graphs with the same bend complexity.

Let $G_1, \ldots, G_4$ be the planar subgraphs of G, and let $P_1, \ldots, P_4$ be the corresponding spinal paths. While constructing the vertex locations, we use a new y-coordinate assignment for the points of S. Instead of placing the points according to the vertex ordering on the path P_3, we create a particular order, by transposing the x- and y-axis, that would help to construct uphill drawings of P_3 and P_4 with bend complexity $O(\sqrt{n})$. That is, we first create a (k', n)-group $S'_{k',n}$ using P_3 and P_4, where $k' \in O(\sqrt{n})$, in a similar way that we created $S_{k,n}$ using P_1 and P_2. We then adjust the y-coordinates of the points of S according to the order these points appear in $S'_{k',n}$. Appendix B includes an example of such a construction.

The construction of G_1 and G_2 remains the same as described in the previous section. However, since P_3 and P_4 now admit uphill drawings on S with respect to y-axis, the drawings of G_3 and G_4 are now analogous to the construction of G_1 and G_2.

3.2.3 Construction when $t > 4$

De Bruijn [19] observed that the result of Erdös-Szekeres [14] can be generalized to higher dimensions. Given a sequence ρ of n tuples, each of size κ, one can find a subsequence of at least $n^{1/\lambda}$ tuples, where $\lambda = 2^\kappa$, such that they are monotone (i.e., increasing or decreasing) in every dimension. If we repeatedly extract such monotone sequences, then we obtain a partition of ρ into a set of monotone subsequences. We use this idea to extend our drawing algorithm to higher thickness.

Let $G_1, \ldots, G_t$ be the planar subgraphs of G, and let $P_1, \ldots, P_t$ be the corresponding spinal paths. Let $v_1, v_2, \ldots, v_n$ be the vertices of G. Construct a corresponding sequence $\rho = (\tau_1, \tau_2, \ldots, \tau_n)$ of n tuples, where each tuple is of size t, and the ith element of a tuple τ_j corresponds to the position of the corresponding vertex v_j in P_i, where $1 \leq i \leq t$ and $1 \leq j \leq n$. We now partition ρ into a set of monotone subsequences. Let $f(n, t)$ be the number of monotone subsequences in this partition.

For each of these monotone sequences, we create an ordered set of consecutive points along the x-axis, where the vertex v_j corresponds to the point p_j. It is now straightforward to observe that these sets correspond to a (k, n)-group $S_{k,n}$, where $k \leq f(n, t)$. Furthermore, since each group corresponds to a monotone sequence of tuples, for each P_i, the positions of the corresponding vertices are either increasing or decreasing. Hence, every path P_i corresponds to a necklace for some smart labelling of $S_{k,n}$. Therefore, by Lemma 3, we can construct an uphill drawing of P_i on S. We now add the remaining edges of G_i following the construction described in Section 3.2.1. Since $k \leq f(n, t)$, the number of bends is bounded by $O(f(n, t))$.

Observe that all the points in the above construction have the same y-coordinate. Therefore, we can improve the construction by distributing the load equally among the x-axis and y-axis as we did in Section 3.2.2. Specifically, we draw the graphs $G_1, \ldots, G_{\lceil t/2 \rceil}$ using the uphill drawings of their spinal paths with respect to the x-axis, and the remaining graphs using the uphill drawings of their spinal paths with respect to the y-axis. Consequently, the bend complexity decreases to $O(f(n, \lceil t/2 \rceil))$. We can improve this bound further by observing that we are free to choose any arbitrary vertex labelling for G while creating the initial sequence of tuples. Instead of using an arbitrary labelling, we could label the vertices according to their ordering on some spinal path, which would reduce the bend complexity to $O(f(n, \lceil (t-2)/2 \rceil))$. As shown in Sections 3.2.1 and 3.2.2, if $t \in \{3, 4\}$, then $f(n, \lceil (t-2)/2 \rceil) \in O(\sqrt{n})$.

▶ **Theorem 4.** *Every n-vertex graph G of thickness $t \geq 3$ admits a drawing on t layers with bend complexity $O(\beta)$, where β is the minimum integer such that the sequence of n tuples obtained from the spinal paths of G can be partitioned into β monotone subsequences. Furthermore, if $t \in \{3, 4\}$, then $\beta \in O(\sqrt{n})$.*

A careful analysis of the generalization of Erdös-Szekeres [14] theorem gives an $O(\sqrt{2}^t \cdot n^{1-(1/\gamma)})$ upper bound on the bend complexity, where $\gamma = 2^{\lceil (t-2)/2 \rceil}$. For the details, we refer to the full version of the paper [11].

4 Drawing Graphs of Linear Arboricity k

In this section we construct polyline drawings, where the layer number and bend complexities are functions of the linear arboricity of the input graphs. We show that the bandwidth of a graph can be bounded in terms of its linear arboricity and the number of vertices, and then the result follows from an application of Lemma 1.

The *bandwidth* of an n-vertex graph $G = (V, E)$ is the minimum integer b such that the vertices can be labelled using distinct integers from 1 to n satisfying the condition that for any edge $(u, v) \in E$, the absolute difference between the labels of u and v is at most b. The following lemma proves an upper bound on the bandwidth of graphs.

▶ **Lemma 5.** *Given an n-vertex graph $G = (V, E)$ with linear arboricity k, the bandwidth of G is at most $\frac{3(k-1)n}{(4k-2)}$.*

Proof. Without loss of generality assume that G is a union of k spanning paths $P_1, \ldots, P_k$. For any ordered sequence σ, let $\sigma(i)$ be the element at the ith position, and let $|\sigma|$ be the number of elements in σ. We now construct an ordered sequence $\sigma = \sigma_1 \circ \sigma_2 \circ \ldots \circ \sigma_k \circ \sigma_{k+1}$ of the vertices in V, as follows.

σ_1: We initially place the first x vertices of P_1 in the sequence, where the exact value of x is to be determined later.
σ_2: We then place the vertices that are neighbors of σ_1 in P_2, in order, i.e., we first place the neighbors of $\sigma_1(1)$, then the neighbors of $\sigma_1(2)$ that have not been placed yet, and so on.
σ_i: For each $i = 3, \ldots, k$, we place the vertices that are neighbors of σ_1 in P_i in order.
σ_{k+1}: We next place the remaining vertices of P_1 in order.

Figure 6(a) illustrates an example for three paths with $x = 2$. Observe that $|\sigma_1| \leq x$, and $|\sigma_t| \leq 2x$, where $1 < t \leq k$. We now compute an upper bound on the bandwidth of G using the vertex ordering of σ.

For any i, j, where $1 \leq i < j \leq k + 1$, let $\sigma_{i,j}$ be the sequence $\sigma_i \circ \ldots \circ \sigma_j$. The edges of P_1 that are in σ_1 have bandwidth 1, and those that are in $\sigma_1(x) \circ \sigma_{2,k+1}$ have bandwidth at most $(n - x)$, e.g., see Figure 6(b). Now let (v, w) be an edge of G that does not belong to P_1. We compute the bandwidth of (v, w) considering the following cases.

Case 1. If none of v and w belongs to σ_1, then the bandwidth of (v, w) is at most $(n - x)$.
Case 2. If both v and w belong to σ_1, then the bandwidth of (v, w) is at most x.
Case 3. If at most one of v and w belongs to σ_1, then without loss of generality assume that v belongs to σ_1. Since (v, w) does not belong to P_1, we may assume that w belongs to the path P_t, where $1 < t \leq k$. By the construction of σ, w belongs to $\sigma_{1,t}$, e.g., see Figure 6(b). Without loss of generality assume that w belongs to σ_r, where $1 < r \leq t$. Let v be the qth vertex in the sequence σ. Then the position of w cannot be more than $q + 2x \cdot (r - 2) + 2q$, where the term $2x \cdot (r - 2)$ corresponds to the length of $\sigma_2 \circ \ldots \circ \sigma_{r-1}$. Therefore, the bandwidth of the edge (v, w) is at most $2x \cdot (r - 2) + 2q \leq 2x(r - 1) \leq 2x(t - 1)$.

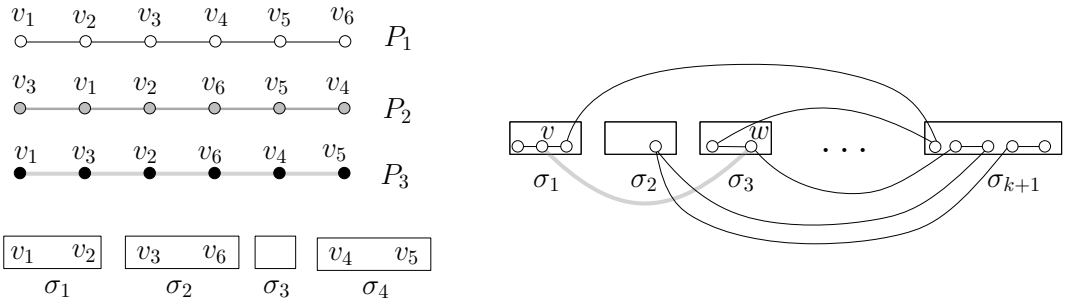

Figure 6 (a) Construction of σ. (b) A schematic representation of P_1 and (v, w), where (v, w) belongs to P_3.

Observe that the bandwidth of the edges of P_1 is upper bounded by $(n - x)$. The bandwidth of any edge that belongs to P_t, where $1 < t \leq k$ is at most $\max\{n - x, 2x(k - 1)\}$. Consequently, the bandwidth of G is at most $\max\{n - x, 2x(k - 1)\} \leq \frac{(2k-2)n}{(2k-1)}$, where $x = \frac{n}{(2k-1)}$. ◀

The following theorem is immediate from the proof of Lemmas 1 and 5.

▶ **Theorem 6.** *Every n-vertex graph with linear arboricity k can be drawn on k layers with at most $\frac{3(k-1)n}{(4k-2)} < 0.75n$ bends per edge.*

5 Conclusions

In this paper we have developed algorithms to draw graphs on few planar layers and with low bend complexity. Although our algorithms do not construct drawings with integral coordinates, it is straightforward to see that these drawings can also be constructed on polynomial-size integer grids, where all vertices and bends have integral coordinates. We leave the task of finding compact grid drawings achieving the same upper bounds as a direction for future research.

We believe our upper bounds on bend complexity to be nearly tight, but we require more evidence to support this intuition. The only related lower bound is that of Pach and Wenger [20], who showed that given a planar graph G and a unique location to place each vertex of G, $\Omega(n)$ bends are sometimes necessary to construct a planar polyline drawing of G with the given vertex locations. Therefore, a challenging research direction would be to prove tight lower bounds on the bend complexity while drawing thickness-t graphs on t layers.

Abstract

We prove, using the subspace embedding guarantee in a black box way, that one can achieve the spectral norm guarantee for approximate matrix multiplication with a dimensionality-reducing map having $m = O(\tilde{r}/\epsilon^2)$ rows. Here $\tilde{r}$ is the maximum stable rank, i.e., the squared ratio of Frobenius and operator norms, of the two matrices being multiplied. This is a quantitative improvement over previous work of [Magen and Zouzias, SODA, 2011] and [Kyrillidis et al., arXiv, 2014] and is also optimal for any oblivious dimensionality-reducing map. Furthermore, due to the black box reliance on the subspace embedding property in our proofs, our theorem can be applied to a much more general class of sketching matrices than what was known before, in addition to achieving better bounds. For example, one can apply our theorem to efficient subspace embeddings such as the Subsampled Randomized Hadamard Transform or sparse subspace embeddings, or even with subspace embedding constructions that may be developed in the future.

Our main theorem, via connections with spectral error matrix multiplication proven in previous work, implies quantitative improvements for approximate least squares regression and low rank approximation, and implies faster low rank approximation for popular kernels in machine learning such as the gaussian and Sobolev kernels. Our main result has also already been applied to improve dimensionality reduction guarantees for k-means clustering, and also implies new results for nonparametric regression.

Lastly, we point out that the proof of the "BSS" deterministic row-sampling result of [Batson et al., SICOMP, 2012] can be modified to obtain deterministic row-sampling for approximate matrix product in terms of the stable rank of the matrices. The original "BSS" proof was in terms of the rank rather than the stable rank.

1 Introduction

Much recent work has successfully utilized randomized dimensionality reduction techniques to speed up solutions to linear algebra problems, with applications in machine learning, statistics, optimization, and several other domains; see the recent monographs [19, 32, 42] for more details. In our work here, we give new spectral norm guarantees for approximate matrix multiplication (AMM). Aside from AMM being interesting in its own right, it has become a useful primitive in the literature for analyzing algorithms for other large-scale linear algebra problems as well. We show applications of our new guarantees to speeding up standard algorithms for generalized regression and low-rank approximation problems. We also describe applications of our results to k-means clustering (discovered in [11]) and nonparametric regression [43].

In AMM we are given A, B each with a large number of rows n, and the goal is to compute some matrix C such that $\|C - A^TB\|_X$ is "small", for some norm $\|\cdot\|_X$. Furthermore, we would like to compute C much faster than the usual time required to exactly compute A^TB.

Work on randomized methods for AMM began with [15], which focused on $\|\cdot\|_X = \|\cdot\|_F$, i.e., Frobenius norm. They showed by picking an appropriate sampling matrix $\Pi \in \mathbb{R}^{m\times n}$, $\|(\Pi A)^T(\Pi B) - A^TB\|_F \le \varepsilon\|A\|_F\|B\|_F$ with good probability if $m = \Omega(1/\varepsilon^2)$. By a *sampling matrix*, we mean the rows of Π are independent, and each row is all zero except for a 1 in a (non-uniformly) random location. If $A \in \mathbb{R}^{n\times d}$ and $B \in \mathbb{R}^{n\times p}$, note $(\Pi A)^T(\Pi B)$ can be computed in $O(mdp)$ time once ΠA and ΠB are formed, as opposed to the straightforward $O(ndp)$ time to compute A^TB.

Frobenius error was also later achieved in [38] via a different approach, with some later optimizations in [22]. This was not via sampling, but rather to use Π drawn from a distribution satisfying an "oblivious Johnson-Lindenstrauss (JL)" guarantee, i.e. a distribution $\mathcal{D}$ over $\mathbb{R}^{m\times n}$ satisfying the following condition for some $\varepsilon, \delta \in (0, 1/2)$: $\forall x \in \mathbb{R}^n$, $\mathbb{P}_{\Pi\sim\mathcal{D}}(|\|\Pi x\|_2^2 - \|x\|_2^2| > \varepsilon\|x\|_2^2) < \delta$. Such a matrix Π can be taken with $m = O(\varepsilon^{-2}\log(1/\delta))$ [21]. Furthermore, one can take Π to be a Fast JL transform [1] (or any of the follow-up improvements [2, 24, 36, 4, 20]) or a sparse JL transform [14, 22] to speed up the computation of ΠA and ΠB. One could also use the Thorup-Zhang sketch [40] combined with a certain technique of [28] (see [42, Theorem 2.10] for details) to efficiently boost success probability.

Other than Frobenius error, the main other error guarantee investigated in previous work is spectral error. That is, we would like $\|C - A^TB\|$ to be small, where $\|M\|$ denotes the largest singular value of M. If one is interested in applying A^TB to some set of input vectors then this type of error is the most meaningful, since $\|C - A^TB\|$ being small is equivalent to $\|Cx\| \approx \|A^TBx\|$ for any x. The first work along these lines was again by [15], who gave a procedure based on entry-wise sampling of the entries of A and B. The works [17, 39] showed that row-sampling according to leverage scores also provides the desired guarantee with few samples.

Then [38], combined with a quantitative improvement in [9], showed that one can take a Π drawn from an oblivious JL distribution with $\delta = 2^{-\Theta(r)}$ where $r(\cdot)$ denotes rank and $r = r(A) + r(B)$. Then for Π with $m = O((r + \log(1/\delta))/\varepsilon^2)$, with probability at least $1 - \delta$ over Π,

$$\|(\Pi A)^T(\Pi B) - A^TB\| \le \varepsilon\|A\|\|B\|. \tag{1}$$

As we shall see shortly via a very simple lemma (Lemma 3), a sufficient deterministic condition implying Eq. (1) is that Π is an $O(\varepsilon)$-*subspace embedding* for the r-dimensional subspace spanned by the columns of A, B. The notion of a subspace embedding was introduced by [38].

▶ **Definition 1.** Π is an *ε-subspace embedding* for $U \in \mathbb{R}^{n\times r}$, $U^TU = I$, if Π satisfies Eq. (1) with $A = B = U$, i.e. $\|(\Pi U)^T(\Pi U) - I\| \leq \varepsilon$. This is equivalent to $\forall x \in \mathbb{R}^r,\ (1-\varepsilon)\|x\|_2^2 \leq \|\Pi U x\|_2^2 \leq (1+\varepsilon)\|x\|_2^2$, i.e. Π preserves norms of all vectors in the subspace spanned by the columns U.

An *(ε, δ, r)-oblivious subspace embedding (OSE)* is a distribution $\mathcal{D}$ over $\mathbb{R}^{m\times n}$ such that $\forall U \in \mathbb{R}^{n\times r},\ U^TU = I$, it holds that $\mathbb{P}_{\Pi\sim\mathcal{D}}(\|(\Pi U)^T(\Pi U) - I\| > \varepsilon) < \delta$.

Fast subspace embeddings Π, i.e. such that the products ΠA and ΠB can be computed quickly, are known using variants on the Fast JL transform such as the Subsampled Randomized Hadamard Transform (SRHT) [38, 29, 41, 30], or via sparse subspace embeddings [9, 33, 34, 27, 12, 10]. We also refer the reader to a slightly improved analysis of the SRHT in our full version [13]. In most applications it is important to have a fast subspace embedding to shrink the time it takes to transform the input data to a lower-dimensional form. The SRHT is a randomized Π with the property that ΠA can be computed in time $O(nd\log n)$. The sparse subspace embedding constructions have some parameter m rows and exactly s non-zero entries per column, so that ΠA can be computed in time $O(s \cdot nnz(A))$, where $nnz(\cdot)$ is the number of non-zero entries, and there is a tradeoff in the upper bounds between m and s.

An issue addressed by the work of [31] is that of robustness. As stated above, achieving Eq. (1) requires Π be a subspace embedding for an r-dimensional subspace. However, consider the case when A (and similarly for B) is of high rank but can be expressed as the sum of a low-rank matrix plus high-rank noise of small magnitude, i.e., $A = \tilde{A} + E_A$ for $\tilde{A}$ of rank $r(\tilde{A}) \ll r$, and where $\|E_A\|$ is very small but E_A has high (even full) rank. One would hope the noise could be ignored, but standard results require Π to have a number of rows at least as large as r, regardless of how small the magnitude of the noise is. Another case of interest (as we will see in Section 3) is when A and B are each of high rank, but their singular values decay at some appropriate rate. As discussed in Section 3, in several applications where AMM is not the final goal but rather is used as a primitive in analyzing an algorithm for some other problem (such as k-means clustering or nonparametric regression), the matrices that arise do indeed have such decaying singular values.

The work [31] remedied this by considering the *stable ranks* $\tilde{r}(A), \tilde{r}(B)$ of A and B. Define $\tilde{r}(A) = \|A\|_F^2/\|A\|^2$. Note $\tilde{r}(A) \leq r(A)$ always, but can be much less if A has a small tail of singular values. Let $\tilde{r}$ denote $\tilde{r}(A) + \tilde{r}(B)$. Among other results, [31] showed that to achieve Eq. (1) with good probability, one can take Π to be a random (scaled) sign matrix with either $m = \Omega(\tilde{r}/\varepsilon^4)$ or $m = \Omega(\tilde{r}\log(d+p)/\varepsilon^2)$ rows. As noted in follow-up work [25], both the $1/\varepsilon^4$ dependence and the $\log(d+p)$ factor are undesirable. In their data-driven low dimensional embedding application, they wanted a dimension m independent of the original dimensions, which are assumed much larger than the stable rank, and also wanted lower dependence on $1/\varepsilon$. To this end, [25] defined the *nuclear rank* as $\tilde{nr}(A) = \|A\|_*/\|A\|$ and showed $m = \Omega(\tilde{nr}/\varepsilon^2)$ rows suffice for $\tilde{nr} = \tilde{nr}(A) + \tilde{nr}(B)$. Here $\|A\|_*$ is the nuclear norm, i.e., sum of singular values of A. Since $\|A\|_F^2$ is the sum of squared singular values, it is straightforward to see that $\tilde{nr}(A) \geq \tilde{r}(A)$ always. Thus there is a tradeoff: the stable rank guarantee is worsened to nuclear rank, but dependence on $1/\varepsilon$ is improved to quadratic.

We show switching to the weaker $\tilde{nr}$ guarantee is unnecessary by showing quadratic dependence on $1/\varepsilon$ holds even with stable rank. This answers the main open question of [31, 25].

To state our results in a more natural way, we rephrase our main result to say that we achieve

$$\|(\Pi A)^T(\Pi B) - A^T B\| \leq \varepsilon\sqrt{\left(\|A\|^2 + \frac{\|A\|_F^2}{k}\right)\left(\|B\|^2 + \frac{\|B\|_F^2}{k}\right)}. \tag{2}$$

for an arbitrary $k \geq 1$, and we do so by using subspace embeddings for $O(k)$-dimensional subspaces in a certain black box way (which will be made precise soon) regardless of the ranks of A, B.

▶ Remark 1. Note that our previously stated main contribution is equivalent, since one could set $k = \tilde{r}(A) + \tilde{r}(B)$ to arrive at the conclusion that subspace embeddings for $O(\tilde{r})$-dimensional subspaces yield the guarantee in Eq. (1). Alternatively one could obtain the Eq. (2) guarantee via Eq. (1) with error parameter $\varepsilon' = \Theta(\varepsilon \cdot \min\{1, \sqrt{(\tilde{r}(A) \cdot \tilde{r}(B))/k}\})$.

Henceforth, we use the following definition.

▶ **Definition 2.** For conforming matrices A^T, B, we say Π satisfies the (k, ε)-*approximate spectral norm matrix multiplication property ((k, ε)-AMM) for* A, B if Eq. (2) holds. If Π is random and satisfies (k, ε)-AMM with probability $1 - \delta$ for any fixed A, B, then we say Π satisfies (k, ε, δ)-AMM.

Our main contribution: We give two different characterizations for Π supporting (k, ε)-AMM, both of which imply (k, ε, δ)-AMM Π having $m = O((k + \log(1/\delta))/\varepsilon^2)$ rows. The first characterization applies to any OSE distribution for which a moment bound has been proven for $\|(\Pi U)^T(\Pi U) - I\|$ (which is true for the best analyses of all known OSE's). In this case, we show a black box theorem: any $(\varepsilon, \delta, 2k)$-OSE provides (k, ε, δ)-AMM. Since matrices with subgaussian entries and $m = \Omega((k + \log(1/\delta))/\varepsilon^2)$ are $(\varepsilon, \delta, 2k)$-OSE's, our originally stated main result follows. This result is optimal, since [35] shows any randomized distribution over Π with m rows having the (k, ε, δ)-AMM property must have $m = \Omega((k + \log(1/\delta))/\varepsilon^2)$ (the hard instance there is when $A = B = U$ has orthonormal columns, and thus rank and stable rank are equal).

Our second characterization (appearing in the full version) identifies certain deterministic conditions which, if satisfied by Π, imply the desired (k, ε)-AMM property. These conditions are of the form: (1) Π should preserve a certain set of $O(\log(1/\varepsilon))$ different subspaces of varying dimensions (all depending on k, ε and not on the ranks of A, B) with varying distortions, and (2) for a certain two matrices in our analysis, left-multiplication by Π should not increase their operator norms by more than an $O(1)$ factor. These conditions are chosen carefully so that matrices with subgaussian entries and $m = \Omega(k/\varepsilon^2)$ satisfy all conditions simultaneously with high probability, again thus proving our main result while also suggesting that the conditions we have identified are the "right" ones.

Due to the black box reliance on the subspace embedding primitive in our proofs, Π need not only be a subgaussian map. Thus not only do we improve on m compared with previous work, but also in terms of the general class of Π our result applies to. For example given our first characterization, not only does it suffice to use a random sign matrix with $\Omega(k/\varepsilon^2)$ rows, but in fact one can apply our theorem to more efficient subspace embeddings such as the SRHT or sparse subspace embeddings, or even constructions discovered in the future. That is, one can automatically transfer bounds proven for the subspace embedding property to the (k, ε)-AMM property. Thus, for example, the best known SRHT analysis (see the full version) implies (k, ε, δ)-AMM for $m = \Omega((k + \log(1/(\varepsilon\delta))\log(k/\delta))/\varepsilon^2)$ rows. For sparse subspace embeddings, the analysis in [10] implies $m = \Omega(k\log(k/\delta)/\varepsilon^2)$ suffices

with $s = O(\log(k/\delta)/\varepsilon)$ non-zeroes per column of Π. The only reason for the $\log k$ loss in m for these particular distributions is not due to our theorems, but rather due to the best analyses for the simpler *subspace embedding* property in previous work already incurring the extra $\log k$ factor (note being a subspace embedding for a k-dimensional subspace is simply a special case of (k, ε)-AMM where $A = B = U$ has k orthonormal columns). In the case of the SRHT, this extra $\log k$ factor is actually necessary [41]; for sparse subspace embeddings, it is conjectured that the $\log k$ factor can be removed and that $m = \Omega((k + \log(1/\delta))/\varepsilon^2)$ actually suffices to obtain an OSE [34, Conjecture 14]. We also discuss in Remark 2 that one can set Π to be $\Pi_1 \cdot \Pi_2$ where Π_1 has subgaussian entries with $O(k/\varepsilon^2)$ rows, and Π_2 is some other fast OSE (such as the SRHT or sparse subspace embedding), and thus one could obtain the best of both worlds: (1) Π has $O(k/\varepsilon^2)$ rows, and (2) can be applied to any $A \in \mathbb{R}^{n\times d}$ in time $T + O(km'd/\varepsilon^2)$, where T is the (fast) time to apply Π_2 to A, and m' is the number of rows of Π_2. For example, by appropriate composition as discussed in Remark 2, Π can have $O(k/\varepsilon^2)$ rows and support multiplying ΠA for $A \in \mathbb{R}^{n\times d}$ in time $O(nnz(A)) + \tilde{O}(\varepsilon^{-O(1)}(k^3 + k^2 d))$.

We also observe the proof of the main result of [3] can be modified to show that given any A, B each with n rows, and given any $\varepsilon \in (0, 1/2)$, there exists a diagonal matrix $\Pi \in \mathbb{R}^{n\times n}$ with $O(k/\varepsilon^2)$ non-zero entries, and that can be computed by a deterministic polynomial time algorithm, achieving (k, ε)-AMM. The original work of [3] achieved Eq. (1) with $m = O(r/\varepsilon^2)$ for r being the sum of ranks of A, B. The work [3] stated their result for the case $A = B$, but the general case of potentially unequal matrices reduces to this case; see Section 4. Our observation also turns out to yield a stronger form of [23, Theorem 3.3]; also see Section 4.

As mentioned, aside from AMM being interesting on its own, it is a useful primitive widely used in analyses of algorithms for several other problems, including k-means clustering [5, 11], nonparametric regression [43], linear least squares regression and low-rank approximation [38], approximating leverage scores [16], and several other problems (see [42] for a recent summary). For all these, analyses of correctness for algorithms based on dimensionality reduction via some Π rely on Π satisfying AMM for certain matrices in the analysis.

After making certain quantitative improvements to connections between AMM and applications, and combining them with our main result, in Section 3 we obtain the following new results.

1. **Generalized regression:** Given $A \in \mathbb{R}^{n\times d}$ and $B \in \mathbb{R}^{n\times p}$, consider the problem of computing $X^* = argmin_{X\in\mathbb{R}^{d\times p}} \|AX - B\|$. It is standard that $X^* = (A^TA)^+A^TB$ where $(\cdot)^+$ is the Moore-Penrose pseudoinverse. The bottleneck here is computing A^TA, taking $O(nd^2)$ time. A popular approach is to instead compute $\tilde{X} = ((\Pi A)^T(\Pi A))^+(\Pi A)^T\Pi B$, i.e., the minimizer of $\|\Pi AX - \Pi B\|$. Note that computing $(\Pi A)^T(\Pi A)$ (given ΠA) only takes a smaller $O(md^2)$ amount of time. We show that if Π satisfies $(k, O(\sqrt{\varepsilon}))$-AMM for $U_A, P_{\bar{A}}B$, and is also an $O(1)$-subspace embedding for a certain $r(A)$-dimensional subspace (see Theorem 7), then

   $$\|A\tilde{X} - B\|^2 \leq (1 + \varepsilon)\|P_AB - B\|^2 + (\varepsilon/k)\|P_AB - B\|_F^2$$

   where P_A is the orthogonal projection onto the column space of A, $P_{\bar{A}} = I - P_A$, and U_A has orthonormal columns forming a basis for the column space of A. The punchline is that if the regression error $P_{\bar{A}}B$ has high actual rank but stable rank only on the order of $r(A)$, then we obtain multiplicative spectral norm error with Π having fewer rows. Generalized regression is a natural extension of the case when B is a vector, and arises for

example in Regularized Least Squares Classification, where one has multiple (non-binary) labels, and for each label one creates a column of B; see e.g. [7] for this and variations.

2. **Low-rank approximation:** We are given $A \in \mathbb{R}^{n\times d}$ and integer $k \geq 1$, and we want to compute $A_k = argmin_{r(X)\leq k} \|A - X\|$. The Eckart-Young theorem implies A_k is obtained by truncating the SVD of A to the top k singular vectors. The standard way to use dimensionality reduction for speedup, introduced in [38], is to let $S = \Pi A$ then compute $\tilde{A} = AP_S$. Then return $\tilde{A}_k$, the best rank-k approximation of $\tilde{A}$, instead of A_k (it is known $\tilde{A}_k$ can be computed more efficiently than A_k; see [8, Lemma 4.3]). We show if Π satisfies $(k, O(\sqrt{\varepsilon}))$-AMM for U_k and $A - A_k$, and is a $(1/2)$-subspace embedding for the column space of A_k, then

$$\|\tilde{A}_k - A\|^2 \leq (1+\varepsilon)\|A - A_k\|^2 + (\varepsilon/k)\|A - A_k\|_F^2.$$

The punchline is that if the stable rank of the tail $A - A_k$ is on the same order as the rank parameter k, then standard algorithms from previous work for Frobenius multiplicative error actually in fact also provide *spectral* multiplicative error. This property indeed holds for any k for popular kernel matrices in machine learning such as the gaussian and Sobolev kernels (see [37] and Examples 2 and 3 of [43]), and low-rank approximation of kernel matrices has been applied to several machine learning problems; see [18] for a discussion.

We also explain in Section 3 how our result has already been applied in recent work on dimensionality reduction for k-means clustering [12], and how it generalizes results in [43] on dimensionality reduction for nonparametric regression to use a larger class of embeddings Π.

1.1 Preliminaries and notation

We frequently use the singular value decomposition (SVD). For a matrix $A \in \mathbb{R}^{n\times d}$ of rank r, consider the compact SVD $A = U_A \Sigma_A V_A^T$ where $U_A \in \mathbb{R}^{n\times r}$ and $V_A \in \mathbb{R}^{d\times r}$ each have orthonormal columns, and Σ_A is diagonal with strictly positive diagonal entries (the singular values of A). We assume $(\Sigma_A)_{i,i} \geq (\Sigma_A)_{j,j}$ for $i < j$. We let $P_A = U_A U_A^T$ denote the orthogonal projection operator onto the column space of A. We use $\text{span}(A)$ to refer to the subspace spanned by A's columns.

Often for a matrix A we write A_k as the best rank-k approximation to A under Frobenius or spectral error (obtained by writing the SVD of A then setting all $(\Sigma_A)_{i,i}$ to 0 for $i > k$). We often denote $A - A_k$ as $A_{\bar{k}}$. For matrices with orthonormal columns, such as U_A, $(U_A)_k$ denotes the $n \times k$ matrix formed by removing all but the first k columns of U. When A is understood from context, we often write $U\Sigma V^T$ instead of $U_A \Sigma_A V_A^T$, and U_k to denote $(U_A)_k$ (and Σ_k for $(\Sigma_A)_k$, etc.).

2 Analysis of matrix multiplication for stable rank

First we record a simple lemma relating subspace embeddings and AMM; proof in full version [13].

▶ **Lemma 3.** *Let $E = \text{span}\{A, B\}$, and let Π be an ε-subspace embedding for E. Then Eq. (1) holds.*

Lemma 3 implies that if A, B each have rank at most r, it suffices for Π to have $\Omega(r/\varepsilon^2)$ rows.

In the following subsection, we give one characterization for Π to provide (k, ε, δ)-AMM, only requiring Π to have $\Omega((k + \log(1/\delta))/\varepsilon^2)$ rows, independent of r. The other characterization also allows for this many rows, but is different in that it identifies certain deterministic conditions such that, if those hold, Π provides (k, ε)-AMM. Thus, the second characterization can even apply to deterministic Π such as the truncated SVD. We provide this second characterization only in the full version.

2.1 Characterization for (k, ε, δ)-AMM via a moment property

Here we provide a way to obtain (k, ε)-AMM for any Π whose subspace embedding property has been established using the moment method, e.g. sparse subspace embeddings [33, 34, 10], dense subgaussian matrices (as analyzed in the full version), or even the SRHT (also, as analyzed in the full version). Our approach in this subsection is inspired by the introduction of the "JL-moment property" in [22] to analyze approximate matrix multiplication with Frobenius error. The following is a generalization of [22, Definition 6.1], which was only concerned with $d = 1$.

▶ **Definition 4.** A distribution $\mathcal{D}$ over $\mathbb{R}^{m\times n}$ has $(\varepsilon, \delta, d, \ell)$-*OSE moments* if for all matrices $U \in \mathbb{R}^{n\times d}$ with orthonormal columns, $\mathbb{E}_{\Pi\sim\mathcal{D}} \left\|(\Pi U)^T(\Pi U) - I\right\|^\ell < \varepsilon^\ell \cdot \delta$.

The acronym "OSE" refers to *oblivious subspace embedding*, a term coined in [34] to refer to distributions over Π yielding a subspace embedding for any fixed subspace of a particular bounded dimension with high probability. We start with a simple lemma; proof in full version.

▶ **Lemma 5.** *Suppose $\mathcal{D}$ satisfies the $(\varepsilon, \delta, 2d, \ell)$-OSE moment property and A, B (1) have the same number of rows, and (2) sum of ranks at most $2d$. Then $\mathbb{E}_{\Pi\sim\mathcal{D}} \left\|(\Pi A)^T(\Pi B) - A^T B\right\|^\ell < \varepsilon^\ell \|A\|^\ell \|B\|^\ell \delta$.*

Then, just as [22, Theorem 6.2] showed that having OSE moments with $d = 1$ implies approximate matrix multiplication with Frobenius norm error, here we show that having OSE moments for larger d implies approximate matrix multiplication with operator norm error.

▶ **Theorem 6.** *Given $k, \varepsilon, \delta \in (0, 1/2)$, let $\mathcal{D}$ be any distribution over matrices with n columns with the $(\varepsilon, \delta, 2k, \ell)$-OSE moment property for some $\ell \geq 2$. Then, for any A, B,*

$$\mathop{\mathbb{P}}_{\Pi\sim\mathcal{D}}\left(\|(\Pi A)^T(\Pi B) - A^T B\| > \varepsilon\sqrt{(\|A\|^2 + \|A\|_F^2/k)(\|B\|^2 + \|B\|_F^2/k)}\right) < \delta \tag{3}$$

Proof. We can assume A, B each have orthogonal columns. This is since, via the full SVD, there exist orthogonal matrices R_A, R_B such that AR_A and BR_B each have orthogonal columns. Since neither left nor right multiplication by an orthogonal matrix changes operator norm,

$$\|(\Pi A)^T(\Pi B) - A^T B\| = \|(\Pi A R_A)^T(\Pi B R_B) - (AR_A)^T B R_B\|.$$

Thus, we replace A by AR_A and similarly for B. We may also assume the columns $a_1, a_2, \ldots$ of A are sorted so that $\|a_i\|_2 \geq \|a_{i+1}\|_2$ for all i. Henceforth we assume A has orthogonal columns in this sorted order (and similarly for B, with columns b_i). Now, treat A as a block matrix in which the columns are blocked into groups of size k, and similarly for B (if the number of columns of either A or B is not divisible by k, then pad them

with all-zero columns until they are). Let the spectral norm of the ith block of A be $s_i = \|a_{(i-1)\cdot k+1}\|_2$, and for B denote the spectral norm of the ith block as $t_i = \|b_{(i-1)\cdot k+1}\|_2$. These equalities for A, B hold since their columns are orthogonal and sorted by norm. We claim $\sum_i s_i^2 \leq \|A\|^2 + \|A\|_F^2/k$ (and similarly for $\sum_i t_i^2$). To see this, let the blocks of A be $A'_1, \ldots, A'_q$ where $s_i = \|A'_i\|$. Note $s_1^2 = \|A'_1\| \leq \|A\|$. Also, for $i > 1$ we have $s_i^2 = \|a_{(i-1)\cdot k+1}\|_2^2 \leq \frac{1}{k}\sum_{(i-2)\cdot k+1 \leq j \leq (i-1)\cdot k} \|a_j\|_2^2 = \frac{1}{k}\|A'_{i-1}\|_F^2$. Thus $\sum_{i>1} s_i^2 \leq \|A\|_F^2/k$.

Define $C = (\Pi A)^T(\Pi B) - A^T B$. Let $v_{\{i\}}$ denote the ith block of a vector v (the k-dimensional vector whose entries consist of entries $(i-1)\cdot k+1$ to $i \cdot k$ of v), and $C_{\{i\},\{j\}}$ the (i,j)th block of C, a $k \times k$ matrix (the entries in C contained in the ith block of rows and jth block of columns).

Now, $\|C\| = \sup_{\|x\|=\|y\|=1} x^T C y$. For any such vectors x and y, we define new vectors x' and y' whose coordinates correspond to entire blocks: we let $x'_i = \|x_{\{i\}}\|$, with y' defined analogously. We similarly define C' with entries corresponding to blocks of C, where $C'_{i,j} = \|C_{\{i\},\{j\}}\|$. Then $x^T C y \leq x'^T C' y'$, simply by bounding the contribution of each block. Thus it suffices to upper bound $\|C'\|$, which we bound by its Frobenius norm $\|C'\|_F$. Now, recalling for a random variable X that $\|X\|_\ell$ denotes $(\mathbb{E}\,|X|^\ell)^{1/\ell}$ and using Minkowski's inequality (that $\|\cdot\|_\ell$ is a norm for $\ell \geq 1$),

$$\begin{aligned}\|\|C'\|_F^2\|_{\ell/2} &= \left\|\sum_{i,j} \|(\Pi A'_i)^T(\Pi B'_j) - A'^T_i B'_j\|^2\right\|_{\ell/2} \leq \sum_{i,j} \|\|(\Pi A'_i)^T(\Pi B'_j) - A'^T_i B'_j\|^2\|_{\ell/2} \\ &\leq \sum_{i,j} \varepsilon^2 s_i^2 t_j^2 \cdot \delta^{2/\ell} \text{ (Lemma 5)} = \varepsilon^2 \left(\sum_i s_i^2\right) \cdot \left(\sum_j t_j^2\right) \delta^{2/\ell},\end{aligned}$$

which is at most $(\varepsilon\sqrt{(\|A\|^2 + \frac{\|A\|_F^2}{k})(\|B\|^2 + \frac{\|B\|_F^2}{k})}\delta^{1/\ell})^2$. Now, $\mathbb{E}\,\|C'\|_F^\ell = \|\|C'\|_F^2\|_{\ell/2}^{\ell/2}$, implying

$$\begin{aligned}&\mathbb{P}\left(\|C'\| > \varepsilon\sqrt{(\|A\|^2 + \frac{\|A\|_F^2}{k})(\|B\|^2 + \frac{\|B\|_F^2}{k})}\right) \\ &\leq \mathbb{P}\left(\|C'\|_F > \varepsilon\sqrt{(\|A\|^2 + \frac{\|A\|_F^2}{k})(\|B\|^2 + \frac{\|B\|_F^2}{k})}\right) \\ &< \frac{\mathbb{E}\,\|C'\|_F^\ell}{\left(\varepsilon\sqrt{(\|A\|^2 + \frac{\|A\|_F^2}{k})(\|B\|^2 + \frac{\|B\|_F^2}{k})}\right)^\ell},\end{aligned}$$

and the latter is at most δ. ◀

We now discuss the implications of applying Theorem 6 to specific OSE's.

2.1.1 Subgaussian maps

In the full version we show that if Π has independent subgaussian entries and $m = \Omega((k + \log(1/\delta))/\varepsilon^2)$ rows, then it satisfies the $(\varepsilon, \delta, 2k, \Theta(k + \log(1/\delta)))$ OSE moment property. Thus Theorem 6 applies to show that such Π will satisfy (k, ε, δ)-AMM.

2.1.2 SRHT

The SRHT is the matrix product $\Pi = SHD$ where $D \in \mathbb{R}^{n\times n}$ is $n \times n$ diagonal with independent ± 1 entries on the diagonal, H is a "bounded orthonormal system" (i.e. an

orthogonal matrix in $\mathbb{R}^{n\times n}$ with $\max_{i,j}|H_{i,j}| = O(1/\sqrt{n})$), and the m rows of S are independent and each samples a uniformly random element of $[n]$. Bounded orthonormal systems include the discrete Fourier matrix and the Hadamard matrix; thus such Π exist supporting matrix-vector multiplication in $O(n\log n)$ time. Thus when computing ΠA for some $n\times d$ matrix A, this takes time $O(nd\log n)$ (by applying Π to A column by column). In the full version we show that the SRHT with $m = \Omega((k+\log(1/(\varepsilon\delta))\log(k/\delta))/\varepsilon^2)$ satisfies the $(\varepsilon,\delta,2k,\log(k/\delta))$-OSE moment property, and thus provides (k,ε,δ)-AMM. Interestingly our analysis of the SRHT in the full version seems to be asymptotically tighter than any other analyses in previous work even for the basic subspace embedding property, and even slightly improves the by now standard analysis of the Fast JL transform given in [1].

2.1.3 Sparse subspace embeddings

The sparse embedding distribution with parameters m, s is as follows [9, 34, 22]. The matrix Π has m rows and n columns. The columns are independent, and for each column exactly s uniformly random entries are chosen without replacement and set to $\pm 1/\sqrt{s}$ independently; other entries in that column are set to zero. Alternatively, one could use the CountSketch [6]: the m rows are equipartitioned into s sets of size m/s each. The columns are independent, and in each column we pick exactly one row from each of the s partitions and set the corresponding entry in that column to $\pm 1/\sqrt{s}$ uniformly; the rest of the entries in the column are set to 0. Note ΠA can be multiplied in time $O(s\cdot nnz(A))$, and thus small s is desirable.

It was shown in [33, 34], slightly improving [9], that either of the above distributions satisfies the $(\varepsilon,\delta,k,2)$-OSE moment property for $m = \Omega(k^2/(\varepsilon^2\delta))$, $s = 1$, and hence (k,ε,δ)-AMM (though this particular conclusion follows easily from [22, Theorem 6.2]). It was also shown in [10], improving upon [34], that they satisfy the $(\varepsilon,\delta,k,\log(k/\delta))$-OSE moment property, and hence also (k,ε,δ)-AMM, for $m = \Omega(Bk\log(k/\delta)/\varepsilon^2), s = \Omega(\log_B(k/\delta)/\varepsilon)$ for any $B > 2$. The work [10] does not explicitly discuss the OSE moment property for sparse subspace embeddings, but it is implied; see the full version. It is conjectured that for $B = O(1)$, $m = \Omega((k+\log(1/\delta))/\varepsilon^2)$ should suffice [34, Conjecture 14].

▶ Remark 2. Currently there appears to be a tradeoff: one can either use Π s.t. ΠA can be computed quickly, such as sparse subspace embeddings or the SRHT, but then m is at least $k\log k$. Alternatively one could achieve the optimal $m = O(k/\varepsilon^2)$ using subgaussian Π, but then multiplying by Π is slower: $O(mnd)$ time for $A\in\mathbb{R}^{n\times d}$. However, settling for a tradeoff is unnecessary. One can obtain the "best of both worlds" by composition so that ΠA will have the desired $O(k/\varepsilon^2)$ rows and ΠA computed in time $O(nnz(A)) + \tilde{O}(\varepsilon^{-O(1)}(k^3+k^2d))$; see full version.

3 Applications

Spectral norm approximate matrix multiplication with dimension bounds depending on stable rank has immediate applications for the analysis of generalized regression and low-rank approximation problems. We also point out to the reader recent applications of this result to kernelized ridge regression [43] and k-means clustering [11].

3.1 Generalized regression

Here we consider generalized regression: attempting to approximate a matrix B as AX, with A of rank at most k. Let P_A be the orthogonal projection operator to the column space of A, with $P_{\bar{A}} = I - P$; then the natural best approximation will satisfy $AX = P_A B$. This minimizes

both the Frobenius and spectral norms of $AX - B$. A standard approximation algorithm for this is to replace A and B with sketches ΠA and ΠB, then solve the reduced problem exactly (see e.g. [8], Theorem 3.1). This will produce $\tilde{X} = U_A((\Pi U_A)^T \Pi U_A)^{-1}(\Pi U_A)^T \Pi B$. Below we give a lemma on the guarantees of the sketched solution in terms of properties of Π; proof is in full version.

▶ **Theorem 7.** *If* Π (1) *satisfies the* $(k, \sqrt{\varepsilon/8})$*-approximate spectral norm matrix multiplication property for* $U_A, P_{\bar{A}}B$*, and* (2) *is a* $(1/2)$*-subspace embedding for the column space of* A *(which is implied by* Π *satisfying the spectral norm approximate matrix multiplication property for* U_A *with itself), then* $\|A\tilde{X} - B\|^2 \leq (1+\varepsilon)\|P_A B - B\|^2 + (\varepsilon/k) \cdot \|P_A B - B\|_F^2$.

3.2 Low-rank approximation

Now we apply the generalized regression result from Section 3.1 to obtain a result on low-rank approximation: approximating A in the form $\tilde{U}_k \tilde{\Sigma}_k \tilde{V}_k^T$, where $\tilde{U}_k$ has only k columns and both $\tilde{U}_k$ and $\tilde{V}_k$ have orthonormal columns. Here, we consider a previous approach (see e.g. [38]): (1) let $S = \Pi A$, (2) let P_S be the orthogonal projection operator to the row space of S and $\tilde{A} = AP_S$, and (3) compute an SVD of $\tilde{A}$ and keep only the top k singular vectors, then return the resulting low rank approximation $\tilde{A}_k$ of $\tilde{A}$. It turns out computing $\tilde{A}_k$ can be done much more quickly than computing A_k; see details in [8, Lemma 4.3]. Let $A_k, U_k, A_{\bar{k}}$ be as in Section 1.1.

▶ **Theorem 8.** *If* Π (1) *satisfies the* $(k, \sqrt{\varepsilon/8})$*-approximate spectral norm matrix multiplication property for* $U_k, A_{\bar{k}}$*, and* (2) *is a* $(1/2)$*-subspace embedding for the column space of* U_k *then* $\|A - \tilde{A}_k\|^2 \leq (1+\varepsilon)\|A - A_k\|^2 + (\varepsilon/k)\|A - A_k\|_F^2$

3.3 Kernelized ridge regression

In nonparametric regression one is given data $y_i = f^*(x_i) + w_i$ for $i = 1, \ldots, n$, and the goal is to recover a good estimate for the function f^*. Here the y_i are scalars, the x_i are vectors, and the w_i are independent noise, often assumed to be distributed as mean-zero gaussian with some variance σ^2. Unlike linear regression where $f^*(x_i)$ is assumed to take the form $\langle \beta, x \rangle$ for some vector β, in nonparametric regression we allow f^* to be an arbitrary function from some function space. Naturally the goal then is to recover some $\tilde{f}$ from the data that is close to f^* whp over the noise.

Recent work [43] considers the well studied problem of obtaining $\tilde{f}$ so that $\|\tilde{f} - f^*\|_n^2$ is small with high probability over the noise w, where one uses the definition $\|f - g\|_n^2 = \frac{1}{n}\sum_{i=1}^n (f(x_i) - g(x_i))^2$. The work [43] considers the case where f^* comes from a space of functions which is the closure of all functions g expressable as $g(x) = \sum_{i=1}^N \alpha_i k(x, z_i)$ over all N, $\alpha \in \mathbb{R}^N$, and vectors z_i for some PSD kernel function k. See the full version for details, but the punchline is the maximum likelihood estimator for $\tilde{f}$ is then the solution f^{LS} to a Kernelized Ridge Regression (KRR) problem, and $f^{LS}(x)$ can be expressed as a linear combination of kernel evaluations $\sum_{i=1}^n \alpha_i k(x, x_i)$. Then defining matrix K with $K_{i,j} = k(x_i, x_j)$, KRR is equivalent to computing

$$\alpha^{LS} = \underset{\alpha \in \mathbb{R}^n}{argmin} \left\{ \frac{1}{2n}\alpha^T K^2 \alpha - \frac{1}{n}\alpha^T K y + \lambda_n \alpha^T K \alpha \right\} = \left(\frac{1}{n}K^2 + 2\lambda_n K \right)^{-1} \cdot \frac{1}{n} K y,$$

which can be computed in $O(n^3)$ time. The work [43] then focuses on speeding this up, by

instead computing a solution to the lower-dimensional problem

$$\tilde{\alpha}^{LS} = \underset{\alpha\in\mathbb{R}^m}{argmin}\left\{\frac{1}{2n}\alpha^T\Pi K^2\Pi^T\alpha - \frac{1}{n}\alpha^T\Pi K y + \lambda_n\alpha^T\Pi K\Pi^T\alpha\right\}$$
$$= \left(\frac{1}{n}\Pi K^2\Pi^T + 2\lambda_n\Pi K\Pi^T\right)^{-1}\cdot\frac{1}{n}\Pi K y$$

and then returning as $\tilde{f}$ the function specified by the weight vector $\tilde{\alpha} = \Pi^T\tilde{\alpha}^{LS}$. Note that once various matrix products are formed (where the running time complexity depends on the Π being used), one only needs to invert an $m\times m$ matrix thus taking $O(m^3)$ time. They then prove that $\|\tilde{f} - f^*\|_n$ is small with high probability as long as Π satisfies two deterministic conditions (see the proof of Lemma 2 [43, Section 4.1.2], specifically equation (26) in that work): (1) Π is a $(1/2)$-subspace embedding for a particular low-dimensional subspace, and (2) $\|\Pi B\| = O(\|B\|)$ for a particular matrix B of low stable rank (B is UD_2 in [43]). Note by the triangle inequality, $\|\Pi B\| \leq \|(\Pi B)^T\Pi B - B^TB\|^{1/2} + \|B\|$, and thus it suffices for Π to provide AMM for the product B^TB, where B has low stable rank. Item (1) simply requires a subspace embedding in the standard sense, and for item (2) [43] avoided AMM by obtaining a bound on $\|\Pi B\|$ directly by their own analyses for gaussian Π and the SRHT. Our result thus provides a unifying analysis which works for a larger and general class of Π, including for example sparse subspace embeddings.

3.4 *k*-means clustering

In the works [5, 11], the authors considered dimensionality reduction methods for k-means clustering. Recall in k-means clustering one is given n points $x_1,\ldots,x_n\in\mathbb{R}^d$, as well as an integer $k\geq 1$, and the goal is to find k points $y_1,\ldots,y_k\in\mathbb{R}^d$ minimizing $\sum_{i=1}^n\min_{j=1}^k\|x_i - y_j\|_2^2$. One key observation common to both [5, 11] is that k-means clustering is closely related to the problem of low-rank approximation. More specifically, given a partition $\mathcal{P} = \{P_1,\ldots,P_k\}$, define the $n\times k$ matrix $X_{\mathcal{P}}$ by $(X_{\mathcal{P}})_{i,j}$ is $1/\sqrt{|P_j|}$ if $i\in P_j$, and zero otherwise. Let $A\in\mathbb{R}^{n\times d}$ have rows $x_1,\ldots,x_n$. Then the k-means problem can be rewritten as computing $\mathcal{P}^* = \text{argmin}_{\mathcal{P}}\|A - X_{\mathcal{P}}X_{\mathcal{P}}^TA\|_F^2$, where $\mathcal{P}$ ranges over all partitions of $\{1,\ldots,n\}$ into k sets (the y_i are the distinct rows of $X_{\mathcal{P}}X_{\mathcal{P}}^TA$). It is easy to verify the columns of $X_{\mathcal{P}}$ are orthonormal, so $X_{\mathcal{P}}X_{\mathcal{P}}^T$ is the orthogonal projection onto the column space of $X_{\mathcal{P}}$. Thus if one defines $\mathcal{S}$ as the set of all rank k orthogonal projections obtained as $X_{\mathcal{P}}X_{\mathcal{P}}^T$ for some k-partition $\mathcal{P}$, then the above can be rewritten as the *constrained rank-k projection problem* of computing $\mathcal{P}^* = \text{argmin}_{P\in\mathcal{S}}\|(I-P)A\|_F^2$.

The work [11] showed that if $\mathcal{S}$ is any subset of projections of rank at most k (henceforth *rank-k projections*) and $\Pi\in\mathbb{R}^{m\times d}$ satisfies certain technical conditions to be divulged soon, then if $\tilde{P}\in\mathcal{S}$ minimizes the Π-reduced problem $\min_{P\in\mathcal{S}}\|(I-P)A\Pi^T\|_F^2$ up to a factor of γ, then $\tilde{P}$ minimizes the original problem $\min_{P\in\mathcal{S}}\|(I-P)A\|_F^2$ up to $(1+O(\varepsilon))\gamma$.

One set of sufficient conditions for Π is as follows (see [11, Lemma 10]). There is a matrix $B\in\mathbb{R}^{(n+2k)\times d}$ of stable rank $O(k)$, where k is the number of cluster centers y_i above, such that if

$$\|(\Pi B^T)^T(\Pi B^T) - BB^T\| < \varepsilon, \tag{4}$$
$$\text{and } \left|\|\Pi B_2\|_F^2 - \|B_2\|_F^2\right| \leq \varepsilon k \tag{5}$$

then $\tilde{P}$ provides good error as discussed above. Thus for Eq. (4) it suffices for Π to provide $(O(k),\varepsilon/2)$-AMM for B^T, B^T, and our results apply. Obtaining Eq. (5) is much simpler and can be derived from the JL moment property (see the proof of [22, Theorem 6.2]).

Without our results on stable-rank AMM provided in this current work, [11] gave a different analysis, avoiding [11, Lemma 10], which for subgaussian Π required $m = \Theta(k \cdot \log(1/\delta)/\varepsilon^2)$ rows (note the product between k and $\log(1/\delta)$ instead of the sum).

4 Stable rank and row selection

As well as random projections, AMM (and subspace embeddings) by row selection are also common in algorithms. This corresponds to setting Π to a diagonal matrix S with relatively few nonzero entries. Unlike random projections, there are no *oblivious* distributions of such matrices S with universal guarantees. Instead, S must be determined (either randomly or deterministically) from the matrices being embedded.

There are two particularly algorithmically useful methods for obtaining such S. The first is importance sampling: independent random sampling of the rows, but with nonuniform sampling probabilities. For rank-k matrices, $O(k(\log k)/\varepsilon^2)$ samples suffice [17, 39]. The second method is the deterministic selection method given in [3], often called "BSS", choosing only $O(k/\varepsilon^2)$ rows. This still runs in polynomial time, but originally required many expensive linear algebra steps and thus was slower in general; see [26] for runtime improvements.

The method used in [39] (matrix Chernoff bound) can be extended to the stable-rank case, making even the log factor in the number of samples depend only on the stable rank; see the full version for details. We here give an extension of BSS that covers low stable rank matrices as well. The proof is in the full version, and follows by observing that it suffices to just perform a slight modification of the original BSS proof.

▶ **Theorem 9.** *Given two matrices A and B, each with n rows, and an $\varepsilon \in (0, 1)$, there exists a diagonal matrix S with $O(k/\varepsilon^2)$ nonzero entries satisfying the (k, ε)-AMM property for A, B. Such an S can be computed by a polynomial-time algorithm.*

When $A = B$ and $A^T A$ is the identity, this is just the original BSS result. It is also stronger than Theorem 3.3 of [23], implying it when A is the combination of the rows $\sqrt{N/T} \cdot v_i$ from that theorem statement with an extra column containing the costs, and a constant ϵ. The techniques in that paper, on the other hand, can prove a result comparable to Theorem 9, but with the row count scaling as k/ε^3 rather than k/ε^2.

Acknowledgments. We thank Jarosław Błasiok for pointing out the connection between low stable rank approximate matrix multiplication and the analyses in [43].

sjeffery@caltech.edu

Abstract

Span programs are a model of computation that have been used to design quantum algorithms, mainly in the query model. It is known that for any decision problem, there exists a span program that leads to an algorithm with optimal quantum query complexity, however finding such an algorithm is generally challenging. In this work, we consider new ways of designing quantum algorithms using span programs. We show how any span program that decides a problem f can also be used to decide "property testing" versions of the function f, or more generally, approximate a quantity called the *span program witness size*, which is some property of the input related to f. For example, using our techniques, the span program for OR, which can be used to design an optimal algorithm for the OR function, can also be used to design optimal algorithms for: threshold functions, in which we want to decide if the Hamming weight of a string is above a threshold, or far below, given the promise that one of these is true; and approximate counting, in which we want to estimate the Hamming weight of the input up to some desired accuracy. We achieve these results by relaxing the requirement that 1-inputs hit some *target* exactly in the span program, which could potentially make design of span programs significantly easier. In addition, we give an exposition of span program structure, which increases the general understanding of this important model. One implication of this is alternative algorithms for estimating the witness size when the phase gap of a certain unitary can be lower bounded. We show how to lower bound this phase gap in certain cases.

As an application, we give the first upper bounds in the adjacency query model on the quantum time complexity of estimating the effective resistance between s and t, $R_{s,t}(G)$. For this problem we obtain $\widetilde{O}(\frac{1}{\varepsilon^{3/2}} n\sqrt{R_{s,t}(G)})$, using $O(\log n)$ space. In addition, when μ is a lower bound on $\lambda_2(G)$, by our phase gap lower bound, we can obtain an upper bound of $\widetilde{O}\left(\frac{1}{\varepsilon} n\sqrt{R_{s,t}(G)/\mu}\right)$ for estimating effective resistance, also using $O(\log n)$ space.

1 Introduction

Span programs are a model of computation first used to study logspace complexity [13], and more recently, introduced to the study of quantum algorithms in [20]. They are of immense theoretical importance, having been used to show that the general adversary bound gives a

tight lower bound on the quantum query complexity of any decision problem [18, 19]. As a means of designing quantum algorithms, it is known that for any decision problem, there exists a span-program-based algorithm with asymptotically optimal quantum query complexity, but this fact alone gives no indication of how to find such an algorithm. Despite the relative difficulty in designing quantum algorithms this way, there are many applications, including formula evaluation [20, 19], a number of algorithms based on the learning graph framework [3], st-connectivity [5] and k-distinctness [2]. Although generally quantum algorithms designed via span programs can only be analyzed in terms of their query complexity, in some cases their time complexity can also be analyzed, as is the case with the quantum algorithm for st-connectivity. In the case of the quantum algorithm for k-distinctness, the ideas used in designing the span program could be turned into a quantum algorithm for 3-distinctness with time complexity matching its query complexity up to logarithmic factors [4].

In this work, we consider new ways of designing quantum algorithms via span programs. Consider Grover's quantum search algorithm, which, on input $x \in \{0,1\}^n$, decides if there is some $i \in [n]$ such that $x_i = 1$ using only $O(\sqrt{n})$ quantum operations [10]. The ideas behind this algorithm have been used in innumerable contexts, but in particular, a careful analysis of the ideas behind Grover's algorithm led to algorithms for similar problems, including a class of *threshold functions*: given $x \in \{0,1\}^n$, decide if $|x| \geq t$ or $|x| < \varepsilon t$, where $|x|$ denotes the Hamming weight; and approximate counting: given $x \in \{0,1\}^n$, output an estimate of $|x|$ to some desired accuracy. The results in this paper offer the possibility of obtaining analogous results for any span program. That is, given a span program for some problem f, our results show that one can obtain, not only an algorithm for f, but algorithms for a related class of threshold functions, as well as an algorithm for estimating a quantity called the *span program witness size*, which is analogous to $|x|$ in the above example (and is in fact exactly $1/|x|$ in the span program for the OR function — see Section 2.3).

We give several new means of constructing quantum algorithms from span programs. Roughly speaking, a span program can be turned into a quantum algorithm that decides between two types of inputs: those that "hit" a certain "target vector", and those that don't. We show how to turn a span program into an algorithm that decides between inputs that get "close to" the target vector, and those that don't. Whereas traditionally a span program has been associated with some decision problem, this allows us to now associate, with one span program, a whole class of threshold problems.

In addition, for any span program P, we can construct a quantum algorithm that estimates the *positive witness size*, $w_+(x)$, to accuracy ε in $\frac{1}{\varepsilon^{3/2}}\sqrt{w_+(x)\widetilde{W}_-}$ queries, where $\widetilde{W}_-$ is the *approximate negative witness complexity* of P. This construction is useful whenever we can construct a span program for which $w_+(x)$ corresponds to some function we care to estimate, as is the case with the span program for OR, in which $w_+(x) = \frac{1}{|x|}$, or the span from for st-connectivity, in which $w_+(G) = \frac{1}{2}R_{s,t}(G)$, where G is a graph, and $R_{s,t}(G)$ is the *effective resistance* between s and t in G. We show similar results for estimating the negative witness size as well.

Our analysis of the structure of span programs increases the theoretical understanding of this important model. One implication of this is alternative algorithms for estimating the witness size when the phase gap (or spectral gap) of a certain unitary associated with the span program can be lower bounded. This is in contrast to previous span program algorithms, including those mentioned in the previous paragraph, which have all relied on *effective spectral gap* analysis. We show how the phase gap can be lower bounded by $\frac{\sigma_{\max}(A)}{\sigma_{\min}(A(x))}$, where A and $A(x)$ are linear operators associated with the span program and some input x, and $\sigma_{\min}$ and $\sigma_{\max}$ are the smallest and largest nonzero singular values.

In addition, our exposition highlights the relationship between span programs and estimating the size of the smallest solution to a linear system, which is a problem solved by Harrow, Hassidim and Lloyd in [11]. It is not yet clear if this relationship can lead to new algorithms, but it is an interesting direction for future work.

An immediate application of our results is a quantum algorithm for estimating the effective resistance between two vertices in a graph, $R_{s,t}(G)$. This example is immediate, because in [5], a span program for st-connectivity was presented, in which the positive witness size corresponds to $R_{s,t}(G)$. The results of [5], combined with our new span program algorithms, immediately yield an upper bound of $\widetilde{O}(\frac{1}{\varepsilon^{3/2}} n\sqrt{R_{s,t}(G)})$ for estimating the effective resistance to relative accuracy ε. This upper bound also holds for time complexity, due to the time complexity analysis of [5]. Using our new spectral analysis techniques, we are also able to get an often better upper bound of $\widetilde{O}\left(\frac{1}{\varepsilon} n\sqrt{R_{s,t}(G)/\mu}\right)$, on the time complexity of estimating effective resistance, where μ is a lower bound on $\lambda_2(G)$, the second smallest eigenvalue of the Laplacian. Both algorithms use $O(\log n)$ space. We also show that a linear dependence on n is necessary, so our results cannot be significantly improved.

These are the first quantum algorithms for this problem in the adjacency query model. Previous quantum algorithms have been in the edge-list model for d-regular graphs [22]. These results can be naively extended to the adjacency query model by simulating an edge query with $\sqrt{n/d}$ adjacency queries, using quantum search, which gives an upper bound of $\widetilde{O}\left(\frac{d^{3/2}}{\Phi^2\varepsilon}\sqrt{n/d}\right)$ queries, where Φ is the *conductance* of the input graph. Our upper bounds improve on this in many cases, including, but not limited to, d-regular graphs with $d > \sqrt[4]{n}$, and furthermore, our results do not assume the input graph is regular. Classically, the effective resistance can be computed exactly by inverting the Laplacian, which costs $O(m) = O(n^2)$, where m is the number of edges in the input graph.

1.1 Preliminaries

To begin, we fix notation. For vector spaces V and W, we let $\mathcal{L}(V, W)$ denote the set of linear operators from V to W. For any operator $A \in \mathcal{L}(V, W)$, we denote by $\mathrm{col}A$ the columnspace, $\mathrm{row}A$ the rowspace, and $\ker A$ the kernel of A. $\sigma_{\min}(A)$ and $\sigma_{\max}(A)$ denote the smallest and largest non-zero singular values, respectively. A^+ denotes the Moore-Penrose pseudo-inverse.

The algorithms in this paper solve either decision problems, or estimation problems. For $f : X \subseteq [q]^n \to \{0, 1\}$, we say that an algorithm *decides f with bounded error* if for any $x \in X$, with probability at least $2/3$, the algorithm outputs $f(x)$ on input x. For $f : X \subseteq [q]^n \to \mathbb{R}_{\geq 0}$, we say that an algorithm *estimates f to relative accuracy ε* with bounded error if for any $x \in X$, with probability at least $2/3$, on input x the algorithm outputs $\tilde{f}$ such that $|f(x) - \tilde{f}| \leq \varepsilon f(x)$. In both cases, using $2/3$ is without loss of generality: any algorithm with success probability bounded above $1/2$ by a constant can be amplified to success probability arbitrarily close to 1 by taking the median of the outputs of a constant number of repetitions of the algorithm. We generally omit the description "with bounded error", as all of our algorithms have bounded error.

All algorithms presented in this paper are based on the following structure. We have some initial state $|\phi_0\rangle$, and some unitary operator U, and we want to estimate $\|\Pi_0|\phi_0\rangle\|$, where Π_0 is the orthogonal projector onto the 1-eigenspace of U. The first step in this process is a quantum algorithm that estimates, in a new register, the phase of U applied to the input state.

▶ **Theorem 1** (Phase Estimation [14, 9]). *Let $U = \sum_{j=1}^{m} e^{i\theta_j}|\psi_j\rangle\langle\psi_j|$ be the spectral decomposition of a unitary, with $\theta_1, \ldots, \theta_m \in (-\pi, \pi]$. For any $\Theta \in (0, \pi)$ and $\varepsilon \in (0, 1)$, there*

exists a quantum algorithm that makes $O\left(\frac{1}{\Theta}\log\frac{1}{\varepsilon}\right)$ *controlled calls to* U *and, on input* $|\psi_j\rangle$*, outputs a state* $|\psi_j\rangle|\omega\rangle$ *such that if* $\theta_j = 0$*, then* $|\omega\rangle = |0\rangle$*, and if* $|\theta_j| \geq \Theta$*,* $|\langle 0|\omega\rangle|^2 \leq \varepsilon$*. If* U *acts on* s *qubits, the algorithm uses* $O(s + \log\frac{1}{\Theta})$ *space.*

The precision needed to isolate $\Pi_0|\phi_0\rangle$ depends on the smallest nonzero phase of U, the *phase gap*.

▶ **Definition 2** (Phase Gap). Let $\{e^{i\theta_j}\}_{j\in S}$ be the eigenvalues of a unitary operator U, with $\{\theta_j\}_{j\in S} \subset (-\pi, \pi]$. Then the *phase gap* of U is $\Delta(U) := \min\{|\theta_j| : \theta_j \neq 0\}$.

In order to estimate $\|\Pi_0|\phi_0\rangle\|^2$, given a state $|0\rangle\Pi_0|\phi_0\rangle + |1\rangle(I-\Pi_0)|\phi_0\rangle$, we use the following.

▶ **Theorem 3** (Amplitude Estimation [7]). *Let* $\mathcal{A}$ *be a quantum algorithm that outputs* $\sqrt{p(x)}|0\rangle|\Psi_x(0)\rangle + \sqrt{1-p(x)}|1\rangle|\Psi_x(1)\rangle$ *on input* x*. Then there exists a quantum algorithm that estimates* $p(x)$ *to precision* ε *using* $O\left(\frac{1}{\varepsilon}\frac{1}{\sqrt{p(x)}}\right)$ *calls to* $\mathcal{A}$*.*

If we know the amplitude is either $\leq p_0$ or $\geq p_1$ for some $p_0 < p_1$, then we can use amplitude estimation to distinguish between these two cases.

▶ **Corollary 4** (Amplitude Gap). *Let* $\mathcal{A}$ *be a quantum algorithm that, on input* x*, outputs* $\sqrt{p(x)}|0\rangle|\Psi_x(0)\rangle + \sqrt{1-p(x)}|1\rangle|\Psi_x(1)\rangle$*. For any* $0 \leq p_0 < p_1 \leq 1$*, we can distinguish between the cases* $p(x) \geq p_1$ *and* $p(x) \leq p_0$ *with bounded error using* $O\left(\frac{\sqrt{p_1}}{p_1-p_0}\right)$ *calls to* $\mathcal{A}$*.*

In order to make use of phase estimation, we will need to analyze the spectrum of a particular unitary, which, in our case, consists of a pair of reflections. The following lemma first appeared in this form in [15]:

▶ **Lemma 5** (Effective Spectral Gap Lemma). *Let* $U = (2\Pi_A - I)(2\Pi_B - I)$ *be the product of two reflections, and let* Π_Θ *be the orthogonal projector onto* $\mathrm{span}\{|u\rangle : U|u\rangle = e^{i\theta}|u\rangle, |\theta| \leq \Theta\}$*. Then if* $\Pi_A|u\rangle = 0$*,* $\|\Pi_\Theta\Pi_B|u\rangle\| \leq \frac{\Theta}{2}\||u\rangle\|$*.*

The following theorem was first used in the context of quantum algorithms by Szegedy [21]:

▶ **Theorem 6** ([21]). *Let* $U = (2\Pi_A - I)(2\Pi_B - I)$ *be a unitary on a space* H *containing* $A = \mathrm{span}\{|\psi_1\rangle, \ldots, |\psi_a\rangle\}$ *and* $B = \mathrm{span}\{|\phi_1\rangle, \ldots, |\phi_b\rangle\}$*. Let* $\Pi_A = \sum_{i=1}^a |\psi_i\rangle\langle\psi_i|$ *and* $\Pi_B = \sum_{i=1}^b |\phi_i\rangle\langle\phi_i|$ *be the orthogonal projectors onto these spaces. Let* $D = \Pi_A\Pi_B$ *be the discriminant of* U*, and suppose it has singular value decomposition* $\sum_{j=1}^r \cos\theta_j|\alpha_j\rangle\langle\beta_j|$*, with* $\theta_j \in [0, \frac{\pi}{2}]$*. Then the spectrum of* U *is* $\{e^{\pm 2i\theta_j}\}_j$*. The 1-eigenspace of* U *is* $(A\cap B)\oplus(A^\perp\cap B^\perp)$ *and the* (-1)*-eigenspace is* $(A \cap B^\perp) \oplus (A^\perp \cap B)$*.*

Let $\Lambda_A = \sum_{j=1}^a |\psi_j\rangle\langle j|$ and $\Lambda_B = \sum_{j=1}^b |\phi_j\rangle\langle j|$. We note that in the original statement of Theorem 6, the discriminant is defined $D' = \Lambda_A^\dagger\Lambda_B$. However it is easy to see that D' and D have the same singular values: if $D' = \sum_i \sigma_i|v_i\rangle\langle u_i|$ is a singular value decomposition of D', then $D = \sum_i \sigma_i\Lambda_A|v_i\rangle\langle u_i|\Lambda_B^\dagger$ is a singular value decomposition of D, since Λ_A acts as an isometry on the columns of D', and Λ_B acts as an isometry on the rows of D'.
The following corollary to Theorem 6 will be useful in the analysis of several algorithms.

▶ **Corollary 7** (Phase Gap and Discriminant). *Let* D *be the discriminant of a unitary* $U = (2\Pi_A - I)(2\Pi_B - I)$*. Then* $\Delta(-U) \geq 2\sigma_{\min}(D)$*.*

2 Approximate Span Programs

2.1 Span Programs and Decision Problems

In this section, we review the concept of span programs, and their use in quantum algorithms.

▶ **Definition 8** (Span Program). A span program $P = (H, V, \tau, A)$ on $[q]^n$ consists of

1. finite-dimensional inner product spaces $H = H_1 \oplus \cdots \oplus H_n \oplus H_{\text{true}} \oplus H_{\text{false}}$, and $\{H_{j,a} \subseteq H_j\}_{j\in[n],a\in[q]}$ such that $H_{j,1} + \cdots + H_{j,q} = H_j$,
2. a vector space V,
3. a *target vector* $\tau \in V$, and
4. a linear operator $A \in \mathcal{L}(H, V)$.

To each string $x \in [q]^n$, we associate a subspace $H(x) := H_{1,x_1} \oplus \cdots \oplus H_{n,x_n} \oplus H_{\text{true}}$.

Although our notation in Definition 8 deviates from previous span program definitions, the only difference in the substance of the definition is that the spaces $H_{j,a}$ and $H_{j,b}$ for $a \neq b$ need not be orthogonal in our definition. This has the effect of removing $\log q$ factors in the equivalence between span programs and the dual adversary bound (for details see [12, Sec. 7.1]). The spaces H_{true} and H_{false} can be useful for designing a span program, but are never required, since we can always add an $(n+1)^{\text{th}}$ variable, set $x_{n+1} = 1$, and let $H_{n+1,0} = H_{\text{false}}$ and $H_{n+1,1} = H_{\text{true}}$.

A span program on $[q]^n$ partitions $[q]^n$ into two sets: *positive* inputs, which we call P_1, and *negative* inputs, which we call P_0. The importance of this partition stems from the fact that a span program may be converted into a quantum algorithm for deciding this partition in the quantum query model [18, 19]. Thus, if one can construct a span program whose partition of $[q]^n$ corresponds to a problem one wants to solve, an algorithm follows. In order to describe how a span program partitions $[q]^n$ and the query complexity of the resulting algorithm, we need the concept of positive and negative witnesses and witness size.

▶ **Definition 9** (Positive and Negative Witness). Fix a span program P on $[q]^n$, and a string $x \in [q]^n$. We say that $|w\rangle$ is a *positive witness for x in P* if $|w\rangle \in H(x)$, and $A|w\rangle = \tau$. We define the *positive witness size of x* as:

$$w_+(x, P) = w_+(x) = \min\{\||w\rangle\|^2 : |w\rangle \in H(x), A|w\rangle = \tau\},$$

if there exists a positive witness for x, and $w_+(x) = \infty$ else. We say that $\omega \in \mathcal{L}(V, \mathbb{R})$ is a *negative witness for x in P* if $\omega A \Pi_{H(x)} = 0$ and $\omega\tau = 1$. We define the *negative witness size of x* as:

$$w_-(x, P) = w_-(x) = \min\{\|\omega A\|^2 : \omega \in \mathcal{L}(V, \mathbb{R}), \omega A \Pi_{H(x)} = 0, \omega\tau = 1\},$$

if there exists a negative witness, and $w_-(x) = \infty$ otherwise. If $w_+(x)$ is finite, we say that x is *positive* (with respect to P), and if $w_-(x)$ is finite, we say that x is *negative*. We let P_1 denote the set of positive inputs, and P_0 the set of negative inputs for P. Note that for every $x \in [q]^n$, exactly one of $w_-(x)$ and $w_+(x)$ is finite; that is, (P_0, P_1) partitions $[q]^n$.

For a decision problem $f : X \subseteq [q]^n \to \{0, 1\}$, we say that P *decides* f if $f^{-1}(0) \subseteq P_0$ and $f^{-1}(1) \subseteq P_1$. In that case, we can use P to construct a quantum algorithm that decides f.

▶ **Theorem 10** ([18]). *Fix $f : X \subseteq [q]^n \to \{0, 1\}$, and let P be a span program on $[q]^n$ that decides f. Let $W_+(f, P) = \max_{x\in f^{-1}(1)} w_+(x, P)$ and $W_-(f, P) = \max_{x\in f^{-1}(0)} w_-(x, P)$. Then there exists a quantum algorithm that decides f using $O(\sqrt{W_+(f, P)W_-(f, P)})$ queries.*

We call $\sqrt{W_+(f,P)W_-(f,P)}$ the *complexity* of P. It is known that for any decision problem, there exists a span program whose complexity is equal, up to constants, to its query complexity [18, 19] ([12, Sec. 7.1] removes log factors in this statement), however, it is generally a difficult task to find such an optimal span program.

2.2 Span Programs and Approximate Decision Problems

Consider a span program P and $x \in P_0$. Suppose there is some $|w\rangle \in H(x)$ such that $A|w\rangle$ comes extremely close to τ. We might say that x is very close to being in P_1. If all vectors in $H(y)$ for $y \in P_0 \setminus \{x\}$ are very far from τ, it might be slightly more natural to consider the partition $(P_0 \setminus \{x\}, P_1 \cup \{x\})$ rather than (P_0, P_1).

As further motivation, we mention a construction of Reichardt [18, Sec. 3 of full version] that takes any quantum query algorithm with one-sided error, and converts it into a span program whose complexity matches the query complexity of the algorithm. The target of the span program is the vector $|1,\bar{0}\rangle$, which corresponds to a quantum state with a 1 in the answer register and 0s elsewhere. If an algorithm has no error on 1-inputs, it can be modified so that it always ends in exactly this state, by uncomputing all but the answer register. An algorithm with two-sided error cannot be turned into a span program using this construction, because there is error in the final state. This is intuitively in opposition to the evidence that span programs characterize bounded (two-sided) error quantum query complexity. The exactness required by span programs seems to contrast the spirit of non-exact quantum algorithms.

This motivates us to consider the *positive error* of an input, or how close it comes to being positive. Since there is no meaningful notion of distance in V, we consider closeness in H.

▶ **Definition 11** (Positive Error)**.** For any span program P on $[q]^n$, and $x \in [q]^n$, we define the *positive error of x in P* as:

$$e_+(x) = e_+(x,P) := \min\left\{\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 : A|w\rangle = \tau\right\}.$$

Note that $e_+(x,P) = 0$ if and only if $x \in P_1$. Any $|w\rangle$ such that $\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 = e_+(x)$ is called a *min-error positive witness for x in P*. We define

$$\tilde{w}_+(x) = \tilde{w}_+(x,P) := \min\left\{\||w\rangle\|^2 : A|w\rangle = \tau, \left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 = e_+(x)\right\}.$$

A min-error positive witness that also minimizes $\||w\rangle\|^2$ is called an *optimal min-error positive witness for x*.

Note that if $x \in P_1$, then $e_+(x) = 0$. In that case, a min-error positive witness for x is just a positive witness, and $\tilde{w}_+(x) = w_+(x)$.

We can define a similar notion for positive inputs, to measure their closeness to being negative.

▶ **Definition 12** (Negative Error)**.** For any span program P on $[q]^n$ and $x \in [q]^n$, we define the *negative error of x in P* as:

$$e_-(x) = e_-(x,P) := \min\left\{\left\|\omega A\Pi_{H(x)}\right\|^2 : \omega(\tau) = 1\right\}.$$

Again, $e_-(x,P) = 0$ if and only if $x \in P_0$. Any ω such that $\left\|\omega A\Pi_{H(x)}\right\|^2 = e_-(x,P)$ is called a *min-error negative witness for x in P*. We define

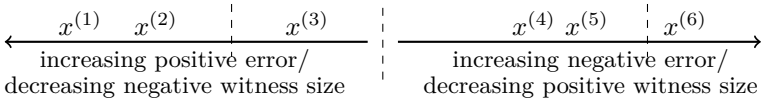
$$\tilde{w}_-(x) = \tilde{w}_-(x,P) := \min\left\{\|\omega A\|^2 : \omega(\tau) = 1, \left\|\omega A\Pi_{H(x)}\right\|^2 = e_-(x,P)\right\}.$$

A min-error negative witness that also minimizes $\|\omega A\|^2$ is called an *optimal min-error negative witness for* x.

It turns out that the notion of span program error has a very nice characterization as exactly the reciprocal of the witness size. We prove in the full version (Theorems 2.10 and 2.11):

$$\forall x \in P_0,\ w_-(x) = \frac{1}{e_+(x)}, \qquad \text{and} \qquad \forall x \in P_1,\ w_+(x) = \frac{1}{e_-(x)}.$$

This is a very nice state of affairs, for a number of reasons. It allows us two ways of thinking about approximate span programs: in terms of how small the error is, or how large the witness size is. That is, we can say that an input $x \in P_0$ is *almost positive* either because its positive error is small, or equivalently, because its negative witness size is large. In general, we can think of P as not only partitioning P into (P_0, P_1), but inducing an ordering on $[q]^n$ from most negative — smallest negative witness, or equivalently, largest positive error — to most positive — smallest positive witness, or equivalently, largest negative error. For example, on the domain $\{x^{(1)}, \ldots, x^{(6)}\} \subset [q]^n$, P might induce the following ordering:



The inputs $\{x^{(1)}, x^{(2)}, x^{(3)}\}$ are in P_0, and $w_-(x^{(1)}) < w_-(x^{(2)}) < w_-(x^{(3)})$ (although it is generally possible for two inputs to have the same witness size). The inputs $\{x^{(4)}, x^{(5)}, x^{(6)}\}$ are in P_1, and $w_+(x^{(4)}) > w_+(x^{(5)}) > w_+(x^{(6)})$. The span program exactly decides the partition $(\{x^{(1)}, x^{(2)}, x^{(3)}\}, \{x^{(4)}, x^{(5)}, x^{(6)}\})$, but we say it *approximates* any partition that respects the ordering. If we obtain a partition by drawing a line somewhere on the left side, for example $(\{x^{(1)}, x^{(2)}\}, \{x^{(3)}, x^{(4)}, x^{(5)}, x^{(6)}\})$, we say P *negatively* approximates the function corresponding to that partition, whereas if we obtain a partition by drawing a line on the right side, for example $(\{x^{(1)}, x^{(2)}, x^{(3)}, x^{(4)}, x^{(5)}\}, \{x^{(6)}\})$, we say P *positively* approximates the function.

▶ **Definition 13** (Functions Approximately Associated with P)**.** Let P be a span program on $[q]^n$, and $f : X \subseteq [q]^n \to \{0,1\}$ a decision problem. For any $\lambda \in (0,1)$, we say that P *positively* λ*-approximates* f if $f^{-1}(1) \subseteq P_1$, and for all $x \in f^{-1}(0)$, either $x \in P_0$, or $w_+(x,P) \geq \frac{1}{\lambda} W_+(f,P)$, where $W_+(f,P) := \max_{x \in f^{-1}(1)} w_+(x,P)$. We say that P *negatively* λ*-approximates* f if $f^{-1}(0) \subseteq P_0$, and for all $x \in f^{-1}(1)$, either $x \in P_1$, or $w_-(x,P) \geq \frac{1}{\lambda} W_-(f,P)$, where $W_-(f,P) := \max_{x \in f^{-1}(0)} w_-(x,P)$. If P decides f exactly, then both conditions hold for any value of λ, and so we can say that P 0-approximates f.

This allows us to consider a much broader class of functions associated with a particular span program. This association is useful, because as with the standard notion of association between a function f and a span program, if a function is approximated by a span program, we can convert the span program into a quantum algorithm that decides f using a number of queries related to the witness sizes. Specifically, we get the following theorem.

▶ **Theorem 14** (Approximate Span Program Decision Algorithms)**.** *Fix* $f : X \subseteq [q]^n \to \{0,1\}$*, and let* P *be a span program that positively* λ*-approximates* f*. Define*

$$W_+ = W_+(f,P) := \max_{x \in f^{-1}(1)} w_+(x,P) \qquad \text{and} \qquad \widetilde{W}_- = \widetilde{W}_-(f,P) := \max_{x \in f^{-1}(0)} \tilde{w}_-(x,P).$$

There is a quantum algorithm that decides f with bounded error in $O\left(\frac{\sqrt{W_+\widetilde{W}_-}}{(1-\lambda)^{3/2}}\log\frac{1}{1-\lambda}\right)$ queries. Similarly, let P be a span program that negatively λ-approximates f. Define

$$W_- = W_-(f,P) := \max_{x\in f^{-1}(0)} w_-(x,P) \qquad \text{and} \qquad \widetilde{W}_+ = \widetilde{W}_+(f,P) := \max_{x\in f^{-1}(1)} \tilde{w}_+(x,P).$$

There is a quantum algorithm that decides f with bounded error in $O\left(\frac{\sqrt{W_-\widetilde{W}_+}}{(1-\lambda)^{3/2}}\log\frac{1}{1-\lambda}\right)$ queries.

With the ability to distinguish between different witness sizes, we can obtain algorithms for estimating the witness size.

▶ **Theorem 15** (Witness Size Estimation Algorithm). *Fix $f : X \subseteq [q]^n \to \mathbb{R}_{\geq 0}$. Let P be a span program such that for all $x \in X$, $f(x) = w_+(x,P)$ and define $\widetilde{W}_- = \widetilde{W}_-(f,P) = \max_{x\in X} \tilde{w}_-(x,P)$. There exists a quantum algorithm that estimates f to accuracy ε in $\widetilde{O}\left(\frac{1}{\varepsilon^{3/2}}\sqrt{w_+(x)\widetilde{W}_-}\right)$ queries. Similarly, let P be a span program such that for all $x \in X$, $f(x) = w_-(x,P)$ and define $\widetilde{W}_+ = \widetilde{W}_+(f,P) = \max_{x\in X} \tilde{w}_+(x,P)$. Then there exists a quantum algorithm that estimates f to accuracy ε in $\widetilde{O}\left(\frac{1}{\varepsilon^{3/2}}\sqrt{w_-(x)\widetilde{W}_+}\right)$ queries.*

Proofs of Theorem 14 and 15 can be found in the full version (Theorems 2.7 and 2.8), but we give a high-level outline here. As in the case of algorithms previously constructed from span programs, our algorithms will consist of phase estimation of a unitary on H, applied to some initial state. Unlike previous applications, we will use $|w_0\rangle = A^+\tau$ (discussed more in full version, Section 2.4), as the initial state. This state is independent of the input, and so can be generated with 0 queries. For *negative span program algorithms*, where we want to decide a function negatively approximated by P, we will use a unitary $U(P,x)$, defined as follows:

$$U(P,x) := (2\Pi_{\ker A} - I)(2\Pi_{H(x)} - I).$$

This is similar to the unitary used in previous span program algorithms. Note that $(2\Pi_{\ker A} - I)$ is input-independent, and so can be implemented in 0 queries. However, in order to analyze the time complexity of a span program algorithm, this reflection must be implemented (as we are able to do for our applications, following [5]). The reflection $(2\Pi_{H(x)} - I)$ depends on the input, but requires only two queries to implement.

For *positive span program algorithms*, where we want to decide a function positively approximated by P, or estimate the positive witness size, we will use a slightly different unitary, $U'(P,x)$.

In order to show how these unitaries can be used to distinguish between inputs with small negative (resp. positive) witnesses, and those that only have large negative (resp. positive) witnesses, we analyze the overlap of the initial state, $|w_0\rangle$ with the 1-eigenspace of $U(P,x)$ (resp. $U'(P,x)$) in terms of the witness size. Specifically, we show that the overlap of $|w_0\rangle$ with the 1-eigenspace of $U(P,x)$ is exactly $\frac{1}{w_-(x,P)}$ (full version, Lemma 3.3), and the overlap of $|w_0\rangle$ with the 1-eigenspace of $U'(P,x)$ is exactly $\frac{1}{w_+(x,P)}$ (full version, Lemma 3.5). We can then use phase estimation, followed by amplitude estimation, to estimate the witness size.

There are then two possibilities for bounding the required precision of phase estimation, which also tells us the number of times we will need to call $U(P,x)$ (resp. $U'(P,x)$), and

therefore, the query complexity of the algorithm. Similar to previous span program algorithms we use the effective spectral gap lemma to show that the overlap of $|w_0\rangle$ with $e^{i\theta}$-eigenspaces of $U(P,x)$ (resp. $U'(P,x)$) is not too large for small θ (full version, Lemmas 3.2 and 3.4). This leads to Theorem 14 and Theorem 15.

The second way to bound the required precision of phase estimation is to lower bound the phase gap of $U(P,x)$ (resp. $U'(P,x)$), which may be very difficult in general. However, by relating the phase gap of $U(P,x)$ (resp. $U'(P,x)$) to the spectrum of A and $A(x) = A\Pi_{H(x)}$ in a novel way, we show how to lower bound the phase gap in some cases, which may give better results. This leads to the following theorem.

▶ **Theorem 16** (Witness Size Estimation Algorithm Using Real Phase Gap). *We say that a span program is* normalized *if* $\|A^+\tau\| = 1$. *Any span program can be normalized by scaling* τ.

Fix $f : X \subseteq [q]^n \to \mathbb{R}_{\geq 0}$ *and let* $P = (H, V, \tau, A)$ *be a normalized span program on* $[q]^n$ *such that for all* $x \in X$, $f(x) = w_+(x,P)$ *(resp.* $f(x) = w_-(x)$*). If* $\kappa \geq \frac{\sigma_{\max}(A)}{\sigma_{\min}(A\Pi_{H(x)})}$ *for all* $x \in X$, *then the quantum query complexity of estimating* $f(x)$ *to relative accuracy* ε *is at most* $\widetilde{O}\left(\sqrt{f(x)}\kappa/\varepsilon\right)$.

In particular, in our application to effective resistance, it is not difficult to bound the phase gap in this way, which leads to an improved upper bound.

2.3 Example

To illustrate how these ideas might be useful, we will give a brief example of how a span program that leads to an algorithm for the OR function can be combined with our results to additionally give algorithms for threshold functions and approximate counting. We define a span program P on $\{0,1\}^n$ as follows:

$$V = \mathbb{R}, \qquad \tau = 1, \qquad H_i = H_{i,1} = \text{span}\{|i\rangle\}, \qquad H_{i,0} = \{0\}, \qquad A = \sum_{i=1}^{n} \langle i|.$$

So we have $H = \text{span}\{|i\rangle : i \in [n]\}$ and $H(x) = \text{span}\{|i\rangle : x_i = 1\}$. It's not difficult to see that P decides OR. In particular, we can see that the optimal positive witness for any x such that $|x| > 0$ is $|w_x\rangle = \sum_{i:x_i=1} \frac{1}{|x|}|i\rangle$. The only linear function $\omega : \mathbb{R} \to \mathbb{R}$ that maps τ to 1 is the identity, and indeed, this is a negative witness for the string $\bar{0} = 0 \ldots 0$, since $H(\bar{0}) = \{0\}$, and so $\omega A\Pi_{H(\bar{0})} = 0$.

Let $\lambda \in (0,1)$, $t \in [n]$, and let f be a threshold function defined by $f(x) = 1$ if $|x| \geq t$ and $f(x) = 0$ if $|x| \leq \lambda t$, with the promise that one of these conditions holds. Note that if $f(x) = 1$, then $w_+(x) = \||w_x\rangle\|^2 = \frac{1}{|x|} \leq \frac{1}{t}$, so $W_+(f,P) = \frac{1}{t}$. On the other hand, if $f(x) = 0$, then $w_+(x) = \frac{1}{|x|} \geq \frac{1}{\lambda t} = \frac{1}{\lambda} W_+(f,P)$, so P positively λ-approximates f. The only approximate negative witness is ω the identity, so we have $\widetilde{W}_- = \|\omega A\|^2 = \|A\|^2 = n$. By Theorem 14, there is a quantum algorithm for f with query complexity $\frac{1}{(1-\lambda)^{3/2}}\sqrt{W_+\widetilde{W}_-} = \frac{1}{(1-\lambda)^{3/2}}\sqrt{n/t}$.

Furthermore, since $w_+(x) = \frac{1}{|x|}$, by Theorem 15, we can estimate $\frac{1}{|x|}$ to relative accuracy ε, and therefore we can estimate $|x|$ to relative accuracy 2ε, in quantum query complexity $\frac{1}{\varepsilon^{3/2}}\sqrt{n/|x|}$.

These upper bounds do not have optimal scaling in ε, as the actual quantum query complexities of these problems are $\frac{1}{1-\lambda}\sqrt{n/t}$ and $\frac{1}{\varepsilon}\sqrt{n/|x|}$ [6, 7, 1], however, using Theorem 16, the optimal query complexities can be recovered.

3 Applications

In this section, we will demonstrate how to apply Theorem 15 and 16 to get new quantum algorithms. Specifically, we will give upper bounds of $\widetilde{O}(n\sqrt{R_{s,t}}/\varepsilon^{3/2})$ and $\widetilde{O}(n\sqrt{R_{s,t}/\lambda_2}/\varepsilon)$ on the time complexity of estimating the effective resistance, $R_{s,t}$, between two vertices, s and t, in a graph. Unlike previous upper bounds, we study this problem in the adjacency model.

A *unit flow* from s to t in G is a real-valued function θ on the directed edges $\vec{E}(G) = \{(u,v) : \{u,v\} \in E(G)\}$ such that:

1. for all $(u,v) \in \vec{E}$, $\theta(u,v) = -\theta(v,u)$;
2. for all $u \in [n] \setminus \{s,t\}$, $\sum_{v\in\Gamma(u)} \theta(u,v) = 0$, where $\Gamma(u) = \{v \in [n] : \{u,v\} \in E\}$; and
3. $\sum_{u\in\Gamma(s)} \theta(s,u) = \sum_{u\in\Gamma(t)} \theta(u,t) = 1$.

Let $\mathcal{F}$ be the set of unit flows from s to t in G. The *effective resistance* from s to t in G is defined:

$$R_{s,t}(G) = \min_{\theta\in\mathcal{F}} \sum_{\{u,v\}\in E(G)} \theta(u,v)^2.$$

This quantity gives the resistance of a network of unit resistors described by G, but is also an interesting quantity for graph theoretic reasons. For instance, the commute time between s and t, which is the expected number of steps in a random walk starting from s to reach t, and then return to s, is exactly the product of the number of edges in G, and $R_{s,t}(G)$ [8].

In the adjacency model, the input is a string $x \in \{0,1\}^{n\times n}$, representing a graph $G_x = ([n], \{\{i,j\} : x_{i,j} = 1\})$ (we assume that $x_{i,i} = 0$ for all i, and $x_{i,j} = x_{j,i}$ for all i,j). The problem of st-connectivity is the following. Given $x \in \{0,1\}^{n\times n}$ and $s,t \in [n]$, decide if there exists a path from s to t in G_x. A span-program-based algorithm for this problem was given in [5], with time complexity $\widetilde{O}(n\sqrt{p})$, under the promise that, if s and t are connected in G_x, they are connected by a path of length $\leq p$. They use the following span program, defined on $\{0,1\}^{n\times n}$:

$$H_{(u,v),0} = \{0\},\ \ H_{(u,v),1} = \mathrm{span}\{|u,v\rangle\},\ \ V = \mathbb{R}^n,\ \ A = \sum_{u,v\in[n]} (|u\rangle - |v\rangle)\langle u,v|,\ \ |\tau\rangle = |s\rangle - |t\rangle.$$

We have $H = \mathrm{span}\{|u,v\rangle : u,v \in [n]\}$, and $H(x) = \mathrm{span}\{|u,v\rangle : \{u,v\} \in E(G_x)\}$. Throughout this section, P will denote the above span program. We will use this span program to define algorithms for estimating the effective resistance. Ref. [5] are even able to show how to efficiently implement a unitary similar to $U(P,x)$, giving a time efficient algorithm. In the full version, we adapt their proof to our setting, showing that our algorithms are time efficient as well.

The effective resistance between s and t is related to st-connectivity by the fact that if s and t are not connected, then $R_{s,t}$ is undefined (there is no flow from s to t) and if s and t are connected then $R_{s,t}$ is related to the number and length of paths from s to t. In particular, if s and t are connected by a path of length p, then $R_{s,t}(G) \leq p$ (take the unit flow that simply travels along this path). In general, if s and t are connected in G, then $\frac{2}{n} \leq R_{s,t}(G) \leq n-1$. The span program for st-connectivity is amenable to the task of estimating the effective resistance due to the following.

▶ **Lemma 17** ([5]). *For any graph G_x on $[n]$, $x \in P_1$ if and only if s and t are connected, and in that case, $w_+(x,P) = \frac{1}{2}R_{s,t}(G_x)$.*

A near immediate consequence of this, combined with Theorem 15, is the following.

▶ **Theorem 18.** *There exists a quantum algorithm for estimating $R_{s,t}(G_x)$ to accuracy ε with time complexity $\widetilde{O}\left(\frac{n\sqrt{R_{s,t}(G_x)}}{\varepsilon^{3/2}}\right)$ and space complexity $O(\log n)$.*

By analyzing the spectra of A and $A(x)$, and applying Theorem 16, we can get an often better algorithm (Theorem 19). The *spectral gap* of a graph G, denoted $\lambda_2(G)$, is the second largest eigenvalue (including multiplicity) of the Laplacian of G, which is defined $L_G = \sum_{u\in[n]} d_u|u\rangle\langle u| - \sum_{u\in[n]}\sum_{v\in\Gamma(u)}|u\rangle\langle v|$, where d_u is the degree of u, and $\Gamma(u)$ is the set of neighbours of u. The smallest eigenvalue of L_G is 0 for any graph G. A graph G is connected if and only if $\lambda_2(G) > 0$. A connected graph G has $\frac{2}{n^2} \leq \lambda_2(G) \leq n$.

The following theorem is an improvement over Theorem 18 when $\lambda_2(G) > \varepsilon$. In particular, it is an improvement for all ε when we know that $\lambda_2(G) > 1$.

▶ **Theorem 19.** *Let $\mathcal{G}$ be a family of graphs such that for all $x \in \mathcal{G}$, $\lambda_2(G_x) \geq \mu$. Let $f : \mathcal{G}\times[n]\times[n] \to \mathbb{R}_{>0}$ be defined by $f(x,s,t) = R_{s,t}(G_x)$. There exists a quantum algorithm for estimating f to relative accuracy ε that has time complexity $\widetilde{O}\left(\frac{1}{\varepsilon}n\sqrt{R_{s,t}(G_x)/\mu}\right)$ and space complexity $O(\log n)$.*

Proof. We will apply Theorem 16. We first compute $\||w_0\rangle\|^2$, in order to normalize P.

▶ **Lemma 20.** $\||w_0\rangle\|^2 = \frac{1}{n}$.

Proof. Recall that $|w_0\rangle = A^+\tau$. This is the smallest $|w_0\rangle$ such that $A|w_0\rangle = \tau$. Since $H(x) = H$ when G_x is the complete graph, by Lemma 17, we need only compute $R_{s,t}$ in the complete graph. It's simple to verify that the optimal unit st-flow in the complete graph has $\frac{1}{n}$ units of flow on every path of the form (s,u,t) for $u \in [n]\setminus\{s,t\}$, and $\frac{2}{n}$ units of flow on the edge (s,t). Thus, $R_{s,t}(K_n) = \sum_{u\in[n]\setminus\{s,t\}} 2(1/n)^2 + (2/n)^2 = 2/n$. Thus $\||w_0\rangle\|^2 = \frac{1}{2}R_{s,t}(K_n) = \frac{1}{n}$. ◀

Next, we compute the following:

▶ **Lemma 21.** *For any $x \in \mathcal{G}$, $\frac{\sigma_{\max}(A)}{\sigma_{\min}(A(x))} = \sqrt{\frac{n}{\lambda_2(G_x)}} \leq \sqrt{\frac{n}{\mu}}$, so $\kappa(f) \leq \sqrt{\frac{n}{\mu}}$.*

Proof. Let L_x denote the Laplacian of G_x. We have:

$$A(x)A(x)^T = \sum_{u\in[n]}\sum_{v\in\Gamma(u)}(|u\rangle - |v\rangle)(\langle u| - \langle v|) = 2\sum_{u\in[n]} d_u|u\rangle\langle u| - 2\sum_{u\in[n]}\sum_{v\in\Gamma(u)}|u\rangle\langle v| = 2L_x.$$

Thus, if L denotes the Laplacian of the complete graph, we also have $AA^T = 2L$. Letting J denote the all ones matrix, we have $L = (n-1)I - (J-I) = nI - J$, and since $J = n|u\rangle\langle u|$ where $|u\rangle = \frac{1}{\sqrt{n}}\sum_{i=1}^n |i\rangle$, if $|u_1\rangle,\ldots,|u_{n-1}\rangle,|u\rangle$ is any orthonormal basis of $\mathbb{R}^n$, then $L = n\sum_{i=1}^{n-1}|u_i\rangle\langle u_i| + n|u\rangle\langle u| - n|u\rangle\langle u| = \sum_{i=1}^{n-1} n|u_i\rangle\langle u_i|$, so the spectrum of L is 0, with multiplicity 1, and n with multiplicity $n-1$. Thus, the only nonzero singular value of A is $\sqrt{2n} = \sigma_{\max}(A)$. Furthermore, since $\lambda_2(G_x)$ is the smallest nonzero eigenvalue of L_x, and $A(x)A(x)^T = 2L_x$, $\sigma_{\min}(A(x)) = \sqrt{2\lambda_2(G_x)}$. The result follows. ◀

Finally, by scaling τ to $\frac{\tau}{\|A^+\tau\|} = n\tau$ to get a normalized span program, which has the effect of scaling all positive witnesses by n, we can apply Theorem 16 to get an algorithm that makes $\widetilde{O}\left(\frac{\kappa(f)}{\varepsilon}\sqrt{nw_+(x,P)}\right) = \widetilde{O}\left(\frac{1}{\varepsilon}\sqrt{n/\mu}\sqrt{nR_{s,t}}\right)$ calls to $U'(P,x)$. In the full version, we show that this algorithm has time complexity $\widetilde{O}\left(\frac{1}{\varepsilon}n\sqrt{R_{s,t}/\mu}\right)$ and space complexity $O(\log n)$. ◀

Both of our upper bounds have linear dependence on n, and this is optimal (see full version). Classically, the best known method of estimating the effective resistance is to compute it, which costs $O(m) = O(n^2)$, where m is the number of edges in the graph. This is accomplished by inverting the Laplacian.

The algorithms from Theorem 18 and 19 are the first quantum algorithms for estimating the effective resistance in the adjacency model, however, the problem has been studied previously in the edge-list model [22], where Wang obtains a quantum algorithm with complexity $\widetilde{O}\left(\frac{d^{3/2}\log n}{\Phi(G)^2\varepsilon}\right)$, where $\Phi(G) \leq 1$ is the conductance (or edge-expansion) of G. In the edge-list model, the input $x \in [n]^{[n]\times[d]}$ models a d-regular graph (or d-bounded degree graph) G_x by $x_{u,i} = v$ for some $i \in [d]$ whenever $\{u, v\} \in E(G_x)$. Wang requires edge-list queries to simulate walking on the graph, which requires constructing a superposition over all neighbours of a given vertex. This type of edge-list query can be simulated by $\sqrt{n/d}$ adjacency queries to a d-regular graph, using quantum search, so Wang's algorithm can be converted to an algorithm in the adjacency query model with cost $\widetilde{O}\left(\frac{d^{3/2}}{\Phi(G)^2\varepsilon}\sqrt{\frac{n}{d}}\right)$. We can compare our results to this by noticing that $R_{s,t} \leq \frac{1}{\lambda_2(G)}$ [8], implying that our algorithm always runs in time at most $\widetilde{O}\left(\frac{1}{\varepsilon}\frac{n}{\mu}\right)$. If G is a connected d-regular graph, then $\lambda_2(G) = d\delta(G)$, where $\delta(G)$ is the spectral gap of a random walk on G. By Cheeger inequalities, we have $\frac{\Phi^2}{2} \leq \delta$ [16], so the complexity of the algorithm from Theorem 19 is at most $\widetilde{O}\left(\frac{1}{\varepsilon}\frac{n}{d\delta}\right) = \widetilde{O}\left(\frac{1}{\varepsilon}\frac{n}{d\Phi^2}\right)$, which is an improvement over the bound of $\widetilde{O}\left(\frac{1}{\varepsilon}\frac{d^{3/2}}{\Phi^2}\sqrt{\frac{n}{d}}\right) = \widetilde{O}\left(\frac{1}{\varepsilon}\frac{d}{\Phi^2}\sqrt{n}\right)$ given by naively adapting Wang's algorithm to the adjacency model whenever $d > \sqrt[4]{n}$. In general our upper bound may be much better than $\frac{1}{\varepsilon}\frac{n}{d\Phi^2}$, since the Cheeger inequality is not tight, and $R_{s,t}$ can be much smaller than $\frac{1}{\lambda_2}$.

4 Conclusion and Open Problems

We have presented several new techniques for turning span programs into quantum algorithms, which we hope will have future applications. Specifically, given a span program P, in addition to algorithms for deciding any function f such that $f^{-1}(0) \subseteq P_0$ and $f^{-1}(1) \subseteq P_1$, we also show how to get several different algorithms for deciding a number of related threshold problems, as well as estimating the witness size. In addition to algorithms based on the standard effective spectral gap lemma, we also show how to get algorithms by analyzing the real phase gap.

We hope that the importance of this work lies not only in its potential for applications, but in the improved understanding of the structure and power of span programs. A number of very important quantum algorithms rely on a similar structure, using phase estimation of a unitary that depends on the input to distinguish between different types of inputs. Span-program-based algorithms represent a very general class of such algorithms, making them not only important to the study of the quantum query model, but to quantum algorithms in general.

The main avenue for future work is in applications of our techniques to obtain new quantum algorithms. We stress that *any* span program for a decision problem can now be turned into an algorithm for estimating the positive or negative witness size, if these correspond to some meaningful function, or deciding threshold functions related to the witness size. A natural source of potential future applications is in the rich area of property testing problems (for a survey, see [17]).

One final open problem is a possible relationship between estimating the witness size and the HHL algorithm [11]. The HHL algorithm can be used to estimate $\|M^+|u\rangle\|^2$, given the

state $|u\rangle$ and access to a row-computable linear operator M. When $M = A(x)$ and $|u\rangle = \tau$, this quantity is exactly $w_+(x)$, so if $A(x)$ is row-computable — that is, there is an efficient procedure for computing the i^{th} nonzero entry of the j^{th} row of $A(x)$, then HHL gives us yet another means of estimating the witness size, whose time complexity is known, rather than only its query complexity. We note that the complexity of HHL depends on $\frac{\sigma_{\max}(A(x))}{\sigma_{\min}(A(x))}$, the *condition number* of $A(x)$, which is upper bounded by $\frac{\sigma_{\max}(A)}{\sigma_{\min}(A(x))}$, upon which the complexity of some of our algorithms depends as well. We leave further exploration of this connection for future research.

Abstract

This paper investigates the power of polynomial-time quantum computation in which only a very limited number of qubits are initially clean in the $|0\rangle$ state, and all the remaining qubits are initially in the totally mixed state. No initializations of qubits are allowed during the computation, nor are intermediate measurements. The main contribution of this paper is to develop unexpectedly strong error-reduction methods for such quantum computations that simultaneously reduce the number of necessary clean qubits. It is proved that any problem solvable by a polynomial-time quantum computation with one-sided bounded error that uses logarithmically many clean qubits is also solvable with exponentially small one-sided error using just two clean qubits, and with polynomially small one-sided error using just one clean qubit. It is further proved in the two-sided-error case that any problem solvable by such a computation with a constant gap between completeness and soundness using logarithmically many clean qubits is also solvable with exponentially small two-sided error using just two clean qubits. If only one clean qubit is available, the problem is again still solvable with exponentially small error in one of the completeness and soundness and with polynomially small error in the other. An immediate consequence is that the Trace Estimation problem defined with *fixed* constant threshold parameters is complete for $\mathrm{BQ}_{[1]}\mathrm{P}$ and $\mathrm{BQ}_{\log}\mathrm{P}$, the classes of problems solvable by polynomial-time quantum computations with completeness 2/3 and soundness 1/3 using just one and logarithmically many clean qubits, respectively. The techniques used for proving the error-reduction results may be of independent interest in themselves, and one of the technical tools can also be used to show the hardness of weak classical simulations of one-clean-qubit computations (i.e., DQC1 computations).

1 Introduction

1.1 Background

One of the most important goals in quantum information processing is to realize a quantum mechanical machine whose computational ability is superior to classical computers. The ultimate goal is, of course, to realize a large scale universal quantum computer, which still seems to be many years off despite extensive experimental efforts. Plenty of attention has thus been paid to "intermediate" (i.e., non-universal) models of quantum computation, which are somehow easier to physically implement. Such intermediate models do not offer universal quantum computation, but are believed to still be able to solve some problems that are hard for classical computers.

The *deterministic quantum computation with one quantum bit (DQC1)*, often mentioned as the *one-clean-qubit model*, is one of the most well-studied examples of such intermediate models. This model was introduced by Knill and Laflamme [15] to reflect some actual experimental setups such as nuclear magnetic resonance (NMR), where pure clean qubits are very hard to prepare and therefore are considered as very expensive resources. For example, in nuclear spin ensemble systems such as liquid state NMR systems, it is usually extremely hard, although not impossible, to polarize a spin (i.e., to initialize a qubit to state $|0\rangle$), since energy scale of a nuclear spin qubit is quite small, while it is favorable for long coherence time. A DQC1 computation over w qubits starts with the initial state of the totally mixed state except for a single clean qubit, namely, $|0\rangle\langle 0| \otimes \left(\frac{I}{2}\right)^{\otimes(w-1)}$. After applying a polynomial-size *unitary* quantum circuit to this state, only a single output qubit is measured in the computational basis at the end of the computing in order to read out the computation result. No initializations of qubits are allowed during the computation, nor are intermediate measurements. The DQC1 model is believed not to have full computational power of the standard polynomial-time quantum computation, and is indeed strictly less powerful under some reasonable assumptions [5]. At first glance the model even looks easy to classically simulate and does not seem to offer any quantum advantage, partly because its highly-mixed initial state obviously lacks "quantumness" such as entanglement, coherence, and discord, which are widely believed to be origins of the power of quantum information processing, and also because any time-evolution over a single-qubit state or a totally mixed state is trivially simulatable by a classical computation. Nevertheless, the DQC1 model is not trivial, either, in the sense that it can efficiently solve several problems for which no efficient classical algorithms are known, such as estimating the spectral density [15], testing integrability [20], calculating the fidelity decay [19], approximating the Jones and HOMFLY polynomials [23, 13], and approximating an invariant of 3-manifolds [12]. As many of these problems have physically meaningful applications, the DQC1 model is one of the most important intermediate quantum computation models.

Despite its importance explained thus far and the fact that tons of papers in physics have focused on it, very little has been studied on the genuinely complexity-theoretic aspects of the DQC1 model (to the best knowledge of the authors, no such studies exist other than Refs. [5, 21, 22]). The primal purpose of the present paper is to establish for the first time the fundamental core of detailed complexity-theoretic treatments of the DQC1 model and its generalization. To provide the very base of the study of computational complexity of such models, this paper investigates how robust these models are against computation error.

Computation error is an inherent feature of quantum computing, as the outcome of a computation is inevitably probabilistic and hence may not always be correct. Error reduction, or success-probability amplification, is thus one of the most fundamental issues in quantum

computing. Computation error can be efficiently reduced to be negligibly small in many standard computation models via a simple repetition-based method. Typical examples are polynomial-time quantum computations with bounded error, and in particular, the error can be made exponentially small in BQP both in completeness and in soundness, which provides a reasonable ground for the well-used definition of BQP that employs bounds 2/3 and 1/3 for completeness and soundness, respectively. In many other computation models, however, it is unclear whether the error can be reduced efficiently by the standard repetition-based method, and more generally, whether error reduction itself is possible. Typically, for models with very limited computational resources like space-bounded quantum computations, it is simply impossible to repeat the original computation sufficiently many times, which becomes an enormous obstacle to error reduction when initializations of qubits are disallowed after the computation starts. Indeed, it is impossible in the case of one-way quantum finite state automata to reduce computation error below a certain constant [4]. Also, the reducibility of computation error is unclear in various logarithmic-space quantum computations. For computations of one-sided bounded error performed by logarithmic-space quantum Turing machines, Watrous [28] presented a nontrivial method that reduces the error to be exponentially small. Other than this result, error-reduction techniques have not been developed much for space-bounded quantum computations.[1]

The computation models with few clean qubits, including DQC1, may be viewed as variants of space-bounded quantum computations in a sense, and thus, it is highly nontrivial to reduce computation error in these models. On the other hand, the reducibility of computation error is particularly desirable in these models, as the DQC1 computations mentioned above that solve the classically-hard problems in fact solve the decisional versions of the problems only with two-sided bounded error. Computation error can be quite large in such computations, and the gap between completeness and soundness is allowed to be polynomially small. The only method known for amplifying success probability of these computations is to sequentially repeat an attempt of the computation polynomially many times, but this requires the clean qubit to be initialized every time after finishing one attempt, and moreover, the result of each attempt must be recorded to classical work space prepared outside of the DQC1 model. It is definitely more desirable if computation error can be reduced without such initializations, the operations that are very expensive for the model. The situation is similar even when the number of clean qubits is allowed to be logarithmically many with respect to the input length. It is also known that any quantum computation of two-sided bounded error that uses logarithmically many clean qubits can be simulated by a quantum computation still of two-sided bounded error that uses just one clean qubit, but the known method for this simulation considerably increases the computational error, and the gap between completeness and soundness becomes polynomially small.

1.2 The results

This paper develops methods of reducing computation error in quantum computations with few clean qubits, including the DQC1 model. As will be presented below, the methods

[1] After the completion of this work, Fefferman, Kobayashi, Lin, Morimae, and Nishimura [10] developed methods of error reduction for space-bounded unitary quantum computations. Both of this very recent method and the one by Watrous [28] do not apply to quantum computations with few clean qubits, for these methods assume the easiness of "exact initialization check" (i.e., the easiness of checking whether the given state is *exactly* equal to the initial state of the computation), which is no longer the case for quantum computations with few clean qubits where many qubits are initially in the totally mixed state.

proposed are unexpectedly powerful and are able to simultaneously reduce both computation error and the number of necessary clean qubits, providing an almost fully satisfying solution in the cases of one-sided bounded error. In the two-sided-error case, the methods in this paper are applicable only when there is a constant gap between completeness and soundness in the original computation, but still significantly improve the situation of quantum computations with few clean qubits as to both the reducibility of computation error and the reducibility of the number of necessary clean qubits. These results are the first error-reducible properties for intermediate quantum computation models, not limited to the DQC1 model.

The results may alternatively be interpreted as that any problem solvable by a DQC1 computation with constant computation error is still solvable with constant computation error even when a bit noisy initial state is given instead of the ideal one-clean-qubit state, for the problem is also solvable with very small error when given an ideal one-clean-qubit initial state, thanks to the error-reduction results. This is perhaps very helpful in actual implementation, as the initial state prepared does not need to be very close to the ideal one-clean-qubit state, and can be away from it by, say, a constant δ in trace distance to still have success probability close to $1-\delta$. In particular, the qubit that is supposed to be clean does not need to be thoroughly purified and may be noisy to some extent.

The result for the two-sided-error case has another implication that the power of DQC1 computations with small two-sided error is characterized by the Trace Estimation problem defined with *fixed* constant threshold parameters. This may also be viewed as the first "gap amplification" result for the Trace Estimation problem. The Trace Estimation problem is ubiquitous in quantum many-body physics as observables, related to various important quantities in physics like the fidelity decay characterizing quantum chaos [9] and the Jones polynomials corresponding to the expected values of the Wilson loops in SU(2) Chern-Simons topological quantum field theory [29]. The results thus provide a useful tool to understand computational complexity of such quantum many-body systems, and establish a new bridge between computational complexity theory and quantum many-body physics.

Simultaneous reducibility of computation error and the number of clean qubits. Let $\mathrm{Q_{log}P}(c,s)$, $\mathrm{Q_{[1]}P}(c,s)$, and $\mathrm{Q_{[2]}P}(c,s)$ denote the classes of problems solvable by polynomial-time quantum computations with completeness c and soundness s that uses logarithmically many clean qubits, one clean qubit, and two clean qubits, respectively. First, in the one-sided-error case, it is proved that any problem solvable by a polynomial-time quantum computation with one-sided bounded error that uses logarithmically many clean qubits is also solvable by that with exponentially small one-sided error using just two clean qubits. If only one clean qubit is available, the problem is still solvable with polynomially small one-sided error (and thus with any small constant one-sided error).

▶ **Theorem 1.1.** *For any polynomially bounded function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ and any polynomial-time computable function $s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $1-s \geq \frac{1}{q}$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$,*

$$\mathrm{Q_{log}P}(1,s) \subseteq \mathrm{Q_{[2]}P}(1,2^{-p}).$$

▶ **Theorem 1.2.** *For any polynomially bounded function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ and any polynomial-time computable function $s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $1-s \geq \frac{1}{q}$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$,*

$$\mathrm{Q_{log}P}(1,s) \subseteq \mathrm{Q_{[1]}P}\Big(1, \frac{1}{p}\Big).$$

The above two theorems are for the case of perfect completeness, and similar statements hold even for the case of perfect soundness, by considering the complement of the problem.

▶ **Corollary 1.3.** *For any polynomially bounded function* $p\colon \mathbb{Z}^+ \to \mathbb{N}$ *and any polynomial-time computable function* $c\colon \mathbb{Z}^+ \to [0,1]$ *satisfying* $c \geq \frac{1}{q}$ *for some polynomially bounded function* $q\colon \mathbb{Z}^+ \to \mathbb{N}$*,*

$$\mathrm{Q_{log}P}(c,0) \subseteq \mathrm{Q_{[2]}P}(1-2^{-p},0) \quad \textit{and} \quad \mathrm{Q_{log}P}(c,0) \subseteq \mathrm{Q_{[1]}P}\Big(1-\frac{1}{p},0\Big).$$

In the two-sided-error case, it is proved that any problem solvable by a polynomial-time quantum computation that uses logarithmically many clean qubits and has a constant gap between completeness and soundness can also be solved by that with exponentially small two-sided error using just two clean qubits. If only one clean qubit is available, the problem is again still solvable with exponentially small error in one of the completeness and soundness and polynomially small error in the other.

▶ **Theorem 1.4.** *For any polynomially bounded function* $p\colon \mathbb{Z}^+ \to \mathbb{N}$ *and any constants* c *and* s *in* $(0,1)$ *satisfying* $c > s$*,*

$$\mathrm{Q_{log}P}(c,s) \subseteq \mathrm{Q_{[2]}P}(1-2^{-p},2^{-p}).$$

▶ **Theorem 1.5.** *For any polynomially bounded function* $p\colon \mathbb{Z}^+ \to \mathbb{N}$ *and any constants* c *and* s *in* $(0,1)$ *satisfying* $c > s$*,*

$$\mathrm{Q_{log}P}(c,s) \subseteq \mathrm{Q_{[1]}P}\Big(1-2^{-p},\frac{1}{p}\Big) \cap \mathrm{Q_{[1]}P}\Big(1-\frac{1}{p},2^{-p}\Big).$$

The ideas for the proofs of these statements and techniques developed therein may be of independent interest in themselves, and will be overviewed in Section 2.

Completeness results for Trace Estimation problem. Define the complexity classes $\mathrm{BQ_{log}P}$ and $\mathrm{BQ_{[1]}P}$ by $\mathrm{BQ_{log}P} = \mathrm{Q_{log}P}\big(\frac{2}{3},\frac{1}{3}\big)$ and $\mathrm{BQ_{[1]}P} = \mathrm{Q_{[1]}P}\big(\frac{2}{3},\frac{1}{3}\big)$, respectively. An immediate but important consequence of Theorem 1.5 is that the Trace Estimation problem is complete for $\mathrm{BQ_{log}P}$ and $\mathrm{BQ_{[1]}P}$ under polynomial-time many-one reduction, even when the problem is defined with *fixed* constant parameters that specify the bounds on normalized traces in the yes-instance and no-instance cases.

Given a description of a quantum circuit that specifies a unitary transformation U, the Trace Estimation problem specified with two parameters a and b satisfying $-1 \leq b < a \leq 1$ is the problem of deciding whether the real part of the normalized trace of U is at least a or it is at most b.

Trace Estimation Problem: $\mathrm{TrEst}(a,b)$

Input:	A description of a quantum circuit Q that implements a unitary transformation U over n qubits.
Yes Instances:	$\frac{1}{2^n}\Re(\mathrm{tr}\,U) \geq a$.
No Instances:	$\frac{1}{2^n}\Re(\mathrm{tr}\,U) \leq b$.

The paper by Knill and Laflamme [15] that introduced the DQC1 model already pointed out that this problem is closely related to the DQC1 computation. This point was further clarified in the succeeding literature (see Refs. [21, 22, 23], for instance). More precisely, consider a variant of the Trace Estimation problem where the two parameters a and b may depend on the input length (i.e., the length of the description of Q). It is known that this version of the Trace Estimation problem, for any a and b such that the gap $a - b$ is bounded from below by an inverse-polynomial with respect to the input length, can be solved by a DQC1 computation with *some* two-sided bounded error where the completeness and soundness parameters c and s depend on a and b. It is also known that, for any two nonnegative parameters a and b such that the gap $a - b$ is bounded from below by an inverse-polynomial with respect to the input length, the corresponding version of the Trace Estimation problem is hard for the complexity class $\mathrm{Q}_{[1]}\mathrm{P}(c, s)$ for *some* completeness and soundness parameters c and s that depend on a and b. Hence, the Trace Estimation problem essentially characterizes the power of the DQC1 computation. One subtle matter to be pointed out in the existing arguments above is that, when the parameters a and b are fixed for the Trace Estimation problem, the completeness c and soundness s with which the problem is in $\mathrm{Q}_{[1]}\mathrm{P}(c, s)$ are *different* from the completeness c' and soundness s' with which the problem is hard for $\mathrm{Q}_{[1]}\mathrm{P}(c', s')$. Namely, given two nonnegative parameters a and b of the problem, the computation solves the problem with completeness $c = (1 + a)/2$ and soundness $s = (1 + b)/2$, while the problem is hard for the class with completeness $c' = a/4$ and soundness $s' = b/4$. Therefore, the existing arguments are slightly short for proving $\mathrm{BQ}_{[1]}\mathrm{P}$-completeness of the Trace Estimation problem with fixed parameters a and b (and $\mathrm{Q}_{[1]}\mathrm{P}(c, s)$-completeness of that for fixed completeness and soundness parameters c and s, in general).

In contrast, with Theorem 1.5 in hand, it is immediate to show that the Trace Estimation problem is complete for $\mathrm{BQ}_{\log}\mathrm{P}$ and for $\mathrm{BQ}_{[1]}\mathrm{P}$ for any constants a and b satisfying $0 < b < a < 1$.

▶ **Theorem 1.6.** *For any constants a and b in $(0, 1)$ satisfying $a > b$, $\mathrm{TrEst}(a, b)$ is complete for $\mathrm{BQ}_{\log}\mathrm{P}$ and for $\mathrm{BQ}_{[1]}\mathrm{P}$ under polynomial-time many-one reduction.*

Hardness of weak classical simulations of DQC1 computation. Recently, quite a few number of studies focused on the hardness of *weak* classical simulations of restricted models of quantum computing under some reasonable assumptions [26, 7, 2, 18, 14, 17, 25, 8, 24]. Namely, a plausible assumption in complexity theory leads to the impossibility of efficient sampling by a classical computer according to an output probability distribution generatable with a quantum computing model. Among them are the IQP model [7] and the Boson sampling [2], both of which are proved hard for classical computers to simulate within multiplicative error, unless the polynomial-time hierarchy collapses to the third level (in fact, the main result of Ref. [2] is a much more meaningful hardness result on the weak simulatability of the Boson sampling within *polynomially small additive error*, but which needs a much stronger complexity assumption than the collapse of polynomial-time hierarchy).

An interesting question to ask is whether a similar result holds even for the DQC1 model. Very recently, Morimae, Fujii, and Fitzsimons [17] settled the case of the $\mathrm{DQC1}_m$-type computation, the generalization of the DQC1 model that allows m output qubits to be measured at the end of the computation, by proving that a $\mathrm{DQC1}_m$-type computation with $m \geq 3$ cannot be simulated within multiplicative error unless the polynomial-time hierarchy collapses to the third level. Their proof essentially shows that any PostBQP circuit can be simulated by a $\mathrm{DQC1}_3$-type computation, where PostBQP is the complexity class

corresponding to bounded-error quantum polynomial-time computations with postselection, which is known equivalent to PP [1]. By an argument similar to that in Ref. [7], it follows that PP is in PostBPP (the version of BPP with postselection), if the $\mathrm{DQC1}_3$-type computation is classically simulatable within multiplicative error. Together with Toda's theorem [27], this implies the collapse of the polynomial-time hierarchy to the third level.

One obvious drawback of the existing argument above is an inevitable postselection measurement inherent to the definition of PostBQP. This becomes a quite essential obstacle when trying to extend this argument to the DQC1 model, where only one qubit is allowed to be measured. To deal with the DQC1 model, this paper takes a different approach by considering the complexity class NQP introduced in Ref. [3] or the class SBQP introduced in Ref. [16]. Let $\mathrm{NQ}_{[1]}\mathrm{P}$ and $\mathrm{SBQ}_{[1]}\mathrm{P}$ be the variants of NQP and SBQP, respectively, in which the quantum computation performed is restricted to a DQC1 computation. From one of the technical tools used for proving the main results of this paper, it is immediate to show that the restriction to a DQC1 computation does not change the classes NQP and SBQP.

▶ **Theorem 1.7.** $\mathrm{NQP} = \mathrm{NQ}_{[1]}\mathrm{P}$ *and* $\mathrm{SBQP} = \mathrm{SBQ}_{[1]}\mathrm{P}$.

If any DQC1 computation were classically simulatable within multiplicative error, however, the class $\mathrm{NQ}_{[1]}\mathrm{P}$ would be included in NP and the class $\mathrm{SBQ}_{[1]}\mathrm{P}$ would be included in SBP, where SBP is a classical version of SBQP in short, introduced in Ref. [6]. Similarly, if any DQC1 computation were classically simulatable within exponentially small additive error, both $\mathrm{NQ}_{[1]}\mathrm{P}$ and $\mathrm{SBQ}_{[1]}\mathrm{P}$ would be included in SBP. Combined with Theorem 1.7, any of the inclusions $\mathrm{NQ}_{[1]}\mathrm{P} \subseteq \mathrm{NP}$, $\mathrm{SBQ}_{[1]}\mathrm{P} \subseteq \mathrm{SBP}$, and $\mathrm{NQ}_{[1]}\mathrm{P} \subseteq \mathrm{SBP}$ further implies an implausible consequence that PH = AM, which in particular implies the collapse of the polynomial-time hierarchy to the second level. Accordingly, the following theorem holds.

▶ **Theorem 1.8.** *The DQC1 model is not classically simulatable either within multiplicative error or exponentially small additive error, unless* PH = AM.

The above argument based on NQP and SBQP to prove Theorem 1.8 is very general, and can also be used to show the hardness of weak classical simulations of other quantum computing models. In particular, it can replace the existing argument based on PostBQP, which was developed in Ref. [7] and has appeared frequently in the literature [2, 14, 17, 25, 8, 24]. This also weakens the complexity assumption necessary to prove the hardness results for such models, including the IQP model [7] and the Boson sampling [2] (the polynomial-time hierarchy now collapses to the second level, rather than the third level when using PostBQP). Moreover, the hardness results for such models now hold for any constant multiplicative error $c \geq 1$, rather than only for c satisfying $1 \leq c < \sqrt{2}$ as in Refs. [7, 17].

2 Overview of error-reduction results

This section presents an overview of the proofs for the error reduction results. First, Subsection 2.1 provides high-level descriptions of the proofs of Theorems 1.1 and 1.2, the theorems for the one-sided error case of perfect completeness. Compared with the two-sided-error case, the proof construction is relatively simpler in the perfect-completeness case, but already involves most of key technical ingredients of this paper. Subsection 2.2 then explains the further idea that proves Theorems 1.4 and 1.5, the theorems for the two-sided-error case.

2.1 Proof ideas of Theorems 1.1 and 1.2

Let $A = (A_{\mathrm{yes}}, A_{\mathrm{no}})$ be any problem in $\mathrm{Q_{log}P}(1, s)$, where the function s defining the soundness is bounded away from one by an inverse-polynomial, and consider a polynomial-time

uniformly generated family of quantum circuits that puts A in $\mathrm{Q_{log}P}(1, s)$. Let Q_x denote the quantum circuit from this family when the input is x, where Q_x acts over $w(|x|)$ qubits for some polynomially bounded function w, and is supposed to be applied to the initial state $(|0\rangle\langle 0|)^{\otimes k(|x|)} \otimes \left(\frac{I}{2}\right)^{\otimes(w(|x|)-k(|x|))}$ that contains exactly $k(|x|)$ clean qubits, for some logarithmically bounded function k.

Theorems 1.1 and 1.2 are proved by constructing circuits with desirable properties from the original circuit Q_x. The construction is essentially the same for both of the two theorems and consists of three stages of transformations of circuits: The first stage reduces the number of necessary clean qubits to just one, while keeping perfect completeness and soundness still bounded away from one by an inverse-polynomial. The second stage then makes the acceptance probability of no-instances arbitrarily close to 1/2, still using just one clean qubit and keeping perfect completeness. Here, it not only makes the soundness (i.e., the upper bound of the acceptance probability of no-instances) close to 1/2, but also makes the acceptance probability of no-instances *at least* 1/2. Finally, in the case of Theorem 1.2, the third stage further reduces soundness error to be polynomially small with the use of just one clean qubit, while preserving the perfect completeness property. If one more clean qubit is available, the third stage can achieve exponentially small soundness, which leads to Theorem 1.1. The analyses of the third stage effectively use the fact that the acceptance probability of no-instances is close to 1/2 after the transformation of the second stage.

The rest of this subsection sketches the ideas that realize each of these three stages.

One-Clean-Qubit Simulation Procedure. The first stage uses a procedure called the One-Clean-Qubit Simulation Procedure. Given the quantum circuit Q_x with a specification of the number $k(|x|)$ of clean qubits, this procedure results in a quantum circuit R_x such that the input state to R_x is supposed to contain just one clean qubit, and when applied to the one-clean-qubit initial state, the acceptance probability of R_x is still one if x is in A_{yes}, while it is at most $1 - \delta(|x|)$ if x is in A_{no}, where δ is an inverse-polynomial function determined by $\delta = 2^{-k}(1 - s)$. It is stressed that the One-Clean-Qubit Simulation Procedure preserves perfect completeness, which is in stark contrast to the straightforward method of one-clean-qubit simulation.

Consider the $k(|x|)$-clean-qubit computation performed with Q_x. Let Q denote the quantum register consisting of the $k(|x|)$ initially clean qubits, and let R denote the quantum register consisting of the remaining $w(|x|) - k(|x|)$ qubits that are initially in the totally mixed state. Further let $\mathsf{Q}^{(1)}$ denote the single-qubit quantum register consisting of the first qubit of Q, which corresponds to the output qubit of Q_x. In the one-clean-qubit simulation of Q_x by R_x, the $k(|x|)$ qubits in Q are supposed to be in the totally mixed state initially and R_x tries to simulate Q_x only when Q initially contains the clean all-zero state. To do so, R_x uses another quantum register O consisting of just a single qubit, and this qubit in O is the only qubit that is supposed to be initially clean.

For ease of explanations, assume for a while that all the qubits in Q are also initially clean even in the case of R_x. The key idea in the construction of R_x is the following simulation of Q_x that makes use of the phase-flip transformation: The simulation first applies the Hadamard transformation H to the qubit in O and then flips the phase if and only if the content of O is 1 *and* the simulation of Q_x results in rejection (which is realized by performing Q_x to (Q, R) and then applying the controlled-Z transformation to $(\mathsf{O}, \mathsf{Q}^{(1)})$, where the content 1 in $\mathsf{Q}^{(1)}$ is assumed to correspond to the rejection in the original computation by Q_x). The simulation further performs the inverse of Q_x to (Q, R) and again applies H to O. At the end of the simulation, the qubit in O is measured in the computational basis, where measuring 0

corresponds to acceptance. The point is that this phase-flip-based construction provides a quite "faithful" simulation of Q_x, meaning that the rejection probability of the simulation is polynomially related to the rejection probability of the original computation of Q_x (and in particular, the simulation never rejects when the original computation never rejects, i.e., it preserves the perfect completeness property).

As mentioned before, all the qubits in Q are supposed to be in the totally mixed state initially in the one-clean-qubit simulation of Q_x by R_x, and R_x tries to simulate Q_x only when Q initially contains the clean all-zero state. To achieve this, each of the applications of the Hadamard transformation H is replaced by an application of the controlled-H transformation so that H is applied only when all the qubits in Q are in state $|0\rangle$. By considering the one-clean-qubit computations with the circuit family induced by R_x, the perfect completeness property is preserved and soundness is still bounded away from one by an inverse-polynomial (although the rejection probability becomes smaller for no-instances by a multiplicative factor of 2^{-k}, where notice that 2^{-k} is an inverse-polynomial as k is a logarithmically bounded function).

Randomness Amplification Procedure. The second stage uses the procedure called the Randomness Amplification Procedure. Given the circuit R_x constructed in the first stage, this procedure results in a quantum circuit R'_x such that the input state to R'_x is still supposed to contain just one clean qubit, and when applied to the one-clean-qubit initial state, the acceptance probability of R'_x is still one if x is in $A_{\rm yes}$, while it is in the interval $\left[\frac{1}{2}, \frac{1}{2} + \varepsilon(|x|)\right]$ if x is in $A_{\rm no}$ for some sufficiently small function ε.

Consider the one-clean-qubit computation performed with R_x. Let O denote the single-qubit register consisting of the initially clean qubit, which is also the output qubit of R_x. Let R denote the quantum register consisting of all the other qubits that are initially in the totally mixed state (by the construction of R_x, R consists of $w(|x|)$ qubits).

Suppose that the qubit in O is measured in the computational basis after R_x is applied to the one-clean-qubit initial state $|0\rangle\langle 0| \otimes \left(\frac{I}{2}\right)^{\otimes w(|x|)}$ in (O, R). Obviously from the property of R_x, the measurement results in 0 with probability exactly equal to the acceptance probability $p_{\rm acc}$ of the one-clean-qubit computation with R_x. Now suppose that R_x is applied to a slightly different initial state $|1\rangle\langle 1| \otimes \left(\frac{I}{2}\right)^{\otimes w(|x|)}$ in (O, R), where O initially contains $|1\rangle$ instead of $|0\rangle$ and all the qubits in R are again initially in the totally mixed state. The key property here to be proved is that, in this case, the measurement over the qubit in O in the computational basis results in 1 again with probability exactly $p_{\rm acc}$, the acceptance probability of the one-clean-qubit computation with R_x. This implies that, after the application of R_x to (O, R) with all the qubits in R being in the totally mixed state, the content of O remains the same with probability exactly $p_{\rm acc}$, and is flipped with probability exactly $1 - p_{\rm acc}$, the rejection probability of the original one-clean-qubit computation with R_x, regardless of the initial content of O.

The above observation leads to the following construction of the circuit R'_x. The construction of R'_x is basically a sequential repetition of the original circuit R_x. The number N of repetitions is polynomially many with respect to the input length $|x|$, and the point is that the register O is reused for each repetition, and only the qubits in R are refreshed after each repetition (by preparing N registers $\mathsf{R}_1, \ldots, \mathsf{R}_N$, each of which consists of $w(|x|)$ qubits, the same number of qubits as R, all of which are initially in the totally mixed state). After each repetition the qubit in O is measured in the computational basis (in the actual construction, this step is exactly simulated without any measurement – a single-qubit totally mixed state is prepared as a fresh ancilla qubit for each repetition so that the content of O is copied to

this ancilla qubit using the CNOT transformation, and this ancilla qubit is never touched after this CNOT application). Now, no matter which measurement result is obtained at the jth repetition for every j in $\{1,\ldots,N\}$, the register O is reused as it is, and the circuit R_x is simply applied to $(\mathsf{O},\mathsf{R}_{j+1})$ at the $(j+1)$st repetition. After the N repetitions, the qubit in O is measured in the computational basis, which is the output of R'_x (the output 0 corresponds to acceptance). The point is that at each repetition, the content of O is flipped with probability exactly equal to the rejection probability of the original one-clean-qubit computation of R_x. Taking into account that O is initially in state $|0\rangle$, the computation of R'_x results in acceptance if and only if the content of O is flipped even number of times during the N repetitions. An analysis on Bernoulli trials then shows that, when the acceptance probability of the original one-clean-qubit computation of R_x was in the interval $\left[\frac{1}{2},1\right)$, the acceptance probability of the one-clean-qubit computation of R'_x is at least $1/2$ and converges linearly to $1/2$ with respect to the repetition number. On the other hand, when the acceptance probability of the original R_x was one, the content of O is never flipped during the computation of R'_x, and thus the acceptance probability of R'_x remains one.

Stability Checking Procedures. In the case of Theorem 1.2, the third stage uses the procedure called the One-Clean-Qubit Stability Checking Procedure. Given the circuit R'_x constructed in the second stage, this procedure results in a quantum circuit R''_x such that the input state to R''_x is still supposed to contain just one clean qubit, and when applied to the one-clean-qubit initial state, the acceptance probability of R''_x is still one if x is in A_{yes}, while it is $1/p(|x|)$ if x is in A_{no} for a polynomially bounded function p predetermined arbitrarily.

Consider the one-clean-qubit computation performed with R'_x. Let Q denote the single-qubit register consisting of the initially clean qubit, which is also the output qubit of R'_x. Let R denote the quantum register consisting of all the other qubits that are initially in the totally mixed state, and let $w'(|x|)$ denote the number of qubits in R.

Again the key observation is that, after the application of R'_x to (Q,R) with all the qubits in R being in the totally mixed state (followed by the measurement over the qubit in Q in the computational basis), the content of Q is flipped with probability exactly equal to the rejection probability of the original one-clean-qubit computation with R'_x, regardless of the initial content of Q.

This leads to the following construction of the circuit R''_x. The construction of R''_x is again basically a sequential repetition of the original circuit R'_x, but this time the qubit in Q is also supposed to be initially in the totally mixed state. The circuit R'_x is repeatedly applied $2N$ times, where N is a power of two and is polynomially many with respect to the input length $|x|$, and again the register Q is reused for each repetition, and only the qubits in R are refreshed after each repetition (by preparing $2N$ registers $\mathsf{R}_1,\ldots,\mathsf{R}_{2N}$, each of which consists of $w'(|x|)$ qubits, all of which are initially in the totally mixed state). The key idea for the construction of R''_x is to use a counter that counts the number of attempts such that the measurement over the qubit in Q results in $|1\rangle$ after the application of R'_x (again each measurement is simulated by a CNOT application using an ancilla qubit of a totally mixed state). Notice that the content of Q is never flipped regardless of the initial content of Q, if the original acceptance probability is one in the one-clean-qubit computation with R'_x. Hence, in this case the counter value either stationarily remains its initial value or is increased exactly by $2N$, the number of repetitions. On the other hand, if the original acceptance probability is close to $1/2$ in the one-clean-qubit computation with R'_x, the content of Q is flipped with probability close to $1/2$ after each application of R'_x regardless of the initial

content of Q. This means that, after each application of R'_x, the measurement over the qubit in Q results in $|1\rangle$ with probability close to 1/2 regardless of the initial content of Q, and thus, the increment of the counter value must be distributed around $\frac{1}{2} \cdot 2N = N$ with very high probability. Now, if the counter value is taken modulo $2N$ and if the unique initially clean qubit is prepared for the most significant bit of the counter (which picks the initial counter value from the set $\{0, \ldots, N-1\}$ uniformly at random), the computational-basis measurement over this most significant qubit of the counter always results in $|0\rangle$ if x is in A_{yes}, while it results in $|1\rangle$ with very high probability if x is in A_{no} (which can be made at least $1 - \frac{1}{p(|x|)}$ for an arbitrarily chosen polynomially bounded function p, by taking an appropriately large number N).

One drawback of the construction of R''_x above via the One-Clean-Qubit Stability Checking Procedure is that, in the case of no-instances, there inevitably exist some "bad" initial counter values in $\{0, \ldots, N-1\}$ with which R''_x is forced to accept with unallowably high probability. For instance, if the initial counter value is 0, R''_x is forced to accept when the increment of the counter is less than N, which happens with probability at least a constant. This is the essential reason why the current approach achieves only a polynomially small soundness in the one-clean-qubit case in Theorem 1.2, as the number of possible initial counter values can be at most polynomially many (otherwise the number of repetitions must be super-polynomially many) and even just one "bad" initial value is problematic to go beyond polynomially small soundness. In contrast, if not just one but two clean qubits are available, one can remove the possibility of "bad" initial counter values, which results in the Two-Clean-Qubit Stability Checking Procedure. This time, the circuit R'_x is repeatedly applied $8N$ times, and the counter value is taken modulo $8N$. The two initially clean qubits are prepared for the most and second-most significant bits of the counter, which results in picking the initial counter value from the set $\{0, \ldots, 2N-1\}$ uniformly at random. Now the point is that the counter value can be increased by N before the repetition so that the actual initial value of the counter is in $\{N, \ldots, 3N-1\}$, which discards the tail sets $\{0, \ldots, N-1\}$ and $\{3N, \ldots, 4N-1\}$ of the set $\{0, \ldots, 4N-1\}$. As the size of the tail sets discarded is sufficiently large, there no longer exists any "bad" initial counter value, which leads to the exponentially small soundness in the two-clean-qubit case in Theorem 1.1.

2.2 Proof ideas of Theorems 1.4 and 1.5

The results for the two-sided error case need more complicated arguments and is proved in eight stages of transformations in total, which are split into three parts.

The first part consists of three stages, and proves that any problem solvable with constant completeness and soundness using logarithmically many clean qubits is also solvable with constant completeness and soundness using just one clean qubit. At the first stage of the first part, by a standard repetition with a threshold-value decision, one first reduces errors to be sufficiently small constants, say, completeness 15/16 and soundness 1/16. For this, if the starting computation has a constant gap between completeness and soundness, one requires only a constant number of repetitions, and thus, the resulting computation still requires only logarithmically many clean qubits. The second stage of the first part then reduces the number of clean qubits to just one. The procedure in this stage is exactly the One-Clean-Qubit Simulation Procedure developed in the first stage of the one-sided error case. The gap between completeness and soundness becomes only an inverse-polynomial by this transformation, but the point is that the gap is still sufficiently larger (i.e., a constant times larger) than the completeness error. Now the third stage of the first part transforms the computation resulting from the second stage to the computation that still uses only one

clean qubit and has constant completeness and soundness. The procedure in this stage is exactly the Randomness Amplification Procedure, developed in the second stage of the one-sided error case, and it makes use of the difference of the rates of convergence to 1/2 of the acceptance probability between the yes- and no-instance cases.

The second part consists of two stages, and proves that any problem solvable with constant completeness and soundness using just one clean qubit is also solvable with almost-perfect (i.e., exponentially close to one) completeness and soundness below 1/2 using just logarithmically many clean qubits. At the first stage of the second part, one reduces both of the completeness and soundness errors to be polynomially small, again by a standard repetition with a threshold-value decision. Note that the computation resulting from the first part requires only one clean qubit. Thus, even when repeated logarithmically many times, the resulting computation uses just logarithmically many clean qubits, and achieves polynomially small errors. The second stage of the second part then repeatedly attempts the computation resulting from the first stage polynomially many times, and accepts if at least one of the attempts results in acceptance (i.e., takes OR of the attempts). A straightforward repetition requires polynomially many clean qubits, and to avoid this problem, after each repetition one tries to recover the clean qubits for reuse by applying the inverse of the computation (the failure of this recovery step is counted as an "acceptance" when taking the OR). This results in a computation that still requires only logarithmically many clean qubits, and has completeness exponentially close to one, while soundness is still below 1/2.

Now the third part is essentially the same as the three-stage transformation of the one-sided error case. From the computation resulting from the second part, the first stage of the third part decreases the number of clean qubits to just one, via the One-Clean-Qubit Simulation Procedure. The completeness of the resulting computation is still exponentially close to one and its soundness is bounded away from one by an inverse-polynomial. The second stage of the third part then applies the Randomness Amplification Procedure to make the acceptance probability of no-instances arbitrarily close to 1/2, while keeping completeness exponentially close to one. Finally, the third stage of the third part proves that one can further decrease soundness error to be polynomially small using just one qubit via the One-Clean-Qubit Stability Checking Procedure, or to be exponentially small using just two qubits via the Two-Clean-Qubit Stability Checking Procedure, while keeping completeness exponentially close to one.

By considering the complement problem, the above argument can also prove the case of exponentially small soundness error in Theorem 1.5.

Abstract

This paper presents a general space-efficient method for error reduction for unitary quantum computation. Consider a polynomial-time quantum computation with completeness c and soundness s, either with or without a witness (corresponding to QMA and BQP, respectively). To convert this computation into a new computation with error at most 2^{-p}, the most space-efficient method known requires extra workspace of $O\left(p \log \frac{1}{c-s}\right)$ qubits. This space requirement is too large for scenarios like logarithmic-space quantum computations. This paper shows an error-reduction method for unitary quantum computations (i.e., computations without intermediate measurements) that requires extra workspace of just $O\left(\log \frac{p}{c-s}\right)$ qubits. This in particular gives the first method of strong amplification for logarithmic-space unitary quantum computations with two-sided bounded error. This also leads to a number of consequences in complexity theory, such as the uselessness of quantum witnesses in bounded-error logarithmic-space unitary quantum computations, the PSPACE upper bound for QMA with exponentially-small completeness-soundness gap, and strong amplification for matchgate computations.

1 Introduction

1.1 Background

A very basic topic in various models of quantum computation is whether computation error can be efficiently reduced within a given model. For polynomial-time bounded error quantum computation, the most standard model of quantum computation, the computation error can

be made exponentially small via a simple repetition followed by a threshold-value decision. This justifies the choice of 2/3 and 1/3 for the completeness and soundness parameters in the definition of the corresponding complexity class BQP. This is also the case for quantum Merlin-Arthur (QMA) proof systems, another central model of quantum computation that models a quantum analogue of NP (more precisely, MA), and the resulting class QMA may again be defined with completeness and soundness parameters 2/3 and 1/3.

An undesirable feature of the simple repetition-based error reduction above is that the necessary workspace enlarges linearly with respect to the number of repetitions. More explicitly, for a given p, the number of repetitions necessary to achieve an error of 2^{-p} is $O\big(\frac{p}{(c-s)^2}\big)$, and thus both the workspace size and the witness size become $O\big(\frac{p}{(c-s)^2}\big)$ times larger. This implies that the simple repetition-based method is no longer useful when either the workspace size or the witness size is required to be logarithmically bounded.

Marriott and Watrous [13] developed a more sophisticated method of error reduction for QMA proof systems that does not increase the witness size at all. For a given p, their method still requires $O\big(\frac{p}{(c-s)^2}\big)$ calls of the original computation and its inverse to achieve the computation error 2^{-p}, but the method reuses both the workspace and the witness every time it calls the original computation and its inverse. Hence, the witness size never increases in their method. This is a strong property that allows them to show the uselessness of logarithmic-size quantum witnesses in QMA proof systems (i.e., $\mathrm{QMA}_{\log} = \mathrm{BQP}$, where $\mathrm{QMA}_{\log}$ is the class of problems having QMA proof systems with logarithmic-size quantum witnesses). Their method is also more efficient in workspace size than the simple repetition-based method, but still requires extra workspace of size $O\big(\frac{p}{(c-s)^2}\big)$, as it must record outcomes of all the calls of the original computation and its inverse.

Nagaj, Wocjan, and Zhang [15] succeeded in reducing to $O\big(\frac{p}{c-s}\big)$ the number of calls of the original computation and its inverse necessary to achieve the computation error 2^{-p} for a given p, while keeping the witness size unchanged. Their method makes use of the phase-estimation algorithm, an essential component of many quantum algorithms including the celebrated factoring algorithm. To achieve error 2^{-p} for a given p, their method must repeat $O(p)$ times the phase-estimation algorithm with precision of at least $O\big(\log \frac{1}{c-s}\big)$ bits and record all these estimated phases. Hence, this phase-estimation-based method uses extra workspace of size $O\big(p \log \frac{1}{c-s}\big)$.

As can be seen from above, both of the Marriott-Watrous method and the phase-estimation-based method are still insufficient for the case where the workspace size must be logarithmically bounded. No efficient error-reduction method is known that keeps the size of additionally necessary workspace logarithmically bounded. This is not limited to the case of QMA proof systems, and in fact almost no efficient error-reduction method is known even in the case of logarithmic-space quantum computations, and in the case of space-bounded quantum computations in general. The study of general space-bounded quantum computations was initiated by Watrous [21] based on quantum Turing machines. Several models of space-bounded quantum computations have been proposed and investigated since then in the literature [22, 23, 24, 9, 14, 18], some considering only logarithmic-space quantum computations and others treating general cases. It is not known whether any of these models are computationally equivalent. It is also not known whether error reduction is possible for logarithmic-space quantum computation defined according to any of these models, except the only known affirmative answer shown by Watrous [22] on computation of one-sided bounded error performed by logarithmic-space quantum Turing machines. As negative evidence in the case where computational resources are too limited, computation error cannot be reduced below a certain constant for one-way quantum finite state automata [1].

1.2 Main result and its consequences

This paper presents a general method of strong and space-efficient error reduction for *unitary* quantum computations. In particular, the method is applicable to logarithmic-space unitary quantum computations and logarithmic-space unitary QMA proof systems. All the results in this paper are model-independent and hold with any model of space-bounded quantum computations as long as it performs *unitary* quantum computations. The unitary model is not the most general in that it does not allow any intermediate measurements (notice that the standard technique of simulating intermediate measurements by unitary gates requires unallowably many ancilla qubits in the case of space-bounded computations), but is arguably one of the most reasonable models of space-bounded quantum computation.

Let $\mathbb{N}$ and $\mathbb{Z}^+$ denote the sets of positive and nonnegative integers, respectively. Let $\mathrm{QMA}_{\mathbf{U}}\mathrm{SPACE}[l_{\mathsf{V}}, l_{\mathsf{M}}](c, s)$ denote the class of problems having QMA proof systems with completeness c and soundness s, where the verifier performs a *unitary* quantum computation that has no time bound but is restricted to use $l_{\mathsf{V}}(n)$ private qubits and to receive a quantum witness of $l_{\mathsf{M}}(n)$ qubits on every input of length n. The main result of this paper is the following strong and space-efficient error-reduction for such QMA-type computations.

▶ **Theorem 1.1.** *For any functions $p, l_{\mathsf{V}}, l_{\mathsf{M}} \colon \mathbb{Z}^+ \to \mathbb{N}$ and for any functions $c, s \colon \mathbb{Z}^+ \to [0, 1]$ satisfying $c > s$, there exists a function $\delta \colon \mathbb{Z}^+ \to \mathbb{N}$ that is logarithmic with respect to $\frac{p}{c-s}$ such that*

$$\mathrm{QMA}_{\mathbf{U}}\mathrm{SPACE}[l_{\mathsf{V}}, l_{\mathsf{M}}](c, s) \subseteq \mathrm{QMA}_{\mathbf{U}}\mathrm{SPACE}[l_{\mathsf{V}} + \delta, l_{\mathsf{M}}](1 - 2^{-p}, 2^{-p}).$$

As will be found later, the proof is based on a reduction that is in space logarithmic and also in time polynomial with respect to $\frac{p}{c-s}$. Actually, the argument used in the reduction is remarkably simple. Nevertheless, the theorem is very powerful in that it fruitfully leads to many consequences that substantially deepen the understanding on the power of QMA proof systems and quantum computations in general, both in the space-bounded scenario and in the usual polynomial-time scenario. In what follows, a function $f \colon \mathbb{Z}^+ \to \mathbb{N}$ is *polynomially bounded* if f is polynomial-time computable and $f(n)$ is in $O(n^d)$ for some constant $d > 0$, and is *logarithmically bounded* if f is logarithmic-space computable and $f(n)$ is in $O(\log n)$.

Strong amplification for unitary BQL. The first consequence of Theorem 1.1 is a remarkably strong error-reducibility in logarithmic-space unitary quantum computations. Let $\mathrm{Q}_{\mathbf{U}}\mathrm{L}(c, s)$ denote the class of problems solvable by logarithmic-space unitary quantum computations with completeness c and soundness s. The following amplifiability is immediate from Theorem 1.1 by taking a function p to be logarithmic-space computable and polynomially bounded, functions c and s to be logarithmic-space computable and to satisfy $c - s \geq 1/q$ for some polynomially bounded function $q \colon \mathbb{Z}^+ \to \mathbb{N}$, a function l_{V} to be logarithmically bounded, and a function $l_{\mathsf{M}} = 0$.

▶ **Corollary 1.2.** *For any polynomially bounded function $p \colon \mathbb{Z}^+ \to \mathbb{N}$ that is logarithmic-space computable and for any logarithmic-space computable functions $c, s \colon \mathbb{Z}^+ \to [0, 1]$ satisfying $c - s \geq 1/q$ for some polynomially bounded function $q \colon \mathbb{Z}^+ \to \mathbb{N}$,*

$$\mathrm{Q}_{\mathbf{U}}\mathrm{L}(c, s) \subseteq \mathrm{Q}_{\mathbf{U}}\mathrm{L}(1 - 2^{-p}, 2^{-p}).$$

This in particular justifies defining the bounded-error class $\mathrm{BQ}_{\mathbf{U}}\mathrm{L}$ of logarithmic-space unitary quantum computations by $\mathrm{BQ}_{\mathbf{U}}\mathrm{L} = \mathrm{Q}_{\mathbf{U}}\mathrm{L}(2/3, 1/3)$, employing $2/3$ and $1/3$ for completeness and soundness parameters. Before this work, Watrous [22] showed a similar strong error-reducibility in the case of one-sided bounded error, and Corollary 1.2 extends this to the two-sided bounded error case.

Uselessness of quantum witnesses in logarithmic-space unitary QMA. Let $\mathrm{QMA}_{\mathbf{U}}\mathrm{L}(c,s)$ denote the class of problems having logarithmic-space unitary QMA proof systems (i.e., such systems in which a verifier performs a logarithmic-space unitary computation upon receiving a logarithmic-size quantum witness) with completeness c and soundness s. Similarly to Corollary 1.2, the following amplifiability is immediate from Theorem 1.1 by taking a function p to be logarithmic-space computable and polynomially bounded, functions c and s to be logarithmic-space computable and to satisfy $c - s \geq 1/q$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$, and functions l_{V} and l_{M} to be logarithmically bounded.

▶ **Corollary 1.3.** *For any polynomially bounded function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ that is logarithmic-space computable and for any logarithmic-space computable functions $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c - s \geq 1/q$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$,*

$$\mathrm{QMA}_{\mathbf{U}}\mathrm{L}(c,s) \subseteq \mathrm{QMA}_{\mathbf{U}}\mathrm{L}(1-2^{-p}, 2^{-p}).$$

Again this justifies defining the bounded-error class $\mathrm{QMA}_{\mathbf{U}}\mathrm{L}$ of logarithmic-space unitary QMA proof systems by $\mathrm{QMA}_{\mathbf{U}}\mathrm{L} = \mathrm{QMA}_{\mathbf{U}}\mathrm{L}(2/3, 1/3)$. By a standard technique of replacing a quantum witness by a totally mixed state as a self-prepared witness (to do this in a unitary computation, one can simply prepare sufficiently many EPR pairs and then take a qubit from each pair), Corollary 1.3 together with Corollary 1.2 further implies the equivalence of $\mathrm{QMA}_{\mathbf{U}}\mathrm{L}$ and $\mathrm{BQ}_{\mathbf{U}}\mathrm{L}$.

▶ **Corollary 1.4.** $\mathrm{QMA}_{\mathbf{U}}\mathrm{L} = \mathrm{BQ}_{\mathbf{U}}\mathrm{L}$.

As mentioned before, Marriott and Watrous [13] showed the equivalence $\mathrm{QMA}_{\log} = \mathrm{BQP}$, the uselessness of quantum witnesses of logarithmic size in the standard QMA proof systems with a polynomial-time verifier. In this respect, Corollary 1.4 states that quantum witnesses of logarithmic size do not increase the power of logarithmic-space unitary quantum computations at all, and indeed extends the result of Marriott and Watrous to logarithmic-space case.

Space-efficient amplification for QMA. Let $\mathrm{QMA}[l_{\mathsf{V}}, l_{\mathsf{M}}](c,s)$ be the time-efficient version of $\mathrm{QMA}_{\mathbf{U}}\mathrm{SPACE}[l_{\mathsf{V}}, l_{\mathsf{M}}](c,s)$, i.e., the class of problems having standard polynomial-time QMA proof systems with completeness c and soundness s in which a polynomial-time unitary quantum verifier receives a quantum witness of $l_{\mathsf{M}}(n)$ qubits and uses workspace of $l_{\mathsf{V}}(n)$ qubits on every input of length n. As the reduction is in time polynomial with respect to $\frac{p}{c-s}$ in the proof of Theorem 1.1, the following amplifiability is immediate from Theorem 1.1 by taking functions p, l_{V}, and l_{M} to be polynomially bounded, and functions c and s to be polynomial-time computable and to satisfy $c - s \geq 1/q$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$.

▶ **Corollary 1.5.** *For any polynomially bounded functions $p, l_{\mathsf{V}}, l_{\mathsf{M}}\colon \mathbb{Z}^+ \to \mathbb{N}$ and for any polynomial-time computable functions $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c - s \geq 1/q$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$, there exists a function $\delta\colon \mathbb{Z}^+ \to \mathbb{N}$ that is logarithmic with respect to $\frac{p}{c-s}$ such that*

$$\mathrm{QMA}[l_{\mathsf{V}}, l_{\mathsf{M}}](c,s) \subseteq \mathrm{QMA}[l_{\mathsf{V}} + \delta, l_{\mathsf{M}}](1-2^{-p}, 2^{-p}).$$

Recall that the Marriott-Watrous amplification [13] requires δ to be in $O\big(\frac{p}{(c-s)^2}\big)$ and the phase-estimation-based method by Nagaj, Wocjan, and Zhang [15] requires δ to be in $O\big(p \log \frac{1}{c-s}\big)$, instead of δ in $O\big(\log \frac{p}{c-s}\big)$ of Corollary 1.5. Hence, the method in this paper is most space-efficient among known error-reduction methods for standard QMA proof systems, and also among those for BQP.

Strong amplification for unitary QMAPSPACE. Let $\mathrm{Q_U PSPACE}(c,s)$ denote the class of problems solvable by polynomial-space unitary quantum computations with completeness c and soundness s, and let $\mathrm{QMA_U PSPACE}(c,s)$ denote the class of problems having polynomial-space unitary QMA proof systems (i.e., such systems in which a verifier performs a polynomial-space unitary computation upon receiving a polynomial-size quantum witness) with completeness c and soundness s. The following corollary states the scaled-up versions of Corollaries 1.2 and 1.3, and again is immediate from Theorem 1.1 by taking a function p to be polynomial-space computable and exponentially bounded, functions c and s to be polynomial-space computable and to satisfy $c - s \geq 2^{-q}$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$, and functions l_{V} and l_{M} to be polynomially bounded (or a function $l_{\mathsf{M}} = 0$ in the case of $\mathrm{Q_U PSPACE}(c,s)$).

▶ **Corollary 1.6.** *For any polynomially bounded function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ and for any polynomial-space computable functions $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c - s \geq 2^{-q}$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$,*

$$\mathrm{Q_U PSPACE}(c,s) \subseteq \mathrm{Q_U PSPACE}\big(1 - 2^{-2^p}, 2^{-2^p}\big), \text{ and}$$
$$\mathrm{QMA_U PSPACE}(c,s) \subseteq \mathrm{QMA_U PSPACE}\big(1 - 2^{-2^p}, 2^{-2^p}\big).$$

Again by a standard technique of replacing a quantum witness by a totally mixed state as a self-prepared witness, the following corollary follows from Corollary 1.6 together with the fact that RevPSPACE = PrQPSPACE = PSPACE [2, 21], where RevPSPACE and PrQPSPACE are the complexity classes corresponding to deterministic polynomial-space reversible computations and unbounded-error polynomial-space quantum computations, respectively.

▶ **Corollary 1.7.** *For any polynomial-space computable functions $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c - s \geq 2^{-q}$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$,*

$$\mathrm{QMA_U PSPACE}(c,s) = \mathrm{PSPACE}.$$

Now the PSPACE upper bound immediately follows for the class of problems having standard polynomial-time QMA proof systems with exponentially small completeness-soundness gap. More precisely, for the class $\mathrm{QMA}(c,s)$ of problems having standard polynomial-time QMA proof systems with completeness c and soundness s, the following corollary holds.

▶ **Corollary 1.8.** *For any polynomially bounded function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ and for any polynomial-time computable functions $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c - s \geq 2^{-q}$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$,*

$$\mathrm{QMA}(c,s) \subseteq \mathrm{PSPACE}.$$

For QMA proof systems with exponentially small completeness-soundness gap, the PSPACE upper bound was known previously only for the one-sided-error case (following from the result in Ref. [7]), and only the EXP upper bound was known for the two-sided-error case (following from the result in Ref. [10]). Natarajan and Wu [16] independently proved a statement equivalent to Corollary 1.8. In fact, statements equivalent to Corollary 1.8 were also proved with different proofs independently by the first and third authors of the present paper in Ref. [4] (see Ref. [5] also) and by the complement subset of the present authors. The first and third authors of the present paper further proved in Refs. [4, 5] that the converse of Corollary 1.8 also holds, i.e., PSPACE is characterized by QMA proof systems with exponentially small completeness-soundness gap.

Strong amplification for matchgate computations. A matchgate is defined to be a two-qubit gate of the form $G(A, B)$ corresponding to the four-by-four unitary matrix in which the four corner elements form A and the four inner-square elements form B for matrices A and B in SU(2), and all the other elements are 0. A matchgate circuit is a quantum circuit such that: (i) the input state is a computational basis state, (ii) all the gates of the circuit are matchgates which are applied to two neighbor qubits, and (iii) the output is a final measurement in the computational basis on any single qubit. Matchgate computations were introduced and proved classically simulable by Valiant [20]. Terhal and DiVincenzo [19] related them to noninteracting-fermion quantum circuits. Let $\mathrm{MG}(c, s)$ denote the class of problems solvable by polynomial-time matchgate computations with completeness c and soundness s. Using the equivalence of polynomial-time matchgate computations and logarithmic-space unitary computations shown by Jozsa, Kraus, Miyake, and Watrous [9, Corollary 3.3], the following is immediate from Corollary 1.2.

▶ **Corollary 1.9.** *For any polynomially bounded function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ that is logarithmic-space computable and for any logarithmic-space computable functions $c, s\colon \mathbb{Z}^+ \to [0, 1]$ satisfying $c - s \geq 1/q$ for some polynomially bounded function $q\colon \mathbb{Z}^+ \to \mathbb{N}$,*

$$\mathrm{MG}(c, s) \subseteq \mathrm{MG}(1 - 2^{-p}, 2^{-p}).$$

2 Overview of the proof of main theorem

We assume familiarity with basic quantum formalism (see Refs. [17, 11, 26], for instance). The main theorem can be proved with three different proofs. Due to space limitations, this version presents only one of the three proofs. The other two proofs, as well as precise definitions and technical proofs, are deferred to the full version [3].

Consider any unitary transformation V_x of the verifier on input x, and let p_{acc} be the maximum acceptance probability of it (and thus, $p_{\mathrm{acc}} \geq c(|x|)$ for yes instances, and $p_{\mathrm{acc}} \leq s(|x|)$ for no instances). Then the idea is to guess p_{acc} with *mild* precision $\delta = 2^{-l(|x|)}$, where $\frac{c-s}{2\sqrt{6q}} < 2^{-l} \leq \frac{c-s}{\sqrt{6q}}$ for some appropriately chosen function q and the (integer-valued) function l determined uniquely by given c, s, and q.

For each j in $\{1, \ldots, 2^{l(|x|)}\}$, let $r_j = j\delta$ be a possible guess of p_{acc}. Pick an integer k from $\{1, \ldots, 2^{l(|x|)}\}$ uniformly at random, and reject immediately if $r_k = k\delta < c(|x|)$ (so that no k can result in a good guess at p_{acc} for no instances). Otherwise r_k is used as a guess at p_{acc}. The point is that, for yes instances, there exists a choice of k such that $|r_k - p_{\mathrm{acc}}| < \delta \leq \frac{c(|x|)-s(|x|)}{\sqrt{6\,q(|x|)}}$, while for no instances, it holds that $|r_k - p_{\mathrm{acc}}| > c(|x|) - s(|x|)$ for any choice of k. Hence, by using the Reflection Procedure [12] combined with the additive adjustment of acceptance probability [8], the acceptance probability can be *mildly* amplified to at least $1 - \frac{(c(|x|)-s(|x|))^2}{6\,q(|x|)}$ in the yes-instance case, if the appropriate guess r_k is made. It is stressed that this mild amplification is the key for the efficiency in workspace. For no instances, the acceptance probability is at most $1 - \big(c(|x|) - s(|x|)\big)^2$ for any guess r_k.

Fix an index k of the guess r_k and let $V'_{x,k}$ be the unitary operator corresponding to the procedure constructed so far. Now repeat the following procedure $N(|x|)$ times for a function N defined by $N = \left\lceil \frac{q}{2(c-s)^2} \right\rceil$: One applies $V'_{x,k}$, and then increments a counter by 1 if the state corresponds to a rejection state of it. One further applies $(V'_{x,k})^\dagger$, and then increments a counter by 1 if any of the work qubits of $V'_{x,k}$ is in state $|1\rangle$. After the repetition, one accepts if and only if the counter value remains 0. In short, these repetitions essentially take the AND of the $N(|x|)$ attempts of $V'_{x,k}$ (with each initialization try by $(V'_{x,k})^\dagger$). The rigorous analysis shows that the initialization steps also contribute to taking AND, and this process is exactly

Additive Adjustment Procedure associated with (U, Δ, Π, l, k)

1. Prepare a single-qubit register B and an l-qubit register R, where all the qubits in B and R are initialized to state $|0\rangle$. Receive a quantum register Q that contains a state in the subspace corresponding to the projection Δ.
2. Apply the Hadamard transformation H to each qubit in (B, R), and apply U to Q.
3. Accept either if B contains 0 *and* the state in Q belongs to the subspace corresponding to Π or if B contains 1 *and* the content of R is greater than k (when viewed as an integer in $\{1, \ldots, 2^l\}$), and reject otherwise.

Figure 1 The Additive Adjustment Procedure.

equivalent to taking the AND of $2\,N(|x|)$ attempts of $V'_{x,k}$. The acceptance probability is at least $\frac{1}{2}$ for yes instances when the appropriate guess r_k at p_{acc} is made, while it is at most $e^{-\,q(|x|)} < 2^{-\,q(|x|)}$ for any guess r_k for no instances. Taking into account that the index k of r_k is chosen uniformly at random, this results in a unitary procedure V''_x with acceptance probability at least $2^{-\,l(|x|)} \cdot \frac{1}{2} > \frac{c(|x|)-s(|x|)}{4\sqrt{6\,q(|x|)}}$ for yes instances and at most $2^{-\,q(|x|)}$ for no instances.

Finally, by using a repetition similar to above based on V''_x that takes OR instead of AND, it is clear that the completeness acceptance probability becomes exponentially close to 1 with respect to q, while the soundness acceptance probability is still exponentially small with respect to q. To achieve error below 2^{-p} for a target p, one chooses q to be slightly larger than p when constructing V''_x (more precisely, one can choose a function $q = \lceil 2\big(p + \log \frac{6p}{c-s} + 1\big)\rceil$).

3 Basic procedures

Let $\Sigma = \{0, 1\}$ denote the binary alphabet set. For every positive integer n, let $\mathbb{C}(\Sigma^n)$ denote the 2^n-dimensional complex Hilbert space whose standard basis vectors are indexed by the elements in Σ^n. In this paper, all Hilbert spaces are complex and of dimension a power of two. A quantum register is a set of single or multiple qubits. For a quantum register R, let I_{R} denote the identity operator over the Hilbert space associated with R.

Let $\mathcal{H}$ be any Hilbert space of dimension a power of two. Given a unitary transformation U and two projections Δ and Π, all acting over $\mathcal{H}$, define the Hermitian operator M over $\mathcal{H}$ by

$$M = \Delta U^\dagger \Pi U \Delta,$$

which plays crucial roles in many well-known amplification methods in quantum computation, including the Grover search [6], the Marriott-Watrous amplification for QMA [13], and quantum rewinding for zero-knowledge proofs against quantum attacks [25].

Additive Adjustment Procedure. Consider the procedure described in Figure 1, called the Additive Adjustment Procedure, which uses the additive adjustment technique of acceptance probability proposed in Ref. [8].

The following properties hold with the Additive Adjustment Procedure.

▶ **Proposition 3.1.** *Let U be a unitary transformation and Δ and Π be projections, all acting over the same Hilbert space. Consider the Hermitian operator $M = \Delta U^\dagger \Pi U \Delta$. For any positive integer l and any integer k in $\{1, \ldots, 2^l\}$, the following two properties hold:*

(Completeness) *Suppose that M has an eigenstate $|\phi_\lambda\rangle$ with its associated eigenvalue λ. Then, the* Additive Adjustment Procedure *associated with (U, Δ, Π, l, k) results in acceptance with probability $\frac{1}{2} + \frac{1}{2}\big(\lambda - \frac{k}{2^l}\big)$ when $|\phi_\lambda\rangle$ is received in register Q in Step 1.*

Reflection Procedure associated with (U, Δ, Π)

1. Receive a quantum register Q that contains a state in the subspace corresponding to the projection Δ.
2. Apply U to Q.
3. Perform a phase-flip (i.e., multiply the phase by -1) if the state in Q belongs to the subspace corresponding to the projection Π. That is, apply the unitary transformation $I_{\mathsf{Q}} - 2\Pi$ to Q.
4. Apply $U^\dagger$ to Q.
5. Reject if the state in Q belongs to the subspace corresponding to Δ, and accept otherwise.

Figure 2 The Reflection Procedure.

(Soundness) *Suppose that all the eigenvalues of M are at most ε for some ε in $[0,1)$. Then, the* Additive Adjustment Procedure *associated with (U, Δ, Π, l, k) results in acceptance with probability at most $\frac{1}{2} + \frac{1}{2}\left(\varepsilon - \frac{k}{2^l}\right)$ regardless of the quantum state received in register Q in Step 1.*

Reflection Procedure. Now consider the procedure described in Figure 2, which is exactly the Reflection Procedure in a general form originally developed in Ref. [12].

The following proposition holds with the Reflection Procedure.

▶ **Proposition 3.2** ([12])**.** *Let U be a unitary transformation and Δ and Π be projections, all acting over the same Hilbert space. Consider the Hermitian operator $M = \Delta U^\dagger \Pi U \Delta$. The following two properties hold:*

(Completeness) *Suppose that M has an eigenstate $|\phi_\lambda\rangle$ with its associated eigenvalue λ. Then, the* Reflection Procedure *associated with (U, Δ, Π) results in acceptance with probability $4\lambda(1-\lambda)$ when $|\phi_\lambda\rangle$ is received in register Q in Step 1.*

(Soundness) *Suppose that none of the eigenvalues of M is in the interval $\left(\frac{1}{2} - \varepsilon, \frac{1}{2} + \varepsilon\right)$ for some ε in $\left(0, \frac{1}{2}\right]$. Then, the* Reflection Procedure *associated with (U, Δ, Π) results in acceptance with probability at most $1 - 4\varepsilon^2$ regardless of the quantum state received in register Q in Step 1.*

AND-Type and OR-Type Repetition Procedures. Given a unitary transformation U and two projections Δ and Π all acting over a Hilbert space, consider the process of applying U to a fixed initial state $|\phi\rangle$ in a quantum register Q that is in the subspace corresponding to Δ and then accepting if and only if the resulting state is projected onto the subspace corresponding to Π by the projective measurement $\{\Pi, I_{\mathsf{Q}} - \Pi\}$. Let p denote the acceptance probability of this process. By running N independent attempts of such a process, the probability clearly becomes p^N for the event that all the attempts result in acceptance, but which requires N copies of the initial state $|\phi\rangle$. When $|\phi\rangle$ is an eigenstate of the Hermitian operator $M = \Delta U^\dagger \Pi U \Delta$, the AND-Type Repetition Procedure described in Figure 3 essentially simulates such independent attempts with just one copy of $|\phi\rangle$.

The following proposition holds with the AND-Type Repetition Procedure.

▶ **Proposition 3.3.** *Let U be a unitary transformation and Δ and Π be projections, all acting over the same Hilbert space, and let N be a positive integer. Consider the Hermitian operator $M = \Delta U^\dagger \Pi U \Delta$. The following two properties hold:*

AND-Type Repetition Procedure associated with (U, Δ, Π, N)

1. Let $l = \lceil \log(2N+1) \rceil$, and prepare an l-qubit register C, where all the qubits in C are initialized to state $|0\rangle$. Receive a quantum register Q that contains a state in the subspace corresponding to the projection Δ.
2. For $j = 1$ to N, perform the following:
   - 2.1. Apply U to Q.
   - 2.2. If the state in Q belongs to the subspace corresponding to the projection $I_{\mathsf{Q}} - \Pi$, apply $U_{+1}(\mathbb{Z}_{2^l})$ to C, where $U_{+1}(\mathbb{Z}_{2^l})$ is the unitary transformation defined by
   $$U_{+1}(\mathbb{Z}_{2^l}) \colon |j\rangle \mapsto \left|(j+1) \bmod 2^l\right\rangle, \quad \forall j \in \mathbb{Z}_{2^l}.$$
   - 2.3. Apply $U^\dagger$ to Q.
   - 2.4. If the state in Q belongs to the subspace corresponding to the projection $I_{\mathsf{Q}} - \Delta$, apply $U_{+1}(\mathbb{Z}_{2^l})$ to C.
3. Accept if the content of C is 0 (i.e., all the qubits in C are in state $|0\rangle$), and reject otherwise.

Figure 3 The AND-Type Repetition Procedure.

(Completeness) *Suppose that M has an eigenstate $|\phi_\lambda\rangle$ with its associated eigenvalue λ. Then, the* AND-Type Repetition Procedure *associated with (U, Δ, Π, N) results in acceptance with probability λ^{2N} when $|\phi_\lambda\rangle$ is received in register Q in Step 1.*

(Soundness) *Suppose that all the eigenvalues of M are at most ε for some ε in $[0, 1)$. Then, the* AND-Type Repetition Procedure *associated with (U, Δ, Π, N) results in acceptance with probability at most ε^{2N} regardless of the quantum state received in register Q in Step 1.*

One can also construct a procedure that essentially simulates the process of taking OR of the N independent attempts mentioned before with just one copy of $|\phi\rangle$. One now applies $U_{+1}(\mathbb{Z}_{2^l})$ to C when the state in Q belongs to the subspace corresponding to the projection Π at Step 2.2, and *rejects* if and only if the content of C is 0 at Step 3. The resulting procedure is called the OR-Type Repetition Procedure, which has the following properties.

▶ **Proposition 3.4.** *Let U be a unitary transformation and Δ and Π be projections, all acting over the same Hilbert space, and let N be a positive integer. Consider the Hermitian operator $M = \Delta U^\dagger \Pi U \Delta$. The following two properties hold:*

(Completeness) *Suppose that M has an eigenstate $|\phi_\lambda\rangle$ with its associated eigenvalue λ. Then, the* OR-Type Repetition Procedure *associated with (U, Δ, Π, N) results in acceptance with probability $1 - (1-\lambda)^{2N}$ when $|\phi_\lambda\rangle$ is received in register Q in Step 1.*

(Soundness) *Suppose that all the eigenvalues of M are at most ε for some ε in $[0, 1)$. Then, the* OR-Type Repetition Procedure *associated with (U, Δ, Π, N) results in acceptance with probability at most $1 - (1-\varepsilon)^{2N}$ regardless of the quantum state received in register Q in Step 1.*

4 Guess-based amplification framework

Consider any QMA-type computation for a problem $A = (A_{\text{yes}}, A_{\text{no}})$ induced by a family $\{V_x\}_{x \in \Sigma^*}$ of a unitary transformation V_x of the verifier on input x in Σ^* that acts over a quantum register $\mathsf{Q} = (\mathsf{V}, \mathsf{M})$, where V is the quantum register consisting of all the private qubits of the verifier, and M is the one for storing a received quantum witness. Let Π_{init} be the projection onto the subspace spanned by the legal initial states of the QMA-type

Mild Completeness Amplification with Guess k associated with (V_x, p)

Define functions l and C by $l = \left\lceil \frac{1}{2} \log \frac{p}{(c-s)^2} \right\rceil$ and $C = \lceil 2^l c \rceil$. Let Π_{init} and Π_{acc} be the projections onto the subspaces spanned by the legal initial states and the accepting states, respectively, in the verification with V_x. Given an integer k in $\{1, \ldots, 2^{l(|x|)}\}$ as a guess, consider the Additive Adjustment Procedure associated with $(V_x, \Pi_{\text{init}}, \Pi_{\text{acc}}, l(|x|), k)$. Let $V'_{x,k}$ be the unitary transformation induced by it, let Π'_{init} be the projection onto the subspace spanned by the legal initial states of it, and let $\Pi'_{\text{acc},k}$ be the projection onto the subspace spanned by the accepting states of it.
Reject if $k < C(|x|)$, and continue otherwise by performing the Reflection Procedure associated with $\left(V'_{x,k}, \Pi'_{\text{init}}, \Pi'_{\text{acc},k}\right)$.

Figure 4 The Mild Completeness Amplification with Guess k.

computation induced by V_x (i.e., the subspace spanned by those in which all the qubits in V is in state $|0\rangle$) and let Π_{acc} be the projection onto the subspace spanned by the accepting states of the QMA-type computation associated with V_x (i.e., the subspace spanned by states for which the designated output qubit of V_x is in state $|0\rangle$).

The maximum eigenvalue of the Hermitian operator $M_x = \Pi_{\text{init}} V_x^\dagger \Pi_{\text{acc}} V_x \Pi_{\text{init}}$ exactly corresponds to the maximum acceptance probability of the verifier on input x over all possible quantum witnesses received in M. Hence, M_x has an eigenvalue at least $c(|x|)$ if x is in A_{yes}, while all eigenvalues of M_x are at most $s(|x|)$ if x is in A_{no}, where $c, s \colon \mathbb{Z}^+ \to [0,1]$ are functions that provide completeness and soundness conditions of the QMA-type computation induced by $\{V_x\}_{x \in \Sigma^*}$, respectively.

Mild completeness amplification with a guess. Fix arbitrarily a function $p \colon \mathbb{Z}^+ \to \mathbb{N}$ and functions $c, s \colon \mathbb{Z}^+ \to [0,1]$ satisfying $c > s$, and let $l, C \colon \mathbb{Z}^+ \to \mathbb{N}$ be functions defined by $l = \left\lceil \frac{1}{2} \log \frac{p}{(c-s)^2} \right\rceil$ and $C = \lceil 2^l c \rceil$. Fix an input x and an integer k in $\{1, \ldots, 2^{l(|x|)}\}$. Given the triplet $(V_x, \Pi_{\text{init}}, \Pi_{\text{acc}})$ and an integer k, one first constructs the Additive Adjustment Procedure associated with $\left(V_x, \Pi_{\text{init}}, \Pi_{\text{acc}}, l(|x|), k\right)$, if k is at least $C(|x|)$ (and automatically rejects otherwise so that no k can result in a good guess at the acceptance probability when the actual value of it is unallowably small). Let $V'_{x,k}$ be the unitary transformation induced by it, let Π'_{init} be the projection onto the subspace spanned by the legal initial states of it, and let $\Pi'_{\text{acc},k}$ be the projection onto the subspace spanned by the accepting states of it. Next, from the triplet $\left(V'_{x,k}, \Pi'_{\text{init}}, \Pi'_{\text{acc},k}\right)$, one constructs the Reflection Procedure associated with $\left(V'_{x,k}, \Pi'_{\text{init}}, \Pi'_{\text{acc},k}\right)$, and performs it. The resulting procedure is called the Mild Completeness Amplification with Guess k, and is summarized in Figure 4.

From the properties of the Additive Adjustment Procedure and the Reflection Procedure (Propositions 3.1 and 3.2), one can show the following lemma.

▶ **Lemma 4.1.** *Given functions $l_{\mathsf{V}}, l_{\mathsf{M}} \colon \mathbb{Z}^+ \to \mathbb{N}$ and $c, s \colon \mathbb{Z}^+ \to [0,1]$ satisfying $c > s$, let $A = (A_{\text{yes}}, A_{\text{no}})$ be a problem in $\mathrm{QMA}_{\mathbf{U}}\mathrm{SPACE}[l_{\mathsf{V}}, l_{\mathsf{M}}](c,s)$, and let $V = \{V_x\}_{x \in \Sigma^*}$ be the $(l_{\mathsf{V}}, l_{\mathsf{M}})$-space-bounded quantum verifier witnessing this membership. Then, for any function $p \colon \mathbb{Z}^+ \to \mathbb{N}$ and for every x in Σ^*, letting $l = \left\lceil \frac{1}{2} \log \frac{p}{(c-s)^2} \right\rceil$,*

(Completeness) *if x is in A_{yes}, there exists an integer k in $\{1, \ldots, 2^{l(|x|)}\}$ as a guess such that the Mild Completeness Amplification with Guess k associated with (V_x, p) results in acceptance with probability at least $1 - \frac{(c(|x|) - s(|x|))^2}{p(|x|)}$, and*

(Soundness) *if x is in A_{no}, for any integer k in $\{1, \ldots, 2^{l(|x|)}\}$ as a guess, the Mild Completeness Amplification with Guess k associated with (V_x, p) results in acceptance with probability at most $1 - \left(c(|x|) - s(|x|)\right)^2$.*

Soundness Error Reduction with Guess k associated with (V_x, p)

Define functions l and N by $l = \left\lceil \frac{1}{2} \log \frac{6p}{(c-s)^2} \right\rceil$ and $N = \left\lceil \frac{p}{2(c-s)^2} \right\rceil$. Given an integer k in $\{1, \ldots, 2^{l(|x|)}\}$, consider the Mild Completeness Amplification with Guess k associated with $(V_x, 6p)$. Let $V'_{x,k}$ be the unitary transformation induced by it, let Π'_{init} be the projection onto the subspace spanned by the legal initial states of it, and let $\Pi'_{\text{acc},k}$ be the projection onto the subspace spanned by the accepting states of it.
Perform the AND-Type Repetition Procedure associated with $\left(V'_{x,k}, \Pi'_{\text{init}}, \Pi'_{\text{acc},k}, N(|x|)\right)$.

Figure 5 The Soundness Error Reduction with Guess k.

Soundness error reduction with a guess. Again fix arbitrarily a function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ and functions $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c > s$, and let $l, N\colon \mathbb{Z}^+ \to \mathbb{N}$ be functions defined by $l = \left\lceil \frac{1}{2} \log \frac{6p}{(c-s)^2} \right\rceil$ and $N = \left\lceil \frac{p}{2(c-s)^2} \right\rceil$. Fix an input x and an integer k in $\{1, \ldots, 2^{l(|x|)}\}$. Given the pair (V_x, p) and the integer k, consider the Mild Completeness Amplification with Guess k associated with $(V_x, 6p)$. As before, let $V'_{x,k}$ be the unitary transformation induced by it, let Π'_{init} be the projection onto the subspace spanned by the legal initial states of it, and let $\Pi'_{\text{acc},k}$ be the projection onto the subspace spanned by the accepting states of it. From the triplet $\left(V'_{x,k}, \Pi'_{\text{init}}, \Pi'_{\text{acc},k}\right)$ and a positive integer $N(|x|)$, one constructs the AND-Type Repetition Procedure associated with $\left(V'_{x,k}, \Pi'_{\text{init}}, \Pi'_{\text{acc},k}, N(|x|)\right)$, and performs it. The resulting procedure is called the Soundness Error Reduction with Guess k, and is summarized in Figure 5.

From the properties of the AND-Type Repetition Procedure and the Mild Completeness Amplification with Guess k (Proposition 3.3 and Lemma 4.1), one can show the following lemma.

▶ **Lemma 4.2.** *Given functions $l_{\mathsf{V}}, l_{\mathsf{M}}\colon \mathbb{Z}^+ \to \mathbb{N}$ and $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c > s$, let $A = (A_{\text{yes}}, A_{\text{no}})$ be a problem in $\mathrm{QMA}_{\mathbf{U}}\mathrm{SPACE}[l_{\mathsf{V}}, l_{\mathsf{M}}](c,s)$, and let $V = \{V_x\}_{x \in \Sigma^*}$ be the $(l_{\mathsf{V}}, l_{\mathsf{M}})$-space-bounded quantum verifier witnessing this membership. Then, for any function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ and for every x in Σ^*, letting $l = \left\lceil \frac{1}{2} \log \frac{6p}{(c-s)^2} \right\rceil$,*

(Completeness) *if x is in A_{yes}, there exists an integer k in $\{1, \ldots, 2^{l(|x|)}\}$ as a guess such that the Soundness Error Reduction with Guess k associated with (V_x, p) results in acceptance with probability at least $\frac{1}{2}$, and*

(Soundness) *if x is in A_{no}, for any integer k in $\{1, \ldots, 2^{l(|x|)}\}$ as a guess, the Soundness Error Reduction with Guess k associated with (V_x, p) results in acceptance with probability at most $2^{-p(|x|)}$.*

Soundness error reduction with a random guess. Again fix arbitrarily a function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ and functions $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c > s$, and let $l\colon \mathbb{Z}^+ \to \mathbb{N}$ be a function defined by $l = \left\lceil \frac{1}{2} \log \frac{6p}{(c-s)^2} \right\rceil$. Fix an input x. Given the pair (V_x, p), consider choosing an integer k from $\{1, \ldots, 2^{l(|x|)}\}$ uniformly at random, and performing the Soundness Error Reduction with Guess k associated with (V_x, p). The resulting procedure is called the Soundness Error Reduction with Random Guess and is summarized in Figure 6.

Lemma 4.3 below follows from the Soundness Error Reduction with Random Guess together with the properties of the Soundness Error Reduction with Guess k stated in Lemma 4.2.

▶ **Lemma 4.3.** *For any functions $p, l_{\mathsf{V}}, l_{\mathsf{M}}\colon \mathbb{Z}^+ \to \mathbb{N}$ and any functions $c, s\colon \mathbb{Z}^+ \to [0,1]$ satisfying $c > s$ and $\frac{c-s}{4\sqrt{6p}} > 2^{-p}$, there exists a function $\delta\colon \mathbb{Z}^+ \to \mathbb{N}$ that is logarithmic with*

Soundness Error Reduction with Random Guess associated with (V_x, p)

Define a function l by $l = \left\lceil \frac{1}{2} \log \frac{6p}{(c-s)^2} \right\rceil$.
Pick an integer k from $\{1, \ldots, 2^{l(|x|)}\}$ uniformly at random and perform the Soundness Error Reduction with Guess k associated with (V_x, p).

Figure 6 The Soundness Error Reduction with Random Guess.

Space-Efficient Amplification Based on Random Guess associated with (V_x, p)

Define functions q and N by $q = \left\lceil 2\left(p + \log \frac{6p}{c-s} + 1\right) \right\rceil$ and $N = \left\lceil \frac{2\sqrt{6q}}{c-s} \cdot p \right\rceil$. Consider the Soundness Error Reduction with Random Guess associated with (V_x, q). Let V'_x be the unitary transformation induced by it, let Π'_{init} be the projection onto the subspace spanned by the legal initial states of it, and let Π'_{acc} be the projection onto the subspace spanned by the accepting states of it.
Perform the OR-Type Repetition Procedure associated with $\left(V'_x, \Pi'_{\text{init}}, \Pi'_{\text{acc}}, N(|x|)\right)$.

Figure 7 The Space-Efficient Amplification Based on Random Guess.

respect to $\frac{p}{c-s}$ *such that*

$$\mathrm{QMA}_{\mathbf{U}}\mathrm{SPACE}[l_{\mathsf{V}}, l_{\mathsf{M}}](c, s) \subseteq \mathrm{QMA}_{\mathbf{U}}\mathrm{SPACE}[l_{\mathsf{V}} + \delta, l_{\mathsf{M}}]\left(\frac{c-s}{4\sqrt{6p}}, 2^{-p}\right).$$

Space-efficient amplification based on a random guess. Again fix a function $p\colon \mathbb{Z}^+ \to \mathbb{N}$ and functions $c, s\colon \mathbb{Z}^+ \to [0, 1]$ satisfying $c > s$ arbitrarily. Let $q, N\colon \mathbb{Z}^+ \to \mathbb{N}$ be functions defined by $q = \left\lceil 2\left(p + \log \frac{6p}{c-s} + 1\right) \right\rceil$ and $N = \left\lceil \frac{2\sqrt{6q}}{c-s} \cdot p \right\rceil$. Fix an input x. Given the pair (V_x, p), consider the Soundness Error Reduction with Random Guess associated with (V_x, q). Let V'_x be the unitary transformation induced by it, let Π'_{init} be the projection onto the subspace spanned by the legal initial states of it, and let Π'_{acc} be the projection onto the subspace spanned by the accepting states of it. From the triplet $\left(V'_x, \Pi'_{\text{init}}, \Pi'_{\text{acc}}\right)$ and a positive integer $N(|x|)$, one constructs the OR-Type Repetition Procedure associated with $\left(V'_x, \Pi'_{\text{init}}, \Pi'_{\text{acc}}, N(|x|)\right)$, and performs it. The resulting procedure is called the Space-Efficient Amplification Based on Random Guess and is summarized in Figure 7.

Now Theorem 1.1, the main theorem of this paper, is proved by using the Space-Efficient Amplification Based on Random Guess combined with the properties of the Soundness Error Reduction with Random Guess and the OR-Type Repetition Procedure stated in Lemma 4.3 and Proposition 3.4, respectively.

Abstract

A canonical result about satisfiability theory is that the 2-SAT problem can be solved in linear time, despite the NP-hardness of the 3-SAT problem. In the quantum 2-SAT problem, we are given a family of 2-qubit projectors Q_{ij} on a system of n qubits, and the task is to decide whether the Hamiltonian $H = \sum Q_{ij}$ has a 0-eigenvalue, or it is larger than $1/n^c$ for some $c = O(1)$. The problem is not only a natural extension of the classical 2-SAT problem to the quantum case, but is also equivalent to the problem of finding the ground state of 2-local frustration-free Hamiltonians of spin 1/2, a well-studied model believed to capture certain key properties in modern condensed matter physics. While Bravyi has shown that the quantum 2-SAT problem has a classical polynomial-time algorithm, the running time of his algorithm is $O(n^4)$. In this paper we give a classical algorithm with linear running time in the number of local projectors, therefore achieving the best possible complexity.

1 Introduction

Various formulations of the satisfiability problem of Boolean formulae arguably constitute the center piece of classical complexity theory. In particular, a great amount of attention has been paid to the SAT problem, in which we are given a formula in the form of a conjunction of *clauses*, where each clause is a disjunction of *literals* (variables or negated variables), and the task is to find a satisfying assignment if there is one, or prove that none exists when the formula is unsatisfiable. In the case of the k-SAT problem, where k is a positive integer, in each clause the number of literals is at most k. While k-SAT is an NP-complete problem [4, 12, 17] when $k \geq 3$, the 2-SAT problem is well-known to be efficiently solvable.

Polynomial time algorithms for 2-SAT come in various flavors. Let us suppose that the input formula has n variables and m clauses. The algorithm of Krom [15] based on the resolution principle and on transitive closure computation decides if the formula is satisfiable in time $O(n^3)$ and finds a satisfying assignment in time $O(n^4)$. The limited backtracking

technique of Even, Itai and Shamir [9] has linear time complexity in m, as well as the elegant procedure of Aspvall, Plass and Tarjan [1] based on computing strongly connected components in a graph. A particularly simple randomized procedure of complexity $O(n^2)$ is described by Papadimitriou [18].

For our purposes the Davis-Putnam procedure [6] is of singular importance. This is a resolution-principle based general SAT solving algorithm, which with its refinement due to Davis, Putnam, Logemann and Loveland [5], forms even today the basis for the most efficient SAT solvers. While on general SAT instances it works in exponential time, on 2-SAT formulae it is of polynomial complexity.

The high level description of the procedure for 2-SAT is relatively simple. Let us suppose that our formula ϕ contains only clauses with two literals. Pick an arbitrary unassigned variable x_i and assign $x_i = 0$. The formula is simplified: a clause $(\bar{x}_i \vee x_j)$ becomes true and therefore can be removed, and a clause $(x_i \vee x_j)$ forces $x_j = 1$. This can be, in turn, propagated to other clauses to further simplify the formula until a contradiction is found or no more propagation is possible. If no contradiction is found and the propagation stops with the simplified formula ϕ_0, then we recurse on the satisfiabilty of ϕ_0. Otherwise, when a contradiction is found, that is at some point the propagation assigns two different values to the same variable, we reverse the choice made for x_i, and propagate the new choice $x_i = 1$. If this also leads to contradiction we declare ϕ unsatisfiable, otherwise we recurse on the result of this propagation, the simplified formula ϕ_1.

There is a deep and profound link between k-SAT formulas and k-local Hamiltonians, the central objects of condensed matter physics. A k-local Hamiltonian on n qubits is a Hermitian operator of the form $H = \sum_{i=1}^{m} h_i$, where each h_i is by itself a Hermitian operator acting non-trivially on at most k qubits. Local Hamiltonians model the local interactions between quantum spins. Of central importance is the minimal eigenstate of the Hamiltonian, known as the *ground state*, and its associated eigenvalue, known as the *ground energy*. The ground state governs much of the low temperature physics of the system, such as quantum phase transitions and collective quantum phenomena [19, 20]. Finding the ground state of a local Hamiltonian shares important similarities with the k-SAT problem: in both problems we are trying to find a global minimum of a set of local constraints. This connection with complexity theory is of physical significance. Indeed, with the advent of quantum information theory and quantum complexity theories, it has become clear that the complexity of finding the ground state and its energy is intimately related to its entanglement structure. In recent years, much attention has been devoted into understanding this structure, revealing a rich an intricate behaviour such as area laws [8] and topological order [13].

The connection between classical k-SAT and quantum local Hamiltonian was formalized by Kitaev [14] who introduced the k-local Hamiltonian problem: one is given a k-local Hamiltonian H, along with two constants $a < b$ such that $b - a > 1/n^{\alpha}$ for some constant α. It is promised that the ground energy of H is at most a (the YES case) or is at least b (the NO case), and the task is to decide which case holds. Broadly speaking, given a quantum state $|\psi\rangle$, the energy of a local term $\langle\psi|h_i|\psi\rangle$ is a measure of how much $|\psi\rangle$ "violates" h_i, hence the ground energy is the quantum analog of the minimal number of violations in a classical k-SAT. Therefore, in spirit, the k-local Hamiltonian problem corresponds to MAX-k-SAT, and indeed Kitaev has shown [14] that the 5-local Hamiltonian problem is QMA-complete, where the complexity class QMA is the quantum analogue of classical class MA, the probabilistic version of NP.

The problem *quantum* k-SAT, the quantum analogue of k-SAT, is a close relative of the k-local Hamiltonian problem. Here we are given a k-local Hamiltonian that is made of k-local

projectors, $H = \sum_{i=1}^{m} Q_i$, and we are asked whether the ground energy is 0 or it is larger than $b = 1/n^{\alpha}$ for some constant α. Notice that in the YES case, the energy of all projectors at the ground state is necessarily 0, since by definition, projectors are non-negative operators. Classically, this corresponds to a perfectly satisfiable formula. Physically, this is an example of a *frustration-free* Hamiltonian, in which the global ground state is also a ground state of every local term. Bravyi [2] has shown that quantum k-SAT was QMA_1-complete for $k \geq 4$, where QMA_1 stands for QMA with one-sided error (that is on YES instances the verifier accepts with probability 1). The QMA_1-completeness of quantum 3-SAT was recently proven by Nagaj [10].

This paper is concerned with the quantum 2-SAT problem, which we will also denote simply by 2QSAT. One major result concerning this problem is due to Bravyi [2], who has proven that it belongs to the complexity class P. More precisely, he has proven that 2QSAT can be decided by a deterministic algorithm in time $O(n^4)$, together with a ground state that has a polynomial classical description. In the case of 2QSAT, the Hamiltonian is given as a sum of 2-qubits projectors; each projector is defined on a 4-dimensional Hilbert space and can therefore be of rank 1, 2 or 3. In this paper, we give an algorithm for 2QSAT of *linear* complexity.

▶ **Theorem 1.** *There is a deterministic algorithm for* 2QSAT *whose running time is* $O(n+m)$ *where* n *is the number of variables and* m *is the number of local terms in the Hamiltonian.*

Our algorithm shares the same trial and error approach of the Davis-Putnam procedure for classical 2SAT, but handles many difficulties arising in the quantum setting. First, a ground state of 2QSAT input may be entangled, a distinctive feature that classical 2SAT does not have. Thus the idea of setting some qubit to a certain state and propagating from there does not have a foundation in the first place. Indeed, if a rank-3 projector forces the only allowed state to be entangled, then any ground state is entangled in those two qubits. We overcome this by showing a *product-state theorem*, which asserts that for any frustration-free 2QSAT instance H that contains only rank-1 and rank-2 projectors, there always exists a ground state in the form of a tensor product of *single-qubit* states.

This structural theorem grants us the following approach: We try some candidate solution $|\psi\rangle_i$ on a qubit i, and propagate this along the graph. If no contradiction is found, it turns out that we can detach the explored part and recurse on the rest of the graph. If a contradiction is found, then we can identify two candidates $(i, |\psi\rangle_i)$ and $(j, |\phi\rangle_j)$ such that either assigning $|\psi\rangle_i$ to qubit i or assigning $|\phi\rangle_j$ to qubit j is correct, if there exists a solution at all. More details follow next.

To illustrate the main idea of our algorithm, let us suppose that the input contains only projectors of rank at most two. Such a system can be further simplified to a system consisting only of rank-1 projectors, by writing every rank-2 projector as a sum of two rank-1 projectors. Consider, for example, qubits 1 and 2 and a rank-1 projector $\Pi_{12} = |\psi\rangle\langle\psi|$ over these qubits. The product-state theorem implies that it suffices to search for a product ground state. Thus on the first two qubits, we are looking for states $|\alpha\rangle, |\beta\rangle$ such that $(\langle\alpha| \otimes \langle\beta|)\Pi_{12}(|\alpha\rangle \otimes |\beta\rangle) = 0$, which is equivalent to $(\langle\alpha| \otimes \langle\beta|) \cdot |\psi\rangle = 0$. In other words, we look for a product state $|\alpha\rangle \otimes |\beta\rangle$ that is perpendicular to $|\psi\rangle$. Assume that we have assigned qubit 1 with the state $|\alpha\rangle$ and we are looking for a state $|\beta\rangle$ for qubit 2. The crucial point, which enables us to solve 2QSAT efficiently, is that just like in the classical case, there are only two possibilities: (i) for any $|\beta\rangle$, the state $|\alpha\rangle \otimes |\beta\rangle$ is perpendicular to $|\psi\rangle$, or (ii) there is only one state $|\beta\rangle$ (up to an overall complex phase), for which $(\langle\alpha| \otimes \langle\beta|) \cdot |\psi\rangle = 0$. The first case happens if and only if $|\psi\rangle$ is by itself a product state of the form $|\psi\rangle = |\alpha^{\perp}\rangle \otimes |\xi\rangle$,

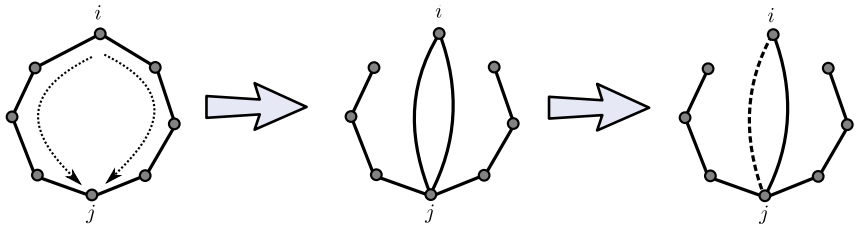

Figure 1 Handling a contradicting cycle: we slide edges that touch i along the two paths to j until we get a double edge with a 'tail'. We then use a structure lemma to deduce that at least one of these edges can be written as a product projector.

where $|\alpha^{\perp}\rangle$ is perpendicular to $|\alpha\rangle$ and $|\xi\rangle$ is arbitrary. If the second case happens, we say that state $|\alpha\rangle$ is propagated to state $|\beta\rangle$ by the constraint state $|\psi\rangle$.

This dichotomy enables us to propagate a product state $|s\rangle$ on part of the system until we reach a contradiction, or find that no further propagation is possible and we are left with a smaller Hamiltonian H_s. This smaller Hamiltonian consists of a subset of the original projectors, *without introducing new projectors*. It turns out that once an edge is checked for potential propagation, then no matter whether a propagation happens along the edge or not, the edge can be safely removed without changing the satisfiability. Thus the satisfiability of the original Hamiltonian H is the same as that of the smaller Hamiltonian H_s.

We still need to specify how the state $|\alpha\rangle$ is chosen to initialize the propagation. An idea is to begin with projectors $|\psi\rangle\langle\psi|$ for which $|\psi\rangle$ is a product state $|\alpha\rangle \otimes |\beta\rangle$. In such cases a product state solution must either have $|\alpha^{\perp}\rangle$ at the first qubit or $|\beta^{\perp}\rangle$ at the second. To maintain a linear running time, we propagate these two choices simultaneously until one of the propagations stops without contradiction, in which case the corresponding qubit assignment is made final. If both propagations end with contradiction, the input is rejected.

The more interesting case of the algorithm happens when we have only entangled rank-1 projectors. What should our initial state be then? We make an arbitrary assignment (say, $|0\rangle$) to any of the still unassigned qubits and propagate this choice. If the propagation ends without contradiction, we recurse. If a contradiction is found then we confront a challenging problem. In the classical case we could reverse our choice, say $x_0 = 0$, and try the other possibility, $x_i = 1$. But in the quantum case we have an infinite number of potential assignment choices. The solution is found by the following observation: Whenever a contradiction is reached, it can be attributed to a cycle of entangled projectors in which the assignment has propagated from qubit i along the cycle and returned to it with another value. Then using the techniques of 'sliding', which was introduced in Ref. [11], one can show that this cycle is equivalent to a system of one double edge and a 'tail' (see Fig. 1). Using a simple structure lemma, we are guaranteed that at least one of the projectors of the double edge can be turned into a product state projector, which, as in the previous stage, gives us two possible free choices.

Let us state here that our algorithm works in the algebraic model of computation: we suppose that every arithmetic operation on complex numbers can be done in unit time.

Classically, Davis-Putnam [6] and DPLL algorithms [5] are widely-used heuristics, forming the basis of today's most efficient solvers for general SAT. For quantum k-SAT, it could also be a good heuristic if we try to find product-state solutions, and in that respect our algorithm makes the first-step exploration.

Simultaneously and independently from our work and approximately at the same time, de Beaudrap and Gharibian [7] have also presented a linear time algorithm for quantum 2SAT.

The main difference between the two algorithms is how they deal with instances with only entangled rank-1 projectors. Contrarily to us, [7] handles these instances by using transfer matrix techniques to find discretizing cycles [16]. Most proofs are omitted from this version of the paper owing to space constraints.

2 Preliminaries

2.1 Notation

We will use the notation $[n] = \{1, \ldots, n\}$. For a graph $G = (V, E)$, and for a subset $U \subseteq V$ of the vertices, we denote by $G(U)$ the subgraph induced by U. Our Hilbert space is defined over n qubits, and is written as $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \cdots \otimes \mathcal{H}_n$, where $\mathcal{H}_i$ is the two-dimensional Hilbert space of the i^{th} qubit. We shall often write $|\alpha\rangle_i$ to emphasize that the 1-qubit state $|\alpha\rangle$ lives in $\mathcal{H}_i$. Similarly, $|\psi\rangle_{ij}$ denotes a 2-qubit state that lives in $\mathcal{H}_i \otimes \mathcal{H}_j$. For a 1-qubit state $|\alpha\rangle = \alpha_0|0\rangle + \alpha_1|1\rangle$, we define its *perpendicular state* as $|\alpha^\perp\rangle = \alpha_1|0\rangle - \alpha_0|1\rangle$.

We shall denote local projectors either by Π_{ij}, or by Π_e, where $e = (i, j)$. When $i < j$, Π_{ij} is a 2-local projector on the qubits i, j; it can be written as $\Pi_{ij} = \hat{\Pi}_{ij} \otimes \mathbb{I}_{rest}$, where $\hat{\Pi}_{ij}$ is a projector working on $\mathcal{H}_i \otimes \mathcal{H}_j$ and $\mathbb{I}_{rest}$ is the identity operator on the rest of the system. Similarly, when $i = j$, $\Pi_{ii} = \hat{\Pi}_{ii} \otimes \mathbb{I}_{rest}$, where $\hat{\Pi}_{ii}$ is a projector defined in $\mathcal{H}_i$. Often, in order not to overload the notation, we shall use Π_{ij} instead of $\hat{\Pi}_{ij}$, even when acting on states in $\mathcal{H}_i \otimes \mathcal{H}_j$. Similarly, with a slight abuse the notation, we define the *rank* of a projector Π_e to be the dimension of the subspace that its local projector $\hat{\Pi}_e$ projects to, and it will be denoted by $\texttt{rank}(\Pi_e)$. We call a rank-1 projector $\Pi_e = |\psi\rangle\langle\psi|$, *entangled* if $|\psi\rangle$ is an entangled state, and *product* if $|\psi\rangle$ is a product state.

2.2 The 2QSAT problem

A quantum 2-SAT Hamiltonian on an n-qubit system is a Hermitian operator $H = \sum_{e \in I} \Pi_e$, for some $I \subseteq \{(i, j) \in [n] \times [n] : 1 \leq i \leq j \leq n\}$. We suppose that $\texttt{rank}(\Pi_{ii}) = 1$, for all $(i, i) \in I$, and $0 < \texttt{rank}(\Pi_{ij}) < 4$, for all $(i, j) \in I$ when $i < j$. The single-qubit projectors of H as well as its 2-qubit projectors of rank-3 are called *maximal* rank.

The *ground energy* of a Hamiltonian $H = \sum_{e \in I} \Pi_e$ is its smallest eigenvalue, and a *ground state* of H is an eigenvector corresponding to the smallest eigenvalue. The subspace of the ground states is called the *ground space*. A Hamiltonian is *frustration-free* if it has a ground state that is also simultaneously the ground state of all local terms. As explained in the introduction, if the Hamiltonian is made of local projectors, it is frustration-free if and only if there is a state that is a mutual zero eigenstate of all projectors, which happens if and only if the ground energy is 0. Therefore, if $|\Gamma\rangle$ is a ground state of a frustration-free quantum 2-SAT Hamiltonian, $\Pi_e|\Gamma\rangle = 0$ for all $e \in I$. We can also view each local projector as a *constraint* on at most two qubits, then a ground state satisfies every constraint.

It turns out that for the representation of the 2QSAT Hamiltonian, it will be helpful to eliminate the rank-2 projectors by decomposing each one of them into a sum of two rank-1 projectors. For every $(i, j) \in I$ such that $\texttt{rank}(\Pi_{ij}) = 2$, let $\Pi_{ij} = \Pi_{ij,1} + \Pi_{ij,2}$, where $\Pi_{ij,1}$ and $\Pi_{ij,2}$ are rank-1 projectors. Such projectors can be found in constant time. We therefore suppose without loss of generality that H is specified by

$$H = \sum_{\texttt{rank}(\Pi_{ij}) \neq 2} \Pi_{ij} + \sum_{\texttt{rank}(\Pi_{ij}) = 2} (\Pi_{ij,1} + \Pi_{ij,2}),$$

which we call the *rank*-1 *decomposition* of H.

To the rank-1 decomposition we associate a weighted, directed multigraph with self-loops $G(H) = (V, E, w)$, the *constraint graph* of H. By definition $V = \{i \in [n] : \exists j \in [n]$ such that $(i,j) \in I$ or $(j,i) \in I\}$, For every rank-3 and rank-1 projector acting on two qubits, there is an edge in each direction between the two nodes representing them. For every projector acting on a single qubit, there is a self-loop. Finally, for every rank-2 projector, there are two parallel edges in each direction between nodes representing its qubits. Because of the parallel edges, E is not a subset of $V \times V$. Formally, $E = E_1 \cup E_2$ where respectively

$$E_1 = \{(i,j) \in [n] \times [n] : (i,j) \in I \text{ and } \mathtt{rank}(\Pi_{ij}) \in \{1,3\}, \text{ or } (j,i) \in I \text{ and } \mathtt{rank}(\Pi_{ji}) \in \{1,3\}\},$$

and

$$E_2 = \{(i,j,b) \in [n] \times [n] \times [2] : (i,j) \in I \text{ and } \mathtt{rank}(\Pi_{ij}) = 2, \text{ or } (j,i) \in I \text{ and } \mathtt{rank}(\Pi_{ji}) = 2\}.$$

We say that an edge $e \in E$ *goes from* i *to* j if $e \in \{(i,j),(i,j,1),(i,j,2)\}$. For a projector Π acting on two qubits, we define its *reverse* projector Π^{rev} by $\Pi^{rev}|\alpha\rangle|\beta\rangle = \Pi|\beta\rangle|\alpha\rangle$, and for $i \leq j$ and $b \in [2]$, we set $\Pi_{ji} = \Pi_{ij}^{rev}$ and $\Pi_{jib} = \Pi_{ijb}^{rev}$. Then for an edge (i,j), its *weight* is defined as $w(i,j) = \Pi_{ij}$, and analogously for an edge (i,j,b), we set $w(i,j,b) = \Pi_{ijb}$.

We will suppose that the input to our problem is the constraint graph $G(H)$ of the Hamiltonian, given in the standard adjacency list representation of weighted graphs, naturally modified for dealing with the parallel edges. In this representation there is a linked list of size at most n containing one element for each vertex, and the element i in this list is also pointing towards a linked list containing an element for every edge (i,j) or (i,j,b). For an edge (i,j), this element contains j, the projector Π_{ij} and a pointer towards the next element in the list, for an edge (i,j,b) it also contains the value b. The problem 2QSAT is defined formally as follows.

2QSAT
Input: The constraint graph $G(H)$ of a 2-local Hamiltonian H, given in the adjacency list representation.
Output: A solution if H is frustration free, "H is unsatisfiable" if it is not.

2.3 Simple ground states

Our algorithm is based crucially on the following *product state theorem*, which says that any frustration-free 2QSAT Hamiltonian composed has a ground state which is a product state of single qubit and two-qubit states, where the latter only appear in the support of rank-3 projectors. A slightly weaker claim of that form has already appeared in Theorem 2 of Ref. [3]. The difference here is that we specifically attribute the 2-qubits states in the product state to rank-3 projectors. Just as in Ref. [3], our derivation begins with Theorem 1 of Ref. [3], which we give below. It relies on the notion of a *genuinely entangled* state in an n-qubit system, which is a pure state that is not a product state with respect to any bi-partition of the system. Then Theorem 1 in [3] states

▶ **Proposition 2.** *A 2-local frustration-free Hamiltonian on n qubits which has a genuinely entangled ground state always has a product ground state, whenever $n \geq 3$.*

We will also need the following simple fact about 2-dimensional subspaces in $\mathbb{C}^2 \otimes \mathbb{C}^2$.

▶ **Fact 3.** *Any 2-dimensional subspace V of the 2-qubit space $\mathbb{C}^2 \otimes \mathbb{C}^2$ contains at least one product state, which can be found in constant time.*

The proofs of Fact 3 and our Product State Theorem are omitted owing to space constraints.

▶ **Theorem 4** (Product State Theorem). *Any frustration-free* 2QSAT *Hamiltonian has a ground state which is a tensor product of one qubit and two-qubit states, where two-qubit states only appear in the support of rank-3 projectors.*

2.4 Assignments

Let $H = \sum_{e \in I}$ be a 2-local Hamiltonian. By Theorem 4, if H is frustration free then it has a ground state which is the tensor product of 1-qubit and 2-qubit entangled states, where the latter only appear in pairs of qubits corresponding to rank-3 projectors. To build up a ground state of such form, our algorithm will use partial assignments, or shortly assignments. An *assignment* s is a mapping from $[n]$. For every $i \in [n]$, the value $s(i)$ is either a 1-qubit state $|\alpha\rangle$, or a 2-qubit entangled state $|\gamma\rangle_{ij}$ for some $j \neq i$, or a symbol from the set $\{\ominus, X\}$. If $s(i) = |\alpha\rangle$ or $s(i) = |\gamma\rangle_{ij}$, then this value is assigned to qubit variable i, and in the latter case the entangled state is shared with variable j. The symbol $\ominus$ is used for unassigned variables, and the symbol X is used when several values are assigned to some variable.

We define the *support* of s by $\mathsf{supp}(s) = \{i \in [n] : s(i) \neq \ominus\}$. The assignment s is *empty* if $\mathsf{supp}(s) = \emptyset$. When there is no danger of confusion, we will denote the empty assignment also by $\ominus$. We say that an assignment is *coherent* if for every i, we have $s(i) \neq X$, and whenever $s(i) = |\gamma\rangle_{ij}$, we also have $s(j) = |\gamma\rangle_{ji}$. For coherent assignments s and s', we say that s' is an *extension* of s, if for every i, such that $s(i) \neq \ominus$, we have $s'(i) = s(i)$. A coherent assignment is *total* if $s(i) \neq \ominus$, for all i. Clearly, a coherent assignments defines a product state of 1-qubit and 2-qubits states on qubits in its support. We denote this state by $|s\rangle$. We say that a coherent assignment s *satisfies* a projector Π_e, or simply that it satisfies the edge e, if for any total extension s' of s we have $\Pi_e|s'\rangle = 0$.

For $H = \sum_{e \in I} \Pi_e$ given in rank-1 decomposition, and a coherent s, we define the *reduced Hamiltonian* H_s of s as $H_s = H - \sum_{s \text{ satisfies } e} \Pi_e$. We will denote the constraint graph $G(H_s)$ of the reduced Hamiltonian H_s by $G_s = (V_s, E_s)$. We call a coherent assignment s a *pre-solution* if it has a total extension s' satisfying every constraint in H, and we call s is a *solution* if s itself satisfies every constraint in H. Obviously, an assignment is a solution if and only if G_s is the empty graph. A coherent assignment s is *closed* if $\mathsf{supp}(s) \cap V_s = \emptyset$.

3 Propagation

The crucial building block of our algorithm is the propagation of values by rank-1 projectors. This is the quantum analog of the classical propagation process when for example the clause $x_i \vee x_j$ propagates the value $x_i = 0$ to the value $x_j = 1$ in the sense that given $x_i = 0$, the choice $x_j = 1$ is the only possibility to make the clause true. In the quantum case this notion has already appeared in Ref. [16], and can in fact be traced back also to Bravyi's original work. Here, we shall adopt the following definition

▶ **Definition 5** (Propagation). Let $\Pi_e = |\psi\rangle\langle\psi|$ be a rank-1 projector acting on variables i, j, and let $|\alpha\rangle$ be either a 1-qubit state assigned to variable i, or a 2-qubit entangled state assigned to variables k, i for some $k \neq j$. We say that Π_e *propagates* $|\alpha\rangle$ if, up to a phase, there exists a unique 1-qubit state $|\beta\rangle$ such that $\Pi_e|\alpha\rangle_i \otimes |\beta\rangle_j = 0$. In such a case we say that $|\alpha\rangle$ is propagated to $|\beta\rangle$ along Π_e, or that Π_e propagated $|\alpha\rangle$ to $|\beta\rangle$.

We establish a sequence of Lemmas on propagation whose proofs are not discussed here owing to space contraints. The first lemma shows how the propagation properties of $\Pi_e = |\psi\rangle\langle\psi|$ are determined by entanglement in $|\psi\rangle$.

▶ **Lemma 6.** *Consider the rank-1 projector $\Pi_e = |\psi\rangle\langle\psi|$, defined on qubits i, j. If $|\psi\rangle$ is entangled, it propagates* every 1*-qubit state $|\alpha\rangle_i$ to a state $|\beta(\alpha)\rangle_j$ such that if $|\alpha\rangle_i \neq |\alpha'\rangle_i$ then $|\beta(\alpha)\rangle_j \neq |\beta(\alpha')\rangle_j$. This propagation can be calculated in constant time. When $|\psi\rangle$ is a product state $|\psi\rangle = |x\rangle_i \otimes |y\rangle_j$, the projector Π_e does not propagate states that are proportional to $|x^\perp\rangle_i$, while all other states are propagated to $|y^\perp\rangle_j$.*

We now present two lemmas that describe the structure of the *global* ground state of the system, if we know that part of it is in a tensor product of 1-qubit or 2-qubits states, which are then propagated by some Π_e.

▶ **Lemma 7** (Single qubit propagation)**.** *Consider a frustration-free* 2QSAT *system $H = \sum_{e\in I} \Pi_e$ with a rank-1 projector $\Pi_e = |\psi\rangle\langle\psi|$ between qubits i, j, and assume that H has a ground state of the form $|\Gamma\rangle = |\alpha\rangle_i \otimes |rest\rangle$. Then:*

1. *If Π_e propagates $|\alpha\rangle_i$ to $|\beta\rangle_j$ then necessarily $|rest\rangle = |\beta\rangle_j \otimes |rest'\rangle$.*
2. *$|\Gamma\rangle$ is also a ground state of the* 2QSAT *Hamiltonian $H - \Pi_e$.*

▶ **Lemma 8** (Entangled 2-qubits propagation)**.** *Consider a frustration-free* 2QSAT *system H with a rank-1 projector $\Pi_e = |\psi\rangle\langle\psi|$ between qubits i, j. Assume that H has a ground state of the form $|\Gamma\rangle = |\phi\rangle_{ik} \otimes |rest\rangle$, where $|\phi\rangle$ is an entangled state on qubits i, k with $k \neq j$. Then:*

1. *$|\psi\rangle$ is a product state $|\psi\rangle = |x\rangle|y\rangle$.*
2. *Π_e propagates $|\phi\rangle$ to $|y^\perp\rangle$ and necessarily $|rest\rangle = |y^\perp\rangle_j \otimes |rest'\rangle$.*
3. *$|\Gamma\rangle$ is also a ground state of the* 2QSAT *Hamiltonian $H - \Pi_e$.*

Let H be a 2QSAT Hamiltonian in rank-1 decomposition, let s be a coherent assignment, and let $G_s = (V_s, E_s)$ be the constraint graph of the reduced Hamiltonian H_s. We would like to describe in G_s the result of the *iterated propagation* process when a value given to variable i is first propagated along all possible projectors, followed by these propagated values being propagated on their turn, and so on until no more values assigned during this process can be propagated further. The propagation can start when the initial value is already assigned by s, that is, when $s(i) = |\delta\rangle$ for $|\delta\rangle \in \{|\alpha\rangle, |\gamma\rangle_{ij}\}$, where $|\alpha\rangle$ is some 1-qubit state and $|\gamma\rangle_{ij}$ some 2-qubit state, or it can get started when $s(i) = \ominus$, in which case we shall explicitly choose a 1-qubit state $|\alpha\rangle$ and assign it to i.

Now, let s, i and $|\delta\rangle$ be such that $s(i) \in \{\ominus, |\delta\rangle\}$. We say that an edge $e \in E_s$, in the constraint graph G_s, from i to j *propagates* $|\delta\rangle$ if Π_e propagates it, and we denote by $\mathsf{prop}(s, e, |\delta\rangle)$ the state $|\delta\rangle$ is propagated to. We further generalize the notion of propagation in G_s from edges to paths. Let $i = i_0, i_1, \ldots i_k$ be vertices in V_s, and let e_j be an edge from i_j to i_{j+1}, for $j = 0, \ldots, k-1$. Let $s(i) \in \{\ominus, |\delta\rangle\}$, and set $|\alpha_0\rangle = |\delta\rangle$. Let $|\alpha_1\rangle, \ldots, |\alpha_k\rangle$ be states such that the propagation of $|\alpha_j\rangle$ along Π_{e_j} is $|\alpha_{j+1}\rangle$, for $j = 0, \ldots, k-1$. Then we say that the path $p = (e_0, \ldots, e_{k-1})$ from i_0 to i_k *propagates* $|\delta\rangle$, and we set $\mathsf{prop}(s, p, |\delta\rangle) = |\alpha_k\rangle$. We say that a vertex $j \in V_s$ is *accessible* by propagating $|\delta\rangle$ from i if either $j = i$ or there is a path from i to j that propagates $|\delta\rangle$. We denote by $V_s^{\mathsf{prop}}(i, |\delta\rangle)$ the set of such vertices, and by $\mathsf{ext}_s^{\mathsf{prop}}(i, |\delta\rangle)$ the extension of s by the values given to the vertices in $V_s^{\mathsf{prop}}(i, |\delta\rangle)$ by iterated propagation.

Let us suppose that $s' = \mathsf{ext}_s^{\mathsf{prop}}(i, |\delta\rangle)$ is also coherent. The set $V_s^{\mathsf{prop}}(i, |\delta\rangle)$ divides the edges E_s into three disjoint subsets: the edges E_1 of the induced subgraph $G(V_s^{\mathsf{prop}}(i, |\delta\rangle))$, the edges E_2 between the induced subgraphs $G(V_s^{\mathsf{prop}}(i, |\delta\rangle))$ and $G(V_s \setminus V_s^{\mathsf{prop}}(i, |\delta\rangle))$, and the

Algorithm 1 Propagation$(s, G_s, i, |\delta\rangle)$

    if ℓ was removed from V_s **then remove** e
  if all edges outgoing from k were removed **then remove** k from V_s

edges E_3 of the induced subgraph $G(V_s \setminus V_s^{\mathsf{prop}}(i, |\delta\rangle))$. While the edges in $E_1 \cup E_2$ are satisfied by s', none of the edges in E_3 is satisfied. Therefore $G_{s'}$ is nothing but $G(V_s \setminus V_s^{\mathsf{prop}}(i, |\delta\rangle))$ without the isolated vertices, and it can be constructed by the following process. Given s and i, the edges in $E_1 \cup E_2$ can be traversed via a breadth first search rooted at i. The levels of the tree are decided dynamically: at any level the next level is composed of those vertices whose value is propagated from the current level. The leaves of the tree are vertices in $V_s \setminus V_s^{\mathsf{prop}}(i, |\delta\rangle)$. The algorithm Propagation uses a temporary queue Q to implement this process.

▶ **Lemma 9** (Propagation Lemma). *Let Propagation$(s, G_s, i, |\delta\rangle)$ be called when H_s doesn't have rank-3 constraints, and $s(i) \in \{\ominus, |\delta\rangle\}$. Let s' and $G' = (V', E')$ be the outcome of the procedure. Then:*

1. *If Propagation$(s, G_s, i, |\delta\rangle)$ doesn't return "unsuccessful" then $s' = \mathsf{ext}_s^{\mathsf{prop}}(i, |\delta\rangle)$ and $G' = G_{s'}$. Moreover, if s is a pre-solution then s' is a pre-solution, and if s is closed then s' is also closed.*
2. *If Propagation(s, G_s, i) returns "unsuccessful" then there is no solution z which is an extension of s and for which $z(i) = |\delta\rangle$.*
3. *The complexity of the procedure is $O(|E_s| - |E_{s'}|)$.*

4 The main algorithm

4.1 Description of the algorithm

We now give in broad strokes the description of our algorithm called 2QSATSolver. It takes as input the adjacency list representation of the constraint graph $G(H)$ of a 2-local Hamiltonian H in rank-1 decomposition. The algorithm uses four global variables: assignments s_0 and s_1 initialized to $\ominus$, and graphs G_0 and G_1 in the adjacency list representation, initialized to $G(H)$. The algorithm consists of four phases, and except the first one, each phase consists of

Algorithm 2 2QSATSolver($G(H)$)

$s_0 = s_1 := \ominus, \quad G_0 = G_1 := G(H)$ ▷ Initialize global variables

MaxRankRemoval() ▷ Remove maximal rank constraints

while there exist $i \in V_0$ such that $s(i) \neq \ominus$ **do** ▷ Propagate all assigned values
  PROPAGATE$(s_0, G_0, i, s_0(i))$ for some vertex i in G_0 such that $s_0(i) \neq \ominus$
  if the propagation returns "unsuccessful" **output** "H is unsatisfiable"
  $s_1 := s_0, G_1 := G_0$

while there exists in G_0 a product edge with constraint $|\alpha_0^\perp\rangle_{i_0} \otimes |\alpha_1^\perp\rangle_{i_1}\langle\alpha_0^\perp|_{i_0} \otimes \langle\alpha_1^\perp|_{i_1}$ **do**
  ParallelPropagation$(i_0, |\alpha_0\rangle, i_1, |\alpha_1\rangle)$ ▷ Remove product constraints

while G_0 is not empty **do** ▷ Remove entangled constraints

output $|s\rangle$ for any total extension s of s_0.

several stages, where essentially one stage corresponds to one Propagation process. In the case of an unsatisfiable *Hamiltonian* the algorithm at some point outputs "H is unsatisfiable" and stops. This happens when either the maximal rank constraints are already unsatisfiable, or at some later point when several values are assigned to the same variable during a necessary propagation process.

In the case of a frustration-free Hamiltonian, at the beginning and end of each stage, we will have $s_0 = s_1$, and $G_0 = G_1 = G_{s_0}$. In the first two phases only (s_0, G_0) develops, and is copied to (s_1, G_1) at the end of the phase. In the last two phases, (s_0, G_0) and (s_1, G_1) develop independently, but only the result of one of the two processes is retained and is copied into the other variable at the end of the phase. This parallel development of the two processes is necessary for complexity considerations, ensuring that the useless work done is proportional to the useful work.

In the first phase the procedure MaxRankRemoval satisfies, if possible, all constraints of maximal rank. In the second phase all these assignments are propagated, which, if successful, result in a closed assignment s such that H_s has only rank-1 constraints. In the third phase the procedure ParallelPropagation satisfies the product constraints one by one and propagates the assigned values. To satisfy a product constraint, the only two possible choices are tried and propagated in parallel. In the fourth phase the remaining entangled constraints are taken care of, again, one by one. To satisfy a constraint, an arbitrary value is tried and propagated. In case of an unsuccessful propagation we are able to efficiently find a product constraint implied by the entangled constraints considered during the propagation, and therefore it becomes possible to proceed as in phase three. In case of success we are left with a satisfying assignment and the empty constraint graph. Theorem 1 is an immediate consequence of the following result.

▶ **Theorem 10.** *Let $G(H) = (V, E)$ be the constraint graph of a 2-local Hamiltonian. Then:*

1. *If H is frustration-free, the algorithm 2QSATSolver($G(H)$) outputs a ground state $|s\rangle$.*
2. *If H is not frustration-free, the algorithm 2QSATSolver($G(H)$) outputs "H is unsatisfiable".*
3. *The running time of the algorithm is $O(|V| + |E|)$.*

The proofs of the series of lemmas in the following sections is omitted. Theorem 10 will be proven in Section 4.5.

Algorithm 3 ParallelPropagation$(i_0, |\alpha_0\rangle, i_1, |\alpha_1\rangle)$

Run in parallel Propagation$(s_0, G_0, i_0, |\alpha_0\rangle)$ and Propagation$(s_1, G_1, i_1, |\alpha_1\rangle)$
until one of them terminates successfully **or** both terminate unsuccessfully

if both propagations terminate unsuccessfully **then**
  output "H is unsatisfiable"
else let Propagation$(s_0, G_0, i_0, |\alpha_0\rangle)$ terminate first (the other case is symmetric)
  undo Propagation$(s_1, G_1, i_1, |\alpha_1\rangle)$
  $s_1 := s_0,\ G_1 := G_0$

4.2 Max rank removal

The MaxRankRemoval procedure is conceptually very simple. Since every maximal rank constraint has a unique solution (up to a global phase), it makes this assignment for each constraint, and then checks if this is globally consistent. The description of the procedure and the proof of Lemma 11 are omitted.

▶ **Lemma 11.** *Let s_0, G_0, s_1, G_1 be the outcome of MaxRankRemoval. Then:*
1. *If MaxRankRemoval doesn't output "H is unsatisfiable" then s_0 is coherent, it satisfies every maximal rank constraint, $G_0 = G(H_{s_0})$ and $s_0 = s_1, G_0 = G_1$. Moreover, if H is satisfiable then s_0 is a pre-solution.*
2. *If MaxRankRemoval outputs "H is unsatisfiable" then indeed H is unsatisfiable.*
3. *The complexity of the procedure is $O(|V| + |E|)|$.*

4.3 Algorithm ParallelPropagation

The procedure ParallelPropagation is called when s_0 is a closed assignment, and in G_{s_0} there is a product edge. Since there are only two ways to satisfy a product constraint, these are tried and propagated in parallel. If one of these propagations terminates successfully, the other is stopped, which ensures that the overall work done is proportional to the progress made.

▶ **Lemma 12.** *Let ParallelPropagation be called when s_0 is closed, H_{s_0} doesn't have rank-3 constraints, $G_0 = G_{s_0}$, in G_0 there exists a product edge from i_0 to i_1 with constraint $|\alpha_0^\perp\rangle \otimes |\alpha_1^\perp\rangle$, and $s_1 = s_0, G_1 = G_0$. Let s_0', s_1', G_0', G_1' be the outcome of the procedure. Then:*
1. *If ParallelPropagation doesn't output "H is unsatisfiable" then s_0' is a proper closed extension of s_0, $G_0' = G_{s_0'}$, and $s_1' = s_0'$, $G_1' = G_0'$. Moreover, if s is a pre-solution then s_0' is a pre-solution.*
2. *If ParallelPropagation outputs "H is unsatisfiable" then indeed H is unsatisfiable.*
3. *The complexity of the procedure is $O(|E_{s_0}| - |E_{s_0'}|)$.*

4.4 Algorithm ProbePropagation

The procedure ProbePropagation is evoked when s_0 is a closed assignment, and in G_{s_0} there are only entangled constraints. It picks an arbitrary vertex in $i \in V_s$, assigns $|0\rangle$ (an arbitrary value) to it, and propagates this choice. In the lucky case of successful propagation this is repeated. Otherwise, we reach a contradiction: there is some $j \in V_s$, such that two propagating paths assign different values to it. We prove below the Sliding Lemma which already appeared in Ref. [11]. It implies that when $i_0 \to i_1 \to \ldots \to i_k$ is a propagating path of

Algorithm 4 ProbePropagation(i)

Propagation$(s_0, G_0, i, |0\rangle)$.
if the propagation is successful **then** $s_1 := s_0$, $G_1 := G_0$
else
Let j such that $|s_0(j)| > 1$
find two paths p_1 and p_2 in G_0 from i to j such that $\mathsf{prop}(s_0, p_1, |0\rangle) \neq \mathsf{prop}(s_0, p_2, |0\rangle)$
find a product state $|\alpha^\perp\rangle_i \otimes |\beta^\perp\rangle_j$ in the two dimensional space $\mathsf{span}\{\mathsf{slide}(p_1), \mathsf{slide}(p_2)\}$
undo Propagation$(s_0, G_0, i, |0\rangle)$
ParallelPropagation$(i, |\alpha\rangle, j, |\beta\rangle)$

entangled rank-1 projectors, the ground space of the Hamiltonian $\Pi_{i_0,i_1} + \Pi_{i_1,i_2} + \ldots + \Pi_{i_{k-1},i_k}$ is equal to the ground state of the Hamiltonian $\Pi_{i_0,i_k} + \Pi_{i_1,i_2} + \ldots + \Pi_{i_{k-1},i_k}$, where Π_{i_0,i_k} is a new projector defined on the qubits (i_0, i_k) that replaces the projector Π_{i_0,i_1}. Graphically, this can be viewed as if we are sliding the (i_0, i_1) edge on the path $i_1 \to \ldots \to i_k$. Therefore, if we have two propagating paths starting at i and ending at j, they define two projectors on qubits (i, j). As we shall see, if these two paths are contradicting then necessarily the two projectors are different, which by Lemma 3 implies the existence of a product constraint between (i_0, i_k) variables. In this case, we can proceed by calling the procedure ProbePropagation.

▶ **Lemma 13** (Sliding Lemma)**.** *Consider a system on 3 qubits i, j and k. Suppose that we have a two rank-1 constraints $\Pi_1 = |\psi_1\rangle\langle\psi_1|_{ij}$ on qubits (i, j) and $\Pi_2 = |\psi_2\rangle\langle\psi_2|_{jk}$ on qubits (j, k). If $|\psi_2\rangle$ is entangled, there is another rank-1 constraint $\Pi_3 = |\psi_3\rangle\langle\psi_3|_{ik}$ on qubits (i, k) such that the ground space of $\Pi_1 + \Pi_2$ is identical to the ground space of $\Pi_2 + \Pi_3$. In addition, if a single qubit state $|\alpha\rangle_i$ is propagated by $\Pi_1 + \Pi_2$ to $|\beta\rangle_k$, then it is also propagated to $|\beta\rangle_k$ directly via Π_3.*

Applying Lemma 13 iteratively, we reach the following corollary

▶ **Corollary 14.** *Let $H = \sum_{e \in I} H_e$ be a 2-local Hamiltonian in rank-1 decomposition. Let $i_0, i_1, \ldots i_k$ be vertices in V, and let e_j be an edge from i_j to i_{j+1}, for $j = 0, \ldots, k-1$ such that the rank-1 constraints Π_{e_j} are entangled. Then there exists a 2-qubit entangled state $|\gamma\rangle$ between i_0 and i_k such that the ground space of $\sum_{j=0}^{k-1} \Pi_{e_j}$ is identical to the ground space of $\sum_{j=1}^{k-1} \Pi_{e_j} + |\gamma\rangle\langle\gamma|_{i_0,i_k}$. Moreover, if $|\alpha\rangle_{i_0}$ is propagated to $|\beta\rangle_{i_k}$ along the path, then it is also propagated directly by $|\gamma\rangle\langle\gamma|_{i_0,i_k}$.*

We will denote the state $|\gamma\rangle$ in the conclusion of the corollary by $\mathsf{slide}(p)$.

▶ **Lemma 15.** *Let ProbePropagation be called when s_0 is closed, H_{s_0} has only rank-1 entangled constraints, $G_0 = G_{s_0}$, and $s_1 = s_0, G_1 = G_0$. Let s'_0, s'_1, G'_0, G'_1 be the outcome of the procedure. Then:*

1. *If ProbePropagation doesn't output "H is unsatisfiable" then s'_0 is a proper closed extension of s_0, $G'_0 = G_{s'_0}$, and $s'_1 = s'_0$, $G'_1 = G'_0$. Moreover, if s is a pre-solution then s'_0 is a pre-solution.*
2. *If ParallelPropagation outputs "H is unsatisfiable" then indeed H is unsatisfiable.*
3. *The complexity of the procedure is $O(|E_{s_0}| - |E_{s'_0}|)$.*

4.5 Analysis of the algorithm

Proof of Theorem 10. If H is frustration free then by Lemma 11 MaxRankRemoval outputs a pre-solution s_0 that satisfies every maximal rank constraint. By the Propagation Lemma, at

the end of Phase two, in addition s_0 is a closed assignment. By Lemma 12 ParallelPropagation outputs s_0 such that there are only entangled constraints in H_s. By Lemma 15 at the end of the algorithm in addition H_s is empty, and therefore s is a solution.

If the algorithm doesn't output "H is unsatisfiable" then by Lemma 11, by the Propagation Lemma, and by Lemmas 12 and 15 it outputs a coherent assignment s such that G_s is the empty graph, and therefore s is a solution.

The complexity of MaxRankRemoval by Lemma 11 is $O(|E|)$. After the second phase, the propagation of the assigned values during MaxRankRemoval, the copying of s_0 and G_0 into respectively s_1 and G_1 can be done by executing the same propagation steps this time with s_1 and G_1. The complexity of the rest of the algorithm by the Propagation Lemma, and Lemmas 12 and 15 is a telescopic sum which sums up to also $O(|E|)$. ◀

Abstract

We consider the number of quantum queries required to determine the coefficients of a degree-d polynomial over $\mathbb{F}_q$. A lower bound shown independently by Kane and Kutin and by Meyer and Pommersheim shows that $d/2 + 1/2$ quantum queries are needed to solve this problem with bounded error, whereas an algorithm of Boneh and Zhandry shows that d quantum queries are sufficient. We show that the lower bound is achievable: $d/2 + 1/2$ quantum queries suffice to determine the polynomial with bounded error. Furthermore, we show that $d/2+1$ queries suffice to achieve probability approaching 1 for large q. These upper bounds improve results of Boneh and Zhandry on the insecurity of cryptographic protocols against quantum attacks. We also show that our algorithm's success probability as a function of the number of queries is precisely optimal. Furthermore, the algorithm can be implemented with gate complexity $\mathrm{poly}(\log q)$ with negligible decrease in the success probability. We end with a conjecture about the quantum query complexity of multivariate polynomial interpolation.

1 Introduction

Let $f(X) = c_d X^d + \cdots + c_1 X + c_0 \in \mathbb{F}_q[X]$ be an unknown polynomial of degree d, specified by its coefficient vector $c \in \mathbb{F}_q^{d+1}$. Suppose q and d are known and we are given a black box that evaluates f on any desired $x \in \mathbb{F}_q$. (We assume $q > d$ so that different coefficients

correspond to distinct functions $f\colon \mathbb{F}_q \to \mathbb{F}_q$.) In the *polynomial interpolation problem*, our goal is to learn f – that is, to determine the vector c – by querying this black box. We would like to determine how many queries are required to solve this problem.

The classical query complexity of polynomial interpolation is well known: $d+1$ queries to f are clearly sufficient and are also necessary to determine the polynomial, even with bounded error. Shamir [17] used this fact to construct a cryptographic protocol that divides a secret into $d+1$ parts such that knowledge of all the parts can be used to infer the secret, but any d parts give no information about the secret. The security of this protocol relies on the fact that if f is chosen uniformly at random, and if we only know d function values $f(x_1), \ldots, f(x_d)$, then we cannot guess the value $f(x_{d+1})$ for a point $x_{d+1} \notin \{x_1, \ldots, x_d\}$ with probability greater than $1/q$ (that is, there is no advantage over random guessing). This example motivates understanding the query complexity of polynomial interpolation precisely, since a single query can dramatically increase the amount of information that can be extracted.

The quantum query complexity of polynomial interpolation has also been studied previously. Kane and Kutin [9] and Meyer and Pommersheim [12] independently showed that $d/2+1/2$ quantum queries are needed to solve the problem with bounded error. Furthermore, Kane and Kutin conjectured that $d+1$ quantum queries might be necessary. This was refuted by Boneh and Zhandry, who showed that d quantum queries suffice to solve the problem with probability $1 - O(1/q)$ [3]. (While the notation $O(\cdot)$ only indicates an asymptotic upper bound on the absolute value, we sometimes write $1 - O(\cdot)$ to indicate a bound on a quantity that is at most 1.) To show this, they described a 1-query quantum algorithm that determines a linear polynomial with probability $1 - O(1/q)$. The result for general d follows because $d-1$ classical queries can be used to reduce the case of a degree-d polynomial to that of a linear polynomial. However, this work left a substantial gap between the lower and upper bounds.

Here we present an improved quantum algorithm for polynomial interpolation. We show that the aforementioned lower bounds are tight: with d fixed, $k = d/2 + 1/2$ queries suffice to solve the problem with constant success probability. While the success probability at this value of k has a q-independent lower bound, it decreases rapidly with k, scaling like $1/k!$. This raises the question of how the success probability increases as we make more queries. We show that there is a sharp transition as k is increased: in particular, with $k = d/2 + 1$ queries, the algorithm succeeds with a probability that approaches 1 for large q.

Our algorithm is motivated by the pretty good measurement (PGM) approach to the hidden subgroup problem (HSP) [1]. In this approach, one queries the black box on uniform superpositions to create *coset states* and then makes entangled measurements on several coset states to infer the hidden subgroup. As in the PGM approach (and in other approaches to the HSP using the so-called standard method), our algorithm makes nonadaptive queries to the black box and performs collective postprocessing. Also, similarly to previous analysis of the PGM approach, we can express our success probability in terms of the number of solutions of a system of polynomial equations.

However, our approach to polynomial interpolation also has significant differences from the PGM approach to the HSP. In particular, we introduce a different way to query the black box that simplifies both the algorithm and its analysis. In the PGM approach, we query the black box on a uniform superposition and then uncompute uniform superpositions over certain sets. For polynomial interpolation, we instead query a carefully-chosen non-uniform superposition of inputs so that the subsequent uncomputation is classical. Furthermore, the success probability of our method is higher, and its analysis is more straightforward, than

if we used a direct analog of the PGM approach. We hope that these techniques will prove useful for other quantum algorithms, perhaps for the hidden subgroup problem or for other applications of the PGM approach [5, 7].

We also show that our strategy is precisely optimal: for any number of queries k, we describe a k-query algorithm with the highest possible success probability. We give a simple algebraic characterization of this success probability, as follows.

▶ **Theorem 1.** *The maximum success probability of any k-query quantum algorithm for interpolating a polynomial of degree d over $\mathbb{F}_q$ is $|R_k|/q^{d+1}$, where $R_k := Z(\mathbb{F}_q^k \times \mathbb{F}_q^k)$ is the range of the function $Z\colon \mathbb{F}_q^k \times \mathbb{F}_q^k \to \mathbb{F}_q^{d+1}$ defined by $Z(x,y)_j := \sum_{i=1}^k y_i x_i^j$ for $j \in \{0,1,\ldots,d\}$.*

We present an explicit quantum algorithm that achieves this success probability, and we show that no algorithm can do better. We establish optimality with an argument based on the dimension of the space spanned by the possible output states, which appears to be distinct from arguments using the two main approaches to proving limitations on quantum algorithms, the polynomial and adversary methods. Instead, our approach is closely related to a linear-algebraic lower bound technique of Radhakrishnan, Sen, and Venkatesh [16] and to the "rank method" of Boneh and Zhandry [3].

We characterize the query complexity by proving bounds on $|R_k|$, as follows.

▶ **Theorem 2.** *For any fixed positive integer d, the success probability of Theorem 1 is*
(i) *$|R_k|/q^{d+1} = \frac{1}{k!}(1 - O(1/q))$ if d is odd and $k = \frac{d}{2} + \frac{1}{2}$, and*
(ii) *$|R_k|/q^{d+1} = 1 - O(1/q)$ if d is even and $k = \frac{d}{2} + 1$.*

To show the former bound, we explicitly characterize the possible $(x,y) \in \mathbb{F}_q^k \times \mathbb{F}_q^k$ such that $Z(x,y)$ takes a particular value. We prove the latter bound in a completely different way, using a second moment argument.

Theorem 2 shows that the success probability has a sharp transition as a function of k, from subconstant for $k < d/2 + 1/2$ (by known lower bounds [9, 12]), to a (d-dependent) constant for $k = d/2 + 1/2$, to $1 - o(1)$ for $k = d/2 + 1$. Note that since k must be an integer, the success probability varies differently with k depending on whether d is odd or even. For fixed even d, $k = d/2 + 1$ queries give success probability $1 - o(1)$, whereas $k = d/2$ queries give success probability $o(1)$. For fixed odd d, the success probability is $o(1)$ for $k = d/2 - 1/2$ and constant for $k = d/2 + 1/2$. To achieve higher success probability, we can make $k = d/2 + 3/2$ queries and treat f as a polynomial of degree $d + 1$ with $c_{d+1} = 0$, giving success probability $1 - o(1)$.

In light of these results, polynomial interpolation is reminiscent of the task of computing the parity of n bits, where the classical query complexity is n (even for bounded error) and the quantum query complexity is $n/2$ [2, 8]. More generally, a similar factor-of-two improvement is possible for the oracle interrogation problem, where the goal is to learn the entire n-bit string encoded by a black box [18]. However, polynomial interpolation is qualitatively different in that the oracle returns values over $\mathbb{F}_q$ rather than $\mathbb{F}_2$. Note that for the oracle interrogation problem over $\mathbb{F}_q$, one can only achieve speedup by a factor of about $1 - 1/q$ [3]*Section 4, which is negligible for large q.

Our algorithm improves results of Boneh and Zhandry giving quantum attacks on certain cryptographic protocols [3]. For a version of the Shamir secret sharing scheme [17] where the shares can be quantum superpositions, their d-query interpolation algorithm shows that a subset of only d parties can recover the secret. Our algorithm considerably strengthens this, showing that a subset of $d/2 + 1/2$ parties can recover the secret with constant probability,

and $d/2+1$ can recover it with probability $1-O(1/q)$. Boneh and Zhandry also formulate a model of quantum message-authentication codes (MACs), where the goal is to tag messages to authenticate the sender. Informally, a MAC is called d-time if, given the ability to create d valid message-tag pairs, an attacker cannot forge another valid message-tag pair. Boneh and Zhandry show that there are $(d+1)$-wise independent functions that are not d-time quantum MACs. Our result improves this to show that there are $(d+1)$-wise independent functions that are not $(d/2+1/2)$-time quantum MACs.

Finally, we consider the gate complexity of polynomial interpolation. We call an algorithm *gate-efficient* if it can be implemented with a number of 2-qubit gates that is only larger than its query complexity by a factor of $\mathrm{poly}(\log q)$. We construct a gate-efficient variant of our algorithm that achieves almost the same success probability. (Note that while our algorithm for $k=d/2+1/2$ has gate complexity polynomial in both $\log q$ and d, the algorithm for $k=d/2+1$ has gate complexity $k!\,\mathrm{poly}(\log q)$. Improving the dependence on d is a natural open question.)

▶ **Theorem 3.** *For any fixed positive integer d, there is a gate-efficient quantum algorithm for interpolating a polynomial of degree d over $\mathbb{F}_q$ using*

(i) $k=\frac{d}{2}+\frac{1}{2}$ *queries, succeeding with probability* $\frac{1}{k!}(1-O(1/q))$*, if d is odd; and*

(ii) $k=\frac{d}{2}+1$ *queries, succeeding with probability* $1-o(1)$*, if d is even.*

The main step in implementing the algorithm is to invert the function Z described in the statement of Theorem 1, i.e., to find some $x,y\in\mathbb{F}_q^k$ so that $Z(x,y)$ takes a given value. We achieve this by characterizing the solutions in terms of a polynomial equation and a system of linear equations.

In Section 5 we discuss the more general case where $f\in\mathbb{F}_q[X_1,\dots,X_n]$ is a multivariate polynomial of degree d. While our algorithm generalizes straightforwardly, the analysis of its success probability is more complicated. We conjecture that the quantum query complexity of this problem is smaller than the classical query complexity by a factor of $n+1$.

The remainder of the paper is organized as follows. After introducing some definitions in Section 2.1, we describe our k-query algorithm in Section 2.2. We analyze the success probability of this algorithm for $k=d/2+1/2$ in Section 2.3, and for $k=d/2+1$ in Section 2.4. We also show in Section 2.5 that essentially the same performance can be achieved using k independent queries to the oracle, each on a uniform superposition of inputs (which might make some cryptographic attacks easier, depending on the model). We establish optimality of our algorithm in Section 3. In Section 4, we describe the gate-efficient version of our algorithm. Finally, we conclude in Section 5 with a brief discussion of some open questions.

2 Quantum algorithm for polynomial interpolation

2.1 Preliminaries

Let $f(X)=c_dX^d+\cdots+c_1X+c_0\in\mathbb{F}_q[X]$ be an unknown polynomial of degree d that is specified by the vector of coefficients $c\in\mathbb{F}_q^{d+1}$, where $q=p^r$ a power of a prime p. Access to f is provided by a black box acting as $|x,y\rangle\mapsto|x,y+f(x)\rangle$ for all $x,y\in\mathbb{F}_q$.

Let $e\colon\mathbb{F}_q\to\mathbb{C}$ be the exponential function $e(z)=\mathrm{e}^{2\pi\mathrm{i}\,\mathrm{Tr}(z)/p}$, where the trace function $\mathrm{Tr}\colon\mathbb{F}_q\to\mathbb{F}_p$ is defined by $\mathrm{Tr}(z)=z+z^p+z^{p^2}+\cdots+z^{p^{r-1}}$. The Fourier transform over $\mathbb{F}_q$ is the unitary transformation acting as $|x\rangle\mapsto\frac{1}{\sqrt{q}}\sum_{y\in\mathbb{F}_q}e(xy)|y\rangle$ for all $x\in\mathbb{F}_q$.

We can compute the value of f into the phase by Fourier transforming the second query register. If we apply the inverse Fourier transform, perform a query, and then apply the

Fourier transform, we have the transformation

$$|x,y\rangle \mapsto \frac{1}{\sqrt{q}} \sum_{z\in\mathbb{F}_q} e(-yz)|x,z\rangle \mapsto \frac{1}{\sqrt{q}} \sum_{z\in\mathbb{F}_q} e(-yz)|x,z+f(x)\rangle \tag{1}$$

$$\mapsto \frac{1}{q} \sum_{z,w\in\mathbb{F}_q} e(-yz+(z+f(x))w)|x,w\rangle = e(yf(x))|x,y\rangle \tag{2}$$

for any $x,y\in\mathbb{F}_q$, where we used the fact that $\sum_{z\in\mathbb{F}_q} e(zv) = q\delta_{z,v}$. We call the transformation $|x,y\rangle \mapsto e(yf(x))|x,y\rangle$ a *phase query*. Since a phase query can be implemented with a single standard query and vice versa, the query complexity of a problem does not depend on which type of query we use.

For vectors $x,y\in\mathbb{F}_q^k$, we denote the inner product over $\mathbb{F}_q$ by $x\cdot y := \sum_{i=1}^k x_i y_i$. The k-fold Fourier transform (i.e., the Fourier transform acting independently on each register) acts as $|x\rangle \mapsto \frac{1}{\sqrt{q^k}} \sum_{y\in\mathbb{F}_q^k} e(x\cdot y)|y\rangle$ for any $x\in\mathbb{F}_q^k$.

2.2 The algorithm

We now describe our algorithm for polynomial interpolation. An ideal algorithm would produce the Fourier transform of the coefficient vector $c\in\mathbb{F}_q^{d+1}$, that is, the state

$$|\hat{c}\rangle = \frac{1}{\sqrt{q^{d+1}}} \sum_{z\in\mathbb{F}_q^{d+1}} e(c\cdot z)|z\rangle. \tag{3}$$

Instead we use k quantum queries to create the approximate state

$$|\hat{c}_{R_k}\rangle := \frac{1}{\sqrt{|R_k|}} \sum_{z\in R_k} e(c\cdot z)|z\rangle \tag{4}$$

for some set $R_k\subseteq\mathbb{F}_q^{d+1}$. A measurement of this state in the Fourier basis gives c with probability $|\langle\hat{c}_{R_k}|\hat{c}\rangle|^2 = |R_k|/q^{d+1}$.

Our algorithm performs k phase queries in parallel, each acting on a separate register. On input $|x,y\rangle$ for $x,y\in\mathbb{F}_q^k$, these k queries introduce the phase $e(\sum_{i=1}^k y_i f(x_i))$. To define the set R_k, recall the function $Z\colon \mathbb{F}_q^k\times\mathbb{F}_q^k\to\mathbb{F}_q^{d+1}$ defined by

$$Z(x,y)_j := \sum_{i=1}^k y_i x_i^j \text{ for } j\in\{0,1,\ldots,d\}. \tag{5}$$

Then we have $\sum_{i=1}^k y_i f(x_i) = \sum_{i=1}^k \sum_{j=0}^d y_i c_j x_i^j = c\cdot Z(x,y)$ for all $x,y\in\mathbb{F}_q^k$. The range $R_k := Z(\mathbb{F}_q^k\times\mathbb{F}_q^k)$ of the function Z is the set

$$R_k = \{Z(x,y) : (x,y)\in\mathbb{F}_q^k\times\mathbb{F}_q^k\}\subseteq\mathbb{F}_q^{d+1}. \tag{6}$$

For each $z\in R_k$ we choose a unique $(x,y)\in\mathbb{F}_q^k\times\mathbb{F}_q^k$ such that $Z(x,y)=z$. Let $T_k\subseteq\mathbb{F}_q^k\times\mathbb{F}_q^k$ be the set of these representatives. Clearly, $Z\colon T_k\to R_k$ is a bijection.

To create the state $|\hat{c}_{R_k}\rangle$, we prepare a uniform superposition over T_k, perform k phase queries, and compute Z in place (i.e., perform the unitary transformation $|x,y\rangle\mapsto|Z(x,y)\rangle$), giving

$$\frac{1}{\sqrt{|T_k|}} \sum_{(x,y)\in T_k} |x,y\rangle \mapsto \frac{1}{\sqrt{|T_k|}} \sum_{(x,y)\in T_k} e(c\cdot Z(x,y))|x,y\rangle \mapsto \frac{1}{\sqrt{|R_k|}} \sum_{z\in R_k} e(c\cdot z)|z\rangle. \tag{7}$$

The above procedure is a k-query algorithm for polynomial interpolation that succeeds with probability $|R_k|/q^{d+1}$, establishing the lower bound on the success probability stated in Theorem 1. To analyze the algorithm, it remains to lower bound $|R_k|$ as a function of k.

2.3 Performance using d/2 + 1/2 queries

We now consider the performance of the above algorithm using $k = d/2 + 1/2$ queries. Let

$$Z^{-1}(z) = \{(x, y) \in \mathbb{F}_q^k \times \mathbb{F}_q^k : Z(x, y) = z\} \tag{8}$$

be the set of those $(x, y) \in \mathbb{F}_q^k \times \mathbb{F}_q^k$ corresponding to a particular $z \in \mathbb{F}_q^{d+1}$. Clearly $|R_k|$ is the number of values of z such that $Z^{-1}(z)$ is nonempty. To analyze this, we focus on "good" values of (x, y). Define $X_k^{\text{good}} := \{x \in \mathbb{F}_q^k : x_i \neq x_j \; \forall\, i \neq j\}$ and $Y_k^{\text{good}} := (\mathbb{F}_q^\times)^k$ and let $Z^{-1}(z)^{\text{good}} := Z^{-1}(z) \cap (X_k^{\text{good}} \times Y_k^{\text{good}})$. We claim the following:

▶ **Lemma 4.** *If $k = d/2 + 1/2$, then for all $z \in \mathbb{F}_q^{d+1}$, either $|Z^{-1}(z)^{\text{good}}| = 0$ or $|Z^{-1}(z)^{\text{good}}| = k!$.*

Proof. See the proof in the extended version [6] of this article. ◀

Using Lemma 4, we can show that $k = d/2 + 1/2$ queries suffice to perform polynomial interpolation with probability that is independent of q, but that decreases with d.

Proof of Theorem 2(i): $k = d/2 + 1/2$**.** We have $|X_k^{\text{good}}| = q!/(q-k)!$ and $|Y_k^{\text{good}}| = (q-1)^k$, so

$$\sum_{z \in \mathbb{F}_q^{d+1}} |Z^{-1}(z)^{\text{good}}| = |X_k^{\text{good}}| \cdot |Y_k^{\text{good}}| = \frac{q!}{(q-k)!}(q-1)^k = q^{2k}(1 - O(1/q)). \tag{9}$$

Thus, invoking Lemma 4, the number of values of z for which $|Z^{-1}(z)^{\text{good}}| = k!$ is at least $\frac{q^{2k}}{k!}(1 - O(1/q))$. Since $k = d/2 + 1/2$, it follows that $|R_k|/q^{d+1}$ is at least $\frac{1}{k!}(1 - O(1/q))$, as claimed. ◀

2.4 Performance using d/2 + 1 queries

Next we show that with more than $d/2 + 1/2$ queries, the success probability approaches 1 for large q.

Proof of Theorem 2(ii): $k = d/2 + 1$**.** Under the uniform distribution on $z \in \mathbb{F}_q^{d+1}$, we have

$$|R_k|/q^{d+1} = 1 - \Pr[|Z^{-1}(z)| = 0]. \tag{10}$$

We use a second moment argument to upper bound the number of $z \in \mathbb{F}_q^{d+1}$ for which $|Z^{-1}(z)| = 0$. The mean of $|Z^{-1}(z)|$ is $\mu := q^{-(d+1)} \sum_{z \in \mathbb{F}_q^{d+1}} |Z^{-1}(z)| = q^{2k-(d+1)}$. Let $\delta[\mathcal{P}]$ be 1 if $\mathcal{P}$ is true and 0 if $\mathcal{P}$ is false. For the second moment, we compute

$$\sum_{z \in \mathbb{F}_q^{d+1}} |Z^{-1}(z)|^2 = \sum_{u,v,x,y \in \mathbb{F}_q^k} \delta[Z(u, v) = Z(x, y)] \tag{11}$$

$$= \sum_{u,v,x,y \in \mathbb{F}_q^k} \frac{1}{q^{d+1}} \sum_{\lambda \in \mathbb{F}_q^{d+1}} e(\lambda \cdot (Z(u, v) - Z(x, y))) \tag{12}$$

$$= \frac{q^{4k}}{q^{d+1}} + \frac{1}{q^{d+1}} \sum_{\lambda \in \mathbb{F}_q^{d+1} \setminus (0,\ldots,0)} \left(\sum_{x,y \in \mathbb{F}_q} e\left(y \sum_{j=0}^{d} \lambda_j x^j \right) \right)^{2k} \tag{13}$$

$$= q^{4k-(d+1)} + \frac{1}{q^{d+1}} \sum_{\lambda \in \mathbb{F}_q^{d+1} \setminus (0,\ldots,0)} \left(q \sum_{x \in \mathbb{F}_q} \delta\left[\sum_{j=0}^{d} \lambda_j x^j = 0 \right] \right)^{2k} \tag{14}$$

$$\leq q^{4k-(d+1)} + (qd)^{2k}. \tag{15}$$

Thus for the variance, we have

$$\sigma^2 := \frac{1}{q^{d+1}} \sum_{z \in \mathbb{F}_q^{d+1}} |Z^{-1}(z)|^2 - \mu^2 \leq \frac{(qd)^{2k}}{q^{d+1}}. \tag{16}$$

(note that $\sigma^2 \geq 0$ by the Cauchy inequality). Applying the Chebyshev inequality, we find

$$\Pr[Z^{-1}(z) = 0] \leq \frac{\sigma^2}{\mu^2} \leq \frac{(qd)^{2k}/q^{d+1}}{q^{4k-2(d+1)}} = d^{2k} q^{d+1-2k}. \tag{17}$$

Therefore $|R_k|/q^{d+1} = 1 - \Pr[Z^{-1}(z) = 0] \geq 1 - d^{2k} q^{d+1-2k}$. With $k = d/2 + 1$, we have

$$|R_k|/q^{d+1} \geq 1 - d^{2k}/q = 1 - O(1/q) \tag{18}$$

as claimed. ◀

Note that one can improve the dependence on d in (16) using results on the distribution of zeros in random polynomials [10].

2.5 An alternative algorithm

The algorithm described above queries the oracle nonadaptively, that is, all k queries can be performed in parallel. However, the input state to these queries is correlated across all k copies. In this section, we describe an alternative algorithm that queries the black box on a state that is independent and identical for each of the k queries, namely, a uniform superposition over all inputs. This algorithm is suboptimal, but its performance is not significantly worse than that of the optimal algorithm described in Section 2.2.

Analogous to the so-called standard method for the hidden subgroup problem, querying f on a uniform superposition gives the state $\frac{1}{\sqrt{q}} \sum_{x \in \mathbb{F}_q^k} |x, f(x)\rangle$. If we use k queries to prepare k copies of this state and then perform the Fourier transform on the second register (or equivalently, perform k independent phase queries), we obtain the state

$$\frac{1}{q^k} \sum_{x,y \in \mathbb{F}_q^k} e(c \cdot Z(x,y)) |x, y\rangle = \frac{1}{q^k} \sum_{z \in \mathbb{F}_q^{d+1}} e(c \cdot z) \sqrt{|Z^{-1}(z)|}\, |Z^{-1}(z)\rangle \tag{19}$$

where $|Z^{-1}(z)\rangle := \sum_{(x,y) \in Z^{-1}(z)} |x, y\rangle / |Z^{-1}(z)|^{1/2}$. Motivated by the PGM approach to the hidden subgroup problem [1], suppose we perform the transformation $|Z^{-1}(z)\rangle \mapsto |z\rangle$, giving the state

$$|\phi_k^c\rangle := \frac{1}{q^k} \sum_{z \in \mathbb{F}_q^{d+1}} e(c \cdot z) \sqrt{|Z^{-1}(z)|}\, |z\rangle. \tag{20}$$

Measuring this state in the Fourier basis gives the outcome c with probability

$$|\langle \phi_k^c | \hat{c} \rangle|^2 = \frac{1}{q^{2k+d+1}} \left(\sum_{z \in \mathbb{F}_q^{d+1}} \sqrt{|Z^{-1}(z)|} \right)^2. \tag{21}$$

If $k = d/2 + 1/2$, we claim that this algorithm succeeds with constant probability. From the proof of Theorem 2 for $k = d/2 + 1/2$, we have that $|Z^{-1}(z)| \geq k!$ for at least $\frac{q^{2k}}{k!}(1 - O(1/q))$ values of z. Therefore the success probability is at least $\frac{1}{k!}(1 - O(1/q))$.

If $k = d/2 + 1$, then this algorithm succeeds with probability that approaches 1 for large q. To see this, recall from the proof of Theorem 2 for $k = d/2 + 1$ that, under a uniform

distribution over $z \in \mathbb{F}_q^{d+1}$, the quantity $Z^{-1}(z)$ has mean $\mu = q$ and standard deviation $\sigma = \sqrt{q}d^k$. Thus, by the Chebyshev inequality, we have

$$\Pr\left[|Z^{-1}(z)| \leq q - \alpha\sqrt{q}d^k\right] \leq \frac{1}{\alpha^2}. \tag{22}$$

It follows that $|\langle\phi_k^c|\hat{c}\rangle|^2 \geq (1 - \frac{\alpha d^k}{\sqrt{q}})(1 - \frac{1}{\alpha^2})^2$ Choosing $\alpha = \Theta(q^{1/6})$, this gives a success probability of $|\langle\phi_k^c|\hat{c}\rangle|^2 = 1 - O(q^{-1/3})$, which approaches 1 for large q.

3 Optimality

In this section, we show that the query complexity of our algorithm is precisely optimal: no k-query algorithm can succeed with a probability larger than $|R_k|/q^{d+1}$. We begin with a basic result showing that m states spanning an n-dimensional subspace can be distinguished with probability at most n/m.

▶ **Lemma 5.** *Suppose we are given a state $|\psi_c\rangle$ with $c \in C$ chosen uniformly at random. Then the probability of correctly determining c with some orthogonal measurement is at most* $\dim \operatorname{span}\{|\psi_c\rangle : c \in C\}/|C|$.

Proof. Consider a measurement with orthogonal projectors E_c, and let Π denote the projection onto $\operatorname{span}\{|\psi_c\rangle : c \in C\}$. Then we have that Pr[success] equals

$$\frac{1}{|C|}\sum_{c\in C}\langle\psi_c|E_c|\psi_c\rangle \leq \frac{1}{|C|}\sum_{c\in C}\operatorname{tr}(E_c\Pi) = \frac{\operatorname{tr}(\Pi)}{|C|} = \frac{\dim \operatorname{span}\{|\psi_c\rangle : c \in C\}}{|C|} \tag{23}$$

as claimed. ◀

We apply this lemma where $|\psi_c\rangle$ is the final state of a given quantum query algorithm when the black box contains $c \in \mathbb{F}_q^{d+1}$. There is no loss of generality in considering an orthogonal measurement at the end of the algorithm since we allow the use of an arbitrary-sized ancilla.

▶ **Lemma 6.** *Let $|\psi_c\rangle$ be the state of any quantum polynomial interpolation algorithm after k queries, where the black box contains $c \in \mathbb{F}_q^{d+1}$. Then* $\dim \operatorname{span}\{|\psi_c\rangle : c \in \mathbb{F}_q^{d+1}\} \leq |R_k|$.

Proof. See the proof in the extended version [6] of this article. ◀

We can now prove our upper bound on the success probability of quantum algorithms for polynomial interpolation.

Proof of Theorem 1 (upper bound on success probability). By combining Lemma 5 with Lemma 6, we see that if the coefficients $c \in \mathbb{F}_q^{d+1}$ are chosen uniformly at random, no algorithm can succeed with probability greater than $|R_k|/q^{d+1}$. Since the minimum cannot be larger than the average, this implies a lower bound on the success probability in the worst case of $|R_k|/q^{d+1}$. ◀

This result also shows that the exact quantum query complexity of polynomial interpolation is maximal.

▶ **Corollary 7.** *The exact quantum query complexity of interpolating a degree-d polynomial is $d + 1$.*

Proof. See the proof in the extended version [6] of this article. ◀

4 Gate complexity

In Section 2, we analyzed the query complexity of our polynomial interpolation algorithm. Here we describe a $(d/2+1/2)$-query algorithm whose gate complexity is $\mathrm{poly}(\log q)$, and whose success probability is close to that of the best algorithm using this number of queries (in particular, for fixed d it still succeeds with constant probability). We also give an algorithm for the case $k = d/2+1$ whose gate complexity is larger by a factor of $\mathrm{poly}(\log q)$, but with an additional factor of $k!$.

4.1 Algorithm for k = d/2 + 1/2 queries

To simplify the computation of unique representatives of values $z \in R_k$, we restrict attention to the "good" case considered in Section 2.3. Let

$$R_k^{\mathrm{good}} := \{Z(x,y) : x \in X_k^{\mathrm{good}},\, y \in Y_k^{\mathrm{good}}\}. \tag{24}$$

For any $z \in R_k^{\mathrm{good}}$, we show how to efficiently compute representative values $x \in X_k^{\mathrm{good}}$ and $y \in Y_k^{\mathrm{good}}$ with $Z(x,y) = z$, defining a set of representatives T_k^{good}. Then we consider an algorithm as described in Section 2.2, but with R_k replaced by R_k^{good} and T_k replaced by T_k^{good}. Clearly the success probability of this algorithm is $|R_k^{\mathrm{good}}|/q^{d+1}$. Our lower bound on $|R_k|$ in Section 2.3 was actually a bound on $|R_k^{\mathrm{good}}|$, so this algorithm still succeeds with probability $\frac{1}{k!}(1+O(1/q))$.

To give a gate-efficient algorithm, it suffices to show how to efficiently compute the function $Z^{-1}\colon R_k^{\mathrm{good}} \to T_k^{\mathrm{good}}$ (that is, to compute this function using $\mathrm{poly}(\log q)$ gates).

▶ **Lemma 8.** *Suppose there is an efficient algorithm to compute $Z^{-1}\colon R_k^{\mathrm{good}} \to T_k^{\mathrm{good}}$. Then the algorithm of Section 2.2 can be made gate-efficient (with R_k replaced by R_k^{good} and T_k by T_k^{good}).*

Proof. It is trivial to compute $Z\colon T_k^{\mathrm{good}} \to R_k^{\mathrm{good}}$ efficiently. Given an efficient procedure for computing $Z^{-1}\colon R_k^{\mathrm{good}} \to T_k^{\mathrm{good}}$, this gives us the ability to efficiently compute Z in place (that is, to perform the transformation $|x,y\rangle \mapsto |z\rangle$ as required by the algorithm). To do this, we first compute z in an ancilla register by evaluating Z (which only requires arithmetic over $\mathbb{F}_q$) and then uncompute (x,y) by applying the circuit for Z^{-1} in reverse.

It remains to prepare the initial uniform superposition over T_k^{good}. This can also be done using the ability to compute Z^{-1}. Suppose we create a uniform superposition over all of $z \in \mathbb{F}_q^{d+1}$ and then attempt to compute Z^{-1}. If $z \notin R_k^{\mathrm{good}}$, this is detected, and we can set a flag qubit indicating failure. Thus we can prepare a state of the form

$$\frac{1}{\sqrt{q^{d+1}}}\left(\sum_{(x,y)\in T_k^{\mathrm{good}}} |Z(x,y),0,x,y\rangle + \sum_{z\in\mathbb{F}_q^{d+1}\setminus R_k^{\mathrm{good}}} |z,1,0,0\rangle\right). \tag{25}$$

A measurement of the flag qubit gives the outcome 0 with probability $|R_k^{\mathrm{good}}|/q^{d+1}$. Since this is our lower bound on the success probability of the overall algorithm, we do not have to repeat this process too many times before we successfully prepare the initial state (and by sufficiently many repetitions, we can make the error probability arbitrarily small). When the measurement succeeds, we can uncompute the first register to obtain the state $\sum_{(x,y)\in T_k^{\mathrm{good}}} |x,y\rangle/|T_k^{\mathrm{good}}|^{1/2}$ as desired. ◀

In the remainder of this section, we describe how to efficiently compute $Z^{-1}(z)$ for $z \in R_k^{\mathrm{good}}$. Our approach appeals to "Prony's method" [14] (a precursor to Fourier analysis)

and the theory of linear recurrences. We start with the following technical result, where e_j denotes the jth elementary symmetric polynomial in k variables, i.e.,

$$e_j(x_1, \ldots, x_k) = \sum_{1 \le i_1 < i_2 < \cdots < i_j \le k} x_{i_1} x_{i_2} \cdots x_{i_j}. \tag{26}$$

▶ **Lemma 9.** *We have* $x_i^k = -\sum_{j=1}^{k} x_i^{k-j}(-1)^j e_j(x_1, \ldots, x_k)$ *for all* $i \in \{1, \ldots, k\}$.

Proof. See the proof in the extended version [6] of this article. ◀

Using this fact, we can show that each component of $Z(x, y)$ satisfies a kth-order linear recurrence.

▶ **Lemma 10.** *If* $z_j = \sum_{i=1}^{k} y_i x_i^j$ *for all nonnegative integers* j*, then we have for all nonnegative integers* n *that* $z_{n+k} = -\sum_{j=0}^{k-1}(-1)^{k-j} e_{k-j}(x_1, \ldots, x_k) z_{n+j}$.

Proof. See the proof in the extended version [6] of this article. ◀

We are now ready to describe the gate-efficient algorithm for polynomial interpolation.

Proof of Theorem 3(i): $k = d/2 + 1/2$**.** By Lemma 8, it suffices to give an efficient algorithm for computing a representative $(x, y) \in Z^{-1}(z)^{\text{good}}$ for any given $z \in R_k^{\text{good}}$. See the proof in the extended version [6] of this article. ◀

4.2 Algorithm for k = d/2 + 1 queries

We now present a similar algorithm for the case $k = d/2 + 1$ that also has gate complexity $\text{poly}(\log q)$, although it has more overhead as a function of d.

To apply the approach of Section 4.1, we again focus on solutions of $Z(x, y) = z$ with $(x, y) \in X^{\text{good}} \times Y^{\text{good}}$. However, recall that our lower bound on the success probability for $k = d/2 + 1$ in Section 2.4 used all solutions $(x, y) \in \mathbb{F}_q^k \times \mathbb{F}_q^k$. Thus we begin by showing that the success probability of the algorithm remains close to 1 even when restricted to good solutions.

▶ **Lemma 11.** *If* $k = d/2 + 1$*, then* $|R_k^{\text{good}}|/q^{d+1} = 1 - O(1/q)$.

Proof. See the proof in the extended version [6] of this article. ◀

Now consider the problem of computing a value $(x, y) \in X^{\text{good}} \times Y^{\text{good}}$ such that $Z(x, y) = z$ for some given $z \in R_k^{\text{good}}$. We can approach this task using the strategy outlined in the proofs of the lemmas of Section 4.1, which can be found in the extended version [6] of this article.

We claim that choosing a random $z_{d+1} \in \mathbb{F}_q$ gives a solution with probability nearly $1/k!$.

▶ **Lemma 12.** *Suppose* $z = (z_0, \ldots, z_d)$ *is chosen uniformly at random from* $\mathbb{F}_q^{d+1}$*. Then with probability* $1 - o(1)$ *(over the choice of* z*), choosing* z_{d+1} *uniformly at random from* $\mathbb{F}_q$ *and solving for* $(x, y) \in Z^{-1}(z)^{\text{good}}$ *as in the proof of Theorem 3(ii) gives a solution with probability* $(1 - o(1))/k!$ *(over the choice of* z_{d+1}*).*

Proof. See the proof in the extended version [6] of this article. ◀

Lemma 12 gives a method for computing a representative $(x, y) \in X^{\text{good}} \times Y^{\text{good}}$ such that $Z(x, y) = z$: simply choose $z_{d+1} \in \mathbb{F}_q$ at random until we find a solution. Repeating this process $O(k!)$ times suffices to find a solution with constant probability (for almost all z). However, since this approach constructs a random $(x, y) \in Z^{-1}(z)^{\text{good}}$ rather than a unique representative, it does not define a set T_k^{good}, and it cannot be directly applied to our quantum algorithm as described so far. Instead, we construct an equivalent algorithm that represents the sets $Z^{-1}(z)^{\text{good}}$ using quantum superpositions.

▶ **Lemma 13.** *Suppose there is an efficient algorithm to generate the quantum state*

$$|Z^{-1}(z)^{\text{good}}\rangle := \frac{1}{\sqrt{|Z^{-1}(z)^{\text{good}}|}} \sum_{(x,y)\in Z^{-1}(z)^{\text{good}}} |x, y\rangle \tag{27}$$

for any given $z \in R_k^{\text{good}}$. Then there is a gate-efficient k-query quantum algorithm for the polynomial interpolation problem, succeeding with probability $|R_k^{\text{good}}|/q^{d+1}$.

Proof. We essentially replace $(x, y) \in T_k^{\text{good}}$ by $|Z^{-1}(Z(x, y))^{\text{good}}\rangle$ throughout the algorithm. More concretely, we proceed as follows.

Observe that the ability to perform the given state generation map $|z\rangle \mapsto |z\rangle|Z^{-1}(z)^{\text{good}}\rangle$ implies the ability to perform the in-place transformation

$$|z\rangle \mapsto |Z^{-1}(z)^{\text{good}}\rangle. \tag{28}$$

After applying the state generation map, we simply uncompute the map Z to erase the register $|z\rangle$.

The algorithm begins by creating a uniform superposition over all of $z \in \mathbb{F}_q^{d+1}$ and applying the map (28). As in the proof of Lemma 8, we can detect whether $z \notin R_k^{\text{good}}$, and we can postselect on the outcomes for which $z \in R_k^{\text{good}}$ with reasonable overhead, giving the state $\sum_{z\in R_k^{\text{good}}} |Z^{-1}(z)^{\text{good}}\rangle/|R_k^{\text{good}}|^{1/2}$. Then perform k phase queries and apply the inverse of the transformation (28), giving the state

$$\frac{1}{\sqrt{|R_k^{\text{good}}|}} \sum_{z\in R_k^{\text{good}}} e(c \cdot z)|Z^{-1}(z)^{\text{good}}\rangle \mapsto \frac{1}{\sqrt{|R_k^{\text{good}}|}} \sum_{z\in R_k^{\text{good}}} e(c \cdot z)|z\rangle. \tag{29}$$

As discussed in Section 2.2, measuring this state gives c with probability $|R_k^{\text{good}}|/q^{d+1}$. ◀

Finally, we show how to prepare $|Z^{-1}(z)^{\text{good}}\rangle$ and thereby give a gate-efficient quantum algorithm for polynomial interpolation with $k = d/2 + 1$ queries.

Proof of Theorem 3(ii): $k = d/2 + 1$. We use $|Z^{-1}(z)^{\text{good}}\rangle$ as a quantum representative of the set of solutions $Z^{-1}(z)^{\text{good}}$ as described in Lemma 13. We claim that we can efficiently perform the transformation $|z\rangle \mapsto |Z^{-1}(z)^{\text{good}}\rangle$ for a fraction $1 - o(1)$ of those $z \in R_k^{\text{good}}$, which in turn are a fraction $1 - o(1)$ of all $z \in \mathbb{F}_q^{d+1}$ (by Lemma 11), giving the claimed success probability.

To prepare $|Z^{-1}(z)^{\text{good}}\rangle$, we first prepare a uniform superposition over $z_{d+1} \in \mathbb{F}_q$ and use the procedure of Section 4.1 to compute the corresponding (x, y), if it exists. Lemma 12 shows that a fraction $(1 - o(1))/k!$ of the values of z_{d+1} correspond to a valid (x, y), so this process can be boosted to prepare a state close to $|Z^{-1}(z)^{\text{good}}\rangle$ with overhead $O(k!)$ (or with amplitude amplification, $O(\sqrt{k!})$), which in particular is independent of q. We can easily uncompute z_{d+1} given (x, y), giving the desired transformation. ◀

5 Open problems

In this paper, we have precisely characterized the quantum query complexity of polynomial interpolation. We conclude by briefly discussing some possible directions for future work.

In Section 4, we gave an algorithm for the case $k = d/2+1$ whose gate complexity is larger than its query complexity by a factor of $k!\operatorname{poly}(\log q)$. This gate complexity is polynomial in $\log(q)$ but superexponential in d. Is it possible to give an algorithm with gate complexity only $\operatorname{poly}(d, \log q)$?

A natural extension of our results would be to consider the problem of learning a multivariate polynomial $f \in \mathbb{F}_q[X_1, \ldots, X_n]$ of degree at most d. Montanaro gave asymptotically optimal bounds for this problem assuming f is multilinear [13], but it is also natural to consider the more general case where f is not necessarily multilinear. The quantum algorithm described in Section 2.2 can be extended to the multivariate case in a fairly straightforward manner, and we conjecture that it performs as follows.

▶ **Conjecture 14.** *For any fixed positive integers d and n, there exists a k-query quantum algorithm for interpolating a degree-d multivariate polynomial in n variables that, as q grows, has success probability $1 - o(1)$ provided $k > \binom{n+d}{d}/(n+1)$.*

Note that classically one needs $\binom{n+d}{d}$ queries to solve the same problem, so our conjecture states that the quantum query complexity is smaller by a factor of $n+1$. We now discuss why computing the success probability of the quantum algorithm appears to be a difficult problem in algebraic geometry.

Let $f \in \mathbb{F}_q[X_1, \ldots, X_n]$ be of degree at most d. For $j \in \mathbb{N}^n$ and $x \in \mathbb{F}_q^n$, we let $x^j := \prod_{t=1}^n x_t^{j_t}$. To define the set of possible polynomials, we use the set of allowed exponents $\mathcal{J}$ with size

$$J := |\mathcal{J}| := |\{j \in \mathbb{N}^n : j_1 + \cdots + j_n \le d\}| = \binom{n+d}{d}. \tag{30}$$

We now define the function $Z\colon (\mathbb{F}_q^n)^k \times \mathbb{F}_q^k \to \mathbb{F}_q^J$ by $Z(x,y)_j = \sum_{i=1}^k y_i x_i^j$ and consider its range $\mathcal{R}_k := Z((\mathbb{F}_q^n)^k \times \mathbb{F}_q^k) \subseteq \mathbb{F}_q^J$. A straightforward generalization of the univariate interpolation algorithm described in Section 2.2 gives a multivariate interpolation algorithm with success probability $|\mathcal{R}_k|/q^J$. We expect that this algorithm solves the interpolation problem with probability $1 - o(1)$ using $\lfloor J/(n+1) \rfloor + 1$ queries. This would be implied by the following:

▶ **Conjecture 15.** *With $J := \binom{n+d}{d}$ and $\mathcal{R}_k$ as above, we have $|\mathcal{R}_k| = q^J(1 - o(1))$ provided $k > J/(n+1)$.*

Note that this holds for $n = 1$ (according to Lemma 11) and also for $d = 1$. Unfortunately, the approach via exponential sums used in the proof of Lemma 11 only works if $k > J/2$. Thus, while it gives a tight result for $n = 1$, it appears to be inefficient for $n > 1$.

Another way to approach Conjecture 15 is to consider the affine variety $\mathcal{V}_k\colon Z(x,y) = z$ in $kn + k + J$ variables $x \in (\mathbb{F}_q^n)^k$, $y \in \mathbb{F}_q^k$, $z \in \mathbb{F}_q^J$. Clearly $|\mathcal{V}_k(\mathbb{F}_q)| = q^{kn+k}$. It is not hard to show that $\mathcal{V}_k$ is a complete intersection and has only one absolutely irreducible component. Thus it suffices to show that for almost all specializations of $z \in \mathbb{F}_q^J$, the corresponding variety $\mathcal{V}_k(\boldsymbol{z})$ is absolutely irreducible; then provided $k(n+1) > J$, a version of the Lang-Weil bound [11] applies and gives the desired result. Although results of this type are known (see [4, 15] and references therein), unfortunately none of them seems to imply the desired statement. Nevertheless, since a generic variety is absolutely irreducible, the conjecture appears plausible.

Lower Bounds for the Approximate Degree of Block-Composed Functions*

Justin Thaler

Yahoo! Research, New York, NY, USA

Abstract

We describe a new hardness amplification result for point-wise approximation of Boolean functions by low-degree polynomials. Specifically, for any function f on N bits, define

$$F(x_1, \ldots, x_M) = \mathrm{OMB}(f(x_1), \ldots, f(x_M))$$

to be the function on $M \cdot N$ bits obtained by block-composing f with a function known as ODD-MAX-BIT. We show that, if f requires large degree to approximate to error $2/3$ in a certain one-sided sense (captured by a complexity measure known as *positive one-sided approximate degree*), then F requires large degree to approximate even to error $1 - 2^{-M}$. This generalizes a result of Beigel (Computational Complexity, 1994), who proved an identical result for the special case $f = \mathrm{OR}$.

Unlike related prior work, our result implies strong approximate degree lower bounds even for many functions F that have low *threshold degree*. Our proof is constructive: we exhibit a solution to the dual of an appropriate linear program capturing the approximate degree of any function. We describe several applications, including improved separations between the complexity classes $\mathbf{P}^{\mathbf{NP}}$ and $\mathbf{PP}$ in both the query and communication complexity settings. Our separations improve on work of Beigel (1994) and Buhrman, Vereshchagin, and de Wolf (CCC, 2007).

1 Introduction

Approximate degree and threshold degree are two measures of Boolean function complexity that capture the difficulty of point-wise approximation by low-degree polynomials. The ε-approximate degree of a function $f\colon \{-1,1\}^n \to \{-1,1\}$, denoted $\widetilde{\deg}_\varepsilon(f)$, is the least degree of a polynomial that point-wise approximates f to error ε. The threshold degree, denoted $\deg_\pm(f)$, is the least degree of a real polynomial that agrees in sign with f point-wise.

Approximate degree and threshold degree have found a diverse array of algorithmic and complexity-theoretic applications. On the complexity side, approximate degree lower bounds underlie many tight lower bounds on quantum query complexity [2, 3, 25, 6, 41], and have proven instrumental in resolving a host of long-standing open problems in communication and circuit complexity [40, 39, 35, 42, 16, 44, 34, 41, 14, 12, 13, 27, 8]. On the algorithms side, upper bounds on these complexity measures underlie the fastest known learning algorithms in a number of important models, including the PAC, agnostic, and mistake-bounded models [23, 24, 20, 36]. They also yield fast algorithms for private data release [49, 11].

Despite these applications, our understanding of approximate and threshold degree remains limited. While tight upper and lower bounds are known for some specific functions, including symmetric functions [32, 38, 15] and certain read-once formulae, few general results are known, and characterizing the approximate and threshold degrees of many simple functions remains open. However, a handful of recent works has established various forms of "hardness amplification" for approximate degree [43, 9, 10, 46, 45, 26, 47]. Roughly speaking, these results show how to take a function f which is hard to approximate by low-degree polynomials in a weak sense, and turn f into a related function F that is hard to approximate by low-degree polynomials in a much stronger sense.

Our Contributions. We extend this recent line of work by establishing a new, generic form of hardness amplification for approximate degree. Unlike prior work, our result implies strong lower bounds even for many functions F that have low threshold degree (e.g., halfspaces). In contrast, analogous hardness amplification results [43, 9, 10, 46, 45, 26, 47] apply only to functions with polynomially large threshold degree. We describe several applications of our result, including an improved separation between the complexity classes $\mathbf{P^{NP}}$ and $\mathbf{PP}$ in both the query and communication complexity settings (see Section 1.3 for details).

We prove our results by constructing explicit *dual polynomials*, which are dual solutions to an appropriate linear program capturing the approximate degree of any function. This "method of dual polynomials" has proven to be a powerful technique for establishing lower bounds on approximate degree. Our construction departs qualitatively from earlier applications of the method, and we believe it to be of interest in its own right. In addition to implying approximate degree lower bounds, dual polynomials have been used to resolve several long-standing open problems in communication complexity, and they yield explicit distributions under which various communication problems are hard [40, 42, 16, 44, 34, 41, 14].

1.1 Overview of Our Results

Let $f : \{-1,1\}^n \to \{-1,1\}$ be a Boolean function. Our hardness amplification method relies heavily on a complexity measure known as *one-sided approximate degree*, or, more precisely, its "positive" and "negative" variants, denoted $\widetilde{\deg}_{+,\varepsilon}(f)$ and $\widetilde{\deg}_{-,\varepsilon}(f)$ respectively. These are intermediate complexity measures that lie between ε-approximate degree and threshold degree, and they have played a central role in recent prior work on hardness amplification for approximate degree [46, 10, 9, 43].[1] Unlike the latter two complexity measures, $\widetilde{\deg}_{+,\varepsilon}(f)$ and $\widetilde{\deg}_{-,\varepsilon}(f)$ treat inputs in $f^{-1}(+1)$ and inputs in $f^{-1}(-1)$ asymmetrically.

In more detail, a polynomial p is said to be a positive one-sided ε-approximation for a Boolean function f if $|p(x) - f(x)| \leq \varepsilon$ for all $x \in f^{-1}(-1)$, and $p(x) \geq 1 - \varepsilon$ for all $x \in f^{-1}(+1)$. The positive one-sided ε-approximate degree of f is the least degree of a positive one-sided ε-approximation for f. Negative one-sided ε-approximate degree is defined analogously. Notice that $\widetilde{\deg}_{+,\varepsilon}(f)$ and $\widetilde{\deg}_{-,\varepsilon}(f)$ are always at most $\widetilde{\deg}_{\varepsilon}(f)$, but can be much smaller. Similarly, $\widetilde{\deg}_{+,\varepsilon}(f)$ and $\widetilde{\deg}_{-,\varepsilon}(f)$ are always at least $\deg_{\pm}(f)$, but can be much larger.

[1] Strictly speaking, the terms positive and negative one-sided approximate degree were introduced by Kanade and Thaler [21], who gave applications of these complexity measures to learning theory. Earlier works on hardness amplification for pointwise approximation by polynomials only used negative one-sided approximate degree, and referred to this complexity measure without qualification as one-sided approximate degree [10, 46]. For our purposes, the distinction between positive and negative one-sided approximate degree is crucial.

Let $\mathrm{OMB} : \{-1,1\}^n \to \{-1,1\}$ denote a specific polynomial size DNF formula known as ODD-MAX-BIT, defined as follows. On input $x = (x_1, \ldots, x_n)$, let i^* denote the largest index such that $x_{i^*} = -1$, and let $i^* = 0$ if no such index exists. We define $\mathrm{OMB}(x_1, \ldots, x_n) = -1$ if i^* is odd, and $\mathrm{OMB}(x_1, \ldots, x_n) = 1$ otherwise. When appropriate, we also use subscripts after function symbols to indicate the number of variables over which the function is defined. Thus, OMB_M denotes the OMB function on M inputs.

For any function $f\colon \{-1,1\}^N \to \{-1,1\}$, define $F : \left(\{-1,1\}^N\right)^M \to \{-1,1\}$ to be the block-composition of OMB_M with f, i.e., $F = \mathrm{OMB}_M(f, \ldots, f)$. Our hardness amplification result establishes that if $\widetilde{\deg}_{+,\varepsilon}(f)$ is large for some ε bounded away from 1, then $\widetilde{\deg}_{+,\varepsilon}(F)$ is large even for ε exponentially close to 1.

▶ **Theorem 1.** *Fix an $f\colon \{-1,1\}^N \to \{-1,1\}$, and let $F = \mathrm{OMB}_M(f, \ldots, f)$. If $\widetilde{deg}_{+,2/3}(f) \geq d$, then $\widetilde{deg}_{+,\varepsilon}(F) \geq d$ for $\varepsilon = 1 - 2^{-M}$.*

A Matching Upper Bound for Theorem 1. To understand the intuition underlying Theorem 1, it is instructive to consider (matching) upper bounds. We begin by giving the well-known sign-representing polynomial for OMB_M itself. Define $p\colon \{-1,1\}^M \to \mathbb{R}$ via

$$p(x_1, \ldots, x_M) := 1 + \sum_{i=1}^{M} (-2)^i \cdot (1 - x_i)/2.$$

It is easy to see that $\mathrm{OMB}_M(x) = \mathrm{sgn}\,(p(x))$, and in fact $2^{-M-1} \cdot p(x)$ approximates OMB_M to error $\varepsilon = 1 - 2^{-M-1}$.

We now turn to constructing approximants for $\mathrm{OMB}_M(f, \ldots, f)$, for an arbitrary inner function f. Fix a $W \geq 2$, and let $q\colon \{-1,1\}^N \to \mathbb{R}$ be any degree d polynomial satisfying the following two properties.

$$q(x) = 0 \quad \text{for all } x \in f^{-1}(+1). \tag{1}$$

$$1 \leq q(x) \leq W - 1 \quad \text{for all } x \in f^{-1}(-1). \tag{2}$$

Denoting an $(M \cdot N)$-bit input as $(x_1, \ldots, x_M) \in \left(\{-1,1\}^N\right)^M$, it is easy to check that

$$F(x_1, \ldots, x_M) = \mathrm{sgn}(h(x_1, \ldots, x_M)), \text{ where } h(x_1, \ldots, x_M) = 1 + \sum_{i=1}^{M} (-W)^i \cdot q(x_i).$$

In fact, $W^{-M-1} \cdot h(x)$ approximates F to error $1 - W^{-M-1}$, and has degree equal to that of q. If $W = O(1)$, then this construction shows that F can be approximated to error $1 - 2^{-O(M)}$ by a degree d polynomial, which matches the error bound of Theorem 1 up to a constant factor in the exponent.

▶ **Observation 2.** *If there exists a polynomial q of degree d satisfying Eq. (1) and Eq. (1) with $W = O(1)$, then $\widetilde{deg}_{\varepsilon}(F) \leq d$ for some $\varepsilon = 1 - 2^{-O(M)}$.*

A few words are in order regarding the relationship between the hypothesis of the upper bound (Observation 2), and the hypothesis of the lower bound (Theorem 1) that $\widetilde{\deg}_{+,2/3}(f) \geq d$. Conditions 1 and 1 together imply that $r(x) := \frac{1}{2W} \cdot (1 - 2q(x))$ is a positive one-sided approximation to f for error parameter $\varepsilon = 1 - \frac{1}{2W}$. Moreover, r has the additional (crucial) property that this approximant is *constant* on inputs in $f^{-1}(+1)$. Observe that the smaller W is, the smaller the error of the one-sided approximant $r(x)$ for $f(x)$, and the smaller the error of the derived approximant $W^{-M-1} \cdot h(x)$ that we constructed for F.

In general, requiring that r be constant on inputs in $f^{-1}(+1)$ is a very stringent condition, which will not be satisfied by all one-sided approximations for f. However, Bun and Thaler [10, Theorem 2] have identified a large class of functions for which *any* one-sided approximation for f can be transformed into one that is constant on inputs in $f^{-1}(+1)$, without increasing its degree. This class includes important functions such as $f = \mathrm{OR}$ (see Section 1.2.2), and $f = \overline{\mathrm{ED}}$, where ED is the well-studied Element Distinctness function that we use in our applications to communication and query complexity. For such functions, Observation 2 implies that Theorem 1 is tight.

Can the Hypothesis in Theorem 1 be Weakened? There are two natural ways to weaken the hypothesis of Theorem 1, and it is natural to wonder whether Theorem 1 would continue to hold under these hypotheses. Specifically, we can ask:

- Does Theorem 1 hold if we replace the outer function OMB_M function with the simpler function OR_M, as in previous hardness amplification results for approximate degree [46, 10, 9, 43]?[2]
- Is a one-sided hardness assumption really essential for Theorem 1 to hold? That is, does OMB_M still amplify the hardness of f if we replace the assumption that $\widetilde{\deg}_{+,2/3}(f) \geq d$ with the weaker assumption that $\widetilde{\deg}_{2/3}(f) \geq d$?

The answer to the first question is no. A counterexample is given by $f = \mathrm{OR}_N$. It is known that $\widetilde{\deg}_{+,2/3}(\mathrm{OR}_N) = \Omega(N^{1/2})$ (see, e.g., [30, 10, 17]), yet $\mathrm{OR}_M(\mathrm{OR}_N, \ldots, \mathrm{OR}_N) = \mathrm{OR}_{N \cdot M}$ can be approximated to error $1 - 1/(MN) \ll 1 - 2^{-M}$ by a polynomial of degree 1. Thus, the use of OMB_M as the "hardness amplifier" is essential to Theorem 1.

The answer to the second question, unfortunately, remains unknown. Formally, we leave the resolution of the following conjecture as an open problem.

▶ **Conjecture 3.** *Suppose that $f\colon \{-1,1\}^N \to \{-1,1\}$ satisfies $\widetilde{deg}_{2/3}(f) \geq d$. Then letting $F = \mathrm{OMB}_M(f, \ldots, f)$, it holds that $\widetilde{deg}_{\varepsilon}(\mathrm{OMB}_M(f, \ldots, f)) \geq d$, for some $\varepsilon = 1 - 2^{-\Omega(M)}$.*

1.2 Technical Comparison to Prior Work

1.2.1 The Method of Dual Polynomials

A dual witness to the statement $\widetilde{\deg}_{\varepsilon}(f) \geq d$ is a non-zero function $\psi : \{-1,1\}^N \to \mathbb{R}$ satisfying two conditions: (a) $\sum_{x \in \{-1,1\}^N} \psi(x) \cdot f(x) \geq \varepsilon \cdot \|\psi\|_1$, where $\|\psi\|_1 = \sum_{x \in \{-1,1\}^N} |\psi(x)|$, and (b) ψ has zero correlation with all polynomials of degree at most d. We refer to Property (a) by saying that ψ is *ε-correlated* with f. We refer to Property (b) by saying that ψ has *pure high degree d*. We refer to ψ as a *dual polynomial* for f.

A dual witness to the statement that $\widetilde{\deg}_{+,\varepsilon}(f) \geq d$ must satisfy an additional correlation condition, namely: (c) $\phi(x)$ agrees in sign with $f(x)$ for all $x \in f^{-1}(+1)$. We refer to Property (c) by saying that ϕ has *positive one-sided error*. (Due to space constraints, we defer further discussion of the duality theory to the full version of the paper.)

We prove Theorem 1 by showing the following: given a dual polynomial ψ_{in} witnessing the assumed $\widetilde{\deg}_{+,2/3}$ lower bound on the inner function f, one can construct an explicit

[2] One may also ask about replacing OMB_M with AND_M in the statement of Theorem 1. Analyses from prior works [10, 46] apply in this case, but show that the resulting function in fact has high threshold degree, and hence is not suitable for our applications to query and communication complexity. We discuss this point in detail in the next section (see Theorem 5, Footnote 5, and the surrounding discussion).

dual polynomial ψ_{comb} witnessing the claimed lower bound on the composed function $F = \text{OMB}(f, \ldots, f)$.

1.2.2 Prior Work on the Approximate Degree of OMB

Beigel [7] proved that for any $d > 0$, there is an $\varepsilon \in 1 - 2^{-\Omega(n/d^2)}$ such that $\widetilde{\deg}_{\varepsilon}(\text{OMB}_n) \geq d$, and used this result[3] to give an oracle separating the (Turing Machine) complexity class **PP** from $\mathbf{P}^{\mathbf{NP}}$. Note that $\text{OMB}_M(\text{OR}_N, \ldots, \text{OR}_N)$ is a sub-function of $\text{OMB}_{M \cdot (2N)}$. As mentioned in Section 1.1, it is known that $\widetilde{\deg}_{+,2/3}(\text{OR}_N) = \Omega(N^{1/2})$. Hence, Theorem 1 can be viewed as a substantial strengthening of Beigel's result: we recover Beigel's lower bound as a special case of Theorem 1 by letting $f = \text{OR}_{d^2}$. Unlike Beigel's proof, which used a non-constructive symmetrization technique, our proof of Theorem 1 constructs an explicit dual polynomial witnessing the lower bound.

For any $\varepsilon > 0$, Klivans and Servedio [24] gave an optimal ε-approximating polynomial for the function OMB, showing that Beigel's lower bound (and hence also our Theorem 1 in the case $f = \text{OR}_N$) is asymptotically tight for all $d > 0$.[4]

1.2.3 Earlier Constructions of Dual Polynomials

Given functions g_M, f_N, Sherstov [45] and Lee [26] independently described a powerful method for constructing a dual polynomial for the composed function $F = g_M(f_N, \ldots, f_N) : \{-1,1\}^{M \cdot N} \to \{-1,1\}$. This method takes a dual polynomial ψ_{in} for f_N, and a dual polynomial ψ_{out} for g, and combines them to obtain a dual polynomial ψ_{comb} for the composed function F. Specifically, denoting an $(M \cdot N)$-bit input as $(x_1, \ldots, x_M) \in \left(\{-1,1\}^N\right)^M$, Sherstov and Lee defined

$$\psi_{\text{comb}}(x_1, \ldots, x_M) = \psi_{\text{out}}\left(\widetilde{\text{sgn}}\left(\psi_{\text{in}}\left(x_1\right)\right), \ldots, \widetilde{\text{sgn}}\left(\psi_{\text{in}}\left(x_M\right)\right)\right) \cdot \prod_{i=1}^{M} |\psi_{\text{in}}(x_i)|. \tag{3}$$

Here, $\widetilde{\text{sgn}} : \mathbb{R} \to \{-1, 0, 1\}$ denotes the function satisfying $\widetilde{\text{sgn}}(t) = 1$ if $t > 0$, $\widetilde{\text{sgn}}(t) = -1$ if $t < 0$, and $\widetilde{\text{sgn}}(0) = 0$.

Recall that for ψ_{comb} to witness a good lower bound for the approximate degree of F, it must be well-correlated with F (Property (a) of Section 1.2.1), and it must have large pure high degree (Property (b) of Section 1.2.1). Sherstov and Lee showed that the pure high degree of ψ_{comb} is multiplicative in the pure high degrees of ψ_{in} and ψ_{out}. That is, if ψ_{in} has pure high degree d_1, and ψ_{out} has pure high degree d_2, then ψ_{comb} has pure high degree $d_1 \cdot d_2$. And while ψ_{comb} is not *in general* well-correlated with the composed function F, several important examples have been identified in which this is the case, as we now explain.

Sherstov [43] and independently Bun and Thaler [9] used the combining technique of Eq. (3) to resolve the (1/3)-approximate degree of the two-level AND-OR tree. Subsequent work by Bun and Thaler [10] used Eq. (3) to establish a hardness amplification result that looks similar to our Theorem 1. Specifically, Bun and Thaler proved:

▶ **Theorem 4** (Bun and Thaler [10]). *Suppose* $\widetilde{deg}_{-,2/3}(f) \geq d$. *Then* $\widetilde{deg}_{-,\varepsilon}(OR_M(f, \ldots, f)) \geq d$, *for* $\varepsilon = 1 - 2^{-M}$.

[3] Beigel describes his result as a lower bound on the *degree-d threshold weight* of OMB_n. However, his argument is easily seen to establish the claimed approximate degree lower bound.

[4] Like Beigel, Klivans and Servedio state their results in terms of degree-d threshold weight. However, their construction is easily seen to imply the claimed upper bound on the approximate degree of OMB_n.

Theorem 4 is identical to our Theorem 1, but for two differences: first, in our Theorem 1, the outer function in the composition is OMB, while in Theorem 4 it is OR. Second, the hypothesis in Theorem 1 is that the inner function f satisfies $\widetilde{\deg}_{+,2/3}(f) \geq d$, while the assumption in Theorem 4 is that $\widetilde{\deg}_{-,2/3}(f) \geq d$. *Both* of these differences are crucial for obtaining a hardness amplification result that applies to functions with low threshold degree (which is essential for our applications to the communication and query complexity described in Section 1.3 below). Indeed, subsequent work by Sherstov refined Theorem 4 to yield a threshold degree lower bound, rather than a $\widetilde{\deg}_{-,\varepsilon}$ lower bound [46].

▶ **Theorem 5** (Sherstov [46]). *Suppose* $\widetilde{deg}_{-,2/3}(f) \geq d$. *Then* $\deg_{\pm}(OR_M(f,\ldots,f)) \geq \min\{d, cM\}$ *for some constant* $c > 0$.[5]

Sherstov gives several proofs of Theorem 5. One proof draws heavily on Eq. (3): he constructs a dual witness of the form $\psi_{\text{comb}} + \psi_{\text{fix}}$, where ψ_{comb} is the dual witness constructed by Bun and Thaler using Eq. (3) to prove Theorem 4, and ψ_{fix} "zeros out" ψ_{comb} on points x such that $0 \neq \widetilde{\mathsf{sgn}}(\psi_{\text{comb}}(x)) \neq \widetilde{\mathsf{sgn}}(\text{OR}_M(f,\ldots,f))$. This ensures that $\psi_{\text{comb}} + \psi_{\text{fix}}$ is perfectly correlated with F.

Sherstov used Theorem 5 to give a depth three circuit with threshold degree $\tilde{\Omega}(n^{2/5})$. He also established the following result, which yields a polynomially stronger lower bound for depth $k > 3$.

▶ **Theorem 6** (Sherstov [46]). *For any* $k \geq 2$, *there is a depth* k *(read-once) Boolean circuit computing a function* F *satisfying* $\deg_{\pm}(F) = \Omega(n^{(k-1)/(2k-1)})$.

Sherstov's proof of Theorem 6 is not a refinement of the proof Theorem 4 from [10]. Rather it relies on an elaborate inductive construction of a dual polynomial (which is nonetheless reminiscent of Eq. (3)).

In the full version of the paper, we explain why any dual witness establishing Theorem 1 must qualitatively depart from the dual witnesses constructed in prior work. In brief, we first argue that the dual witnesses constructed in prior work are implicitly tailored to show optimality of a specific technique for approximating block-composed functions. We then explain that this technique is far from optimal for the functions to which Theorem 1 applies.

1.3 Applications

This section gives an overview of our applications to query and communication complexity. Due to space constraints, formal definitions of the complexity classes involved in these applications, and statements and proofs of the relevant theorems, are deferred to the full version of the paper.

Notation. Given a query or communication model $\mathbf{C}$ and a function f, the notation $\mathbf{C}(f)$ denotes the least cost of a protocol computing f in the model $\mathbf{C}$. Following Babai et al. [4], we define a corresponding complexity class, also denoted $\mathbf{C}$, consisting of all problems that have polylogarithmic cost protocols in the model $\mathbf{C}$. Throughout, we use the superscript cc to denote communication complexity classes, and the subscript query to denote query complexity classes. Any complexity class without a subscript refers to a classical (Turing Machine) class.

[5] By De Morgan's laws and the observation that $\widetilde{\deg}_{-,\varepsilon}(f) = \widetilde{\deg}_{+,\varepsilon}(\overline{f})$, the following is an equivalent formulation of Theorem 5. Suppose that $\widetilde{\deg}_{+,2/3}(f) \geq d$. Then $\deg_{\pm}(\text{AND}_M(f,\ldots,f)) \geq \min\{d, cM\}$ for some constant $c > 0$.

1.3.1 Query Complexity

Connecting Query Complexity, Approximate Degree, and Oracle Separations. A significant motivation for studying query complexity is that separations of query complexity classes immediately yield oracle separations of their classical counterparts. Such oracle separations are sometimes construed as evidence that the same separation applies to the classes' classical counterparts. At a minimum, oracle separations imply a formal barrier (called the *relativization* barrier [5]) to disproving the corresponding Turing Machine separation.

It is well-known that approximate degree lower bounds imply lower bounds on (even quantum) query complexity. So to summarize, approximate degree lower bounds imply query complexity lower bounds, which in turn often imply oracle separations for classical complexity classes.

ODD-MAX-BIT, Counting, and the Polynomial Hierarchy. An important question in complexity theory is to determine the relative power of alternation (as captured by the polynomial-hierarchy **PH**), and counting (as captured by the complexity class #**P** and its decisional variant **PP**). Both **PH** and **PP** generalize **NP** in natural ways. Toda famously showed that their power is related: $\mathbf{PH} \subseteq \mathbf{P}^{\mathbf{PP}}$ [50].

Beigel [7] was interested in determining how much of the Polynomial Hierarchy is contained in **PP** itself, and he set out to give an oracle separating $\mathbf{P}^{\mathbf{NP}}$ from **PP**. To do so, he introduced the function OMB and observed that OMB is in the query complexity of analog of $\mathbf{P}^{\mathbf{NP}}$ – essentially, the query protocol uses the **NP** oracle to perform a binary search for the largest index i^* such that $x_{i^*} = -1$. Then, to show that OMB is not in the query complexity analog of **PP**, Beigel proved a lower bound on the approximate degree of OMB. (Recall from Section 1.2.2 that in [7] Beigel proved that for any $d > 0$, there is an $\varepsilon \in 1 - 2^{-\Omega(n/d^2)}$ such that $\widetilde{\deg}_{\varepsilon}(\mathrm{OMB}_n) \geq d$).

Thus, Beigel's result separated the query complexity classes $\mathbf{PP}_{\mathsf{query}}$ and $\mathbf{P}^{\mathbf{NP}}_{\mathsf{query}}$, and this in turn implied an oracle separating the classical classes **PP** from $\mathbf{P}^{\mathbf{NP}}$.

An Improved Separation for Query Complexity. Quantitatively, Beigel's analysis implies that $\mathbf{PP}_{\mathsf{query}}(\mathrm{OMB}) = \Omega(n^{1/3})$, and prior to our work, this was the best known separation between $\mathbf{PP}_{\mathsf{query}}(f)$ and $\mathbf{P}^{\mathbf{NP}}_{\mathsf{query}}(f)$ for any function f. We improve on this separation by giving a function F in $\mathbf{P}^{\mathbf{NP}}_{\mathsf{query}}$ such that $\mathbf{PP}_{\mathsf{query}}(F) = \tilde{\Omega}(n^{2/5})$.

Details of the separation. The function F we use to exhibit this improved separation is

$$F := \mathrm{OMB}_{n^{2/5}}(\overline{\mathrm{ED}}_{n^{3/5}}, \ldots, \overline{\mathrm{ED}}_{n^{3/5}}), \tag{4}$$

where $\overline{\mathrm{ED}}$ is the negation of the well-studied Element Distinctness function (due to space constraints, we defer a formal definition of the Element Distinctness function to the full version of the paper). Prior work has shown that $\overline{\mathrm{ED}}_N$ satisfies $\widetilde{\deg}_{+,2/3}(\overline{\mathrm{ED}}_N) = \tilde{\Omega}(N^{2/3})$ [10], so Theorem 1 implies that $\widetilde{\deg}_{+,\varepsilon}(F) = \tilde{\Omega}(n^{2/5})$ even for $\varepsilon = 1 - 2^{-n^{2/5}}$. This in turn implies the claimed lower bound $\mathbf{PP}_{\mathsf{query}}(F) = \tilde{\Omega}(n^{2/5})$. Meanwhile, $\overline{\mathrm{ED}}$ is in $\mathbf{NP}_{\mathrm{query}}$, and hence the same binary search-based $\mathbf{P}^{\mathbf{NP}}_{\mathsf{query}}$ protocol that works for OMB also works for F.

1.3.2 Communication Complexity

Babai, Frankl, and Simon [4] defined the (two-party) communication analogs of many complexity classes from the Turing Machine world. Since their seminal paper, these communication classes have been studied intensely, with the following motivation.

Relationship to Turing Machine Complexity. Just as query complexity separations are sometimes construed as evidence that the same separation applies to the classes' classical counterparts, so too are communication complexity separations. In addition, Aaronson and Wigderson [1] showed that a separation of communication complexity classes implies a formal barrier (called the *algebraization* barrier) to disproving the analogous separation in the Turing Machine world. Their result is analogous to how query complexity separations imply that the relativization barrier applies in the Turing Machine world. Thus, studying $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}$ and $\mathbf{PP}^{\mathbf{cc}}$ sheds additional light on the relationship between their Turing Machine counterparts. These communication classes are also of interest in their own right, as we now explain.

The class $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}$. $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}$ lies near the frontier of our current understanding of communication complexity classes, in that it is one of the most powerful communication models against which we know how to prove lower bounds. This communication class has received considerable attention in recent years: Impagliazzo and Williams [19] were the first to prove lower bounds against this class, and Papakonstantinou et al. [31] characterized the class in terms of limited memory communication models. Göös et al. [18] related $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}$ to various other communication classes near the frontier of understanding.

The class $\mathbf{PP}^{\mathbf{cc}}$. $\mathbf{PP}^{\mathbf{cc}}$ captures the difficulty of computing functions to small-bias, and it turns out to be characterized by an important combinatorial quantity known as *discrepancy* [22]. Motivated in part by this characterization, $\mathbf{PP}^{\mathbf{cc}}$ has received intense study (cf. [40, 39, 8, 18, 22, 29, 48] and many others).

An improved separation between $\mathbf{PP}^{\mathbf{cc}}$ and $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}$. Buhrman, Vereshchagin, and de Wolf [8] gave the first separation between $\mathbf{PP}^{\mathbf{cc}}$ and $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}$.[6] Specifically, they "lifted" Beigel's query complexity lower bound for OMB to the communication setting, showing that a certain communication problem G derived from OMB satisfies $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}(G) = O(\log^2 n)$, but $\mathbf{PP}^{\mathbf{cc}}(G) = \Omega(n^{1/3})$. Prior to our work, this was the best separation between these two communication classes.

We improve on this separation. By applying Sherstov's pattern matrix method [40] to the function F of Eq. (4), we obtain a communication problem F' that satisfies $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}(F') = O(\log^2 n)$, but $\mathbf{PP}^{\mathbf{cc}}(F') = \tilde{\Omega}(n^{2/5})$.

An improved separation between $\mathbf{PP}^{\mathbf{cc}}$ and $\mathbf{UPP}^{\mathbf{cc}}$ for an $\mathbf{AC}^{\mathbf{0}}$ function. Buhrman et al.'s function G also exhibited the first separation between $\mathbf{PP}^{\mathbf{cc}}$ and a related communication class called $\mathbf{UPP}^{\mathbf{cc}}$, which captures the difficulty of computing f to strictly positive bias (Sherstov [37] independently separated these two classes). In more detail, the function G used by Buhrman et al. satisfies $\mathbf{UPP}^{\mathbf{cc}}(G) = O(\log n)$, while $\mathbf{PP}^{\mathbf{cc}}(G) = \Omega(n^{1/3})$, and until our work this remained the best known separation between $\mathbf{PP}^{\mathbf{cc}}$ and $\mathbf{UPP}^{\mathbf{cc}}$ for any function in AC^0. Our communication problem F' improves on this separation, giving a function F' in AC^0 satisfying $\mathbf{UPP}^{\mathbf{cc}}(F') = O(\log n)$, but $\mathbf{PP}^{\mathbf{cc}}(F') = \tilde{\Omega}(n^{2/5})$.

To further motivate this application, we mention that $\mathbf{PP}^{\mathbf{cc}}$ is characterized not only by discrepancy, but also by the learning-theoretic notion of *margin complexity* [29, 28], while $\mathbf{UPP}^{\mathbf{cc}}$ is characterized by the notion of *dimension complexity* [33]. Both margin complexity

[6] Buhrman et al. framed their result as an exponential separation between the $\mathbf{PP}^{\mathbf{cc}}$ and a related class called $\mathbf{UPP}^{\mathbf{cc}}$. As pointed out in subsequent work [18], their result also separates $\mathbf{P}^{\mathbf{NP}^{\mathbf{cc}}}$ and $\mathbf{PP}^{\mathbf{cc}}$.

and dimension complexity underly state-of-the-art learning algorithms for constant-depth circuits in a variety of learning models (for details, see [24, 35, 10, 40, 23] and the references therein). Separating these two quantities sheds light on the relative power of these algorithms.

1.3.3 Roadmap for the Rest of the Paper

We introduce notation and establish preliminary lemmas in Section 2. Section 3 provides an intuitive overview of the dual witness we construct to prove Theorem 1, before providing proof details. In the full version of the paper, we collect formal definitions of approximate degree and its one-sided variants, along with their dual characterizations, and formalize our applications to query and communication complexity.

2 Notation and Preliminary Facts

Given a set $T \subseteq \{-1,1\}^N$, we let $\mathbb{I}_T$ denote the indicator vector of T; that is, $\mathbb{I}_T(x) = 1$ if $x \in T$, and $\mathbb{I}_T(x) = 0$ otherwise. Given a dual polynomial $\psi : \{-1,1\}^N \to \mathbb{R}$, we define the L_1-*weight* of T under ψ to be $W_\psi(T) = \sum_{x \in T} |\psi(x)|$. We use the standard notation $\|\psi\|_1 := W_\psi(\{-1,1\}^N)$, and refer to $\|\psi\|_1$ as the L_1-*norm* of ψ. Define the function $\widetilde{\mathsf{sgn}} : \mathbb{R} \to \{-1,0,1\}$ via: $\widetilde{\mathsf{sgn}}(t) = 1$ if $t > 0$, $\widetilde{\mathsf{sgn}}(t) = -1$ if $t < 0$, and $\widetilde{\mathsf{sgn}}(t) = 0$ if $t = 0$. We say that a dual polynomial ψ for a function f *makes an error* on input x if $0 \neq \widetilde{\mathsf{sgn}}(\psi(x)) \neq \widetilde{\mathsf{sgn}}(f(x))$.

Crucial to our proof are the following two facts that provide methods of combining multiple dual witnesses while preserving their pure high degree.

▶ **Fact 7.** *If $\psi_1, \psi_2 : \left(\{-1,1\}^N\right)^M \to \{-1,1\}$ both have pure high degree d, then so does $\psi_1 + \psi_2$.*

▶ **Fact 8.** *Suppose that $\psi_1, \ldots, \psi_M : \{-1,1\}^N \to \{-1,1\}$ are each defined over disjoint sets of variables, and there is some i such that ψ_i has pure high degree d. Then so does the function $\psi : \left(\{-1,1\}^N\right)^M \to \{-1,1\}$ defined via $\psi(x_1, \ldots, x_M) = \prod_{i=1}^M \psi_i(x_i)$.*

3 Proof of Theorem 1

This section proves Theorem 1, which we restate here for the reader's convenience. Recall from the introduction that for any Boolean function $f : \{-1,1\}^N \to \{-1,1\}$, F denotes the function $\mathrm{OMB}_M(f, \ldots, f)$ that maps $\{-1,1\}^{M \cdot N}$ to $\{-1,1\}$.

▶ **Theorem 1** (restated). *If $\widetilde{deg}_{+,2/3}(f) \geq d$, then $\widetilde{deg}_{+,\varepsilon}(F) \geq d$ for $\varepsilon = 1 - 2^{-M}$*

Proof. Let ψ_{in} denote a dual witness for the fact that $\widetilde{\deg}_{+,2/3}(f) \geq d$, normalized to ensure that its L_1-norm is 1. Recall from Section 1.2.1 that ψ_{in} satisfies three properties: (a) ψ_{in} has pure high degree at least d, (b) ψ_{in} has correlation $\varepsilon' \geq 2/3$ with f, and (c) ψ_{in} has positive one-sided error for f, i.e., $\psi_{\text{in}}(x_i) \geq 0$ for all $x_i \in f^{-1}(+1)$. Let E denote the set of all $x_i \in \{-1,1\}^N$ on which $\psi_{\text{in}}(x_i)$ is in error, i.e., $0 \neq \widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_i)) \neq \widetilde{\mathsf{sgn}}(f(x_i))$.

Proof Overview. For any vector $x = (x_1, \ldots, x_M) \in \left(\{-1,1\}^N\right)^M$, we think of x_M as the "most significant" block in x, because if $f(x_M) = -1$, then F evaluates to -1 regardless of the values of the other blocks $x_1, \ldots, x_{M-1}$. Similarly, we think of x_1 as the "least significant block" of x.

We think of our dual witness ψ_{comb} as being constructed iteratively. The first iteration creates a dual witness $\psi^{(1)}$ that "uses" the least significant block x_1 to "achieve" pure high

degree at least d. That is, $\psi^{(1)}$ will be uncorrelated with any polynomial p, unless the degree of p is at least d *even when restricted to the variables in the first block*. However, $\psi^{(1)}$ will only have correlation ε' with F, and hence it will make errors if $\varepsilon' < 1$. The second iteration creates a dual witness $\psi^{(2)}_{\text{comb}} = \psi^{(1)} + \psi^{(2)}$, where $\psi^{(2)}$ is a correction term that zeros out there errors of $\psi^{(1)}$. Moreover, $\psi^{(2)}$ will use the second block x_2 to achieve pure high degree at least d. By Fact 7, this ensures that $\psi^{(2)}_{\text{comb}}$ also has pure high degree at least d.

If $\psi^{(2)}$ zeroed out all of the errors of $\psi^{(1)}$ without introducing any new errors, then $\psi^{(2)}_{\text{comb}}$ would have perfect correlation with F, and we would be done. Unfortunately, $\psi^{(2)}$ does introduce new errors. But we have made tangible progress: we show that the number of errors $\psi^{(2)}$ makes, relative to $\psi^{(1)}$, falls by a factor of $W_{\psi_{\text{in}}}(f^{-1}(+1))/W_{\psi_{\text{in}}}(E) = \varepsilon'/(1-\varepsilon')$. Since $\varepsilon' \geq 2/3$, we conclude that $\varepsilon'/(1-\varepsilon') \geq 2$, and hence that $\psi^{(2)}$ makes at most half as many errors as $\psi^{(1)}$.

In general, the ith iteration adds in a correction term $\psi^{(i)}$ that zeros out all of the errors of the dual witness $\psi^{(i-1)}_{\text{comb}}$ constructed in the previous iteration. $\psi^{(i)}$ will use the ith input block x_i to achieve pure high degree at least d, and will introduce at most a $W_{\psi_{\text{in}}}(E)/W_{\psi_{\text{in}}}(f^{-1}(+1)) \leq 1/2$ fraction of the errors made by $\psi^{(i-1)}$. At the end of iteration M, we have constructed a dual witness $\psi_{\text{comb}} := \sum_{i=1}^{M} \psi^{(i)}$ that makes only a $\big(W_{\psi_{\text{in}}}(E)/W_{\psi_{\text{in}}}(f^{-1}(+1))\big)^M = ((1-\varepsilon')/\varepsilon')^M \leq 2^{-M}$ fraction of the errors made by $\psi^{(1)}$, and we are done.

Proof Details. Throughout, we assume without loss of generality that M is odd (we only exploit this assumption in the proof of Lemma 17, which shows that ψ_{comb} has positive one-sided error for F).

Properties of ψ_{in}. Throughout, we let $Q^-, Q^+ \subseteq \{-1,1\}^N$ denote the set of inputs x_i for which $\psi_{\text{in}}(x_i) < 0$ and $\psi_{\text{in}}(x_i) > 0$ respectively. We assume $d \geq 1$, as otherwise Theorem 1 holds trivially. We make use of the following simple facts about $\mathbb{I}_{Q^+}$ and $\mathbb{I}_{Q^-}$.

▶ **Fact 9.** $\sum_{x_i \in \{-1,1\}^N} \mathbb{I}_{Q^-}(x_i) \cdot |\psi_{in}(x_i)| = \sum_{x_i \in \{-1,1\}^N} \mathbb{I}_{Q^+}(x_i) \cdot |\psi_{in}(x_i)| = 1/2$.

Proof. Since ψ_{in} witnesses the fact that $\widetilde{\deg}_{+,1/2}(f) \geq d$, ψ_{in} has pure high degree at least $d \geq 1$. In particular, ψ_{in} is uncorrelated with any constant function. Hence, $\sum_{x_i \in \{-1,1\}^N} \psi_{\text{in}}(x_i) = 0$. Since $\sum_{x_i \in \{-1,1\}^N} |\psi_{\text{in}}(x_i)| = 1$, it follows that $\sum_{x_i \in \{-1,1\}^N : x_i \in Q^+} |\psi_{\text{in}}(x_i)| = \sum_{x_i \in \{-1,1\}^N : x_i \in Q^-} |\psi_{\text{in}}(x_i)| = 1/2$, which is equivalent to what we wished to prove. ◀

A crucial implication of the fact that ψ_{in} has positive one-sided error is that if ψ_{in} outputs a negative value on input x_i, we can "trust" that $f(x_i) = -1$. This is formalized as follows.

▶ **Fact 10.** *For all $x_i \in Q^-$, it holds that $f(x_i) = -1$. Equivalently, $E \subseteq f^{-1}(-1)$, or in other words $E \cap f^{-1}(+1) = \emptyset$.*

The following two facts relate the correlation of ψ_{in} with f to the L_1-weight of the sets E and $f^{-1}(+1)$ under ψ_{in}.

▶ **Fact 11.** $W_{\psi_{in}}(E) = (1-\varepsilon')/2$.

Proof. By Property (a), $\varepsilon' = \sum_{x_i \in \{-1,1\}^N} \psi_{\text{in}}(x_i) \cdot f(x_i) = 1 - 2\sum_{x_i \in E} |\psi_{\text{in}}(x_i)|$. ◀

▶ **Fact 12.** $W_{\psi_{in}}(f^{-1}(+1)) = \varepsilon'/2$.

Proof. This holds by the following sequence of equalities:

$$1/2 = \sum_{x_i \in Q^+} |\psi_{\text{in}}(x_i)| = \sum_{x_i \in E} |\psi_{\text{in}}(x_i)| + \sum_{x_i \in f^{-1}(+1)} |\psi_{\text{in}}(x_i)| = (1/2 - \varepsilon'/2) + \sum_{x_i \in f^{-1}(+1)} |\psi_{\text{in}}(x_i)|.$$

The first equality holds by Fact 9, the second because ψ_{in} satisfies Property (c), and the third by Fact 11. ◀

Construction of ψ_{comb}. The dual witness we construct is:

$$\psi_{\text{comb}}(x_1, \ldots, x_M) = \sum_{i=1}^{M} \psi^{(i)}, \text{ where} \tag{5}$$

$$\psi^{(i)} = (-1)^{i-1} \cdot (2/\varepsilon')^{M-1} \left(\prod_{j<i} \mathbb{I}_E(x_j) \cdot |\psi_{\text{in}}(x_j)| \right) \cdot \psi_{\text{in}}(x_i) \cdot \left(\prod_{j=i+1}^{M} \mathbb{I}_{f^{-1}(+1)}(x_j) \cdot |\psi_{\text{in}}(x_j)| \right). \tag{6}$$

Recall that, to show that ψ_{comb} is a dual witness for the property $\widetilde{\deg}_{+,\varepsilon}(F) \geq d$ for $\varepsilon = 1 - 2^{-M}$, it suffices to establish three properties of ψ_{comb} (cf. Section 1.2.1): (a) it must have pure high degree at least d, (b) it must satisfy $\sum_{x \in (\{-1,1\}^N)^M} \psi_{\text{comb}}(x) \cdot F(x) \geq \|\psi\|_1 \cdot \varepsilon$, where $\|\psi\|_1 = \sum_{(x \in \{-1,1\}^N)^M} |\psi_{\text{comb}}(x)|$, and (c) it must have positive one-sided error. We establish each in turn below, in Propositions 13, 14, and 17.

▶ **Proposition 13.** *ψ_{comb} has pure high degree at least d.*

Proof. Since ψ_{in} has pure high degree at least d, Fact 8 implies that each term $\psi^{(i)}$ in the sum within Eq. (5) also has pure high degree at least d. The lemma then follows by Fact 7. ◀

▶ **Proposition 14.** $\sum_{x \in (\{-1,1\}^N)^M} \psi_{comb}(x) \cdot F(x) \geq \|\psi\|_1 \cdot \varepsilon$.

The proof of Proposition 14 will make use of the following two lemmas.

▶ **Lemma 15.** $\|\psi\|_1 \geq 1/2$.

Proof. Consider the set $S = \{(x_1, \ldots, x_M) : x_1 \in Q^- \text{ and } x_2, \ldots, x_M \in f^{-1}(+1)\}$. We claim that the weight, $W_{\psi_{\text{comb}}}(S)$, that ψ_{comb} places on the set S is $1/2$. The lemma clearly follows.

To see this, fix $x = (x_1, \ldots, x_M) \in S$. We first note that for all $i \geq 2$, $\psi^{(i)}(x) = 0$. Indeed, $Q^- \cap E = \emptyset$ (cf. Fact 10), and hence $\mathbb{I}_E(x_1) = 0$. Thus, it is immediate from Eq. (6) that $\psi^{(i)}(x) = 0$ for $i \geq 2$.

So it suffices to show that $\sum_{x \in S} -\psi^{(1)}(x) \geq 1/2$. This follows from the following calculation:

$$\sum_{x \in S} -\psi^{(1)}(x) = (2/\varepsilon')^{M-1} \cdot \left(\sum_{x_1 \in Q^-} -\psi_{\text{in}}(x_1) \right) \cdot \left(\prod_{j=2}^{M} \left(\sum_{x_j \in \{-1,1\}^N} \mathbb{I}_{f^{-1}(+1)}(x_j) \cdot |\psi_{\text{in}}(x_j)| \right) \right)$$

$$= (2/\varepsilon')^{M-1} \cdot (1/2) \cdot \prod_{j=2}^{M} (\varepsilon'/2) = 1/2,$$

where the first equality holds by Eq. (6), and the second holds by Facts 9 and 12. ◀

▶ **Lemma 16.** *Let $E_{comb} \subseteq \left(\{-1,1\}^N\right)^M$ denote the set of inputs on which ψ_{comb} makes an error, i.e., $0 \neq \widetilde{\mathsf{sgn}}(\psi_{comb}(x)) \neq \widetilde{\mathsf{sgn}}(F(x))$. Let $E^M \subseteq \left(\{-1,1\}^N\right)^M$ denote $\{(x_1,\ldots,x_M) : x_i \in E \text{ for all } i\}$. Then $E_{comb} = E^M$.*

Proof. We first show that $E^M \subseteq E_{\text{comb}}$ before showing that $E_{\text{comb}} \subseteq E^M$. Suppose that $x = (x_1,\ldots,x_M) \in E^M$. Fact 10 states that $E \subseteq f^{-1}(-1)$, and hence $\mathbb{I}_{f^{-1}(+1)}(x_M) = 0$. It is then immediate from Eq. (6) that $\psi^{(i)}(x) = 0$ for all $i < M$. Meanwhile, by Eq. (6) it holds that

$$\widetilde{\mathsf{sgn}}(\psi^{(M)}(x)) = (-1)^{M-1} \cdot \widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_M)) = (-1)^{M-1}.$$

Here, we used the fact that $\widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_M)) > 0$ if $x_M \in E$. (To see this, note that since $x_M \in E$, it holds that $0 \neq \widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_M)) \neq f(x_M) = -1$, where the final equality holds because $E \subseteq f^{-1}(-1)$.) At the same time,

$$F(x) = \text{OMB}_M(-1,-1,\ldots,-1) = (-1)^M.$$

Thus, $x \in E_{\text{comb}}$ as claimed.

Fix any $x = (x_1,\ldots,x_M) \in \left(\{-1,1\}^N\right)^M$ such that there exists an $i \in \{1,\ldots,M\}$ satisfying $x_i \notin E$. To show that $E_{\text{comb}} \subseteq E^M$, we must show that $x \notin E_{\text{comb}}$. To this end, let i^* be the smallest coordinate such that $x_{i^*} \notin E$. It is clear that $\psi_{\text{comb}}(x) = 0$ if $\psi_{\text{in}}(x_i) = 0$ for any $i \in [M]$, and hence $x \notin E_{\text{comb}}$. So assume throughout that $\psi_{\text{in}}(x_i) \neq 0$ for all i. The proof proceeds via a case analysis.

- Case 1: There exists a $j > i^*$ such that $x_j \notin f^{-1}(+1)$. In this case, $\mathbb{I}_{f^{-1}(+1)}(x_j) = 0$, so it is immediate from Eq. (6) that $\psi^{(k)}(x) = 0$ for all $k < j$. Meanwhile, since $\mathbb{I}_E(x_{i^*}) = 0$, it is immediate from Eq. (6) that $\psi^{(k)}(x) = 0$ for all $k \geq j$. Thus, $\psi_{\text{comb}}(x) = \sum_{k=0}^{M} \psi^{(k)}(x) = 0$, implying that $x \notin E_{\text{comb}}$.
- Case 2: $i^* = 1$, and $x_j \in f^{-1}(+1)$ for all $j > i^*$. In this case, it is clear by Eq. (6) that

$$\widetilde{\mathsf{sgn}}(\psi^{(1)}(x)) = (-1)^0 \cdot \widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_1)) = \widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_1)) = \widetilde{\mathsf{sgn}}(f(x_1)) = F(x_1,\ldots,x_M). \quad (7)$$

  Here, the third equality holds because $x_1 \notin E$, and the fourth equality exploits the fact that if $x_j \in f^{-1}(+1)$ for all $j > 1$, then $F(x) = f(x_1)$.
  Meanwhile, since $x_1 \notin E$, it holds that $\mathbb{I}_E(x_1) = 0$, and so it is clear by Eq. (6) that $\psi^{(k)}(x) = 0$ for all $k \geq 2$. Combining this with Eq. (7), we conclude that $\widetilde{\mathsf{sgn}}(\psi_{\text{comb}}(x)) = \widetilde{\mathsf{sgn}}(\psi^{(1)}(x)) = F(x_1,\ldots,x_M)$. Thus, $x \notin E_{\text{comb}}$.
- Case 3: $i^* \geq 2$, and $x_j \in f^{-1}(+1)$ for all $j > i^*$. First, we argue that $\psi^{(k)} = 0$ for all $k < i^* - 1$. Indeed, for all such k, $x_{k+1} \in E \subseteq f^{-1}(-1)$ (cf. Fact 10), and so it holds that $\mathbb{I}_{f^{-1}(+1)}(x_{k+1}) = 0$. Hence, it is immediate from Eq. (6) that $\psi^{(k)}(x) = 0$.
  Next, we argue that $\psi^{(k)} = 0$ for all $k \geq i^* + 1$. Indeed, $x_{i^*} \notin E$, so $\mathbb{I}_E(x_{i^*}) = 0$. It is then immediate from Eq. (6) that $\psi^{(k)}(x) = 0$ for all $k \geq i^* + 1$.
  Finally, we claim that either $\psi^{(i^*-1)}(x) + \psi^{(i^*)}(x) = 0$ or $\widetilde{\mathsf{sgn}}(\psi^{(i^*-1)}(x) + \psi^{(i^*)}(x)) = F(x)$. This follows from the following calculation.
  - Case 3a: Suppose $x_{i^*} \notin f^{-1}(+1)$, i.e., that $\mathbb{I}_{f^{-1}(+1)}(x_{i^*}) = 0$. Then is clear from Eq. (6) that $\psi^{(i^*-1)}(x) = 0$. Meanwhile, since $x_{i^*} \notin E$, it is clear from Eq. (6) that

$$\widetilde{\mathsf{sgn}}(\psi^{(i^*)}(x)) = (-1)^{i^*-1} \cdot \widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_{i^*})) = (-1)^{i^*-1} \cdot f(x_{i^*}) = F(x),$$

    where the final equality exploits the fact that if $x_j \in f^{-1}(+1)$ for all $j > i^*$, and $x_{i^*-1} \in E \subseteq f^{-1}(-1)$ (Fact 10), then $F(x) = (-1)^{i^*-1} \cdot f(x_{i^*})$.

- Case 3b: Suppose $x_{i^*} \in f^{-1}(+1)$. We claim that it holds that $\psi^{(i^*-1)}(x) = -\psi^{(i^*)}(x)$. To see this, note that in this case

$$\psi^{(i^*-1)}(x) = (-1)^{i^*-2} \cdot (2/\varepsilon')^{M-1} \cdot \psi_{\text{in}}(x_{i^*-1}) \cdot \prod_{j \neq i^*-1} |\psi_{\text{in}}(x_j)|, \text{ and} \tag{8}$$

$$\psi^{(i^*)}(x) = (-1)^{i^*-1} \cdot (2/\varepsilon')^{M-1} \cdot \psi_{\text{in}}(x_{i^*}) \cdot \prod_{j \neq i^*} |\psi_{\text{in}}(x_j)|. \tag{9}$$

  Both of the above quantities are clearly equal in absolute value, but it remains to show that $\psi^{(i^*-1)}(x) = -\psi^{(i^*)}(x)$. Since $x_{i^*-1} \in E \subseteq f^{-1}(-1)$ (Fact 10), it holds that $\widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_{i^*-1})) = +1$. Meanwhile, since $x_{i^*} \notin E$, $\widetilde{\mathsf{sgn}}(\psi_{\text{in}}(x_{i^*})) = f(x_{i^*}) = +1$. Hence, $\widetilde{\mathsf{sgn}}(\psi^{(i^*-1)}(x)) = (-1)^{i^*-2}$, while $\widetilde{\mathsf{sgn}}(\psi^{(i^*)}(x)) = (-1)^{i^*-1}$, completing the proof.

Combining all of the above, we conclude that $\psi_{\text{comb}}(x) = \sum_{j=1}^{M} \psi_{\text{comb}}^{(j)}(x) = \psi_{\text{comb}}^{(i^*-1)}(x) + \psi_{\text{comb}}^{(i^*)}(x)$, and the latter expression is either equal to 0 or agrees in sign with $F(x)$. Thus, $x \notin E_{\text{comb}}$. This completes the proof of Lemma 16. ◀

Proof of Proposition 14. Note that

$$\begin{aligned}\sum_{x \in (\{-1,1\}^N)^M} \psi_{\text{comb}}(x) \cdot F(x) &= \sum_{x \in (\{-1,1\}^N)^M} |\psi_{\text{comb}}(x)| - 2 \sum_{x \in E_{\text{comb}}} |\psi_{\text{comb}}(x)| \\ &= \|\psi\|_1 - 2 \sum_{x \in E_{\text{comb}}} |\psi_{\text{comb}}(x)|, \end{aligned} \tag{10}$$

where we recall from Lemma 16 that $E_{\text{comb}} = E^M$ is the set of points on which ψ_{comb} makes an error. Observe that for each j:

$$\sum_{x \in E^M} \psi^{(j)}(x) \leq (2/\varepsilon')^{M-1} \prod_{i=1}^{M} \left(\sum_{x_i \in E} |\psi_{\text{in}}(x_i)| \right) \leq (2/\varepsilon')^{M-1} \cdot \prod_{i=1}^{M} ((1-\varepsilon')/2) \leq 3^{M-1}/6^M < 2^{-M-1} \tag{11}$$

Here, the first equality holds because, for all $x \in E^M$ and $j < M$, $\psi^{(j)}(x) = 0$; this follows by combining Eq. (6) with the fact that $E \cap f^{-1}(+1) = \emptyset$ (Fact 10) (see also the $E^M \subseteq E_{\text{comb}}$ direction in the proof of Lemma 16). The second inequality holds by Fact 11, and the third because $\varepsilon' \geq 2/3$. Combining Lemma 15 with Eq. (10) and Eq. (11), we conclude that $\sum_{x \in (\{-1,1\}^N)^M} \psi_{\text{comb}}(x) \cdot F(x) \geq \|\psi\|_1 - 2^{-M-1} \geq \|\psi\|_1 (1 - 2^{-M})$, completing the proof. ◀

▶ **Proposition 17.** *$\psi_{comb}(x) \geq 0$ for all $x \in F^{-1}(+1)$.*

Proof. Lemma 16 implies that the set E_{comb} on which ψ_{comb} makes an error is equal to E^M. Since $E \subseteq f^{-1}(-1)$ (cf. Fact 10), and we assumed that M is odd, it is obvious from the definition of F that $E^M \subseteq F^{-1}(-1)$. It follows that ψ_{comb} makes no errors on $F^{-1}(+1)$, implying the proposition. ◀

Theorem 1 follows from Propositions 13, 14, 17 and the dual characterization of $\widetilde{\deg}_{+,\varepsilon}$. ◀

Abstract

In this paper we study graph problems in dynamic streaming model, where the input is defined by a sequence of edge insertions and deletions. As many natural problems require $\Omega(n)$ space, where n is the number of vertices, existing works mainly focused on designing $\tilde{O}(n)$ space algorithms. Although sublinear in the number of edges for dense graphs, it could still be too large for many applications (e.g. n is huge or the graph is sparse). In this work, we give single-pass algorithms beating this space barrier for two classes of problems. We present $o(n)$ space algorithms for estimating the number of connected components with additive error εn and $(1+\varepsilon)$-approximating the weight of minimum spanning tree. The latter improves previous $\tilde{O}(n)$ space algorithm given by Ahn et al. (SODA 2012) for connected graphs with bounded edge weights. We initiate the study of approximate graph property testing in the dynamic streaming model, where we want to distinguish graphs satisfying the property from graphs that are ε-far from having the property. We consider the problem of testing k-edge connectivity, k-vertex connectivity, cycle-freeness and bipartiteness (of planar graphs), for which, we provide algorithms using roughly $\tilde{O}(n^{1-\varepsilon})$ space, which is $o(n)$ for any constant ε. To complement our algorithms, we present $\Omega(n^{1-O(\varepsilon)})$ space lower bounds for these problems, which show that such a dependence on ε is necessary.

1 Introduction

Graphs or networks are a natural way to describe structural information. For example, users of Facebook and the acquaintance relations among them form a social network, the proteins together with interactions between them define a biological network, and web-pages and hyperlinks give rise to a huge web graph. Due to the rapid development of information technology, many such graphs become extremely large, and are constantly changing, which poses great challenges for analyzing their structures. Over the last decade, the data stream model [34] has proven to be successful in dealing with *big data*. In this model, the algorithm should make only one pass (or a few passes) over the stream, and use sublinear working space. The time required to output the final answer and process each element is also important. There is a growing body of work studying graph problems over data streams. Graph streams

were first considered by Henzinger et al. [24], and later have been extensively studied in the *insertion-only* model (eg., [17, 18, 34]), where there is no edge deletion in the stream. Recently, starting from the seminal works of Ahn, Guha and McGregor [2, 3], the interest has shifted to the *dynamic streaming model*, where the edges can be both inserted and deleted (see eg., [28, 29, 1, 5, 9, 10, 7, 31, 6, 33, 15, 23]). In this setting, most algorithms designed are linear sketch-based, which is also an effective technique for processing distributed graphs. For more information about graph streaming algorithms see the recent survey by McGregor [32].

For graph streams, both insertion-only and dynamic, the research in the past has mostly focused on the *semi-streaming model*, in which the algorithms are allowed to use $\tilde{O}(n)$ space, where n is the number vertices in the graph. (For notational convenience, we will use $\tilde{O}(g)$ and $\tilde{\Omega}(g)$ to hide $\operatorname{poly}\log(g)$ factors.) The reason behind this is that even in the insertion-only model, many natural graph problems require $\Omega(n)$ space (e.g. testing if the graph is connected [18]). Note that the allowed space in semi-streaming model is sublinear in the input size as the number of edges of the graph might be as large as $\Omega(n^2)$. However, in many real applications n is huge and the input graph is already very sparse, an $\tilde{O}(n)$ algorithm might be even worse than just storing all the edges. From this perspective, one may naturally ask the question *which kind of problems can be solved with even less space, i.e., $o(n)$ space.*

To the best of our knowledge, very few results are known in this direction. Chitnis et al. [10] and Fafianie and Kratsch [16] introduced parameterized graph stream algorithms which may only use $o(n)$ space with some promise of the size of the solution. This parameterized setting has been further investigated in [9]. In addition, it has been shown that the size of the maximum matching can be approximated within constant factor in $\tilde{O}(n^{4/5})$ space for graphs with bounded arboricity [14, 9, 7].

In this paper, we study two classes of graph problems that admit single-pass $o(n)$ space algorithms in the dynamic streaming model. The first class contains the problems of estimating the number of connected components and the weight of minimum spanning tree (MST). We show that one can estimate the number of connected components within an *additive* error of εn with $o(n)$ space and post-processing time, for any small constant $\varepsilon > 0$. We also present an algorithm to $(1+\varepsilon)$-approximate the weight of MST with $o(n)$ space and post-processing time for connected graphs with bounded edge weights, which improves the best known algorithm with $\tilde{O}(n)$ space in the same setting given by Ahn et al. [2]. It is worthy noting that the problem of estimating the number of connected components within small *multiplicative* error requires $\Omega(n)$ space, as it is generally harder than the problem of (exactly) testing graph connectivity; and that estimating the weight of MST for graphs with arbitrarily large edge weights (e.g., $\Omega(\log n)$) requires $\Omega(n)$ space (see Theorem 12). Previously these two problems have been studied in the framework of *sublinear time algorithms* (see eg. [8, 39]).

The second class consists of problems that are relaxations of deciding graph properties. Given a huge graph, it is very useful to know whether the graph has some predetermined property, such as k-connectivity, bipartiteness, cycle-freeness and etc., which provide valuable information about the graph. However, besides the requirement of $\Omega(n)$ space, exactly testing of these properties sometimes is a too strong requirement for analyzing highly dynamic graphs, since the answer may change in the next second due to an insertion or deletion of a single edge. In this paper, we initiate the study of *approximate graph property testing* in the dynamic streaming model: we want to test whether a graph satisfies some property or one has to modify a small constant fraction of edges to make it have the property. This notion of approximation is adapted from the framework of *property testing* [21, 22, 36], and a large number of existing literatures have given efficient testing algorithms (called *testers*) for many properties under different query models (see surveys [20, 38]). We show that some

Table 1 Upper and lower bounds of streaming testers.

	Space $\tilde{O}$	Space lower bound Ω
Connectivity	$n^{1-\varepsilon}$	$n^{1-8\varepsilon}$
k-edge connectivity	$k^{1+\varepsilon} \cdot n^{1-\varepsilon}$	
k-vertex connectivity	$\frac{k^{1+\varepsilon/4}}{\varepsilon} \cdot n^{1-\varepsilon/4}$	
Cycle-freeness	$n^{1-\varepsilon+\varepsilon^2}$	$n^{1-8\varepsilon}$
Bipartiteness of planar graphs	$n^{1-\Omega(\varepsilon^2)}$	$n^{1-4\varepsilon}$

fundamental properties can be tested in both $o(n)$ space and post-processing time in the dynamic streaming model and we also present close lower bounds for these problems which hold even in the insertion-only model. We remark that McGregor [32] also suggested to study the (approximate) property testers in graph streaming model, and asked whether more space-efficient algorithms exist for these problems, and we thus give affirmative answer to this question.

1.1 Our results

Now we formally state our main results. Our results regarding estimating the number of connected components and the MST weight are as follows.

- **Estimating the number of connected components.** We present a dynamic streaming algorithm that estimates the number of connected components within additive error εn in $\tilde{O}(n^{1-\varepsilon+\varepsilon^{q+1}})$ space and post-processing time for any constant $q \geq 1$. We note that a lower bound of $\Omega(n^{1-O(\varepsilon)})$ for this problem follows from the work [41].
- **Estimating the weight of minimum spanning tree (MST).** In this problem, we want to estimate the weight of the MST of a graph with edge weights in the set $\{1, 2, \cdots, W\}$. We give a dynamic streaming algorithm that computes a $(1+\varepsilon)$-approximation of the MST weight and uses space and post-processing time $\tilde{O}(Wn^{1-\frac{\varepsilon}{W-1}+\frac{\varepsilon^t}{(W-1)^t}})$ for any constant $t \geq 1$. By an argument in [8], the result can be extended to non-integral weights, as long as the ratio between the largest and the smallest weight is bounded. A space lower bound of $\Omega(n^{1-\frac{4\varepsilon}{W-1}})$ is shown for this problem.

We also present approximate testing algorithms for a number of fundamental graph properties. Before stating the performance of these algorithms, we first introduce some definitions. Given a graph property Π, an m-edge graph G is called *ε-far from having* Π if one has to modify more than εm edges of G to get a graph G' satisfying Π. This distance definition is adapted from [36] and is most suitable for general graphs where neither edge density nor maximum degree is restricted. We call an algorithm a *(dynamic) streaming tester* for Π, if it makes a single-pass over a stream of edge insertions and deletions, with probability at least $2/3$, accepts any graph satisfying Π, and rejects any graph that is ε-far from having Π.

We give sketch-based streaming testers for properties of being connected, k-edge connected, k-vertex connected, cycle-freeness and bipartite (for planar graphs). The performance of our testers are summarized in Table 1. We stress that most of our testers have (asymptotically) the same post-processing time as the space they used except for testing k-edge connectivity when $k \geq \Omega(n^{\varepsilon/(1+\varepsilon)})$ and k-vertex connectivity when $k \geq \Omega(n^{\varepsilon/(4+\varepsilon)})$.

1.2 Our techniques

To estimate the number of connected components with small additive error εn, we note that it is sufficient to estimate the number $\mathrm{scc}(G)$ of connected components of small size (i.e., $O(1/\varepsilon)$), since the number of components of size larger than this is at most $O(\varepsilon n)$ (see also [8]). To estimate $\mathrm{scc}(G)$, the following vertex sampling framework is used: we sample a sufficient large set of vertices S by sampling each vertex in G with some probability p, and then use the statistics of the sampled connected components of the original graph to estimate $\mathrm{scc}(G)$. For any small connected component C in G, it is likely that all the vertices in C will be sampled out. Conditioned on this, we add $1/p^{|C|}$ to our final estimator, which is the reciprocal of the probability that C is entirely sampled out. Now the task is then to identify which subsets of S are connected components in the original graph. A trivial way is to check all subsets of S, which takes too much time. A more efficient way is to only check all the connected components in $G[S]$, since a sampled component of G must also form a component in $G[S]$. We carefully use a set of linear sketches to do this. More specifically, we first recover all connected components in $G[S]$ by invoking a sketch-based streaming algorithm given in [2], which only needs space near-linear in $|S|$. Then we use (different) linear sketches to check if any of these components is indeed a connected component of the original graph. We remark that the first set of linear sketches of a vertex v sketch its neighborhood information in $G[S]$, while the second set sketch its neighborhood information in G. Our $o(n)$ space streaming algorithm for $(1+\varepsilon)$-approximating the weight of MST follows via a connection between the number of connected components and the weight of MST established in [8].

To give testers for some graph property Π in dynamic streaming model, we start from the observation that if a graph G is far from having Π, then typically, there exist many small disjoint subgraphs, each of which is a witness that the graph G does not satisfy Π. (For example, if Π is connectivity, then there exists at least $\Omega(\varepsilon m)$ connected components of size at most $O(1/\varepsilon)$ in a graph that is ε-far from being connected.) This implies that by sampling a sufficient large set of vertices, with high probability, one of such subgraphs will be entirely sampled. Checking which vertices form a witness of the original graph can then be done by using the aforementioned framework. Different sketches will be used for testing different properties.

To prove lower bounds for our studied problems, we give reductions from *Boolen Hidden Hypermatching (BHH)* problem that was studied in [41]. Our reductions share similarity with the reduction in [41] to the cycle-counting problem and the reductions in [27, 30] to the approximate max-cut problem.

1.3 Related work

Ahn et al. [2] initiated the study of graph sketches, and gave dynamic semi-streaming algorithms for computing a spanning forest (which can be used to count the exact number of connected components), and $(1+\varepsilon)$-approximate the weight of MST. They also proposed algorithms to *exactly* testing of a set of properties, including testing connectivity, k-edge connectivity, and bipartiteness. Recently, Guha et al. gave dynamic streaming algorithms for exactly testing of k-vertex connectivity [23]. All these algorithms use $\tilde{O}(n)$ space ($\tilde{O}(kn)$ for k-connectivity). On the other hand, the randomized space lower bounds for these exact testing problems were known to be $\Omega(n)$ in the insertion-only model [17, 18]. Recently, Sun and Woodruff improved these lower bounds to $\Omega(n \log n)$ [40]. Verbin and Yu [41] proved a lower bound for cycle-counting, which implied a lower bound of $\Omega(n^{1-O(\varepsilon)})$ for estimating the number of components.

In the *random order* insertion-only model Kapralov et al. [26] gave a one pass streaming algorithm that estimates the maximum matching size with polylogarithmic approximation ratio in polylogarithmic space. Although sublinear in n, the model considered is very different from ours.

Sublinear time algorithms for estimating the number of connected component and the weight of MST were first given by Chazelle et al. [8]. Later these two problems have been further considered in geometric settings [11, 13, 19]. In particular, Frahling et al. studied the problem of $(1+\varepsilon)$-approximating the weight of MST in dynamic geometric data stream [19].

There has been a rich line of work on graph property testing in the query model (see surveys [38, 20]) and the goal there is to design fast algorithms that make as few queries as possible. The query models that are mostly related to ours are bounded degree model and general graph model. In particular, our definition of ε-far is adapted from the general graph model. Goldreich and Ron [22] initiated the study of property testers in bounded degree graph model, and gave testers for connectivity, k-edge connectivity, $2,3$-vertex connectivity, cycle-freeness, Eulerianity. Testing k-vertex connectivity in bounded degree graphs for arbitrary constant k was given in [42]. These testers have later been generalized to general graph model [36, 35]. Testing bipartiteness in planar graphs was studied in [12].

After having submitted the paper, we became aware that Hossein Jowhari [25] has independently studied the problem of estimating the number of connected components and provided similar results as ours, while he did not consider the streaming property testers considered here.

2 Preliminaries

2.1 Notations

We use $[n] = \{1, \cdots, n\}$ to denote the vertex set of the graph G defined by the stream, and let m denote the number of edges of G. For an undirected graph $G = ([n], E)$ and a vertex $i \in [n]$, we let $\Gamma(i)$ denote all the neighbors of i. For a set $C \subseteq [n]$, let $\Gamma(C)$ denote the set of vertices in $V \setminus C$ that have at least one neighbor in C, that is, $\Gamma(C) = \cup_{i \in C} \Gamma(i) \setminus C$. Let $E(C, V \setminus C)$ denote the set of edges crossing C and $V \setminus C$. We will use $G[C]$ to denote the subgraph induced by C.

For each vertex i, we define two vectors $\mathbf{\Delta}^i \in \{-1, 0, 1\}^{\binom{n}{2}}$ and $\mathbf{\Lambda}^i \in \{0, 1\}^n$ to encode the neighborhood information of i as follows:

$$\mathbf{\Delta}^i_{j,k} = \begin{cases} 1 & \text{if } i = j < k \text{ and } (j,k) \in E \\ -1 & \text{if } j < k = i \text{ and } (j,k) \in E \\ 0 & \text{otherwise} \end{cases} \qquad \mathbf{\Lambda}^i_j = \begin{cases} 1 & \text{if } j \in \Gamma(i) \text{ or } j = i \\ 0 & \text{otherwise} \end{cases}$$

By simple induction arguments, it is easy to prove that for any vertex set $C \subset V$, the nonzero entries in the vector $\mathbf{\Delta}^C := \sum_{i \in C} \mathbf{\Delta}^i$ corresponds to the edges between C and its complement $V \setminus C$. The nonzero entries in $\sum_{i \in C} \mathbf{\Lambda}^i$ corresponds exactly to vertices in $C \cup \Gamma(C)$.

2.2 Linear sketches

Linear sketch (or sketch for short) is a powerful tool widely used in the streaming model and other areas. Given a large vector $\mathbf{x} \in \mathbb{R}^n$, we want to construct a small sketch $\mathcal{L}(\mathbf{x})$, from which certain properties of $\mathbf{x}$ can be recovered. We call $\mathcal{L}$ a linear sketch if $\mathcal{L}(\mathbf{x}+\mathbf{y}) = \mathcal{L}(\mathbf{x}) + \mathcal{L}(\mathbf{y})$ for all $\mathbf{x}, \mathbf{y}$, and this additive property make it trivial to implement linear sketches in the

dynamic streaming model. As in the previous works, we will use linear sketches as our main tool.

AGM sketch. We will use a dynamic streaming algorithm for constructing a spanning forest of a graph by Ahn, Guha and McGregor [2], which is summarized as follows.

▶ **Theorem 1** (AGM sketch [2]). *There exists a single-pass sketch-based dynamic streaming algorithm that uses $O(n \log^3 n)$ space, and recovers a spanning forest of the graph with probability 0.99. The recovery time of the algorithm is $\tilde{O}(n)$, and the update time is $\operatorname{poly}\log n$.*

AMS sketch. To check whether the input vector $\mathbf{x}$ is $\mathbf{0}$ or not, one can simply maintain a constant approximation of its *second frequency moment*, that is $F_2(\mathbf{x}) := \sum_i x_i^2$, which can be done in $O(\log n)$ space by using the classical AMS sketch that was introduced by Alon, Matias and Szegedy [4].

Exact k-sparse recovery. We call a vector k-sparse if $|\mathrm{supp}(\mathbf{x})| \leq k$. Given a non-zero vector $\mathbf{x} \in \mathbb{R}^n$, the goal here is to recover $\mathbf{x}$ if $\mathbf{x}$ is k-sparse, otherwise outputs **Fail**. We have the following result from [37].

▶ **Lemma 2** ([37]). *There exists an $O(k \log n \log_k \delta^{-1})$ space sketch-based algorithm that takes as input a non-zero vector $\boldsymbol{x} \in \mathbb{R}^n$, and with probability $1-\delta$, recovers $\boldsymbol{x}$ if $\boldsymbol{x}$ is k-sparse, otherwise outputs **Fail**. The update time is $O(\operatorname{poly}\log n)$ and the recovery time is $O(k \cdot \operatorname{poly}\log n)$.*

3 Estimating the number of connected components and MST weight

In this section, we present and analyze our algorithms for estimating the number of the connected components in a graph and $(1+\varepsilon)$-approximating the weight of the MST.

3.1 Estimating the number of connected components

Our first observation is that, to estimate the number of connected components within additive error εn, we can simply ignore all the large components (see also [8]). In particular, the number of components of size larger than $\Omega(1/\varepsilon)$ is at most $O(\varepsilon n)$. Thus it will be sufficient to estimate the number of components of small size, for which we have the following theorem.

▶ **Theorem 3.** *For any constant $t \geq 1$, there exists a one-pass dynamic streaming algorithm that uses $O(e^t n^{1-\varepsilon} \cdot \operatorname{poly}\log n)$ space and post-processing time to estimates the number of connected components of size at most $1/\varepsilon$ within an additive error $\varepsilon^t n$. The update time is $O(\operatorname{poly}\log n)$.*

By invoking Theorem 3 with parameter $\varepsilon' = (1-\varepsilon^q)\varepsilon$ and $t = (q+1)$, we get an estimator for the number of connected components of size smaller than $1/\varepsilon'$ within additive error at most $\varepsilon^{q+1} n$. Since the number of components of size at least $1/\varepsilon'$ is at most $\varepsilon' n = \varepsilon n - \varepsilon^{1+q} n$, the estimator also approximates the total number of connected components within additive error at most εn. The space of the algorithm is $\tilde{O}(e^{q+1} n^{1-\varepsilon+\varepsilon^{q+1}})$, and we have the following result.

▶ **Theorem 4.** *Let $q \geq 1$ be a constant. There exists a one-pass dynamic streaming algorithm that with constant success probability, estimates the number of connected components of a graph within an additive error εn in $O(e^{q+1} n^{1-\varepsilon+\varepsilon^{q+1}} \cdot \operatorname{poly}\log n)$ space and post-processing time.*

Algorithm 1 `EstimateNumSCC`

1: Sample each vertex with probability $p := (\varepsilon^{2t}n/16)^{-\varepsilon}$. If more than $16np$ vertices are sampled, then abort and output **Fail**. Let S denote the set of sampled vertices.
2: Maintain an AGM sketch of $G[S]$ using Theorem 1.
3: For each $v \in S$, maintain an AMS sketch $AMS(\mathbf{\Delta}^v)$, sketching the neighborhood of v in G.
4: **Post-Processing:**
5: Use the AGM sketch to recover a spanning forest F of the induced graph $G[S]$ using Theorem 1.
6: For each component $C \in F$, estimate $F_2(\mathbf{\Delta}^C)$ using the AMS sketch $AMS(\mathbf{\Delta}^C) = \sum_{v\in C} AMS(\mathbf{\Delta}^v)$, and set $X_C = 1$ if $F_2 = 0$, otherwise set $X_C = 0$. For each $1 \le \ell \le \frac{1}{\varepsilon}$, let $X_\ell := \sum_{C:|C|=\ell} X_C$.
7: Output $Y := \sum_{\ell \le \frac{1}{\varepsilon}} \frac{X_\ell}{p^\ell}$.

Now we give the proof of Theorem 3. Recall that the vectors $\mathbf{\Delta}^C$ encode the information of the number of edges between C and $V \setminus C$.

Proof of Theorem 3. Let $\mathrm{scc}(G)$ denote the number of connected components of size at most $1/\varepsilon$ in G. Our algorithm for estimating $\mathrm{scc}(G)$ is as follows. We first sample each vertex with probability $p := (\varepsilon^{2t}n/16)^{-\varepsilon}$. Let S be the set of sampled vertices. We then use the AGM sketch from Theorem 1 to maintain a spanning forest F of the subgraph induced by S. Then for each component C in F, we test whether C is actually a connected component in G by testing whether the vector $\mathbf{\Delta}^C := \sum_{v\in C} \mathbf{\Delta}^v$ is $\mathbf{0}$, which can be done by the AMS sketch. If $\mathbf{\Delta}^C = \mathbf{0}$, we set $X_C = 1$, otherwise set $X_C = 0$. Our estimator is then defined as $\sum_C \frac{X_C}{p^{|C|}}$, where C ranges over all components of F with size at most $\frac{1}{\varepsilon}$. See Algorithm 1 for the details.

Note that the algorithm samples at most $16np = O(\varepsilon^{-2t\varepsilon} \cdot n^{1-\varepsilon})$ vertices and we maintained an AGM sketch on $G[S]$ and an AMS sketch for each sampled vertex, which imply that the space complexity of the algorithm is $O(\varepsilon^{-2t\varepsilon} n^{1-\varepsilon} \cdot \mathrm{poly}\log n)$. By simple calculus, for any ε, it holds that $\varepsilon^{-2\varepsilon} \le e^{2/e} < e$, so the space is at most $\tilde{O}(e^t n^{1-\varepsilon})$. The post-processing time is near linear in the space, and the update time is $O(\mathrm{poly}\log n)$.

Now we prove the correctness of the above algorithm. First we note that the expected number of sampled vertices in Step (1) is np, and thus by Markov inequality, the probability that more than $16np$ vertices are sampled is at most $\frac{1}{16}$. Also note that with probability at least $1 - \frac{1}{16}$, the AGM sketch returns a true spanning forest of $G[S]$. In addition, since the number of components in F is at most n, we will query the AMS sketch at most n times. Thus if we set the error probability of the AMS sketch to be $\frac{1}{16n}$ (with an extra $\log n$ factor in space), then with probability at least $1 - \frac{1}{16}$, all invocations of AMS sketches for testing if $\mathbf{\Delta}^C = \mathbf{0}$ will give the correct answer. Conditioned on this event, X_ℓ defined in Step (6) is exactly the number of connected components B of size ℓ in G such that all vertices in B are sampled out, which is true since for any component $C \in F$, $F_2(\mathbf{\Delta}^C) = \mathbf{0}$ if and only if C is a connected component in G.

Let $B_1, \cdots, B_{\mathrm{scc}(G)}$ be the connected components of size at most $\frac{1}{\varepsilon}$ of G. For any integer $\ell \le \frac{1}{\varepsilon}$, let $\mathcal{B}_\ell$ denote the set of connected components of size ℓ in G, that is, $\mathcal{B}_\ell = \{B_i : 1 \le i \le \mathrm{scc}(G), |B_i| = \ell\}$. Let $b_\ell := |\mathcal{B}_\ell|$. Note that $\mathrm{scc}(G) = \sum_{\ell \le \frac{1}{\varepsilon}} b_\ell$. For any set B, let Z_B denote the indicator random variable that all the vertices in B have been sampled. Note that $\Pr[Z_B = 1] = p^{|B|}$. Now by the above argument, $X_\ell = \sum_{B\in\mathcal{B}_\ell} Z_B$,

and $\mathrm{E}[X_\ell] = b_\ell \cdot p^\ell$. Furthermore, we have $Y = \sum_{\ell \le \frac{1}{\varepsilon}} \frac{X_\ell}{p^\ell} = \sum_{\ell \le \frac{1}{\varepsilon}} \frac{\sum_{B \in \mathcal{B}_\ell} Z_B}{p^\ell}$, and thus $\mathrm{E}[Y] = \sum_{\ell \le \frac{1}{\varepsilon}} b_\ell = \mathrm{scc}(G)$.

Note that all Z_{B_i}'s are mutually independent for all i, so it holds that

$$\begin{aligned}\mathrm{Var}[Y] &= \sum_{\ell \le \frac{1}{\varepsilon}} \frac{\sum_{B \in \mathcal{B}_\ell} \mathrm{Var}[Z_B]}{p^{2\ell}} = \sum_{\ell \le \frac{1}{\varepsilon}} \frac{b_\ell (p^\ell - p^{2\ell})}{p^{2\ell}} \le \sum_{\ell \le \frac{1}{\varepsilon}} \frac{b_\ell}{p^\ell} \\ &\le \frac{\sum_{\ell \le \frac{1}{\varepsilon}} b_\ell}{p^{1/\varepsilon}} = \frac{\mathrm{scc}(G)}{p^{1/\varepsilon}} \le \frac{n}{p^{1/\varepsilon}} = \varepsilon^{2t} n^2/16, \qquad (1)\end{aligned}$$

where we use the fact that $\mathrm{scc}(G) \le n$, and $p = (\varepsilon^{2t} n/16)^{-\varepsilon}$. Then by Chebyshev's inequality,

$$\Pr[|Y - \mathrm{scc}(G)| \ge \varepsilon^t n] = \Pr[|Y - \mathrm{E}[Y]| \ge \varepsilon^t n] \le \frac{\mathrm{Var}[Y]}{\varepsilon^{2t} n^2} \le 1/16.$$

By the union bound, the algorithm will succeed with probability at least $\frac{2}{3}$. ◀

3.2 Approximating the weight of minimum spanning tree

We use the previous algorithm on estimating the number of connected components to approximate the weight of a minimum spanning tree of a weighted graph. Let $W \ge 2$ be an integer, G be a connected graph with integer edge weights from $[W] := \{1, \cdots, W\}$, and $c(\mathrm{MST})$ be the weight of an MST of G. For any $1 \le \ell \le W$, let $G^{(\ell)}$ denote the subgraph of G consisting of all edges of weight at most ℓ. Let $\mathrm{cc}^{(\ell)}$ denote the number of connected components of $G^{(\ell)}$. Chazelle et al. [8] give the following lemma relating the weight of MST to the number of connected components of $G^{(\ell)}$.

▶ **Lemma 5** ([8]). *It holds that* $c(MST) = n - W + \sum_{\ell=1}^{W-1} cc^{(\ell)}$.

For a connected graph with integer edge weights, the weight of any MST is at least $n-1$, so it is sufficient to estimate $cc^{(\ell)}$ within an additive error of $\varepsilon n/(W-1)$ for each ℓ. To do this, we can simply run $W-1$ parallel instances of Theorem 4, each of which sketches a subgraph $G^{(\ell)}$. Then the space of the algorithm will be $\tilde{O}(W n^{1-\frac{\varepsilon}{W-1}})$.

▶ **Theorem 6.** *Let $t \ge 1$ be any constant. There exists a single-pass dynamic streaming algorithm that uses space and post-processing time $O(e^t W n^{1-\frac{\varepsilon}{W-1}+\frac{\varepsilon^t}{(W-1)^t}} \operatorname{poly}\log n)$ to compute a $(1+\varepsilon)$-approximation of the weight of the MST.*

We remark that Ahn et al. [2] have given a dynamic streaming algorithm for this problem for any graph with maximum edge weight upper bounded by $O(\mathrm{poly}(n))$, and their algorithm uses space $O(n \cdot \operatorname{poly}\log n)$. Our algorithm uses $o(n)$ space for any connected graph with maximum edge weight bounded by $o(\log n)$ (for constant ε), which improves the algorithm of [2] in this setting. We also note that $\Omega(n)$ space is necessary for estimating the weight of MST for graphs with maximum edge weight at least $c \log n$ for constant ε and some large universal constant c (see Theorem 12). Finally, we remark that the algorithm can also be extended to the setting where non-integral weights are allowed (see [8] for more details).

4 Dynamic streaming testers

In this section, we give our streaming testers for k-edge connectivity and cycle-freeness. Due to space constraints, we present the testers for k-vertex connectivity, Eulerianity and planar graph bipartiteness in the full version of the paper.

Algorithm 2 TestConnectivity

1: Sample each vertex with probability $p := (\varepsilon n/10)^{-\varepsilon}$. If more than $16np$ vertices are sampled, abort and output **Fail**. Let S denote the set of sampled vertices.
2: For each $v \in S$, maintain an AMS sketch $AMS(\mathbf{\Delta}^v)$, sketching the neighborhood of v in G.
3: Maintain an AGM sketch of $G[S]$ using Theorem 1.
4: **Post-Processing:**
5: Use the above sketch to construct a spanning forest F of $G[S]$ as guaranteed by Theorem 1.
6: For each connected component $C \in F$, estimate $F_2(\mathbf{\Delta}^C)$ using the AMS sketch $AMS(\mathbf{\Delta}^C) = \sum_{v \in C} AMS(\mathbf{\Delta}^v)$. If the answer $\tilde{F}_2 = 0$, **Reject**.
7: **Accept**.

4.1 Testing k-edge connectivity

A graph is k-edge connected if the minimum cut of the graph has size at least k. We start from the simplest case, i.e., $k = 1$, which is equivalent to the problem of testing connectivity.

4.1.1 Connectivity

It is clear that if G is ε-far from being connected, one must add at least εm edges to make it connected, which implies that there are at least $\varepsilon m + 1$ connected components in G [22, 36]. Therefore, we can also solve this by estimating the number connected components by setting the error parameter appropriately, however, by a more careful analysis, we can improve this by a factor of $O(n^{O(\varepsilon)})$.

▶ **Theorem 7.** *There exists a dynamic streaming tester for* 1*-edge connectivity that runs in* $\tilde{O}(n^{1-\varepsilon})$ *post-processing time and space.*

Proof. First observe that one can simply reject the input graph if $m < n - 1$, since in this case, the graph is disconnected. Thus, in the following we assume $m \geq n - 1$ and our tester is described in Algorithm 2.

It is easy to see that Algorithm 2 only use $\tilde{O}(|S|)$ space, which is bounded by $\tilde{O}(np) = \tilde{O}(\varepsilon^{-\varepsilon} n^{1-\varepsilon}) = \tilde{O}(n^{1-\varepsilon})$. The post-processing time is nearly linear in the size of S, since the AGM algorithm needs $\tilde{O}(|S|)$ post-processing time, and we invoke at most $|S|$ AMS queries, each of which takes $\tilde{O}(1)$ time. The update time is $\operatorname{poly}\log n$.

For the correctness of the algorithm, we condition on the event that the number of sampled vertices is at most $16np$, which occurs with probability at least $1 - \frac{1}{16}$, and on the event that the spanning forest F is constructed correctly, which occurs with probability 0.99. By setting the error probability of the AMS sketch to be $1/n^2$ (with an extra $\log n$ factor in space), with probability 0.99, all the answers from AMS sketches are all correct, and we also condition on this.

If G is connected, then it will always be accepted, since for each $C \in F$, $\mathbf{\Delta}^C \neq \mathbf{0}$, and conditioned on the correctness of the AMS sketch, $\tilde{F}_2$ will never be 0. On the other hand, if the graph is ε-far from being connected, the number of connected components in G, denoted as $\operatorname{cc}(G)$, is at least $1 + \varepsilon m \geq \varepsilon n$. Let $B_1, \cdots, B_{\operatorname{cc}(G)}$ denote all connected components in G. Let $p_i = p^{|B_i|}$ for $1 \leq i \leq \operatorname{cc}(G)$. Using the inequality $1 - x \leq e^{-x}$ for all x, the probability that none of the components is entirely sampled out is $(1-p_1)\cdot(1-p_2)\cdot\cdots\cdot(1-p_{\operatorname{cc}(G)}) \leq e^{-\sum_i p_i}$. Then by the AM-GM inequality, this probability is at most

$$e^{-\operatorname{cc}(G)\cdot(\prod_i p_i)^{1/\operatorname{cc}(G)}} = e^{-\operatorname{cc}(G)\cdot p^{n/\operatorname{cc}(G)}} \leq e^{-\operatorname{cc}(G)\cdot p^{1/\varepsilon}} \leq e^{-\varepsilon n \cdot p^{1/\varepsilon}} \leq 1/16,$$

where we use the fact that $p = (\varepsilon n/10)^{-\varepsilon}$ and $\mathrm{cc}(G) \geq \varepsilon n$. So the probability that at least one of the components is sampled out is at least 15/16. Conditioned on this, $F_2(\boldsymbol{\Delta}^C) = 0$ for some component in $G[S]$ and the algorithm will output **Reject**. By union bound, our algorithm will succeed with probability $1 - \frac{1}{16} - 0.01 - 0.01 - \frac{1}{16} > 3/4$. ◀

4.1.2 k-edge connectivity: $k \geq 2$

By using a slightly more involved argument and replacing AMS sketches with $(k-1)$-sparse recovery sketches, we can generalize the above idea to testing k-edge connectivity for $k \geq 2$. We have the following theorem on testing k-edge connectivity. See the full version for the proof.

▶ **Theorem 8.** *Let $k \leq O(n^{\varepsilon/(1+\varepsilon)})$. There exists a single-pass dynamic streaming tester for k-edge connectivity with post-processing time and space $O(k^{1+\varepsilon} \cdot n^{1-\varepsilon} \cdot \mathrm{poly}\log n)$.*

4.2 Testing cycle-freeness

Now we consider the problem of testing cycle-freeness, which is equivalent to testing if the graph is a forest. Let $\mathrm{cc}(G)$ denote the number of connected components of the input graph G. Let $B_1, \cdots, B_{\mathrm{cc}(G)}$ be the connected components in G. Note that if G is cycle-free, then for each $i \leq \mathrm{cc}(G)$, $|E(B_i)| = |B_i| - 1$, and thus the total number of edges in G is

$$m = \sum_{i=1}^{\mathrm{cc}(G)} |E(B_i)| = \sum_{i=1}^{\mathrm{cc}(G)} (|B_i| - 1) = n - \mathrm{cc}(G),$$

that is, $\mathrm{cc}(G) = n - m$. If G is ε-far from being cycle-free, i.e., one has to delete more than εm edges to make it cycle-free, then $\mathrm{cc}(G) > n - m + \varepsilon m$. Therefore, to test cycle-freeness of a graph, it will be sufficient to approximate the number of connected components with additive error $\varepsilon m/2$. One may try to directly invoke Algorithm 1 with parameter $\varepsilon' = \frac{\varepsilon m}{2n}$. However, m could be much smaller than n and we do not know m in advance. We overcome this obstacle by a case analysis.

▶ **Theorem 9.** *There exists a single-pass dynamic streaming algorithm that tests cycle-freeness of a graph with space and post-processing time $O(n^{1-\varepsilon+\varepsilon^2} \cdot \mathrm{poly}\log n)$.*

Proof. Note that if $m > n - 1$, then the graph must contain at least one cycle, and thus we can safely reject the graph. In the following, we assume that $m \leq n - 1$. Our algorithm for testing cycle-freeness depends on the construction of AGM sketch, in which each vertex u maintains a linear sketch of $\boldsymbol{\Delta}^u$ (denoted as $\mathcal{A}(\boldsymbol{\Delta}^u)$). Each such sketch has size $\mathrm{poly}\log n$ and the property that $\mathcal{A}(\mathbf{0}) = \mathbf{0}$ (it consists of $O(\log n)$ l_0-samplers, see [2] for details). Our main idea is to maintain a sparse recovery sketch for the AGM sketch (i.e. a composition of sparse recovery sketch and AGM sketch). Now we describe our algorithm as follows.

Note that the space used by the algorithm is $\max\{\tilde{O}(np), k \cdot \mathrm{poly}\log n\} = \tilde{O}(n^{1-\varepsilon+\varepsilon^2})$, and the post-processing time is near linear in space. Now we prove the correctness of the algorithm. We define $G' \subseteq G$ to be a subgraph which consists of all the vertices of positive degree. Let $n' = |G'|$. Note that $m \geq n'/2$. If $n' \leq n^{1-\eta}$, then the vector $\boldsymbol{\Upsilon}$ is $\tilde{O}(n^{1-\eta})$-sparse, since for all isolated vertices u, we have $\mathcal{A}(\boldsymbol{\Delta}^u) = \mathbf{0}$, and thus we can recover the entire $\boldsymbol{\Upsilon}$ exactly. Then by Step (2) and Theorem 1, we can get the exact number of components of G'. Since the number of vertices of G' is $|Y|$, and $\lambda = m$ is the total number of edges, then the graph is cycle-free if and only if $\tilde{c}_1 = |Y| - \lambda$.

Algorithm 3 TestCycleFreeness

1: Maintain a count λ of the number of edges.
2: Let $\eta = \varepsilon/(1+\varepsilon+\varepsilon^2)$. Let $k = n^{1-\eta}\text{poly}\log n$. Maintain an exact k-sparse recovery sketch $\mathcal{S}$ of the vector $\boldsymbol{\Upsilon} := (\mathcal{A}(\boldsymbol{\Delta}^u))_{u\in V}$ using Lemma 2.
3: Run Algorithm 1 with parameter $p = (2^{2t}n^{1-\eta}/16)^{-\eta}$, while in step (6) of Algorithm 1, ignore all the isolated vertices that are sampled out (i.e., set $X_C = 0$ whenever $|C| = 1$).
4: **Post-Processing:**
5: Recover $\boldsymbol{\Upsilon}$ from $\mathcal{S}$.
6: **if** The recovery does not fail **then**
7: Use $\boldsymbol{\Upsilon}$ to construct a spanning forest on vertex set $Y := \{u : \mathcal{A}(\boldsymbol{\Delta}^u) \neq \mathbf{0}\}$ using Theorem 1. Let $\tilde{c}_1$ denote the number of connected components of this forest. If $\tilde{c}_1 = |Y| - \lambda$, **Accept**; otherwise, **Reject**.
8: **else**
9: Let $\tilde{c}_2$ be the resulting estimator of Algorithm 1 in Step 3. If $\tilde{c}_2 \leq n - (1-\varepsilon-\frac{\varepsilon^3}{4})\lambda$, **Accept**; otherwise, **Reject**.
10: **end if**

If $n' > n^{1-\eta}$, then by Theorem 3, $\tilde{c}_2$ is an estimator for the number of components in G' of size smaller than $1/\eta$ with additive error $\eta^t\sqrt{n'n^{1-\eta}}$. This follows by the upper bound $\eta^{2t}n^{1-\eta}n'/16$ of the variance of the estimator (which can be shown similarly to inequality (1) in Section 3) and the Chebyshev's inequality. Now note that the additive error is at most $\eta^t n' \leq \varepsilon^3 m/8$ for some constant t since $n' > n^{1-\eta}$ and $m \geq n'/2$. Let L be the number of components in G' of size larger than $1/\eta$, then $-\varepsilon^3 m/8 \leq \text{cc}(G') - \tilde{c}_2 \leq L + \varepsilon^3 m/8$ holds with high probability. Conditioned on this, Step (8) outputs the correct answer if $L + \varepsilon^3 m/8 + \varepsilon^3 m/8 = L + \varepsilon^3 m/4 < \varepsilon m$. Now if $L < \varepsilon m/4$, we are done. If $L \geq \varepsilon m/4$, then by our choice of η and the fact that $m \geq L \cdot (1/\eta - 1)$, $\varepsilon m \geq L + L\varepsilon^2 \geq L + \varepsilon^3 m/4$. This completes the proof of the theorem. ◀

5 Lower bounds

In this section we present lower bounds, which hold in the insertion-only model. Our proofs are based on the reductions to the *Boolean Hidden Hypermatching (BHH)* problem (See [41]), which are in the same spirit as the lower bound proof for the *Cycle Counting* problem in [41]. We first give the definition of the boolean hidden hypermatching problem.

▶ **Definition 10** (BHH_n^t)**.** In this problem, Alice gets a boolean vector $x \in \{0,1\}^n$, where $n = 2kt$ for some integer k. Bob gets a partition (or hypermatching) of the set $[n]$, $\{m_1, \cdots, m_{n/t}\}$, where the size of each m_i is t, and a vector $w \in \{0,1\}^{n/t}$. For convenience, we will also use the corresponding n-dimensional boolean indicator vector M_i to represent m_i, and let M be a $n/t \times n$ matrix, the i row of which is M_i. The promise of the input is either $Mx + w = \mathbf{1}$ or $Mx + w = \mathbf{0}$, where all the operations are modulo 2. The goal of the problem is to output 1 when $Mx + w = \mathbf{1}$, and output 0 otherwise.

▶ **Theorem 11** ([41])**.** *The randomized one-way communication complexity of BHH_n^t when $n = 2kt$ for some integer $k \geq 1$ is $\Omega(n^{1-1/t})$.*

Our lower bounds will be built upon the following basic construction.

Construction of $G(x, M)$. Given vector x and matrix M respectively, Alice and Bob construct a bipartite graph $G(x, M) = (U, V, E)$, where $U = \{u_1, \cdots, u_{2n}\}$ and $V =$

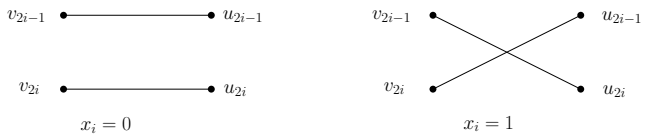

Figure 1 Parallel (left) and crossing (right) matching according to the value of x_i.

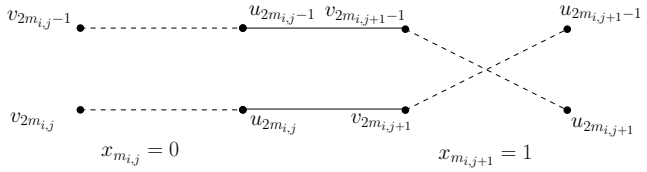

Figure 2 Bob connects $(u_{2m_{i,j}-1}, v_{2m_{i,j+1}-1})$ and $(u_{2m_{i,j}}, v_{2m_{i,j+1}})$ for each $j \in [t-1]$.

$\{v_1, \cdots, v_{2n}\}$, as follows. Given $x \in \{0,1\}^n$, Alice adds a perfect matching between U and V. For each $i \in [n]$, if $x_i = 0$, she adds two parallel edges (u_{2i-1}, v_{2i-1}) and (u_{2i}, v_{2i}); otherwise if $x_i = 1$, she adds two crossing edges (u_{2i-1}, v_{2i}) and (u_{2i}, v_{2i-1}) (see Figure 1).

Given M, Bob will do the following. For each $i \in [n/t]$ and the hyperedge $m_i \subset [n]$ (that corresponds to the ith row M_i), we use $m_{i,j} \in [n]$ to denote the jth element in m_i and we let $S_i := \{w | w = v_{2m_{i,j}-1}$ or $v_{2m_{i,j}}$ or $u_{2m_{i,j}-1}$ or $u_{2m_{i,j}}, j \in [t]\}$. For each $i \in [n/t]$ and $j \in [t-1]$, Bob adds two edges $(u_{2m_{i,j}-1}, v_{2m_{i,j+1}-1})$ and $(u_{2m_{i,j}}, v_{2m_{i,j+1}})$ (See Figure 2).

Observe that the edges added by Alice and Bob form two paths p_{2i-1}, p_{2i} over vertex set S_i, where p_{2i-1} starts from $v_{2m_{i,1}-1}$ and p_{2i} starts from $v_{2m_{i,1}-1}$ for each i. The entire graph $G(x, M)$ consists of $2n/t$ disjoint paths $\{p_1 \cdots, p_{2n/t}\}$.

Note that $G(x, M)$ has the following property. Based on the value of $(Mx)_i$, we have: 1) if $(Mx)_i = 0$, then p_{2i-1} is a path from $v_{2m_{i,1}-1}$ to $u_{2m_{i,t}-1}$ and p_{2i} is a path from $v_{2m_{i,1}}$ to $u_{2m_{i,t}}$; 2) if $(Mx)_i = 1$, then p_{2i-1} is a path from $v_{2m_{i,1}-1}$ to $u_{2m_{i,t}}$ and p_{2i} is a path from $v_{2m_{i,1}}$ to $u_{2m_{i,t}-1}$.

5.1 Minimum spanning tree

▶ **Theorem 12.** *In the insertion-only model, if all edges of the graph have weights in $[W]$, any algorithm that $(1 \pm \varepsilon)$-approximates the weight of the MST must use $\Omega(n^{1-\frac{4\varepsilon}{W-1}})$ bits of space.*

Proof. Given x and M, Alice and Bob first construct the graph $G(x, M)$ as describe above. Next Bob adds $(u_{2m_{i,t}-1}, v_{2m_{i,1}-1})$ and $(u_{2m_{i,t}}, v_{2m_{i,1}})$ if $w_i = 0$; adds $(u_{2m_{i,t}-1}, v_{2m_{i,1}})$ and $(u_{2m_{i,t}}, v_{2m_{i,1}-1})$ if $w_i = 1$. The weight of all the edges added so far is 1. Next Bob places edges $(v_{2m_{i,t}}, v_{2m_{i+1,1}})$ with weight 1 for $i = 1, \cdots, n/t - 1$ and edges $(v_{2m_{i,t}}, u_{2m_{i,t}})$ with weight W for each $i \in [n/t]$, so that the graph become connected. By similar argument as above, if $Mx + w = \mathbf{0}$, all the edges $(v_{2m_{i,t}}, u_{2m_{i,t}})$ must be picked in any minimum spanning tree, since each of these edges forms a cut, and thus the weight of any MST is $nW/t + 4n - n/t - 1 = 4n\varepsilon + 4n - 1$, where we set $t = (W-1)/4\varepsilon$. On the other hand, when $Mx + w = \mathbf{1}$, the weight of the MST is $4n - 1$, since in this case, the graph is already connected without those edges with weight W. So if the algorithm can compute an $(1+\varepsilon)$-approximation of the weight of the minimum spanning tree, it solves the BHH_n^t problem. This completes the proof. ◀

5.2 Testing connectivity

▶ **Theorem 13.** *In the insertion-only model, to distinguish whether a graph of $4n$ vertices is connected or $\frac{1}{8t+1}$-far from being connected, any algorithm must use $\Omega(n^{1-1/t})$ bits of space.*

Proof. Given x and M, Alice and Bob first construct the graph $G(x, M)$. Next Bob adds another set of edges based on vector w. If $w_i = 0$, he adds $(u_{2m_{i,t}-1}, v_{2m_{i,1}-1})$ and $(u_{2m_{i,t}}, v_{2m_{i,1}})$; if $w_i = 1$, he adds $(u_{2m_{i,t}-1}, v_{2m_{i,1}})$ and $(u_{2m_{i,t}}, v_{2m_{i,1}-1})$. So when $(Mx)_i + w_i = 0$, p_{2i-1} and p_{2i} become 2 disjoint cycles. On the other hand, when $(Mx)_i + w_i = 1$, p_{2i-1} and p_{2i} together form a larger cycle. Now Bob places $(v_{2m_{i,t}}, v_{2m_{i+1,1}})$ in E for $i = 1, \cdots, n/t - 1$ which connect p_{2i} with $p_{2(i+1)}$ for all $i \in [n/t - 1]$, i.e. all the paths in $G(x, M)$ with even indices become a connected component. The total number of edges is $8n + n/t$. When $Mx + w = \mathbf{0}$, the graph has $n/t + 1$ components which is $\frac{1}{8t+1}$-far from connected; when $Mx + w = \mathbf{1}$ the graph is connected. So if a streaming algorithm can distinguish whether a graph of size $4n$ is connected or $1/8t$-far from being connected, it solves BHH_n^t, since Alice can first run the algorithm on her part of the graph and send the memory to Bob, and then Bob continues to run the algorithm on his part and output the answer. Therefore, the communication lower bound of BHH_n^t implies a space lower bound of testing connectivity. ◀

5.3 Testing cycle-freeness

As in the proof of Theorem 13, given x and M, Alice and Bob first construct $G(x, M)$. Then, for $i \in [n/t]$, Bob adds $(u_{2m_{i,t}-1}, v_{2m_{i,1}-1})$ if $w_i = 0$; adds $(u_{2m_{i,t}-1}, v_{2m_{i,1}})$ if $w_i = 1$. The total number of edges is less than $8n$. Through similar arguments, it is easy to verify that if if $Mx + w = \mathbf{0}$, the graph has exactly n/t cycles and n/t paths, which is $1/8t$-far from cycle-free. On the contrary, if $Mx + w = \mathbf{1}$, the graph has n/t paths and no cycle. So if an algorithm can distinguish whether a graph of size $4n$ is cycle-free or $1/8t$-far from cycle-free, it solves BHH_n^t.

▶ **Theorem 14.** *In the insertion-only model, any algorithm that can distinguish whether a graph of $4n$ vertices is cycle-free or $1/8t$-far from being cycle-free, must use $\Omega(n^{1-1/t})$ bits of space.*

5.4 Testing bipartiteness of planar graphs

Alice and Bob first construct the graph $G(x, M)$. Next, for each $i \in [n/t]$, Bob adds edges $(v_{2m_{i,1}-1}, \xi_1)$ and $(v_{2m_{i,1}}, \xi_2)$, where ξ_1, ξ_2 are new vertices. For $i \in [n/t]$, Bob also adds $(u_{2m_{i,t}-1}, \xi_1)$ and $(u_{2m_{i,t}}, \xi_2)$ if $w_i = 0$; adds $(u_{2m_{i,t}-1}, \xi_2)$ and $(u_{2m_{i,t}}, \xi_1)$ if $w_i = 1$. For this problem we assume t is odd. So by similar arguments, we can easily verify that, if $Mx + w = \mathbf{0}$, the graph contains $2n/t$ edge-disjoint cycles of length $2t + 1$, and if $Mx + w = \mathbf{1}$, the graph has no odd cycle, and thus bipartite. The graph constructed is planar and has $4n + 2$ vertices and $8n + 4n/t$ edges, so we have the following lower bound for testing bipartiteness.

▶ **Theorem 15.** *In the insertion-only model, any algorithm that can distinguish whether a planar graph of $4n + 2$ vertices is bipartite or $\frac{1}{4t+2}$-far from being bipartite, must use $\Omega(n^{1-1/t})$ bits space.*

Abstract

In this paper we develop streaming algorithms for the diameter problem and the k-center clustering problem in the sliding window model. In this model we are interested in maintaining a solution for the N most recent points of the stream. In the diameter problem we would like to maintain two points whose distance approximates the diameter of the point set in the window. Our algorithm computes a $(3+\epsilon)$-approximation and uses $O(1/\epsilon \ln \alpha)$ memory cells, where α is the ratio of the largest and smallest distance and is assumed to be known in advance. We also prove that under reasonable assumptions obtaining a $(3-\epsilon)$-approximation requires $\Omega(N^{1/3})$ space.

For the k-center problem, where the goal is to find k centers that minimize the maximum distance of a point to its nearest center, we obtain a $(6+\epsilon)$-approximation using $O(k/\epsilon \ln \alpha)$ memory cells and a $(4+\epsilon)$-approximation for the special case $k=2$. We also prove that any algorithm for the 2-center problem that achieves an approximation ratio of less than 4 requires $\Omega(N^{1/3})$ space.

1 Introduction

Analyzing big data sets from streams is a topic that has received considerable attention among theoretical and applied researchers. One of the most popular summarization and aggregation tasks studied in this context is to determine k clusters that represent key features of the input data with respect to certain properties.

In this paper we focus on variants of the k-center problem where we aim to find k points such that the maximum distance over all points to their closest center is minimized.

In the standard streaming setting, we constrain our algorithms to use as little space as possible while computing high-quality solutions. The complexity of clustering in general and k-center in particular is well understood for insertion-only streams where input points arrive one by one. The more general settings like dynamic streams and the sliding window

* Supported by Deutsche Forschungsgemeinschaft within the Collaborative Research Center SFB 876, project A2

model have also received some attention for other clustering objectives. Both models aim to incorporate dynamic behavior; in dynamic streams input points are removed via a dedicated delete operation and in the sliding window model older input expires as new elements arrive. In this paper, we consider a fixed window size consisting of N points, which is the most widely studied variant of this model in theoretical computer science, but our algorithms also work in the case that the maximum number of points within the window is a function of time.

Our Contribution

The metric diameter problem is to find two points of maximum distance among a set of points lying in some metric space. For this problem, we give a $(3+\varepsilon)$-approximation algorithm in the sliding window model that stores $O(\frac{1}{\varepsilon}\log\alpha)$ points, where $\alpha = \frac{\max_{p,q}\operatorname{dist}(p,q)}{\min_{p,q}\operatorname{dist}(p,q)}$ is the ratio of largest and smallest possible distance between the points. This is a substantial improvement over the best and to our knowledge only sliding window algorithm for diameter in general metric spaces by Chan and Sadjad [8] which computes a $(2^{m+2}-2+\varepsilon)$ approximation with $O(N^{1/(m+1)}\log\alpha)$ points for any $m > 0$.

Under reasonable assumptions (which are common for our model of computation), we obtain a lower bound of $\Omega(\sqrt[3]{N})$ for any algorithm achieving a $3-\varepsilon$ approximation to the diameter problem for any $\varepsilon > 0$.

To our knowledge there exists no previous work on k-center in sliding windows. For 2 centers our diameter algorithm yields a $(4+\varepsilon)$-approximate clustering. Under the aforementioned assumptions, we are also able to obtain a matching lower bound. For arbitrary values of k, we are able to obtain a $(6+\varepsilon)$-approximate algorithm using $O(k/\varepsilon\log\alpha)$ points in metric spaces.

Techniques

The popular histogram approaches introduced by Datar et al. [12] and Braverman and Ostrovsky [6] do not seem to be applicable to max-norm objectives such as diameter and k-center. Our algorithm for the diameter (see Section 3) aims to find for each estimate of the value γ of the diameter two certificate points with distance greater than γ, while maintaining the two most recent points close to the two points forming the certificate. With every additional input point, we check whether we are able to update the certificate to a more recent timestamp.

For our lower bounds, we utilized the fact that any algorithm working in the metric distance model is restricted to storing only input points. For deterministic algorithms, we are then able to insert an appropriately hard instance based on the points forgotten by the input. For randomized algorithms, we add additional points in which we hide a hard, randomly chosen instance for deterministic algorithms. A more in-depth description of our approach as well as a discussion on the generality of our results can be found in Section 5.

The analysis of the 2-center algorithm is similar to that of the popular 2-approximation by Gonzales [14] and Hochbaum and Shmoys [16]. Since it does not yield an approximation of the optimum value, this technique seems difficult to generalize for larger values of k.

Related Work

Diameter

Feigenbaum et al. [13] were the first to consider the diameter in the sliding window model. For d dimensions in Euclidean space, their algorithm uses $O(\left(\frac{1}{\varepsilon}\right)^{(d+1)/2}\log^3 N(\log\alpha+\log\log N+$

$\frac{1}{\varepsilon}$)) bits of space. They also give a lower bound of $\Omega(\frac{1}{\varepsilon}\log N \log \alpha)$ for a $(1+\varepsilon)$ approximation factor in one dimension and, implicitly, a $\Omega(\log \alpha)$ space bound for any multiplicative approximation factor. This lower bound was later matched by Chan and Sadjad [8], who also gave an improved space bound of $O((\frac{1}{\varepsilon})^{(d+1)/2} \log \frac{\alpha}{\varepsilon})$ points for higher dimensions. For more general metric spaces, they obtain a $(2^{m+2}-2+\varepsilon)$ approximation with $O(N^{1/(m+1)})$ points.

In the metric distance oracle model (formally defined in Section 2) there exists a folklore 2 approximation that maintains the first point p and the point with maximum distance from p. Guha [15] showed this algorithm to be essentially optimal, as no algorithm storing less than $\Omega(n)$ points can achieve a ratio better than $2-\varepsilon$ for any $\varepsilon > 0$. For Euclidean spaces, the best streaming algorithm with a polynomial dependency on d is due to Agarwal and Sharathkumar [2] with an almost tight approximation ratio of $\sqrt{2}+\varepsilon$ in $O(d\varepsilon^{-3}\log(1/\varepsilon))$ space. Agarwal et al. [1] proposed a $(1+\varepsilon)$-approximation using $O(\varepsilon^{-(d-1)/2})$ points. Similar space bounds seem likely for dynamic streams although none have been published to our knowledge. For large d, Indyk [17] gave a sketching scheme with approximation factor $c > \sqrt{2}$ and space $O(dn^{1/(c^2-1)}\log n)$.

k-Center

In one of the earliest works on clustering in streams, Charikar et al. [9] gave a number of incremental clustering algorithms for metric k-center, among other results. While storing no more than $k+1$ points at any given time, they were able to derive a deterministic 8 approximation and a randomized $2e \approx 5.437$ approximation. They also show that no incremental algorithm can be better than 3. McCutchen and Khuller [19] and Guha [15] independently derived a $(2+\varepsilon)$-approximate algorithm using $O(k/\varepsilon \log 1/\varepsilon)$ space, with Guha giving an almost tight lower bound of $\Omega(n)$ space for any algorithm achieving a better approximation ratio than 2. In their paper, McCutchen and Khuller [19] also studied the problem with z outliers, giving a $(4+\varepsilon)$ approximate algorithm that stores $O(\varepsilon^{-1}kz)$ points, see also Charikar et al. [10] for an earlier treatment of the problem. Further improvements are possible in Euclidean spaces. Zarrabi-Zadeh showed how to maintain ε-coresets in streams using $O(k\varepsilon^{-d})$ points for k-center [20]. For small values of k, Kim and Ahn [18] were able to break the 2 barrier without having an exponential dependency on d, giving a $1.8+\varepsilon$ approximation while storing $O(2^k(k+3)!\varepsilon^{-1})$ points. The special case of $k=1$ for Euclidean distances also known as the minimum enclosing ball problem is one of the most extensively studied topics in streaming literature. We only review the best known bounds. Zarrabi-Zadeh gave an insertion-only algorithm storing $O(\varepsilon^{-(d-1)/2}\log 1/\varepsilon)$ points [21]. Agarwal and Sharathkumar [2] showed that no algorithm with polynomial dependency on d can achieve a better approximation ratio than $(1+\sqrt{2})/2 \approx 1.207$ and provided an algorithm which after a re-analysis by Chan and Pathak [7] is now known to give a 1.22 approximation with space roughly $O(d)$.

We are not aware of any work on k-center in sliding windows, though Babcock et al. [3] and more recently Braverman et al. [4, 5] gave a $O(1)$ approximation for metric and a $(1+\varepsilon)$ approximation for Euclidean k-median and k-means problems. The related problem of cut sparsification has also received some attention, see Crouch et al. [11].

The structure of the paper is as follows. Section 2 introduces the model and the definitions. Section 3 is dedicated to the description and analysis of our algorithm for the diameter problem. The analysis and description of our algorithm for the k-center problem is in Section 4. Finally, Section 5 contains the lower bounds for both the diameter and k-center problems.

2 Preliminaries

Let (A, dist) be a metric space where A is a set of points and $\text{dist} : A \times A \mapsto R_+$ is a distance function. A stream is a (potentially infinite) sequence of points from the metric space A (note that a point can be appear multiple times in the stream). The sliding window of size N contains the most recent N elements of the stream.

We introduce the *Time To Live* value of a point p: Upon insertion $TTL(p)$ is set to the window size N and with each subsequently inserted point it is decremented. We say that p *expires* if $TTL(p) = 0$. We extend the common use of TTL to negative numbers to indicate the number of points submitted after expiration, i. e., $TTL(p) = -10$ means that 10 points were submitted after the expiration of p. We define the aspect ratio $\alpha = \frac{\max_{p,q \in A} \text{dist}(p,q)}{\min_{p,q \in A} \text{dist}(p,q)}$. To query the distance between two points p and q, we invoke a distance oracle $\text{dist}(p, q)$. We assume that the oracle can accessed only for those points we currently keep in memory and that the oracle itself requires no additional space.

3 The Metric Diameter Problem

For a given estimate γ of the diameter, our algorithm for the metric diameter problem either produces two witness points at distance greater than γ or a point c that has a certain degree of centrality among the points in the current window. More formally, all points of the window inserted up to the insertion time of c will be proven to have distance at most 2γ from one another and points inserted after c will have distance at most γ from c. Thus, the diameter is at most 3γ.

Specifically, Algorithm 1 aims at maintaining a certificate for the diameter consisting of two points c_{old} and c_{new} such that $\text{dist}(c_{old}, c_{new}) > \gamma$ and $TTL(c_{old}) < TTL(c_{new})$. In addition, we also store the point q submitted immediately prior to c_{new} and the most recent point r. When a new point arrives, we test whether, based on the points we currently keep in memory, we can produce two points each with a larger TTL than $TTL(c_{old})$ with distance more than γ. If we find such a pair, we update the points accordingly, if not we update r and possibly q.

The algorithm has two different states depending on whether it found a pair of points of distance more than γ or not. The first state is indicated by $c_{new} = \textbf{null}$ and corresponds to the case that no such pair of points has been found. In this case, the algorithm maintains the following invariant, which certifies that the diameter of the points in the sliding window is at most $3 \cdot \gamma$.

We first observe that c_{old} is always inside the sliding window.

▶ **Invariant 1.** If $c_{new} = \textbf{null}$, the following statements hold:
(a) For any points a, b with $0 \leq TTL(a), TTL(b) \leq TTL(c_{old})$, we have $\text{dist}(a, b) \leq 2 \cdot \gamma$.
(b) For any point a with $TTL(a) > TTL(c_{old})$, we have $\text{dist}(a, c_{old}) \leq \gamma$.

The second state corresponds to the case that we discover two points c_{old} and c_{new} with distance more than γ and is indicated by $c_{new} \neq \textbf{null}$. Besides the obvious invariant that $TTL(c_{new}) > TTL(c_{old})$, we also have to maintain the following technical invariants that are required for a new assignment of c_{old} when it expires from the window.

▶ **Invariant 2.** If $c_{new} \neq \textbf{null}$ then the following statements hold:
(a) $\text{dist}(c_{old}, c_{new}) > \gamma$.
(b) For any point a with $TTL(c_{old}) < TTL(a) < TTL(c_{new})$, we have $\text{dist}(a, c_{old}) \leq \gamma$.
(c) For any point a with $TTL(c_{new}) < TTL(a)$, we have $\text{dist}(a, c_{new}) \leq \gamma$.
(d) If $c_{old} \neq q$ then for any point a with $TTL(q) < TTL(a)$, we have $\text{dist}(a, q) \leq \gamma$.

We observe that all the invariants hold initially, i.e. before line 3 of the algorithm is executed the first time. We also observe that Invariants 2a)-d) only apply to points that appear after c_{old}. It suffices to focus on these points because we only change c_{old} to points that arrive later and so we maintain our certificate at least until the time when c_{old} expires (and so all earlier points are gone).

▶ **Lemma 1.** *If $c_{new} =$ **null** and Invariant 1 is satisfied before* Insert *then one of the following statements holds:*
1. *If $c_{new} =$ **null** after line 12 then Invariant 1 is satisfied.*
2. *If $c_{new} \neq$ **null** after line 12 then Invariant 2 is satisfied.*

Proof. We never execute lines 19–26 of Insert. If $\text{dist}(p, r) > \gamma$ then $c_{new} \neq \textbf{null}$ and Invariant 2(a) holds due to line 16, Invariant 2(b) holds due to the fact that there exists no point a with $TTL(c_{old}) < TTL(a) < TTL(c_{new})$, Invariant 2(c) holds due to the fact that there exists no point a with $TTL(c_{new}) < TTL(a)$, and Invariant 2(d) holds due to $c_{old} = q$. If $\text{dist}(p, r) \leq \gamma$ and $\text{dist}(p, c_{old}) > \gamma$ then $c_{new} \neq \textbf{null}$, and Invariant 2(a) holds due to line 18, Invariant 2(b) holds due to Invariant 1(b), Invariant 2(c) holds due to the fact that there exists no point a with $TTL(c_{new}) < TTL(a)$, and Invariant 2(d) holds due to $r = q$ (before line 12) and line 15. If $\text{dist}(p, r) \leq \gamma$ and $\text{dist}(p, c_{old}) \leq \gamma$ then Invariant 1 continues to be satisfied for all points with TTL smaller than p and for the point p due to line 17. ◀

▶ **Lemma 2.** *If $c_{new} \neq$ **null** and Invariant 2 is satisfied before* Insert*, then Invariant 2 is satisfied after line 12.*

Proof. If $\text{dist}(p, r) > \gamma$ then Invariant 2(a) holds due to line 21, Invariant 2(b) holds due to the fact that there exists no point a with $TTL(c_{old}) < TTL(a) < TTL(c_{new})$, Invariant 2(c) holds due to the fact that there exists no point a with $TTL(c_{new}) < TTL(a)$, and Invariant 2(d) holds due to $c_{old} = q$. If $\text{dist}(p, r) \leq \gamma$ and $\text{dist}(p, c_{new}) > \gamma$ then Invariant 2(a) holds due to line 23, Invariant 2(b) and 2(d) hold due to Invariant 2(c) before Insert, and Invariant 2(c) holds due to the fact that there exists no point a with $TTL(c_{new}) < TTL(a)$. If $\text{dist}(p, r) \leq \gamma$

and $\text{dist}(p, c_{new}) \leq \gamma$, and $\text{dist}(p, q) > \gamma$ and $q \neq c_{old}$ then Invariant 2(a) holds due to line 26, Invariant 2(b) holds due to Invariant 2(d) before INSERT, Invariant 2(c) holds due to the fact that there exists no point a with $TTL(c_{new}) < TTL(a)$, and Invariant 2(d) holds due to $q = r$ and line 20. If $\text{dist}(p, r) \leq \gamma$ and $\text{dist}(p, c_{new}) \leq \gamma$, and $\text{dist}(p, q) > \gamma$ and $q = c_{old}$ or $\text{dist}(p, q) \leq \gamma$, the Invariants 2(a)–(d) hold for all points except for the newest, for which the invariants hold due to lines 20, 22, 24 and 25. ◀

▶ **Lemma 3.** *If $c_{new} =$ **null** and Invariant 1 is satisfied before the line 4, then it is satisfied before INSERT (line 11).*

Proof. If c_{old} does not expire, then the claim obviously holds. Otherwise we execute line 10. Let c'_{old} be the expired point. Then we have for any two points a, b with $TTL(c'_{old}) < TTL(a), TTL(b) \leq TTL(r)$ $\text{dist}(a, c'_{old}), \text{dist}(b, c'_{old}) \leq \gamma$ due to Invariant 1(b) before line 4 and hence $\text{dist}(a, b) \leq 2\gamma$. Invariant 1(b) follows from $c_{old} = r$. ◀

▶ **Lemma 4.** *If $c_{new} \neq$ **null** and Invariant 2 is satisfied before the line 4, then one of the following statements holds before INSERT (line 11):*
1. *$c_{new} =$ **null** and Invariant 1 is satisfied.*
2. *$c_{new} \neq$ **null** and Invariant 2 is satisfied.*

Proof. If c_{old} does not expire the second claim immediately holds. Otherwise, we denote by c'_{old} the expired point. If $c'_{old} = q$, then we execute line 6. We set $c_{old} = r$, naturally satisfying Invariant 1(b). Further, at this time we have $TTL(c_{new}) = 1$, and for any two points a, b with $TTL(c_{new}) \leq TTL(a), TTL(b) \leq TTL(r)$ we have $\text{dist}(a, c_{new}), \text{dist}(b, c_{new}) < \gamma$ due to Invariant 2(c) before line 4 and hence $\text{dist}(a, b) \leq 2\gamma$, satisfying Invariant 1(a).

If $c'_{old} \neq q$, then we execute line 8. We set $c_{old} = q$. For any two points a, b with $TTL(c'_{old}) < TTL(a), TTL(b) < TTL(c_{new})$ $\text{dist}(a, c'_{old}), \text{dist}(b, c'_{old}) \leq \gamma$ due to Invariant 2(b) before line 4 and hence $\text{dist}(a, b) \leq 2\gamma$, satisfying Invariant 1(a). For all points a with $TTL(a) > q$, Invariant 1(b) after line 12 follows from Invariant 2(d) before line 4. ◀

The proof of the theorem is a direct consequence of the invariants but included for completeness.

▶ **Theorem 5.** *Given a set of points A with aspect ratio α and a window of size N, there exists an algorithm computing a $3(1+\epsilon)$-approximate solution for the metric diameter problem storing at most $8/\epsilon \cdot \ln \alpha$ points. The update time per point is $O(\varepsilon^{-1} \log \alpha)$.*

Proof. For any given estimate γ, we either have two points at distance at least γ, or Invariant 1 holds. In the latter case, we can bound the maximum diameter of two points p and q via the following case analysis.
$\boldsymbol{TTL(p), TTL(q) \leq TTL(c_{old})}$**:** Then $\text{dist}(p, q) \leq 2\gamma$.
$\boldsymbol{TTL(p) \leq TTL(c_{old}) < TTL(q)}$**:** Then $\text{dist}(p, q) \leq \text{dist}(p, c_{old}) + \text{dist}(c_{old}, q) \leq 3\gamma$.
$\boldsymbol{TTL(c_{old}) < TTL(p), TTL(q)}$**:** Then $\text{dist}(p, q) \leq \text{dist}(p, c_{old}) + \text{dist}(c_{old}, q) \leq 2\gamma$.
Now define an exponential sequence to the base of $(1 + \varepsilon)$, such that any value between $\min \text{dist}(p, q)$ and $\max \text{dist}(p, q)$ is $(1 + \varepsilon)$ approximated. For each power of $(1 + \varepsilon)$, we run Algorithm 1. Let γ be the largest value for which one of the instances of Algorithm 1 returns two points. The next larger estimate $\gamma \cdot (1 + \varepsilon)$ guarantees us no diameter of size $3(1 + \varepsilon)\gamma$, proving an approximation guarantee of at most $\frac{3(1+\varepsilon)\gamma}{\gamma} = 3(1 + \varepsilon)$ The memory usage of the algorithm consists of 4 points per instance of Algorithm 1 and $\log_{1+\varepsilon} \alpha = \frac{\ln \alpha}{\ln(1+\varepsilon)} \leq \frac{2}{\varepsilon} \ln \alpha$ instances. ◀

▶ Remark. To adapt this algorithm for windows where the maximum number of points are time dependent (e. g., the diameter of all points seen in the last hour) rather than the last N points, we can simply decouple the insertion procedure from the deletion routine. Whenever a point we currently keep in memory expires, we execute lines (4-10) and whenever a new point arrives, we call the INSERT procedure and line 12. Neither the invariants nor the proofs are affected in any way by this change.

4 The k-Center Problem

A 4-Approximation for Metric 2 Center

We run Algorithm 1 and show that, in the case of $k = 2$, it outputs a solution of cost at most 4 times the optimal solution. More precisely, let γ be the smallest estimate such that Algorithm 1 produces one point c with $\text{dist}(q, c) \leq 2\gamma$ for any point q in the current window. Further let a and b be the two points at distance greater than $\frac{\gamma}{1+\varepsilon}$ outputted by Algorithm 1 for the next smaller estimate. W.l.o.g let $\text{dist}(a, c) \geq \text{dist}(b, c)$. Then $\{a, c\}$ form a 4 approximation.

▶ **Theorem 6.** *Given a set of points A with aspect ratio α and a window of size S, there exists an algorithm computing a $4(1+\epsilon)$-approximate solution for the 2-center problem storing at most $8/\epsilon \cdot \ln \alpha$ points. The update time per point is $O(\varepsilon^{-1} \log \alpha)$.*

Proof. For c, the conditions of Invariant 1 apply, i.e. for any point p in our current window, we have $\text{dist}(p, c) \leq 2\gamma$. We now distinguish between two cases.

OPT $\geq \frac{\gamma}{2(1+\varepsilon)}$: We have $\text{dist}(p, \{a, c\}) \leq \text{dist}(p, c) \leq 2\gamma \leq 4 \cdot (1 + \varepsilon) \cdot \text{OPT}$.

OPT $< \frac{\gamma}{2(1+\varepsilon)}$: We first observe that a and b each fall into distinct clusters as their pairwise minimum distance is at least $\frac{\gamma}{1+\varepsilon}$. If a and c lie in distinct clusters, we have a 2-approximate solution, so we assume this not be the case. Then $\text{dist}(a, c) \leq 2 \cdot \text{OPT}$ and by construction, $\text{dist}(a, c) \geq \text{dist}(b, c)$. Then for any point p in the same cluster as b we have $\text{dist}(p, b) \leq 2 \cdot \text{OPT}$ and hence $\text{dist}(p, c) \leq \text{dist}(p, b) + \text{dist}(b, c) \leq 2 \cdot \text{OPT} + 2 \cdot \text{OPT} = 4 \cdot \text{OPT}$.

The proof of the space bound is analogous to that of Theorem 5. ◀

6-Approximation for Metric k-Center

A high level description of our algorithm is as follows, see also Algorithm 2 for pseudocode. We maintain a set A of at most $k+1$ *attraction points*. For each attraction point a, we maintain the newest point $R(a)$ within radius 2γ as a *representative*, i.e. $R(a) = \underset{p:\ \text{dist}(p,a)\leq 2\gamma}{\text{argmax}} TTL(R(a))$. When an attraction point expires, the representative point remains in memory. Call the set of representative points whose attraction points expired, the *orphaned representatives* O, and the set of representative points whose attraction points are still in the current window *active representatives* R. A new point p may become an attraction point if its distance is greater than 2γ to any point in A upon insertion. If the cardinality of A is greater than k, we retain the newest $k+1$ attraction points of A and all points with a greater TTL than the minimum TTL of A.

When asked to provide a clustering, we iterate through all estimates and either provide a counter example, or find a clustering which is then guaranteed to be a $6(1+\varepsilon)$-approximation. Our set of centers C first consists of an arbitrarily chosen point $p \in A \cup R \cup O$. Thereafter we greedily add any point point $q \in A \cup R \cup O$ with distance $\text{dist}(q, C) > 2\gamma$. If upon

termination $|C| > k$, we have a certificate for OPT $> \gamma$ and move to the next higher estimate. The smallest estimate with $|C| \leq k$ is then guaranteed to be a 6 approximation.

We start by giving the space bound.

Algorithm 2 Sliding Window Algorithm for $(\gamma, 6 \cdot \gamma)$-gap k-Center

```
1:  A, R, O ← ∅;
2:  for all element p of the stream do
3:      if q ∈ O expires then
4:          O ← O \ {q};
5:      if a ∈ A expires then
6:          DeleteAttraction(a);
7:      Insert(p);
8:  procedure DeleteAttraction(a)
9:      O ← O ∪ {R(a)};
10:     R ← R \ {R(a)};
11:     A ← A \ {a};
12: procedure Insert(p)
13:     D ← {a ∈ A | dist(p, a) ≤ 2 · γ};
14:     if D = ∅ then
15:         A ← A ∪ {p}
16:         R(p) ← p
17:         R ← R ∪ {R(p)}
18:         if |A| > k + 1 then
19:             a_old ← argmin_{a∈A} TTL(a);
20:             DeleteAttraction(a_old);
21:         if |A| > k then
22:             t ← min_{a∈A} TTL(a);
23:             for all q ∈ O do
24:                 if TTL(q) < t then
25:                     O ← O \ {q};
26:     else
27:         for all a ∈ D do
28:             Exchange R(a) with p in R;
```

▶ **Lemma 7.** *At any given time, the number of points kept in memory is bounded by at most* $3(k+1)$.

Proof. We number all attraction points we keep in memory via the sequence in which they arrived, i.e. a_1 is the first attraction point, a_2 the second, etc. Call this sequence S. Note that in this sequence a_1 also expires before a_2.

At any given time, we maintain at most $k+1$ attraction points A and $k+1$ active representative points R due to lines 18-20 and the subroutine DeleteAttraction (lines 8-11). What remains to be shown is that the number of orphaned representative points O also never exceeds $k+1$.

First, we show that $TTL(a_{i+k+1}) > TTL(R(a_i)) \geq TTL(a_i)$. We distinguish between two cases. If a_i expires, then a_{i+k+1} gets inserted after a_i exits the window, hence $TTL(a_{i+k+1}) > N+1+TTL(a_i)$ and $TTL(R(a_i))+N \leq TTL(a_i)$. Otherwise, a_i gets deleted via lines 18-20 in the exact same time step in which a_{i+k+1} got inserted, in which case the claim also holds.

Now consider any point of time and let j be the maximum index of any attraction point in S that has expired. By the above reasoning, any representative spawned by $a_{j-(k+1)}$ is no longer in memory, and the space bounds holds. ◀

▶ **Lemma 8.** *Let P be a set of points in a given window, $\gamma > 0$ an estimate of the clustering cost, $A \cup R \cup O$ the set of points we currently keep in memory with $|A| \leq k$. Then* $\max_{q \in P} \text{dist}(p, R \cup O) \leq 4\gamma$.

Proof. We note that for any attraction point a, the representative $R(a)$ has maximum TTL among all points with distance at most 2γ. When a point p arrives, it has distance at most 2γ to some attraction point (which may be identical to p if we create a new one). Hence, if $R(a)$ is still in memory, the claim holds for p.

We now argue that by executing lines 18-25, all points p with $\text{dist}(p, R \cup O) > 4\gamma$ have $TTL(p) < \min_{a \in A} TTL(a)$. If $TTL(p) > \min_{a \in A} TTL(a)$, then there exists an attraction point a' such that $\text{dist}(p, a') \leq 2\gamma$. Then we have $TTL(R(a')) \geq TTL(p) > \min_{a \in A} TTL(a)$ and $\text{dist}(p, R(a')) \leq 4\gamma$. Due to lines 24-25, $R(a')$ is never deleted until it expires. ◀

Combining these lemmas and using arguments analogous to those of the proof of Theorem 5, we have:

▶ **Theorem 9.** *Given a set of points P with aspect ratio α and a window size N, there exists an algorithm computing a $6(1+\epsilon)$-approximate solution for the metric k-center problem storing $6(k+1)\ln(\alpha)/\epsilon)$ points. The update time per point is $O(k^2\varepsilon^{-1}\log\alpha)$.*

Proof. Again define an exponential sequence to the base $(1+\varepsilon)$ and run Algorithm 2 in parallel for all powers of $(1+\varepsilon)$ as objective value estimates. The space bound then follows from Lemma 7.

For each estimate γ, we greedily compute a clustering of $A \cup R \cup O$ where the pairwise distance between centers is greater than 2γ. Now consider the smallest estimate γ' for which the greedy clustering requires at most k centers C.

We have $\max_{p \in A \cup R \cup O} \text{dist}(p, C) \leq 2\gamma'$. We further have for any point q in the current window $\max_{q \in P} \text{dist}(q, C) \leq \max_{q \in P} \text{dist}(q, R \cup O) + \max_{p \in A \cup R \cup O} \text{dist}(p, C) \leq 4\gamma' + 2\gamma' \leq 6\gamma'$ due to Lemma 8. Since we have $\text{OPT} > \frac{\gamma'}{1+\varepsilon}$, C is a $6(1+\varepsilon)$ approximation. ◀

5 Lower Bounds

Our lower bounds for the studied problems hold for the metric oracle distance model. Whenever we wish to know the distance between two points p, q, we have to store the points in their entirety in order to invoke the oracle. The fundamental assumption used in the proofs of this section is that the algorithm cannot create new points, unlike, for instance, in Euclidean spaces, where we can store projections, means and similar points. In particular, this implies that once a point is discarded by the algorithm, it cannot be recalled by any means at a later date. Without any assumptions as to how the points are encoded, we measure the space complexity of an algorithm via the number of stored points, rather than the number of bits. We do not consider the space required to store the distance oracle, the TTL of each point or any other information we might wish to store. A similar reasoning can be also found in the paper by Guha [15], where the author was able to derive a lower bound of $\Omega(k^2)$ points for any deterministic single-pass streaming algorithm approximating the cost of the optimal k-center clustering up to a factor $2 + 1/k$.

We first describe an adversarial input sequence for deterministic algorithms for the diameter problem and give a proof for randomized algorithms. With some modification, these ideas can be extended to the k-center problem, as well. We aim for a lower bound of $\Omega(\sqrt{N})$ points for deterministic algorithms. We divide the input into $\sqrt{N}$ buckets containing $\sqrt{N}$ points each. Unless the distances between two points are further specified, we will set these distances to 1. Denote the ith bucket by B_i and the jth point of bucket B_i by

$p_{i,j}$ with $i, j \in \{0, \ldots, \sqrt{N} - 1\}$. The points appear bucket by bucket, that is, $p_{i,j}$ is the $i \cdot \sqrt{N} + j + 1$th input point.

We assume that an algorithm always stores less than $\sqrt{N}$ points. Therefore, the algorithm must discard at least one point of bucket B_i before reading the first point of bucket B_{i+1}. Let f_i be such a discarded point in B_i. To any point from some bucket B_j, $j > i$, we then set the distance to f_i to be 2. By the same reason, there is at least one bucket without any stored points when the $N+1$st input point is read. Let B_t be this bucket. We now introduce the $N+1$st input point p that satisfies the distances $\text{dist}(p, p_{i,j}) = 1$ if $i > t$, $\text{dist}(p, p_{i,j}) = 3$ and $\text{dist}(p, p_{i,j}) = 2$ otherwise.

We proceed to insert copies of p until all points in buckets B_i with $i < t$ are expired. Therefore, there is no pair of points in memory with distance larger than 1. The algorithm can only output two points at distance 1 whereas the true diameter is 3.

▶ **Theorem 10.** *For windows of size N, any deterministic sliding window algorithm outputting a solution of cost greater than $\frac{1}{3}OPT$ for the distance oracle metric diameter problem with constant aspect ratio requires $\Omega(\sqrt{N})$ points.*

Recall that the algorithm by Chan and Sadjad [8] achieves a $2^{m+2} - 2 + \varepsilon$ approximation using $O(N^{1/(m+1)} \log \alpha)$ points, and it also falls under the same computational restrictions for the algorithms of this lower bound. Therefore, this lower bound cannot be strengthened by much, as their algorithm achieves a better approximation than 3 using roughly $N^{0.76}$ points by setting $m < \log 5/4$.

To utilize this instance for randomized algorithms, we require two modifications. First, we add additional points per bucket and uniformly choose f_i such that a randomized algorithm has little chance of retaining the correct point per bucket. Second, we use p (and its copies) to uniformly select a bucket B_t which the algorithm will have discarded with good probability.

▶ **Theorem 11.** *For windows of size N, any randomized sliding window algorithm outputting a solution of cost greater than $\frac{1}{3}OPT$ with probability greater than $\frac{1}{2}$ for the distance oracle metric diameter problem with constant aspect ratio requires $\Omega(\sqrt[3]{N})$ points.*

Proof. For ease of exposition, we will use a window of size $\Theta(N)$. The theorem then follows by rescaling N. We use $4N^{1/3}$ buckets consisting of $32N^{2/3}$ points each. In the following, any distance that is not further specified is set to be 1.

We iteratively replace one randomly chosen point from bucket B_i with f_i where f_i has distance 2 to any point from bucket B_j with $j > i$. At the end of the stream, we insert a point p with the following distances. First, choose a random bucket B_t and set $\text{dist}(p, f_t) = 3$ and $\text{dist}(p, q) = 2$, where $q \in B_t \setminus \{f_t\}$. Any point inserted after bucket B_t has distance 1 to p and any point inserted before B_t has distance 2. We then repeatedly add copies of p at total of N times.

To show that the distances still satisfy the triangle inequality, we first observe that only $\text{dist}(p, f_t)$ is neither 1 or 2 and thus requires special consideration. Here, we have $3 = \text{dist}(p, f_t) \leq \text{dist}(p, q) + \text{dist}(q, f_t) = 1 + 2$ for $q \in B_i$ with $i > t$, and $3 = \text{dist}(p, f_t) \leq \text{dist}(p, q) + \text{dist}(q, f_t) \leq 2 + 1$ for $q \in B_i$ with $i \leq t$.

At any given time, the algorithm has to output a pair of points whose distance is within a factor 3 of the diameter of the current window. Observe that if the algorithm did not store any of the replaced points $\{f_0, \ldots, f_{4N^{1/3}-1}\}$ and not any point of bucket B_t then the algorithm is not able to produce two points at distance greater than 1. Hence, by Yao's minimax principle, it is sufficient to bound the number of points used by any deterministic algorithm against the above input distribution.

We first bound the probability that the algorithm stores some point f_i. Call this event A. If we assume that the algorithm did not store any of the points $\{f_1, \dots, f_i\}$ it follows that the points in bucket B_{i+1} all have the same distance to the stored points. This implies that we can assume that the decision which points of bucket B_{i+1} will be kept is already fixed. The probability that f_i is one of these points is bounded by the hypergeometric distribution with population $32 \cdot N^{2/3}$, $N^{1/3}$ samples and 1 success in both population and sample: $\frac{\binom{32\cdot N^{2/3}-1}{N^{1/3}-1}\cdot\binom{1}{1}}{\binom{32\cdot N^{2/3}}{N^{1/3}}}$. Then the probability that no f_i is stored for any of the $4 \cdot N^{1/3}$ buckets can be lower bounded by

$$1 - \mathbb{P}[A] \geq \left(1 - \frac{\binom{32\cdot N^{2/3}-1}{N^{1/3}-1}\cdot\binom{1}{1}}{\binom{32\cdot N^{2/3}}{N^{1/3}}}\right)^{4\cdot N^{1/3}} = \left(1 - \frac{N^{1/3}}{32 \cdot N^{2/3}}\right)^{4\cdot N^{1/3}} \geq 1 - \frac{1}{8} = \frac{7}{8}.$$

Now we bound the probability that the algorithm retains any point from bucket t upon submission, which we call event B. Again, conditioned on the event that A does not hold ($\overline{A}$), the buckets from which the algorithm stores at least one point are fixed. The probability that B_t is among the stored buckets again follows a hypergeometric distribution with population $4 \cdot N^{1/3}$, $N^{1/3}$ samples and 1 success in both population and sample. Therefore $\mathbb{P}[B|\overline{A}] = \frac{\binom{4\cdot N^{1/3}-1}{N^{1/3}-1}\cdot\binom{1}{1}}{\binom{4\cdot N^{1/3}}{N^{1/3}}} = \frac{1}{4}$. Since one of the events A or B has to hold for the algorithm to output a solution with approximation factor greater than $\frac{1}{3}$, the probability that an algorithm storing less than $N^{1/3}$ points produces a solution with the desired approximation guarantee is at most $\mathbb{P}[A \cup B] \leq \mathbb{P}[A] + \mathbb{P}[B] = \mathbb{P}[A] + \mathbb{P}[B|A] \cdot \mathbb{P}[A] + \mathbb{P}[B|\overline{A}] \cdot \mathbb{P}[\overline{A}] \leq 2 \cdot \mathbb{P}[A] + \mathbb{P}[B|\overline{A}] \leq \frac{2}{8} + \frac{1}{4} = \frac{1}{2}$. ◀

We only briefly describe the k-center lower bound. The instance is also divided into sufficiently large buckets, from which the algorithm is forced to discard one point each. The main difference with the previous proof will be that the distances between all the points (except for a randomly chosen missing point f_t) are 2 and the distance from f_t to the more recent buckets is 4.

▶ **Theorem 12.** *For windows of size N, any randomized sliding window algorithm achieving an approximation factor less than 4 with probability greater than $\frac{1}{2}$ for the distance oracle metric 2 center problem with constant aspect ratio requires $\Omega(\sqrt[3]{N})$ points.*

Abstract

We consider the problem of computing a $(1+\varepsilon)$-approximation of the Hamming distance between a pattern of length n and successive substrings of a stream. We first look at the one-way randomised communication complexity of this problem. We show the following:

- If Alice and Bob both share the pattern and Alice has the first half of the stream and Bob the second half, then there is an $\mathcal{O}(\varepsilon^{-4}\log^2 n)$ bit randomised one-way communication protocol.
- If Alice has the pattern, Bob the first half of the stream and Charlie the second half, then there is an $\mathcal{O}(\varepsilon^{-2}\sqrt{n}\log n)$ bit randomised one-way communication protocol.

We then go on to develop small space streaming algorithms for $(1+\varepsilon)$-approximate Hamming distance which give worst case running time guarantees per arriving symbol.

- For binary input alphabets there is an $\mathcal{O}(\varepsilon^{-3}\sqrt{n}\log^2 n)$ space and $\mathcal{O}(\varepsilon^{-2}\log n)$ time streaming $(1+\varepsilon)$-approximate Hamming distance algorithm.
- For general input alphabets there is an $\mathcal{O}(\varepsilon^{-5}\sqrt{n}\log^4 n)$ space and $\mathcal{O}(\varepsilon^{-4}\log^3 n)$ time streaming $(1+\varepsilon)$-approximate Hamming distance algorithm.

1 Introduction

We study the complexity of one of the most basic problems in pattern matching, that of approximating the Hamming distance. Given a pattern P of length n the task is to output a $(1+\varepsilon)$-approximation of the Hamming distance between P and every n-length substring of a longer text. We provide the first efficient one-way randomised communication protocols as well as a new, fast and space efficient streaming algorithm for this problem.

The general task of efficiently computing the Hamming distances offline between a pattern and a text has been studied for many years. When the input is binary and the text has length proportional to that of the pattern, then all outputs can be computed exactly in $\mathcal{O}(n\log n)$ time by repeated application of the fast Fourier transform [14]. For larger alphabets, $\mathcal{O}(n\sqrt{n\log n})$ time solutions were first discovered in the 1980s [1, 22]. The fastest randomised algorithm for $(1+\varepsilon)$-approximate Hamming distance computation for large alphabets was due for many years to Karloff from 1993 [20] running in $\mathcal{O}(\varepsilon^{-2}n\log^2 n)$ time overall. In a breakthrough paper in 2015 a new algorithm was given improving the time complexity to $\mathcal{O}(\varepsilon^{-1}n\log^3 n\log\varepsilon^{-1})$ [21]. These fast methods all require linear space and up until this point no sublinear space solutions have been known.

The first basic question that arises is whether it is in fact possible to give a $(1+\varepsilon)$-approximation to the Hamming distance in a streaming setting while using only sublinear space. In order to explore this question we start our study by considering two natural

communication complexity problems which may also be of independent interest. Any lower bound for these communication problems will give a lower bound for the space usage of a corresponding streaming algorithm. This follows from a standard reduction where a space efficient streaming algorithm is converted into a communication protocol by taking a snapshot of memory after some symbol of the input has been read in and then sending this snapshot to the other player. On the other hand, the communication upper bounds we provide will set targets for space bounds for algorithms in the streaming setting.

Any streaming pattern matching algorithm using a pattern of length n can be reduced to repeated application of a streaming algorithm that runs on texts of length $2n$. This is done by splitting the stream into substreams of length $2n$ which overlap by n symbols. As a result we consider communication problems with these parameter settings for pattern and text length.

▶ **Problem 1.** *Consider a text T of length $2n$ and a pattern P of length n. Let Alice hold the information about the first half of the text and the whole of the pattern, and let Bob hold the information about the second half of the text and the whole of the pattern. Bob must output $(1+\varepsilon)$-approximations of the Hamming distance for each alignment of P and T.*

A lower bound for the communication complexity of this problem follows from a combination of the lower bound for the communication complexity of a windowed counting problem introduced by Datar et al. in 2002 [13] and the one-way communication complexity lower bound for approximating the Hamming distance between two n-bit strings from [18].

For the first part consider the following communication problem. Assume that there is a bit vector B of length $2n$. Let Alice hold the information about the first half of B, and let Bob hold the information about the second half of B. Bob must output $(1+\varepsilon)$-approximations of the number of set bits in each window of length n. Datar et al. showed that Alice will have to send to Bob $\Omega(\varepsilon^{-1}\log^2\varepsilon^{-1}n)$ bits of information. There is a straightforward reduction from this basic counting problem to Problem 1 which then gives us the same lower bound. We set $T=B$ and $P=00\ldots0$ and then a $(1+\varepsilon)$-approximation of the Hamming distance at an alignment i of P and T gives a $(1+\varepsilon)$-approximation of the number of set bits in the window $T[i,i+n-1]$. For the second part we use Theorem 4.1 from [18] which states that the one-way communication complexity of $(1+\varepsilon)$-approximate Hamming distance for two strings of length n is $\Omega(\varepsilon^{-2}\log n)$ for constant error probability. Combining these two lower bounds together we get a lower bound of $\Omega(\varepsilon^{-2}\log n+\varepsilon^{-1}\log^2\varepsilon^{-1}n)$ for the communication complexity of Problem 1.

Our first result is an efficient one-way communication protocol for Problem 1 whose complexity is only slightly higher than this lower bound. In our protocol Alice uses the fact that Bob knows the pattern as well to give an efficient encoding for parts of her half of the text which are at small Hamming distance from the pattern.

▶ **Theorem 1.** *Problem 1 has one-way randomised communication complexity $\mathcal{O}(\varepsilon^{-4}\log^2 n)$.*

As a model for streaming pattern matching, this communication upper bound requires that a copy of the pattern is available at all times. Our main interest is however in algorithms whose total space complexity is sublinear in the pattern size. In order to model this situation more accurately we now consider a stronger three party communication problem.

▶ **Problem 2.** *Assume that there is a text T of length $2n$ and a pattern P of length n. Let Alice hold the information about the pattern, let Bob hold the information about the first half of the text, and let Charlie hold the information about the second half of the text. Alice will send one message to Bob who will then send one message to Charlie. Charlie must output $(1+\varepsilon)$-approximations of the Hamming distance for each alignment of P and T.*

Somewhat surprisingly, we are still able to obtain a sublinear protocol for this new problem although the bound is higher than for the simpler Problem 1. The main technical elements of this communication protocol combine the newly introduced idea of approximate periods with succinct run-length encoded representations of the input.

▶ **Theorem 2.** *Problem 2 has one-way randomised communication complexity* $\mathcal{O}(\frac{\sqrt{n}}{\varepsilon^2}\log n)$.

Having investigated the communication complexity of $(1+\varepsilon)$-approximate Hamming distance we can now define the streaming $(1+\varepsilon)$-approximate Hamming distance problem.

▶ **Problem 3.** *Consider a pattern P of length n and a stream arriving one symbol at a time. We must output a $(1+\varepsilon)$-approximation to the Hamming distance between P and the latest n-length suffix of the stream as soon as a new symbol arrives. In this setting we cannot, for example, store a copy of the pattern or stream without accounting for it in our space usage.*

The upper bounds for the communication complexity of Problem 2 suggest space upper bounds we shall aim for in order to develop an optimal algorithm for the $(1+\varepsilon)$-approximate Hamming distance in the streaming setting. We make the first step towards this direction and show two randomised sublinear-space algorithms for the problem. We start by giving a solution for the case when both the pattern and the text are binary strings.

▶ **Theorem 3.** *When both P and T are binary, there is an algorithm for Problem 3 which uses $\mathcal{O}(\varepsilon^{-3}\sqrt{n}\log^2 n)$ bits of space and runs in $\mathcal{O}(\varepsilon^{-2}\log n)$ time per arriving symbol.*

The same bounds hold for alphabets of constant size σ as we can map each occurrence of the i^{th} symbol of the alphabet in the pattern or in the text to a binary string $0^{i-1}10^{\sigma-i}$, which will result in doubling the Hamming distance between the pattern and the text at each particular alignment.

For polynomial size alphabets our bounds are higher by a factor $\varepsilon^{-2}\log^2 n$ and our approach is based on the mapping idea of Karloff [20]. In that paper he showed that there exists $\Theta(\varepsilon^{-2}\log^2 n)$ mappings map_j of the alphabet onto $\{0,1\}$ such that an $(1+\varepsilon/3)$-approximation of the Hamming distance between P and T at a particular alignment can be given by a normalised average of the Hamming distances between $map_j(P)$ and $map_j(T)$ at this alignment. Moreover, Karloff showed that the mappings can be generated in $\mathcal{O}(\varepsilon^{-2}\log^3 n)$ space and $\mathcal{O}(\log n)$ time per symbol. For each pattern-text pair mapped on to a binary alphabet we then run the algorithm of Theorem 3 to find $(1+\varepsilon/3)$-approximations and finally obtain:

▶ **Theorem 4.** *There is an algorithm for Problem 3 which uses $\mathcal{O}(\varepsilon^{-5}\sqrt{n}\log^4 n)$ bits of space and runs in $\mathcal{O}(\varepsilon^{-4}\log^3 n)$ time per arriving symbol.*

Our solution has guaranteed worst case complexity per arriving symbol and uses roughly the square root of the space required by the known offline $(1+\varepsilon)$-approximate algorithms. A key technical innovation for our space reduction is the notion we introduce of a super-sketch. This a compact and efficiently updateable representation of consecutive text substrings which we require to be able to achieve sublinear space. For simplicity we will make the natural assumption throughout that $\varepsilon < 1/2$.

1.1 Related work and lower bounds

The one-way communication complexity of a number of variants of Hamming distance computation has been studied over the years. These includes $(1+\varepsilon)$-approximation [18],

the so called gap Hamming problem [9] and a bounded version known as k-mismatch [15]. However all this previous work has assumed that both Alice and Bob have strings of the same length and so need only give a single output. There has also been great interest in efficient streaming algorithms over the last 20 years, following the seminal work of [2]. In relation specifically to pattern matching problems, where space is not limited but where an output must be computed after every new symbol of the text arrives, the Hamming distance between the pattern and the latest suffix of the stream can be computed online in $O(\sqrt{n \log n})$ worst-case time per arriving symbol or $O(\sqrt{k} \log k + \log n)$ time for the k-mismatch version [11]. Both these methods however require $\Theta(n)$ space. Using the same approach, a number of other approximate pattern matching algorithms have also been transformed into efficient linear space online algorithms including [4, 3, 5, 8, 7, 6, 23]. In 2013 a small space streaming pattern matching algorithm was shown for parameterised matching [17] and in 2016 for the k-mismatch problem [10]. The latter k-mismatch paper is of particular relevance to our work. In [10] as a part of a space-efficient streaming algorithm for the k-mismatch problem, the authors presented a $(1+\varepsilon)$-approximate algorithm with space $\mathcal{O}(\varepsilon^{-2}k^2 \log^7 n)$ and running time $\mathcal{O}(\varepsilon^{-2} \log^5 n)$ per arriving symbol that returns a $(1+\varepsilon)$-approximation for all alignments of the pattern and text where the Hamming distance is at most k. The algorithm we give in this current paper can be seen a generalisation of this work, both removing the requirement for a prespecified threshold k and also using less space when $k \gtrsim n^{1/4}$.

2 Overview

In this section we give an overview of the main ideas needed for our results. We will make extensive use of sketching. Alon, Matias and Szegedy were first to show that sketching can be used to approximate frequency statistics of a stream with a particular emphasis on F_2 [2]. Later their sketching technique was generalized to allow approximation of $||x_1 - x_2||_p$ for two vectors x_1 and x_2 and any $p \in (0; 2]$ by Indyk et al. [16, 12]. We will use the sketches of Indyk et al. to show the communication complexity upper bounds. These sketches are based on p-stable distributions and have the advantage that they can be used even for large-size alphabets. For our streaming algorithm where we assume that the input alphabet is binary we will use simpler sketches based on the original technique of Alon et al.

2.1 Communication complexity

To show communication complexity bounds we will be using sketches based on p-stable distributions (see [16] and Sections 4.1 and 5.1 of [12]). Setting σ to be the alphabet size, a sketch of a string x is defined as a vector $sk(x)$ of length $\Theta(\varepsilon^{-2})$ such that

$$sk(x)[i] = \sum_j Y_{i,j} \cdot x[j]$$

where each $Y_{i,j}$ is drawn independently from a random stable distribution with parameter $p \leq \varepsilon / \log \sigma$. For two vectors x_1 and x_2 it can be shown that with constant probability the median of values $|sk(x_1)[i] - sk(x_2)[i]|$, appropriately scaled, is a $(1+\varepsilon)$-approximation of the Hamming distance. Importantly, variables $Y_{i,j}$ can be generated when we need them with the help of Nisan's pseudo-random generator, which requires only $\mathcal{O}(\log^2 n)$ random bits.

2.1.1 Problem 1 – both Alice and Bob know the pattern

The main idea of our communication complexity upper bound for Problem 1 is that if the Hamming distance between the text and the pattern at a particular alignment is (relatively) small, then Alice and Bob can use the pattern to describe the part of the text aligned with the pattern.

At each alignment the pattern can be divided into two parts – a prefix, aligned with Alice's half of the text, and a suffix, aligned with Bob's half of the text. Alice needs to transmit information that will help Bob approximate the Hamming distance between these different prefixes of the pattern and her half of the text. She does so by selecting a logarithmic number of prefixes of the pattern with Hamming distances $\Theta(\varepsilon^{-j})$ from the text. She then divides the part of the text aligned with each of these prefixes into blocks such that the mismatches are evenly spread across the blocks, and sends each block's starting position and sketch to Bob.

When Bob wants to compute the Hamming distance between a prefix P' of the pattern and the text and he knows that this Hamming distance is at least $\Theta(\varepsilon^{-(j-1)})$, he uses the prefix P_j with Hamming distance $\Theta(\varepsilon^{-j})$ and the sketches of associated text blocks. The part of Alice's text aligned with P' can be composed of several full blocks and at most one block suffix. Hamming distances between P' and the full blocks can be approximated with the help of the sketches. To approximate the Hamming distance between P' and the suffix of the block, Bob will substitute the suffix with the aligned part of P_j. As the number of mismatches between the suffix and P_j is small compared to $\Theta(\varepsilon^{-(j-1)})$, it will give a good approximation of the Hamming distance.

2.1.2 Problem 2 – only Alice knows the pattern

We start by reviewing some notation introduced in [10].

▶ **Definition 5.** The x-period of a string S of length n is the smallest integer $\ell > 1$ such that the Hamming distance between $S[1, n-\ell]$ and $S[\ell, n]$ is at most x.

▶ **Definition 6.** We define the ℓ-RLE encoding of S to be the ordered set of the run-length encodings of strings $S_i = S[i]S[\ell+i]S[2\ell+i]\dots S[\lfloor (n-i)/\ell \rfloor \cdot \ell + i]$, where $i \in [1, \ell]$. The size of the ℓ-RLE encoding is the total number of runs in the encodings of strings S_i.

▶ **Example 7.** Let $S = aabaabaabaabaabaabaac$. The 3-RLE encoding of S is: the run-length encoding $(a, 7)$ of $S_1 = aaaaaaa$, the run-length encoding $(a, 7)$ of $S_2 = aaaaaaa$, and the run-length encoding $(b, 6)(c, 1)$ of $S_3 = bbbbbbc$. The size of the encoding is $1 + 1 + 2 = 4$.

Note that ℓ-RLE encoding of S is deterministic and lossless. In [10] it was also shown that if ℓ is the x-period of a string S for some integer x, then the size of the ℓ-RLE encoding is $\mathcal{O}(\ell + x)$. Intuitively, this is because each new run in the encoding of S_i corresponds to a mismatch between $S[1, n-\ell]$ and $S[\ell, n]$, and therefore there can be at most $\ell + x$ runs.

We now explain the idea of the communication protocol for Problem 2. Let the block size $B = \sqrt{n}$ and the threshold $\tau = 2\varepsilon^{-1}\sqrt{n}$. Bob will compute a sketch for each B^{th} suffix of his half of the text and send it to Charlie. Consider a particular alignment of the pattern and of the text.

Case 1: Hamming distance is large. The pattern can be divided into three parts: a prefix of length at most $B - 1$, a middle part aligned with one of the n/B sketched suffixes of Bob's half of the text, and a suffix aligned with Charlie's half of the text. If the Hamming

distance at the alignment is larger than τ, then the prefix can be discarded as it will change the Hamming distance by at most $B = (\varepsilon/2) \cdot \tau$. The Hamming distance between the rest of the pattern and the text can be approximated easily. Charlie has received the sketch of the middle part of the pattern as well as the sketch of the suffix of Alice's half of the text which aligns with it. Charlie can combine the sketch from Alice's part of the text with the information he has about his half of the text and then compare this sketch to the pattern sketch as required.

Case 2: Hamming distance is small. The main challenge is therefore alignments where the Hamming distance is smaller than τ. If the $(2+\varepsilon)\tau$-period of the pattern is larger than B, then there are at most n/B such alignments. In this case, Bob can simply send the Hamming distances for all these alignments to Bob. If the period is at most B, then Bob will find the first alignment with small Hamming distance and will use the ℓ-RLE encoding of the pattern and the full list of mismatches to describe the text. Using this description Charlie will be able to fully recover the corresponding suffix of the text and to compute the Hamming distances for all remaining alignments. The only technicality is that Bob does not know Charlie's half of the text and thus will not be able to compute the Hamming distances between the whole pattern and the text. We elaborate on this in Section 3.2.

2.2 A small space streaming algorithm

In our small space streaming algorithm we will use simpler sketches which provide a $(1+\varepsilon)$-approximation to the Hamming distance between two binary strings of the same length B. The method is now folklore but is essentially an application of the technique of the Johnson-Lindenstrauss lemma [19]. To do this we create a random $\varepsilon^{-2} \times B$ matrix M whose entries are from $\{-1, 1\}$. The sketch of a string x of length B is then defined to be equal to Mx, and it is known that the appropriately scaled square of the L_2 norm of the difference of the sketches of two strings gives a $(1+\varepsilon)$-approximation of the Hamming distance between them. We will also be using M to define sketches of strings of length $\ell < B$. In this case, we simply append the strings with $(B-\ell)$ zeros and use the method describe above. The original analysis applies here as well. Finally, we will use M to define "super-sketches" of strings of length $n - B$. Assume that a string of length $n - B$ is divided into $n/B - 1$ non-overlapping blocks of size B. A super-sketch is then defined to be a linear combination of the sketches of the blocks. We elaborate more on sketches and super-sketches in Section 4.

Now we give a high-level overview of our algorithm. The algorithm starts by preprocessing the pattern P. It computes and stores a super-sketch of each $(n - B)$-length substring of P. The algorithm then processes the text in non-overlapping blocks of length B, computing a sketch for each block. The blocks' sketches can be maintained efficiently as we need to maintain only one sketch at a time. The algorithm also maintains a super-sketch of the last $n/B - 1$ blocks. To compute an approximation of the Hamming distance at a particular alignment, the algorithm divides the pattern into three parts: a prefix of length $(B - i)$, a middle part of length $(n - B)$, and a suffix of length i, where the middle part is aligned with a block border (see Figure 1).

The algorithm then starts by computing the $(1 + \varepsilon)$-approximation of the Hamming distance between the middle part and the text with the help of the super-sketches. If the Hamming distance is large, the algorithm can simply discard the prefix and suffix parts. Otherwise, the algorithm also needs to approximate the Hamming distance between the prefix or the suffix of the pattern and the text. To approximate the Hamming distance between the prefix of the pattern and the text the idea is to use the information Alice transfers to

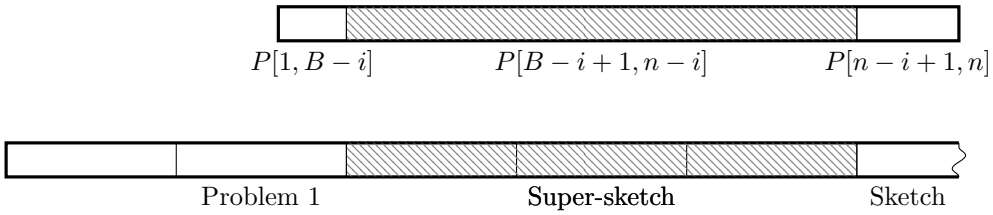

Figure 1 To estimate the Hamming distances at a particular position the algorithm uses a data structure containing the information Alice transfers to Bob in our solution for Problem 1 for the prefix $P[1, B-i]$, a super-sketch for the middle part $P[B-i+1, n-i]$, and a sketch for the suffix $P[n-i+1, n]$.

Bob in our solution for Problem 1. For the suffix, the algorithm will use the sketch of the part of the block between its start and the current alignment.

3 Communication complexity

In this section we show upper bounds for communication complexities of Problems 1 and 2.

3.1 Problem 1

We start by showing an upper bound for the communication complexity of Problem 1. Remember that in this problem we have two players, Alice and Bob. Alice knows the first half of the text T and the pattern P, and Bob knows the second half of the text T and the pattern P. We will show that the communication complexity of this problem is $\mathcal{O}(\varepsilon^{-4}\log^2 n)$.

Let us first explain what Alice sends to Bob. For simplicity, we denote $k = 6/\varepsilon$. First, Alice selects $q = \lfloor \log_k n \rfloor$ positions $n \geq i_1 \geq i_2 \geq \ldots \geq i_q \geq 1$ such that the Hamming distance between $T[i_j, n]$ and the prefix $P[1, n-i_j+1]$ is at most k^{j+1}. She does this in turn starting from $j = 1$ and selecting the leftmost possible position for each j. Alice then sends to Bob $\mathcal{O}(k^2 \cdot \varepsilon^{-2}\log n) = \mathcal{O}(\varepsilon^{-4}\log n)$ bits of information for each j. She starts by dividing $T[i_j, n]$ into k^2 blocks such that the Hamming distance between each block and the corresponding substring of the pattern is at most k^{j-1}. If $n \geq b_1 > b_2 > \ldots > b_{k^2} = i_j$ are the borders of the blocks, she sends Bob $b_1, b_2, \ldots, b_{k^2} = i_j$ and the $(1+\varepsilon/6)$-approximate sketches of $T[b_\ell, n]$ for all $\ell \in [1, k^2]$. In total, Alice sends to Bob $\mathcal{O}(\varepsilon^{-4}\log^2 n)$ bits of information.

To see how Bob can use this information, consider a particular position i. At this position $P[1, n-i+1]$ is aligned with Alice's half of the text, whereas $P[n-i+2, n]$ is aligned with Bob's half of the text. As Bob knows the pattern, he can compute the exact Hamming distance between $P[n-i+2, n]$ and his half of the text with no additional information. We now go on to explain how he can estimate the Hamming distance h between $P[1, n-i+1]$ and Alice's half of the text.

Bob starts by locating the position i_j that is closest to i from the left, and the block $T[b_{\ell+1}, b_\ell]$ of $T[i_j, n]$ containing i (see Figure 2). The border b_ℓ divides the pattern into two parts, P_1 and P_2. Let h_1 be the Hamming distance between P_1 and the text, and h_2 be the Hamming distance between P_2 and the text, $h_1 + h_2 = h$. To find a $(1+\varepsilon)$-approximation h_2' of h_2, Bob uses the sketch of $T[b_\ell, n]$. He cannot use sketches to estimate h_1 as P_1 is not aligned with the block $T[b_{\ell+1}, b_\ell]$, but he knows that there are only a few mismatches between $T[b_\ell, b_{\ell+1}]$ and the pattern aligned at the position i_j. So he estimates h_1 by computing

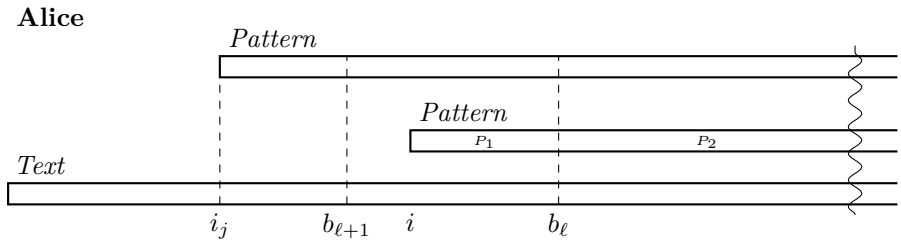

Figure 2 Figure shows Alice's half of the text and the rightmost position $i_j < i$. Dashed lines show block borders for $T[i_j, n]$. Borders $b_{\ell+1}$ and b_ℓ are the closest to i from the left and from the right respectively. The border b_ℓ divides the pattern into two parts P_1 and P_2. To estimate the Hamming distance h_1 between P_1 and T, Bob uses the pattern aligned at i_j. To estimate the Hamming distance h_2 between P_2 and T, he uses the sketch of $T[b_\ell, n]$.

the Hamming distance h'_1 between P_1 and the pattern aligned at the position i_j. The next lemma shows that Bob can output $h' = (h'_1 + h'_2)/(1 - \varepsilon/3)$ as a $(1+\varepsilon)$-approximation of h.

▶ **Lemma 8.** *h' is a $(1+\varepsilon)$-approximation of h.*

Proof. Remember that h'_1 is the Hamming distance between P_1 and the pattern aligned at the position i_j, and h_1 is the Hamming distance between P_1 and the text. The Hamming distance between the pattern aligned at the position i_j and $T[b_{\ell+1}, b_\ell]$ is at most k^{j-1}. Therefore,

$$h_1 - k^{j-1} \le h'_1 \le h_1 + k^{j-1}$$

On the other hand, h'_2 is a $(1+\varepsilon/6)$-approximation of h_2. Hence,

$$h_1 + h_2 - k^{j-1} \le h'_1 + h'_2 \le h_1 + k^{j-1} + (1+\varepsilon/6) \cdot h_2 \,.$$

We now substitute $h = h_1 + h_2$ and estimate $h_2 \le h$ to obtain

$$h - k^{j-1} \le h'_1 + h'_2 \le (1+\varepsilon/6) \cdot h + k^{j-1} \,.$$

Finally, by our choice of i_j we have $h \ge k^{j+1}$, and therefore

$$(1-\varepsilon/3) \cdot h \le (1-\varepsilon/6) \cdot h \le h'_1 + h'_2 \le (1+\varepsilon/3) \cdot h \,.$$

Dividing all parts of this inequality by $(1-\varepsilon/3)$, we obtain

$$h \le h' = (h'_1 + h'_2)/(1-\varepsilon/3) \le \frac{1+\varepsilon/3}{1-\varepsilon/3}\, h \le (1+\varepsilon) \cdot h \,. \qquad \blacktriangleleft$$

3.2 Problem 2

In this section we show an upper bound for the communication complexity of Problem 2. Remember that in this problem we have three players, Bob, Charlie, and Alice. Bob knows the first half of the text T, Charlie knows the second half of the text T, and Alice knows the pattern P. We will show that the communication complexity of this problem is $\mathcal{O}(\varepsilon^{-2}\sqrt{n}\log n)$.

Let the block size $B = \sqrt{n}$ and the threshold $\tau = 2\varepsilon^{-1}\sqrt{n}$. We start by explaining what the players send to each other. Alice sends to Bob the following information:

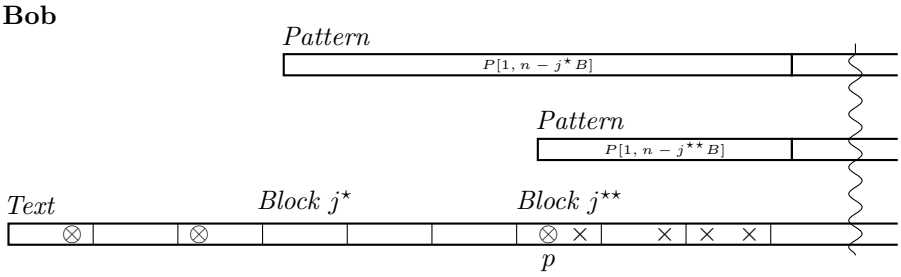

Figure 3 The figure shows Bob's half of the text. Crosses show alignments where the Hamming distance is at most τ. $P[1, n - j^\star B]$ is the longest prefix with $\tau(2+\varepsilon)$-period smaller than B. Block $j^{\star\star} \geq j^\star$ is the first block containing a cross. Bob sends to Charlie sketches of text suffixes starting at blocks' borders, locations of all encircled crosses, and the last block.

1. $(1+\varepsilon/2)$-approximate sketches of suffixes $P[i, n]$ for all $i \in [1, B]$ (Charlie will use them to estimate large Hamming distances);
2. $(1+\varepsilon/2)$-approximate sketches of prefixes $P[1, n - jB]$ for all $j \in [1, n/B]$ (Bob will use them to find alignments with small Hamming distances);
3. The ℓ-RLE encoding of the longest prefix $P[1, n - j^\star B]$ with $(2+\varepsilon)\tau$-period ℓ smaller than B (Bob will use it to describe the text).

Overall Alice sends $\mathcal{O}((n/B + B) \cdot \varepsilon^{-2} \log n + ((2+\varepsilon)\tau + B) \cdot \log n) = \mathcal{O}(\varepsilon^{-2}\sqrt{n} \log n)$ bits of information.

Bob starts by forwarding the information he received from Alice to Charlie. Bob also sends him $(1+\varepsilon/2)$-approximate sketches of all suffixes $T[jB, n]$. Next, for each $j < j^\star$ Bob uses the sketch of $P[1, n - jB]$ to find $(1+\varepsilon/2)$-approximations of Hamming distances in a block j. (Remember that Bob knows $T[1, n]$ and can compute a sketch for any its substring.) If the approximate value of the Hamming distance for some alignment is smaller than $(1+\varepsilon/2)\tau$, he sends it to Charlie. Note that there is at most one such alignment in a block. Indeed, if we have two such alignments in the block, then the Hamming distance between the patterns at these alignments is at most $(2+\varepsilon)\tau$, which is a contradiction with the $(2+\varepsilon)\tau$-period being larger than B. Moreover, Bob will not miss any alignment with the Hamming distance smaller than τ.

After that, Bob decodes $P[1, n - j^\star B]$ from its ℓ-RLE encoding and computes the Hamming distances between $P[1, n - jB]$ and the text for all alignments in blocks $j \geq j^\star$ precisely. He finds the first block $j^{\star\star} \geq j^\star$ where there is an alignment of $P[1, n - j^{\star\star} B]$ with the Hamming distance at most τ. Bob sends Charlie the starting position p of this alignment and the positions of the mismatches. Finally, he sends Charlie all bits of the last block of his half of the text. Overall, Bob sends to Charlie $\mathcal{O}(\varepsilon^{-2}\sqrt{n} \log n + (\varepsilon^{-2} \log n + \log n) \cdot (n/B) + \tau) = \mathcal{O}(\varepsilon^{-2}\sqrt{n} \log n)$ bits of information.

We now explain how Charlie computes the Hamming distances. If the Hamming distance at a particular alignment i in a block $j < j^{\star\star}$ is smaller than τ, then Charlie already knows its approximate value. If it is bigger than τ, then Charlie computes its approximation using the sketch of the longest suffix $P[jB - i, n]$ of P aligned with a block border, the sketch of $T[(j+1)B, n]$, and $T[n+1, 2n]$. Let h be the Hamming distance between the text and the pattern at the alignment i and let h' be the Hamming distance between $T[(j+1)B, i+n-1]$ and $P[jB - i, n]$.

▶ **Lemma 9.** $h \leq h' + B \leq (1+\varepsilon) \cdot h$.

Proof. The left inequality is trivial. To prove the right one, remember that $\tau \leq h$, which implies $B = (\varepsilon/2)\tau \leq (\varepsilon/2) \cdot h$. ◀

We now go on to the remaining blocks. The Hamming distances at alignments $i < p$ in the block $j^{\star\star}$ are bigger than τ and Charlie can find their approximation in the way described above. Charlie then decodes $P[1, n - j^{\star}B]$ and recovers $T[p, n]$ by fixing the at most $\sqrt{n}$ mismatches between $P[1, n - j^{\star}B]$ and $T[p, p + n - j^{\star\star}B + 1]$ and appending the last $p - (j^{\star\star} - 1)B$ symbols of T (Remember that Charlie knows all symbols of the last block of $T[1, n]$). Using $T[p, n]$, $T[n + 1, 2n]$, and the sketch of P, he can approximate the Hamming distances for all alignments to the right of p.

4 Streaming algorithm

We now show a streaming algorithm for Problem 3. In this problem we are asked to output a $(1 + \varepsilon)$-approximation of the Hamming distance between the pattern and the text at each alignment, and we do not assume that we store a copy of the pattern or of the text. For $\varepsilon < 1/2$, the algorithm uses $\mathcal{O}(\varepsilon^{-3}\sqrt{n}\log^{1.5} n)$ bits of space and its running time is $\mathcal{O}(\varepsilon^{-2}\log n)$ per arriving symbol. For simplicity, we will set $k = 1/\varepsilon > 2$ for the rest of this section.

Let $B = k\sqrt{n}$. The algorithm starts by selecting a $9k^2 \times B$ matrix M and a vector $(\sigma_1, \sigma_2, \ldots, \sigma_{n/B-1})$ of i.u.d. ± 1 random variables. The algorithm then preprocesses the pattern P. It remembers the first B symbols of P, as well as a super-sketch of each $(n - B)$-length substring of P. To compute the super-sketches the algorithm divides a substring into $(n/B - 1)$ blocks of length B, computes their sketches using M as described in Section 2, and then sums the sketches multiplying them by σ_i. The algorithm also computes sketches of the last B suffixes of P. The sketch of a suffix $P[n - i + 1, n]$ is defined to be equal to $M \cdot S_i$, where $S_i = P[n - i + 1, n]\, 0^{B-i}$. Finally, for each $i \in [1, B]$ and for each $j \in [0, \log_{1+\varepsilon} n]$ it stores the maximal length of pattern's prefix such that the Hamming distance between this prefix aligned at position i and the pattern is at most $(1 + \varepsilon)^j$, which takes $\mathcal{O}(\varepsilon^{-1}B\log^2 n)$ bits since $\log_{1+\varepsilon} n = \mathcal{O}(\varepsilon^{-1}\log n)$.

4.1 Text processing

The algorithm processes the text in non-overlapping blocks of length B. For each of the last n/B blocks the algorithm maintains its sketch and a data structure containing the information Alice transfers to Bob in our solution for Problem 1.

Let us start by explaining how the algorithm maintains the sketches. At the starting index of each block it initialises the block's sketch with a zero vector of length $9k^2$. When the j^{th} symbol of the block arrives, the algorithm adds the product of the j^{th} column of M and the symbol to the sketch in $\mathcal{O}(9k^2)$ time. While reading the block the algorithm also computes the super-sketch of the $(n - B)$-length substring consisting of the $n/B - 1$ most recent blocks. Recall that the super-sketch is defined to be equal to the sum of the blocks' sketches multiplied by the variables σ_i. The total time needed for computing the sum is $\mathcal{O}(9k^2 n/B)$. The algorithm de-amortises this time over the block executing $\Omega(9k^2 n/B^2)$ steps per arriving symbol.

For each block the algorithm maintains a data structure containing the information Alice transmits to Bob in our solution for Problem 1. The algorithm starts computing the data structure when it has received the entire block. It then computes the Hamming distance between prefixes $P[1], P[1, 2], \ldots, P[1, B]$ as being aligned at the right border of the block

and the block by running the fast Fourier transform algorithm on $P[1, B]$ and the block appended with B zeros, which takes $\mathcal{O}(B)$ space and $\mathcal{O}(B \log B)$ time in total [14]. The algorithm then finds $i_1, i_2, \ldots, i_q$, where $q = \lceil \log_k B \rceil$ as defined in Problem 1 and for each i_j it computes the borders and the sketches of the blocks, where the sketches are defined with the help of the matrix M. Remember that the algorithm stores the block and the first B symbols of the pattern, so this could be done in a naive way, using symbol-by-symbol comparison. Finally, the algorithm builds binary search trees on $i_1, i_2, \ldots, i_q$ and the block borders for each i_j to allow fast access to the information. The total construction time of the data structure is $\mathcal{O}((B + k^2) \cdot \log n)$. Note that the data structure will only be used $n/B - 1 \geq 2$ blocks later, so we can de-amortise the construction time over the succeeding block executing $\Omega((1 + k^2/B) \cdot \log n)$ steps of the construction process per symbol. The data structure occupies $\mathcal{O}(k^4 \log^2 n)$ bits of space.

4.2 Hamming distance

To compute the Hamming distance at an alignment i, the algorithm divides the pattern into three parts: a prefix of length $(B - i)$, a middle part of length $(n - B)$, and a suffix of length i, where the middle part is aligned with a block border. The algorithm then starts by computing the square N of the norm of the difference between the super-sketches of the middle part and the corresponding text substring. Both super-sketches are already known as the middle part is an $(n - B)$-length substring of the pattern and we store its super-sketch explicitly, while the super-sketch of the text substring was computed at the end of the preceding block. As both sketches have length $9k^2$, it takes $\mathcal{O}(9k^2)$ time. Next, the algorithm computes the Hamming distance H_s between the sketch of the suffix of the pattern and the part of the text block seen so far. This again takes $\mathcal{O}(9k^2)$ time. Finally, the algorithm computes an approximation H_p of the Hamming distance between the prefix and the text as described in Problem 1. With the help of the binary search trees, $i_j, b_{\ell+1}$ and b_ℓ can be found in $\mathcal{O}(\log \log n + \log \log k^2)$ time. Recall that b_ℓ divides the prefix into two parts. The Hamming distance between the second part of the prefix and the text can be approximated in $\mathcal{O}(9k^2)$ time with the help of the sketches as in Problem 1, but it is not possible to use symbol-by-symbol comparison for the first part as this would take too much time. Instead, the algorithm does binary search on the prefixes' lengths it calculated during the preprocessing step which allows him to find $(1 + \varepsilon)$-approximation of the Hamming distance in $\mathcal{O}(\log \log_{1+\varepsilon} n)$ time. It then outputs $H_p + H_m + H_s$, where $H_m = \varepsilon^2 N / 9(1 - \varepsilon/3)$.

4.3 Analysis

The running time of the algorithm is $\mathcal{O}(\varepsilon^{-2} \log n)$ per arriving symbol. The space used is $\mathcal{O}(\varepsilon^{-3} \sqrt{n} \log^2 n)$ bits. We now need to show that $H_p + H_m + H_s$ is a $(1 + \varepsilon)$-approximation of the Hamming distance with constant probability. It suffices to show that H_m is a $(1 + \varepsilon)$-approximation of the Hamming distance between the middle part of the pattern and the text. Consider two binary strings t and p of length $(n - B)$. Let sk_t and sk_p be their super-sketches of length $9k^2$ calculated with the help of M and σ_i and let $N = \|sk_t - sk_p\|_2^2$ and $\tilde{H} = \tilde{\varepsilon}^2 N$, where $\tilde{\varepsilon} = \varepsilon/3$. We will show that $\tilde{H}$ is a good approximation of the Hamming distance between t and p. Recall that t and p are binary, and therefore the Hamming distance between them is equal to $\|t - p\|_2^2$.

▶ **Lemma 10.** *With constant probability* $(1 - \tilde{\varepsilon}) \cdot \|t - p\|_2^2 \leq \tilde{H} \leq (1 + \tilde{\varepsilon}) \cdot \|t - p\|_2^2$.

Proof. Let t_i and p_i, $i \in [1, n/B-1]$, be the blocks of t and p of length B. We have

$$\mathbb{E}\left[\tilde{H}\right] = \tilde{\varepsilon}^2 \cdot \mathbb{E}\left[\left\|\sum_i \sigma_i M \cdot (t_i - p_i)\right\|_2^2\right] = \tilde{\varepsilon}^2 \sum_j \mathbb{E}\left[\left(\sum_i \sigma_i M_j \cdot (t_i - p_i)\right)^2\right]$$

where M_j is the j^{th} row of M. As all rows of M are identically distributed, we have $\mathbb{E}\left[(\sum_i \sigma_i M_j \cdot (t_i - p_i))^2\right] = \mathbb{E}\left[(\sum_i \sigma_i M_1 \cdot (t_i - p_i))^2\right]$ for all j, which is equal to $\|t-p\|_2^2$ as if at least one of the inequalities $i_1 = i_2$ or $j_1 = j_2$ does not hold, then the variables $\sigma_{i_1} M_1[j_1]$ and $\sigma_{i_2} M_1[j_2]$ are independent and the expectation of $\sigma_{i_1}\sigma_{i_2} M_1[j_1] M_1[j_2]$ is equal to zero, and otherwise it is equal to one. So finally we have $\mathbb{E}\left[\tilde{H}\right] = \|t-p\|_2^2$.

We now compute the variance of H. We again use the fact that the rows of M are independent and identically distributed.

$$\mathrm{Var}\left[\tilde{H}\right] = \tilde{\varepsilon}^2 \cdot \mathrm{Var}\left[\left(\sum_i \sigma_i M_1 \cdot (t_i - p_i)\right)^2\right] \leq \tilde{\varepsilon}^2 \cdot \mathbb{E}\left[\left(\sum_i \sigma_i M_1 \cdot (t_i - p_i)\right)^4\right].$$

By Khintchine's inequality there exists a universal constant $c > 0$ such that

$$\mathrm{Var}\left[\tilde{H}\right] \leq c\,\tilde{\varepsilon}^2 \cdot \mathbb{E}\left[\left(\sum_i \sigma_i M_1 \cdot (t_i - p_i)\right)^2\right]^2 \leq c\,\tilde{\varepsilon}^2 \cdot \|t-p\|_2^4 .$$

The claim then follows by Chebyshev's inequality. ◀

Let now $H = \varepsilon^2 N/9(1-\varepsilon/3) = \tilde{H}/(1-\varepsilon/3)$. The probability H is a $(1+\varepsilon)$-approximation of the Hamming distance between t and p is at least the probability $\tilde{H}$ is in $[(1-\varepsilon/3)\cdot \|t-p\|_2^2, (1-\varepsilon/3)(1+\varepsilon)\cdot\|t-p\|_2^2]$, which in turn can be estimated from below as

$$\Pr\left[\tilde{H} \in [(1-\varepsilon/3)\cdot\|t-p\|_2^2, (1+\varepsilon/3)\cdot\|t-p\|_2^2]\right] \geq 1 - 1/c \text{ (Lemma 10.)}$$

To justify the last transition note that $(1-\varepsilon/3)(1+\varepsilon) \geq (1+\varepsilon/3)$ for all $\varepsilon < 1$. From above it follows that with constant probabilities H_p, H_m, and H_s are $(1+\varepsilon)$-approximations of the Hamming distances for the prefix, the middle part, and the suffix of the pattern respectively. We note that the probabilities can be made arbitrarily small by Chebyshev's inequality if we run a constant number of independent instances of the algorithm in parallel and output the sum of the medians of the values H_p, H_m, H_s. Correctness of the algorithm follows by the union bound.

Acknowledgements. We are grateful to T.S. Jayram and Paul Beame for helpful and inspiring conversations about the problems in this paper and to Ely Porat for introducing the original streaming pattern matching problem to us and for explaining how to solve Problem 3 in $\mathcal{O}(n^{2/3}poly(1/\varepsilon)))$ space. We were also informed that Ely Porat had independently developed a solution that uses $\mathcal{O}(\sqrt{n}/\varepsilon^2)$ space and for each alignment with Hamming distance H outputs some integer in the interval $[(1-\varepsilon)\cdot H - 1/2\sqrt{n}, (1+\varepsilon)\cdot H + 1/2\sqrt{n}]$ [24].

Abstract

We study competition in a general framework introduced by Immorlica, Kalai, Lucier, Moitra, Postlewaite, and Tennenholtz and answer their main open question. Immorlica et al. considered classic optimization problems in terms of competition and introduced a general class of games called dueling games. They model this competition as a zero-sum game, where two players are competing for a user's satisfaction. In their main and most natural game, the ranking duel, a user requests a webpage by submitting a query and players output an ordering over all possible webpages based on the submitted query. The user tends to choose the ordering which displays her requested webpage in a higher rank. The goal of both players is to maximize the probability that her ordering beats that of her opponent and gets the user's attention. Immorlica et al. show this game directs both players to provide suboptimal search results. However, they leave the following as their main open question: "does competition between algorithms improve or degrade expected performance?" (see the introduction for more quotes) In this paper, we resolve this question for the ranking duel and a more general class of dueling games.

More precisely, we study the quality of orderings in a competition between two players. This game is a zero-sum game, and thus any Nash equilibrium of the game can be described by minimax strategies. Let the value of the user for an ordering be a function of the position of her requested item in the corresponding ordering, and the social welfare for an ordering be the expected value of the corresponding ordering for the user. We propose the price of competition which is the ratio of the social welfare for the worst minimax strategy to the social welfare obtained by a social planner. Finding the price of competition is another approach to obtain structural results of Nash equilibria. We use this criterion for analyzing the quality of orderings in the ranking duel. Although Immorlica et al. show that the competition leads to suboptimal strategies, we prove the quality of minimax results is surprisingly close to that of the optimum solution. In particular, via a novel factor-revealing LP for computing price of anarchy, we prove if the value of the user for an ordering is a linear function of its position, then the price of competition is at least 0.612 and bounded above by 0.833. Moreover we consider the cost minimization version of the problem. We prove, the social cost of the worst minimax strategy is at most 3 times the optimal social cost.

Last but not least, we go beyond linear valuation functions and capture the main challenge for bounding the price of competition for any arbitrary valuation function. We present a principle which states that the lower bound for the price of competition for all 0-1 valuation functions is the same as the lower bound for the price of competition for all possible valuation functions. It is

worth mentioning that this principle not only works for the ranking duel but also for all dueling games. This principle says, in any dueling game, the most challenging part of bounding the price of competition is finding a lower bound for 0-1 valuation functions. We leverage this principle to show that the price of competition is at least 0.25 for the generalized ranking duel.

1 Introduction

The conventional wisdom is that competition among suppliers will increase social welfare by providing consumers with competitive prices, high-quality products, and a wide range of options. A classic example is the Bertrand competition [10] where suppliers compete in price to incentivize consumers to buy from them and as a result the market price decreases to the point that it matches the marginal cost of production. Indeed there are many theoretical and empirical studies for supporting this belief in the economic literature (see, e.g., [29, 25, 24, 2]). However while in many markets the competition steers businesses to optimize their solutions for consumers, there are competitive markets in which businesses do not offer the best option to consumers. An interesting example for describing this situation is a dueling game, namely, a zero-sum game where two players compete to attract users. Immorlica, Kalai, Lucier, Moitra, Postlewaite, and Tennenholtz [19] showed surprisingly if players are aimed to beat their opponents in a dueling game, they may offer users suboptimal results. However, they raised this question regarding the efficiency of the competition as the authors write, *"Perhaps more importantly, one could ask about performance loss inherent when players choose their algorithms competitively instead of using the (single-player) optimal algorithm. In other words, what is the price of anarchy*[1] *of a given duel? ... Our main open question is (open question 1): does competition between algorithms improve or degrade expected performance?"* As we describe below, we study this open question for a set of dueling games and in particular for the ranking duel which is an appropriate representative of dueling games due to Immorlica et al. [19].

Dueling games. A *dueling game* $\mathcal{G}$ is a zero-sum game where two players compete for the attention of a user [2]. In a dueling game both players try to beat the other player and offer a better option with a higher value to the user. In particular, while the user's request is unknown to both players and they only have access to probability distribution p, the goal for each player is to maximize the probability that her offer is better than her opponent's offer. This framework falls within a general and natural class of ranking or social context games [7, 11], where each player plays a base game separately and then ultimate payoffs are determined by both their own outcomes and the outcomes of others. Immorlica et al. argue that this class of games models a variety of scenarios of competitions between algorithm designers, such as, competition between search engines (who must choose how to rank search

[1] Indeed Immorlica et al. [19] use the term of the *price of anarchy* in their aforementioned open question for the same concept of the *price of competition* in this paper.

[2] One can see the user as a population of users with the same behavior.

results), or competition between hiring managers (who must choose from a pool of candidates in the style of the secretary problem).

To be more precise a dueling game is defined by 4-tuple $\mathcal{G} = (\Omega, p, S, v)$, where Ω is the set of all possible requests from the user, p is a probability distribution over set Ω i.e., p_ω is the probability of requesting $\omega \in \Omega$ by the user, S is the set of all possible pure strategies for both players, and $v_\omega(s)$ is the value of pure strategy $s \in S$ for the user upon request $\omega \in \Omega$. Note that v is usually considered to be the valuation of the players, but in this paper valuation function v denotes the value for the user. While a mixed strategy is a probability distribution over all possible pure strategies in S, we write the value of mixed strategy $\mathbf{x}$ as $v_\omega(\mathbf{x}) = E_{s\sim\mathbf{x}}[v_\omega(s)]$.

A social planner is often interested in choosing a strategy which maximizes the social welfare, even though it may be a bad strategy in the competition between players. This means the social welfare maximizer strategy may not appear in any Nash equilibrium of the game, and thus the competition between players results in a suboptimal outcome for the users. Knowing the fact that Nash equilibria of a dueling game can be formed by suboptimal strategies, the following question seems to be an important question to ask regarding the inefficiency of this competition:

> What is the social welfare of any Nash equilibrium in a dueling game in comparison to the social welfare of the optimal strategy?

Price of competition. As aforementioned while in so many cases the competition motivates businesses to optimize their solutions for consumers, there are competitive markets and in particular dueling games of Immorlica et al. [19], in which businesses do not offer the best option to consumers. We define *price of competition* in this paper to capture this phenomenon.

First we note that since dueling games are two-player zero-sum games, Nash equilibria of these games are characterized by minimax strategies. Therefore, one can measure the inefficiency of any Nash equilibrium by comparing the welfare of any minimax strategy, in a game of competition between two players, with the welfare achieved by a social welfare maximizer. We are now ready to define the following criterion for measuring the quality of minimax strategies in a dueling game.

▶ **Definition 1. Price of competition (PoC)** is the ratio between the social welfare of the worst minimax strategy and the social welfare of the best possible strategy.

The proposed concept of the price of competition has the same spirit as the concept of the price of anarchy, and both concepts try to measure the inefficiency of Nash equilibria quantitatively. The price of anarchy, introduced by the seminal work of Koutsoupias and Papadimitriou [23], is a well-known concept in game theory that measures the ratio of the social welfare of the worst Nash equilibrium to the optimal social welfare. Although these two concepts are defined to capture properties of Nash equilibria, they are meaningfully different. In the price of anarchy, the social welfare is defined as the expected utility of all players in an equilibrium "outcome"[3] which is always zero for any zero-sum game. However, in the price of competition, the social welfare is the expected utility of the user (which is not a player) in a minimax "strategy". In fact, the price of competition is aimed to analyze the impact of the competition between players on an external user.

[3] Which is essentially the same as the sum of utilities of all players.

Since the price of competition captures the inefficiency of minimax strategies in two-player zero-sum games and all Nash equilibria of any two-player zero-sum game can be described by the set of minimax strategies, we believe the price of competition sheds new light on the structural analysis of Nash equilibria in two-player zero-sum games. Indeed as Alon, Demaine, Hajiaghayi, and Leighton [5] mention understanding the structure of Nash equilibiria, and not just the price of anarchy, is very important in general and thus our work is exactly toward this direction.

Due to the space constraints, all the missing proofs are provided in the appendices.

1.1 Our results

Ranking duel: To define the ranking duel more precisely, consider a ranking duel with two players. When a user submits a query to a player, she is basically searching a webpage which is unknown to the player. The player only has a prior knowledge about the requested webpage, i.e., for each webpage the probability that this webpage is requested by the user is known. The strategy of each player is an ordering for displaying webpages. When the requested webpage is realized, the player which puts this webpage in a higher rank gets the user attention, and thus wins the competition. The goal of each player is to maximize the probability of winning the competition. In this situation, a social planner who wants to minimize the expected rank of the requested webpage lists webpages in a decreasing order of their probabilities. However, this strategy may lose the competition to another strategy.[4]

We first investigate the quality of minimax strategies and prove that surprisingly the social welfare of any minimax strategy is not far from that of the optimal solution; it is 0.612 of the optimal solution for the linear valuation functions and 0.25 of the optimal for any arbitrary valuation function.

▶ **Theorem 1.** *Consider an instance of the raking duel. If the valuation function is a non-negative linear function of the rank, the price of competition is at least* 0.612 *for* $|\Omega| \geq 10$*, and at most* 0.833*.*

Our proof needs a careful understanding of properties for minimax strategies and has three main steps. First, we prove nice structural properties of minimax strategies. This step is the main step toward bounding the price of competition and gives an insight into properties of the polytope of minimax strategies. For example for every two webpages ω_1 and ω_2 with $p_{\omega_1} > p_{\omega_2}$, we prove there is a lower bound on the probability that any minimax strategy ranks webpage ω_1 before webpage ω_2. In the next step, we leverage these properties to write a factor-revealing mathematical program for bounding PoC. At last, we find a linear program where the set of its feasible solutions is a superset of the set of feasible solutions of the former mathematical program. We find the optimal solution of this linear program to formally prove the theorem for $|\Omega| \geq 10$. Moreover, we write a computer program to find the optimal solution of the corresponding linear program and show the price of competition is at least 0.637 for $|\Omega| \geq 100$ (which is slightly better the case that $\Omega \geq 10$). To the best of our knowledge, we are the first to use factor-revealing techniques to bound the inefficiency of equilibria.

[4] For example consider a situation when the user submits a query and she is interested in webpages w_1, w_2, and w_3 with probabilities 0.35, 0.33 and 0.32 respectively. In this situation the social planner ranks webpage w_i at position i, for $i = 1, 2, 3$. However, if a player plays based on this strategy, her opponent puts webpages w_2, w_3, and w_1 at positions 1, 2, and 3 respectively, and thus wins the competition when the user requests webpages w_2 or w_3. This means the social planner strategy loses the competition with probability 0.65.

Afterwards, we consider the cost minimization version of the ranking duel and prove a constant upper bound for the social cost of the game using the same technique of Theorem 1. Note that the only difference between the cost minimization and welfare maximization of a dueling game is that function v is a cost function rather than a valuation function, and once a webpage is searched the winner of the cost minimization game is the player who provides a solution with a lower cost. Moreover, we define the PoC_{cost} of the ranking duel as the ratio between the minimax strategy with the highest cost and the strategy with the least cost. In the following theorem we show that $\text{PoC}_{cost} \leq 3$.

▶ **Theorem 2.** *For a ranking duel with a linear cost function, we have* $PoC_{cost} \leq 3$.

It is worth mentioning that the structural properties of minimax strategies do not depend on the valuation function, and thus the polytope of minimax strategies remains unchanged for every valuation function which is a decreasing (increasing) function of rank in the welfare maximization (cost minimization) variant of the game. Therefore, we leverage structural properties of the polytope of minimax strategies, which is presented in Theorem 1, for proving Theorem 2 and in general one can apply our techniques for characterizing the polytope of minimax strategies for an arbitrary valuation function. Nevertheless, writing the factor-revealing mathematical program totally depends on the linearity of the valuation function.

General valuation functions: There are situations where the value of the user is not a linear function of rank. For example, consider a user that only cares about the top search results and will be satisfied if and only if her requested webpage is ranked higher than a certain threshold. We investigate the efficiency of minimax strategies for any non-negative non-linear valuation function. Moreover, we go beyond the ranking duel and consider other dueling games, in the pioneering work of [19]. While bounding the social welfare for arbitrary valuation functions and general dueling games seems to be challenging, we present a general principle to capture the main challenge of this problem. The proposed principle has the same spirit as the classic 0-1 principle in the sorting network which states: "a sorting network will sort any given input if and only if it sorts any given 0-1 input [13]." The following principle has the same message and shows if one can bound the social welfare for any 0-1 valuation function, the same bound holds for any arbitrary valuation function. This means the main challenge for bounding the social welfare is to bound it for 0-1 valuation functions. The main idea for proving Theorem 3 is to decompose any valuation function into 0-1 valuation functions.

▶ **Theorem 3.** *0-1 Principle: Consider a dueling game. If the price of competition is greater than* α *when the social welfare is defined based on any 0-1 valuation function, then it is greater than* α *when the social welfare is defined based on any valuation function.*

One can leverage this principle to analyze the efficiency of competition in any dueling game. For example, we show that the price of competition in the ranking duel is at least 0.25 for an arbitrary valuation function.

▶ **Theorem 4.** *The price of competition is at least* 0.25 *for the ranking duel, when the social welfare is defined based on an arbitrary valuation function.*

In the proof of Theorem 4, based on the 0-1 principle, we first consider the problem with pseudo-valuation functions in which the value of each position is either 0 or 1. We consider $\mathbf{x}^*$ as the minimax strategy with the least social welfare and construct a response strategy $\mathbf{x}'_i$ for the second player for every $1 \leq i \leq n$ as follows:

- Draw a permutation randomly based on strategy $\mathbf{x}^*$. If the value of the position of the i-th webpage is 1 then play that permutation. Otherwise, swap the position of the i-th webpage with one of the positions with value 1 at random and play the new permutation.

Next, we use the fact that minimax strategy $\mathbf{x}^*$ does not lose to strategy $\mathbf{x}'_i$ for proving a set of inequalities which later on helps us to bound the price of competition. Finally, we use the 0-1 principle to show that this lower bound holds for all possible valuation functions.

This principle also helps us to provide upper bounds on the price of competition when one considers a general valuation function. For example we show that the PoC of the following game introduced by Immorlica et al. [19] cannot be bounded by any constant value:

Binary search duel: The binary search duel is a dueling game where each player chooses a binary search tree over the set of all possible requests Ω. When the user's request $\omega \in \Omega$ is realized, the value for each strategy is defined based on the depth of request ω in the corresponding binary search tree.

▶ **Theorem 5.** *The price of competition is $\mathcal{O}(\frac{1}{|\Omega|})$ for the binary search duel, when the social welfare is defined based on an arbitrary valuation function.*

In order to construct bad instances for these duels, we design a valuation function which is 1 for low depths, 0 for high depths, and a small positive value ϵ in between. We show the price of competition is less than any given number $\beta > 0$ for the binary search duel by constructing an instance of the binary search duel with $|\Omega| = \Theta(\frac{1}{\beta})$.

1.2 Related work

Immorlica et al. [19] are the first who considered the concept of dueling games. They present dueling games in the context of dueling algorithms, where two competitive algorithms try to maximize the probability of outperforming their opponent for an unknown stochastic input. While we employ the same model in this paper, our goal completely differs from that of Immorlica et al. [19]. Immorlica et al. [19] present polynomial-time algorithm for finding a minimax strategy of a dueling game when the polytope of minimax strategies can be represented by a polynomial number of linear constraints. Knowing the fact that the polytope of minimax strategies of any ranking duel has polynomially many facets, they propose a polynomial-time algorithm for finding a minimax strategy of ranking duels. This method was later generalized by [3] to solve the Colonel Blotto game. Immorlica et al. [19] leave the problem of analyzing the social welfare of competitive algorithms as their main open question. In this paper, we do not deal with the computational complexity of finding minimax strategies, but we focus on answering the posted open question and analyze the social welfare of minimax strategies for a given duel.

As we are interested in quantifying the inefficiency of Nash equilibria, our proposed concept of the price of competition has the same flavor as the concept of the price of anarchy [23, 26]. The price of anarchy is commonly used for quantifying the inefficiency of a system which is constructed by selfish agents. For example, it has been used to analyze the inefficiency of Nash equilibria in congestion games [27, 12], network creation games [16, 14, 4, 5], and selfish scheduling games [6, 20]. (See, e.g. [26] for more examples).

Kempe and Lucier [21] recently study the impact of competition on the social welfare in a competitive sponsored search market. In their model, which is a departure from the model of Immorlica et al. [19], search engines again compete to obtain more users. A user's request is defined by a set S of webpages which is unknown to search engines, and the user is satisfied if and only if at least one of webpages in S is ranked in a better position than a given threshold t. The strategy of each search engine is an ordering over all possible webpages.

At last, the user chooses a search engine based on a selection rule which is a function of probability of being satisfied by each search engine. Kempe and Lucier [21] prove that if search engines extract utility from satisfied users or the search engine selection rule is convex, then the social welfare of the game is at least half of the optimum social welfare. Moreover, they show if the utility of search engines is driven from all customers and the search engine selection rule is concave, then the social welfare of the game is bounded away from that of the optimum solution by a factor of $\Omega(n)$, where n is the number of all possible webpages. We would like to note that our model is a general model for studying all dueling games which is exactly the same as the model of Immorlica et al. [19], and is significantly different from that of Kempe and Lucier [21].

There is a line of research that study a competition between advertisers in sponsored search auctions [1, 9, 17, 15, 22]. These works analyze the revenue of a single search engine in various settings regarding users' behavior and the business model of advertisers. However, in ranking duel we investigate a competition between players who provide orderings rather than advertisers.

There is a rich literature in economics that explains product differentiation in competitive markets. While producing similar products is supported by classical models such as the Hotelling model [18], Aspremont, Gabszewicz, and Thisse [8] argue that competitive producers may improve their revenue by producing different products. See, e.g., [29, 25, 24] for details on this literature. The same phenomenon can be seen in the sponsored search market, e.g., Telang, Rajan, and Mukhopadhyay [28] show low-quality search engines may extract revenue from the sponsored search market.

2 Model

2.1 Dueling games

In dueling game $\mathcal{G}$ both players try to beat the other player and offer a better value in the competition. Assume players A and B play pure strategies s_A and s_B respectively, and event ω has occurred. In this situation, player A wins the competition if and only if $v_\omega(s_A) > v_\omega(s_B)$, and thus the utility of player A given event ω can be written as follows:

$$u^A_\omega(s_A, s_B) = \begin{cases} +1 & \text{if } v_\omega(s_A) > v_\omega(s_B) \\ 0 & \text{if } v_\omega(s_A) = v_\omega(s_B) \\ -1 & \text{if } v_\omega(s_A) < v_\omega(s_B) \end{cases}$$

Now consider a situation where players A and B play mixed strategies $\mathbf{x}$ and $\mathbf{y}$ respectively and event ω has occurred. The utility of player A is the probability that player A wins the competition minus the probability that player B wins the competition and can be defined as follows:

$$u^A_\omega(\mathbf{x}, \mathbf{y}) = Pr_{\substack{s_A \sim \mathbf{x} \\ s_B \sim \mathbf{y}}}[v_\omega(s_A) > v_\omega(s_B)] - Pr_{\substack{s_A \sim \mathbf{x} \\ s_B \sim \mathbf{y}}}[v_\omega(s_A) < v_\omega(s_B)]$$

Finally the overall utility of player A is $u^A(\mathbf{x}, \mathbf{y}) = \sum_\omega p_\omega u^A_\omega(\mathbf{x}, \mathbf{y})$. Since dueling game $\mathcal{G}$ is a zero-sum game the utility of player B is the negation of the utility of player A for each ω, i.e., $u^B_\omega(\mathbf{x}, \mathbf{y}) = -u^A_\omega(\mathbf{x}, \mathbf{y})$ and thus $u^B(\mathbf{x}, \mathbf{y}) = -u^A(\mathbf{x}, \mathbf{y})$.

▶ **Definition 2** (Minimax strategy). Strategy $\mathbf{x}$ of player A is minimax if $\mathbf{x} \in \text{argmax}_{\mathbf{x}'}\{\min_{\mathbf{y}}\{u^A(\mathbf{x}', \mathbf{y})\}\}$. Similarly, Strategy $\mathbf{y}$ of player B is minimax if $\mathbf{y} \in \text{argmax}_{\mathbf{y}'}\{\min_{\mathbf{x}}\{u^B(\mathbf{x}, \mathbf{y}')\}\}$.

Based on the definition of dueling games and the fact that the set of all possible pure strategies for both players is S, we can conclude the outcome of both players in any Nash equilibrium is 0 and moreover the set of minimax strategies of both players coincide. We define the set of minimax strategies by $\mathcal{M}$.

▶ **Definition 3** (Social welfare)**.** Consider dueling game $\mathcal{G} = (\Omega, p, S, v)$. The social welfare of pure strategy s is the expected value of this strategy over all possible events and can be written as $\mathrm{SW}(s) = \sum_\omega p_\omega v_\omega(s)$. The social welfare of mixed strategy $\mathbf{x}$ is $\mathrm{SW}(\mathbf{x}) = E_{s\sim\mathbf{x}}[\mathrm{SW}(s)]$.

In this paper, we are interested to study the social welfare of the game in equilibria. Note that the customer locks into one of the players in long term. On the other hand, both players only try to offer the customer a better option than the other one, and thus play a minimax strategy in the competition. These cause inefficiency in the game. Here we define a new criterion to measure this inefficiency in the game.

▶ **Definition 4** (Price of competition)**.** The price of competition is the ratio of the worst minimax strategy to the optimal solution which is:

$$\frac{\min_{\mathbf{x}\in\mathcal{M}} \mathrm{SW}(\mathbf{x})}{\max_{\mathbf{x}} \mathrm{SW}(\mathbf{x})} = \frac{\min_{\mathbf{x}\in\mathcal{M}} \mathrm{SW}(\mathbf{x})}{\max_{s\in S} \mathrm{SW}(s)}.$$

Similar to the welfare maximization model, we consider the cost minimization model in which players try to beat the opponent by offering a lower cost to the user. In particular we have a cost function c, such that $c_\omega(s)$ denotes the cost of strategy s and event ω. Hence, the utility of player A would be defined as

$$u^A_\omega(\mathbf{x}, \mathbf{y}) = Pr_{\substack{s_A\sim\mathbf{x}\\ s_B\sim\mathbf{y}}}[c_\omega(s_A) < c_\omega(s_B)] - Pr_{\substack{s_A\sim\mathbf{x}\\ s_B\sim\mathbf{y}}}[c_\omega(s_A) > c_\omega(s_B)].$$

Similarly we define the social cost $\mathrm{SC}(s) = \sum_\omega p_\omega c_\omega(s)$ for a pure strategy s and $\mathrm{SC}(\mathbf{x}) = E_{s\sim\mathbf{x}}[\mathrm{SC}(s)]$ for a mixed strategy $\mathbf{x}$. Finally the price of competition in cost minimization version is defined as

$$\frac{\max_{\mathbf{x}\in\mathcal{M}} \mathrm{SC}(\mathbf{x})}{\min_{\mathbf{x}} \mathrm{SC}(\mathbf{x})} = \frac{\max_{\mathbf{x}\in\mathcal{M}} \mathrm{SC}(\mathbf{x})}{\min_{s\in S} \mathrm{SC}(s)}.$$

2.2 Ranking duel

Ranking duel is a dueling game where $\Omega = \{1, \cdots, n\}$ is the set of n webpages which can be requested by a user. In this game, the set of pure strategies S is equal to the set of all possible permutations over Ω, i.e., each player outputs an ordering of webpages for the user. We denote each pure strategy of the ranking duel by π (instead of s) where $\pi(\omega)$ is the rank of webpage ω. The valuation function v of a raking duel can be defined based on function $f : \{1, \cdots, n\} \to R^+ \cup \{0\}$ as $v_\omega(\pi) = f(\pi(\omega))$. Consider mixed strategy $\mathbf{x}$ where $\mathbf{x}_\pi$ is the probability that strategy $\mathbf{x}$ outputs permutation π. The *social welfare* of strategy $\mathbf{x}$ can be defined as:

$$\mathrm{SW}(\mathbf{x}) = \sum_\omega \sum_\pi p_\omega \mathbf{x}_\pi f(\pi(\omega)). \tag{1}$$

3 Price of competition in the linear ranking duel

3.1 Welfare maximization ranking duel

In this section we give bounds for the PoC in the ranking duel when the valuation function is non-negative and linear, in other words $f(i) = c(n - i) + d$, where $c, d \geq 0$.

First we formulate the social welfare of strategy $\mathbf{x}$ and the optimal social welfare. Without loss of generality in this section we assume $p_1 \geq p_2 \geq \ldots \geq p_n$. Let $Pr_{\pi\sim\mathbf{x}}[\pi(a) = i]$ denote the probability that in a randomly drawn permutation π from strategy $\mathbf{x}$, the rank of webpage a is i. Similarly let $Pr_{\pi\sim\mathbf{x}}[\pi(a) < \pi(b)]$ denote the probability that in a randomly drawn permutation π from strategy $\mathbf{x}$, webpage a comes before webpage b.

▶ **Proposition 5.** *In a ranking duel with valuation function f and n webpages, the social welfare of a strategy $\mathbf{x}$ is $SW_f(\mathbf{x}) = \sum_{a=1}^{n}\sum_{i=1}^{n} p_a Pr_{\pi\sim\mathbf{x}}[\pi(a) = i]f(i)$.*

Let OPT be the strategy with the maximum social welfare. Hence SW(OPT) is formulated as follows.

▶ **Proposition 6.** *In a ranking duel with valuation function f and n webpages, the optimal social welfare is $SW_f(OPT) = \sum_{a=1}^{n} p_a f(a)$.*

Lemma 7 shows that for any minimax strategy $\mathbf{x}$ and any linear function $f(i) = c(n-i)+d$ with $c, d \geq 0$, the PoC is no less than the case in which $f(i) = n - i$.

▶ **Lemma 7.** *For valuation functions $f(i) = n - i$, $f'(i) = c(n - i) + d$ with $c, d \geq 0$, and any strategy $\mathbf{x}$, $\frac{SW_f(\mathbf{x})}{SW_f(OPT)} \leq \frac{SW_{f'}(\mathbf{x})}{SW_{f'}(OPT)}$.*

Thus any lower bound for the PoC with $f(i) = n - i$, is also a lower bound for the PoC with any other linear valuation function. Therefore, from now on we assume $f(i) = n - i$, and use SW($\mathbf{x}$) and SW(OPT) instead of $\text{SW}_f(\mathbf{x})$ and SW_f(OPT), respectively. Hence $\text{SW(OPT)} = \sum_{a=1}^{n} p_a(n - a)$. Now we try to compute SW($\mathbf{x}$) from a different perspective.

▶ **Proposition 8.** *In a ranking duel with n webpages, the social welfare of strategy $\mathbf{x}$ is*

$$SW(\mathbf{x}) = \sum_{a=1}^{n}\sum_{b=a+1}^{n} p_a Pr_{\pi\sim\mathbf{x}}[\pi(a) < \pi(b)] + p_b Pr_{\pi\sim\mathbf{x}}[\pi(b) < \pi(a)].$$

Intuitively by Proposition 8 we can compute the social welfare of a strategy by comparing the ranks of every pairs of webpages. Therefore we define $h_{ab}(\mathbf{x})$ to be the amount that the pair of webpages a and b adds to the social welfare in strategy $\mathbf{x}$, i.e. $h_{ab}(\mathbf{x}) = p_a Pr_{\pi\sim\mathbf{x}}[\pi(a) < \pi(b)] + p_b Pr_{\pi\sim\mathbf{x}}[\pi(b) < \pi(a)]$. Thus we can rewrite Proposition 8 as $\text{SW}(\mathbf{x}) = \sum_{a=1}^{n}\sum_{b=a+1}^{n} h_{ab}(\mathbf{x})$. Hence for every strategy $\mathbf{x}$,

$$\frac{\text{SW}(\mathbf{x})}{\text{SW(OPT)}} = \frac{\sum_{a=1}^{n}\sum_{b=a+1}^{n} h_{ab}(\mathbf{x})}{\sum_{a=1}^{n} p_a(n-a)}.$$

In Lemma 9 we provide our main tool for bounding the price of competition in the linear ranking duel.

▶ **Lemma 9.** *Given a strategy $\mathbf{x}$, if there exist an integer k such that $2 \leq k \leq n$ and for all k different indices $i_1 < i_2 < \ldots < i_k$,*

$$\frac{\sum_{a=1}^{k}\sum_{b=a+1}^{k} h_{i_a i_b}(\mathbf{x})}{\sum_{a=1}^{k} p_{i_a}(k-a)} \geq \alpha,$$

then $\frac{SW(\mathbf{x})}{SW(OPT)} \geq \alpha$.

Now our goal is to provide a lower bound for α when $\mathbf{x}$ is a minimax strategy. In order to do that, first we provide some structural properties of the minimax strategies. Leveraging

these properties we write a mathematical program with k variables p_a and $\binom{k}{2}$ variables h_{ab}. Finally, we provide a factor-revealing linear program to obtain a close lower bound for α in the corresponding mathematical program.

In Lemmas 10, 11, 13, and Proposition 12 we provide the structural properties of the minimax strategies.

▶ **Lemma 10.** *Let* $\mathbf{x}$ *be a minimax strategy and* a *and* b *be two webpages such that* $p_a \geq p_b$. *Let* π_{ba} *be any permutation in the support of* $\mathbf{x}$ *in which* b *precedes* a. *Let* $i < j$ *be the respective position of* a *and* b *in* π_{ba}, *then strategy* $\mathbf{x}$ *must satisfy,*

$$Pr_{\pi\sim\mathbf{x}}[i < \pi(b) \leq j] + Pr_{\pi\sim\mathbf{x}}[i \leq \pi(b) < j] \geq \frac{p_a}{p_b}(Pr_{\pi\sim\mathbf{x}}[i < \pi(a) \leq j] + Pr_{\pi\sim\mathbf{x}}[i \leq \pi(a) < j]).$$

Intuitively Lemma 10 shows that if $p_a \geq p_b$ and there is a permutation in which b comes before a, then the probability that $\mathbf{x}$ ranks b in interval $[i, j]$ (counting the non-endpoint elements twice) is greater than the probability that $\mathbf{x}$ ranks a in this interval by a factor of $\frac{p_a}{p_b}$. Otherwise, by swapping the rank of a and b we can achieve a strategy that beats $\mathbf{x}$.

▶ **Lemma 11.** *Let* $\mathbf{x}$ *be a minimax strategy and* $\mathbf{x}_\pi$ *be the probability that strategy* $\mathbf{x}$ *plays permutation* π. *For every pair of webpages* a *and* b *with* $p_a \geq p_b$, *we have*

$$Pr_{\pi\sim\mathbf{x}}[\pi(a) < \pi(b)] \geq (\frac{p_a}{2p_b} - 1) Pr_{\pi\sim\mathbf{x}}[\pi(b) < \pi(a)]. \tag{2}$$

Briefly, in the proof of Lemma 11 we propose an algorithm to find a set of permutations Π in $\mathbf{x}$, such that 1) for each $\pi \in \Pi$, b comes before a, 2) for each permutation π' in $\mathbf{x}$ in which b comes before a, there is a permutation $\pi \in \Pi$, such that $\pi(b) \leq \pi'(a) \leq \pi(a)$, and 3) the interval of the ranks of b and a are distinct, i.e. for two permutations $\pi, \pi' \in \Pi, [\pi(b), \pi(a)] \cap [\pi'(b), \pi'(a)] = \emptyset$. We apply the inequality in Lemma 10 for all permutations in Π to achieve Lemma 11.

In Proposition 12 and Lemma 13 we provide lower bounds for $h_{ab}(\mathbf{x})$ when $\mathbf{x}$ is a minimax strategy. Hence we can use these lower bounds in the proposed mathematical program to achieve a lower bound for the PoC.

▶ **Proposition 12.** *For minimax strategy* $\mathbf{x}$ *and webpages* a *and* b *such that* $p_a \geq p_b$, $h_{ab}(\mathbf{x}) \geq p_b$.

▶ **Lemma 13.** *For minimax strategy* $\mathbf{x}$ *and webpages* a *and* b *such that* $p_a \geq p_b$, $h_{ab}(\mathbf{x}) \geq p_a - 2p_b + \frac{2p_b^2}{p_a}$.

Leveraging the properties of the minimax strategies we write MP 3. In MP 3, Constraints 5 and 6 force p_a's to satisfy the probability constraints. Using Proposition 12, Constraint 7 forces h_{ab} to be no less than p_b and due to Lemma 13, Constraint 7 forces h_{ab} to be no less than $p_a - 2p_b + \frac{2p_b^2}{p_a}$. By Lemma 9, α in Constraint 4 gives a lower bound for the PoC.

$$\text{minimize} \quad \alpha \tag{3}$$

$$\text{subject to} \quad \alpha = \frac{\sum_{a=1}^{k}\sum_{b=a+1}^{k} h_{ab}}{\sum_{a=1}^{k} p_a(k-a)} \tag{4}$$

$$p_a \geq 0 \qquad \forall 1 \leq a \leq k \tag{5}$$

$$\sum_{1\leq a\leq k} p_a \leq 1 \tag{6}$$

$$h_{ab} \geq p_b \qquad \forall 1 \leq a < b \leq k \tag{7}$$

$$h_{ab} \geq p_a - 2p_b + \frac{2p_b^2}{p_a} \qquad \forall 1 \leq a < b \leq k \tag{8}$$

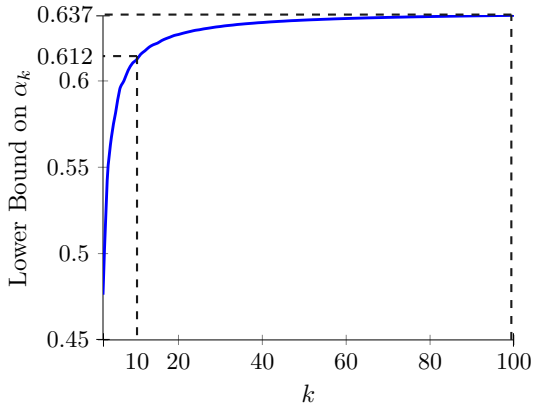

Figure 1 Lower bound on the solution of MP 3. While we formally prove $\alpha_{10} \geq 0.612$, this figure shows lower bounds on α_k for $2 \leq k \leq 100$ found by a computer program. Note that, by Lemma 14 the PoC of the ranking duel with linear valuation function is at least α_k for all $n \geq k$.

For each k, let α_k be the optimal value of the objective function in MP 3.

▶ **Lemma 14.** *α_k is a lower bound for the PoC of the linear ranking duel where $n \geq k$.*

In Theorem 15 we formally prove $\alpha_{10} \geq 0.612$, which results in PoC ≥ 0.612 for any ranking duel with $n \geq 10$ webpages. Moreover, we write a computer program to find α_k for $2 \leq k \leq 100$ (see Figure 1).

▶ **Theorem 15.** *For a linear ranking duel with $n \geq 10$ webpages, PoC ≥ 0.612.*

The proof idea is as follows. We design a linear program from MP 3. Constraints 4 and 8 in MP 3 are not linear, thus we first try to replace Constraint 8 by three linear constraints. Afterwards, intuitively we scale the probabilities such that $\sum_{a=1}^{k} p_a(k-a)$ equals 1, hence we can have a linear constraint instead of Constraint 4. Then we show each feasible solution for MP 3 is also a feasible solution for the achieved linear program. Finally by finding a feasible solution for the dual of the corresponding LP, we provide a lower bound for α in the primal LP, which is a lower bound for the optimal solution of MP 3 as well.

4 General framework

In this section we present a general framework for analyzing the price of competition in dueling games. Proving lower bounds for the price of competition in dueling games highly depends on the valuation functions and it becomes more challenging when the valuation functions are complex. However, the behavior of minimax strategies only depends on the comparison of the valuation functions rather than actual values. We leverage this fact to provide Theorem 16 which enables us to prove bounds for the price of competition without concerning the complexities of the valuation functions. We refer to this theorem as the *0-1 principle*.

Let (Ω, p, S, v) be a dueling game and α be a non-negative real number. We define the trigger function $v_\omega^\alpha(s)$ for a pure strategy s in the following way:

$$v_\omega^\alpha(s) = \begin{cases} 1 & \text{if } v_\omega(s) \geq \alpha \\ 0 & \text{if } v_\omega(s) < \alpha \end{cases}$$

Moreover, we define the pseudo-welfare function $\mathrm{SW}^\alpha(s)$ as the summation of the values of the trigger functions when a player is playing strategy s with respect to α, $\mathrm{SW}^\alpha(s) = \sum_{\omega\in\Omega} p_\omega v^\alpha_\omega(s)$. Furthermore, the pseudo-welfare function for a mixed strategy $\mathbf{x}$ is defined as $\mathrm{SW}^\alpha(\mathbf{x}) = E_{s\sim\mathbf{x}}[\mathrm{SW}^\alpha(s)]$. Let PoC^α be the pseudo-welfare of the minimax strategy with the least social welfare over SW(OPT) which can be formulated by $\mathrm{PoC}^\alpha = \frac{\mathrm{SW}^\alpha(\mathbf{x}^*)}{\mathrm{SW}^\alpha(\mathrm{OPT})}$, where $\mathbf{x}^*$ is the minimax strategy with the least social welfare and OPT is the strategy with highest social welfare. Note that optimal and minimax strategies are determined regardless of the pseudo-welfare function. For simplicity, we consider $\mathrm{PoC}^\alpha = 1$ when $\mathrm{SW}^\alpha(\mathrm{OPT}) = 0$. In the following we show that the PoC of every dueling game is bounded by $\min_{\alpha\geq 0}\{\mathrm{PoC}^\alpha\}$.

▶ **Theorem 16** (0-1 principle). *For every dueling game we have* $PoC \geq \min_{\alpha\geq 0}\{PoC^\alpha\}$.

In the following subsections we show how we can apply the 0-1 principle to dueling games in order to present lower bounds for the PoC. In Subsection 4.1 we show that the PoC of the ranking duel is at least $\frac{1}{4}$ regardless of the valuation function. Note that, for every α, one could design a valuation function in such a way that $|v^\alpha_\omega(\mathbf{x}) - v_\omega(\mathbf{x})| \leq \epsilon$ while the optimal and minimax strategies remain the same. Therefore, we have the lowest PoC when the range of the valuation function is $[0, \epsilon] \cup [1, 1 + \epsilon]$.

4.1 Ranking duel with general valuation function

Recall that in the ranking duel each position of the permutation has a valuation $f(i)$, each pure strategy of the players is a permutation of webpages $\pi = \langle \pi^{-1}(1), \pi^{-1}(2), \pi^{-1}(3), \ldots, \pi^{-1}(n)\rangle$, and $\Omega = \{1, 2, \ldots, n\}$ is the set of elements of uncertainty. For a webpage $\omega \in \Omega$, $v_\omega(\pi) = f(\pi(\omega))$, where $\pi(\omega)$ is the rank of ω in π. In the following, we use the 0-1 principle to show that the PoC of the ranking duel with an arbitrary valuation function is at least $\frac{1}{4}$.

▶ **Theorem 17.** *The PoC of the ranking duel is at least* $\frac{1}{4}$.

4.2 Binary search duel with general valuation function

In this subsection we study the binary search duel and show that the PoC of this game can be $\Omega(\frac{1}{n})$. In this game $\Omega = \{1, 2, \ldots, n\}$ and each pure strategy of the players is a binary tree such that its in-order traversal visits the elements of Ω in the sorted order. Moreover, $v_\omega(s)$ is determined by $f(d_s(\omega))$ where $d_s(\omega)$ denotes the depth of element ω in the binary search tree corresponding to s and $f : \mathbb{N} \to \mathbb{R}_{\geq 0}$ is a decreasing function.

▶ **Theorem 18.** *For every* $\beta > 0$ *there is an instance of the binary search duel with* $|\Omega| = \theta(\frac{1}{\beta})$ *and* $PoC \leq \beta$.

Popular Half-Integral Matchings

Telikepalli Kavitha*

Tata Institute of Fundamental Research, Mumbai, India

Abstract

In an instance $G = (A \cup B, E)$ of the stable marriage problem with strict and possibly incomplete preference lists, a matching M is popular if there is no matching M' where the vertices that prefer M' to M outnumber those that prefer M to M'. All stable matchings are popular and there is a simple linear time algorithm to compute a maximum-size popular matching. More generally, what we seek is a *min-cost* popular matching where we assume there is a cost function $c : E \to \mathbb{Q}$. However there is no polynomial time algorithm currently known for solving this problem. Here we consider the following generalization of a popular matching called a popular *half-integral* matching: this is a fractional matching $\vec{x} = (M_1 + M_2)/2$, where M_1 and M_2 are the 0-1 edge incidence vectors of matchings in G, such that $\vec{x}$ satisfies popularity constraints. We show that every popular half-integral matching is equivalent to a stable matching in a larger graph G^*. This allows us to solve the min-cost popular half-integral matching problem in polynomial time.

1 Introduction

Let $G = (A \cup B, E)$ be an instance of the stable marriage problem on n vertices and m edges. Each vertex has a strict preference list ranking its neighbors. A matching M is stable if M admits no *blocking edge*, i.e., an edge (a, b) such that both a and b prefer each other to their respective assignments in M. The existence of stable matchings in G and the Gale-Shapley algorithm [7] to find one are classical results in graph algorithms.

Stability is a very strict condition and here we consider a relaxation of this called *popularity*. This notion was introduced by Gärdenfors [9] in 1975. We say a vertex $u \in A \cup B$ *prefers* matching M to matching M' if u is matched in M and unmatched in M' or it is matched in both and $M(u)$ ranks better than $M'(u)$ in u's preference list. For any two matchings M and M' in G, let $\phi(M, M')$ be the number of vertices that prefer M to M'.

▶ **Definition 1.** A matching M is *popular* if $\phi(M, M') \geq \phi(M', M)$ for every matching M' in G, i.e., $\Delta(M, M') \geq 0$ where $\Delta(M, M') = \phi(M, M') - \phi(M', M)$.

Every stable matching is popular [9]. In fact, it is known that every stable matching is a minimum-size popular matching [10]. In applications such as matching students to projects or applicants to posts, it may be useful to consider a weaker notion (such as popularity) than the total absence of blocking edges for the sake of obtaining larger-sized matchings. Popularity provides "global stability" since a popular matching never loses an election to another matching; by relaxing stability to popularity, we have a larger pool of candidate matchings to choose from in such an application.

When there is a cost function $c : E \to \mathbb{Q}$, what we seek is a min-cost popular matching. There are several polynomial time algorithms known [11, 5, 6, 16, 14, 15] for computing a min-cost stable matching in G. However, while a maximum-size popular matching can be computed in linear time [12], no polynomial time algorithm is currently known for computing a min-cost popular matching in an instance $G = (A \cup B, E)$ with strict preference lists, except when preference lists are complete [4].

A fractional matching $\vec{p}$ is a convex combination of matchings, i.e., $\vec{p} = \sum_i p_i \cdot I(M_i)$ where $\sum_i p_i = 1$, $p_i \geq 0$ for all i, M_i's are matchings in G, and $I(M)$ is the 0-1 edge incidence vector of M. The fractional matching $\vec{p}$ is *popular* if $\Delta(\vec{p}, M) \geq 0$ for all matchings M in G where $\Delta(\vec{p}, M) = \sum_i p_i \cdot \Delta(M_i, M)$ (see Definition 1). It follows by linearity that if $\vec{p}$ is a popular fractional matching then $\Delta(\vec{p}, \vec{q}) \geq 0$ for all fractional matchings $\vec{q}$.

Let $\mathcal{P}$ be the polytope defined by the constraints that $\vec{p}$ belongs to the matching polytope of G and $\Delta(\vec{p}, M) \geq 0$ for all matchings M in G. A simple description of $\mathcal{P}$ was given in [13]. Thus a min-cost popular *fractional* matching can be computed in polynomial time.

Our results and techniques. Our main result is a polynomial time algorithm to compute a min-cost popular *half-integral* matching in G. A popular half-integral matching is a vector $\vec{x} \in \{0, \frac{1}{2}, 1\}^m \cap \mathcal{P}$. For any two popular matchings M_1 and M_2 in G, the half-integral matching $(I(M_1) + I(M_2))/2$ is popular. However not every popular half-integral matching is a convex combination of popular matchings – we show such an example in Section 2. Thus if $\mathcal{Q}$ is the convex hull of popular half-integral matchings in G, then $\mathcal{Q}$ need not be integral.

We show that every extreme point of $\mathcal{Q}$ is a stable matching in a new (larger) graph G^* that we construct here. Thus the min-cost popular half-integral matching problem in G becomes the min-cost stable matching problem in G^* which can be solved in polynomial time. This also gives us a simple description of the polytope $\mathcal{Q}$ via the stable matching polytope of G^* (i.e., the convex hull of stable matchings in G^*).

The main tool that we use here is the description of the polytope $\mathcal{P}$ from [13]. We first show that every stable matching S in the new graph G^* can be mapped to a half-integral matching in G whose incidence vector belongs to $\mathcal{P}$. We then show that every extreme point $\vec{p}$ of the convex hull $\mathcal{Q}$ of popular half-integral matchings in G can be realized as a stable matching in G^*. We use the fact that $\vec{p} \in \mathcal{P}$ along with the fact that G is bipartite to show a "helpful witness" $(\alpha_u)_{u \in A \cup B} \in \{\pm 1, 0\}^n$. This witness will guide us in building a stable matching S in G^* that corresponds to $\vec{p}$.

A graph G', similar to the graph G^* used here, was recently used in [4] to show that any stable matching in G' maps to a maximum-size popular matching M in G. However every maximum-size popular matching in G need not be obtained as a stable matching in G'. In the special case when preference lists are complete (i.e., G is $K_{|A|,|B|}$), all popular matchings in G can be realized as stable matchings in G'. The method used in [4] is similar to the method used in previous algorithms to compute maximum-size popular matchings [10, 12] – these show that there is no *popularity-improving* alternating path or cycle with respect to the matching returned. In contrast, our technique here is based on linear programming.

A min-cost popular half-integral popular matching has applications – consider the problem of assigning projects to students where each project can be split into two half-projects. Each half-project can be assigned to a distinct student and a student can be assigned two half-projects. A min-cost popular half-integral matching is a feasible assignment here that is popular and has the least cost. While fractional matchings, in general, may not be feasible in typical applications, half-integral matchings are more natural and suitable to applications.

Background. Algorithms for computing popular matchings [1] were first considered in the one-sided preference lists model where it is only vertices in A that have preferences and cast votes while vertices in B have no preferences. Popular matchings need not always exist in this model, however it was shown in [13] that popular fractional matchings always exist and using the description of $\mathcal{P}$, such a fractional matching can be found in polynomial time (via linear programming).

In the two-sided preference lists model, when preference lists have ties, $G = (A \cup B, E)$ need not always admit a popular matching and it is known that determining if G admits a popular matching or not is an NP-complete problem [2, 3]. When preference lists are strict, every stable matching is popular. The min-cost stable matching problem in an instance $G = (A \cup B, E)$ with strict preference lists is well-studied and descriptions of the stable matching polytope were given by Vande Vate [16], Rothblum [14], and Teo and Sethuraman [15].

We discuss preliminaries in Section 2. Section 3 describes the graph G^* and shows that every stable matching in G^* is a popular half-integral matching in G. Section 4 shows how every popular half-integral matching in G that is an extreme point of $\mathcal{Q}$ (the popular half-integral matching polytope) can be obtained as a stable matching in G^*.

2 Preliminaries

For any vertex $u \in A \cup B$ and neighbors v and w, we will use the following function to show u's preference for v vs w: $\mathsf{vote}_u(v, w) = 1$ if u prefers v to w, it is -1 if u prefers w to v, else (i.e., when $v = w$) it is 0. We will be using this function in the description of the popular fractional matching polytope $\mathcal{P}$.

Recall that a popular fractional matching is a point $\vec{x} = (x_e)_{e \in E}$ in the matching polytope of G such that $\Delta(\vec{x}, M) \geq 0$ for all matchings M in G. It will be convenient to assume that each vertex $u \in A \cup B$ is completely matched in every fractional matching $\vec{x}$ in G. So we will revise $\vec{x}$ so that each vertex u gets matched to an artificial last-resort neighbor $\ell(u)$ (which is placed at the bottom of u's preference list) with weight $(1 - \sum_{e \in E(u)} x_e)$, where the sum is over all the edges e incident on u.

For convenience, we will continue to use $\vec{x}$ to denote the revised $\vec{x}$ in $[0, 1]^{m+n}$. We use $\tilde{E}$ to denote the edge set $E \cup \{(u, \ell(u)) : u \in A \cup B\}$ and $\tilde{E}(u)$ is the set of edges in $\tilde{E}$ that are incident on u. The following simple description of $\mathcal{P}$ was given in [13]. In the constraints below, a variable α_u is associated with each $u \in A \cup B$ and not to last-resort neighbors.

$$\alpha_a + \alpha_b \geq \sum_{(a,b') \in \tilde{E}(a)} x_{(a,b')} \cdot \mathsf{vote}_a(b, b') + \sum_{(a',b) \in \tilde{E}(b)} x_{(a',b)} \cdot \mathsf{vote}_b(a, a') \quad \forall (a, b) \in \tilde{E}$$

$$\sum_{u \in A \cup B} \alpha_u = 0 \quad \text{and} \quad \sum_{e \in \tilde{E}(u)} x_e = 1 \quad \forall u \in A \cup B \quad \text{and} \quad x_e \geq 0 \quad \forall e \in \tilde{E}.$$

The constraints above arise as the dual to the maximum weight matching problem in the graph $\tilde{G}_x$ which is G augmented with last-resort neighbors and with edge set $\tilde{E}$, where the weight of an edge (a, b) is $\sum_{(a,b') \in \tilde{E}(a)} x_{(a,b')} \cdot \mathsf{vote}_a(b, b') + \sum_{(a',b) \in \tilde{E}(b)} x_{(a',b)} \cdot \mathsf{vote}_b(a, a')$. The constraint $\sum_{u \in A \cup B} \alpha_u = 0$ is equivalent to saying that the maximum weight of a matching in $\tilde{G}_x$ is 0, in other words, $\vec{x}$ is popular. We refer the reader to Section 3 of [13] for all the details.

For any fractional matching $\vec{x}$, if there exists $\vec{\alpha} = (\alpha_u)_{u \in A \cup B}$ such that $\vec{x}$ and $\vec{\alpha}$ satisfy the above constraints, then we say $\vec{x} \in \mathcal{P}$. The vector $\vec{\alpha}$ will be called a *witness* to $\vec{x}$'s popularity.

a_0	v_1			
a_1	b_1	v_1		
a_2	b_1	b_2		
u_1	v_1	v_2	b_0	
u_2	v_2	b_2	v_1	

b_0	u_1			
b_1	a_2	a_1		
b_2	a_2	u_2		
v_1	u_2	a_1	u_1	a_0
v_2	u_1	u_2		

Figure 1 The above table describes the preference lists of all the men and women in G. Here a_0 has a single neighbor v_1 while a_1's top choice is b_1, second choice is v_1 and so on for each vertex.

$\mathcal{P}$ is not integral. We now show an example of a graph G and a fractional matching $\vec{p} \in \mathcal{P}$, however $\vec{p}$ is not a convex combination of popular matchings. Let $A = \{a_0, a_1, a_2, u_1, u_2\}$, $B = \{b_0, b_1, b_2, v_1, v_2\}$, and the preference lists of vertices are described in Figure 1.

Consider the half-integral matching $\vec{p}$ which has $p_{(a_1,b_1)} = p_{(a_2,b_2)} = 1$ and $p_e = \frac{1}{2}$ for $e \in \{(u_1, v_1), (u_2, v_2), (u_1, v_2), (u_2, v_1)\}$. For any other edge e, we have $p_e = 0$. This fractional matching belongs to $\mathcal{P}$ by using the following α values: $\alpha_{a_0} = \alpha_{b_0} = 0$; $\alpha_{a_2} = \alpha_{b_1} = 1$; $\alpha_{a_1} = \alpha_{b_2} = -1$; and $\alpha_w = 0$ for $w \in \{u_1, u_2, v_1, v_2\}$.

There is only one way to express $\vec{p}$ as a convex combination of integral matchings, that is, $\vec{p} = (I(M_1) + I(M_2))/2$, where $M_1 = \{(a_1, b_1), (a_2, b_2), (u_1, v_1), (u_2, v_2)\}$ and $M_2 = \{(a_1, b_1), (a_2, b_2), (u_1, v_2), (u_2, v_1)\}$. We show below that neither M_1 nor M_2 is popular.

The matching $M_1' = \{(u_1, b_0), (a_1, v_1), (a_2, b_1), (u_2, v_2)\}$ is more popular than M_1 and the matching $M_2' = \{(a_0, v_1), (u_2, b_2), (a_2, b_1), (u_1, v_2)\}$ is more popular than M_2. Thus $\vec{p}$ is not in the convex hull of popular matchings in G.

The graph G'. Our input is a graph $G = (A \cup B, E)$ on n vertices and m edges. Note that there are no last-resort neighbors here – they were added only for the formulation of the polytope $\mathcal{P}$. Vertices in A and in B are usually referred to as men and women, respectively, and we follow the same convention here.

The construction of the following graph $G' = (A' \cup B', E')$, based on G, was shown in [4]. The set A' has two copies a_0 and a_1 of each man $a \in A$, the men in $\{a_0 : a \in A\}$ are called *level 0 men* of G' and those in $\{a_1 : a \in A\}$ are called *level 1 men* of G'. The set B' consists of all the women in B along with *dummy vertices* $\cup_{a \in A}\{d(a)\}$, where there is one dummy vertex per man in A. The preference lists of the vertices are as follows:

- each level 0 man a_0 has the same preference list as the corresponding man a in G except that the dummy vertex $d(a)$ occurs as his *least* preferred neighbor at the bottom of his preference list
- each level 1 man a_1 has the same preference list as the corresponding man a in G except that the dummy vertex $d(a)$ occurs as his *most* preferred neighbor at the top of his preference list
- each dummy vertex $d(a)$ has a_0 and a_1 as its neighbors: top choice is a_0, followed by a_1
- every woman $b \in B$ has the following preference list in G': all her level 1 neighbors (in the same order of preference as in G) followed by all her level 0 neighbors (in the same order of preference as in G).

We will be using this graph G' here; in fact, we will have two such graphs G' and G'' combining to form our new graph G^*. The graph G'' is analogous to the graph G' except that the roles of men and women (and also that of levels 0 and 1) are swapped here.

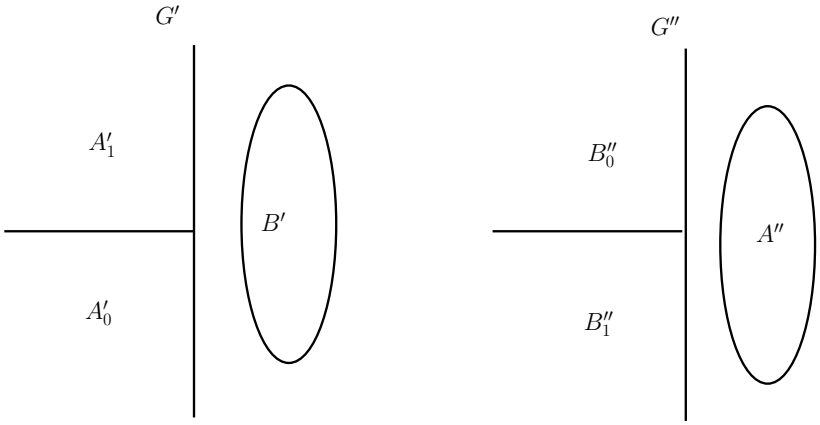

Figure 2 The graph G' on the left and the graph G'' on the right in G^*. For $i = 0, 1$, we use A'_i to refer to level i men in G' and we use B''_i to refer to level i women in G''.

3 The graph G^*

We define the graph G^* as follows: G^* consists of two vertex-disjoint subgraphs G' and G'' (see Figure 2). The graph G' was described in Section 2.

In the graph $G'' = (B'' \cup A'', E'')$, women are on the left side of G'' and men are on the right side – the set B'' has two copies b_0 and b_1 of each woman $b \in B$, the women in $\{b_0 : b \in B\}$ are called *level 0 women* of G'' and those in $\{b_1 : b \in B\}$ are called *level 1 women* of G''.

The set A'' consists of all the men in A along with new dummy vertices $\cup_{b \in B}\{d(b)\}$, where there is one dummy vertex per woman in B. The preference lists of the vertices are as follows:

- each level 0 woman b_0 has the same preference list as the corresponding woman b in G except that the dummy vertex $d(b)$ occurs as her *most* preferred neighbor at the top of her preference list
- each level 1 woman b_1 has the same preference list as the corresponding woman b in G except that the dummy vertex $d(b)$ occurs as her *least* preferred neighbor at the bottom of her preference list
- each dummy vertex $d(b)$ has only b_0 and b_1 as its neighbors: its top choice is b_1, followed by b_0
- every man $a \in A$ has the following preference list in G'': all his level 0 neighbors (in the same order of preference as in G) followed by all his level 1 neighbors (in the same order of preference as in G).

We want all stable matchings in G^* to be perfect matchings – note that all level 0 men in G' and all level 1 women in G'' will be matched in any stable matching in G^* since they are top-choice neighbors for their respective dummy neighbors. However the same cannot be said about level 1 men in G' and level 0 women in G''.

In order to take care of these vertices, we add the following "self-loop" edges to G^*: the edge (a_1, a) for each man a in A, where $a_1 \in A'_1$ and $a \in A''$, and the edge (b_0, b) for each woman b in B, where $b_0 \in B''_0$ and $b \in B'$. The vertex $a_1 \in A'_1$ regards $a \in A''$ as his worst ranked neighbor and similarly, $b_0 \in B''_0$ regards $b \in B'$ as her worst ranked neighbor.

For any man $a \in A''$, the vertex a_1 is in the middle of his preference list, sandwiched between all his level 0 neighbors and all his level 1 neighbors as shown in (1) below. More

precisely, a_1 is sandwiched between b''_0 and b'_1, where $b' > \cdots > b''$ is a's preference list in G. Thus b''_0 is a's worst level 0 neighbor and b'_1 is a's best level 1 neighbor.

$$a:\ b'_0 > \cdots > b''_0 > \underline{a_1} > b'_1 > \cdots > b''_1; \qquad b:\ a'_1 > \cdots > a''_1 > \underline{b_0} > a'_0 > \cdots > a''_0. \quad (1)$$

Similarly, for any woman $b \in B'$, the vertex b_0 is in the middle of her preference list, sandwiched between all her level 1 neighbors and all her level 0 neighbors as shown in (1). More precisely, b_0 is sandwiched between a''_1 and a'_0, where $a' > \cdots > a''$ is b's preference list in G. Using the fact that all stable matchings in G^* match the same set of vertices [8], it can be shown that every stable matching in G^* is perfect.

The function f. We now define a function f : {stable matchings in G^*} $\to$ {half-integral matchings in G}. Observe that every stable matching in G^* has to match all dummy vertices since each of these is a top-choice neighbor for someone. Thus out of a_0 and a_1 in A', only one is matched to a non-dummy neighbor and similarly, out of b_0 and b_1 in B'', only one is matched to a non-dummy neighbor.

Let S be any stable matching in G^*. By removing all self-loops that occur in S and those edges in S that contain a dummy vertex, the resulting matching is the union of two matchings S' and S'' in G. We define $f(S)$ to be $(I(S') + I(S''))/2$, where $I(M) \in \{0,1\}^m$ is the 0-1 edge incidence vector of M. So $f(S)$ is a valid half-integral matching in G.

▶ **Theorem 2.** *For any stable matching S in G^*, the half-integral matching $f(S)$ is popular in G.*

Proof. We are given a stable matching S in G^*. Recall that we pruned all edges that contain a dummy vertex and all self-loops from S to define $f(S)$. We now prune all dummy vertices, their partners in S, and self-loops from G^* also – let H^* denote the pruned graph G^*. Let H' denote the pruned subgraph G' and let H'' denote the pruned subgraph G''.

The men in the graph H' consist of one copy of each $a \in A$ – some of these are in level 0 and the rest are in level 1. The women in H' are exactly those in B. The women in H'' consist of one copy of each $b \in B$ – some of these are in level 0 and the rest are in level 1. The men in H'' are exactly those in A. Thus H' and H'' are two copies of the graph G.

Let S' be the pruned matching (resulting from S) restricted to H' and let S'' be the pruned matching (resulting from S) restricted to H''. Let $\tilde{A}'_i$ denote the set of level i men in H', for $i = 0, 1$ (see Figure 3). Let $\tilde{B}'_i$ consist of women matched in S' to men in $\tilde{A}'_i$, for $i = 0, 1$. Women unmatched in S' are added to $\tilde{B}'_1$.

Similarly, $\tilde{B}''_i$ consists of level i women in the H'' part of H^* and $\tilde{A}''_i$ denotes the set of men matched in S'' to women in $\tilde{B}''_i$, for $i = 0, 1$. Men unmatched in S'' are added to $\tilde{A}''_0$.

For each edge $e = (a, b) \in H'$, define the function $w'(e)$ as follows: $w'(e) = \mathsf{vote}_a(b, S'(a)) + \mathsf{vote}_b(a, S'(b))$. If $S'(u)$ is undefined for any vertex u, then $\mathsf{vote}_u(v, S'(u)) = 1$ for any neighbor v of u since every vertex prefers being matched to being unmatched. Note that if $(a, b) \in S'$ then $w'(e) = 0$.

Similarly, for each edge $e = (a, b) \in H''$, define the function $w''(e)$ as follows: $w''(e) = \mathsf{vote}_a(b, S''(a)) + \mathsf{vote}_b(a, S''(b))$. For any vertex u that is unmatched in S'', we take $\mathsf{vote}_u(v, S''(u)) = 1$, for any neighbor v of u. Note that $w'(e)$ and $w''(e)$ always take values in $\{-2, 0, 2\}$. Due to the stability of the matching S in G^*, the following observations hold:

- Every edge $e \in \tilde{A}'_1 \times \tilde{B}'_0$ has to satisfy $w'(e) = -2$. Similarly, every edge $e \in \tilde{A}''_1 \times \tilde{B}''_0$ has to satisfy $w''(e) = -2$.

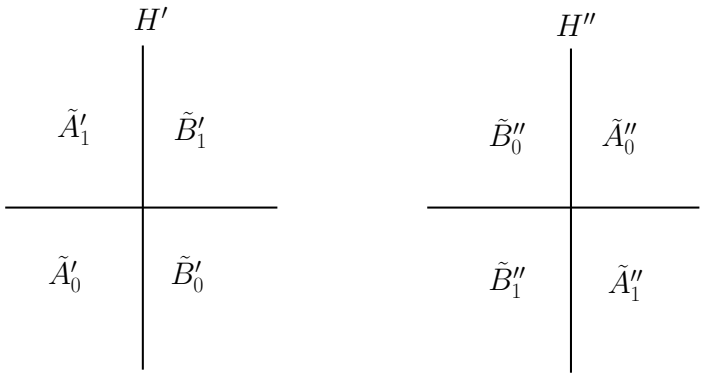

Figure 3 The graph H' on the left and the graph H'' on the right in the graph H^*.

Consider an edge (a_1, b) in $\tilde{A}'_1 \times \tilde{B}'_0$. It follows from the definition of preference lists of women in G' that the woman b prefers a_1 (a level 1 man) to her partner $S'(b)$ (a level 0 man). Since S is stable, it follows that a_1 prefers his partner $S'(a_1)$ to b. Moreover, a_0 prefers b to $S'(a_0) = d(a)$, since $d(a)$ is a_0's last choice. Thus b prefers her partner $S'(b)$ to a_0. So $\mathsf{vote}_a(b, S'(a)) = \mathsf{vote}_b(a, S'(b)) = -1$. A similar proof holds for any edge $e \in \tilde{A}''_1 \times \tilde{B}''_0$.

- Every edge e such that $w'(e) = 2$ has to be in $\tilde{A}'_0 \times \tilde{B}'_1$. Similarly, every edge e such that $w''(e) = 2$ has to be in $\tilde{A}''_0 \times \tilde{B}''_1$.

If e is an edge in H' such that $w'(e) = 2$, then $e \notin \tilde{A}'_i \times \tilde{B}'_i$ (for $i = 0, 1$) as such an edge would block S. We have already seen that any edge $e \in \tilde{A}'_1 \times \tilde{B}'_0$ satisfies $w'(e) = -2$. Thus any edge e such that $w'(e) = 2$ has to be in $\tilde{A}'_0 \times \tilde{B}'_1$. We can similarly show that any edge e in H'' such that $w''(e) = 2$ has to be in $\tilde{A}''_0 \times \tilde{B}''_1$.

We will now show that $f(S) \in \mathcal{P}$ by assigning appropriate α_u values for all u in $A \cup B$. We first define α'_u and α''_u:

- let $\alpha'_u = -1$ if $u \in \tilde{A}'_1 \cup \tilde{B}'_0$ and let $\alpha'_u = 1$ if $u \in \tilde{A}'_0 \cup \tilde{B}'_1$.
- let $\alpha''_u = -1$ if $u \in \tilde{A}''_1 \cup \tilde{B}''_0$ and let $\alpha''_u = 1$ if $u \in \tilde{A}''_0 \cup \tilde{B}''_1$.

The following is an immediate corollary of the above observations and the definitions of α'_u and α''_u: $\alpha'_a + \alpha'_b \geq w'(a, b)$ and $\alpha''_a + \alpha''_b \geq w''(a, b)$ for all edges (a, b). Also for any vertex u that is unmatched in S' and S'', we have $\alpha'_u + \alpha''_u = 0$.

Define $\alpha_u = (\alpha'_u + \alpha''_u)/2$ for all $u \in A \cup B$. Observe that $\sum_{u:A\cup B} \alpha_u = 0$. The above constraints imply that $(\alpha_u)_{u\in A\cup B}$ and the incidence vector of $f(S)$ satisfy the constraints of the polytope $\mathcal{P}$. Thus $f(S)$ is a popular half-integral matching. ◀

4 Constructing a stable matching in G^*

We showed in the previous section that f maps stable matchings in G^* to popular half-integral matchings in G. In fact, $f(S)$ is what we will call a *full* half-integral matching, i.e., for every vertex $u \in A \cup B$, either u is fully matched in $f(S)$ or it is fully unmatched in $f(S)$. Let $\vec{p} \in \{0, \frac{1}{2}, 1\}^m$ be a full half-integral matching that is popular. Since $\vec{p} \in \mathcal{P}$, there exists a witness $(\alpha_u)_{u\in A\cup B}$ to $\vec{p}$'s popularity. The following lemma will be useful to us.

▶ **Lemma 3.** *There exists a witness $(\alpha_u)_{u\in A\cup B}$ to $\vec{p}$'s popularity such that $\alpha_u \in \{\pm 1, 0\}$, for each $u \in A \cup B$.*

Proof. In order to show such a witness, we will consider the following linear program:

$$\text{minimize} \sum_{u \in A \cup B} \alpha_u \qquad \text{(LP1)}$$

subject to

$$\alpha_a + \alpha_b \;\geq\; \textstyle\sum_{(a,b') \in \tilde{E}(a)} p_{(a,b')} \cdot \mathsf{vote}_a(b, b') + \sum_{(a',b) \in \tilde{E}(b)} p_{(a',b)} \cdot \mathsf{vote}_b(a, a') \;\forall\, (a,b) \in \tilde{E}$$

Recall that $\tilde{E}$ is the set $E \cup \{(u, \ell(u)) : u \in A \cup B\}$, where $\ell(u)$ is the artificial last-resort neighbor of vertex u. In the above constraints, let us denote the right hand side quantity corresponding to edge e by $\mathsf{value}_p(e)$. Since $\vec{p}$ is a full half-integral matching, it is easy to see that $\mathsf{value}_p(e)$ is integral for all edges e.

Consider the polyhedron defined by the above constraints $N \cdot \vec{\alpha} \geq \vec{c}$, where N is the above $(m+n) \times n$ constraint matrix, $\vec{\alpha}$ is the column of unknowns α_u, for $u \in A \cup B$, and $\vec{c}$ is the column vector of $\mathsf{value}_p(\cdot)$ values. The top $m \times n$ sub-matrix of N is the edge-vertex incidence matrix U of the graph G and the bottom $n \times n$ matrix is the identity matrix I. Since the graph G is bipartite, the matrix U is totally unimodular and hence the matrix N is totally unimodular. Since $\vec{c}$ is an integral vector, it follows that all the vertices of $N \cdot \vec{\alpha} \geq \vec{c}$ are integral.

Thus there is an integral optimal solution to (LP1), call it $\vec{\alpha}^*$. We need to now show that $\vec{\alpha}^* \in \{\pm 1, 0\}^n$. It follows from the constraints corresponding to the edges $(u, \ell(u))$ that $\alpha^*_u \geq -1$ if u is matched in $\vec{p}$ and $\alpha^*_u \geq 0$ for u unmatched in $\vec{p}$. We now show the following claim.

▶ **Claim 4.** *Let $e = (a, b)$ be any edge such that $p_e > 0$. Then the constraint in (LP1) corresponding to e is tight, i.e., $\alpha^*_a + \alpha^*_b = \mathsf{value}_p(e)$.*

Proof. Consider the dual program of (LP1): it is the maximum weight matching problem in the graph G augmented with last-resort neighbors and with edge set $\tilde{E}$, where the weight of edge e is $\mathsf{value}_p(e)$. A maximum weight matching in this graph has weight 0 (because $\vec{p}$ is popular). Since $\Delta(\vec{p}, \vec{p}) = 0$, the fractional matching $\vec{p}$ is an optimal dual solution. It follows from complementary slackness conditions that if $p_{(a,b)} > 0$, then the constraint in (LP1) for edge (a, b) is tight. ◀

Observe that for any vertex u, there has to be an edge e incident on it with $p_e > 0$ and either $\mathsf{value}_p(e) = 0$ or $\mathsf{value}_p(e) = -1$ (the edge e between u and its worse partner v in $\vec{p}$). Using Claim 4 and the fact that $\alpha^*_v \geq -1$, we can now conclude that $\alpha^*_u \leq 1$. ◀

We will use the above lemma to show the following theorem in this section.

▶ **Theorem 5.** *Let $\vec{p} \in \{0, \frac{1}{2}, 1\}^m$ be a full half-integral matching that is popular. Then $\vec{p} = f(S)$ for some stable matching S in G^*.*

We will now build a stable matching S in the graph G^* such that $f(S) = \vec{p}$. For every edge $e = (a, b)$ such that $p_e > 0$, we need to decide which of the edges $(a_0, b), (a_1, b), (b_0, a), (b_1, a)$ will get included in S. In order to make this decision, we will build a graph H^*. The graph H^* consists of two copies H' and H'' of the input graph G.

Every vertex $u \in A \cup B$ gets assigned a level, denoted by $\mathsf{level}'(u)$, in H'. For $a \in A$, $\mathsf{level}'(a) = i$ fixes $a_i \in \{a_0, a_1\}$ to be the one that will be matched to a woman (i.e., a non-dummy vertex) in S. For $b \in B$, we say $\mathsf{level}'(b) = i$ to fix b getting matched to some level i man in H'. We will say u is in level i in H' to mean $\mathsf{level}'(u) = i$.

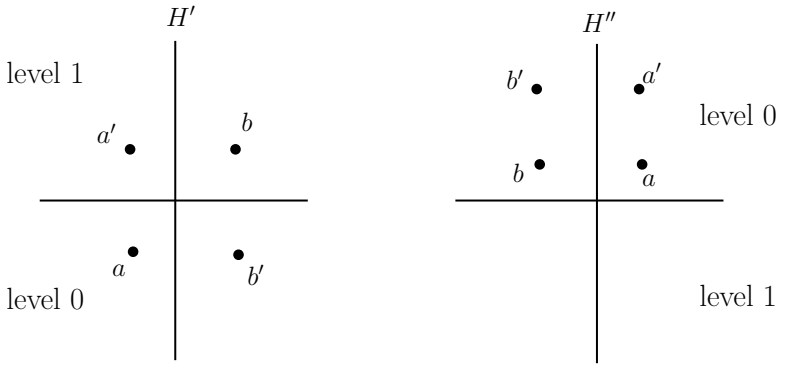

Figure 4 Since $\alpha^*_a = 1$ and $\alpha^*_{b'} = -1$, we have $\mathsf{level}'(a) = \mathsf{level}'(b') = 0$ and similarly, $\mathsf{level}''(a) = \mathsf{level}''(b') = 0$. Since $\alpha^*_b = \alpha^*_{a'} = 0$, we have $\mathsf{level}'(b) = \mathsf{level}'(a') = 1$ and similarly, $\mathsf{level}''(b) = \mathsf{level}''(a') = 0$. So we place a and b' in level 0 in both H and H' and we place a' and b in level 1 in H' and in level 0 in H''.

Similarly, every vertex $u \in A \cup B$ gets assigned a level, denoted by $\mathsf{level}''(u)$, in H''. For $b \in B$, $\mathsf{level}''(b) = j$ fixes $b_j \in \{b_0, b_1\}$ to be the one that will be matched to a man (i.e., a non-dummy vertex) in S. For $a \in A$, we say $\mathsf{level}''(a) = j$ to fix a getting matched to some level j woman in H''. We will say u is in level j in H'' to mean $\mathsf{level}''(u) = j$.

Since $\vec{p}$ is a full half-integral matching that is popular, we know from Lemma 3 that there exists a witness $\vec{\alpha}^* = (\alpha^*_u)_{u \in A \cup B}$ in $\{-1, 0, 1\}^n$ to the popularity of $\vec{p}$. We will use $\vec{\alpha}^*$ to fix $\mathsf{level}'(u)$ and $\mathsf{level}''(u)$ for each vertex u as follows.

- $\alpha^*_u = -1$: If $u \in A$ then $\mathsf{level}'(u) = \mathsf{level}''(u) = 1$. If $u \in B$ then $\mathsf{level}'(u) = \mathsf{level}''(u) = 0$.
- $\alpha^*_u = 1$: If $u \in A$ then $\mathsf{level}'(u) = \mathsf{level}''(u) = 0$. If $u \in B$ then $\mathsf{level}'(u) = \mathsf{level}''(u) = 1$.
- $\alpha^*_u = 0$: For all $u \in A \cup B$, $\mathsf{level}'(u) = 1$ and $\mathsf{level}''(u) = 0$.

As an example, consider the 4-cycle G on 2 men a, a' and 2 women b, b' where both a and a' prefer b to b' and both b and b' prefer a to a'. Let $\vec{p}$ be the half-integral matching with $p_e = 1/2$ for each edge e. This is popular and $\alpha^*_a = 1$, $\alpha^*_b = \alpha^*_{a'} = 0$, and $\alpha^*_{b'} = -1$ is a witness to $\vec{p}$'s popularity. Figure 4 shows how these vertices get placed in H' and in H''.

For any vertex u, let v and v' be its neighbors in G such that $\vec{p}$ has positive support on (u, v) and (u, v'). We will refer to v and v' as *partners* of u in $\vec{p}$. We need to show that either (i) $\mathsf{level}'(u) = \mathsf{level}'(v)$ and $\mathsf{level}''(u) = \mathsf{level}''(v')$, or (ii) $\mathsf{level}'(u) = \mathsf{level}'(v')$ and $\mathsf{level}''(u) = \mathsf{level}''(v)$. In other words, we need to show that u, v are level-compatible in one of H', H'' and u, v' are level-compatible in the other graph in H', H''.

We will now show that our allocation of levels to men and women based on their α^*-values ensures this. If $v = v'$ then $p_{(u,v)} = 1$ and the (tight) constraint for edge (u, v) in the description of $\mathcal{P}$ is $\alpha^*_u + \alpha^*_v = 0$. Thus (α^*_u, α^*_v) has to be one of $(1, -1), (0, 0), (-1, 1)$: in all three cases we have level-compatibility in both H' and H''. The following lemma shows that even when u has two distinct partners v and v' in $\vec{p}$, there is level-compatibility.

▶ **Lemma 6.** *Every vertex that has two distinct partners in $\vec{p}$ is level-compatible in H' with one partner and is level-compatible in H'' with another partner.*

Proof. We will show this lemma for any vertex $b \in B$. An analogous proof holds for any vertex in A. Let $a \neq a'$ be the partners of b in $\vec{p}$ and let b prefer a to a'. We know that $p_{(a,b)} = p_{(a',b)} = 1/2$. Since $\vec{p}$ is a full half-integral matching, a (similarly, a') has another neighbor $r(a)$ (resp., $r(a')$) with positive support in $\vec{p}$. We have four cases depending on how a and a' rank b versus $r(a)$ and $r(a')$, respectively.

1. If both a and a' prefer $r(a)$ and $r(a')$ respectively to b, then $\mathsf{value}_p(a,b) = -\frac{1}{2}+\frac{1}{2} = 0$ and $\mathsf{value}_p(a',b) = -\frac{1}{2}-\frac{1}{2} = -1$. By Claim 4, we know that $\alpha^*_a + \alpha^*_b = 0$ and $\alpha^*_{a'} + \alpha^*_b = -1$. So $(\alpha^*_a, \alpha^*_b, \alpha^*_{a'})$ is either $(1,-1,0)$ or $(0,0,-1)$.
   - In the former case $\mathsf{level}'(a) = \mathsf{level}'(b) = 0$ and $\mathsf{level}''(a') = \mathsf{level}''(b) = 0$.
   - In the latter case $\mathsf{level}'(a') = \mathsf{level}'(b) = 1$ and $\mathsf{level}''(a) = \mathsf{level}''(b) = 0$.
2. If both a and a' prefer b to $r(a)$ and $r(a')$ respectively, then $\mathsf{value}_p(a,b) = \frac{1}{2}+\frac{1}{2} = 1$ and $\mathsf{value}_p(a',b) = \frac{1}{2}-\frac{1}{2} = 0$. By Claim 4, we know that $\alpha^*_a + \alpha^*_b = 1$ and $\alpha^*_{a'} + \alpha^*_b = 0$. So $(\alpha^*_a, \alpha^*_b, \alpha^*_{a'})$ is either $(0,1,-1)$ or $(1,0,0)$.
   - In the former case $\mathsf{level}'(a) = \mathsf{level}'(b) = 1$ and $\mathsf{level}''(a') = \mathsf{level}''(b) = 1$.
   - In the latter case $\mathsf{level}'(a') = \mathsf{level}'(b) = 1$ and $\mathsf{level}''(a) = \mathsf{level}''(b) = 0$.
3. If a prefers b to $r(a)$ while a' prefers $r(a')$ to b, then $\mathsf{value}_p(a,b) = \frac{1}{2}+\frac{1}{2} = 1$ and $\mathsf{value}_p(a',b) = -\frac{1}{2}-\frac{1}{2} = -1$. By Claim 4, we know that $\alpha^*_a + \alpha^*_b = 1$ and $\alpha^*_{a'} + \alpha^*_b = -1$. So $(\alpha^*_a, \alpha^*_b, \alpha^*_{a'})$ is $(1,0,-1)$.
   - Here $\mathsf{level}'(a') = \mathsf{level}'(b) = 1$ and $\mathsf{level}''(a) = \mathsf{level}''(b) = 0$.
4. If a prefers $r(a)$ to b while a' prefers b to $r(a')$, then $\mathsf{value}_p(a,b) = -\frac{1}{2}+\frac{1}{2} = 0$ and $\mathsf{value}_p(a',b) = \frac{1}{2}-\frac{1}{2} = 0$. By Claim 4, we know that $\alpha^*_a + \alpha^*_b = 0$ and $\alpha^*_{a'} + \alpha^*_b = 0$. So $(\alpha^*_a, \alpha^*_b, \alpha^*_{a'})$ is $(1,-1,1)$ or $(0,0,0)$ or $(-1,1,-1)$.
   - In the first case, all three vertices a, b, and a' are in level 0 in both H' and H''.
   - In the second case, all three vertices are in level 1 in H' and in level 0 in H''.
   - In the third case, all three vertices are in level 1 in both H' and H''. ◀

For any vertex u with partners v and v' in $\vec{p}$, where u prefers v to v', we call v the *better partner* of u and v' the *worse partner* of u. If $p_{(a,b)} = 1$ for some edge (a,b), then we regard a as both the better partner and the worse partner of b.

We are now ready to describe the construction of our matching S. We give the following two pairing rules for any $b \in B$ (let a be b's better partner and a' be b's worse partner):

1. if $\alpha^*_b \in \{\pm 1\}$ then pair b with a in H' and with a' in H''.
2. if $\alpha^*_b = 0$ then pair b with a' in H' and with a in H''.

More precisely, if $\alpha^*_b = -1$ then we include (a_0, b) and (b_0, a') in S; if $\alpha^*_b = 1$ then we include (a_1, b) and (b_1, a') in S; and if $\alpha^*_b = 0$ then we include (a'_1, b) and (b_0, a) in S.

Note that the above rules for pairing vertices follow from the proof of Lemma 6. A woman b with $\alpha^*_b = -1$ (similarly, $\alpha^*_b = 1$) is level-compatible with her better partner in level 0 (resp., level 1) in H' and with her worse partner in level 0 (resp., level 1) in H''. Similarly, if $\alpha^*_b = 0$ then b is level-compatible with her worse partner in level 1 in H' and with her better partner in level 0 in H''.

Thus level-compatibility unambiguously fixes for us in which of H, H' a vertex gets paired with which partner till we are left with a set T of vertices forming a cycle: each vertex in T has both its partners in T, and all these vertices are in the same level in both H' and H''. We again know from the proof of Lemma 6 that this happens only when $(\alpha^*_a, \alpha^*_b) \in \{(1,-1),(0,0),(-1,1)\}$ for each edge (a,b) in this cycle. The cycle can be resolved as per the two rules above (which is what our algorithm for constructing S does). Thus rule 1 and rule 2 given above always work.

As the last step, we add the dummy vertices to H' and H''. We also add the *inactive* men and women (the ones who will get matched to dummy vertices in S). We now add to S the edges $(a_j, d(a))$ for all inactive men a_j and similarly, the edges $(b_j, d(b))$ for all inactive women b_j. We also add self-loops to match each unmatched vertex with its copy on the other side, i.e., we add the edges (a_1, a) for each $a \in A$ that is unmatched in $\vec{p}$ and the edges (b_0, b)

for each $b \in B$ that is unmatched in $\vec{p}$. Thus the final matching S is a perfect matching in the graph G^* and it follows from the construction of S that $f(S) = \vec{p}$.

In order to prove that the matching S is stable in G^*, we show in Lemmas 7 and 8 that S has no blocking edge in G'. We can similarly show that S admits no blocking edge in G''. Regarding the other edges in G^*, no self-loop (a_1, a) or (b_0, b) can be a blocking edge since a is the least preferred neighbor of a_1 and similarly, b is the least preferred neighbor of b_0. Similarly, since the dummy vertex $d(a)$ is the least preferred neighbor of a_0 and since a_1 is the least preferred neighbor of $d(a)$, no edge $(a_i, d(a))$ can block S. It is the same with edges $(b_i, d(b))$, for $i = 0, 1$. Hence S is a stable matching in G^* and Theorem 5 follows.

▶ **Lemma 7.** *Let $a \in A$ be in level 0 in H' and b be any neighbor of a in G. Neither edge (a_0, b) nor edge (a_1, b) in G' can block S.*

Proof. The following are the three cases that we need to consider here and show that none is a blocking edge to S:

1. the edge (a_1, b),
2. the edge (a_0, b) where b is in level 1 in H',
3. the edge (a_0, b) where b is in level 0 in H'.

Consider Case 1. Since a is in level 0 in H', the vertex a_1 is matched to $d(a)$ in S. Since $d(a)$ is a_1's most preferred neighbor, it follows that the edge (a_1, b) cannot block S for any neighbor b.

Consider Case 2. The woman b is in level 1 and this implies that $S(b)$ is a level 1 vertex in H'. Since b prefers any level 1 neighbor to a level 0 neighbor in G', it follows that b prefers $S(b)$ to a_0, thus (a_0, b) cannot block S.

Consider Case 3. Since both a and b are in level 0 in H', we have $\alpha^*_a = 1$ and $\alpha^*_b = -1$. These α^*-values and $p_{(a,b)}$ satisfy the constraint corresponding to edge (a, b) in the description of the popular matching polytope $\mathcal{P}$. Thus we have $0 \geq \mathsf{value}_p(a, b)$, where $\mathsf{value}_p(a, b)$ is the right hand side of the constraint for (a, b) in $\mathcal{P}$. The following sub-cases can occur here (since $\mathsf{value}_p(a, b) \leq 0$):

- **(i)** both the partners of a are better than b or both the partners of b are better than a
- **(ii)** $p_{(a,b)} = 1/2$ and either a regards its other partner better than b or vice-versa
- **(iii)** a has one partner better than b and the other worse than b and similarly, b has one partner better than a and the other worse than a

Sub-case (i) is straightforward and it is easy to see that (a_0, b) does not block S here. In sub-cases (ii) and (iii), we know that a woman b with $\alpha^*_b = -1$ gets matched to her better partner in H'. Thus in sub-case (ii) either b is matched to a (if a is b's better partner) or to a partner that b prefers to a. Similarly, in sub-case (iii), b gets matched to a neighbor that she prefers to a, thus (a_0, b) does not block S in any of these cases. This completes the proof of Lemma 7. ◀

▶ **Lemma 8.** *Let $a \in A$ be in level 1 in H' and b be any neighbor of a in G. Neither edge (a_0, b) nor edge (a_1, b) in G' can block S.*

Proof. The following are the three cases that we need to consider here and show that none is a blocking edge to S:

1. the edge (a_0, b),
2. the edge (a_1, b) where b is in level 0 in H',
3. the edge (a_1, b) where b is in level 1 in H'.

Consider Case 1. When b is in level 1 in H', she is matched to a level 1 man; since b prefers any level 1 neighbor to a level 0 neighbor in G', it follows that b prefers $S(b)$ to a_0, thus (a_0, b) cannot block S.

Let us consider the case when b is in level 0 in H'. So $\alpha_b^* = -1$. Since a is in level 1 in H', we have either $\alpha_a^* = -1$ or $\alpha_a^* = 0$. So $\mathsf{value}_p(a, b) \leq -1$. Hence b prefers her better partner to a and since b satisfies $\alpha_b^* = -1$, she gets matched to her better partner in H'. Thus (a_0, b) does not block S.

Consider Case 2. We will show that a_1 prefers his partner $S(a_1)$ to b. Either (i) $\alpha_a^* = -1$ in which case $\mathsf{value}_p(a, b) \leq -2$ or (ii) $\alpha_a^* = 0$ in which case $\mathsf{value}_p(a, b) \leq -1$.

In case (i), $\mathsf{vote}_a(b, S(a_1)) = -1$ and so a prefers $S(a_1)$ to b. In case (ii), $\mathsf{vote}_a(b, S(a_1)) \leq 0$ and so a prefers his better partner in $\vec{p}$ to b. It follows from the proof of Lemma 6 that if $\alpha_a^* = 0$, then the man a is matched to his better partner in H'. Thus (a_1, b) does not block S in either case.

Consider Case 3. There are four sub-cases here based on possible values of (α_a^*, α_b^*): (i) $(\alpha_a^*, \alpha_b^*) = (-1, 1)$, (ii) $(\alpha_a^*, \alpha_b^*) = (-1, 0)$, (iii) $(\alpha_a^*, \alpha_b^*) = (0, 1)$, and (iv) $(\alpha_a^*, \alpha_b^*) = (0, 0)$.

- Cases (i) and (iv) are analogous to case 3 in the proof of Lemma 7 since $\mathsf{value}_p(a, b)$ is at most 0 in both these cases and a similar proof holds here for both these cases.
- In case (ii) above, we have $\mathsf{value}_p(a, b) \leq -1$. So either (I) a prefers both his partners in $\vec{p}$ to b or vice-versa, in which case (a_1, b) does not block S or (II) $p_{(a,b)} = 1/2$ and both a and b prefer their other partners in $\vec{p}$ to each other, in which case $(a_1, b) \in S$.
- In case (iii) above, we know that both a and b get paired to their respective better partners in H' (since $\alpha_a^* = 0$ and $\alpha_b^* = 1$). We have $\mathsf{value}_p(a, b) \leq 1$ here. So either (I) a prefers its better partner in $\vec{p}$ to b or vice-versa (in which case (a_1, b) does not block S) or (II) $p_{(a,b)} = 1/2$ and both a and b prefer each other to their other partners in $\vec{p}$, in which case $(a_1, b) \in S$. Thus (a_1, b) does not block S in any of these cases. ◀

Thus we have shown that f is a surjective map from the set of stable matchings in G^* to the set of full half-integral matchings in G that are popular. It can be shown that if $\vec{p}$ is a popular half-integral matching that is *not* full, then the edge incidence vector of $\vec{p}$ is a convex combination of the edge incidence vectors of popular half-integral matchings that are full. Hence the extreme points of the convex hull $\mathcal{Q}$ of popular half-integral matchings are the full ones. Thus the description of $\mathcal{Q}$ can be obtained in a straightforward manner from the description of the stable matching polytope of G^*.

We have shown the following theorem.

▶ **Theorem 9.** *A min-cost popular half-integral matching in $G = (A \cup B, E)$ with strict preference lists and cost function $c : E \to \mathbb{Q}$ can be computed in polynomial time.*

Conclusions. We gave a simple description of the convex hull of popular half-integral matchings in a stable marriage instance $G = (A \cup B, E)$ with strict preference lists. This allowed us to solve the min-cost popular half-integral matching problem in G in polynomial time. The main open problem here is to settle the complexity of the min-cost popular matching in G.

Acknowledgments. Thanks to Naveen Garg for useful discussions on this problem. Thanks to the reviewers for their helpful comments.

Abstract

We study novel variations of Voronoi games and associated random processes that we call *Voronoi choice games*. These games provide a rich framework for studying questions regarding the power of small numbers of choices in multi-player, competitive scenarios, and they further lead to many interesting, non-trivial random processes that appear worthy of study.

As an example of the type of problem we study, suppose a group of n miners (or players) are staking land claims through the following process: each miner has m associated points independently and uniformly distributed on an underlying space (such as the unit circle, the unit square, or the unit torus), so the kth miner will have associated points $p_{k1}, p_{k2}, \ldots, p_{km}$. We generally here think of m as being a small constant, such as 2. Each miner chooses one of these points as the base point for their claim. Each miner obtains mining rights for the area of the square that is closest to their chosen base; that is, they obtain the Voronoi cell corresponding to their chosen point in the Voronoi diagram of the n chosen points. Each player's goal is simply to maximize the amount of land under their control. What can we say about the players' strategy and the equilibria of such games?

In our main result, we derive bounds on the expected number of pure Nash equilibria for a variation of the 1-dimensional game on the circle where a player owns the arc starting from their point and moving clockwise to the next point. This result uses interesting properties of random arc lengths on circles, and demonstrates the challenges in analyzing these kinds of problems. We also provide several other related results. In particular, for the 1-dimensional game on the circle, we show that a pure Nash equilibrium always exists when each player owns the part of the circle nearest to their point, but it is NP-hard to determine whether a pure Nash equilibrium exists in the variant when each player owns the arc starting from their point clockwise to the next point. This last result, in part, motivates our examination of the random setting.

1 Introduction

Consider the following prototypical problem: a group of miners are staking land claims. The kth miner – or player – has m associated points $p_{k1}, p_{k2}, \ldots, p_{km}$ in the unit torus (which is the unit square with wraparound at the boundaries, providing symmetry). Each miner via some process will choose exactly one of their m points as the base for their claim. The resulting n points yield a Voronoi diagram, and each miner obtains their corresponding Voronoi cell. Each player's goal is simply to maximize the amount of land under their control. We wish to study player behavior in this and similar games, focusing on equilibria.

As another application, political candidates can often be mapped according to their political views into a small-dimensional space; e.g., American candidates are often viewed as being points in a two-dimensional space, measuring how liberal/conservative they are on economic issues in one dimension and social issues on the other. Suppose parties must choose a candidate simultaneously, and their probability of winning is increasing in the area of the political space closest to their point. Again, the goal in this case is to maximize the corresponding area in a Voronoi diagram.

There are numerous variations one can construct from this setting. Most naturally, if the players are (lazy) security guards instead of miners, who have to patrol the area closest to their chosen base, their goal might be to minimize the area under their purview. Other alternatives stem from variations such as whether player choices are simultaneous or sequential, how the points for players are chosen, the underlying metric space, the type of equilibrium sought, and the utility function used to evaluate the final outcome.

However, the variations share the following fundamental features. There are n players, with the kth player having m_k associated points in some metric space. (We will focus on $m_k = m$ for a fixed m for all players.) Each player will have to choose to adopt one of their available points. A Voronoi diagram is then constructed, and each player is then associated with the corresponding area in the diagram. We refer to this general setting as *Voronoi choice games*. We discuss below how Voronoi choice games differ from similar recent work, but the key point is in the problems we study different players have different available choices; this asymmetry creates new problems and requires distinct methods.

We are particularly interested in the setting where each player's points are chosen uniformly at random from the underlying space. While uniform random points are not motivated by practice, the framework leads to an interesting and, from the standpoint of probabilistic analysis and geometry, very natural class of games. Our work suggests many potential connections, to work on Voronoi diagrams for random point sets, and to work on balanced allocations (or "the power of two choices"), where choice is used to improve load balancing. Moreover, looking at the setting of uniform random points gives us the opportunity to understand the nature of these games at a high level; specifically, do most instances have no pure Nash equilibrium, or could they have exponentially many possible pure Nash equilibria?

In general, however, we find that results for these types of problems seem very challenging. In our main result, we limit ourselves to the setting where each player has m associated points chosen uniformly at random from the unit circle, and each player owns the arc starting from their point clockwise to the next point – that is, the distance is unidirectional around the circle. We derive bounds on the expected number of pure Nash equilibria. Even in this simple setting, our result is quite technical, requiring a careful analysis based on interesting properties of distributions of random arcs on a circle. This appears, however, to be the "easiest" interesting version of the problem; currently, higher-dimensional Voronoi diagrams

are beyond our reach. However, our work suggests that further results are likely to involve interesting mathematics.

The random case of this specific version of the problem is also motivated by the following results. We show it is NP-hard to determine whether a pure Nash equilibrium exists when a player owns the arc starting from their point clockwise to the next point for $m \geq 4$, nearly resolving the worst case. Further, for the different setting when a player owns an arc of the circle corresponding to the standard Voronoi diagrams, that is a player own all points nearest to their point, we show a Nash equilibrium always exists (as long as all the possible choices for the players are distinct).

While other similar Voronoi game models have been introduced previously, our primary novelty is to introduce this natural type of asymmetric "choice" into these types of games. We believe this addition provides a rich framework with many interesting combinatorial, geometric, and game theoretic problems, as we describe throughout the paper. As such, we leave many natural open questions.

1.1 Related Work

The classical foundations for problems of this type can be found in the work by Hotelling [11], who studied the setting of two vendors who had to determine where to place their businesses along a line, corresponding to the main street in a town, with the assumption of uniformly distributed customers who would walk to the nearer vendor. Hotelling games have been considered for example in work on regret minimization and the price of anarchy, where the model studied players choosing points on a general graph instead of on the line as in the original model [4]. Recent work has also shown that for a Hotelling game on a given graph, once there are sufficiently many players a pure Nash equilibrium always exists [8]. A useful survey on economic location-based models is provided by Gabszewicz and Thisse [9].

Other variations of Voronoi games have appeared in the literature. More recent work refers to these generally as *competitive location games*; see for example [7, 14, 18, 13], which discuss Voronoi games on graphs, for additional references.

Our setting appears different from previous work, in that it focuses on players with *limited* sets of choices that *vary* among the players. Our starting point was aiming to build connections between Voronoi games and random processes based on "the power of two choices" [3, 15, 6, 1]. While in our games, each player has a limited (typically constant) set of distinct points to choose from, in previous work generally *all players* could choose from *any point* in the universe of possible choices. In economic terms, in relation to the Hotelling model, our work models that different businesses may have available a limited number of differing locations where they may establish their business. For example, businesses may have optioned the right to set up a franchise at specific locations in advance, and must then choose which location to actually build. While they could know the options available to other competing franchises, they may have to decide where to build without knowing the choices made by competitors. In other situations, it may be possible for franchises to move (at some cost) to an alternative location. We emphasize that our model is very different than previously studied symmetric versions of the game; we do not recover earlier results, and earlier results do not appear to apply once asymmetry is introduced.

1.2 Models

Before beginning, we explain the general class of games we are interested in. We refer to the following as the *k-D Simultaneous Voronoi Game*:

- Each of the n players has m associated points from the k-dimensional unit torus $[0,1]^k$. We assume that all players know about all of the possible points that can be chosen by every player (it is a game of complete information).
- The n players must simultaneously choose one of their m associated points.
- A Voronoi diagram is constructed for the n chosen points, and each player receives utility equal to the volume of its point's Voronoi cell in the maximization variation of the game. (In the minimization version, the utility could be the negation of the corresponding volume.)

The easiest version to think about is the 1-D version; each player chooses from m points on the unit circle, and after their choice they own an arc of the circle corresponding to all points closest to their chosen point. If each player tries to maximize their arc length, then the utility of a player is the length of their arc. (Or, if each player tries to minimize their arc length, the negation of the arc length is the utility.) On the unit circle, there is another variant that we refer to as the *One Way 1-D Simultaneous Voronoi Game*, in which a player owns the arc starting from their point and continuing in a clockwise direction until the next chosen point. Such a variation is quite natural in one dimension; it corresponds to assigning a "direction" to the unit circle. This variation is chiefly motivated by our connections to the power-of-two choices. In particular, it resembles the distributed hashing scheme of [6] in which peers correspond to points on a circle and keys are mapped to the closest peer in one direction along the circle.

Our contributions include highlighting differences between the 1-D problem and the One Way 1-D problem, showing that in this case a small difference in the model subtlety leads to large differences in the behavior with respect to equilibria. Indeed, as we explain, we believe the One Way 1-D problem potentially offers more insight into the behavior of the k-D Simultaneous Voronoi Game for $k \geq 2$ with respect to pure Nash equilibria.

We focus on analyzing the equilibria of these games. The most common equilibrium to study is the Nash equilibrium [16], in which each player has a random distribution on strategies such that no player can improve their expected utility by changing their distribution. While Nash's results imply the Voronoi games above all have Nash equilibria, we do not determine the complexity of finding Nash equilibria for these games; this is left as an open question. We here focus on pure Nash equilibrium. A pure Nash equilibrium is a Nash equilibrium in which each player's distribution has a support of size one. In other words, each player picks a single strategy to play and, given the other players' strategies, no player can improve their utility by choosing a different strategy. Unlike the Nash and correlated equilibria, a pure Nash equilibrium is not guaranteed to exist.

Pure Nash equilibria can be viewed as a setting where each player can choose to switch to any of their adopted points at any time. The question is then what are the stable states, where no player individually has the incentive to switch their adopted point. These stable states correspond to pure Nash equilibria, and may not even exist. A natural question is whether simple local dynamics – such as myopic best response, where at each time step some subset of players decides whether or not to switch the point it has adopted – reach a stable state quickly. To motivate our study of the random case, we examine the computational complexity of determining the existence of stable states in the 1-D Simultaneous Voronoi Game and One Way 1-D Simultaneous Voronoi Game in Section 2. For the former, we show (making use of known techniques) that a pure Nash equilibrium always exists; for the latter, we show that determining whether a pure Nash equilibrium exists is NP-complete.

In Section 3 we consider the existence of a pure Nash equilibrium for the Randomized One Way 1-D Simultaneous Voronoi Game, where each players possible choices for points

are selected uniformly at random from the unit circle. Here we bound the expected number of pure Nash equilibria, through a careful analysis based on properties of distributions of random arcs on a circle.

We also note that we have some results for another type of equilibrium, known as the correlated equilibrium. Whereas Nash equilibria have the players independently choosing their strategies, a correlated equilibrium allows the players' random distributions to be correlated (for example, by an external party). The stability requirement is then that given knowledge only of the overall distribution of outcomes and their own randomly chosen strategy, a player cannot improve their expected utility by deviating from their given strategy distribution [2]. Since a Nash equilibrium is a special case of a correlated equilibrium, a correlated equilibrium for the above games must exist. We discuss the computational complexity of finding a correlated equilibrium for the k-D Simultaneous Voronoi Game in Section 4.

We provide additional results in the full paper [5], including an empirical investigation of the probability that myopic best response will find a stable state in the Randomized One Way 1-D Simultaneous Voronoi Game and Randomized 2-D Simultaneous Voronoi Game, and several related conjectures related to the Randomized One Way 1-D Simultaneous Voronoi Game.

2 Pure Nash Equilibria

In this section, we show a fundamental difference between the One Way 1-D Simultaneous Voronoi Game and the 1-D Simultaneous Voronoi Game. Recall that for these problems each of the n players has a choice of m points on the unit circle; all players simultaneously choose one of their m points. The utility for the One Way variation of given player is equal to the distance to the nearest chosen point clockwise from its chosen point, while for the standard variation the utility is the size of the Voronoi cell (in this case, an arc).

We show the standard Voronoi variation always has at least one pure Nash equilibrium (for any number of choices per player), while it is NP-hard to determine if the maximization version of the One Way variation has a pure Nash equilibrium. We also suggest the implications of these results for the higher dimensional setting.

2.1 Existence of Pure Nash Equilibria in the 1-D Simultaneous Voronoi Game

In the argument that follows we assume the choices of points are distinct. The analysis can be easily modified for the case where multiple players can choose the same point if ownership of that point is determined by a fixed preference order (and other players have zero utility). However, if players choosing the same point share utility, then the theorem does not hold, as shown in [14].

▶ **Theorem 1.** *A pure Nash equilibrium for the maximization and minimization versions of the 1-D Simultaneous Voronoi Game exists for any set of points.*

Proof. We follow an approach utilized in [7, Lemma 4]. We define a natural total ordering on multi-sets of numbers A and B. For any two such multi-sets A and B, if $|A| < |B|$ we have $A \succ B$. When $|A| = |B|$, we have $A \succ B$ if $\max A > \max B$. If $\max A = \max B$, then let A' be A with one copy of the value $\max A$ removed, and similarly for B'; then $A \succ B$ also when $\max A = \max B$ and $A' \succ B'$.

Now consider a collection of choices in the 1-D Simultaneous Voronoi Game, and let $A = \{a_0, a_1, \ldots, a_{n-1}\}$ be the corresponding arc lengths, starting from some chosen point

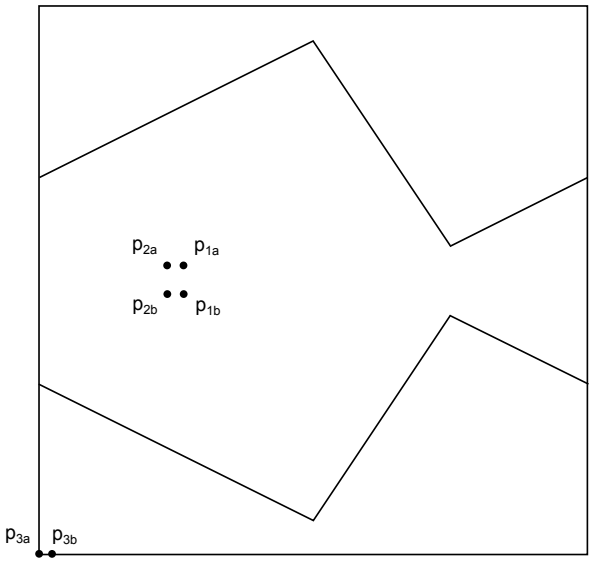

Figure 1 This is an example of a 2-D Simultaneous Voronoi Game in which no pure Nash equilibria exists. Player 1 has points $(p_{1a}, p_{1b}) = ((1/4 + \varepsilon^2, 1/2 + \varepsilon), (1/4 + \varepsilon^2, 1/2 - \varepsilon))$, player 2 has points $(p_{2a}, p_{2b}) = ((1/4 - \varepsilon^2, 1/2 + \varepsilon), (1/4 - \varepsilon^2, 1/2 - \varepsilon))$, and player 3 has points $(p_{3a}, p_{3b}) = ((0, 0), (\varepsilon, 0))$. The Voronoi diagram shown is constructed from the points $(1/4, 1/2)$ and $(0, 0)$.

and then in clockwise order around the circle, induced by the choice of points. Each player's payoff is given by a value of the form $(a_i + a_{i+1})/2$ for a suitable value of i. (One player's payoff is $(a_{n-1} + a_0)/2$.) Consider the maximization version of the game. If some player has a move that improves their utility, let them make that move. Without loss of generality, suppose this player's payoff was given by $(a_i + a_{i+1})/2$, and it moves somewhere on the arc with length a_j. Note this means $a_j > a_i + a_{i+1}$. We see that the arc lengths A' are those of A but with a_i, a_{i+1}, and a_j replaced by $a_i + a_{i+1}, x$, and y where $x + y = a_j$. Hence $A \succ A'$, so after a finite number of moves, this version of myopic best response converges to a pure Nash equilibrium.

The argument for the minimization variation is analogous. ◀

We note that we leave as an open question to determine a bound on the number of steps a myopic best response approach would take to reach a pure Nash equilibrium; in particular, we do not yet know if the approach of Theorem 1 yields a pure Nash equilibrium in a polynomial number of steps.

We might have hoped that the above technique could allow us to show that for the 2-D Simultaneous Voronoi Game (and higher dimensions) that a pure Nash equilibrium exists. Unfortunately, that is not the case. One can readily find choices of 2 points for each of 3 players where no pure Nash equilibrium exists for both the maximization and minimization version of the problem. We have generated many such examples randomly, computing the Voronoi diagrams for the eight resulting configurations. One example in two dimensions is depicted in Figure 1. In this example, player 1 has choices $((1/4 + \varepsilon^2, 1/2 + \varepsilon), (1/4 + \varepsilon^2, 1/2 - \varepsilon))$, player 2 has choices $((1/4 - \varepsilon^2, 1/2 + \varepsilon), (1/4 - \varepsilon^2, 1/2 - \varepsilon))$, and player 3 has choices $((0, 0), (\varepsilon, 0))$ for sufficiently small $\varepsilon > 0$. The idea here is that player 3's choice is irrelevant, and players 1 and 2 are dividing up the Voronoi cell owned by point $(1/4, 1/2)$ in the Voronoi diagram of the points $(1/4, 1/2)$ and $(0, 0)$. If both player 1 and 2 choose their first point, or both choose their second point, then they divide the cell with a vertical line, which due to the geometry

of the cell favors player 1. However, if one of them chooses their first point and the other chooses their second point then they divide the cell with a roughly horizontal line, which gives each of them roughly half. Thus, there is no choice of points for which neither wants to deviate. This example applies equally in higher dimensions (by making higher dimensional coordinates all zero).

This example can be extended to show that for any number of players n, there are settings of points for the players so no pure Nash equilibrium exists, showing that this setting differs from previous work on symmetric Hotelling games on graphs, where it has been shown that when there are sufficiently many players a pure Nash equilibrium always exists [8]. Specifically, use the same example but for players $4, \ldots, n$ both of their choices will be in an epsilon-small neighborhood of $(0, 0)$. We note that such examples do not disprove the possibility that a pure Nash equilibrium exists with high probability if the points are chosen randomly.

Given that the 1-D Simultaneous Voronoi Game appears to have a very special structure (in terms of the existence of pure Nash equilibrium) that differs from k-D Simultaneous Voronoi Game for $k \geq 2$, it is natural to seek a 1-D variant that might shed more insight into the behavior in higher dimensions. This motivates us to look at the One Way 1-D Simultaneous Voronoi Game.

2.2 NP-Hardness of the One Way 1-D Simultaneous Voronoi Game

In contrast to the result of the previous subsection, we prove the NP-hardness of the maximization version of the One Way 1-D Simultaneous Voronoi Game whenever each player has $m \geq 4$ choices. We leave as an open question to find a reduction for $m = 2$ or 3, as well as for the minimization version.

▶ **Theorem 2** (For proof see [5]). *The problem of determining if a pure Nash equilibrium (PNE) exists in the maximization version of a One Way 1-D Simultaneous Voronoi Game is NP-hard for $m \geq 4$.*

We conjecture that determining if a pure Nash equilibrium exists in the k-D Simultaneous Voronoi Game is NP-hard for $k \geq 2$; however, we suspect that building the corresponding gadgets will prove technically challenging.

3 Random Voronoi Games

We now consider random variations of the Voronoi games we have considered, where each player's available choices are chosen uniformly at random from the underlying universe. While it is not clear such a model corresponds to any specific real-world scenario, such random problems are intrinsically interesting combinatorially and in relation to other similar studied problems. For example, in the context of load-balancing in distributed peer-to-peer systems, the authors of [6] study a model where one begins with a Voronoi diagram on N points (chosen uniformly at random from the universe, say the unit torus) corresponding to N servers. Then M agents sequentially enter; each is assigned k random points from the universe; and each agent chooses the one of its k points that lies in the Voronoi cell with the smallest number of agents, or *load* for that server. Other "power-of-choice" problems, such as the Achlioptas process [1], have spurred new understanding of phenomena such as explosive percolation.

Given our hardness results, a natural question is whether the One Way 1-D Simultaneous Voronoi Game has (or does not have) a pure Nash equilibrium with high probability in the

random variation. While we have not proven this result, we have proven bounds on the expected number of pure Nash equilibria in the random setting that are interesting in their own right and nearly answer this question. In particular, our careful analysis builds on the interesting relationship between random arcs on a circle and weighted sums of exponentially distributed random variables.

The following is our main result.

▶ **Theorem 3.** *The expected number of PNE for the maximization version of the One Way 1-D Simultaneous Voronoi Game is at most m, and at least $0.19^{m-1}m$.*

Interestingly, our bounds depend on the number of choices m, not the number of players. Unfortunately, this means that we cannot use these expectation bounds directly to show that, for example, the probability of a PNE existing is exponentially small in n. But the bounds provide insight by showing that pure Nash equilibria are typically few in number in the random case.

In proving Theorem 3, we need the following well-known property of exponential random variables. Let $X_1, \ldots, X_n$ be i.i.d. exponential random variables. Let $S_n = \sum_{j=1}^{n} X_j$. Recall that S_n is said to have a *gamma distribution*, and we use facts about the gamma distribution later in our analysis. Similarly, S_{n-1}/S_n is said to have a *beta distribution*, and we use facts about beta distributions as well. For example,

▶ **Lemma 4.** *$S_n, \frac{S_1}{S_2}, \frac{S_2}{S_3}, \ldots, \frac{S_{n-1}}{S_n}$ are all mutually independent.*

See e.g. [10] for its discussion of exponential random variables. In particular, the X_i can be viewed as the gaps in the arrivals of a Poisson process; the $n-1$ arrivals before the last are uniformly distributed on the interval $[0, S_n]$, from which one can derive the lemma above.

Another important fact we use is the following:

▶ **Fact 5.** *We have* $\mathrm{E}\left[(S_j/S_{j+1})^t\right] = \prod_{i=0}^{t-1} \frac{j+i}{j+1+i} = \frac{j}{j+t}$, *since* $S_j/S_{j+1} \sim \mathit{Beta}\,(j,1)$.

We note that in some of our arguments, the ordering of the variables becomes reversed, and we consider sums of the form $\sum_{j=n-i+1}^{n} X_j$. Of course this has the same distribution as $\sum_{j=1}^{i} X_i$, and the corresponding version of Lemma 4 holds. Where convenient, we therefore refer to $\sum_{j=n-i+1}^{n} X_j = S_i$ where there is no ambiguity as to the desired meaning.

Proof of Theorem 3. We begin by using linearity of expectations to write the expected number of PNE in terms of the probability that each player choosing their first choice will yield a stable configuration.

$$\begin{aligned}\mathrm{E}[\#\text{ PNE}] &= m^n \cdot \Pr[\text{first choices are stable}] \\ &= m^n \cdot \mathrm{E}[\Pr[\text{first choices are stable} \mid \text{position of first choices}]].\end{aligned}$$

Partition the circle into arcs according to the players' first choice points. Let A_i be the length of the ith smallest arc. As shown in [10], the A_i are distributed jointly as

$$A_i \sim \frac{1}{S_n} \sum_{j=n-i+1}^{n} \frac{X_j}{j}$$

where again the X_j are i.i.d. exponential random variables of mean 1 and $S_n = \sum_{j=1}^{n} X_j$. We say that an arc is stable if the player whose point starts the arc (going clockwise) does not wish to deviate to any of their other points. Given the position of the first choices, the

probability each arc is stable depends only on the other choices available to the player that owns the arc, and hence the stability of the arcs are independent. Therefore

$$\begin{aligned}&\Pr[\text{first choices are stable} \mid \text{position of first choices}]\\ &= \prod_{i=1}^{n} \Pr[i\text{th smallest arc is stable} \mid \text{position of first choices}].\end{aligned}$$

If the arc is the ith smallest, then it will be stable if the other choices fall in the same arc, one of the $i-1$ smaller arcs, or the front A_i-length portion of the $(n-i)$ larger arcs – except in the latter two cases, we must take into account that if a choice falls immediately backward into the arc directly counterclockwise of the current arc, then the arc is not stable. We therefore have the following calculation:

$$\begin{aligned}&\Pr[i\text{th smallest arc is stable} \mid \text{position of first choices}]\\ &= \left((n-i)A_i + \sum_{j=1}^{i} A_j - \min(A_i, \text{length of arc before i})\right)^{m-1}\\ &\le \left((n-i)A_i + \sum_{j=1}^{i} A_j\right)^{m-1}\\ &= S_n^{-(m-1)} \left((n-i)\sum_{j=n-i+1}^{n} \frac{X_j}{j} + \sum_{j=1}^{i}\sum_{k=n-j+1}^{n} \frac{X_k}{k}\right)^{m-1}\\ &= S_n^{-(m-1)} \left((n-i)\sum_{j=n-i+1}^{n} \frac{X_j}{j} + \sum_{k=n-i+1}^{n} (k-n+i)\frac{X_k}{k}\right)^{m-1}\\ &= S_n^{-(m-1)} \left(\sum_{j=n-i+1}^{n} (n-i+j-n+i)\frac{X_j}{j}\right)^{m-1}\\ &= S_n^{-(m-1)} \left(\sum_{j=n-i+1}^{n} X_j\right)^{m-1}\\ &= \left(\frac{S_i}{S_n}\right)^{m-1}.\end{aligned}$$

Note we have used $\sum_{j=n-i+1}^{n} X_j = S_i$ for convenience. Our resulting bound has a surprisingly clean form in terms of the S_i.

Thus, by Lemma 4 and Fact 5:

$$\begin{aligned}\Pr[\text{first choices are stable}] &\le \mathrm{E}\left[\prod_{i=1}^{n}\left(\frac{S_i}{S_n}\right)^{m-1}\right]\\ &= \mathrm{E}\left[\prod_{i=1}^{n-1}\left(\frac{S_i}{S_{i+1}}\cdot\frac{S_{i+1}}{S_{i+2}}\cdot\ldots\cdot\frac{S_{n-1}}{S_n}\right)^{m-1}\right]\\ &= \mathrm{E}\left[\prod_{i=1}^{n-1}\left(\frac{S_i}{S_{i+1}}\right)^{i(m-1)}\right] = \prod_{i=1}^{n-1}\mathrm{E}\left[\left(\frac{S_i}{S_{i+1}}\right)^{i(m-1)}\right]\\ &= \prod_{i=1}^{n-1}\frac{i}{i+i\,(m-1)} = \frac{1}{m^{n-1}}.\end{aligned}$$

It then follows that

$$\mathrm{E}\left[\#\mathrm{PNE}\right] \leq m^n \cdot \frac{1}{m^{n-1}} = m.$$

We can similarly find a lower bound, although some additional technical work is required.

$$\begin{aligned}
&\Pr[i\text{th smallest arc is stable} \mid \text{position of first choices}] \\
&= \left((n-i)A_i + \sum_{j=1}^{i} A_j - \min(A_i, \text{length of arc before i})\right)^{m-1} \\
&\geq \left((n-i)A_i + \sum_{j=1}^{i} A_j - A_i\right)^{m-1} \\
&= \left((n-i-1)A_i + \sum_{j=1}^{i} A_j\right)^{m-1} \\
&= S_n^{-(m-1)} \left(\sum_{j=n-i+1}^{n} (n-i-1+j-n+i)\frac{X_j}{j}\right)^{m-1} \\
&= S_n^{-(m-1)} \left(\sum_{j=n-i+1}^{n} \frac{(j-1)X_j}{j}\right)^{m-1}
\end{aligned}$$

Hence

$$\Pr[\text{first choices are stable}] \geq \mathrm{E}\left[S_n^{-(m-1)n} \prod_{i=1}^{n} \left(\sum_{j=n-i+1}^{n} \frac{(j-1)X_j}{j}\right)^{m-1}\right].$$

A simple stochastic domination argument (provided in full version of the paper [5]) shows that the expectation on the right side decreases if, in each term in the product, we equalize the coefficient, so that instead of terms of the form $\frac{(j-1)X_j}{j}$, the coefficient for all terms of the sum in the ith term of the product is the average $c_i = \frac{1}{i}\sum_{j=n-i+1}^{n} \frac{j-1}{j}$. This gives

$$\begin{aligned}
\Pr[\text{first choices are stable}] &\geq \mathrm{E}\left[S_n^{-(m-1)n} \prod_{i=1}^{n} \left(\sum_{j=n-i+1}^{n} c_i X_j\right)^{m-1}\right] \\
&= \mathrm{E}\left[S_n^{-(m-1)n} \prod_{i=1}^{n} (c_i S_i)^{m-1}\right] \\
&= \left(\prod_{i=1}^{n} c_i^{m-1}\right) \mathrm{E}\left[\prod_{i=1}^{n} \left(\frac{S_i}{S_n}\right)^{m-1}\right].
\end{aligned}$$

Observe that this expectation is the same as the one we computed in the upper bound. Therefore

$$\mathrm{E}[\#\ \mathrm{PNE}] \geq \left(\prod_{i=1}^{n} c_i^{m-1}\right) m \geq 0.19^{m-1} m.$$

The proof of the final inequality is presented in the full version of the paper [5]. ◀

We note that similar calculations can be done for the minimization version, although we have not found a clean form for the upper bound. We can, however, state the following lower bound, showing the expected number of pure Nash equilibria is at least inverse polynomial in n for a fixed number of choices m.

▶ **Theorem 6** (For proof see [5]). *The expected number of PNE for the minimization version of the One Way 1-D Simultaneous Voronoi Game is at least* $\frac{m(m-1)}{(mn-1)n^{m-1}}$.

We have done several experiments regarding Random Voronoi games, which prove consistent with our theoretical results and suggest some interesting conjectures, particularly for the 2-D Simultaneous Voronoi Game. Chief among these conjectures is that the Random k-D Simultaneous Voronoi game has a pure Nash Equilibrium with probability approaching 1 as n grows. The complete discussion of these results can be found in the full version of the paper

4 Correlated Equilibria

Our goal in this section is to show that, for the k-D Simultaneous Voronoi Game, correlated equilibria can be found in polynomial time. We present the results for $k = 1, 2$, and 3. The results appear to extend to higher dimensions but the geometric details are technical; we note the time required to determine the correlated equilibrium appears to grow as $n^{O(k)}$. The results also apply to the One Way 1-D Simultaneous Voronoi Game.

▶ **Theorem 7.** *For $k = 1, 2$, and 3, and for a fixed m, there is a polynomial time algorithm for finding a correlated equilibrium in the k-D Simultaneous Voronoi Game.*

We appeal to [17] and [12], who present polynomial time algorithms for finding a correlated equilibrium of games *polynomial type*. (The running times for these algorithms are not specifically presented in the papers and appear rather large, but are still polynomial.) A game of polynomial type is one that can be represented in polynomial space such that given each player's strategy, their utilities can be computed in polynomial time. The k-D Simultaneous Voronoi Game is of polynomial type because it can be represented in $O(nmk)$ space by a list of each players point choices and, given the players' strategies, the utilities can be found by computing the Voronoi diagram of the chosen points.

▶ **Theorem 8** (Theorem 4.5, [12]). *Given a game of polynomial type and a polynomial time algorithm for computing the expected utility of a player under any product distribution on strategies, there exists a polynomial time algorithm for finding a correlated equilibrium in that game.*

Jiang et al. proved Theorem 8 by constructing a linear program with a variable for each of the 2^n possible strategy profiles. The LP's constraints are non-negativity, and the constraints requiring that the variables form a correlated equilibrium. They do not, however, enforce that the variables sum to one, or even at most one, and rather use the sum of these variables as the objective. Thus, since a correlated equilibrium is guaranteed to exist by Nash's Theorem, this LP is unbounded and its dual is infeasible. They then run the ellipsoid algorithm for a polynomial number of steps on the dual LP (this takes polynomial time, since the dual LP has only polynomially many variables). They argue that the intermediate steps of the ellipsoid algorithm can be used to construct product distributions of which there is a convex combination that is a valid correlated equilibrium, and which can be found with a second linear program.

The second linear program's separation oracle requires as a subroutine a polynomial time algorithm for computing the expected utility of a player given a product distribution over the strategies. (This requirement is referred to in [17] and [12] as the *polynomial expectation property*.) Our work is to demonstrate polynomial time algorithms for this subroutine. We note that it is not immediate that such an algorithm should exist, even when each player has only $m = 2$ choices, as the number of possible configurations is m^n. Hence, we cannot simply sum over all configurations when calculating the expectation. In [17] it is noted that for certain congestion games, these expectations can be computed using dynamic programming, essentially adding one player in at a time and updating accordingly. Our approach is similar in spirit, but requires taking advantage of the underlying geometry.

▶ **Lemma 9** (For proof see [5]). *Computing a player's expected utility under a product distribution on strategies in the k-D Simultaneous Voronoi Game takes* $O(n^{2k-1} \log n)$ *time for* $k \leq 3$.

The proof is trivial for one dimension. For two and three dimensions, the key idea is to partition the space into regions where the possible Voronoi cell boundaries do not cross.

5 Conclusion

We have introduced a new but we believe important set of variants on Voronoi games, where each player has a disjoint set of points to choose from. We believe these variations are motivated both by natural economic settings, and because of the possible connections to other "power-of-choice" processes in which participants choose from a limited set of random options.

In particular, we note that the Voronoi choice games we propose offer the chance to consider randomized versions of the problem, where the set of possible choices for each player is chosen uniformly over of the space. We have conjectured that the Random k-D Simultaneous Voronoi Game has a pure Nash equilibrium with high probability, based on a simulation study. While this is perhaps the most natural open question in this setting, there remain several other questions for both the simultaneous and sequential versions of Voronoi choice problems, in the worst case and with random point sets.

Abstract

The Jordan curve theorem and Brouwer's fixed-point theorem are fundamental problems in topology. We study their computational relationship, showing that a stylized computational version of Jordan's theorem is PPAD-complete, and therefore in a sense computationally equivalent to Brouwer's theorem. As a corollary, our computational result implies that these two theorems directly imply each other mathematically, complementing Maehara's proof that Brouwer implies Jordan [10]. We then turn to the combinatorial game of Hex which is related to Jordan's theorem, and where the existence of a winner can be used to show Brouwer's theorem [6]. We establish that determining who won an (implicitly encoded) play of Hex is PSPACE-complete by adapting a reduction (due to Goldberg [7]) from Quantified Boolean Formula (QBF). As this problem is analogous to evaluating the output of a canonical path-following algorithm for finding a Brouwer fixed point – and which is known to be PSPACE-complete [8] – we thereby establish a connection between Brouwer, Jordan and Hex higher in the complexity hierarchy.

1 Introduction

The Jordan curve theorem states that a simple closed curve C in $\mathbb{R}^2$ divides the plane into two connected components S_1, S_2 [9]. In particular, any continuous curve from a point $x \in S_1$ to a point $y \in S_2$ must intersect C. There are several known proofs of this basic topological fact, including one via Brouwer's fixed point theorem by Maehara [10]. In an earlier paper, Gale explores the equivalence between Brouwer's theorem and a theorem closely related to Jordan's, pertaining to the combinatorial game Hex [6]. In Hex, a rhomboidal board is partitioned into hexagonal tiles as in Figure 1, and two players claim tiles of the board until one of the players can connect the two opposite sides of the board that belong to him. The Hex theorem states that, once all tiles on the board are claimed, at least one of the two players has won.

In this paper we study the relationship of the Jordan, Brouwer and Hex theorems from both a computational and a mathematical standpoint. In particular, our goal is to show their 'equivalence' in both domains. We say that two theorems are *mathematically equivalent* if

* This work was partially supported by the NSF (grant CCF-1551875) and ONR (grant N00014-12-1-0999).

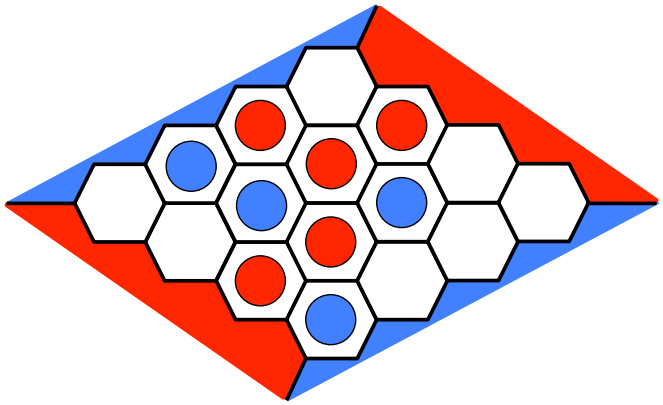

Figure 1 A sample Hex position, where Player 1 (red) has won.

(informally) they can be used to prove each other in an 'elementary' way, and *computationally equivalent* if the search problems with solutions guaranteed by them are complete in the same complexity class. This study is catalyzed by defining a stylized computational problem inspired by Jordan curve theorem as follows:

ZeroSurfaceCrossing
`Input:` Two circuits $F_1, F_2 : \{0,1\}^n \times \{0,1\}^n \to \{-2^m+1, \ldots, 2^m-1\}$, defining two continuous surfaces $f_1, f_2 : [0,1]^2 \to \mathbb{R}$ in $\mathbb{R}^3$ via interpolation.[a]

`Output:` A point (x, y) such that $f_1(x, y) = f_2(x, y) = 0$, or a violation of the following boundary conditions:

(1) $f_1(0, y) \geq 0$ and (2) $f_1(1, y) \leq 0$ for all y;

(3) $f_2(x, 0) \geq 0$ and (4) $f_2(x, 1) \leq 0$ for all x.

[a] The input to each circuit is interpreted in the obvious way as specifying a point $(x, y) \in [0,1]^2$, where both x and y are integer multiples of $1/(2^n - 1)$. Hence these circuits determine the values of f_1, f_2 at all such points. The values of f_1, f_2 at all other points are determined from these values via interpolation.

It is quite intuitive that, if Conditions 1–4 are satisfied, then the surfaces f_1 and f_2 should have an intersection on the zero plane. One way to show this is using the Jordan curve theorem; see Lemma 10. Moreover, given that f_1, f_2 are defined by circuits via interpolation, it is easy to see that the problem belongs to NP and thus in TFNP, the class of total problems in NP. The question is how it relates to other classes in TFNP [11]. We show the following:

▶ **Theorem 1.** ZeroSurfaceCrossing *is PPAD-complete.*

Given that Brouwer, the stylized computational problem of computing fixed points of continuous functions (defined formally in Section 3), is also PPAD-complete [11, 3, 5], Theorem 1 implies that ZeroSurfaceCrossing and Brouwer are computationally equivalent. Additionally, it helps establish the mathematical equivalence of the Brouwer and Jordan theorems. Maehera showed that Brouwer implies Jordan's theorem. Exploiting the proof of Theorem 1, we show the other direction, that Jordan implies Brouwer's theorem. Moreover, in view of Gale's proof that the Hex and Brouwer theorems are mathematically equivalent [6], our result also establishes that all three theorems are equivalent.

▶ **Proposition 2.** *The Jordan, Brouwer and Hex theorems are mathematically equivalent.*

1.1 Jordanian Action Inside PPAD

A close variant of the problem defined above is the curve crossing problem defined as follows.

CrossingCurves
`Input:` Two circuits $F_1, F_2 : \{0,1\}^n \to \{0, 2^{-m}, 2 \cdot 2^{-m}, \ldots, 1\}^2$, defining two continuous curves $f_1, f_2 : [0,1] \to [0,1]^2$ in $[0,1]^2$ via interpolation.[a]

`Output:` A pair $t_1, t_2 \in [0,1]$ such that $f_1(t_1) = f_2(t_2)$, or a violation of the following boundary conditions:

(1) $f_1(0) = (0,0)$; (2) $f_1(1) = (1,1)$; (3) $f_2(0) = (0,1)$ and (4) $f_2(1) = (1,0)$.

[a] The input to each circuit is interpreted in the obvious way as specifying an integer multiple of $1/(2^n-1)$, so that F_i defines the location of curve f_i for all inputs in $\{0, 1/(2^n-1), \ldots, 1\}$. The location of the curve at any $t \in [j/(2^n-1), (j+1)/(2^n-1)]$, where $j \in \{0, \ldots, 2^n-1\}$, is determined by linearly interpolating between the locations of the curve at $j/(2^n-1)$ and $(j+1)/(2^n-1)$.

Again it is quite intuitive that, unless Conditions (1)–(4) in the definition of the problem fail, the curves defined by any input to CrossingCurves should cross. Indeed, this can be proven via the Jordan curve theorem, and because of Proposition 2 via Brouwer's fixed point theorem as well. We provide a direct proof using Brouwer's fixed point theorem, which implies as a corollary that the problem lies within PPAD.

▶ **Theorem 3.** CrossingCurves *is in PPAD.*

Under monotonicity conditions on at least one of the two curves, it is easy to see that CrossingCurves is in P. For example, suppose that at least one of the two curves f_i satisfies that, for all $0 \le t < t' \le 1$, $f_i(t)_1 < f_i(t')_1$, where $f_i(t)_1$ represents the first coordinate of $f_i(t)$ and similarly for $f_i(t')_1$. Under this condition, CrossingCurves can be easily solved via binary search. Similar conditions can be defined with respect to the second coordinate. When neither curve satisfies such a monotonicity condition with respect to neither coordinate, we do not see how to construct a polynomial time algorithm. At the same time, we do not see how an instance of CrossingCurves can encode the several paths and cycles that may co-exist in an instance of EndOfTheLine, the canonical PPAD-complete problem—see Section 2. (In comparison, the intersections of the surfaces of ZeroSurfaceCrossing with the zero-plane may comprise several paths and cycles, which allow encoding EndOfTheLine instances.) We leave pinning down the precise complexity of CrossingCurves for future work, expecting that the complexity classes defined in [4] may be useful in this classification.

1.2 Jordanian Action Over PPAD

While so far all action has taken place inside TFNP, we also explore how the three theorems, Jordan, Brouwer and Hex, are related higher in the complexity hierarchy. It was recently established that several algorithms for computing Brouwer fixed points and Nash equilibria are in fact capable of solving all of PSPACE [8]. For example, given an instance $\mathcal{I}$ of some problem in PSPACE, one can construct a 2-player game $\mathcal{G}$ such that the Nash equilibrium output by the Lemke-Howson algorithm provides a solution to $\mathcal{I}$ as a byproduct. Similar facts are known for homotopy methods.

We are thus interested in whether computational problems relating to Jordan and Hex also have the power of solving PSPACE. We propose the problem WhoWonHex, asking to determine whether player 1 is the winner of a Hex play. An instance of the problem comprises a circuit that takes as input the binary description of a cell in the Hex board and outputs the name of the player, 1 or 2, who claimed it during the play. We provide a formal

description of Hex in Section 2.3, and define WhoWonHex in Section 5.2, establishing the following:

▶ **Theorem 4.** WhoWonHex *is PSPACE-complete.*

The proof of Theorem 4 can be obtained fairly easily using recent work of Goldberg [7]. There is a canonical method to determine who is the winner in a play of Hex by performing a walk on the Hex board. The walk starts at one of the corners of the Hex board and performs pivoting steps depending on which player has claimed the cells neighboring the current location of the walk, until another corner of the board is reached, which always happens due to topological reasons. What corner is reached determines which player won. This pivoting algorithm is quite reminiscent to the canonical algorithm for solving instances of 2-dimensional Sperner. An instance of this problem provides a succinct description of the coloring of the vertices of a square lattice using 3 colors and asks to identify a trichromatic triangle or a violation of certain boundary conditions by the coloring. The problem is PPAD-complete [11, 3, 2] and Goldberg recently established that identifying the tri-chromatic triangle reachable by the standard pivoting algorithm for this problem is PSPACE-complete. Theorem 4 is proven by making an analogy between the pivoting algorithms that solve Sperner and WhoWonHex. The precise details are a bit more intricate than this intuition, as we have to exploit the structure of the Sperner instances constructed in Goldberg's proof.

It is worth pointing out that the problem WhoWonHex that we study is very different than the typical computational problem studied in combinatorial game theory, namely determining given a configuration of the board whether some player has a winning strategy. Our problem is instead to determine who is the winner, once the play is completed.

Roadmap. We provide basic definitions in Section 2, recalling the Jordan curve theorem and Brouwer's fixed point theorem. We also describe the game of Hex and define the computational problems Brouwer and EndOfTheLine along with the class PPAD. In Section 3, we show that Brouwer and Jordan are equivalent, both mathematically and computationally (through the ZeroSurfaceCrossing problem). In Section 4, we discuss CurveCrossing showing that it is in PPAD. Finally, in Section 5, we show that WhoWonHex is PSPACE-complete. In Section 6 we conclude with some open problems suggested by our work.

2 Preliminaries

In this section, we will formally define all the theorems, problems, and constructs which we will analyze; in particular, we will define:

1. Brouwer's fixed-point theorem;
2. the Jordan curve theorem;
3. the game of Hex and the Hex theorem;
4. the complexity class PPAD, and the canonical computational problem EndOfTheLine that is associated with it.

Additionally, in order to formally describe the computational problems given above, we also need to define the interpolation schemes we use to transform functions over bitstrings to functions over the (continuous) unit square. We use a standard technique of using the bitstring to describe a point on a lattice; then, for inputs not on the lattice, the output is defined by interpolating from the outputs on the lattice. The formal construction is given in our full paper [1].

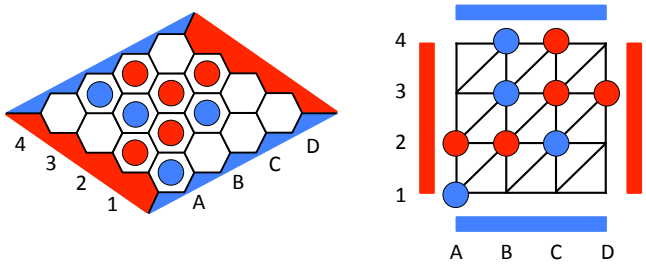

Figure 2 A Hex board and its corresponding dual-graph representation.

2.1 Brouwer's Fixed-Point Theorem and the Jordan Curve Theorem

We define here the theorems of Brouwer and Jordan. For Brouwer, we give a special case in two dimensions, involving functions from the unit square to itself. (This can be extended to the general two-dimensional case on any compact and convex set and higher dimensions; see e.g. [11, 3, 5] and their references.)

▶ **Theorem 5** (Brouwer's fixed-point theorem). *Given any continuous function* $f : [0,1]^2 \to [0,1]^2$*, there is a* fixed point*, i.e. some* $x \in [0,1]^2$ *such that* $f(x) = x$*.*

▶ **Theorem 6** (The Jordan curve theorem). *Any simple closed curve* ϕ *in* $\mathbb{R}^2$ *divides the space into two regions, one finite (the inside) and one infinite (the outside).*

2.2 PPAD and its Related Computational Problems

▶ **Definition 7** (The PPAD graph). Let N and P be circuits, both of which take as input an n-bit string and return an n-bit string as output. We then consider the directed graph whose vertices are n-bit strings such that there is an edge (u, v) if and only if $N(u) = v$ and $P(v) = u$.

By this definition, it is clear that each vertex has in- and out-degree of at most 1 (since any vertex u can only be preceded by $P(u)$ and succeeded by $N(u)$), and thus the graph must consist of a disjoint collection of isolated vertices, directed paths, and directed cycles. We now consider the following computational problem on this graph:

▶ **Definition 8** (EndOfTheLine). Given circuits N and P defining the PPAD graph G:

1. if the vertex 0^n is not a source vertex (with in-degree 0 and out-degree 1), return 0^n;
2. if the vertex 0^n is a source vertex, return any *other* unbalanced vertex (with in-degree and out-degree not equal).

EndOfTheLine is the canonical PPAD-complete problem. Because no directed graph can have exactly one unbalanced vertex, the existence of a solution is guaranteed. Of particular interest to us is the fact that a computational variant of Brouwer's fixed-point theorem (which we will formally describe in the next section) is also PPAD-complete.

2.3 The Game of Hex

The game of Hex is a combinatorial game, played (in its normal, two-player two-dimensional version) on a hexagonally-tiled board (such as the one shown on the left in Figure 2). Each player (player 1 represented in red, and player 2 represented in blue) starts in the possession of two opposing sides of the board; they take turns placing stones of their color on unoccupied tiles. Each has the goal of connecting their two sides with a path (or *bridge*) of stones of

their color; the first to do so wins. For ease of representation, we imagine instead that the players are placing stones on the *vertices* (rather than facets) of the dual graph, which is represented on the right in Figure 2. In order to escape the restriction that the number of red and blue stones is the same (or at most differ by 1), we allow players to 'pass' (i.e. not put a stone down); there is no reason to do so if the player is trying to win, but it makes the following analysis simpler and more general.

Although seemingly just a simple combinatorial game, Hex is known to have very deep mathematical properties. First, a very elegant proof shows that some player is guaranteed to win [6], i.e. if every vertex (in the dual-graph representation) is occupied by a stone, then there must be a pair of opposing sides which are joined by a path of stones of their corresponding color. In fact, exactly one player must win (the fact that it's impossible for both players to have bridges at the same time is intuitively connected to the Jordan curve theorem). Intriguingly, the theorem that Hex must have a winner (which seems at first to be merely an interesting curiosity) can, like Sperner's Lemma, be used to actually prove Brouwer's fixed-point theorem [6].

3 Brouwer vs. Jordan in TFNP

In this section, we consider the relationship between Brouwer's fixed-point theorem and the Jordan curve theorem. In particular, we want to show that Brouwer's fixed-point theorem can be proven directly from the Jordan curve theorem, thus complementing Maehara's result that the Jordan curve theorem can be proved directly from Brouwer's fixed-point theorem [10]. We then consider a computational version of the Jordan curve theorem, which we call ZeroSurfaceCrossing; this problem is a search problem where the existence of a solution is guaranteed by the Jordan curve theorem. We then show that ZeroSurfaceCrossing is PPAD-complete. This makes it equivalent to the computational problem of finding a fixed point of a function (where the existence of a solution is guaranteed by Brouwer's fixed-point theorem), thus demonstrating a computational link between the two theorems in addition to the mathematical link.

3.1 The Zero Surface Crossing Problem

We define a problem where the existence of a solution is intended to be guaranteed by Jordan.

▶ **Definition 9** (Zero Surface Crossing). We are given continuous functions $f_1, f_2 : [0,1]^2 \to [-1,1]$ (which are therefore 2-dimensional surfaces in $\mathbb{R}^3$) satisfying the following conditions:
1. $f_1(0,y) \geq 0$ and $f_1(1,y) \leq 0$ for all y;
2. $f_2(x,0) \geq 0$ and $f_2(x,1) \leq 0$ for all x.

The goal is to find some $(x,y) \in [0,1]^2$ such that $f_1(x,y) = f_2(x,y) = 0$.

We wish to show that the Jordan curve theorem implies that such a point (x,y) exists; in order to give this proof, we consider the computational version defined in the introduction as ZeroSurfaceCrossing.

We will first show that the Jordan curve theorem implies that the computational version is guaranteed to have a valid output; we will then use basic topological principles to show that the mathematical version given in Definition 9 also must have a solution. We need the following notation:
1. let $X_0 = \{(0,y) : 0 \leq y \leq 1\}$ and $X_1 = \{(1,y) : 0 \leq y \leq 1\}$;
2. let $Y_0 = \{(x,0) : 0 \leq x \leq 1\}$ and $Y_1 = \{(x,1) : 0 \leq x \leq 1\}$.

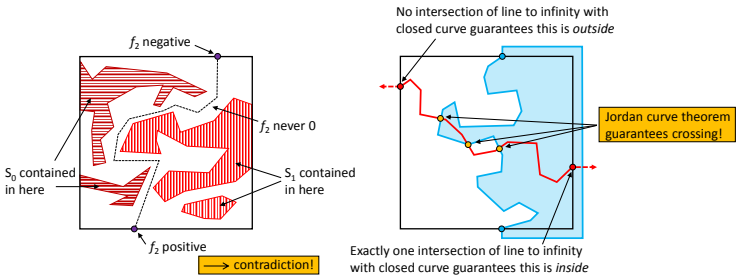

Figure 3 *Left:* illustration of proof of assertion 1; *Right:* illustration of proof of assertion 2.

In short, these sets are the four sides of the square $[0,1]^2$. For these lemmas, we sketch the proofs; the full formal proofs are given in the full version of the paper [1].

▶ **Lemma 10** (Jordan to Computational ZeroSurfaceCrossing). *The Jordan curve theorem implies that the computational version of* ZeroSurfaceCrossing *has a valid output.*

Proof Sketch. We assume that the boundary conditions hold; we thus want to show the existence of a point $(x,y) \in [0,1]^2$ such that $f_1(x,y) = f_2(x,y) = 0$. We will show the following:

1. there exists a path from X_0 to X_1 such that at every point on the path, f_2 has value 0; by symmetry, there then must also be a path from Y_0 to Y_1 such that at every point, f_1 has value 0.
2. the Jordan curve theorem then implies that these two paths must cross, giving a point $(x,y) \in [0,1]^2$ such that $f_1(x,y) = f_2(x,y) = 0$.

The proofs are depicted in Figure 3 (assertion 1 on the left, assertion 2 on the right). We remark that assertion 1 only holds because of the computational setting, where the function is defined by a circuit and the interpolation procedure (see full proof for details). ◀

We can now use this to tackle the problem of showing the existence of a solution to the mathematical version as given in Definition 9.

▶ **Proposition 11** (Jordan to Non-Computational Zero Surface Crossing). *The Jordan curve theorem implies that the mathematical version of Zero Surface Crossing always has a solution.*

Proof Sketch. We use the following general strategy: we note that only the set of points where f_1 is 0 and the set of points where f_2 is 0 matters. Thus, we can use instead two functions f_1^* and f_2^* which are 0 at the same points, but which are Lipschitz. We can then show that for any $\epsilon > 0$, if we approximate f_1^* and f_2^* with circuits F_1, F_2 with sufficiently many bits, any point which is a zero of the circuits must be within ϵ of 0 for f_1^*, f_2^*. We then take a sequence of such approximate zeroes as $\epsilon \to 0$; by compactness of $[0,1]^2$, this sequence must have at least one limit point, which we can then show is a shared zero of f_1^*, f_2^* and hence of f_1 and f_2. ◀

Finally, we can use this result to prove Brouwer as a consequence of Jordan.

▶ **Theorem 12** (Jordan implies Brouwer). *Brouwer's fixed-point theorem can be shown as a direct consequence of the Jordan curve theorem.*

Proof. Given any mapping $g : [0,1]^2 \to [0,1]^2$, we wish to show the existence of a fixed point (x, y) such that $g(x, y) = (x, y)$. Let g_x and g_y be the x- and y-components of g respectively.

We then define the functions $f_1, f_2 : [0,1]^2 \to [-1,1]$ as follows: $f_1(x, y) = g_x(x, y) - x$ and $f_2(x, y) = g_y(x, y) - y$. First, we note that the outputs of f_1, f_2 indeed must fall in $[-1, 1]$; this is because g_x and g_y have outputs in $[0, 1]$ and $-x$ and $-y$ each range through $[-1, 0]$. We also note that f_1, f_2 satisfy the boundary conditions given in Definition 9, since $f_1(0, y) = g_x(0, y) \geq 0$ and $f_1(1, y) = g_x(1, y) - 1 \leq 0$ for all y, and similarly $f_2(x, 0) = g_y(x, 0) \geq 0$ and $f_2(x, 1) = g_y(x, 1) - 1 \leq 0$ for all x. Thus, we can apply Proposition 11 to show that there is some (x, y) such that $f_1(x, y) = f_2(x, y) = 0$.

But this implies that $g_x(x, y) = f_1(x, y) + x = x$ and $g_y(x, y) = f_2(x, y) + y = y$, i.e. that $g(x, y) = (x, y)$, thus proving Brouwer's fixed-point theorem as a consequence of Zero Surface Crossing and hence as a consequence of the Jordan curve theorem. ◀

This, along with Maehara's result on showing Jordan from Brouwer [10] and Gale's result on the equivalence of Brouwer and the Hex theorem [6], thus concludes the proof of Proposition 2 (that Brouwer, Jordan, and Hex are all mathematically equivalent theorems). We also remark that reversing the above reduction yields an alternative proof that Brouwer's fixed-point theorem can be used to prove the Jordan curve theorem; however, as this is a known result, we will not show this in detail.

3.2 Computational Equivalence of Brouwer and Jordan

We now want to show that ZeroSurfaceCrossing is PPAD-complete. To do this, we first define the computational version of Brouwer, which is well-known to be PPAD-complete [11]:

> Brouwer
> `Input:` A circuit $G : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}^n \times \{0,1\}^n$, defining a mapping $g : [0,1]^2 \to [0,1]^2$ via interpolation (as described in Appendix A).
>
> `Output:` a point (x, y) such that $g(x, y) = (x, y)$ (i.e. a fixed point of g).

▶ **Lemma 13.** ZeroSurfaceCrossing *is PPAD-hard.*

Proof. We prove this by showing that Brouwer can be reduced to it, using the same reduction as in the proof of Theorem 12. In particular, we note that this reduction requires no fudging with outputs, as if (x, y) is a lattice point (where x and y can each be expressed by an n-bit string) then $f_1(x, y) = g_x(x, y) - x$ can be expressed by an $(n+1)$-bit string, since the output $g_x(x, y)$ is an n-bit string as well; the same obviously holds for $f_2(x, y) = g_y(x, y) - y$. We then note that since all lattice points behave well under the transformation, and the interpolation given in Appendix A is linear in both cases, the reduction requires no further steps; a solution to the derived ZeroSurfaceCrossing instance is immediately a fixed point of the original Brouwer instance. ◀

▶ **Lemma 14.** ZeroSurfaceCrossing *is in PPAD.*

Proof. We show this by reducing ZeroSurfaceCrossing to Brouwer. Without loss of generality, we assume that f_1 and f_2 take two n-bit strings as input and output two $(n+1)$-bit strings (we add the extra bit to account for the fact that they can have negative output, so as to keep the interval size constant). We can now define $g : [0,1]^2 \to [0,1]^2$ as follows; this is essentially the above reduction, reversed and with outputs truncated to be within $[0, 1]$:

$$g_x(x, y) = \max\big[\min[x + f_1(x, y), 1], 0\big], \text{ and } g_y(x, y) = \max\big[\min[y + f_2(x, y), 1], 0\big].$$

As before, since the reduction holds exactly at lattice points, it holds exactly everywhere else as well (by how the interpolation works). Furthermore, it trivially has a fixed point at any (x, y) such that $f_1(x, y) = f_2(x, y) = 0$. We now wish to show that any *additional* fixed points can only be a result of f_1 or f_2 violating a boundary condition (which we recally is an acceptable output to ZeroSurfaceCrossing).

The only way g could have another fixed point is if the capping of g_x or g_y to be between 0 and 1 held the displacement to 0 when otherwise it would have been nonzero. This happens only if the input is already on the boundary (otherwise the cap cannot completely remove a nonzero displacement in any direction); hence, it can only happen if one of the following four events happens: (a) $f_1(0, y) < 0$; (b) $f_1(1, y) > 0$; (c) $f_2(x, 0) < 0$; or (d) $f_2(x, 1) > 0$, which all represent violations of the boundary conditions set by ZeroSurfaceCrossing. Hence, any fixed point of g corresponds to a solution to ZeroSurfaceCrossing, which means that ZeroSurfaceCrossing can be reduced to Brouwer, and so it is in PPAD. ◀

Lemmas 13 and 14 thus imply Theorem 1 (ZeroSurfaceCrossing is PPAD-complete).

4 Crossing Curves

We now discuss the CrossingCurves problem; in particular, we show that it is in PPAD.

Proof of Theorem 3. We recall that the CrossingCurves problem involves two curves $f_1, f_2 : [0, 1] \to [0, 1]^2$ such that $f_1(0) = (0, 0)$, $f_1(1) = (1, 1)$, $f_2(0) = (0, 1)$ and $f_2(1) = (1, 0)$; these curves are formally defined by circuits which map n-bit strings to points on a discrete lattice in $[0, 1]^2$ (with the continuous curves defined by interpolation over these circuits). We denote f_1^x, f_1^y, f_2^x, and f_2^y as the functions describing f_1 and f_2's outputs in the dimensions x and y. We note that although $f_1^x(0) = f_2^x(0) = 0$ and $f_1^x(1) = f_2^x(1) = 1$, f_1^x and f_2^x are not necessarily monotonically increasing; the two curves can snake back and forth. Nevertheless, the Jordan curve theorem does guarantee that there will be a crossing point, i.e. a pair of *times* (if we interpret the input of f_1 and f_2 to be a time between 0 and 1) t_1, t_2 such that $f_1(t_1) = f_2(t_2)$. The task is to find the crossing point.

We do this by defining the function $g : [0, 1]^2 \to \mathbb{R}^2$ (where its x and y components are denoted g^x and g^y respectively) such that

$$g^x(t_1, t_2) = t_1 - f_1^x(t_1) + f_2^x(t_2) \text{ and } g^y(t_1, t_2) = t_2 - f_1^y(t_1) + f_2^y(t_2)\,.$$

Clearly this function is continuous, and (t_1, t_2) is a fixed point if and only if $f_1^x(t_1) = f_2^x(t_2)$ and $f_1^y(t_1) = f_2^y(t_2)$, i.e. if and only if $f_1(t_1) = f_2(t_2)$. This is already very close to showing what we need to show; the only trouble is that an application of g might end up at a point outside of $[0, 1]^2$, breaking our use of Brouwer. We thus define $\hat{g}$ to be g, but with upper and caps to its values at 1 and 0 respectively. Formally:

$$\hat{g}^x(t_1, t_2) = \max\left[\min[g^x(t_1, t_2), 1], 0\right] \text{ and } \hat{g}^y(t_1, t_2) = \max\left[\min[g^y(t_1, t_2), 1], 0\right].$$

We now have a function which does not leave $[0, 1]^2$ and has a fixed point at any t_1, t_2 such that $f_1(t_1) = f_2(t_2)$. The only trouble is we need to make sure we did not create any new fixed points by this capping method;

A new fixed point can only happen if one of the following four events happens:

1. $-f_1^x(t_1) + f_2^x(t_2) < 0$ when $t_1 = 0$;
2. $-f_1^x(t_1) + f_2^x(t_2) > 0$ when $t_1 = 1$;
3. $-f_1^y(t_1) + f_2^y(t_2) < 0$ when $t_2 = 0$;
4. $-f_1^y(t_1) + f_2^y(t_2) > 0$ when $t_2 = 1$.

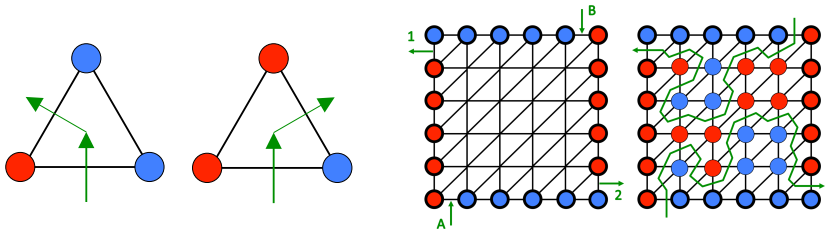

Figure 4 *Left:* proceeding on a Hex walk through a cell; each step is forced. *Right:* an empty board (with player-owned edges) has two entries, A and B, and two exits 1 and 2. If the walk entering at A exits through 2 (as shown at far right), then player 1 is the winner; if it exits through 1, then player 2 is the winner.

But we note that since $f_1^x(0) = 0$ and $f_1^x(1) = 1$ (and both f_1 and f_2 are constrained to be in $[0, 1]$ in both components) that the first two cannot happen; furthermore, since $f_2^y(0) = 1$ and $f_2^y(1) = 0$, the second two cannot happen. Thus, a fixed point still occurs at (t_1, t_2) if *and only if* $f_1(t_1) = f_2(t_2)$, as we wanted. We can thus apply the Brouwer fixed-point algorithm to $\hat{g} : [0, 1]^2 \to [0, 1]^2$ and read off a solution to the crossing-curves problem. Since finding a Brouwer fixed-point is in PPAD [11], CrossingCurves is also in PPAD. ◀

5 Hex, Brouwer, and Jordan in PSPACE

We have already established that the Hex, Brouwer, and Jordan theorems are mathematically equivalent. We have also identified two problems motivated by Jordan's curve theorem that lie in PPAD. One of these is in fact PPAD-complete and thereby computationally equivalent to Brouwer. It is natural to ask whether a computational version of the Hex theorem is also related to PPAD. The link between PPAD and the Hex theorem is more immediate and striking than that between the Jordan curve theorem and PPAD. In particular, Gale's proof that Hex always has a winner [6] is strikingly similar to the proof of Sperner's lemma, another well-known topological fact giving rise to the PPAD-complete problem called Sperner. Gale's proof generates a PPAD type graph, as defined in Section 2.2. In the next sections, we briefly summarize Gale's results and discuss natural questions arising from it in relation to PPAD and, as it turns out, PSPACE.

5.1 Hex and PPAD

As with all PPAD-type problems, in Hex the proof of existence of a 'bridge' (a winning sequence for one of the two players) in a filled board comes with a pivoting algorithm to find it; this algorithm was described by Gale, who (remarkably) used it to show that Brouwer's fixed-point theorem and the Hex theorem are mathematically equivalent. The pivoting algorithm is briefly sketched in Figure 4 on the dual-graph representation of the Hex board (in which the stones are placed on vertices, rather than faces, of the graph). In brief, there are two places on the edge of the board where one can enter with red on their left and blue on their right, as shown in the figure; suppose one starts at A. Then, one walks over the faces of the dual graph (or, equivalently, on the vertices of the original board), keeping red on their left and blue on their right, until they exit the board at either 1 or 2. Exiting at 2 implies a victory for player 1 (red), and exiting at 1 implies a loss. This pivoting algorithm is especially reminiscent of the Sperner's Lemma pivoting algorithm [11], and induces a (directed) PPAD graph with nodes corresponding to the faces of the dual-graph board.

Even though Gale's proof induces a PPAD graph, there is no natural analogue of the EndOfTheLine problem for Hex. This is because the PPAD graph induced by Gale's argument only has four unbalanced vertices, corresponding to the entries A and B and the exits 1 and 2. The natural question is which pairs of unbalanced vertices are connected, which is equivalent to asking *"who won?"* after a game of Hex has filled the board. This corresponds to finding the *specific* unbalanced vertex of the PPAD graph which is connected to the starting one, corresponding to entry A. Of course, this would be polynomial-time solvable if the board were polynomially-sized, so we will assume an *exponentially-large* board where a polynomially-sized circuit tells us who claimed any particular tile.

5.2 WhoWonHex

WhoWonHex

Input: a Hex board, such that it takes n bits to uniquely specify a tile (the canonical way to do this is via the dual graph, by having $n/2$ bits dedicated to specifying the position of the tile in each dimension); a circuit C which takes an n-bit string (i.e. a tile) and outputs either 0 ('player 1 does not occupy this tile') or 1 ('player 1 does occupy this tile').

Output: 0 if there does not exist a bridge of tiles occupied by player 1 from the left facet to the right facet ('player 1 has not won'), and 1 if there does exist such a bridge ('player 1 has won'). Formally, with the canonical tile-specifying scheme described above, a 'bridge' is defined as a sequence of tiles $v_1, v_2, \ldots, v_m$ such that: (a) v_i is adjacent to v_{i+1} for all $i = 1, 2, \ldots, m-1$; (b) $C(v_i) = 1$ for all i; (c) the first $n/2$ bits of v_1 are all 0 (it's adjacent to the left facet), and the first $n/2$ bits of v_m are all 1 (it's adjacent to the right facet).

We want to show that WhoWonHex is PSPACE-complete (Theorem 4). It is tempting to try to prove this hardness via a reduction from the so-called OtherEndOfThisLine problem,[1] which is PSPACE-hard [8], by simulating paths in a given PPAD graph via "Gale paths." However, Gale paths do not cross, and the usual embedding of a PPAD graph into a 2-dimensional plane without crossings results in a drastic change of the graph topology (unbalanced vertices remain unbalanced vertices, but which unbalanced vertices are connected to each other changes) [2, 7]. Instead, we will obtain our result as a direct consequence of Goldberg's proof that it is PSPACE-hard to identify the solution output by a path-following algorithm for Sperner [7].

Goldberg's proof proceeds directly from the well-known PSPACE-complete problem of evaluating a *quantified Boolean formula* (QBF). Since our proof is an application of Goldberg's proof, we only explain how to make the gadgets required to modify his proof for our purposes.

Proof of Theorem 4. As described above, we will be adapting Goldberg's proof that identifying the solution chosen by the standard pivoting algorithm for Sperner is PSPACE-hard. (The inclusion into PSPACE is easy to establish; the details are given in the full version of our paper [1])). Given a QBF instance Goldberg defines horizontal and vertical wires in an exponentially large square lattice in such a way that the existence of a connected path of

[1] This problem is: given a PPAD graph via circuits P, N, identify the unbalanced vertex connected to 0^n, if 0^n is itself unbalanced.

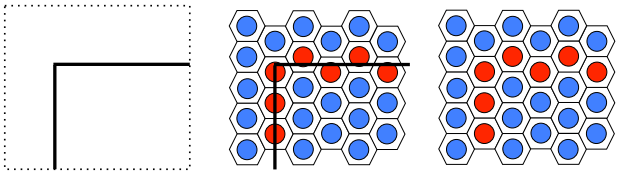

Figure 5 *Left:* A wire occupying part of the space. *Middle:* The wire, superimposed on the Hex board, with the appropriate tiles turned to red to carry the wire. *Right:* The wire, represented only as a sequence of red Hex tiles.

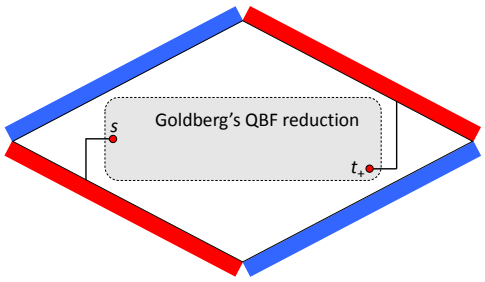

Figure 6 Embedding Goldberg's rectangular reduction into a Hex board, so that player 1 wins if and only if s is connected to t_+.

wires from a special point s to a special point t_+ (which themselves always lie on wires but may not be connected through wires) is equivalent to the QBF instance evaluating to 1. He also provides an efficient algorithm to determine if a wire passes through a specific point, and then simulates wires with paths in the PPAD graph of a Sperner instance.

Our result will be based on a 'wire' gadget that is based on Hex rather than Sperner – which is simply a connected path of red tiles 'insulated' from other red tiles by blue tiles (in fact, all tiles not on a 'wire' gadget are defined to be occupied by blue stones, i.e. player 2). For simplicity, we use only wires whose segments are perfectly vertical or horizontal; how a wire translates into tiles is shown in Figure 5.

Usefully the special points s and t_+ in Goldberg's construction lie on the left and right boundary of the square lattice respectively. This allows us to embed Goldberg's construction into a Hex board as shown in Figure 6. In particular:

- we allocate a part of the board where we replicate Goldberg's construction using our wire gadget, as described above given a QBF instance;
- we add wires connecting s to the bottom-left edge of the board;
- we add wires connecting t_+ to the up-right edge of the board.

Since s and t_+ lie on wires they are red tiles.

Since we do not have any wires not defined by Goldberg's construction (other than those from s and t_+ to the boundary of the Hex board shown in Figure 6), there is a bridge connecting the red edges of the Hex board if and only if s is connected to t_+ by wires inside Goldberg's construction. This is PSPACE-hard to determine, hence it is PSPACE-hard to determine if Player 1 wins. ◀

We remark that this proof had to be derived from Goldberg's *construction* itself, and not his result in a black-box manner. This is because the construction guarantees that the end-points s and t_+ in the proof above lie on the boundaries of the construction (and thus can be wired to the bottom-left and upper-right edges of the Hex board).

In contrast, general SPERNER instances may very well have the solution reachable through the standard path-following algorithm residing in the interior of the construction (thereby making it hard to translate into Hex, since the question in Hex is whether there is a bridge of red stones joining the left and right edges of the board).

6 Conclusion

In this paper, we explored the links between Brouwer's fixed-point theorem, the Jordan curve theorem, and the game of Hex. We showed that Brouwer and Jordan are mathematically and computationally equivalent, complementing Maehara's result that Jordan is a consequence of Brouwer. Combined with Gale's result that Brouwer's fixed-point theorem is mathematically equivalent to the seemingly innocuous Hex theorem (that a completed game of Hex must have a winner), our result implies that all three theorems, Brouwer, Jordan and Hex, are mathematically equivalent. Within PPAD, we defined two computational problems, CURVECROSSING and ZEROSURFACECROSSING, which always have solutions by dint of the Jordan curve theorem. We show that both lie in PPAD, and the second is also PPAD-complete. Finally, we relate the Hex theorem to results in the literature pertaining to the complexity of standard pivoting algorithms for ENDOFTHELINE, BROUWER and SPERNER. It has been shown that identifying the solution computed by standard pivoting algorithms for these problems is PSPACE-complete, and we show that the problem WHOWONHEX, of determining who is the winner in a play of Hex, is also PSPACE-complete. We thereby establish computational relations among Brouwer, Hex and Jordan both within PPAD and at the level of PSPACE. The main problem left open by our work is the complexity of CURVECROSSING. Is it PPAD-complete? We discuss structural properties of instances of CURVECROSSING that make us believe that the problem could lie lower in TFNP. It would be interesting to identify a potential function argument guaranteeing a solution to this problem, thereby placing it in the intersection of PLS and PPAD, and potentially one of the classes defined in [4].

A Interpolations of Functions on the Unit Square

In order to develop computational problems relating to our theorems of interest, we need to give a formal definition of how circuits can represent functions on the unit square. We will consider two types of functions we wish to represent: $f : [0,1]^2 \to [-1,1]$, and $g : [0,1]^2 \to [0,1]^2$. They are represented by the following circuits:

1. f is represented by a circuit F which takes two n-bit strings as input (representing a point in $[0,1]^2$) and returns an m-bit string (representing the value of the function);
2. g is represented by a circuit G which takes two n-bit strings as input and returns two new n-bit strings.

These circuits directly define the values of their respective functions at lattice points in $[0,1]^2$, namely points whose coordinates are integer multiples of $1/(2^n-1)$; for the values of f and g at points which are not on this lattice, we use the triangulations depicted in Figure 7. For f, we take the output at lattice points (which is directly given by F) and use them to generate a 'mesh' which defines f at points not on the lattice; for g, we make a similar construction as shown at center and right in the figure.

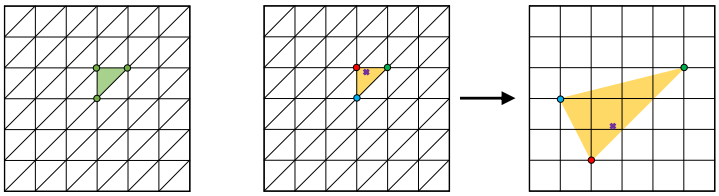

Figure 7 *Left:* the value of f at the three marked lattice points uniquely determines a plane; for input points in the triangle shared by the three, the output of f is consistent with this plane. *Center and Right:* the marked lattice points at right are the outputs of g at the marked lattice points at center; inputs in the triangle shared by them are mapped to the corresponding point in the triangle shared by their outputs (for example, the purple 'x' at center is mapped to the purple 'x' at right).

Fractals for Kernelization Lower Bounds, With an Application to Length-Bounded Cut Problems*

Abstract

Bodlaender et al.'s [6] cross-composition technique is a popular method for excluding polynomial-size problem kernels for NP-hard parameterized problems. We present a new technique exploiting triangle-based fractal structures for extending the range of applicability of cross-compositions. Our technique makes it possible to prove new no-polynomial-kernel results for a number of problems dealing with length-bounded cuts. Roughly speaking, our new technique combines the advantages of serial and parallel composition. In particular, answering an open question of Golovach and Thilikos [13], we show that, unless NP $\subseteq$ coNP / poly, the NP-hard Length-Bounded Edge-Cut problem (delete at most k edges such that the resulting graph has no s-t path of length shorter than ℓ) parameterized by the combination of k and ℓ has no polynomial-size problem kernel. Our framework applies to planar as well as directed variants of the basic problems and also applies to both edge and vertex deletion problems.

1 Introduction

Lower bounds are of central concern all over computational complexity analysis. With respect to fixed-parameter tractable problems, currently there are two main streams in this context: (i) ETH-based lower bounds for the running times of exact algorithms [18] and (ii) lower bounds on problem kernel sizes; more specifically, the exclusion of polynomial-size problem kernels [17]. Both these research directions for lower bounds rely on plausible complexity-theoretic assumptions, namely the Exponential-Time Hypothesis (ETH) and NP $\not\subseteq$ coNP / poly, respectively. In this work, we contribute to the second research direction, developing a new technique that exploits a triangle-based fractal structure in order to exclude polynomial-size problem kernels (polynomial kernels for short) for edge and vertex deletion problems in the context of length-bounded cuts.

Kernelization is a key method for designing fixed-parameter algorithms [14, 17]; among all techniques of parameterized algorithm design, it has the presumably greatest potential for delivering practically relevant algorithms. Hence, it is of key interest to explore its power and its limitations. In a nutshell, the fundamental idea of kernelization is as follows. Given a parameterized problem instance I with parameter k, in polynomial time preprocess I by applying data reduction rules in order to simplify it and reduce it to an "equivalent" instance (so-called (problem) kernel) of the same problem. For NP-hard problems the best one can hope for is a problem kernel of size polynomial in the parameter k. In a way, one may interpret kernelization (requested to run in polynomial time) as an "exact counterpart" of polynomial-time approximation algorithms. Indeed, linear-size problem kernels often imply constant-factor approximation algorithms [20, page 15]. Approximation algorithmics has a highly developed theory (having produced concepts such as MaxSNP-hardness and the famous PCP theory) for proving (relative to some plausible complexity-theoretic assumption) lower bounds on the approximation factors [24].

It is fair to say that in the younger field of kernelization the arsenal for proving lower bounds (particularly excluding polynomial kernels) so far is of smaller scope and needs further development. The most influential result in this context is due to Bodlaender et al. [5] and Fortnow and Santhanam [12]: Based on the assumption NP $\not\subseteq$ coNP / poly, it is shown that e.g. the NP-hard graph problem Longest Path parameterized by solution size has no polynomial kernel. The core tool for showing this are so-called "OR-compositions". To ease the use of this kernel-lower-bound framework, one natural idea is to use "polynomial parameter transformations", that is, a form of "parameter-preserving reductions" [7, 10]. An easier-to-use generalization of the OR-composition technique is given by so-called OR-cross-compositions [6]. Currently, these two approaches constitute the known core tools to exclude polynomial kernels. Building on OR-cross-compositions, we add a further tool (which we baptized "fractalism") in order to extend the range of problems to be addressed by OR-cross-compositions. The usefulness of our new technique is substantiated by resolving an open problem posed by Golovach and Thilikos [13], here specifically applying our technique to the NP-hard Length-Bounded Edge-Cut problem.

Next, we discuss in some more detail OR-(cross)-compositions. Roughly speaking, the idea behind an OR-composition for a parameterized problem is to encode the logical "or" of t instances with parameter value k into a single instance of the same problem with parameter value $k' = k^{O(1)}$. In particular, given t instances, the obtained instance is a yes-instance if and only if at least one of the given instances is a yes-instance. If an OR-composition is possible, then this excludes polynomial kernels. Whereas in OR-compositions one combines instances of an NP-hard parameterized problem into one instance of a parameterized problem,

in OR-cross-compositions one combines instances of classical NP-hard problems into one instance of a parameterized problem (see Section 2 for details and formal definitions).

While for some problems, for example Longest Path with parameter solution size [5], a simple disjoint union yields the desired OR-composition, other problems seem to require involved constructions, for example Set Cover with parameter universe size [10]. Indeed, devising a cross-composition can be quite challenging and the task becomes even harder when considering several, seemingly orthogonal parameterizations at once. To illustrate the problem with such combined parameters, let us consider the problem Length-Bounded Edge-Cut (LBEC). Herein, an undirected graph $G = (V, E)$ with $s, t \in V$, and two integers $k, \ell \in \mathbb{N}$ are given, and the question is whether it is possible to delete at most k edges such that the shortest s-t path is of length at least ℓ. Using a simple branching algorithm, one can show that LBEC(k, ℓ) is fixed-parameter tractable for the combined parameter (k, ℓ) [13, 3]. To exclude the existence of a polynomial kernel for LBEC(k, ℓ), we would like to apply the OR-cross-composition framework to the problem, and as a natural candidate for the input problem we decide for LBEC itself.

A standard approach to applying the OR-cross-composition to a problem like LBEC would be to concatenate the input instances on the source and sink vertices, also referred to as "serial" composition. To this end, one needs some additional gadgets to ensure that only in one instance edges are deleted. This form of composition, however, induces a dependency of the second parameter ℓ on the number of instances, which is not allowed. Another standard approach is introducing a "global" sink and source vertex, and connecting all source vertices with the global source and all sink vertices, also referred to as a "parallel" composition. This form of composition would keep ℓ small enough, but induces a dependency of the first parameter k on the number of instances. Summarizing, the parameter k seems to ask for a serial composition and the parameter ℓ seems to ask for a parallel composition. For some problems using a tree as "instance selector" was helpful, see for example Bevern et al. [4] or Bazgan et al. [2]. The problem with trees is that they introduce small (constant-size) s-t cuts, which is problematic for Length-Bounded Edge-Cut. In this work, we introduce a fractal structure as instance selector which has the nice properties of trees but does not introduce small cuts. So, our fractal structure helps to exclude polynomial kernels for several problems.

Our contributions. Our main technical contribution is to introduce a family of graphs that we call T-fractals and that build on triangles. T-fractals feature a fractal-like structure, in the sense of self-similarity and scale-invariance. Using these T-fractals in OR-cross-compositions, we show that the following parameterized graph modification problems and several of their variants do not admit polynomial kernels (unless NP $\subseteq$ coNP / poly):

- Length-Bounded Edge-Cut(k, ℓ) (LBEC(k, ℓ)), where k is the number of edges to delete, and ℓ is the lower bound on the length of the shortest path.
- Minimum Diameter Edge Deletion(k, ℓ) (MDED(k, ℓ)), that is, given an undirected connected graph $G = (V, E)$ and two integers k, ℓ (the parameters), decide whether there are at most k edge deletions such that the remaining graph remains connected and has diameter at least ℓ.
- Directed Small Cycle Transversal(k, ℓ) (DSCT(k, ℓ)), that is, given a directed graph $G = (V, E)$ and two integers k, ℓ (the parameters), decide whether there are at most k edge deletions such that the remaining graph has no cycle of length smaller than ℓ.

Table 1 surveys our no-polynomial-kernel results and spots an open question.

Table 1 Survey of the concrete results of this paper (under the assumption that NP $\not\subseteq$ coNP / poly). PK stands for polynomial kernel and a "?" indicates that it is open whether a polynomial kernel exists. We remark that the no-polynomial-kernel results for LBEC(k, ℓ) on directed graphs still hold for directed acyclic graphs. Note that we claim without proof that, except for the planar variants, our proofs also transfer to the vertex deletion case, both for directed and undirected graphs.

2 Preliminaries

Graph Theory. Let $G = (V, E)$ be a graph. For $C \subseteq V(G)$ ($C \subseteq E(G)$) we write $G - C$ for the graph G where all vertices (edges) in C are deleted. Let $s, t \in V(G)$. An edge set $C \subseteq E(G)$ is an *s-t edge cut* in G if the vertices s and t are disconnected in $G - C$. An s-t edge cut C is called *minimal* if $C \backslash \{e\}$ is not an s-t edge cut in G for all $e \in C$. An s-t edge cut C is called *minimum* if there is no s-t edge cut C' in G such that $|C'| < |C|$.

The length of a path (cycle) is the number of edges in the path (cycle). An s-t path is a path where the vertices s and t are the endpoints of the path. In directed graphs, an s-t path is a path where all arcs are directed toward t, and a cycle is a connected graph where every vertex has outdegree and indegree exactly one. The *diameter* of a graph G is the maximum length of any shortest v-w path over all $v, w \in V(G)$, $v \neq w$.

For $v, w \in V(G)$, we say we *merge* the vertices v and w if we add a new vertex vw to V as well as the edge set $\{\{vw, x\} \mid \{x, v\} \in E\} \cup \{\{vw, x\} \mid \{x, w\} \in E\}$ to E, and we delete the vertices v and w and all edges incident to v and w.

Parameterized Complexity. A *parameterized problem* is a set of instances $(\mathcal{I}, k)$ where $\mathcal{I} \in \Sigma^*$ for a finite alphabet Σ, and $k \in \mathbb{N}$ is the *parameter*. A parameterized problem L is *fixed-parameter tractable (fpt)* if it can be decided in $f(k) \cdot |\mathcal{I}|^{O(1)}$ time whether $(\mathcal{I}, k) \in L$, where f is a computable function only depending on k. We say that two instances $(\mathcal{I}, k)$ and $(\mathcal{I}', k')$ of parameterized problems P and P' are *equivalent* if $(\mathcal{I}, k)$ is YES for P if and only if $(\mathcal{I}', k')$ is YES for P'. A *kernelization* is an algorithm that, given an instance $(\mathcal{I}, k)$ of a parameterized problem P, computes in polynomial time an equivalent instance $(\mathcal{I}', k')$ of P (the *kernel*) such that $|\mathcal{I}'| + k' \leq f(k)$ for some computable function f only depending on k. We say that f measures the *size* of the kernel, and if $f \in k^{O(1)}$, we say that P admits a polynomial kernel. We remark that a decidable parameterized problem is fixed-parameter tractable if and only if it admits a kernel [8].

Given an NP-hard problem L, an equivalence relation $\mathcal{R}$ on the instance of L is a *polynomial equivalence relation* if (i) one can decide for any two instances in time polynomial in their sizes whether they belong to the same equivalence class, and (ii) for any finite set S of instances, $\mathcal{R}$ partitions the set into at most $(\max_{x \in S} |x|)^{O(1)}$ equivalence classes.

▶ **Definition 1.** Given an NP-hard problem L, a parameterized problem P, and a polynomial equivalence relation $\mathcal{R}$ on the instances of L, an *OR-cross-composition* of L into P (with respect to $\mathcal{R}$) is an algorithm that takes ℓ $\mathcal{R}$-equivalent instances $\mathcal{I}_1, \ldots, \mathcal{I}_\ell$ of L and constructs

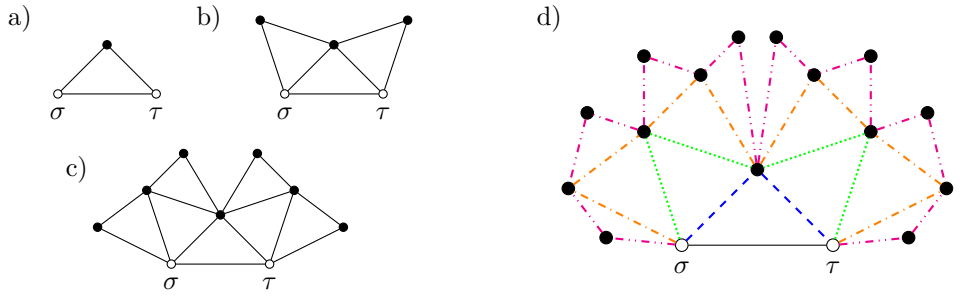

Figure 1 T-fractals a) $\triangle_1$, b) $\triangle_2$, c) $\triangle_3$, and d) $\triangle_4$. The two special vertices σ and τ are highlighted by empty circles. In $\triangle_4$ the different boundaries are highlighted by line-types (solid: boundary B_0; dashed: boundary B_1; dotted: boundary B_2; dash-dotted: boundary B_3; dash-dot-dotted: boundary B_4).

in time polynomial in $\sum_{i=1}^{\ell} |\mathcal{I}_\ell|$ an instance $(\mathcal{I}, k)$ such that
1. k is polynomially upper-bounded in $\max_{1\leq i\leq \ell} |\mathcal{I}_i| + \log(\ell)$ and
2. $(\mathcal{I}, k)$ is YES for P if and only if there is at least one $\ell' \in [\ell]$ such that $\mathcal{I}_{\ell'}$ is YES for L.

If a parameterized problem P admits an OR-cross-composition for some NP-hard problem L, then P does not admit a polynomial kernel with respect to its parameterization, unless NP $\subseteq$ coNP / poly [6]. We remark that we can assume that $\ell = 2^j$ for some $j \in \mathbb{N}$ since we can add trivial NO-instances from the same equivalence class to reach a power of two. We refer to the survey of Kratsch [17] for an overview on kernelization and lower bounds.

3 The "Fractalism" Technique

In this section, we describe our new technique based on *triangle fractals* (*T-fractals* for short). We provide a general construction scheme for cross-compositions using T-fractals. To this end, we first define T-fractals and then discuss several of their properties in Section 3.1. Subsequently, in Section 3.2 we present a "construction manual" for an application of T-fractals in cross-compositions.

Roughly speaking, a T-fractal can be constructed by iteratively putting triangles on top of each other, see Figure 1 for four examples.

▶ **Definition 2.** For $q \geq 1$, the *q-T-fractal* $\triangle_q$ is the graph constructed as follows:
(1) Set $\triangle_0 := \{\sigma, \tau\}$ with $\{\sigma, \tau\}$ being a "marked edge" with endpoints σ and τ, subsequently referred to as special vertices.
(2) Let F be the set of marked edges.
(3) For each edge $e \in F$, add a new vertex and connect it by two new edges with the endpoints of e, and mark the two added edges.
(4) Unmark all edges in F.
(5) Repeat (2)–(4) $q - 1$ times.

The fractal structure of $\triangle_q$ might be easier to see when considering the following equivalent recursive definition of $\triangle_q$: For the base case we define $\triangle_0 := \{\sigma, \tau\}$ as in Definition 2. Then, the q-T-fractal $\triangle_q$ is constructed as follows. Take two $(q-1)$-T-fractals $\triangle'_{q-1}$ and $\triangle''_{q-1}$, where σ', τ' and σ'', τ'' are the special vertices of $\triangle'_{q-1}$ and $\triangle''_{q-1}$, respectively. Then $\triangle_q$ is obtained by merging the vertices τ' and σ'' and adding the edge $\{\sigma', \tau''\}$. Set $\sigma = \sigma'$ and $\tau = \tau''$ as the special vertices of $\triangle_q$. We remark that we make use of the recursive structure in later proofs.

In the ith execution of (2)–(4) in Definition 2, we obtain 2^{i-1} many triangles. We say that these triangles have depth i. The *boundary* $B_i \subseteq E(\triangle_q)$, $i \in [q]$, are those edges of the triangles of depth i which are not edges of the triangles of depth $i-1$. As a convention, the edge $\{\sigma, \tau\}$ connecting the two special vertices σ and τ forms the boundary B_0. Refer to Figure 1 for an illustration of the boundaries in the T-fractal $\triangle_4$. Moreover, by construction, we obtain the following:

▶ **Observation 3.** *In every T-fractal, each boundary forms a σ-τ path, and all boundaries are pairwise edge-disjoint.*

Note that the boundary B_q contains $p = 2^q$ edges. Thus, the number of edges in $\triangle_q$ is $\sum_{i=0}^{q} 2^i = 2^{q+1} - 1 = 2 \cdot p - 1$. Further observe that all vertices of $\triangle_q$ are incident with the edges in B_q, and B_q forms a σ-τ path. Hence, $\triangle_q$ contains $p+1$ vertices.

Reducing the Weighted to the Unweighted Case. In the remainder of the paper, we focus on the unweighted case of T-fractals without multiple edges or loops. This is possible due to the following reduction of the weighted to the unweighted case. Equip the T-fractal with an *edge cost*, that is, the cost for deleting any edge in the T-fractal. If $c \in \mathbb{N}$ is the edge cost of $\triangle_q$, then we write $\triangle_q^c$ (we drop the superscript if $c = 1$). To reduce to the case with an unweighted, simple graph, we add $c-1$ further copies for each edge. Thus, to make two adjacent vertices non-adjacent, it requires c edge-deletions. To make the graph simple, we subdivide each edge. We remark that in this way we double the distances of the vertices in the original T-fractal. Thus, whenever we consider distances in the fractal with edge cost and the graph obtained by the reduction above, we have to take into account a factor of two.

3.1 Properties of T-Fractals

The goal of this subsection is to prove several properties of T-fractals that are used in later constructions. Some key properties of T-fractals appear in the context of σ-τ edge cuts in $\triangle_q$.

The minimum edge cuts in $\triangle_q$ will play a central role when using T-fractals in cross-compositions since the minimum edge cuts serve as instance selectors (see Section 3.2). First, we discuss the size and structure of the minimum edge cuts in $\triangle_q$.

▶ **Lemma 4.** *Every minimum σ-τ edge cut in $\triangle_q$ is of size $q+1$.*

Proof. Let C be a minimum σ-τ edge cut in $\triangle_q$. Note that the degrees of σ and τ are exactly $q+1$, and thus $|C| \leq q+1$. Moreover, the boundaries in $\triangle_q$ are pairwise edge-disjoint and each boundary forms a σ-τ path (Observation 3). Since $\triangle_q$ contains $q+1$ boundaries, it follows that there are at least $q+1$ disjoint σ-τ paths in $\triangle_q$. Menger's theorem [21] states that in a graph with distinct source and sink, the maximum number of disjoint source-sink paths equals the minimum size of any source-sink edge cut. Thus, by Menger's theorem, it follows that $|C| \geq q+1$. Hence $|C| = q+1$. ◀

From the fact that the boundaries are pairwise edge-disjoint and each boundary forms a σ-τ path, we can immediately derive the following from Lemma 4.

▶ **Corollary 5.** *Every minimum σ-τ edge cut in $\triangle_q$ contains exactly one edge of each boundary.*

In the following we describe a (hidden) dual structure in $\triangle_q$, that is, a complete binary tree with p leaves. We refer to Figure 2 for an example of the dual structure in $\triangle_3$. To talk

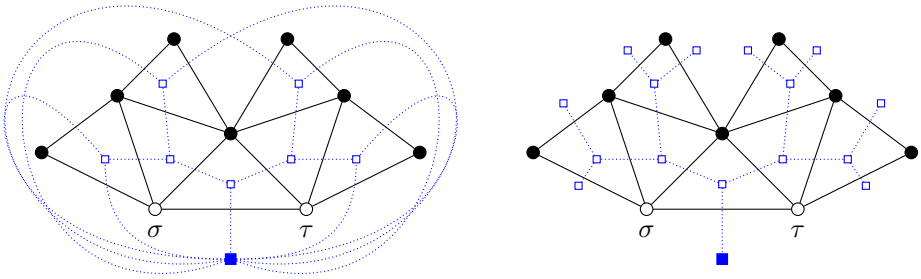

Figure 2 Left: The T-fractal $\triangle_3$ (circles and solid lines) and its dual graph (squares and dotted lines). The filled square is the vertex dual to the outer face in the dual graph. Right: The T-fractal $\triangle_3$ (circles and solid lines) and its dual structure T_3, illustrated by squares and dotted lines, where the filled square corresponds to the root of the dual structure.

about the dual structure by means of duality of plane graphs, we need a plane embedding of $\triangle_q$. Hence we assume that $\triangle_q$ is embedded as in Figure 1 (iteratively extended). By T_q we denote the dual structure in $\triangle_q$, where the vertex dual to the outer face is replaced by $p+1$ vertices (*split vertices*) such that each edge incident with the dual vertex is incident with exactly one split vertex. We consider the split vertex incident with the vertex dual to the triangle containing the edge $\{\sigma, \tau\}$ as the root vertex of the dual structure T_q. Thus, the other split vertices correspond to the leaves of the dual structure T_q. Note that the depth of a triangle one-to-one corresponds to the depth of the dual vertex in T_q.

Observe that there is a one-to-one correspondence between the edges in T_q and the edges in $\triangle_q$. The following lemma states duality of root-leaf paths in T_q and minimum σ-τ edge cuts in $\triangle_q$, demonstrating the utility of the dual structure T_q.

▶ **Lemma 6.** *There is a one-to-one correspondence between root-leaf paths in the dual structure T_q of $\triangle_q$ and minimum σ-τ edge cuts in $\triangle_q$. Moreover, there are exactly $p = 2^q$ pairwise different minimum σ-τ edge cuts in $\triangle_q$.*

Proof. Observe that each path from the root to a leaf in the dual structure T_q corresponds to a cycle in the dual graph. It is well-known that there is a one-to-one correspondence between minimal edge cuts in a plane graph and cycles in its dual graph [9, Proposition 4.6.1]. Herein, every cycle in the dual graph that "cuts" the edge $\{\sigma, \tau\}$ in $\triangle_q$ is a root-leaf path in T_q. Thus, the only minimal σ-τ edge cuts are those corresponding to the root-leaf paths. By the one-to-one correspondence of the depth of the triangles in $\triangle_q$ and the depth of the vertices in T_q, these edge cuts are of cardinality $q+1$. Hence, by Lemma 4, these edge cuts are minimum edge cuts.

Since $|B_q| = p$, there are exactly p leaves in T_q, and thus there are exactly p different root-leaf paths in T_q. It follows that the number of pairwise different minimum σ-τ edge cuts in $\triangle_q$ is exactly $p = 2^q$. ◀

Further, we obtain the following.

▶ **Lemma 7.** *Let C be a minimum σ-τ edge cut in $\triangle_q$. Let $\{x, y\} = C \cap B_q$, where x is in the same connected component as σ in $\triangle_q - C$. Then $\mathrm{dist}(\sigma, x) + \mathrm{dist}(y, \tau) = q$ in $\triangle_q - C$.*

Proof. We prove the lemma by induction on q. For the base case $q = 0$, observe that $C = \{\sigma, \tau\}$ and $\mathrm{dist}_{\triangle_0 - C}(\sigma, x) + \mathrm{dist}_{\triangle_0 - C}(y, \tau) = 0$.

For the induction step, assume that the statement of the lemma is true for $\triangle_{q-1}$. Now, let C be a minimum σ-τ edge cut in $\triangle_q$. Hence, $\{\sigma, \tau\} \in C$. Denote by u the (unique)

vertex that is adjacent to the two special vertices σ and τ. Let $\triangle'_{q-1}$ and $\triangle''_{q-1}$ be the two $(q-1)$-T-subfractals of $\triangle_q$, so that $\triangle'_{q-1}$ ($\triangle''_{q-1}$) has the special vertices σ and u (u and τ). By Lemma 6, the minimum σ-τ edge cut C corresponds to a root-leaf path in T_q. Hence, $C' := C \setminus \{\sigma, \tau\}$ is either a subset of $E(\triangle'_{q-1})$ or of $E(\triangle''_{q-1})$. Assume w.l.o.g. that $C' \subseteq E(\triangle'_{q-1})$. It follows from the induction hypothesis that $\mathrm{dist}_{\triangle'_{q-1}-C'}(\sigma, x) + \mathrm{dist}_{\triangle'_{q-1}-C'}(y, u) = q - 1$. Since $\mathrm{dist}_{\triangle_q - C}(y, \tau) = \mathrm{dist}_{\triangle'_{q-1}-C'}(y, u) + 1$, it follows that $\mathrm{dist}_{\triangle_q - C}(\sigma, x) + \mathrm{dist}_{\triangle_q - C}(y, \tau) = q$. ◀

▶ Remark. By an inductive proof like the one of Lemma 7, one can easily show that the maximum degree Δ of $\triangle_q$ is exactly $2 \cdot q$ for $q > 0$. Moreover, due to Lemma 7, the diameter of $\triangle_q$ is bounded in $O(q)$.

Another observation on $\triangle_q$ is that any deletion of d edges increases the length of any shortest σ-τ path to at most $d + 1$, unless the edge deletion forms a σ-τ edge cut.

▶ **Lemma 8.** *Let $D \subseteq E(\triangle_q)$ be a subset of edges of $\triangle_q$. If D is not a σ-τ edge cut, then there is a σ-τ path of length at most $|D| + 1$ in $\triangle_q - D$.*

Proof. We prove the statement of the lemma by induction on q. For the induction base with $q = 0$, observe that since D is not a σ-τ edge cut, it follows that $D = \emptyset$ and, hence, σ and τ have distance one.

For the induction step, assume that the statement of the lemma is true for $\triangle_{q-1}$. Now, let $D \subseteq E(\triangle_q)$ be a subset of edges of $\triangle_q$ such that D is not a σ-τ edge cut. If $\{\sigma, \tau\} \notin D$, then there is a σ-τ path of length one and the statement of the lemma holds. Now consider the case $\{\sigma, \tau\} \in D$. Denote by u the (unique) vertex that is adjacent to the two special vertices σ and τ. If $\{\sigma, \tau\} \in D$, then every σ-τ path in $\triangle_q - D$ contains u and hence $\mathrm{dist}_{\triangle_q - D}(\sigma, \tau) = \mathrm{dist}_{\triangle_q - D}(\sigma, u) + \mathrm{dist}_{\triangle_q - D}(u, \tau)$. (If there is no σ-u-path or no u-τ-path in $\triangle_q - D$, then D is a σ-τ edge cut; a contradiction to the assumption of the lemma.) Now let $\triangle'_{q-1}$ and $\triangle''_{q-1}$ be the two $(q-1)$-T-subfractals of $\triangle_q$, so that $\triangle'_{q-1}$ ($\triangle''_{q-1}$) has the special vertices σ and u (u and τ). It follows that D can be partitioned into $D = D' \cup D'' \cup \{\sigma, \tau\}$ with $D' \subseteq E(\triangle'_{q-1})$ and $D'' \subseteq E(\triangle''_{q-1})$. By induction hypothesis, it follows that there is a σ-u path of length at most $|D'| + 1$ in $\triangle'_{q-1} - D'$ and a u-τ path of length at most $|D''| + 1$ in $\triangle''_{q-1} - D''$. Hence, there is a σ-τ path of length at most $|D'| + |D''| + 2 = |D| + 1$ in $\triangle_q - D$. ◀

We remark that there is a directed version of T-fractals. Herein, the edges of a T-fractal are directed in such a way that each boundary forms a directed σ-τ path. Note that the obtained graph is acyclic, and σ has no incoming arcs, and τ has no outgoing arcs. We further remark that all stated lemmas also hold for the directed T-fractal. The dual structure of a directed T-fractal is defined as the dual structure of the underlying undirected T-fractal. For more details we refer to the full version.

3.2 Application Manual for T-Fractals

The aim of this subsection is to provide a general guideline on how to use T-fractals in cross-compositions to obtain kernel lower bounds.

▶ **Construction 9.** *Given $p = 2^q$ instances $\mathcal{I}_1, \ldots, \mathcal{I}_p$ of an NP-hard graph problem, where each instance $\mathcal{I}_i$ has a unique source vertex s_i and a unique sink vertex t_i.*

(i) *Equip $\triangle_q^c$ with some "appropriate" edge cost $c \in \mathbb{N}$.*

(ii) *Let $v_0, \ldots, v_p$ be the vertices of the boundary B_q, labeled by their distances to σ in the σ-τ path corresponding to B_q (observe that $v_0 = \sigma$ and $v_p = \tau$).*

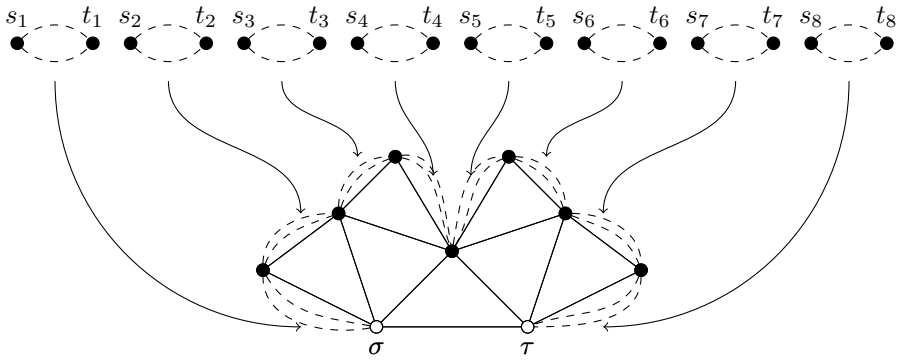

Figure 3 Illustration of Construction 9 with $p = 2^3 = 8$. The vertices $s_1, \ldots, s_8$ indicate the source vertices in the eight input instances, and $t_1, \ldots, t_8$ indicate the sink vertices in the eight input instances. We use dashed lines to sketch the input graphs.

(iii) *Incorporate each of the p graphs of the input instances into $\triangle_q^c$ as follows: for each $i \in [p]$, merge s_i with vertex v_{i-1} in $\triangle_q^c$ and merge t_i with v_i in $\triangle_q^c$.*

Refer to Figure 3 for an illustrative example of Construction 9.

In Construction 9, the T-fractal works as an instance selector by deleting edges corresponding to a minimum edge cut, which, by Lemma 4, is of size $q+1$. Hence, each minimum edge cut costs $c \cdot (q+1)$. The idea is that if we choose an appropriate value for c (larger than the budget in the instances $\mathcal{I}_1, \ldots, \mathcal{I}_p$) and an appropriate budget in the composed instance (e. g. $c \cdot (q+1)$ plus the budget in the instances $\mathcal{I}_1, \ldots, \mathcal{I}_p$), then we can only afford to delete at most $q+1$ edges in $\triangle_q^c$. Furthermore, if the at most $q+1$ edges chosen to be deleted do not form a minimum σ-τ edge cut in $\triangle_q^c$, then, by Lemma 8, the shortest σ-τ path has length at most $q+2$. Thus, by requiring in the composed instance that σ and τ have distance more than $q+2$, we enforce that any solution for the composed instance contains a minimum σ-τ edge cut in $\triangle_q^c$. By Lemma 6, each such minimum edge cut corresponds to one root-leaf path in the dual structure T_q of $\triangle_q^c$. Observe that each leaf in the dual structure of $\triangle_q^c$ one-to-one corresponds to an attached source instance. Hence, with an appropriate choice of c, the budget in the composed instance, and the required distance between σ and τ, the T-fractal ensures that one instance is "selected". We say that a minimum σ-τ edge cut in $\triangle_q^c$ *selects* an instance $\mathcal{I}$ if the edge cut corresponds to the root-leaf path with the leaf corresponding to instance $\mathcal{I}$.

▶ **Observation 10.** *Every minimum edge cut C in $\triangle_q^c$ selects exactly one instance $\mathcal{I}$. Conversely, every instance $\mathcal{I}$ can be selected by exactly one minimum edge cut.*

We use Construction 9 in OR-cross-compositions to rule out the existence of polynomial kernels. We call this approach *fractalism*. In particular, we provide the source and the target problem, appropriate values for the edge cost c and the budget in the composed instance, and the required distance between the special vertices σ and τ.

We remark that there is a similar construction for directed graph problems using the directed T-fractal. Moreover, the construction with directed acyclic input graphs yields a directed acyclic graph. For more details, we refer to the full version.

4 Applications to Length-Bounded Cut Problems

In this section, we rule out the existence of polynomial kernels for several problems (and their variants) under the assumption that NP $\not\subseteq$ coNP / poly. To this end, we combine the framework of OR-cross-compositions with our fractalism technique as described in Section 3.2.

4.1 Length-Bounded Edge-Cut

Our first fractalism application is the Length-Bounded Edge-Cut problem [1], also known as the problem of finding bounded edge undirected cuts [13], or the Shortest Path Most Vital Edges problem [19, 3].

Length-Bounded Edge-Cut (LBEC)
Input: An undirected graph $G = (V, E)$, with $s, t \in V$, and two integers k, ℓ.
Question: Is there a subset $F \subseteq E$ of cardinality at most k such that $\text{dist}_{G-F}(s, t) \geq \ell$?

The problem is NP-complete [16] and fixed-parameter tractable with respect to (k, ℓ) [13]. If k is at least the size of any s-t edge cut, then the problem becomes polynomial-time solvable by simply computing a minimum s-t edge cut. Thus, throughout this section, we assume that k is smaller than the size of any minimum s-t edge cut. The generalized problem where each edge is equipped with positive length remains NP-hard even on series-parallel and outerplanar graphs [1]. The directed variant with positive edge lengths remains NP-hard on planar graphs where the source and the sink vertex are incident to the same face [22]. Recently, Dvořák and Knop [11] showed that the problem can be solved in polynomial time on graphs of bounded treewidth. Here, we answer an open question [13] concerning the existence of a polynomial kernel with respect to the combined parameter (k, ℓ).

▶ **Theorem 11.** *Unless* NP $\subseteq$ coNP / poly*,* Length-Bounded Edge-Cut *parameterized by* (k, ℓ) *does not admit a polynomial kernel.*

Proof. We OR-cross-compose $p = 2^q$ instances of LBEC into one instance of LBEC(k', ℓ'). An instance $(G_i, s_i, t_i, k_i, \ell_i)$ of LBEC is called *bad* if $\max\{k_i, \ell_i\} > |E(G_i)|$ or $\min\{k_i, \ell_i\} < 0$. We define the polynomial equivalence relation $\mathcal{R}$ on the instances of LBEC as follows: two instances $(G_i, s_i, t_i, k_i, \ell_i)$ and $(G_j, s_j, t_j, k_j, \ell_j)$ of LBEC are $\mathcal{R}$-equivalent if and only if $k_j = k_i$ and $\ell_j = \ell_i$, or both are bad instances. Clearly, the relation $\mathcal{R}$ fulfills condition (i) of an equivalence relation (see Section 2). Observe that the number of equivalence classes of a finite set of instances is upper-bounded by the maximal size of a graph over the instances, hence condition (ii) holds. Thus, we consider p $\mathcal{R}$-equivalent instances $\mathcal{I}_i := (G_i, s_i, t_i, k, \ell)$, $i = 1, \ldots, p$. We remark that we can assume that $\ell \geq 3$, since otherwise LBEC is solvable in polynomial time by counting all edges connecting the source with the sink vertex. We OR-cross-compose into one instance $\mathcal{I} := (G, s, t, k', \ell')$ of LBEC(k', ℓ') with $k' = k^2 \cdot (\log(p) + 1) + k$ and $\ell' = \ell + \log(p)$ as follows.

Construction: Apply Construction 9 with edge cost $c = k^2$. In addition, set $s := \sigma$ and $t := \tau$. Let G denote the obtained graph.

Correctness: We show that $\mathcal{I}$ is a YES-instance if and only if there exists an $i \in [p]$ such that $\mathcal{I}_i$ is a YES-instance.

"⇐": Let $i \in [p]$ be such that $\mathcal{I}_i$ is YES. Following Observation 10 in Section 3.2, let C be the minimum s-t cut in $\triangle_q^c$ that selects instance $\mathcal{I}_i$. Recall that C is of size $q+1$ and that the edge cost equals k^2. Thus, the minimum s-t cut C has cost $(q+1) \cdot k^2 = (\log(p)+1) \cdot k^2$.

Note that after deleting the edges in C, the vertices s and t are only connected via paths through the incorporated graph G_i. Since $\mathcal{I}_i$ is YES, we can delete k edges (equal to the remaining budget) such that the distance of s_i and t_i in G_i is at least ℓ. Together with Lemma 7 in Section 3.1, such an additional edge deletion increases the length of any shortest s-t path in G to at least $\ell + \log(p) = \ell'$. Hence, $\mathcal{I}$ is a YES-instance.

"⇒": Suppose that one can delete at most k' edges in G such that each s-t path is of length at least ℓ'. Since the budget allows $\log(p)+1$ edge-deletions in $\triangle_q^c$, by Lemma 8 in Section 3.1, if we do not cut s and t in $\triangle_q^c$, then there is an s-t path of length $\log(p)+2$. Since $\ell \geq 3$, such an edge deletion does not yield a solution. Thus, in every solution of $\mathcal{I}$, a subset of the deleted edges forms a minimum s-t edge cut in $\triangle_q^c$ and thus, by Observation 10, selects an input instance.

Consider an arbitrary solution to $\mathcal{I}$, that is, an edge subset of $E(G)$ of cardinality at most k' whose deletion increases the shortest s-t path to at least ℓ'. Let $\mathcal{I}_i$, $i \in [p]$, be the selected instance. Note that any shortest s-t path contains edges in the selected instance $\mathcal{I}_i$. By Lemma 7, we know that the length of the shortest s-s_i path and the length of the shortest t_i-t path sum up to exactly $\log(p)$. It follows that the remaining budget of k edge deletions is spent in G_i in such a way that there is no path from s_i to t_i of length smaller than ℓ in G_i. Hence, $\mathcal{I}_i$ is a YES-instance. ◀

Using LBEC on planar graphs and on planar directed acyclic graphs as the input problem, fractalism yields the following (the proof is deferred to the full version).

▶ **Theorem 12.** *Unless* NP $\subseteq$ coNP / poly, LENGTH-BOUNDED EDGE-CUT *on planar undirected graphs as well as on planar directed acyclic graphs parameterized by* (k, ℓ) *does not admit a polynomial kernel.*

4.2 Further Applications

We present two further problems (and their variants) to which the fractalism technique applies. First, we consider the following NP-hard [23] problem.

MINIMUM DIAMETER EDGE DELETION (MDED)
Input: A connected, undirected graph $G = (V, E)$, two integers k, ℓ.
Question: Is there a subset $F \subseteq E$ of cardinality at most k such that $G - F$ remains connected and $\operatorname{diam}(G - F) \geq \ell$?

Note that MDED on directed strongly connected graphs asks for a subset of arcs such that the graph after deleting the arcs remains strongly connected and has diameter at least ℓ. Our second NP-hard [15] problem is the following.

DIRECTED SMALL CYCLE TRANSVERSAL (DSCT)
Input: A directed graph $G = (V, E)$, two integers k, ℓ.
Question: Is there a subset $F \subseteq E$ of cardinality at most k such that there is no induced directed cycle of length at most ℓ in $G - F$?

Both problems are fixed-parameter tractable with respect to (k, ℓ) (see full version). The fractalism technique yields the following (the proofs are deferred to the full version).

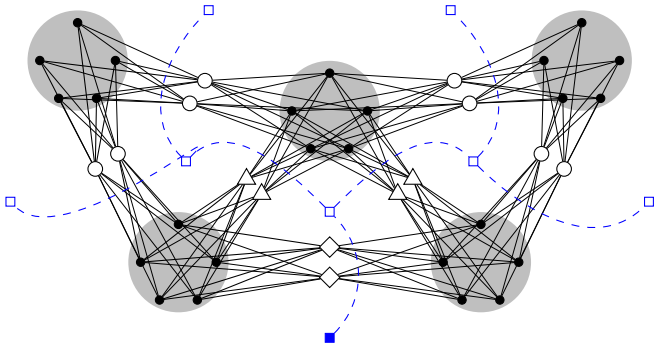

Figure 4 The vertex deletion variant $\triangle_2^{2;5}$ of T-fractals. Vertex types: empty diamonds belong to the boundary B_0, empty triangles belong to the boundary B_1, empty circles belong to the boundary B_2. The squares and dashed lines indicate the dual structure, where the filled square corresponds to the root. We highlighted vertices in gray-filled circles that correspond to the vertices in the edge-deletion variant $\triangle_2$.

▶ **Theorem 13.** *Unless* NP $\subseteq$ coNP / poly, Minimum Diameter Edge Deletion *on undirected, connected, planar graphs and on directed, strongly connected, planar graphs parameterized by* (k, ℓ) *does not admit a polynomial kernel.*

▶ **Theorem 14.** *Unless* NP $\subseteq$ coNP / poly, Directed Small Cycle Transversal *on planar directed graphs parameterized by* (k, ℓ) *does not admit a polynomial kernel.*

Like in the proof of Theorem 11, in the proofs of Theorems 13 and 14 we use LBEC as input problem and compose instances of LBEC using a T-fractal. The main difference is that we slightly modify the T-fractal. Roughly speaking, for MDED(k, ℓ) we append "long enough" paths to σ and τ, with endpoints σ' and τ' different to σ and τ. Those paths ensure that the only two vertices that can yield the required diameter are σ' and τ'. For DSCT(k, ℓ) we add the arc (τ, σ) to the directed T-fractal. Recall that the directed T-fractal is acyclic, and thus, every directed cycle in the composed graph contains the arc (τ, σ). For more details, we refer to the full version.

5 Conclusion

We start with briefly sketching how our technique can be adapted such that it also applies to the vertex deletion (instead of edge deletion) versions of the considered problems. Afterwards, we discuss future challenges and open problems.

Extension to Vertex-Deletion Variants. Most of our results can be transferred to the vertex deletion variants of the considered edge deletion problems as follows.

To this end, we modify the T-fractal as displayed in Figure 4:

First, subdivide each edge. Then, replace each vertex v in the original T-fractal by many pairwise non-adjacent vertices with the same neighborhood as v. The number of these introduced "false twins" is larger than the given budget such that the only way to disconnect vertices in the new fractal will be to delete vertices introduced from the subdivision of the edges. In this way, deleting a vertex in the new T-fractal corresponds to deleting an edge in the original fractal. This new fractal might not be planar anymore, but, as in the edge deletion variant, one can direct the edges in such a way that the obtained directed graph is acyclic.

We claim that the new T-fractal can be used in the same way as the original T-fractal in order to exclude polynomial kernels for vertex deletion variants of the problems discussed in this work – both in undirected and directed, but not for planar variants.

Outlook. We provided several case studies where our fractalism technique applies. It remains open to further explore the limitations and possibilities of our technique in more contexts. Table 1 in Section 1 presents an open question which should be clarified. Moreover, we could not settle the cases for vertex deletion problems when the underlying graphs are planar.

Acknowledgement. We thank Manuel Sorge (TU Berlin) for fruitful discussions.

Abstract

A key result in the field of kernelization, a subfield of parameterized complexity, states that the classic Disjoint Cycle Packing problem, i.e. finding k vertex disjoint cycles in a given graph G, admits no polynomial kernel unless NP $\subseteq$ coNP/poly. However, very little is known about this problem beyond the aforementioned kernelization lower bound (within the parameterized complexity framework). In the hope of clarifying the picture and better understanding the types of "constraints" that separate "kernelizable" from "non-kernelizable" variants of Disjoint Cycle Packing, we investigate two relaxations of the problem. The first variant, which we call Almost Disjoint Cycle Packing, introduces a "global" relaxation parameter t. That is, given a graph G and integers k and t, the goal is to find at least k distinct cycles such that every vertex of G appears in at most t of the cycles. The second variant, Pairwise Disjoint Cycle Packing, introduces a "local" relaxation parameter and we seek at least k distinct cycles such that every two cycles intersect in at most t vertices. While the Pairwise Disjoint Cycle Packing problem admits a polynomial kernel for all $t \geq 1$, the kernelization complexity of Almost Disjoint Cycle Packing reveals an interesting spectrum of upper and lower bounds. In particular, for $t = \frac{k}{c}$, where c could be a function of k, we obtain a kernel of size $\mathcal{O}(2^{c^2} k^{7+c} \log^3 k)$ whenever $c \in o(\sqrt{k})$. Thus the kernel size varies from being sub-exponential when $c \in o(\sqrt{k})$, to quasi-polynomial when $c \in o(\log^{\ell} k)$, $\ell \in \mathbb{R}_+$, and polynomial when $c \in \mathcal{O}(1)$. We complement these results for Almost Disjoint Cycle Packing by showing that the problem does not admit a polynomial kernel whenever $t \in \mathcal{O}(k^{\epsilon})$, for any $0 \leq \epsilon < 1$.

1 Introduction

Polynomial-time preprocessing is one of the widely used methods to tackle NP-hard problems in practice, as it plays well with exact algorithms, heuristics, and approximation algorithms. Until recently, there was no robust mathematical framework to analyze the performance of

preprocessing routines. Progress in parameterized complexity [11] made such an analysis possible. In parameterized complexity, each problem instance is coupled with a parameter k and the parameterized problem is said to admit a *kernel* if there is a polynomial-time algorithm, called a *kernelization* algorithm, that reduces the input instance down to an instance whose size is bounded by a function $f(k)$ in k, while preserving the answer. Such an algorithm is called an $f(k)$-*kernel* for the problem. If $f(k)$ is a polynomial, quasi-polynomial, subexponential, or exponential function of k, we say that this is a polynomial, quasi-polynomial, subexponential, or exponential kernel, respectively. Over the last decade or so, kernelization has become a very active field of study, especially with the development of complexity-theoretic tools to show that a problem does not admit a polynomial kernel [3, 12, 16, 18], or a kernel of a specific size [8, 9, 19]. We refer the reader to the survey articles by Kratsch [20] and Lokshtanov et al. [21] for recent developments.

One of the first and important problems to which the lower-bounds machinery was applied is the NP-complete Disjoint Cycle Packing problem. In the Disjoint Cycle Packing problem, we are given as input an n-vertex graph G and an integer k, and the task is to find a collection $\mathcal{C}$ of at least k pairwise disjoint vertex sets of G, such that every set $C \in \mathcal{C}$ induces a cycle in G. The Disjoint Cycle Packing problem can be solved in $\mathcal{O}(k^{k \log k} n^{\mathcal{O}(1)})$ using dynamic programming over graphs of bounded treewidth [2, 4]. Bodlaender et al. [5] showed that, when parameterized by k, Disjoint Cycle Packing does not admit a polynomial kernel unless NP $\subseteq$ coNP/poly (and the polynomial hierarchy collapses to its third level, which is considered very unlikely). Beyond the aforementioned negative result for polynomial kernels and the folklore $\mathcal{O}(k^{k \log k} n^{\mathcal{O}(1)})$-time algorithm, the Disjoint Cycle Packing problem has remained mostly unexplored from the viewpoint of parameterized complexity.

Our problems and results. In this paper we study two variants of Disjoint Cycle Packing, obtained by relaxing the disjointness constraint. In particular, we focus on the kernelization complexity of the Disjoint Cycle Packing problem by considering two relaxed versions of the problem, one with a "local" relaxation parameter and the other with a "global" relaxation parameter. In the locally relaxed variant, which we call Pairwise Disjoint Cycle Packing, the goal is to find at least k distinct cycles in a graph G such that they pairwise intersect in at most t vertices.

Pairwise Disjoint Cycle Packing	**Parameter:** k
Input: An undirected (multi) graph G and integers k and t	
Question: Does G have at least k distinct cycles $C_1, \ldots, C_k$ such that $\lvert V(C_i) \cap V(C_j) \rvert \leq t$ for all $i \neq j$?	

We consider two cycles to be distinct whenever their edge sets differ by at least one element. Note that when $t = 0$, Pairwise Disjoint Cycle Packing corresponds to the original Disjoint Cycle Packing problem. However, when $t = |V(G)|$ the Pairwise Disjoint Cycle Packing problem is solvable in time polynomial in $|V(G)|$ and k since we can enumerate distinct cycles in a graph with polynomial delay [24]. In other words, any k distinct cycles in a graph will trivially pairwise intersect in at most $|V(G)|$ vertices. We show that Pairwise Disjoint Cycle Packing remains NP-complete when $t = 1$. Then, we complement this result by showing that the problem admits a polynomial kernel for $t = 1$ and a polynomial compression for $t \geq 2$. An interesting problem which remains unclear is to determine what value of t separates NP-hard instances from polynomial-time solvable ones.

The second relaxation we consider is Almost Disjoint Cycle Packing. The goal in Almost Disjoint Cycle Packing is to determine whether G contains at least k distinct

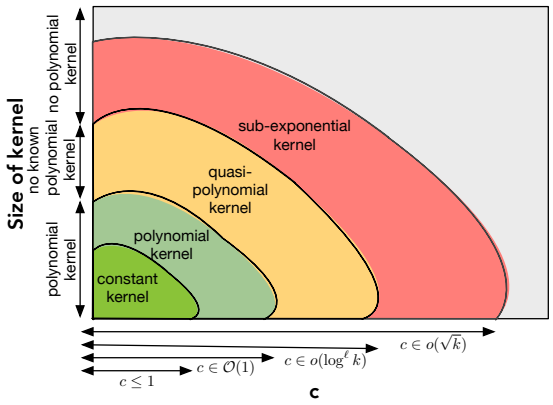

Figure 1 Spectrum of kernelization algorithms for Almost Disjoint Cycle Packing as c grows in the denominator of $t = \frac{k}{c}$.

cycles such that every vertex in $V(G)$ appears in at most t of them. As we shall see, the kernelization complexity landscape for Almost Disjoint Cycle Packing is much more diverse than that of Pairwise Disjoint Cycle Packing. In some sense, this suggests that the global relaxation parameter does a "better job" of capturing the "hardness" of the original problem.

Almost Disjoint Cycle Packing	**Parameter:** k
Input: An undirected (multi) graph G and integers k and t	
Question: Does G have at least k distinct cycles $C_1, \ldots, C_k$ such that every vertex in $V(G)$ appears in at most t of them?	

Again, for $t = 1$, Almost Disjoint Cycle Packing corresponds to Disjoint Cycle Packing and when $t = k$ the problem is solvable in time polynomial in $|V(G)|$ and k by simply enumerating distinct cycles. However, and rather surprisingly, we show that t has to be "very close" to k for this relaxation to become "easier" than the original problem, at least in terms of kernelization. In fact, we show that as long as $t = \mathcal{O}(k^{1-\epsilon})$, where $0 < \epsilon \leq 1$, Almost Disjoint Cycle Packing remains NP-complete and admits no polynomial kernel unless NP $\subseteq$ coNP/poly. We complement our hardness result by a spectrum of kernel upper bounds. To that end, we consider the case $t = \frac{k}{c}$, where c is a constant or a function of k. We show that we can (in polynomial time) compress an instance of Almost Disjoint Cycle Packing into an equivalent instance with $\mathcal{O}(2^{c^2} k^{7+c} \log^3 k)$ vertices. This implies polynomial, quasi-polynomial, or subexponential size kernels for Almost Disjoint Cycle Packing, depending on whether c is a constant, $c \in o(\log k)$, or $c \in o(\sqrt{k})$, respectively. It remains open whether the problem is in P or NP-hard for $t = \frac{k}{c}$, when c is a constant. A high level summary of our results for Almost Disjoint Cycle Packing is given in Figure 1. Most of the technical details and proofs have been omitted from this extended abstract.

Related Results. Our results also fit into the relatively new direction of research that is concerned with the parameterized complexity of problems with relaxed packing/covering constraints. For several important problems (that we need to solve), there are settings in which we need not be very strict about constraints. This is particularly interesting for "strict" problems where, e.g., (a) it is known that no polynomial kernels are possible unless NP $\subseteq$ coNP/poly, or where (b) the algorithm with the best running time matches

the known lower bound, or where (c) no considerable improvements have been made either algorithmically or in terms of kernel upper/lower bounds. The Disjoint Cycle Packing problem falls into categories (a) and (c) and is the main subject of this work. Before we state our results, let us look at some examples where the introduction of relaxation parameters has been successful. Abasi et al. [1], followed by Gabizon et al. [17], studied a generalization of the k-Path problem, namely r-Simple k-Path, where the task is to find a walk of length k that never visits any vertex more than r times. Here r is the relaxation parameter. By definition, the generalized problem is computationally harder than the original. However, observe that for $r = 1$ the problem is exactly the problem of finding a simple path of length k in G. On the other hand, for $r = k$ the problem is easily solvable in polynomial time, as any walk in G of length k will suffice. In some sense, the "further away" an instance of the generalized problem is from being an instance of the original, the easier the instance is. Put differently, gradually increasing r from 1 to k should make the problem computationally easier. This intuition was confirmed by the authors by providing, amongst other results, algorithms for the generalized problem whose worst-case running time matches the running time of the best algorithm for the original problem up to constants in the exponent, and improves significantly as the relaxation parameter increases. Also closely related is the work of Romero et. al. [26, 27] and Fernau et al. [14] who studied relaxations of graph packing problems allowing certain overlaps.

2 Preliminaries

We let $\mathbb{N}$ denote the set of natural numbers, $\mathbb{R}$ denote the set of real numbers, $\mathbb{R}_+$ denote the set of non-zero positive real numbers, and $\mathbb{R}_{\geq 1}$ denote the set of real numbers greater than or equal to one. For $r \in \mathbb{N}$, by $[r]$ we denote the set $\{1, 2, \ldots, r\}$.

Graphs. We use standard terminology from the book of Diestel [10] for those graph-related terms which are not explicitly defined here. We only consider finite graphs possibly having loops and multi-edges. For a graph G, $V(G)$ and $E(G)$ denote the vertex and edge sets of the graph G, respectively. For a vertex $v \in V(G)$, we use $d_G(v)$ to denote the degree of v, i.e the number of edges incident on v, in the (multi) graph G. We also use the convention that a loop at a vertex v contributes two to its degree. For a vertex subset $S \subseteq V(G)$, $G[S]$ and $G - S$ are the graphs induced on S and $V(G) \setminus S$, respectively. For a vertex subset $S \subseteq V(G)$, we let $N_G(S)$ and $N_G[S]$ denote the open and closed neighborhood of S in G. That is, $N_G(S) = \{v \mid (u, v) \in E(G), u \in S\} \setminus S$ and $N_G[S] = N_G(S) \cup S$. For a graph G and an edge $e \in E(G)$, G/e denotes the graph obtained by contracting e in G.

A *path* in a graph is a sequence of distinct vertices $v_0, v_1, \ldots, v_\ell$ such that (v_i, v_{i+1}) is an edge for all $0 \leq i < \ell$. A *cycle* in a graph is a sequence of distinct vertices $v_0, v_1, \ldots, v_\ell$ such that $(v_i, v_{(i+1) \mod \ell})$ is an edge for all $0 \leq i \leq \ell$. We note that both a double edge and a loop are cycles. If P is a path from a vertex u to a vertex v in graph G then we say that u and v are the end vertices of the path P and P is a (u, v)-path. For a path P, we use $V(P)$ to denote the set of vertices in the path P and the length of P is denoted by $|P|$ (i.e, $|P| = |V(P)|$). For a cycle C, we use $V(C)$ to denote the set of vertices in the cycle C and length of C, denoted by $|C|$, is $|V(C)|$. For a path or a cycle Q we use $N_G(Q)$ and $N_G[Q]$ to denote the set $N_G(V(Q))$ and $N_G[V(Q)]$, respectively. For a collection of paths/cycles $\mathcal{Q}$, we use $|\mathcal{Q}|$ to denote the number of paths/cycles in $\mathcal{Q}$ and $V(\mathcal{Q})$ to denote the set $\bigcup_{Q \in \mathcal{Q}} V(Q)$. We sometimes refer to a path or a cycle Q as a $|Q|$-path or $|Q|$-cycle. Given a vertex $v \in V(G)$, a *v-flower* of order k is a set of k cycles in G whose pairwise

intersection is exactly $\{v\}$. We say a set of distinct vertices $P = \{v_1, \ldots, v_\ell\}$ in G forms a *degree-two path* if P is a path and all vertices $\{v_1, \ldots, v_\ell\}$ have degree exactly two in G. We say P is a *maximal degree-two path* if no proper superset of P also forms a degree-two path. Finally, a *feedback vertex set* is a subset S of vertices such that $G - S$ is a forest.

▶ **Theorem 1** ([13]). *There exists a constant c such that every (multi) graph either contains k vertex disjoint cycles or it has a feedback vertex set of size at most $ck \log k$. Moreover, there is a polynomial-time algorithm that takes a graph G and an integer k as input, and outputs either k vertex disjoint cycles or a feedback vertex set of size at most $ck \log k$.*

Parameterized Complexity. We only state the basic definitions and general results needed for our purposes. For more details on parameterized complexity in general, and kernelization in particular, we refer the reader to the books of Downey and Fellows [11], Flum and Grohe [15], Niedermeier [23], and the more recent book by Cygan et al. [7].

▶ **Definition 2.** A *polynomial compression* of a parameterized language $L \subseteq \Sigma \times \mathbb{N}$ into a language $R \subseteq \Sigma^*$ is an algorithm that takes as input an instance $(I, k) \in \Sigma \times \mathbb{N}$, works in time polynomial in $|I| + k$, and returns a string I' such that:

- $|I'| \leq p(k)$ for some polynomial $p(.)$, and
- $|I'| \in R$ if and only if $(I, k) \in L$.

In case $|\Sigma| = 2$, the polynomial $p(.)$ is called the *bitsize* of the compression.

Note that polynomial compressions are a generalization of kernels and being able to rule out a compression algorithm automatically rules out a kernelization algorithm.

▶ **Definition 3.** Let $L, R \subseteq \Sigma \times \mathbb{N}$ be two parameterized problems. An algorithm $\mathcal{A}$ is called a *polynomial parameter transformation* from L to R if, given an instance (I, k) of problem :, $\mathcal{A}$ works in polynomial time and outputs an equivalent instance (I', k') of problem R, i.e., $(I, k) \in L$ if and only if $(I', k') \in R$, such that $k' \leq p(k)$ for some polynomial $p(.)$.

▶ **Theorem 4** ([7]). *Let $L, R \subseteq \Sigma \times \mathbb{N}$ be two parameterized problems and assume there exists a polynomial parameter transformation from L to R. Then, if R does not admit a polynomial compression, neither does L. In particular, if R does not admit a polynomial kernel unless NP $\subseteq$ coNP/poly then the same holds for L.*

3 Almost Disjoint Cycle Packing

As previously noted, Bodlaender et al. [5] showed that Disjoint Cycle Packing admits no polynomial kernel unless NP $\subseteq$ coNP/poly. On the other hand, finding k distinct cycles in a graph is solvable in time polynomial in n and k [24]. The intuition is that the more cycles we allow a vertex to belong to, the easier the problem of finding k distinct cycles should become. In this section, we study the spectrum of kernelization algorithms for Almost Disjoint Cycle Packing based on the "distance" between k and t. Recall that given an instance (G, k, t) of Almost Disjoint Cycle Packing, our goal is to find at least k distinct cycles such that each vertex appears in at most t of them. To formalize the notion of distance between k and t, we define the following class of problems.

Let $L = \{(G, k, t) \mid$ G has k cycles such that every vertex appears in at most t of them$\}$. Basically, L is the language Almost Disjoint Cycle Packing. For a monotonically increasing computable function $f : \mathbb{N} \to \mathbb{R}_+$, we define the following sub-language of L.

$$L_f = \{(G, k, t) \mid (G, k, t) \in L \text{ and } t = \lceil k/f(k) \rceil\}.$$

When f is the identity function, i.e. when $f(k) = k$, L_f is exactly the Disjoint Cycle Packing problem which is known not to admit a polynomial kernel [5]. In Section 3.1, we show that even when $f(k) = k^\epsilon$, for any fixed $0 < \epsilon \leq 1$, L_f (or equivalently Almost Disjoint Cycle Packing with $t = k^{1-\epsilon}$) is NP-complete and does not admit a polynomial kernel unless NP $\subseteq$ coNP/poly. If $f = a$ (a constant function), where $a \leq 1$ and $a \in \mathbb{R}_+$, then L_f can be decided in polynomial time (as finding any k distinct cycles is enough). This implies that for $f = a$ we have a constant kernel. In Section 3.2, we obtain a polynomial kernel for $f = c$ (another constant function), where $c > 1$ and $c \in \mathbb{R}$. In fact, our result implies that for $f \in \mathcal{O}(1)$, $f \in o(\log^\ell k)$ ($\ell \in \mathbb{N}$), or $f \in o(\sqrt{k})$, we can (in polynomial time) compress an instance of Almost Disjoint Cycle Packing into an equivalent instance of polynomial, quasi-polynomial, or subexponential size, respectively (see Figure 1).

Before we consider the kernelization complexity of the Almost Disjoint Cycle Packing problem, we first show, using standard arguments, that the problem is fixed-parameter tractable when parameterized by k. Armed with Theorem 1, we can assume that, for an instance (G, k, t) of Almost Disjoint Cycle Packing, the treewidth of G is at most $\mathcal{O}(k \log k)$; as G has a feedback vertex set of size at most $\mathcal{O}(k \log k)$. Courcelle's Theorem [6] gives a powerful way of quickly showing that a problem is fixed-parameter tractable on bounded treewidth graphs. That is, it suffices to show that our problem can be expressed in monadic second-order logic (MSO_2).

▶ **Theorem 5** ([6]). *If a graph property can be described as a formula ϕ in the monadic second-order logic of graphs, then it can be recognized in time $f(||\phi||, tw(G))(|E(G)| + |V(G)|)$ if a given graph G has this property, where f is a computable function, $||\phi||$ is the length of the encoding of ϕ as a string, and $tw(G)$ is the treewidth of G.*

▶ **Lemma 6.** Almost Disjoint Cycle Packing *can be solved in $f(k)n^{\mathcal{O}(1)}$ time, for some computable function f. In other words, the problem is fixed-parameter tractable when parameterized by k.*

3.1 Refuting polynomial kernels for $t = \mathcal{O}(k^{1-\epsilon})$

We now show that Almost Disjoint Cycle Packing restricted to L_f, where $f(k) = k^\epsilon$, does not admit a polynomial kernel, for any $0 < \epsilon \leq 1$, unless NP $\subseteq$ coNP/poly. Here k is the number of required cycles and $t = \frac{k}{f(k)} = k^{1-\epsilon}$ is the maximum number of cycles a vertex can belong to. Below we define the Disjoint Factors problem [5] which is known to admit no polynomial compression unless NP $\subseteq$ coNP/poly.

Let Σ_q be an alphabet set of q elements. By $\Sigma_q^\star$ we denote the set of all strings over Σ_q. A factor of a string $\bar{y} = y_1 y_2 \dots y_n \in \Sigma_q^\star$ is a pair (s, e), where $s, e \in [n]$ and $s < e$, such that $y_s y_{s+1} \dots y_e$ is a substring of $\bar{y}$ and $y_s = y_e$. Two factors (s, e) and (s', e') of $\bar{y}$ are said to be disjoint if $\{s, s+1, \dots, e\} \cap \{s', s'+1, \dots, e'\} = \emptyset$. The string $\bar{y}$ is said to have a disjoint factor over Σ_q if for all $x \in \Sigma_q$ there is a factor (s_x, e_x) such that $y_{s_x} = y_{e_x} = x$, and for all $x, \hat{x} \in \Sigma_q$, (s_x, e_x) and $(s_{\hat{x}}, e_{\hat{x}})$ are disjoint factors.

Disjoint Factors	**Parameter:** q
Input: Alphabet set Σ_q, string $\bar{y} \in \Sigma_q^\star$	
Question: Does $\bar{y}$ have a disjoint factor?	

Construction. We give a polynomial parameter transformation from an instance $(\Sigma_q, \bar{y})$ of Disjoint Factors to an instance (G, k, t) of Almost Disjoint Cycle Packing. For

technical reasons, we will assume that $t-1 = 2^l$, for some $l \in \mathbb{N}$. Note that this can be achieved by at most doubling the value of t while keeping t in $\mathcal{O}(k^{1-\epsilon})$. We let $l = \log_2(t-1)$. The end goal will be to construct a graph in which we have to find k cycles such that every vertex appears in at most $t = \mathcal{O}(k^{1-\epsilon})$ of them.

The reduction is as follows. Let $\Sigma_q = \{x_1, x_2, \dots x_q\}$. We create a vertex $\hat{x}_i \in V(G)$ corresponding to each element x_i, where $i \in [q]$. For $\bar{y} = y_1 y_2 \dots y_n \in \Sigma_q^\star$ we create a path $P_y = (u, \hat{y}_1, \hat{y}_2, \dots \hat{y}_n, u')$. We add an edge between $\hat{x}_i$ and $\hat{y}_j$, for $i \in [q]$ and $j \in [n]$, if and only if $x_i = y_j$. We also add four more vertices u_1, u_2, u_1', and u_2' to $V(G)$ and add edges (u_1, u_2), (u_2, u), (u, u_1), (u_1', u_2'), (u_2', u'), and (u', u_1') to $E(G)$. For each $x_i \in \Sigma$, we attach $t-1$ triangles to $\hat{x}_i$, i.e. we add edges $\{(z_i^1, \tilde{z}_i^1), (z_i^2, \tilde{z}_i^2), \dots, (z_i^{t-1}, \tilde{z}_i^{t-1})\}$ and $(z_i^j, \hat{x}_i), (\hat{x}_i, \tilde{z}_i^j)$, for $j \in [t-1]$. Next, we create a path $P_w = (w_1, w_1', w_2, w_2', \dots, w_l, w_l')$ in G. We add a set $R = \{r_i \mid i \in [l]\}$ of l of independent vertices and for $i \in [l]$, we add the edges (w_i, r_i) and (w_i', r_i) to $E(G)$. Finally, we add edges (u, w_1) and (w_l', u'). We set $k = tq + t + l + 1$, which completes the construction.

▶ **Proposition 7.** *Let $P = (s, a_1, a_1', a_2, a_2', \dots, a_n, a_n', s')$ be a path and $B = \{b_i \mid i \in [n]\}$ be a set of independent vertices. Let H be the graph consisting of path P, the set B, and, for $i \in [n]$, the edges (a_i, b_i) and (a_i', b_i). Then, for each $B' \subseteq B$, there is a path $P_{B'}$ such that $V(P_{B'}) \cap B = B'$. Moreover, the set $\mathcal{B} = \{P_{B'} \mid B' \subseteq B\}$ is the set of all possible paths between s, s' in H.*

Applying Proposition 7 to G, for each $R' \subseteq R$, we have a (unique) cycle $C_{R'}$ which contains all the vertices in $V(P_y)$, all the vertices in P_w, and exactly R' vertices from R. We define a family of cycles $\mathcal{R} = \{C_{R'} \mid R' \subseteq R\} \cup \{(w_i, w_i', r_i) \mid i \in [l]\}$. Note that $|\mathcal{R}| = 2^l + l = t + l - 1$ and each $C \in \mathcal{R}$ is a cycle in G. The intuition of having the set of cycles $\{C_{R'} \mid R' \subseteq R\}$ in G is that each vertex in path P_y must be used $t-1$ times and can therefore participate in one additional cycle (which contains vertices in $V(P_y)$). We associate each such extra cycle with a factor.

▶ **Theorem 8.** *Let $f : \mathbb{N} \to \mathbb{R}_{\geq 1}$ be a computable monotonically increasing function such that $f(k) \in \mathcal{O}(k^\epsilon)$, where $0 < \epsilon \leq 1$. Then,* Almost Disjoint Cycle Packing *admits no polynomial kernel over L_f unless NP $\subseteq$ coNP/poly.*

3.2 A kernel for Almost Disjoint Cycle Packing

Let $f : \mathbb{N} \to \mathbb{R}_{\geq 1}$ be a computable monotonically increasing function such that $f(k) \in o(\sqrt{k})$. In this section, we consider the Almost Disjoint Cycle Packing problem restricted to L_f. The kernelization algorithm presented below is inspired by the *lossy kernel* for the Cycle Packing problem given in [22]. To simplify notation, we let $c = f(k)$ and use c instead of $f(k)$ throughout the section, which implies that $t = \lceil \frac{k}{c} \rceil$. As we shall see, the assumption $c \in o(\sqrt{k})$ is required to guarantee that our kernelization algorithm does in fact run in time polynomial in the input size. We show that, as long as $c \in o(\sqrt{k})$, we can in polynomial time reduce an instance to at most $\mathcal{O}(2^{\lceil c \rceil^2} k^{7+\lceil c \rceil} \log^3 k)$ vertices. Our kernelization algorithm can be more or less divided into three stages. We start by computing (using Theorem 1) a feedback vertex set of size at most $\mathcal{O}(k \log k)$ and denote this set by F (assuming no k vertex disjoint cycles were found). We let $T = G - F$ and let $T_{\leq 1}$, T_2, and $T_{\geq 3}$, denote the sets of vertices in T having degree at most one in T, degree exactly two in T, and degree greater than two in T, respectively. Moreover, we let $\mathcal{P}$ denote the set of all maximal degree-two paths in $G[T_2]$. Next, we bound the size of $T_{\leq 1}$, which implies a bound on the size of $T_{\geq 3}$ and $\mathcal{P}$. In the second stage, we show that (roughly speaking) the graph can have at most

$\lceil c \rceil - 1$ vertices of high degree. Using this fact, the last stage consists of bounding the size of T_2.

Bounding the size of $T_{\leq 1}$. First, we get rid of vertices of degree one and two using Reduction Rules A1 and A2.

▶ **Reduction Rule A1.** *Delete vertices of degree zero or one in G.*

▶ **Reduction Rule A2.** *If there is a vertex v of degree exactly two in G then delete v and connect its two neighbors by a new edge.*

▶ **Reduction Rule A3.** *If there exists an edge $(u, v) \in E(G)$ of multiplicity more than $2t$ then reduce its multiplicity to $2t \leq 2k$.*

The fact that we can assume $2t \leq 2k$ follows from the observation that when $t = k$ the problem becomes solvable in time polynomial in n and k. Once Reduction Rules A1, A2, and A3 are no longer applicable, the minimum degree of the graph is three and the multiplicity of every edge is at most $2t$. Note that every vertex in $T_{\leq 1}$ is either a leaf or an isolated vertex in T. Therefore, every vertex of $T_{\leq 1}$ has at least two neighbours in F. For $(u, v) \in F \times F$, let $L(u, v)$ be the set of vertices of degree at most one in $T = G - F$ such that each $x \in L(u, v)$ is adjacent to both u and v (if $u = v$, then $L(u, u)$ is the set of vertices which have degree at most one in $T = G - F$ and at least two edges to u). For each pair $(u, v) \in F \times F$, we mark $|F|\lceil \frac{k}{c} \rceil + 2k + 1$ vertices from $L(u, v)$ if $L(u, v) > |F|\lceil \frac{k}{c} \rceil + 2k + 1$ and mark all vertices in $L(u, v)$ if $L(u, v) \leq |F|\lceil \frac{k}{c} \rceil + 2k + 1$.

▶ **Reduction Rule A4 [22].** *If $|T_{\leq 1}| \geq |F|^2(|F|\lceil \frac{k}{c} \rceil + 2k + 1) + 1$ then there exists an unmarked vertex $v \in T_{\leq 1}$.*

- *If $d_{G-F}(v) = 0$ then delete v.*
- *If $d_{G-F}(v) = 1$ contract the unique edge in $G - F$ which is incident to v. We let e denote this unique edge and we let w denote the other endpoint onto which we contract e.*

Bounding the number of high-degree vertices. When none of the aforementioned reduction rules are applicable, the size of $T_{\leq 1}$, $T_{\geq 3}$, and $\mathcal{P}$, is at most $|F|^2(|F|\lceil \frac{k}{c} \rceil + 2k + 1) = \mathcal{O}(k^4 \log^3 k)$. Consider $\mathcal{P}$, i.e. the collection of maximal degree-two paths in T_2, and assume that there exists a set $F_{\lceil c \rceil} = \{x_1, \ldots, x_{\lceil c \rceil}\} \subseteq F$ (of size $\lceil c \rceil$) such that for every vertex $x \in F_{\lceil c \rceil}$ there exists a path $P \in \mathcal{P}$ such that x has at least $4k\lceil c \rceil$ neighbours in P. We show that if $F_{\lceil c \rceil}$ exists then we have a yes-instance.

▶ **Reduction Rule A5.** *If there exists a set of $\lceil c \rceil$ vertices $F_{\lceil c \rceil} = \{x_1, \ldots, x_{\lceil c \rceil}\} \subseteq F$ such that for all x_i, $1 \leq i \leq \lceil c \rceil$, $|N_G(x_i) \cap V(\mathcal{P})| > |F|^2(|F|\lceil \frac{k}{c} \rceil + 2k + 1)4k\lceil c \rceil$, then return a trivial yes-instance.*

After applying Reduction Rule A5, there can be at most $\lceil c \rceil - 1$ vertices in F having more than $|F|^2(|F|\lceil \frac{k}{c} \rceil + 2k + 1)4k\lceil c \rceil = \mathcal{O}(k^5 \log^3 k)$ neighbors in T_2. We let $F_{\lceil c \rceil - 1} \subseteq F$ denote the maximum sized such subset and we let $F^\star = F \setminus F_{\lceil c \rceil - 1}$. For any vertex $x \in F^\star$, $|N_G(x) \cap V(\mathcal{P})| \leq |F|^2(|F|\lceil \frac{k}{c} \rceil + 2k + 1)4k\lceil c \rceil$ and, consequently, $|N_G(F^\star) \cap V(\mathcal{P})| \leq |F|^2(|F|\lceil \frac{k}{c} \rceil + 2k + 1)4k\lceil c \rceil |F^\star| \leq |F|^3(|F|\lceil \frac{k}{c} \rceil + 2k + 1)4k\lceil c \rceil = \mathcal{O}(k^6 \log^3 k)$.

Bounding the size of T_2. We start by marking all vertices in F, $T_{\leq 1}$, $T_{\geq 3}$, and $N_G(F^\star) \cap V(\mathcal{P})$. The total number of marked vertices is therefore in $\mathcal{O}(k^6 \log^3 k)$. Moreover, all the unmarked vertices must be in T_2 and form degree-two paths. Each unmarked vertex must

have at least one neighbor in $F_{\lceil c\rceil-1}$ and cannot have neighbors in $F^\star$. We call a set of unmarked vertices a *region* if they form a maximal path in $G[T_2]$. At this point, the total number of regions is in $\mathcal{O}(k^6 \log^3 k)$, as the number of marked vertices is in $\mathcal{O}(k^6 \log^3 k)$. Therefore, our last step is to bound the size of each region. To do so, we first recursively further subdivide each region as follows. Fix a region R and check for each vertex $x_i \in F_{\lceil c\rceil-1}$, the value of $|N_G(x_i) \cap R|$. If $|N_G(x_i) \cap R| < 4k\lceil c\rceil 2^{\lceil c\rceil}$, then we again mark the vertices in $N_G(x_i) \cap R$, increasing the number of regions by a multiplicative factor of at most $4k\lceil c\rceil 2^{\lceil c\rceil}$. We repeat this process as long as there exists a region R and a vertex $x_i \in F_{\lceil c\rceil-1}$ satisfying $|N_G(x_i) \cap R| < 4k\lceil c\rceil 2^{\lceil c\rceil}$. Since $|F_{\lceil c\rceil-1}| < \lceil c\rceil$, repeating this procedure for every region and every vertex in $F_{\lceil c\rceil-1}$ increases the number of regions to at most $\mathcal{O}(2^{\lceil c\rceil^2} k^{6+\lceil c\rceil} \log^3 k)$; each of the initial $\mathcal{O}(k^6 \log^3 k)$ regions can be subdivided into at most $(4k\lceil c\rceil 2^{\lceil c\rceil})^{\lceil c\rceil}$ subregions.

▶ **Lemma 9.** *Let H be a graph consisting of a path P and an independent set $X = \{x_1, \ldots, x_{\lceil c\rceil}\}$ of size $\lceil c\rceil \geq 1$. Let $k \geq \lceil c\rceil^2$ be an integer. If $\forall x \in X$ we have $|N_H(x)| \geq 4k\lceil c\rceil 2^{\lceil c\rceil}$ and $\forall p \in V(P)$ we have $|N_H(p) \cap X| > 0$, then we can construct a set of distinct cycles $\mathcal{C} = \mathcal{C}_1 \cup \ldots \cup \mathcal{C}_{\lceil c\rceil}$ such that (a) $|\mathcal{C}_i| = \lceil \frac{k}{c} \rceil$, (b) all cycles in $\mathcal{C}_i$ pairwise intersect in x_i, and (c) every vertex in P appears in at most one cycle in $\mathcal{C}$.*

Using Lemma 9, we can get an upper bound on the size of a region R by applying the following reduction rule. Recall that by construction (and after subdividing regions), vertices of a region have neighbours only in $F_{\lceil c\rceil-1}$, where $F_{\lceil c\rceil-1}$ is a set of at most $\lceil c\rceil - 1$ vertices. In fact, for each region R, there exists a set $F_R \subseteq F_{\lceil c\rceil-1}$ such that each vertex in R has at least one neighbor in F_R and each vertex in F_R has at least $4k\lceil c\rceil 2^{\lceil c\rceil}$ neighbors in R.

▶ **Reduction Rule A6.** *Let R be a region such that $|R| > 4k\lceil c\rceil 4^{\lceil c\rceil}$. Let $\mathcal{Q} = \{Q_1, Q_2, \ldots\}$ be a family of sets which partitions R such that for any two vertices $u, v \in R$, we have $u, v \in Q_i$ if and only if $N_G(u) \cap F_R = N_G(v) \cap F_R$. In other words, two vertices belong to the same set in $\mathcal{Q}$ if and only if they share the same neighborhood in F_R. Since $|R| > 4k\lceil c\rceil 4^{\lceil c\rceil}$ and $|\mathcal{Q}| \leq 2^{\lceil c\rceil}$, there exists a set $Q \in \mathcal{Q}$ such that $|Q| > 4k\lceil c\rceil 2^{\lceil c\rceil}$. Let v be a vertex in Q and let w be a neighbor of v in R (v can have at most two neighbors in R). Contract the edge (v, w) onto w. Note that since $|Q| > 4k\lceil c\rceil 2^{\lceil c\rceil}$, each vertex in F_R has at least $4k\lceil c\rceil 2^{\lceil c\rceil}$ neighbors in R even after the contraction.*

Since the number of regions is in $\mathcal{O}(2^{\lceil c\rceil^2} k^{6+\lceil c\rceil} \log^3 k)$ and the size of a region is at most $4kc4^c$, the theorem follows.

▶ **Theorem 10.** *Let $f : \mathbb{N} \to \mathbb{R}_{\geq 1}$ be a computable monotonically increasing function such that $f(k) \in o(\sqrt{k})$. For $c = f(k)$,* Almost Disjoint Cycle Packing *admits a kernel consisting of at most $\mathcal{O}(2^{c^2} k^{7+c} \log^3 k)$ vertices over L_f.*

Theorem 10 implies that when $c \in o(\sqrt{k})$ the Almost Disjoint Cycle Packing problem admits a subexponential kernel. When $c \in o(\log^\ell k)$, $\ell \in \mathbb{N}$, the problem admits a quasi-polynomial kernel. Finally, when $c \in \mathcal{O}(1)$ the problem admits a polynomial kernel.

4 Pairwise Disjoint Cycle Packing

Recall that in the Pairwise Disjoint Cycle Packing problem, given a graph G and integers k and t, the goal is to find at least k cycles such that every pair of cycles intersects in at most t vertices. To show NP-completeness of Pairwise Disjoint Cycle Packing, for $t = 1$, we give a reduction from a variant of SAT called 2/2/4-SAT defined as follows: Each clause contains four literals, each variable appears four times in the formula, twice

negated and twice not negated, and the question is whether there is a truth assignment of the variables such that in each clause there are exactly two true literals. This variant was shown NP-complete by Ratner and Warrnuth [25].

▶ **Theorem 11.** Pairwise Disjoint Cycle Packing *is NP-complete for* $t = 1$.

4.1 A polynomial kernel for $t = 1$

There are many similarities but also some subtle differences when dealing with the cases $t = 1$ and $t \geq 2$. For instance, for any value of $t \geq 1$, finding a flower of order k in the graph is sufficient to solve the problem. On the other hand, not all vertices of degree two can be bypassed when $t \geq 2$. More importantly, finding two vertices in G with more than $2k$ common neighbors is enough to solve the problem for $t \geq 2$ but not for $t = 1$. As we shall see, this seemingly small difference requires major changes when dealing with the case $t = 1$. We start with some classical results and reduction rules which will be used throughout. Whenever some reduction rule applies, we apply the lowest-numbered applicable rule.

The first step in our kernelization algorithm is to run the algorithm of Theorem 1 and either output a trivial yes-instance (if k vertex disjoint cycles are found) or mark the vertices of the feedback vertex set and denote this set by F. We proceed with the following simple reduction rules to handle low-degree vertices and self-loops in the graph.

▶ **Reduction Rule B1.** *Delete vertices of degree zero or one in* G.

▶ **Reduction Rule B2.** *If there is a vertex* v *of degree exactly two in* G *then delete* v *and connect its two neighbors by a new edge.*

▶ **Reduction Rule B3.** *If there exists a vertex* $v \in V(G)$ *with a self-loop then delete the loop (not the vertex) and decrease the parameter* k *by one.*

▶ **Reduction Rule B4.** *If there is a pair of vertices* u *and* v *in* $V(G)$ *such that there are more than two parallel edges between them then reduce the multiplicity of the edge to two.*

Once none of the above reduction rules are applicable, our next goal is to bound the maximum degree in the graph. To do so, we make use of the following.

▶ **Lemma 12** ([7]). *Given a (multi) graph* G*, an integer* k*, and a vertex* $v \in V(G)$*, there is a polynomial-time algorithm that either finds a* v*-flower of order* k *or finds a set* Z_v *such that* $Z_v \subseteq V(G) \setminus \{v\}$ *intersects all cycles passing through* v*,* $|Z_v| \leq 2k$*, and there are at most* $2k$ *edges incident to* v *and with second endpoint in* Z_v.

A *q-star*, $q \geq 1$, is a graph with $q + 1$ vertices, one vertex of degree q and all other vertices of degree 1. Let G be a bipartite graph with vertex bipartition (A, B). A set of edges $M \subseteq E(G)$ is called a *q-expansion* of A into B if (i) every vertex of A is incident with exactly q edges of M and (ii) M saturates exactly $q|A|$ vertices in B, i.e. there is a set of $q|A|$ vertices in B which are incident to edges in M.

▶ **Lemma 13** (See [7, 28]). *Let* q *be a positive integer and* G *be a bipartite graph with vertex bipartition* (A, B) *such that* $|B| \geq q|A|$ *and there are no isolated vertices in* B*. Then, there exist nonempty vertex sets* $X \subseteq A$ *and* $Y \subseteq B$ *such that:*

- X *has a* q*-expansion into* Y *and*
- *no vertex in* Y *has a neighbour outside* X*, i.e.* $N(Y) \subseteq X$.

Furthermore, the sets X *and* Y *can be found in time polynomial in the size of* G.

For every vertex $v \in V(G)$ of high degree (which will be specified later), we apply the algorithm of Lemma 12. If the algorithm finds a v-flower of order k, the following reduction rule allows us to deal with it.

▶ **Reduction Rule B5.** *If G has a vertex v such that there is a v-flower of order at least k then return a trivial yes-instance.*

Hence, in what follows we assume that no such flower was found but instead we have a set Z_v of size at most $2k$ such that $Z_v \subseteq V(G)$ intersects all cycles passing through v. Consider the connected components of the graph $G[V(G) \setminus (Z_v \cup \{v\})]$. At most $k-1$ of those components can contain a cycle, as otherwise we again have a trivial yes-instance consisting of k vertex disjoint cycles.

▶ **Reduction Rule B6.** *If there are k or more components in $G \setminus (\{v\} \cup Z_v)$ containing a cycle then return a trivial yes-instance.*

Moreover, for every component D of $G[V(G) \setminus (Z_v \cup \{v\})]$, we have $|N_G(v) \cap V(D)| \leq 1$. In other words, v has at most one neighbor in any component and out of those components at most $k-1$ are not trees. Let $\mathcal{D} = \{D_1, D_2, \ldots, D_q\}$ denote those trees in which v has a neighbor. Since the minimum degree of the graph is three, every leaf of a tree in $\mathcal{D}$ must have at least one neighbor in Z_v.

▶ **Lemma 14.** *Let $\mathcal{C} = \{C_1, \ldots, C_k\}$ be a solution in G and let C be a cycle in $\mathcal{C}$ such that $V(C) \cap (Z_v \cup \{v\}) \neq \emptyset$. Then, C can intersect with at most $2k+1$ components in $\mathcal{D}$ and therefore the solution $\mathcal{C}$ can intersect with at most $2k^2 + k$ components in $\mathcal{D}$.*

We now construct a bipartite graph $\mathcal{H}$ with bipartition $(A = Z_v, B = \mathcal{D})$. We slightly abuse notation and assume that every component in $\mathcal{D}$ corresponds to a vertex in B and every vertex in Z_v corresponds to a vertex in A. For every $D_i \in \mathcal{D}$ and for every $z \in Z_v$, $(D_i, z) \in E(\mathcal{H})$ if and only if there exists $u \in V(D_i)$ such that $(u, z) \in E(G)$. After exhaustive application of Reduction Rule B4, every pair of vertices in G can have at most two edges between them. In particular, there can be at most two edges between any $z \in Z_v$ and v. Therefore, if the degree of v in G is more than $(2k^2 + k + 2)2k + 3k - 1$ then the number of components $|\mathcal{D}|$ is at least $(2k^2 + k + 2)2k$ (taking into account the at most $k-1$ neighbors of v in components containing a cycle as well as the at most $2k$ edges incident to v and some vertex in Z_v). Consequently, $|\mathcal{D}| \geq (2k^2 + k + 2)|Z_v|$. We are now ready to state our main reduction rule.

▶ **Reduction Rule B7.** *If there exists a vertex $v \in V(G)$ such that $d_G(v) > (2k^2 + k + 2)2k + 3k - 1$ then apply Lemma 13 with $q = 2k^2 + k + 2$ in the bipartite graph $\mathcal{H}$.*

- *Let $\mathcal{D}' \subseteq \mathcal{D}$ and $Z'_v \subseteq Z_v$ be the sets obtained after applying Lemma 13 with $q = 2k^2 + k + 2$, $A = Z_v$, and $B = \mathcal{D}$, such that Z'_v has a $(2k^2 + k + 2)$-expansion into $\mathcal{D}'$ in $\mathcal{H}$.*
- *Delete all the edges of the form $(u, v) \in E(G)$ such that $u \in D_i$ and $D_i \in \mathcal{D}'$.*
- *Add two parallel edges between v and every vertex in Z'_v.*

We now have all the required ingredients to bound the size of our kernel. From Theorem 1, we know that the graph has a feedback vertex set F of size at most $\mathcal{O}(k \log k)$. The degree of any vertex in the graph is at least three (Reduction Rule B2) and at most in $\mathcal{O}(k^3)$ (Reduction Rule B7). Theorem 16 follows from combining these facts with Lemma 15.

▶ **Lemma 15** ([7]). *Let $G = (V, E)$ be an undirected (multi) graph having minimum degree at least three, maximum degree at most d, and a feedback vertex set of size at most r. Then, $|V(G)| < (d+1)r$ and $|E(G)| < 2dr$.*

▶ **Theorem 16.** *For $t = 1$,* Pairwise Disjoint Cycle Packing *admits a kernel with $\mathcal{O}(k^4 \log k)$ vertices and $\mathcal{O}(k^4 \log k)$ edges.*

4.2 A polynomial compression for $t \geq 2$ (independent of t)

When $t \geq 2$, finding two vertices in G with $2k$ internally vertex-disjoint paths connecting them is enough to pack k cycles pairwise intersecting in at most 2 vertices. Hence, bounding the maximum degree is relatively easy. We first mark the feedback vertex set F and exhaustively apply Reduction Rule B1 and the following modified variant of Reduction Rule B2.

▶ **Reduction Rule B8.** *If there exists a set of vertices $P = \{v_1, \ldots, v_{t+2}\} \subseteq V(G)$ such that $G[P]$ is a path, $d_G(v_i) = 2$, $2 \leq i \leq t+1$, and $|P| \geq t+2$, then contract the edge v_1v_2.*

As before, for every vertex $v \in V(G)$, we apply the algorithm of Lemma 12. If the algorithm finds a v-flower of order k, we apply Reduction Rule B5. Otherwise, consider the connected components of the graph $G[V(G) \setminus (Z_v \cup \{v\})]$. We ignore the at most $k-1$ components that can contain a cycle and focus on the set $\mathcal{D} = \{D_1, D_2, \ldots, D_q\}$ of trees in which v has a neighbor (recall that $|N_G(v) \cap V(D)| \leq 1$ for all $D \in \mathcal{D}$ and each component D must have a neighbor in Z_v).

▶ **Reduction Rule B9.** *If $|\mathcal{D}| > 4k-2$ (or equivalently if $d_G(v) > 7k-3$) return a trivial yes-instance.*

Having bounded the maximum degree of any vertex by $\mathcal{O}(k)$, we immediately obtain a bound of $\mathcal{O}(k^2 \log k)$ on $|T_{\leq 1}|$, $|T_{\geq 3}|$, and the number of maximal degree-two paths in T_2. Recall that $T_{\leq 1}$, T_2, and $T_{\geq 3}$, are the sets of vertices in $T = G[V(G) \setminus F]$ having degree at most one in T, degree exactly two in T, and degree greater than two in T, respectively. To bound the size of T_2, note that if we mark all vertices in $F \cup N_G(F)$ we would have marked a total of $\mathcal{O}(k^2 \log k)$ vertices and the only unmarked vertices form (not necessarily maximal) degree-two paths in T_2 (and G), which we call segments. However, we know from Reduction Rule B8 that the size of any segment is at most $t+1$. Moreover, the total number of such segments is at most $\mathcal{O}(k^2 \log k)$. Putting it all together, we now have a kernel with $\mathcal{O}(tk^2 \log k)$ vertices.

▶ **Lemma 17.** *For any $t \geq 2$,* Pairwise Disjoint Cycle Packing *admits a kernel with $\mathcal{O}(tk^2 \log k)$ vertices.*

More work is needed to get rid of the dependence on t. The first step is to show that we can solve Pairwise Disjoint Cycle Packing in $c^{p(k)}n^{\mathcal{O}(1)}$ time, where c is a fixed constant and $p(.)$ is a polynomial function in k. In the second step, we introduce a "succinct" version of Pairwise Disjoint Cycle Packing, namely Succinct Pairwise Disjoint Cycle Packing, and show that we can reduce Pairwise Disjoint Cycle Packing to an instance of Succinct Pairwise Disjoint Cycle Packing where all the information can be encoded using a number of bits polynomially bounded in k alone.

Succinct Pairwise Disjoint Cycle Packing	**Parameter:** k
Input: An undirected (multi) graph G, integers k and t, a weight function $\alpha : V(G) \to \mathbb{N}$, and a weight function $\beta : E(G) \to \mathbb{N}$	
Question: Does G have at least k distinct cycles $C_1, \ldots, C_k$ such that $\alpha(V(C_i) \cap V(C_j)) \leq t$ and $\beta(E(C_i) \cap E(C_j)) \leq t$ for all $i \neq j$?	

▶ **Lemma 18.** *For any $t \geq 2$,* Pairwise Disjoint Cycle Packing *can be solved in $2^{k^3 \log k} n^{\mathcal{O}(1)}$ time.*

▶ **Theorem 19.** *For any $t \geq 2$, we can compress an instance of* Pairwise Disjoint Cycle Packing *to an equivalent instance of* Succinct Pairwise Disjoint Cycle Packing *using at most $\mathcal{O}(k^5 \log^2 k)$ bits. In other words,* Pairwise Disjoint Cycle Packing *admits a polynomial compression.*

Abstract

Given a directed graph G and a list $(s_1, t_1), \ldots, (s_k, t_k)$ of terminal pairs, the Directed Steiner Network problem asks for a minimum-cost subgraph of G that contains a directed $s_i \to t_i$ path for every $1 \leq i \leq k$. The special case Directed Steiner Tree (when we ask for paths from a root r to terminals $t_1, \ldots, t_k$) is known to be fixed-parameter tractable parameterized by the number of terminals, while the special case Strongly Connected Steiner Subgraph (when we ask for a path from every t_i to every other t_j) is known to be W[1]-hard parameterized by the number of terminals. We systematically explore the complexity landscape of directed Steiner problems to fully understand which other special cases are FPT or W[1]-hard. Formally, if $\mathcal{H}$ is a class of directed graphs, then we look at the special case of Directed Steiner Network where the list $(s_1, t_1), \ldots, (s_k, t_k)$ of requests form a directed graph that is a member of $\mathcal{H}$. Our main result is a complete characterization of the classes $\mathcal{H}$ resulting in fixed-parameter tractable special cases: we show that if every pattern in $\mathcal{H}$ has the combinatorial property of being "transitively equivalent to a bounded-length caterpillar with a bounded number of extra edges," then the problem is FPT, and it is W[1]-hard for *every* recursively enumerable $\mathcal{H}$ not having this property. This complete dichotomy unifies and generalizes the known results showing that Directed Steiner Tree is FPT [Dreyfus and Wagner, *Networks* 1971], Strongly Connected Steiner Subgraph is W[1]-hard [Guo et al., *SIAM J. Discrete Math.* 2011], and Directed Steiner Network is solvable in polynomial-time for constant number of terminals [Feldman and Ruhl, *SIAM J. Comput.* 2006], and moreover reveals a large continent of tractable cases that were not known before.

cost tree connecting the terminals. The problem is well known to be NP-hard, in fact, it was one of the 21 NP-hard problems identified by Karp's seminal paper [22]. There is a large literature on approximation algorithms for Steiner Tree and its variants, resulting for example in constant-factor approximation algorithms for general graphs and approximation schemes for planar graphs (see [8, 15, 9, 4, 3, 2, 7, 26, 24, 23, 1, 17]). From the viewpoint of parameterized algorithms, the first result is the classic dynamic-programming algorithm of Dreyfus and Wagner [17] from 1971, which solves the problem with $k = |R|$ terminals in time $3^k \cdot n^{O(1)}$, showing that the problem is fixed-parameter tractable (FPT) parameterized by the number of terminals. More recently, the running time was improved to $2^k \cdot n^{O(1)}$ by Björklund et al. [5] using the technique of fast subset convolution. Steiner Forest is the generalization where the input contains an edge-weighted graph G and a list $(s_1, t_1), \ldots, (s_k, t_k)$ of pairs of terminals and the task is to find a minimum-cost subgraph containing an s_i–t_i path for every $1 \leq i \leq k$. The fixed-parameter tractability of Steiner Forest follows from the observation that the connected components of the solution induces a partition on the set $\{s_1, \ldots, s_k, t_1, \ldots, t_k\}$ of terminals, and hence we can solve the problem by for example trying every partition and invoking a Steiner Tree algorithm for each class of the partition.

On directed graphs, Steiner problems can become significantly harder, and while there is a richer landscape of variants, very few results are known [21, 11, 18, 10, 27, 14, 13]. A natural and well-studied generalization of Steiner Tree to directed graphs is Directed Steiner Tree (DST), where an arc-weighted directed graph G and terminals $r, t_1, \ldots, t_k$ are given and the tasks is to find a minimum-cost subgraph containing an $r \to t_i$ path for every $1 \leq i \leq k$. Using essentially the same techniques as in the undirected case [5, 17], one can show that this problem is also FPT parameterized by the number of terminals. An equally natural generalization of Steiner Tree to directed graphs is the Strongly Connected Steiner Subgraph (SCSS) problem, where an arc-weighted directed graph G with terminals $t_1, \ldots, t_k$ is given, and the task is to find a minimum-cost subgraph containing a $t_i \to t_j$ path for any $1 \leq i, j \leq k$ with $i \neq j$. Guo et al. [21] showed that, unlike DST, the SCSS problem is W[1]-hard parameterized by the number k of terminals (see also [14]). A common generalization of DST and SCSS is the Directed Steiner Network (DSN) problem (also called Directed Steiner Forest or Point-to-Point Connection), where an arc-weighted directed graph G and a list $(s_1, t_1), \ldots, (s_k, t_k)$ of terminal pairs are given and the task is to find a minimum-cost subgraph containing an $s_i \to t_i$ path for every $1 \leq i \leq k$. Being a generalization of SCSS, the Directed Steiner Network problem is also W[1]-hard, but Feldman[1] and Ruhl [18] showed that the problem is solvable in time $n^{O(k)}$, that is, in polynomial time for every constant k.

Besides Directed Steiner Tree, what other special cases of Directed Steiner Network are fixed-parameter tractable? Our main result gives a complete map of the complexity landscape of directed Steiner problems, precisely describing all the FPT/W[1]-hard variants and revealing highly non-trivial generalizations of Directed Steiner Tree that are still tractable. Our results are expressed in the following formal framework. The pairs $(s_1, t_1), \ldots, (s_k, t_k)$ in the input of DSN can be interpreted as a directed (unweighted) *pattern graph* on a set R of terminals. If this pattern graph is an out-star, then the problem is precisely DST; if it is a bidirected clique, then the problem is precisely SCSS. More generally, if $\mathcal{H}$ is any class of graphs, then we define the Directed Steiner $\mathcal{H}$-Network ($\mathcal{H}$-DSN) problem as the restriction of DSN where the pattern graph is a member of $\mathcal{H}$. That is, the

[1] We note that Jon Feldman (co-author of [18]) is not the same person as Andreas Emil Feldmann (co-author of this paper).

Figure 1 Two 4-caterpillars: an out- (left) and an in-caterpillar (right).

input of $\mathcal{H}$-DSN is an arc-weighted directed graph G, a set $R \subseteq V(G)$ of terminals, and an unweighted directed graph $H \in \mathcal{H}$ on R; the task is to find a minimum-cost network $N \subseteq G$ such that N contains an $s \to t$ path for every $st \in E(H)$.

We give a complete characterization of the classes $\mathcal{H}$ for which $\mathcal{H}$-DSN is FPT or W[1]-hard. We need the following definition of "almost-caterpillar graphs" to describe the borderline between the easy and hard cases (see Figure 1).

▶ **Definition 1.** A λ_0-*caterpillar* graph is constructed as follows. Take a directed path $(v_1, \ldots, v_{\lambda_0})$ from v_1 to v_{λ_0}, and let $W_1, \ldots, W_{\lambda_0}$ be pairwise disjoint vertex sets such that $v_i \in W_i$ for each $i \in \{1, \ldots, \lambda_0\}$. Now add edges such that either every W_i forms an out-star with root v_i, or every W_i forms an in-star with root v_i. In the former case we also refer to the resulting λ_0-caterpillar as an *out-caterpillar*, and in the latter as an *in-caterpillar*. A 0-caterpillar is the empty graph. The class $\mathcal{C}_{\lambda,\delta}$ contains all directed graphs H such that there is a set of edges $F \subseteq E(H)$ of size at most δ for which the remaining edges $E(H) \setminus F$ span a λ_0-caterpillar for some $\lambda_0 \leq \lambda$.

If there is an $s \to t$ path in the pattern graph H for two terminals $s, t \in R$, then adding the edge st to H does not change the problem: connectivity from s to t is already implied by H, hence adding this edge does not change the feasible solutions. That is, adding a transitive edge does not change the solution space and hence it is really only the transitive closure of the pattern H that matters. We say that two pattern graphs are *transitively equivalent* if their transitive closures are isomorphic. We denote the class of patterns that are transitively equivalent to some pattern of $\mathcal{C}_{\lambda,\delta}$ by $\mathcal{C}^*_{\lambda,\delta}$. Our main result is a sharp dichotomy saying that $\mathcal{H}$-DSN is FPT if every pattern of $\mathcal{H}$ is transitively equivalent to an almost-caterpillar graph and it is W[1]-hard otherwise. We measure the running time in λ, δ, and the *vertex cover number* τ of the input pattern H, i.e. τ is the size of the smallest vertex subset W of H such that every edge of H is incident to a vertex of W.

▶ **Theorem 2.** *Let $\mathcal{H}$ be a recursively enumerable class of patterns.*

1. *If there are constants λ and δ such that $\mathcal{H} \subseteq \mathcal{C}^*_{\lambda,\delta}$, then $\mathcal{H}$-DSN with parameter $k = |R|$ is FPT and can be solved in $2^{O(k+\max\{\omega^2,\, \tau\omega \log \omega)\})} n^{O(\omega)}$ time, where $\omega = (1+\lambda)(\lambda+\delta)$ and τ is the vertex cover number of the given input pattern $H \in \mathcal{H}$.*
2. *Otherwise, if there are no such constants λ and δ, then the problem is* W[1]*-hard for parameter k.*

Invoking Theorem 2 with specific classes $\mathcal{H}$, we can obtain algorithmic or hardness results for specific problems. For example, we may easily recover the following facts:

- If $\mathcal{H}_{\text{DST}}$ is the class of all out-stars, then $\mathcal{H}_{\text{DST}}$-DSN is precisely the DST problem. As $\mathcal{H}_{\text{DST}} \subseteq \mathcal{C}^*_{1,0}$ holds, Theorem 2(1) recovers the fact that DST can be solved in time $2^{O(k)} n^{O(1)}$ and is hence FPT parameterized by the number $k = |R|$ of terminals [17, 5].
- If $\mathcal{H}_{\text{SCSS}}$ is the class of all bidirected cliques, then $\mathcal{H}_{\text{SCSS}}$-DSN is precisely the SCSS problem. One can observe that $\mathcal{H}_{\text{SCSS}}$ is not contained in $\mathcal{C}^*_{\lambda,\delta}$ for any constants λ, δ (for example, because every graph in $\mathcal{C}_{\lambda,\delta}$ has at most $\lambda + 2\delta$ vertices with both positive

in-degree and positive out-degree, and this remains true also for the graphs in $\mathcal{C}^*_{\lambda,\delta}$). Hence Theorem 2(2) recovers the fact that SCSS is W[1]-hard [21].

- Let $\mathcal{H}_d$ be the class of directed graphs with at most d edges. As $\mathcal{H}_d \subseteq \mathcal{C}^*_{0,d}$ holds, Theorem 2(1) recovers the fact that Directed Steiner Network with at most d requests is polynomial-time solvable for every constant d [18]. Note that any pattern of $\mathcal{H}_{\text{SCSS}}$ is transitively equivalent to a bidirected star, which has vertex cover number $\tau = 1$. Hence for the important spacial case of SCSS, our algorithm recovers the running time of $2^{O(d \log d)} n^{O(d)} = n^{O(d)}$ given in [18].
- Very recently, Suchý [25] studied the following generalization of DST and SCSS: in the q-Root Steiner Tree (q-RST) problem, a set of q roots and a set of k leaves are given, and the task is to find a minimum-cost network where the roots are in the same strongly connected component and every leaf can be reached from every root. Building on the work of [18], Suchý [25] presented an algorithm with running time $2^{O(k)} \cdot n^{O(q)}$ for this problem, which shows that it is FPT for every constant q. Let $\mathcal{H}_{q\text{-RST}}$ be the class of directed graphs that are obtained from an out-star by making $q-1$ of the edges bidirected. Observe that $\mathcal{H}_{q\text{-RST}}$ is a subset of $\mathcal{C}_{1,q-1}$, that q-RST can be expressed by an instance of $\mathcal{H}_{q\text{-RST}}$-DSN, and that any pattern of $\mathcal{H}_{q\text{-RST}}$ has vertex cover number $\tau = 1$. Thus Theorem 2(1) implies that q-RST can be solved in time $2^{O(k+q \log q)} \cdot n^{O(q)} = 2^{O(k)} \cdot n^{O(q)}$, recovering the fact that it is FPT for every constant q.

Thus the algorithmic side of Theorem 2 unifies and generalizes three algorithmic results: the fixed-parameter tractability of DST (which is based on dynamic programming on the tree structure of the solution) and q-RST (which is based on simulating a "pebble game"), and also the polynomial-time solvability of DSN with constant number of requests (which also is based on simulating a "pebble game"). Let us point out that our algorithmic results are significantly more general than just the unification of these three results: the generalization from stars to bounded-length caterpillars is already a significant extension and very different from earlier results. We consider it a major success of the systematic investigation that, besides finding the unifying algorithmic ideas generalizing all previous results, we were able to find tractable special cases in an unexpected new direction.

There is a surprising non-monotonicity in the classification result of Theorem 2. As DST is FPT and SCSS is W[1]-hard, one could perhaps expect that $\mathcal{H}$-DSN becomes harder as the pattern become denser. However, it is possible that the addition of further requests makes the problem easier. For example, if $\mathcal{H}$ contains every graph that is the vertex-disjoint union of two out-stars, then $\mathcal{H}$-DSN is classified to be W[1]-hard by Theorem 2(2). However, if we consider those graphs where there is also a directed edge from the center of one star to the other star, then these graphs are 2-caterpillars (i.e., contained in $\mathcal{C}_{2,0}$) and hence $\mathcal{H}$-DSN becomes FPT by Theorem 2(1). This unexpected non-monotonicity further underlines the importance of completely mapping the complexity landscape of the problem area: without complete classification, it would be very hard to predict what other tractable/intractable special cases exist.

We mention that one can also study the vertex-weighted version of the problem, where the input graph has weights on the vertices and the goal is to minimize the total vertex-weight of the solution. In general, vertex-weighted problems can be more challenging than edge-weighted variants [15, 4, 23, 12]. However, for general directed graphs, there are easy transformations between the two variants. Thus the results of this paper can be interpreted for the vertex-weighted version as well.

1.1 Our techniques

We prove Theorem 2 the following way. In Section 2, we first establish the combinatorial bound that there is a solution whose cutwidth, and hence also (undirected) treewidth, is bounded by the number of requests.

▶ **Theorem 3.** *A minimal solution M to a pattern H has cutwidth at most $7m$ if $m = |E(H)|$.*

Then in Section 3 we go on to generalize this to almost-caterpillars, showing that if the pattern is in $\mathcal{C}^*_{\lambda,\delta}$, then the (undirected) treewidth can be bounded in λ and δ.

▶ **Theorem 4.** *The treewidth of a minimal solution to any pattern graph in $\mathcal{C}^*_{\lambda,\delta}$ is at most $7(1+\lambda)(\lambda+\delta)$.*

This combinatorial bound can be exploited in an algorithm that restricts the search for a bounded-treewidth solution.

▶ **Theorem 5.** *Let an instance of $\mathcal{H}$-DSN be given by a graph G with n vertices, and a pattern H on k terminals with vertex cover number τ. If the optimum solution to H in G has treewidth ω then the optimum can be computed in time $2^{O(k+\max\{\omega^2,\, \tau\omega\log\omega\})}n^{O(\omega)}$.*

Combining Theorem 4 and Theorem 5 proves the algorithmic side of Theorem 2. We remark that the proof is completely self-contained (with the exception of some basic facts on treewidth) and in particular we do not build on the algorithms of Feldman and Ruhl [18]. As combining Theorem 3 and Theorem 5 already proves that DSN with a constant number of requests can be solved in polynomial time, as a by-product this gives an independent proof for the result of Feldman and Ruhl [18]. One can argue which algorithm is simpler, but perhaps our proof (with a clean split of a combinatorial and an algorithmic statement) is more methodological and better reveals the underlying reason why the problem is tractable.

Finally, in Section 4 we show that whenever the patterns in $\mathcal{H}$ are not transitively equivalent to almost-caterpillars, the problem is W[1]-hard. We first show that there is only a small number of obstacles for not being transitively equivalent to almost-caterpillars: the graph class contains (possibly after identification of vertices) arbitrarily large strongly connected graphs, pure diamonds, or flawed diamonds (see Lemma 22 for the precise statement). We provide a separate W[1]-hardness proof for each of these cases, completing the proof of the hardness side of Theorem 2.

Due to space limitations we defer all missing proofs to the full version of this extended abstract, including the algorithm that implies Theorem 5.

2 The cutwidth of minimal solutions for bounded-size patterns

Consider a *minimal* solution M to an instance of $\mathcal{H}$-DSN, in which no edge can be removed without making the solution infeasible. The goal of this section is to prove Theorem 3: we bound the *cutwidth* of a minimal solution M to a pattern H in terms of $m = |E(H)|$. A *layout* of a graph G is an injective function $\psi : V(G) \to \mathbb{N}$ inducing a total order on the vertices of G. Given a layout, we define the set $V_i = \{v \in V(G) \mid \psi(v) \leq i\}$ and say that an edge *crosses the cut* $(V_i, \overline{V}_i)$ if it has one endpoint in V_i and one endpoint in $\overline{V}_i := V(G) \setminus V_i$. The *cutwidth of the layout* is the maximum number of edges crossing any cut $(V_i, \overline{V}_i)$ for any $i \in \mathbb{N}$. The cutwidth of a graph is the minimum cutwidth over all its layouts.

Like Feldman and Ruhl [18], we consider the two extreme cases of *directed acyclic graphs (DAGs)* and *strongly connected components (SCCs)* in our proof. Contracting all SCCs of M without removing parallel edges sharing the same head and tail, but removing

the resulting self-loops, results in a directed acyclic multi-graph D, the so-called *condensation graph* of M. We bound the cutwidth of D and the SCCs of M separately, and then put together these two bounds to obtain a bound for the cutwidth of M. As we will see, bounding the cutwidth of the acyclic multi-graph D and putting together the bounds are fairly simple. The main technical part is bounding the cutwidth of the SCCs.

We will need two simple facts about cutwidth. First, the cutwidth of an acyclic multi-graph can be bounded using the existence of a *topological ordering* of the vertices. That is, for any acyclic graph G there is an injective function $\varphi : V(G) \to \mathbb{N}$ such that $\varphi(u) < \varphi(v)$ if $uv \in E(G)$. Note that such a function in particular is a layout.

▶ **Lemma 6.** *The layout given by a topological ordering φ_D of an acyclic directed multi-graph D that is the union of m paths, has cutwidth at most m.*

▶ **Lemma 7.** *Let G be a directed graph and D be its condensation multi-graph. If the cutwidth of D is x and the cutwidth of every SCC of G is at most y, then the cutwidth of G is at most $x + y$.*

▶ **Lemma 8.** *Any SCC U of a minimal solution M to a pattern H with at most m edges has cutwidth at most $6m$.*

Proof. First we establish that U is a minimal solution to a certain pattern.

▶ **Claim 9.** *U is a minimal solution to a pattern H_U with at most m edges.*

Let R_U be the terminals in the pattern H_U given by Claim 9 and let us select an arbitrary root $t \in R_U$. Note that H_U has at most m edges, hence $|R_U| \leq 2m$. Let S_{in} (resp., S_{out}) be an in-star (resp., out-star) connecting t with every other vertex of R_U. As U is a strongly connected graph containing every vertex of R_U, it is also a solution to the pattern S_{in} on R_U. Let us select an $A_{in} \subseteq U$ that is a minimal solution to S_{in}; it is not hard to see that A_{in} is an in-arborescence with at most $2m$ leaves. Similarly, let $A_{out} \subseteq U$ be an out-arborescence that is a minimal solution to S_{out}. Observe that U has to be exactly $A_{in} \cup A_{out}$: if there is an edge $e \in E(U)$ that is not in $A_{in} \cup A_{out}$, then $U \setminus e$ still contains a path from every vertex of R_U to every other vertex of R_U though t, contradicting the fact that U is a minimal solution to pattern H_U.

Let Z be the set of edges obtained by reversing the edges in $E(A_{in}) \setminus E(A_{out})$. As reversing edges does not change the cutwidth, bounding the cutwidth of $A_{out} \cup Z$ will also imply a bound on the cutwidth of $U = A_{in} \cup A_{out}$.

▶ **Claim 10.** *The union $A_{out} \cup Z$ is a directed acyclic graph.*

Claim 10 implies a topological ordering on the vertices of $A_{out} \cup Z$. This order can be used as a layout for U. Using some more structural insights, the number of edges crossing a given cut can be bounded in the number of edges of the pattern graph, as the following claim shows.

▶ **Claim 11.** *Any topological ordering φ of the graph $A_{out} \cup Z$ has cutwidth at most $6m$.*

As the underlying undirected graph of U and $A_{out} \cup Z$ are the same, Claim 11 implies that the cutwidth of U is at most $6m$. This completes the proof of Lemma 8. ◀

The proof of Theorem 3 follows easily from putting together the ingredients. We remark that the bound on the cutwidth in Claim 11 is asymptotically tight: Take a constant degree expander on m vertices. It has treewidth $\Omega(m)$ [20], and so its cutwidth is at least as large. Now bi-direct each (undirected) edge $\{u, v\}$ by replacing it with the directed edges uv and vu.

Next subdivide every edge uv to obtain edges ut and tv for a new vertex t, and make t a terminal of R. This yields a strongly connected instance G. The pattern graph H for this instance is a cycle on R, which has $O(m)$ edges, since the terminals are subdivision points of bi-directed edges of a constant degree graph with m vertices. As H is strongly connected, every minimal solution to H contains the edges ut and tv incident to each terminal t. Thus a minimal solution contains all of G and has cutwidth $\Omega(m)$. Since G is strongly connected, it also contains the required arborescences A_{in} and A_{out}.

3 The treewidth of minimal solutions to almost-caterpillar patterns

In this section, we prove that any minimal solution M to a pattern $H \in \mathcal{C}^*_{\lambda,\delta}$ has the following structure.

▶ **Theorem 12.** *A minimal solution M to a pattern $H \in \mathcal{C}^*_{\lambda,\delta}$ consists of a subgraph M^c that is a minimal solution to a sub-pattern H^c of H with at most $(1+\lambda)(\lambda+\delta)$ edges, and a forest $M \setminus M^c$ of out-arborescences, each of which intersects M^c only at the root.*

According to Theorem 3, the cutwidth of the core M^c is therefore at most $7(1+\lambda)(\lambda+\delta)$. It is well known [6] that the cutwidth is an upper bound on the treewidth of a graph, and so also the treewidth of M^c is at most $7(1+\lambda)(\lambda+\delta)$. It is easy to see that attaching any number of arborescences to M^c does not increase the treewidth. Thus we obtain Theorem 4, which is the basis for our algorithm to solve $\mathcal{H}$-DSN in case every pattern of $\mathcal{H}$ is transitively equivalent to an almost-caterpillar.

In particular, when adding δ edges to the pattern of the DST problem, which is a single out-star, i.e., a 1-caterpillar, then the pattern becomes a member of $\mathcal{C}_{1,\delta}$ and hence our result implies a linear treewidth bound of $O(\delta)$. The example given at the end of Section 2 also shows that there are patterns $H \in \mathcal{C}_{\lambda,\delta}$ for which every minimal solution has treewidth $\Omega(\lambda+\delta)$: just consider the case when H is a cycle of length $\lambda+\delta$ (i.e., it contains a trivial caterpillar graph). One interesting question is whether the treewidth bound of $7(1+\lambda)(\lambda+\delta)$ in Theorem 4 is tight. We conjecture that the treewidth of any minimal solution to a pattern graph $H \in \mathcal{C}^*_{\lambda,\delta}$ actually is $O(\lambda+\delta)$.

Proof (of Theorem 12). Let M be a minimal solution to a pattern $H \in \mathcal{C}^*_{\lambda,\delta}$. Since every pattern in $\mathcal{C}^*_{\lambda,\delta}$ has a transitively equivalent pattern in $\mathcal{C}_{\lambda,\delta}$ and replacing a pattern with a transitively equivalent pattern does not change the space of feasible solutions, we may assume that H is actually in $\mathcal{C}_{\lambda,\delta}$, i.e., H consists of a caterpillar of length at most λ and δ additional edges.

The statement is trivial if $|E(H)| \leq \delta$. Otherwise, according to Definition 1, H contains a λ_0-caterpillar for some $1 \leq \lambda_0 \leq \lambda$ and at most δ additional edges. Hence let us fix a set F of at most δ edges of H, such that the remaining edges of H form a λ_0-caterpillar C, for some $1 \leq \lambda_0 \leq \lambda$, with a path $(v_1, \ldots, v_{\lambda_0})$ on the roots of the stars S_i. We only consider the case when C is an out-caterpillar as the other case is symmetric, i.e., every S_i is an out-star. Define $I = H \setminus \bigcup_{i=1}^{\lambda_0} S_i$ to be all of H except the stars. Note that $|E(I)| \leq \lambda+\delta$. We fix a subgraph M_I of M that is a minimal solution to the sub-pattern I, and for every $st \in E(I)$ we fix a path P_{st} in M_I. Note that M_I is the union of these at most $\lambda+\delta$ paths, since M_I is a minimal solution. For each star S_i, let us consider a minimal solution $M_{S_i} \subseteq M$ to S_i; note that M_{S_i} has to be an out-arborescence.

For $i \in \{1, \ldots, \lambda_0\}$, let ℓ be a leaf of S_i, and let e be an edge of M. If $M \setminus e$ has no path from v_i to ℓ, then we say that e is *ℓ-necessary*. More generally, we say that e is *i-necessary* if e is ℓ-necessary for some leaf ℓ of S_i.

▶ **Claim 13.** *Let P be a path in M, and for some $i \in \{1, \ldots, \lambda_0\}$, let $W_i \subseteq E(M)$ contain all i-necessary edges f for which $f \notin E(P)$, but the head of f is a vertex of P. Then there exists one leaf ℓ of S_i such that every $f \in W_i$ is ℓ-necessary.*

Using this observation, we identify the core M^c of M using the at most $\lambda + \delta$ paths P_{st} that make up M_I, and then selecting an additional at most λ_0 paths for each P_{st}. To construct M^c together with its pattern graph H^c, we initially let $M^c = M_I$ and $H^c = I$ and repeat the following step for every $st \in E(I)$ and $1 \leq i \leq \lambda_0$. For a given st and i, let us check if there are i-necessary edges $f \notin E(P_{st})$ that have their heads on the path $P_{st} \subseteq M_I$. If so, then by Claim 13 all these edges are ℓ-necessary for some leaf ℓ of S_i. We add an arbitrary path of M from v_i to ℓ (which contains all these edges) to M^c and add the edge $v_i\ell$ to H^c. After repeating this step for every $st \in E(H)$ and i, we remove superfluous edges from M^c: as long as there is an edge $e \in E(M^c)$, which can be removed while maintaining feasibility for the pattern H^c, i.e., for every $vw \in E(H^c)$ there is a $v \to w$ path in M^c not containing e, we remove e. Finally, we remove any isolated vertices from M^c.

Note that the resulting network M^c is a minimal solution to H^c by construction. Also note that H^c contains at most $\lambda + \delta$ edges from I and at most $\lambda_0 \leq \lambda$ additional edges for each edge of I, so that $|E(H^c)| \leq (1 + \lambda)(\lambda + \delta)$. We prove that the remaining graph $M^c \setminus E(M)$ consists of arborescences, each of which intersects M^c only at the root. For this, we rely on the following key observation.

▶ **Claim 14.** *If a vertex u has at least two incoming edges in M, then every such edge is in the core M^c.*

Proof. First we show that there is an $st \in E(I)$ such that every $s \to t$ path in M goes through u. Suppose for contradiction that for every $st \in E(I)$ there is a path from s to t in M avoiding u. Since M is a minimal solution, the edges entering u must then be needed for some stars S_i of the pattern H instead. Let e and f be two edges entering u. As e and f have the same head, they cannot be part of the same out-arborescence M_{S_i}. Therefore, there are indices $i < j$ such that (w.l.o.g.) e is i-necessary and f is j-necessary.

There is a path in M from the root v_i of S_i to the root v_j of S_j, due to the path $(v_1, \ldots, v_{\lambda_0})$ in the caterpillar $C \subseteq H$. Since path $(v_1, \ldots, v_{\lambda_0})$ is part of I, our assumption on e and f implies that there is a path P in M from v_i to v_j that avoids both e and f. As $f \in E(M_{S_j})$, there is a path Q in M starting in v_j and passing through f. This path cannot contain e, as e and f have the same head u. The existence of P and Q implies that u can be reached from v_i by a path through v_j and f, avoiding the edge e. Thus for any edge $v_i\ell \in E(S_i)$, if there is a $v_i \to \ell$ path going through e (and hence vertex u), then it can be rerouted to avoid e and use edge f instead. This however contradicts the fact that e is i-necessary.

We have proved that there is an $st \in E(I)$ such that every $s \to t$ path in M goes through u. Suppose that there is an edge $e \notin E(M^c)$ entering u. If e is needed for some $s't' \in E(I)$ in M, then e is also present in M^c, and we are done. Otherwise, as M is a minimal solution, edge e is i-necessary for some $i \in \{1, \ldots, \lambda_0\}$. Consider now the step in the construction of M^c when we considered $st \in E(I)$ and integer i. As we have shown, the $s \to t$ path P_{st} goes through u. Thus e is an i-necessary edge not in $E(P_{st})$ such that its head is on P_{st}. This means that we identified a leaf ℓ of S_i such that e is ℓ-necessary, introduced $v_i\ell$ into H^c, and added a $v_i \to \ell$ path to H^c, which had to contain e. Moreover, since all paths from v_i to ℓ in M pass through e, edge e then remains in M^c when removing superfluous edges. ◀

We are now ready to show that every component of the remaining part is an out-arborescence and intersects the core only in a single vertex.

▶ **Claim 15.** *The remaining graph $M^+ := M \setminus E(M^c)$ is a forest of out-arborescences, each of which intersects M^c only at the root.*

Since we have already established that M^c is a minimal solution to H^c with $|E(H^c)| \leq (1+\lambda)(\lambda+\delta)$, Claim 15 completes the proof of Theorem 12. ◀

4 Characterizing the hard cases

We now turn to proving the second part of Theorem 2, i.e., that $\mathcal{H}$-DSN is W[1]-hard for every class $\mathcal{H}$ where the patterns are not transitively equivalent to almost-caterpillars.

▶ **Theorem 16.** *Let $\mathcal{H}$ be a recursively enumerable class of patterns for which there are no constants λ and δ such that $\mathcal{H} \subseteq \mathcal{C}^*_{\lambda,\delta}$. Then the problem $\mathcal{H}$-DSN is* W[1]*-hard for parameter k.*

A major technical simplification is to assume that the class $\mathcal{H}$ is closed under identifying terminals and transitive equivalence. As we show in Section 4.1, this assumption is not really restrictive: it is sufficient to prove hardness for the closure of $\mathcal{H}$ under identification and transitive equivalence, since any W[1]-hardness result for the closure can be transferred to $\mathcal{H}$. For classes closed under these operations, it is possible to give an elegant characterization of the classes that are not almost-caterpillars. There are only a few very specific reasons why a class $\mathcal{H}$ is not in $\mathcal{C}^*_{\lambda,\delta}$ for any λ and δ: either $\mathcal{H}$ contains every directed cycle, or $\mathcal{H}$ contains every "pure diamond," or $\mathcal{H}$ contains every "flawed diamond" (see Section 4.2 for the precise definitions). Then in Section 4.3, we provide a W[1]-hardness proof for each of these cases, completing the hardness part of Theorem 2.

4.1 Closed classes

We define the operation of *identifying terminals* in the following way: given a partition $\mathcal{V}$ of the vertex set $V(H)$ of a pattern graph H, each set $W \in \mathcal{V}$ is identified with a single vertex of W, after which any resulting isolated vertices and self-loops are removed, while parallel edges having the same head and tail are replaced by only one copy of that edge. A class of patterns is *closed* under this operation if for any pattern H in the class, all patterns that can be obtained by identifying terminals are also in the class. Similarly, we say that a class $\mathcal{H}$ is closed under transitive equivalence if whenever H and H' are two transitively equivalent patterns such that $H \in \mathcal{H}$, then H' is also in $\mathcal{H}$. The closure of the class $\mathcal{H}$ under identifying terminals and transitive equivalence is the smallest closed class $\mathcal{H}' \supseteq \mathcal{H}$. It is not difficult to see that any member of the closure can be obtained by a replacement with a transitively equivalent pattern and a single application of identifying terminals.

The following lemma shows that if we want to prove W[1]-hardness for a class, then it is sufficient to prove hardness for its closure. More precisely, due to an slight technicality, the actual statement we prove is that it is sufficient to prove W[1]-hardness for a decidable subclass of the closure.

▶ **Lemma 17.** *Let $\mathcal{H}$ be a recursively enumerable class of patterns, let $\mathcal{H}'$ be the closure of $\mathcal{H}$ under identifying terminals and transitive equivalence, and let $\mathcal{H}''$ be a decidable subclass of $\mathcal{H}'$. There is a parameterized reduction from $\mathcal{H}''$-DSN to $\mathcal{H}$-DSN with parameter k.*

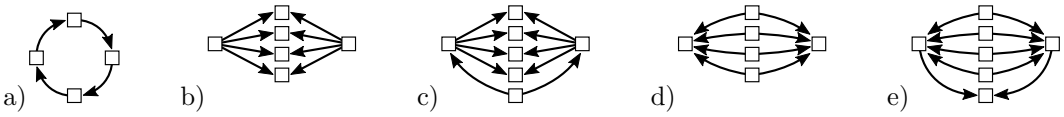

Figure 2 The obstruction appearing in Lemma 19: a) a directed cycle of length 4, b) a pure 4-out-diamond, c) a flawed 4-out-diamond, d) a pure 4-in-diamond, e) a flawed 4-in-diamond.

4.2 Obstructions: SCCs and diamonds

To show the hardness for a closed class that is not the subset of $\mathcal{C}^*_{\lambda,\delta}$ for any λ and δ, we will characterize such a class in terms of the occurrence of arbitrarily large cycles, and another class of patterns called "diamonds" (cf. Figure 2).

▶ **Definition 18.** A *pure α-diamond* graph is constructed as follows. Take a vertex set L of size $\alpha \geq 1$, and two additional vertices r_1 and r_2. Now add edges such that L is the leaf set of either two in-stars or two out-stars S_1 and S_2 with roots r_1 and r_2, respectively. If we add an additional vertex x with edges r_1x and r_2x if S_1 and S_2 are in-stars, and edges xr_1 and xr_2 otherwise, the resulting graph is a *flawed α-diamond*. We refer to both pure α-diamonds and flawed α-diamonds as *α-diamonds*. If S_1 and S_2 are in-stars we also refer to the resulting α-diamonds as *in-diamonds*, and otherwise as *out-diamonds*.

The goal of this section is to prove the following useful characterization precisely describing classes that are not almost-caterpillars.

▶ **Lemma 19.** *Let $\mathcal{H}$ be a class of pattern graphs that is closed under identifying terminals and transitive closure. Exactly one of the following statements is true:*

- *$\mathcal{H} \subseteq \mathcal{C}^*_{\lambda,\delta}$ for some constants λ and δ.*
- *$\mathcal{H}$ contains every directed cycle, or every pure in-diamond, or every pure out-diamond, or every flawed in-diamond, or every flawed out-diamond.*

For the proof of Theorem 16, we only need the fact that at least one of these two statements hold: if the class $\mathcal{H}$ is not in $\mathcal{C}^*_{\lambda,\delta}$, then we can prove hardness by observing that $\mathcal{H}$ contains one of the hard classes. For the sake of completeness, we give a simple proof that the two statements cannot hold simultaneously in the full version of this extended abstract.

Showing that at least one of the two statements of Lemma 19 hold is not as easy to prove. First, the following two lemmas show how a large cycle or a large diamond can be identified if certain structures appear in a pattern. The main part of the proof is to show that if $\mathcal{H}$ contains patterns that are arbitrarily far from being a caterpillar, then one of these two lemmas can be invoked (see Lemma 22).

▶ **Lemma 20.** *Let $\mathcal{H}$ be a class of pattern graphs that is closed under identifying terminals and transitive closure. If some $H \in \mathcal{H}$ contains a matching of size α, then $\mathcal{H}$ contains a directed cycle of length α.*

Proof. A *matching* of a graph is a subset M of its edges such that no two edges of M share a vertex. A matching $e_1, \ldots, e_\alpha$ of α edges can be transformed into a cycle of length α by identifying the head of e_i and tail of e_{i+1} (and the head of e_α with the tail of e_1). All remaining vertices that do not belong to the cycle can then be identified with any vertex of the cycle, so that the resulting graph consists of the cycle and some additional edges. Since $\mathcal{H}$ is closed under identifying terminals, this graph would be contained in $\mathcal{H}$. As this graph is strongly connected and $\mathcal{H}$ is closed also under transitive equivalence, we can conclude that $\mathcal{H}$ contains a cycle of length α. ◀

Next we give a sufficient condition for the existence of large diamonds. We say that an edge uv of a graph H is *transitively non-redundant* if there is no $u \to v$ path in $H \setminus uv$.

▶ **Lemma 21.** *Let $\mathcal{H}$ be a class of pattern graphs that is closed under identifying terminals and transitive equivalence. Let $H \in \mathcal{H}$ be a pattern graph that contains two out-stars (or two in-stars) S_1 and S_2 as induced subgraphs, with at least α edges each and roots r_1 and r_2, respectively. The class $\mathcal{H}$ contains an α-diamond if*

1. *H contains neither a path from r_1 to r_2, nor from r_2 to r_1,*
2. *the leaves of S_1 and S_2 have out-degree 0 (if S_1 and S_2 are out-stars) or in-degree 0 (if S_1 and S_2 are in-stars), and*
3. *the edges of the stars are transitively non-redundant.*

To show that at least one of the two statements of Lemma 19 hold, we prove that if the second statement is false, then the first statement is true. That is, if $\mathcal{H}$ does not contain all cycles (i.e., there is an α_1 such that $\mathcal{H}$ contains no cycle larger than α_1), $\mathcal{H}$ does not contain all pure out-diamonds (i.e., there is an α_2 such that $\mathcal{H}$ contains no pure out-diamond larger than α_2), etc., then $\mathcal{H} \subseteq \mathcal{C}^*_{\lambda,\delta}$ for some constants λ and δ. In other words, if we let α to be the maximum of α_1, α_2, etc., then we may assume that $\mathcal{H}$ contains no pure of flawed α-diamond or cycle of length α, and we need to prove $\mathcal{H} \subseteq \mathcal{C}^*_{\lambda,\delta}$ under this assumption. Thus the following lemma completes the proof of Lemma 19.

▶ **Lemma 22.** *Let $\mathcal{H}$ be a class of pattern graphs that is closed under identifying terminals and transitive equivalence. If for some integer α the class $\mathcal{H}$ contains neither a pure α-diamond, flawed α-diamond, nor a cycle of length α, then there exist constants λ and δ (depending on α) such that $\mathcal{H} \subseteq \mathcal{C}^*_{\lambda,\delta}$.*

Proof. Suppose that there is such an integer α. Let $\lambda := 2\alpha$ and $\delta := 4\alpha^3 + 6\alpha^2$. Given any $H' \in \mathcal{H}$, we show how a transitively equivalent pattern $H \in \mathcal{C}_{\lambda,\delta}$ can be constructed, implying that H' belongs to $\mathcal{C}^*_{\lambda,\delta}$. A *vertex cover* of a graph is a subset X of its vertices such that every edge is incident to a vertex of X. By Lemma 20, H' cannot contain a matching of size α. It is well-known that if a graph has no matching of size α, then it has a vertex cover of size at most 2α (take the endpoints of any maximal matching). Let us fix a vertex cover X of H' having size at most 2α.

To obtain H from H', we start with a graph H on $V(H')$ having no edges and perform the following three steps.

1. Let us take the transitive closure on the vertex set X in H', i.e., let us introduce into H every edge uv with $u, v \in X$ such that there is a $u \to v$ path in H'.
2. Let us add all edges uv of H' to H for which $u \notin X$ or $v \notin X$.
3. Fixing an ordering of the edges introduced in step 2, we remove transitively redundant edges: following this order, we subsequently remove those edges uv for which there is a path from u to v in the remaining graph H that is not the edge uv itself.

It is clear that H is transitively equivalent to H'. Note that X is a vertex cover of H as well, and hence its complement $I = V(H) \setminus X$ is an *independent set*, i.e. no two vertices of I are adjacent. Let $E_I \subseteq E(H)$ be the set of edges between X and I. In the rest of the proof, we argue that the resulting pattern H belongs to $\mathcal{C}_{\lambda,\delta}$. We show that H can be decomposed into a path $P = (v_1, \ldots, v_{\lambda_0})$ in X, a star S_{v_i} centered at each v_i using the edges in E_I, and a small set of additional edges. This small set of additional edges is constructed in three steps, by considering a sequence of larger and larger sets $F_1 \subseteq F_2 \subseteq F_3$.

As E_I consists of edges between X and I, it can be partitioned into a set of stars with roots in X. The following claim shows that almost all of these edges are directed towards X or almost all of them are directed away from X.

▶ **Claim 23.** *Either there are less than $2\alpha^2$ edges uv in E_I with head in X, or less than $2\alpha^2$ edges uv in E_I with tail in X.*

Assume that the former case of Claim 23 is true, so that the number of edges in E_I with heads in X is bounded by $2\alpha^2$; the other case can be handled symmetrically. We will use the out-stars spanned by E_I for the caterpillar, which means that we obtain an out-caterpillar. We use the set F_1 to account for the edges in E_I with heads in X. Additionally, we will also introduce into F_1 those edges in E_I with tails in X that are adjacent to an edge of the former type. Formally, for any edge $uv \in E_i$ with $v \in X$, we introduce into F_1 every edge of E_I incident to u. After this step, F_1 contains less than $4\alpha^3$ edges, since there are less than $2\alpha^2$ edges $uv \in E_I$ with $v \in X$ and u can only be adjacent to vertices in X, which has size less than 2α.

For any vertex $v \in X$, let S_v denote the out-star formed by the edges of $E_I \setminus F$ incident to v. Let $X' \subseteq X$ contain those vertices $v \in X$ for which S_v has at least α leaves.

▶ **Claim 24.** *For any two distinct $u, v \in X'$, at least one of uv and vu is in H, and the stars S_u and S_v are vertex disjoint.*

We extend F_1 to F_2 by adding all edges of stars S_v with $v \in X \setminus X'$ to F_2. Since X contains less than 2α vertices and we extend F_1 only by stars with less than α edges, this step adds less than $2\alpha^2$ edges, i.e., $|F_2| \leq |F_1| + 2\alpha^2 = 4\alpha^3 + 2\alpha^2$.

By Claim 24, X' induces a *semi-complete* directed graph in H, i.e., at least one of the edges uv and vu exists for every pair $u, v \in X'$. It is well-known that every semi-complete directed graph contains a Hamiltonian path (e.g., [16, Chapter 10, Exercise 1]), and so there is a path $P = (v_1, \ldots, v_{\lambda_0})$ with $\lambda_0 = |X'| \leq 2\alpha = \lambda$ in H on the vertices of X'. We extend F_2 to F_3 by including any edge induced by vertices of X' that is not part of P. There are less than $4\alpha^2$ such edges, and hence we have $|F_3| \leq |F_2| + 4\alpha^2 \leq 4\alpha^3 + 6\alpha^2 = \delta$. The edges of H not in F_3 span the path P and disjoint out-stars S_{v_i} with $i \in \{1, \ldots, \lambda_0\}$, i.e., they form a λ_0-caterpillar. This proves that $H \in \mathcal{C}_{\lambda,\delta}$ and hence $H' \in \mathcal{C}^*_{\lambda,\delta}$, what we had to show. ◀

4.3 Reductions

Lemma 19 implies that in order to prove Theorem 16, we need W[1]-hardness proofs for the class of all directed cycles, the class of all pure in-diamonds, the class of all pure out-diamonds, etc. We provide these hardness proofs and then formally show that they imply Theorem 16.

Let us first consider the case when $\mathcal{H}$ is the class of all directed cycles. Recall that, given an arc-weighted directed graph G and a set $R \subseteq V(G)$ of terminals, the Strongly Connected Steiner Subgraph (SCSS) problem asks for a minimum-cost subgraph that is strongly connected and contains every terminal in R. This problem is known to be W[1]-hard parameterized by the number $k := |R|$ of terminals [21]. We can reduce SCSS to an instance of DSN where the pattern H is a directed cycle on R, which expresses the requirement that all the terminals are in the same strongly connected component of the solution. Thus the W[1]-hardness of SCSS immediately implies the W[1]-hardness of $\mathcal{H}$-DSN if $\mathcal{H}$ contains all directed cycles.

▶ **Lemma 25** (follows from [21]). *If $\mathcal{H}$ is the class of directed cycles, then $\mathcal{H}$-DSN is* W[1]*-hard parameterized by the number of terminals.*

Next we turn our attention to classes containing all diamonds. The following reductions are from the W[1]-hard Multicoloured Clique problem [19], in which an undirected graph together with a partition $\{V_1, \ldots, V_k\}$ of its vertices into k sets is given, such that for

any $i \in \{1, \ldots, k\}$ no two vertices of V_i are adjacent. The aim is to find a clique of size k, i.e. a set of pairwise adjacent vertices $\{w_1, \ldots, w_k\}$ with $w_i \in V_i$ for each $i \in \{1, \ldots, k\}$.

▶ **Lemma 26.** *If $\mathcal{H}$ is the class of all pure out-diamonds, then $\mathcal{H}$-DSN is* W[1]*-hard parameterized by the number of terminals. The same holds if $\mathcal{H}$ is the class of all pure in-diamonds.*

The reduction for the case when the pattern is a flawed α-diamond is essentially the same as the one for pure α-diamonds, as we show next.

▶ **Lemma 27.** *If $\mathcal{H}$ is the class of all flawed out-diamonds, then $\mathcal{H}$-DSN is* W[1]*-hard parameterized by the number of terminals. The same holds if $\mathcal{H}$ is the class of all flawed in-diamonds.*

Given the three reductions above, we can now prove Theorem 16, based on the additional reduction given in Lemma 17. We defer the final proof to the full version of this extended abstract.

Abstract

Choosability, introduced by Erdős, Rubin, and Taylor [*Congr. Number.* 1979], is a well-studied concept in graph theory: we say that a graph is c-choosable if for any assignment of a list of c colors to each vertex, there is a proper coloring where each vertex uses a color from its list. We study the complexity of deciding choosability on graphs of bounded treewidth. It follows from earlier work that 3-choosability can be decided in time $2^{2^{O(w)}} \cdot n^{O(1)}$ on graphs of treewidth w. We complement this result by a matching lower bound giving evidence that double-exponential dependence on treewidth may be necessary for the problem: we show that an algorithm with running time $2^{2^{o(w)}} \cdot n^{O(1)}$ would violate the Exponential-Time Hypothesis (ETH). We consider also the optimization problem where the task is to delete the minimum number of vertices to make the graph 4-choosable, and demonstrate that dependence on treewidth becomes triple-exponential for this problem: it can be solved in time $2^{2^{2^{O(w)}}} \cdot n^{O(1)}$ on graphs of treewidth w, but an algorithm with running time $2^{2^{2^{o(w)}}} \cdot n^{O(1)}$ would violate ETH.

1 Introduction

Most NP-hard algorithmic problems become significantly easier when restricted to bounded-treewidth graphs. There are notable exceptions that remain NP-hard on graphs of constant treewidth (e.g., Steiner Forest [1, 20], List Edge Coloring [37], Edge-disjoint Paths [41]), but most of the natural combinatorial problems can be solved in polynomial time (or even in linear time) if treewidth is bounded. Courcelle's Theorem [11] is a meta-result showing that if a problem can be expressed in the language of monadic second order logic (MSOL), then it can be solved in linear-time on bounded-treewidth graphs: there is an algorithm with running time $f(w) \cdot n$, where w is the treewidth of the graph. While this result

immediately gives algorithms for a large number of combinatorial problems, focus has shifted in recent years towards trying to obtain a tighter understanding of how the running time has to depend on treewidth, that is, understanding what the best possible $f(w)$ in the running time can be. On the one hand, recent algorithm advances, such as *Cut & Count* [14] and fast subset convolution [3, 47], resulted in improved dependence on treewidth for various problems. On the other hand, conditional results based on the Exponential-Time Hypothesis (ETH) [25, 26, 34] give lower bounds on the best possible dependence that can be achieved, and in many cases these lower bounds tightly match the known algorithms [13, 14, 33, 35, 43]. (ETH can be informally stated as n-variable 3SAT cannot be solved in time $2^{o(n)}$.) Most of these tight bounds are of the form $2^{O(w)}$ (e.g., 3-Coloring, Hamiltonian Cycle, Triangle Packing, etc.), but there are surprising exceptions where the best possible dependence on treewidth is $2^{O(w \log w)}$ [14, 35] or even $2^{O(w^c)}$ for some constant $c > 1$ [13]. A result of Frick and Grohe [19] shows that, assuming $\mathsf{P} \neq \mathsf{NP}$, the dependence on treewidth can be really bad for some problems: Courcelle's Theorem does not remain true if we impose any *elementary* bound on the function $f(w)$. That is, for every $h \geq 1$, there are MSOL sentences and corresponding model-checking problems for which the dependence on treewidth is an exponential tower of height h. Pan and Vardi [42] gave strong evidence that this bad performance is expected for problems high up in the polynomial hierarchy: they showed that, under ETH, there is a strict hierarchy of lower bounds of the form $2^{2^{\cdots^{2^{o(w)}}}}$ inside PSPACE. In this paper, we present two fairly standard graph-theoretic problems that require double-exponential and triple-exponential dependence on treewidth, respectively.

1.1 k-Choosability

A proper k-coloring of a graph G is a mapping $f : V(G) \to [k]$ such that $f(u) \neq f(v)$ for any two adjacent $u, v \in V(G)$. List coloring is the generalization where instead of having the same set $[k]$ of colors available at each vertex, each vertex v has its own list $L(v)$ of available colors and the question is whether there is a proper coloring f that assigns a color $f(v) \in L(v)$ to each vertex v. The algorithmic aspects of list coloring have received significant interest [2, 10, 23, 24, 29, 32, 37, 38, 46].

Erdős, Rubin, and Taylor [16] defined a combinatorial property related to list colorings: we say that a graph G is k-choosable if it has a coloring for any list assignment L that has size k at each vertex. Clearly, k-choosability implies k-colorability. One may feel that the converse implication could also be true: after all, it may seem safe to guess that the "worst case" of list coloring is when every vertex has the same list $[k]$. But this intuition is wrong: for example, for any $k \geq 1$, there are 2-colorable graphs that are not k-choosable.

From the computational complexity point of view, deciding k-choosability is a much harder algorithmic problem than deciding k-colorability. Deciding k-choosability does not seem to belong to the class NP (a witness for k-choosability would need to prove colorability for *every* list assignment L) or to the class coNP (an uncolorable list assignment would be a good witness for non-k-choosability, but it cannot be verified in polynomial time). In fact, the k-choosability problem is known to lie higher in the polynomial hierarchy.

▶ **Theorem 1** (from [21]). *k-Choosability for $k \geq 3$ is Π_2^p-complete.*

We observe a similar gap in complexity between the two problems when looking at algorithms parameterized by treewidth. 3-colorability can be decided in time $3^w \cdot n^{O(1)}$ using standard techniques [12]. Fellows et al. [17] showed that deciding 3-choosability is fixed-parameter tractable parameterized by treewidth. One can make this result quantitative

by observing that the running time is actually $2^{2^{O(w)}} \cdot n^{O(1)}$ for graphs of treewidth w. Our first result shows that this double exponential dependence on treewidth is best possible, assuming ETH.

▶ **Theorem 2.** *For every fixed $k \geq 3$:*

1. *There is an algorithm for k-Choosability with running time $2^{2^{O(w)}} \cdot n^{O(1)}$ on graphs of treewidth w.*
2. *Assuming ETH, there is no algorithm for k-Choosability with running time $2^{2^{o(w)}} \cdot n^{O(1)}$ on graphs of treewidth w.*

1.2 k-Choosability Deletion

Given any class $\mathcal{C}$ of graphs, one can define various graph modification problems where the task is to transform a given graph G into a member of $\mathcal{C}$ with the minimum number of vertex deletions/edge deletions/edge additions. The parameterized algorithms literature is especially rich in this type of problems, where the goal is, for example, to make the graph acyclic [9, 15], bipartite [27, 36, 44, 45], planar [28, 40], chordal [5, 7, 18, 30, 39], or interval [4, 6, 8]. Investigating these problems on graphs of bounded treewidth is an interesting question on its own right, but additional motivation comes from the fact that some of the algorithms on *general graphs* first reduce the treewidth and then invoke an algorithm exploiting bounded treewidth [28, 39, 40].

If we look at the vertex deletion versions of coloring and choosability problems, then we can observe an even larger gap than in the decision version. For technical reasons, we give a proof only for $k \geq 4$ colors. It is not difficult to show (we leave it as an exercise to the reader) that there is an algorithm with running time $2^{O(w)} \cdot n^{O(1)}$ for 4-Coloring Deletion that, given a graph G of treewidth w, computes the minimum number of vertices that needs to be deleted to make the graph 4-colorable. On the other hand, if we consider the 4-Choosability Deletion problem, which asks for the minimum number of vertices that need to be deleted to make a given graph G 4-choosable, then we need *triple-exponential* dependence on treewidth.

▶ **Theorem 3.** *For every fixed $k \geq 4$:*

1. *There is an algorithm for k-Choosability Deletion with running time $2^{2^{2^{O(w)}}} \cdot n^{O(1)}$ on graphs of treewidth w.*
2. *Assuming ETH, there is no algorithm for k-Choosability Deletion with running time $2^{2^{2^{o(w)}}} \cdot n^{O(1)}$ on graphs of treewidth w.*

As a side result, we show that k-Choosability Deletion lies one level higher than k-Choosability in the polynomial hierarchy (compare this with the fact that k-Coloring and k-Coloring Deletion are both in NP).

▶ **Theorem 4.** *For every $k \geq 3$, k-Choosability Deletion is Σ_3^p-complete.*

The reader may feel that the Π_2^p- and Σ_3^p-completeness of these problems already give sufficient explanation why double- or triple-exponential dependence on treewidth is needed. This is true in some sense: the quantifier alternations in the problem definitions are the common underlying reasons for being in the higher levels of the polynomial hierarchy and for requiring unusually large dependence on treewidth. But let us point out that these two types of complexity results require very different proof structures. In Π_2^p- or Σ_3^p-completeness proofs, we start with a canonical Π_2^p- or Σ_3^p-complete quantified satisfiability problem and we use the alternations inherent in the definitions of k-Choosability or k-Choosability

Deletion to express the alternations in quantified satisfiability. On the other hand, in the proofs of Theorems 2(2) and 3(2), we start with problems in NP and use the alternations inherent in k-Choosability or k-Choosability Deletion for *compression*: we want to express the original instance by a graph having treewidth only $O(\log n)$ or $O(\log \log n)$. Thus the main theme of our proofs is trading alternation for compression: we want to use alternation to allow the succinct encoding and verification of information. Note also that both k-Choosability and k-Choosability Deletion can be solved in time $2^{n^{O(1)}}$, hence the exponential explosion appears only in the context of bounded-treewidth graphs.

2 Preliminaries

▶ **Definition 5** (List coloring)**.** Given graph G together with sets $\mathcal{L}(v) \subset \mathbb{N}$, one for every vertex v (we shall call $\mathcal{L}(v)$ the *list* of v), then G is *$\mathcal{L}$-colorable* if there exists a coloring $c : V(G) \to \mathbb{N}$, which is proper and for which $\forall v \in V(G), c(u) \in \mathcal{L}(v)$. In that case, c is called a *proper $\mathcal{L}$-coloring*.

▶ **Definition 6** (Choice number)**.** Given G and some $k \in \mathbb{N}$, G is called *k-choosable* if for any list assignment $\mathcal{L} : V(G) \to 2^{\mathbb{N}}$ with $|\mathcal{L}(v)| = k$ for all $v \in V(G)$, G is $\mathcal{L}$-colorable. The *choice number* (or *list-chromatic number*) of G, denoted by $\chi_\ell(G)$, is the minimum number k such that G is k-choosable.

The notion of f-choosability defined below generalizes k-choosability, but for arbitrary list sizes for each vertex.

▶ **Definition 7** (f-choosable graphs)**.** A graph G is called *f-choosable* for some function $f : V(G) \to \mathbb{N}$ (called *list-capacity function*) if G is $\mathcal{L}$-colorable for any list assignment $\mathcal{L} : V(G) \to 2^{\mathbb{N}}$ where $|\mathcal{L}(v)| = f(v)$ for all $v \in V(G)$.

As a direct consequence of the definition, we get that the null graph K_0 with no vertices is f-choosable for any list-capacity function f. The reason is the vacuous truth that, for any list assignment $\mathcal{L}$, the empty function $e : \emptyset \to \mathbb{N}$ is a proper $\mathcal{L}$-coloring of K_0.

▶ **Definition 8** (Color Compatibility)**.** Given a graph G, a list assignment $\mathcal{L}$, an ordered k-tuple $(u_1, u_2, \ldots, u_k) \in V(G)^k$ and an ordered k-tuple of colors $(c_1, c_2, \ldots, c_k)$ with $c_i \in \mathcal{L}(u_i)$ for $i \in [k]$, we say that $(c_1, c_2, \ldots, c_k)$ is *compatible* on $(u_1, u_2, \ldots, u_k)$ if there exists a proper $\mathcal{L}$-coloring g of G with $g(u_i) = c_i$. We may omit G and $\mathcal{L}$ if they are clear from the context.

We define the following algorithmic problems:

- (i, j)-Choosability: Given a graph G, integers $i, j \in \mathbb{N}$ where $i \leq j$, and a list-capacity function f for which $f(v) \in \{i, \ldots, j\}$ for any vertex $v \in V$, decide whether G is *f-choosable*.
- k-Choosability:= (k, k)-Choosability.
- (i, j)-Choosability Deletion: Given a graph G, integers $i, j, r \in \mathbb{N}$ with $i \leq j$, and a list-capacity function f for which $f(v) \in \{i, \ldots, j\}$ for any vertex $v \in V$, decide whether there exists $U \subset V$ with $|U| \leq r$ such that $G - U$ is *f-choosable*.
- k-Choosability Deletion:= (k, k)-Choosability Deletion.

Below are some known results about Choosability.

▶ **Theorem 9** (from [16])**.** $(2, 3)$-Choosability *is Π_2^p-complete.*

▶ **Theorem 10** (from [21])**.** k-Choosability *for $k \geq 3$ is Π_2^p-complete.*

▶ **Theorem 11** (from [17])**.** k-Choosability *parameterized by the treewidth of the input graph is in* FPT.

3 Double-exponential lower bound for k-Choosability

The topic of this section is proving Theorem 2(2), the double-exponential lower bound on 3-Choosability parameterized by treewidth. For the proof, we will find it convenient to start the reduction from Edge 3-Coloring, where given a graph G, the task is to decide if G has a proper edge 3-coloring (that is, whether there is an assignment $c : E(G) \to \{1, 2, 3\}$ such that $c(e_1) \neq c(e_2)$ for any two edges e_1 and e_2 sharing an endpoint). Holyer's proof [22] for the NP-hardness of Edge 3-Coloring on 3-regular graphs can be observed to give a tight lower bound under ETH. Note that a 3-regular graph on n vertices has exactly $3n/2 = O(n)$ edges. We state the lower bound in a slightly awkward way, but this type of bound is what we exactly need.

▶ **Theorem 12** (follows from [22]). *Assuming ETH,* Edge 3-Coloring *cannot be decided in time* $2^{2^{o(\log n)}}$*, where* n *is the number of vertices of the graph. Moreover, this remains true even if we consider only 3-regular graphs whose number of vertices is an integer power of* 2.

That is, if we reduce Edge 3-Coloring to some other problem by creating an equivalent instance with treewidth $O(\log n)$, then an algorithm of the target problem with running time $2^{2^{o(w)}} \cdot n^{O(1)}$ for graphs of treewidth w would yield an algorithm with running time $2^{2^{o(\log n)}} \cdot n^{O(1)}$ for Edge 3-Coloring, contradicting Theorem 12.

The reason why reducing from this problem is convenient for our proof is that Edge 3-Coloring involves constraints of the form "the three edges e_1, e_2, e_3 incident to a vertex u use all three colors from $\{1, 2, 3\}$," and this type of constraints will be easy to express in our reduction. However, there is an unfortunate presentation issue: when talking about colors, vertices, and edges, it may not be immediately clear if we refer to the source Edge 3-Coloring instance or to the target 3-Choosability instance, and this may cause confusion. Therefore, we prefer to treat Edge 3-Coloring as a constraint satisfaction problem and use terminology appropriate to that. Formally, an instance of Edge 3-Coloring can be interpreted as a problem where we have a set X of n variables (corresponding to the edges of G), each variable has the domain $\{1, 2, 3\}$, and we have a set Y of m constraints (corresponding to the vertices of G). Each constraint contains exactly three distinct variables, and the constraint is satisfied if these variables are assigned three different values. Then the proper edge 3-colorings of G are in one-to-one correspondence with the satisfying assignments of this constraint satisfaction problem. Note that each variable appears in exactly two constraints.

Given an instance H of the constraint satisfaction problem described above, we create an instance of $(2, 3)$-Choosability, i.e, a graph G and a list-capacity function $f : V \to \{2, 3\}$. Then we show that there is a satisfying assignment of I if and only if G is *not* $(2, 3)$-choosable. We will further make sure that $\mathrm{tw}(G) = O(\log m)$, which will imply the desired time lower bound. For the forward direction, all we need to do is, given a satisfying assignment $h : X \to \{1, 2, 3\}$ of H, use h in order to define a list assignment $\mathcal{L}$ for which G is not $\mathcal{L}$-colorable. The converse direction is somewhat more involved, as we need to start from the assumption that G is not f-choosable and, given some uncolorable list assignment $\mathcal{L}'$, show that H is satisfiable. However, since we do not know exactly how the list assignment $\mathcal{L}'$ which fails to proper $\mathcal{L}'$-color G looks like, we need to consider more general properties which apply to any such potential list assignment.

3.1 Gadgets

Before presenting the main reduction, we introduce three different types of gadgets and prove their properties. Corresponding to the two directions of the proof of correctness of the

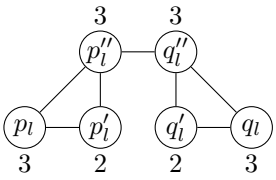

Figure 1 The *Bit-chooser* gadget B_l of the l^{th} bit.

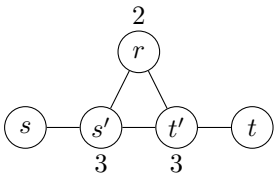

Figure 2 The *Weak-edge* gadget W_{st}, connecting vertices s, t.

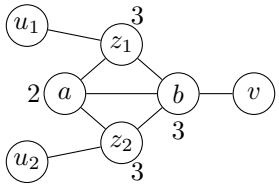

Figure 3 The *Weak-star* gadget S_i for variable x_i.

reduction, we show two types of properties for each gadget: an "$\exists$ list $\mathcal{L}$" property, which we use in order to define a list assignment $\mathcal{L}$ for the forward direction, and a "$\forall$ lists $\mathcal{L}$" property, which shall be useful in proving the converse direction.

1. Bit-chooser gadget B_l (Figure 1). Informally, a list assignment of the bit chooser gadget can enforce that a certain color appears on at least one of the two outputs p_l and q_l, but this is all it can do: in every list assignment, there is a "good" color on p_l and q_l that is compatible with every color on the other output.

▶ **$\exists\mathcal{L}$-Property 1.** There exists a list assignment $\mathcal{L}$ and a color c with $c \in \mathcal{L}(p_l) \cap \mathcal{L}(q_l)$ such that for any proper $\mathcal{L}$-coloring of B_l, at least one of p_l, q_l should receive color c.

▶ **$\forall\mathcal{L}$-Property 1.** For every list assignment $\mathcal{L}$, there exists a color $c \in \mathcal{L}(p_l)$ (resp., $\mathcal{L}(q_l)$) such that for every color $c' \in \mathcal{L}(q_l)$ (resp., $c' \in \mathcal{L}(p_l)$) the pair (c, c') is compatible on (p_l, q_l) (resp., on (q_l, p_l)).

2. Weak-edge gadget W_{st} (Figure 2). Informally, the Weak-edge gadget can prevent a certain combination (c, c') of colors appearing on the two outputs, but it cannot prevent more than one such combinations.

▶ **$\exists\mathcal{L}$-Property 2.** There exists a list assignment $\mathcal{L}$ and colors $c \in \mathcal{L}(s)$, $c' \in \mathcal{L}(t)$ such that the pair (c, c') is incompatible on (s, t).

▶ **$\forall\mathcal{L}$-Property 2.** For every list assignment $\mathcal{L}$, there exists at most one $(c, c') \in \mathcal{L}(s) \times \mathcal{L}(t)$ such that (c, c') incompatible on (s, t). In fact, if (c, c') is incompatible on (s, t), then the following hold: $c, c' \notin \mathcal{L}(r)$; $\mathcal{L}(s') = \{c\} \cup \mathcal{L}(r)$; and $\mathcal{L}(t') = \{c'\} \cup \mathcal{L}(r)$.

Because of their properties, the Weak-edges, if given an appropriate list assignment $\mathcal{L}$, can define an incompatible pair of colors being mutually assigned to their endpoints. Another way to view a Weak-edge is to consider it a directed edge between a precolored vertex s and an uncolored vertex t potentially forbidding a particular color from being assigned to t: if, for W_{st}, (c, c') is incompatible on (s, t) and s has already been assigned color c, then we know that t cannot receive color c'. Observe that, because of the $\forall\mathcal{L}$-Property, each Weak-edge defines at most one such incompatible pair between the endpoints.

3. Weak-star gadget S_i (Figure 3). Informally, the Weak-star gadget has the property that there is at most one color c on v that can forbid one specific color c_1 on u_1 and one specific color c_2 on u_2. When using this gadget on a vertex v whose list size is 2, it will act like an OR-gadget: if this specific color appears on u_1 or u_2, then it forbids color c on v, and hence forces it to take the other color in the list of v.

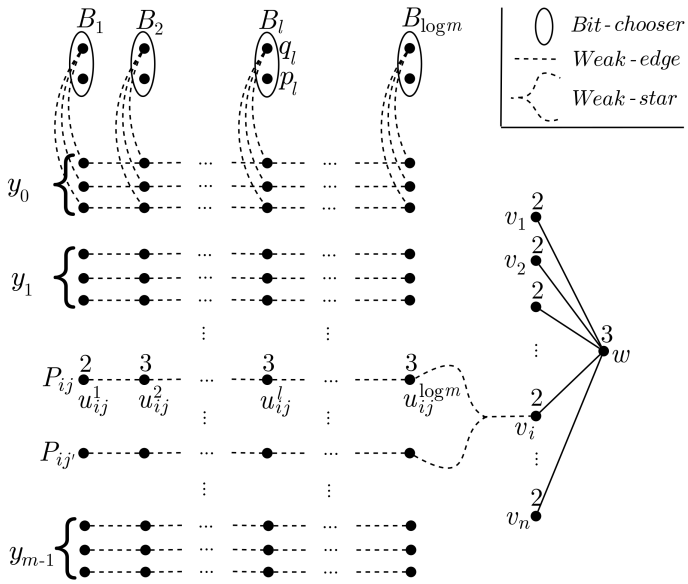

Figure 4 An overview of the construction.

▶ **$\exists\mathcal{L}$-Property 3.** There exist a list assignment $\mathcal{L}$ and a color $c \in \mathcal{L}(u_1) \cap \mathcal{L}(u_2) \cap \mathcal{L}(v)$ such that (c, c) is incompatible on both (u_1, v) and (u_2, v).

▶ **$\forall\mathcal{L}$-Property 3.** For every list assignment $\mathcal{L}$, there exist colors $c_1 \in \mathcal{L}(u_1), c_2 \in \mathcal{L}(u_2), c \in \mathcal{L}(v)$ such that if (d_1, d_2, d) is incompatible on (u_1, u_2, v) then $d = c$ and $(d_1 = c_1) \vee (d_2 = c_2)$.

3.2 Construction

We will now proceed with the description of the construction of G. Consider an arbitrary ordering of the m constraints of Y, assigning a unique index $\{0, \ldots, m-1\}$ to each of them. Now construct $\log m$ *Bit-chooser* gadgets $B_1, \ldots, B_{\log m}$ as shown in Figure 1. For gadget B_l, vertex p_l shall correspond to bit 1 and vertex q_l to 0.

Furthermore, for each appearance of a variable x_i in constraint y_j we construct a *Chain* P_{ij}, which is essentially a path on $\log m$ vertices $u_{ij}^1, \ldots, u_{ij}^{\log m}$, where we have substituted every edge (u_{ij}^l, u_{ij}^{l+1}) by a *Weak-edge* gadget $W_{u_{ij}^l u_{ij}^{l+1}}$ as the one shown in Figure 2, by identifying u_{ij}^l with s and u_{ij}^{l+1} with t. We also set $f(u_{ij}^1) = 2$ and $f(u_{ij}^l) = 3$ for $l > 1$.

Then we need to connect the Chains to the Bit-choosers. To do so, for each Chain P_{ij}, we write j in binary representation and for $l = 1, \ldots, \log m$, if the l^{th} bit is 1, we connect u_{ij}^l to p_l, else we connect it to q_l. The connection is by a Weak-edge $W_{p_l u_{ij}^l}$ or $W_{q_l u_{ij}^l}$ respectively.

In addition, we construct n variable-vertices $v_1, \ldots, v_n$, one for each variable $x_1, \ldots, x_n$ and we set $f(v_i) = 2$. Eventually, we need to connect the two Chains which correspond to the two appearances of x_i to vertex v_i. In order to do so, we use a *Weak-star* gadget S_i (see Figure 3). For Chains P_{ij} and $P_{ij'}$ with $j < j'$, corresponding to variable x_i in constraints y_j and $y_{j'}$, respectively, we identify $u_{ij}^{\log m}$ with u_1, $u_{ij'}^{\log m}$ with u_2, and v with variable-vertex v_i.

Last, we construct a *checker* vertex w with $f(w) = 3$ and connect it to all $v_1, \ldots, v_n$ (using an ordinary edge). This completes the construction. Our claim is that H is satisfiable if and only if G is not f-choosable.

It is easy to verify that the constructed graph G has pathwidth (and hence treewidth) bounded by $O(\log m)$.

▶ **Lemma 13.** *$pw(G) = O(\log m)$.*

3.3 Satisfying assignment ⇒ uncolorable list assignment

In this section, we prove the forward direction of the correctness of the reduction.

▶ **Lemma 14.** *If H is satisfiable, then G is not f-choosable.*

Proof. Assume that H is satisfiable. Then there should be an assignment $h : X \to \{1, 2, 3\}$ satisfying all the constraints in Y. We will produce a list assignment $\mathcal{L}$ for which the graph will not be $\mathcal{L}$-colorable.

First, we construct the lists of the v_i's according to the satisfying assignment of H, $\mathcal{L}(v_i) = \{h(x_i), c\}$. For the checker vertex w, we have $\mathcal{L}(w) = \{1, 2, 3\}$. For the main vertices of the Chains P_{ij}, we set $\mathcal{L}(u^1_{ij}) = \{c, c'\}$ and $\mathcal{L}(u^l_{ij}) = \{c, c', c''\}$, for $l \in \{2, \ldots, \log m\}$. Last, for the gadget vertices, we shall construct their lists according to those from the proofs of the $\exists\mathcal{L}$-Properties, as described below.

- For vertices in the Bit-choosers, lists match exactly those in the proof of $\exists\mathcal{L}$-Property 1.
- For vertices in the Weak-stars, lists match exactly those in the proof of $\exists\mathcal{L}$-Property 3.
- The Weak-edges should specify appropriate incompatible pairs of colors on their endpoints, and the list assignment should follow that of proof of $\exists\mathcal{L}$-Property 2: Weak-edges connecting Bit-choosers to Chains should forbid (c, c') on (p_l, u^l_{ij}) (resp., (q_l, u^l_{ij})); Weak-edges interconnecting Chain-vertices should forbid (c, c'') on $(u^{(l-1)}_{ij}, u^l_{ij})$.

Let us now explain why G is not $\mathcal{L}$-colorable, no matter which colors we pick from the lists. We are going to show that any possible coloring of the Bit-choosers accordant with $\mathcal{L}$ corresponds to selecting a constraint y, by selecting a 0-1 value for $\log m$ bits, which together select a constraint index in $\{0, \ldots, m-1\}$.

From $\exists\mathcal{L}$-Property 1 and for the particular list assignment which emerges from its proof, we are required to *select* (at least) one of the two endpoints p_l, q_l by giving it a special color c. Selecting p_l is interpreted as setting the l^{th} bit to 1, whereas selecting q_l is interpreted as setting it to 0. A selection of $\log m$ bit-vertices (one from each Bit-chooser) corresponds to picking a binary number, which shall represent the index of the constraint we select.

Suppose that a constraint $y_j = (x_{j_1}, x_{j_2}, x_{j_3})$ is selected this way. This means that for the 3 Chains $P_{j_1 j}, P_{j_2 j}, P_{j_3 j}$ we have color c' being removed from all $\mathcal{L}(u^l_{j_i j})$. In particular, this means that $u^1_{j_i j}$ has the unique color c available for it, which in turn forces color c to $u^2_{j_i j}$ by forbidding c'', and so on. This way, color c will propagate throughout the Chains, forcing color c on $u^{\log m}_{ij}$.

From $\exists\mathcal{L}$-Property 3 and for the list described in its proof, forcing color c on $u^{\log m}_{ij}$ forbids color c on v_i, forcing us to choose color $h(x_i)$, which in turn should forbid $h(x_i)$ from w. Since we have three variable-vertices $v_{j_1}, v_{j_2}, v_{j_3}$ with forced choices and $x_{j_1}, x_{j_2}, x_{j_3}$ belong to the same constraint y_j which h satisfies, $h(x_{j_1}), h(x_{j_2}), h(x_{j_3})$ should all be distinct values from $\{1, 2, 3\}$. Thus, all three colors should be forbidden in w, which is fatal since $\mathcal{L}(w) = \{1, 2, 3\}$. ◀

3.4 Uncolorable list assignment ⇒ satisfying assignment

Let us now proceed with the converse direction. First we determine some properties that every uncolorable list assignment $\mathcal{L}'$ of G needs to have. Then we extract an assignment

from $\mathcal{L}'$ for H and use the properties of the lists to show that it is a satisfying assignment.

The following definition will be convenient in the proofs. Let B' be the vertices of all the $\log m$ Bit-choosers. Given some list assignment $\mathcal{L}$, we say that a partial $\mathcal{L}$-coloring $g : B' \to \mathbb{N}$ *activates* vertex u^l_{ij} if $g(p_l) = c$ for some color $c \in \mathcal{L}(p_l)$ and there is a Weak-edge $W_{p_l u^l_{ij}}$ forbidding (c, c') on (p_l, u^l_{ij}) (or similarly for q_l). Thus, if we were to extend g to a proper $\mathcal{L}$-coloring of the whole graph, we would have one less choice for u^l_{ij}. In this case, vertex u^l_{ij} is called *active*. A Chain P_{ij} is called *active* if all its vertices are active. The crucial observation is that if a Chain P_{ij} is not active, no matter what color $c \in \mathcal{L}'(u^{\log m}_{ij})$ we assign to $u^{\log m}_{ij}$, this can be extended to a proper $\mathcal{L}'$-partial coloring of the chain P_{ij}. Suppose for example that vertex u^l_{ij} is not activated, that is, the coloring on the Bit-chooser B_l does not forbid any color on u^l_{ij}. Then we can start coloring the vertices u^1_{ij}, u^2_{ij}, …, u^{l-1}_{ij} in this order, then the vertices $u^{\log m}_{ij}$, $u^{\log m-1}_{ij}$, …, u^{l+1}_{ij} in this order, and there is still at least one available color left for u^l_{ij}. Furthermore, even if P_{ij} is active, it is possible to extend the partial coloring of the Bit-choosers to it, but this may force a certain color on $u^{\log m}_{ij}$.

▶ **Lemma 15.** *If G is not $\mathcal{L}'$-colorable, then any partial $\mathcal{L}'$-coloring of the Bit-choosers activates at least 3 of the Chains.*

Proof. Consider a partial $\mathcal{L}'$-coloring of the Bit-choosers. Suppose that only two Chains $P_{i_1 j_1}$, $P_{i_2 j_2}$ are activated, potentially forcing a coloring on $u^{\log m}_{i_1 j_1}$ and $u^{\log m}_{i_2 j_2}$. By $\forall\mathcal{L}$-Property 3, the $\mathcal{L}'$-coloring can be extended through the Weak-stars S_{i_1} and S_{i_2} even if $i_1 = i_2$, potentially reducing $|\mathcal{L}'(v_{i_1})|$ and $|\mathcal{L}'(v_{i_2})|$ to a unique choice. For every other vertex $u^{\log m}_{ij}$ vertex, any color can be extended to its Chain. Hence the Weak-star S_i for $i \notin \{i_1, i_2\}$ does not forbid any color on v_i.

Now observe that, even if both v_{i_1}, v_{i_2} have forced colors c_1, c_2, there is always a third color $c \in \mathcal{L}'(w)$, $c_1 \neq c \neq c_2$, which we can assign to w. Further observe that, since all other v_i have two available compatible choices with the rest of G, there will be at least one color in every v_i's list which should be different than c. Use these colors to complete a proper $\mathcal{L}'$-coloring for G. Of course this is a contradiction. Thus there should be exactly 3 active Chains. ◀

▶ **Lemma 16.** *For every list assignment $\mathcal{L}'$, there is some partial $\mathcal{L}'$-coloring of the Bit-choosers that activates exactly 3 Chains. Furthermore, for every constraint there exists a partial $\mathcal{L}'$-coloring that activates its 3 corresponding Chains.*

Proof. From $\forall\mathcal{L}$-Property 1, we know that there exists a color $c_p \in \mathcal{L}'(p_l)$ which is compatible with all colors in $\mathcal{L}'(q_l)$ and a color $c_q \in \mathcal{L}'(q_l)$ which is compatible with all colors in $\mathcal{L}'(p_l)$. Let c'_p be an arbitrary color of $\mathcal{L}'(p_l)$ different from c_p, and let c'_q be an arbitrary color of $\mathcal{L}'(q_l)$ different from c_q. Note that both (c_p, c'_q) and (c'_p, c_q) can be extended to the Bit-chooser B_l and we obtain two different colorings for B_l this way.

Let us consider all possible colorings of the Bit-choosers that arise from selecting one of these two colorings for each B_l; there are $2^{\log m} = m$ combinations. We claim that each Chain P_{ij} is activated by at most one of these colorings. Suppose that there are two colorings that both activate P_{ij}. The two colorings must differ on at least one of the Bit-choosers, say, on B_l. Suppose that P_{ij} is connected to p_l with a Weak-edge (the case when it is connected to q_l is analogous). Color c_p appears on p_l in one of the colorings and color c'_p appears in the other coloring. As $c_p \neq c'_p$, it is not possible that the Weak-edge $W_{p_l u^l_{ij}}$ forces a color on u^l_{ij} in both cases, a contradiction.

Since each of the m colorings activates at least 3 Chains by Lemma 15 and we have shown that each of the $3m$ Chains is activated by at most one of the colorings, a counting argument shows that each coloring activates exactly 3 Chains, and each Chain is activated by exactly one of the m colorings. That is, the Chains can be partitioned into m triples, and each triple can be activated by one of the colorings. To prove the second statement of the lemma, we need to show that each such triple contains Chains corresponding to one of the constraints. Suppose for a contradiction that one of the m colorings activates two Chains P_{ij} and $P_{i'j'}$ with $j \neq j'$. As the numbers j and j' are different, there is a bit l where they differ, which means that, without loss of generality that P_{ij} is connected to p_l, while $P_{i'j'}$ is connected to q_l. Suppose that this coloring assigns (c_p, c'_q) to (p_l, q_l) (the case when (c'_p, c_q) appears is similar). Recall that c_p on p_l is compatible with any color of $\mathcal{L}'(q_l)$ appearing on q_l. Let c''_q be the third color of $\mathcal{L}'(q_l)$, different from c_q and c'_q. We may modify the coloring on B_i such that (c_p, c''_q) appears on Bit-chooser B_l. Then $P_{i'j'}$ will no longer be activated: if color c'_q on q_l activated $u^l_{i'j'}$ via Weak-edge $W_{q_l u^l_{i'j'}}$, then color c''_q surely does not activate it. We observe that this modified coloring cannot activate any Chain that was not active before. Indeed, if some Chain $P_{i^*j^*}$ becomes activated by color c''_q on q_l, then $P_{i^*j^*}$ was not activated by any of the m colorings we considered before, as those colorings assigned only colors c_q and c'_q to q_l. This contradicts our earlier claim that each P_{ij} is activated by exactly one of the m colorings. Thus the modified coloring satisfies strictly less than 3 of the Chains, which contradicts Lemma 15. Thus we can conclude that each of the m colorings activates a (different) triple of Chains corresponding to one the m constraints. ◀

▶ **Lemma 17.** *If G is not f-choosable, then H is satisfiable.*

Proof. We may assume without loss of generality that $\mathcal{L}'(w) = \{1, 2, 3\}$. For every Weak-star S_i, consider the color $c_i \in \mathcal{L}'(v_i)$ given by $\forall\mathcal{L}$-Property 3. We define the assignment $h(x_i) := c^*_i$, where $\{c^*_i\} = \mathcal{L}(v_i) \setminus \{c_i\}$. We show that this gives a satisfying assignment: for every constraint $y_j = (x_{i_1}, x_{i_2}, x_{i_3})$, the colors appearing on the variables x_{i_1}, x_{i_2}, x_{i_3} form the set $\{1, 2, 3\}$; in particular, this will imply $h(i) \in \{1, 2, 3\}$ for every i.

Let us verify that that constraint $y_j = (x_{i_1}, x_{i_2}, x_{i_3})$ is satisfied. By Lemma 16, there is a partial assignment to the Bit-choosers that activates exactly the Chains $P_{i_1 j}$, $P_{i_2 j}$, and $P_{i_3 j}$. This means that the vertices $u^{\log m}_{i_1 j}$, $u^{\log m}_{i_2 j}$, and $u^{\log m}_{i_3 j}$ are forced to some color, but the other vertices $u^{\log m}_{ij}$ are unaffected. Thus for $i \notin \{i_1, i_2, i_3\}$, the Weak-star S_i does not prevent any color on v_{i_t}. But for $t = 1, 2, 3$, the Weak-star S_t may forbid the use of color c_{i_t} on v_{i_t}. In order to avoid any conflicts, we assign color $h(x_{i_t}) \neq c_{i_t}$ to v_i. If $\{h(x_{i_1}), h(x_{i_2}), h(x_{i_3})\} \neq \{1, 2, 3\}$, then we can assign to w a color not appearing on v_{i_1}, v_{i_2}, v_{i_3}, and then extend the coloring to v_i for each $i \notin \{i_1, i_2, i_3\}$ by choosing a color different from the color of w. This would contradict the assumption that $\mathcal{L}'$ is not colorable. Thus $\{h(x_{i_1}), h(x_{i_2}), h(x_{i_3})\} = \{1, 2, 3\}$, that is, constraint y_j is satisfied. ◀

3.5 Lower Bounds

Now we are ready to establish the lower bounds stated in Theorem 2(2).

▶ **Theorem 18.** (2, 3)-Choosability *cannot be decided in time $2^{2^{o(pw)}} \cdot n^{O(1)}$, where pw is the pathwidth of the input graph, under ETH.*

Proof. Suppose we could decide (2,3)-Choosability in time $2^{2^{o(\mathrm{pw})}} \cdot n^{O(1)}$. We know from Lemma 13 that $\mathrm{pw} = O(\log m)$.

Thus $2^{2^{o(\mathrm{pw})}} \cdot n^{O(1)} = 2^{2^{o(\log m)}} \cdot n^{O(1)}$. From Lemmas 14 and 17, this would imply solving Edge 3-Coloring in time $2^{2^{o(\log m)}}$. This contradicts Theorem 12. ◀

▶ **Corollary 19** (Theorem 2(2)). *Assuming ETH, k-Choosability for any $k \geq 3$ cannot be decided in time $2^{2^{o(pw)}} \cdot n^{O(1)}$, where pw is the pathwidth of the input graph.*

Proof. First observe that the problem for $k \geq \mathrm{pw} + 1$ is meaningless, since the answer is trivially yes: a graph G of pathwidth pw is pw-degenerate, and thus $(\mathrm{pw}+1)$-choosable.

Gutner and Tarsi [21] give a reduction from $(2,3)$-Choosability to k-Choosability, where the pathwidth of the constructed graph G' is $O(\mathrm{pw}(G))$. ◀

4 Triple-exponential lower bound for k-Choosability Deletion

The goal of this section is to prove Theorem 3(2): the triple-exponential lower bound for k-Choosability Deletion. For this proof, we choose a variant of list coloring as the source problem of the reduction.

Our reduction is from Bipartite List 3-Coloring: given a bipartite graph H with vertex set $X = X_1 \cup X_2, X_1 = \{x_{10}, x_{11}, \ldots x_{1(n-1)}\}, X_2 = \{x_{20}, x_{21}, \ldots, x_{2(n-1)}\}$, edge set Y with $|Y| = m$, and a list assignment $\mathcal{D} : X \to 2^{\{1,2,3\}}$ with $|\mathcal{D}(x)| \geq 2$ for all $x \in X$, the task is to find a proper 3-coloring $\phi : V(G) \to \{1,2,3\}$ of G where $\phi(v) \in \mathcal{D}(v)$ for every vertex v. This problem is known to be NP-hard [31] (to ensure $|\mathcal{D}(x)| \geq 2$, one needs to observe that any vertex with $|\mathcal{D}(x)| = 1$ can be removed from the graph after omitting its unique color from the lists of its neighbors). The NP-hardness proof can be observed to give a tight lower bound, which we state in the following form.

▶ **Lemma 20.** *Assuming ETH, there is no algorithm for* Bipartite List 3-Coloring *with running time $2^{2^{2^{o(\log\log n)}}}$ on bipartite graphs with n vertices on each side. This remains true if we consider only graphs where $\log\log n$ is integer.*

Proof. Given a 3SAT formula with n_0-variables and m_0-clauses, the reduction of Kratochvíl [31] creates an equivalent instance $(G, \mathcal{D})$ of Bipartite List 3-Coloring with $n_1 = O(n_0+m_0)$ vertices and $m_1 = O(n_0+m_0)$ edges. Let n be the smallest integer not smaller than n_1 such that $\log\log n$ is integer. Observe that $n \leq n_1^2$ (as $\log\log n \leq \log\log n_1 + 1$ and hence $\log n \leq 2\log n_1$), hence $\log\log n = \log\log n_1^2 = O(\log\log n_1) = O(\log\log(n_0+m_0))$. Let us add dummy vertices to G until each side has exactly n vertices. Using the assumed algorithm with running time $2^{2^{2^{o(\log\log n)}}}$, we would be able to solve the Bipartite List 3-Coloring instance and hence the equivalent 3SAT instance in time $2^{2^{2^{o(\log\log(n_0+m_0))}}} = 2^{o(n_0+m_0)}$, contradicting ETH. ◀

Given an instance of Bipartite List 3-Coloring, we construct an equivalent instance of $(1,4)$-Choosability Deletion consisting of a graph G and a list-capacity function f. More precisely, there exists a proper $\mathcal{D}$-coloring $h : X \to \{1,2,3\}$ of H if and only if there exists a subset $U \subseteq V(G)$ of vertices with $|U| \leq 4n$ such that $G - U$ is f-choosable. Moreover, graph G has treewidth $O(\log\log n)$. Thus an algorithm for $(1,4)$-Choosability Deletion on graphs of treewidth w with running time $2^{2^{2^{o(w)}}} \cdot n^{O(1)}$ would give an algorithm for Bipartite List 3-Coloring with running time $2^{2^{2^{o(\log\log n)}}} \cdot n^{O(1)}$, contradicting Lemma 20.

Similarly to Section 3, we reformulate Bipartite List 3-Coloring as a constraint satisfaction problem to improve the presentation: the appearance of colors and lists of colors in both the source and target problems would be a source of confusion. We can view Bipartite List 3-Coloring as a constraint satisfaction problem, where the variable set is X and constraints $y = (y_1, y_2) \in Y \subset X_1 \times X_2$ have arity 2. We call an assignment $h : X \to \{1,2,3\}$ a *legal assignment* if we have $h(x) \in \mathcal{D}(x)$ for every $x \in X$. We say

that H is satisfiable if there exists a legal assignment $h : X \to \{1, 2, 3\}$ such that we have $h(y_1) \neq h(y_2)$ for every $y = (y_1, y_2) \in Y$.

Observe that Choosability Deletion has inherently three levels of quantifier alternations in its definition: $\exists$ (set of deleted vertices) $\forall$ (list assignments $\mathcal{L}$) $\exists$ (choice of colors consistent with $\mathcal{L}$). The main idea of the reduction is that we can redefine Bipartite List 3-Coloring using three levels of quantifier alternations. Furthermore, in order to achieve the triple-exponential lower bound, we need to perform an even tighter compression than the one we achieved in Section 3. Keeping those two things in mind we proceed with re-defining Bipartite List 3-Coloring as follows.

From the original definition of Bipartite List 3-Coloring, we have that H is satisfiable if there exists legal assignment $h : X_1 \cup X_2 \to \{1, 2, 3\}$, such that for all $x_{1i} \in X_1$, $x_{2j} \in X_2$ with $h(x_{1i}) \neq h(x_{2j})$, we have $(x_{1i}, x_{2j}) \notin Y$. The latter requirement $(x_{1i}, x_{2j}) \notin Y$ can be re-written as $\forall y = (x_{1i'}, x_{2j'}) \in Y$, either $i' \neq i$ or $j' \neq j$. For some $i < n$, let $\mathcal{B}(i) = [\mathcal{B}(i)_0, \mathcal{B}(i)_1, \ldots, \mathcal{B}(i)_{\log n - 1}]$ be the binary representation of i. Then $i \neq i'$ can be expressed as saying that there exists a $k \in \{0, \ldots, \log n - 1\}$ such that $\mathcal{B}(i)_k \neq \mathcal{B}(i')_k$.

Putting everything together, we have:

▶ **Definition 21** (CSP Bipartite List 3-Coloring defined with 3 levels of quantifier alternations)**.** Given a set $X = X_1 \cup X_2$ of variables with $X_\xi = \{x_{\xi 0}, x_{\xi 1}, \ldots, x_{\xi(n-1)}\}$ for $\xi \in \{1, 2\}$ and a set $Y \subseteq X_1 \times X_2$ of constraints, the task is to decide if

- $\exists$ legal assignment $h : X_\xi \to \{1, 2, 3\}$, such that
- $\forall x_{1i} \in X_1$, $\forall x_{2j} \in X_2$, $\forall y = (x_{1i'}, x_{2j'}) \in Y$ with $h(x_{1i}) = h(x_{2j})$, we have
- $\exists k \in \{0, \ldots, \log n - 1\}$ such that either $\mathcal{B}(i)_k \neq \mathcal{B}(i')_k$ or $\mathcal{B}(j)_k \neq \mathcal{B}(j')_k$.

The reduction closely follows this equivalent definition of Bipartite List 3-Coloring: we use the three levels of alternation in the definition of $(1, 4)$-Choosability Deletion to express these three levels of alternation. Note also that the last level of alternation, when quantifying over $k \in \{0, \ldots, \log n - 1\}$ can be described as the selection of $\log \log n$ bits. This choice will be expressed by the introduction of $\log \log n$ Bit-choosers, which will be the dominating factor in the treewidth of the constructed instance.

Abstract

We study the cryptographic complexity of two-party differentially-private protocols for a large natural class of boolean functionalities. Information theoretically, McGregor et al. [FOCS 2010] and Goyal et al. [Crypto 2013] demonstrated several functionalities for which the maximal possible accuracy in the distributed setting is significantly lower than that in the client-server setting. Goyal et al. [Crypto 2013] further showed that "highly accurate" protocols in the distributed setting for any non-trivial functionality in fact imply the existence of one-way functions. However, it has remained an open problem to characterize the exact cryptographic complexity of this class. In particular, we know that semi-honest oblivious transfer helps obtain optimally accurate distributed differential privacy. But we do not know whether the reverse is true.

We study the following question: *Does the existence of optimally accurate distributed differentially private protocols for any class of functionalities imply the existence of oblivious transfer (or equivalently secure multi-party computation)?* We resolve this question in the affirmative for the class of boolean functionalities that contain an XOR embedded on adjacent inputs. We give a reduction from oblivious transfer to:

- *Any distributed optimally accurate ϵ-differentially private protocol with $\epsilon > 0$* computing a functionality with a boolean XOR embedded on adjacent inputs.
- *Any distributed non-optimally accurate ϵ-differentially private protocol with $\epsilon > 0$, for a constant range of non-optimal accuracies and constant range of values of ϵ,* computing a functionality with a boolean XOR embedded on adjacent inputs.

Enroute to proving these results, we demonstrate a connection between optimally-accurate two-party differentially-private protocols for functions with a boolean XOR embedded on adjacent inputs, and noisy channels, which were shown by Crépeau and Kilian [FOCS 1988] to be sufficient for oblivious transfer.

1 Introduction

Differential privacy [7, 8, 11, 14] is a very well-studied and popular privacy notion of recent years[1]. It provides powerful input privacy guarantees to participants of a statistical query database. Informally a randomized function computed on a database is said to be differentially private, if the output distribution of the function evaluated on the database, induced by the presence of a particular record, is statistically close to the output distribution induced when the record is absent. Note that this can be trivially achieved by computing an output that is independent of the entries in the database. Therefore, to be useful, a non-trivial differentially private algorithm must compute outputs that satisfy some meaningful notion of accuracy.

Consider a confidential dataset owned by a trusted server. The server must release the output of some statistic evaluated on the dataset, to an untrusted client. Even in this setting, where privacy is a concern only at the server's end, there is an evident tradeoff between privacy and accuracy. In fact, for any given privacy parameter ϵ, there is a maximum possible accuracy (which we call the *optimal accuracy*) such that any algorithm with better than optimal accuracy will fail to remain differentially private. Such privacy-accuracy tradeoffs are reasonably well-understood in the client-server setting [7, 12, 15, 23]. There has also been a huge body of work in designing algorithms that achieve close to optimal accuracies for various functionalities and data mining tasks in the client-server setting.

The focus of this work is the distributed setting, where a database is jointly hosted by multiple mutually distrusting servers. This was first studied by Dwork et al. [10]. As an illustrative example, consider two hospitals which together wish to compute the correlation between the occurrence of smoking and lung cancer by taking into account their combined patient records. In this setting, we require the servers to engage in a protocol, at the end of which the privacy of each record of both the servers must be guaranteed without a significant loss in accuracy. Note that the privacy requirements must be met for both servers, *given their entire view of the protocol transcript*, not just the computed output; possibly necessitating an additional loss in accuracy (over and above the loss in the client-server setting).

The intuition that the distributed setting would necessitate a greater accuracy loss than the client-server setting has been proved to be correct in the information theoretic world for different classes of functions. Beimel, Nissim and Omri [1] showed accuracy limits for distributed differentially-private protocols for n parties each holding their own inputs. McGregor, Mironov, Pitassi, Reingold, Talwar and Vadhan [36] showed large accuracy gaps in the two-party setting for several natural functionalities with n-bit inputs. Goyal, Mironov, Pandey and Sahai [19] demonstrated a constant gap between the maximal achievable accuracies in the client-server and distributed settings for any non-trivial boolean functionality.

In the computational setting this gap vanishes, if a semi-honest protocol for oblivious transfer exists. In this case, both servers can use secure multi-party computation [18] to simulate the client-server differentially private function evaluation, thereby obtaining the

[1] See [9] for a survey of results.

optimally accurate output evaluated on the union of their databases. Although oblivious transfer is sufficient to close this gap, it is not clear whether this is a *necessary* assumption.

Indeed, there has been a separate line of work, starting with Haitner, Omri and Zarosim [21] demonstrating black-box separations between one-way functions and distributed differentially private algorithms with optimal accuracies, for two-party functionalities with long outputs. Khurana, Maji and Sahai [25] showed a black-box separation between public-key encryption and distributed differentially private algorithms with optimal accuracies for two-party boolean functionalities. These separations also extend to a range of non-optimal accuracies that are information theoretically impossible to achieve in the distributed setting. These results provide evidence that some "strong" cryptographic assumption is likely necessary for optimally accurate (or close to optimally accurate) distributed differentially private function evaluation. Despite this research, the following question has remained elusive:

> *"Does there exist any class of functionalities whose distributed differentially private evaluation with optimal accuracy – necessitates the existence of oblivious transfer?"*

We prove that any protocol computing the boolean XOR functionality in a distributed differentially private manner with optimal accuracy and overwhelming probability of agreement (on the output) between both parties, implies the existence of oblivious transfer. Our result also directly lends itself to *any* boolean functionality that contains an embedded XOR on two adjacent inputs. Roughly, a function f is said to contain an embedded XOR if and only if the ideal functionality for f can be used to compute the boolean XOR functionality in the semi-honest setting. We give a formal definition of what it means for a function to contain an embedded XOR in the technical sections of the paper.

Interestingly, in the setting of secure computation, the ideal XOR functionality is known to be trivial. This is because the output of this functionality combined with the input of any individual party completely reveals the input of the other party. Thus, parties can simply send each other their inputs – and this corresponds to a secure evaluation of the XOR functionality. However, an optimally accurate distributed differentially private (noisy) protocol for XOR is not trivial, in fact we show that it implies oblivious transfer. Our proof makes use of the fact that an ideal (non-noisy) XOR is fully informative about the input of the other party.

Finally, it is interesting to observe the "philosophical" differences between differential privacy and secure computation:

- In (computationally) differentially-private protocols, "privacy comes first." We would like to first ensure privacy of each individual input and then with this constraint, would like to compute an output which is as accurate as possible.
- In secure computation, "accuracy comes first." We would like to release an accurate output to the function we are computing – and with this constraint, would like to ensure privacy of the inputs to the extent possible. Here, we require the transcript to leak no information about the inputs beyond what can be deduced from the output itself.

Nevertheless, as already mentioned, general secure computation immediately helps achieve the same (optimal) level of accuracy in distributed differentially-private protocols as the best achievable accuracy in the client-server setting. By relying completely on oblivious transfer for secure computation [26], our results show that the reverse is true as well (at least for the differentially private evaluation of any two-party functionality with an embedded XOR).

1.1 Our Contribution

Before elaborating upon our results, we briefly summarize what is known so far about accuracy gaps in the distributed differentially private computation of boolean functionalities.

Alice and Bob with inputs x and y, respectively, wish to compute $f(x, y)$ in a differentially private manner in the distributed setting. An ϵ-differentially private protocol for some functionality f ensures that the probability of Alice's views conditioned on y and y' are $\lambda := e^{\epsilon}$ multiplicatively-close to each other, where y and y' represented as bit-strings differ only in one coordinate (i.e. they are adjacent inputs). A protocol between them is α-accurate if for any x and y, the output of the protocol agrees with $f(x, y)$, with probability at least α.

For boolean functionalities, the optimal accuracy (in the client-server model) is $\alpha^*_\epsilon := \frac{\lambda}{\lambda+1}$, where $\lambda = e^{\epsilon}$. Goyal et al. [19] showed that in the information theoretic setting, $f = \mathsf{AND}$ can only be computed ϵ-differentially privately up to accuracy $\alpha^{(\mathsf{AND})}_\epsilon := \frac{\lambda(\lambda^2+\lambda+2)}{(\lambda+1)^3}$. Similarly, for $f = \mathsf{XOR}$ the maximal achievable accuracy in the information theoretic setting is $\alpha^{(\mathsf{XOR})}_\epsilon := \frac{\lambda^2+1}{(\lambda+1)^2}$. Note that $\alpha^{(\mathsf{XOR})}_\epsilon < \alpha^{(\mathsf{AND})}_\epsilon < \alpha^*_\epsilon$, for any finite $\epsilon > 0$.

We say that a function f contains an embedded XOR if there exist inputs x_0, x_1, y_0, y_1 and outputs z_0, z_1 such that $f(x_a, y_b) = z_{\mathsf{XOR}(a,b)}$ for all $a, b \in \{0, 1\}$. Similarly, we can define an embedded AND (equivalently, an embedded OR). By observing that any boolean function f which is sensitive to both parties' inputs either contains an embedded XOR or AND *on adjacent inputs* [3], the maximal achievable accuracy becomes

$$\alpha^{(f)}_\epsilon := \begin{cases} \alpha^{(\mathsf{XOR})}_\epsilon, & \text{if } f \text{ contains an embedded } \mathsf{XOR} \text{ on adjacent inputs} \\ \alpha^{(\mathsf{AND})}_\epsilon, & \text{otherwise.} \end{cases} \tag{1}$$

Given a semi-honest secure protocol for oblivious transfer, the optimal accuracy α_ϵ is achievable for any boolean f. With respect to the necessity of cryptographic assumptions, Goyal et al. [19] showed that achieving any accuracy between α_ϵ and $\alpha^{(f)}_\epsilon$ for any function f in the distributed setting implies the existence of one-way functions. We strengthen their result to show that any two-party differentially private protocol that computes the XOR functionality in a differentially private manner with accuracy close to α_ϵ implies the existence of semi-honest secure oblivious transfer. Our result also extends to a weaker variant of differential privacy, namely *computational differential privacy* [37]. All our results hold for two-party functionalities where both parties obtain the same output with overwhelming probability. Our results can be summarized as follows (with k denoting the security parameter):

▶ **Informal Theorem 1.** *Semi-honest oblivious transfer reduces to any two-party ϵ DP protocol for XOR with accuracy $\rho(> 1/2)$ such that $\rho \geq \alpha_\epsilon = \frac{e^\epsilon}{1+e^\epsilon}$ (the optimal accuracy).*

▶ **Informal Theorem 2.** *Semi-honest OT reduces to any two-party ϵ_k computationally DP protocol for XOR with accuracy $\rho_k \geq \alpha_{\epsilon_k} = \frac{e^{\epsilon_k}}{1+e^{\epsilon_k}}$ (the optimal accuracy).*

▶ **Informal Theorem 3.** *A $(\rho_k, \frac{\lambda_k}{m_k} - 1, \frac{\lambda}{m_k} - 1)$ weak noisy channel [6, 43] reduces to any two-party ϵ_k computationally DP protocol for XOR with (possibly non-optimal) accuracy $\rho_k(> 1/2)$ where $\lambda_k = e^{\epsilon_k}$ and $m_k = \rho_k/(1 - \rho_k)$.*

We prove the first two theorems via a reduction from (standard) noisy channels, which are known to imply semi-honest OT [5]. The first theorem is just a restriction of the second to the information-theoretic setting. The first two can also be viewed as special cases of the third. Furthermore, for a range of non-optimal accuracies we also show a reduction to weak noisy channels [6, 43]. Invoking known reductions of OT to weak binary symmetric channels, we obtain that for a small range of values of ϵ_k and possibly non-optimal accuracies ρ_k such that $\alpha^{(f)}_{\epsilon_k} \geq \rho_k >> \alpha^*_{\epsilon_k}$, there exist constants $c_1, \left\{c_2 < \frac{e^{c_1}}{1+e^{c_1}}\right\}$ such that for all $\epsilon_k > c_1$ and $\rho_k > c_2$, any two-party ϵ_k-private ρ_k-accurate computational DP protocol for XOR (or more generally any functionality with an embedded XOR on adjacent inputs) implies OT.

1.2 Related Work

The tradeoff between privacy and accuracy is quite central in designing differentially private algorithms. As mentioned before, in the client-server setting (where a single trusted server owns the entire database), the work of Dinur and Nissim [7] first showed limitations for a wide class of private algorithms. These limitations were further explored in [12, 15, 23].

The work of Dwork et al. [8, 11] proposed generic techniques for differentially private function evaluation, based on adding noise as a function of the sensitivity of database queries. The optimality of such techniques was studied in various settings in [13, 22, 41]. Variants of these techniques were shown to be optimal for certain classes of queries by [17, 20], and were shown to be non-optimal for other classes by Brenner and Nissim [2].

As mentioned before, there has also been a significant amount of work characterizing the accuracy of two-party differentially-private protocols. McGregor et al. [36] first showed that information theoretically, a large accuracy loss is inherent to the distributed differentially private computation of functionalities such as the inner product and hamming distance over n-bit inputs. This was followed by the work of Goyal et al. [19] who showed large gaps in the client-server and two-party accuracies for the differentially-private computation of boolean functionalities. Finally, the works of Haitner et al. [21] and Khurana et al. [25] showed that it is impossible to use one-way functions or even key-agreement in a black-box way to bridge any of these accuracy gaps. Our work subsumes these results for the case of XOR.

There has also been a bulk of work on the complexity of two-party finite functionalities in the information theoretic setting [26, 3, 32, 27, 28, 29, 31, 33]. Chor and Kushilevitz [4] established that all Boolean functions either reduce to SFE or can be trivially simulated. In the computationally bounded setting, Maji et al. [34] give a complete characterization of deterministic two-party finite functionalities while a series of works [35, 30, 24] give an information-theoretic characterization of (randomized, fixed-role) two-party functionalities.

Note that all constant communication protocols for Boolean functionalities can be viewed as two-party ideal finite functionalities, and therefore characterized according to [35, 30, 24]. Yet, our characterization extends to any polynomial-round *protocols* for differentially private computation with optimal accuracy, of certain classes of Boolean functionalities. This requires extra techniques to account for the entire transcript of protocol execution, which may leak information over and above the output of the ideal functionality.

1.3 Technical Overview

We consider the simple setting of distributed differentially private evaluation of boolean functions. Alice and Bob, with inputs x and y respectively, execute a protocol to compute a Boolean function $f(x, y)$. The protocol must preserve privacy (according to the differential privacy guarantee) of the input of each party. From [19], we know that any non-trivial Boolean function must embed an AND or an XOR minor on adjacent inputs. In this work, we focus on the XOR functionality; and our proof directly extends to any functionality with an embedded XOR on adjacent inputs. We also consider protocols with perfect agreement, that is, where Alice and Bob always get the same output at the end of the protocol (which is equivalent to saying that the output is part of the transcript). However, our proof also extends to protocols where parties agree on the output with overwhelming probability.[2]

[2] Note that if we relax the requirement of output agreement, then there is a simple information theoretically secure protocol achieving optimal accuracy.

Our main idea will be to use any protocol that implements the XOR functionality to construct an ideal noisy channel. An ideal noisy channel with flip probability $p < 1/2$ is a functionality that takes input a bit X from the sender, samples an independent bernoulli random variable (the 'error') E, where $E \sim \mathsf{Ber}(p)$, computes $\tilde{X} = (X \oplus E)$ and outputs it to the receiver.

Consider an optimally accurate differentially private evaluation of the boolean XOR functionality, where both parties agree on the output with overwhelming probability (and can then publish the output). In this case, the output of the differentially private functionality can be interpreted as a "noisy" version of the correct output. In the optimally accurate setting, the probability that the output is correct is exactly $\alpha_\epsilon = \frac{e^\epsilon}{1+e^\epsilon}$. In other words, let Z denote the output of the protocol, then for all inputs X, Y; the output $Z = (X \oplus Y) \oplus E$, where E is a bernoulli random variable $E \sim \mathsf{Ber}(\frac{1}{1+e^\epsilon})$.

Our protocol to realize a noisy channel is simple: the sender (Alice) and receiver (Bob) sample independent random (private) input bits $X \xleftarrow{\$} \{0,1\}$ and $Y \xleftarrow{\$} \{0,1\}$. They invoke the differentially private protocol for XOR with inputs (X, Y) and obtain output Z, where $Z = (X \oplus Y) \oplus E$, and E is the error as defined above. The sender outputs X and the receiver outputs $Z \oplus Y (= X \oplus E)$. It is easy to see that this protocol *correctly* implements a noisy channel with noise $E \sim \mathsf{Ber}(\frac{1}{1+e^\epsilon})$. However observe that the underlying differentially private protocol for XOR may not be an ideal secure computation protocol for the noisy XOR functionality. In particular, the protocol transcript may leak extra information over the official output. Thus, it remains to prove that the above protocol implements a secure noisy channel – while only relying on the security guarantee of the differential privacy condition.

In the computational setting, the ideal noisy channel functionality can be realized by a protocol with the following security property [5]: roughly, no efficient distinguisher on the sender's end, or on the receiver's end respectively, should be able to distinguish the cases when the error E was 0 from when E was 1. More formally, let $\mathcal{D}_R$ denote a distinguisher that obtains the entire view of the receiver, and $\mathcal{D}_S$ denote a distinguisher that obtains the entire view of the sender at the end of the protocol. Then, for any non-uniform PPT distinguisher $\mathcal{D}_R$, the following security guarantee is required to hold: $\Pr[\mathcal{D}_R = 1|E = 0] - \Pr[\mathcal{D}_R = 1|E = 1] = \mathsf{negl}(k)$ over the randomness of the protocol. Symmetrically, at the sender's end, for any non-uniform PPT distinguisher $\mathcal{D}_S$, $\Pr[\mathcal{D}_S = 1|E = 0] - \Pr[\mathcal{D}_S = 1|E = 1] = \mathsf{negl}(k)$ over the randomness of the protocol. Here $\mathsf{negl}(\cdot)$ denotes some function that is asymptotically smaller than the inverse of any polynomial function, and k denotes the security parameter.

Now, the challenge is to prove that the protocol outlined above satisfies these security properties – that is, no efficient distinguisher on the sender side, or on the receiver side can distinguish the case when $E = 0$ from when $E = 1$. Here, we use the following properties of the optimally accurate differentially private XOR functionality.

- Because of optimal accuracy, the protocol output is correct with probability exactly $\frac{e^\epsilon}{1+e^\epsilon}$.
- The (ideal, non-noisy) XOR functionality is fully informative: its output along with any of the parties' inputs, can be used to correctly compute the input of the other party.

Since the protocol is optimally accurate, the protocol output is correct – that is, $Z = X \oplus Y$ with probability exactly $\alpha_\epsilon = \frac{e^\epsilon}{1+e^\epsilon}$. Moreover, by the fully-informative property of XOR, the correct output, together with the input of any party can be used to correctly compute the other party's input. In other words, for all X, Y, the noisy output Z of the differentially private protocol, together with the input Y, helps compute a guess for the other party's input that is correct with probability at least α_ϵ ($Z \oplus Y$ equals X with probability α_ϵ).

Note that if a party could guess the other party's input with probability any better than α_ϵ, this would directly violate differential privacy. Therefore, the output already allows

computing the best possible guess (upto differential privacy limits) for the other party's input. Informally, this means that any extra information about the error (say, leaked from the transcript) could be used to obtain a better guess of the other party's input and directly violate differential privacy. To prove security of our noisy channel, we must formalize these arguments. This is done in Section 3 and forms the core of our proof of security.

2 Preliminaries

Notation. Let $\pi := \langle A, B \rangle$ be a two-party protocol. Let $\mathsf{view}_\pi^P(x_A, x_B)$ be the random variable which, in a random execution of π with inputs (x_A, x_B) consists of $(x_P, R_P, \mathsf{trans})$, where R_P is the randomness used by party P and trans is the sequence of messages exchanged between the parties in the sampled execution. Let out_P be the function applied by party P on $\mathsf{view}_\pi^P(x_A, x_B)$ to obtain the output for P, $\mathsf{out}_P(\mathsf{view}_\pi^P(x_A, x_B))$. We say that the protocol is *symmetric* if both parties receive the same output, i.e., for every x, y: $\mathsf{out}_A(\mathsf{view}_\pi^A(x_A, x_B)) = \mathsf{out}_B(\mathsf{view}_\pi^B(x_A, x_B))$. This is called the *official* output of the protocol, denoted by $\mathsf{out}_\pi(x_A, x_B)$. For the rest of this paper, we consider only symmetric protocols, however we note that our results can be easily extended to protocols in which both parties agree on the output with overwhelming probability.

In the computational setting, we consider a family of protocols $\{\pi_k\}_{k\in\mathbb{N}}$, where k is the security parameter. Then, the view of party $P \in \{A, B\}$ is denoted by $\mathsf{view}_\pi^P(k, x_A, x_B)$.

2.1 Noisy Channels

Informally, a noisy channel takes as input a bit b and outputs bit $b' = b \oplus e$ where *error bit* $e \sim \mathsf{Ber}(1-\rho)$ is sampled independently, and $\oplus$ is the bitwise exclusive-or operation. Roughly, the security requirement is that the error e remains "semantically secure" for both the sender and the receiver. Somewhat counterintuitively, we consider the flip probability of a ρ-noisy channel to be $(1-\rho)$. This is done deliberately to match DP protocols.

A (ρ, α, β)-weak binary symmetric channel [6, 43] is a noisy channel where the error is no longer "semantically secure". In particular, a malicious sender or receiver obtains partial leakage on the error added by the channel, and (α, β) denote sender and receiver leakage respectively. We defer the formal definitions to the full version.

Any protocol implementing a noisy channel is sufficient to implement the semi-honest OT functionality. A reduction between these primitives was first given by Crépeau and Kilian [5]. Furthermore, [43] showed that any protocol implementing the weak binary symmetric channel for a certain range of parameters of $\rho, \alpha, \beta)$, is sufficient to implement OT. Although these reductions are information-theoretic, they also carry over to the computational setting. We use the following corollary from [43]:

▶ **Corollary 1.** *Let ρ, α, β be constants, and let $\bar{\epsilon} = \frac{(1-\rho)^2}{(1-\rho)^2+\rho^2}$. If at least one of the conditions $2\alpha+\beta+\bar{\epsilon} \le 0.12$, or $\beta+\bar{\epsilon} < \frac{(1-\alpha)^4}{44}$, or $88\alpha+44\bar{\epsilon} < (1-\beta)^2$, or $196\alpha+98\beta+\frac{49}{2} < (1-2\bar{\epsilon})^2$ holds, then there exists a protocol that uses a (ρ, α, β)-passive weak BSC and efficiently implements OT secure in the semi-honest model.*

2.2 Differential Privacy

We give the formal definition of a weak notion of computational differential privacy. Assuming dense sets, this is a strictly weaker definition than other (simulation-based) definitions of CDP [37]. Therefore, our reductions automatically extend to other definitions.

▶ **Definition 2** (ϵ-Indistinguishable-Computational Differential Privacy, [37])**.** We say that an ensemble $\{M_k\}_{k\in\mathbb{N}}$ of randomized functions $M_k : \{0,1\}^n \mapsto \mathcal{R}_k$ with finite range $\mathcal{R}_k$, provides ϵ_k-IND-CDP if there exists a negligible function $\mathsf{negl} : \mathbb{N} \mapsto \mathbb{R}$ such that for every non-uniform PPT algorithm ("distinguisher") D, every polynomial $p(\cdot)$, every sufficiently large $k \in \mathbb{N}$, every $(x, x') \in \{0,1\}^n \times \{0,1\}^n$ satisfying $|x - x'|_h = 1$, and every advice string z_k of size at most $p(k)$ it holds that: $\Pr[D_k(M_k(x)) = 1] \leq e^{\epsilon_k} \times \Pr[D_k(M_k(x')) = 1] + \mathsf{negl}(k)$, where we write $D_k(y)$ for $D(1^k, z_k, y)$ and the probability is over the mechanism M_k and D_k.

▶ **Definition 3** (Differential Privacy over a subset of transcripts)**.** We say that an ensemble $\{M_k\}_{k\in\mathbb{N}}$ of randomized functions $M_k : \{0,1\}^n \mapsto \mathcal{R}_k$ with finite range $\mathcal{R}_k$, provides ϵ_k-IND-CDP over some subset of executions $\mathbb{S}$ if there exists a negligible function $\mathsf{negl} : \mathbb{N} \mapsto \mathbb{R}$ such that for every non-uniform PPT algorithm ("distinguisher") D, every polynomial $p(\cdot)$, every sufficiently large $k \in \mathbb{N}$, every adjacent pair $(x, x') \in \{0,1\}^n \times \{0,1\}^n$, and every advice string z_k of size $\leq p(k)$ $\Pr[D_k(M_k(x)) = 1 \wedge (M_k(x) \in \mathbb{S}_k)] \leq e^{\epsilon_k} \times \Pr[D_k(M_k(x')) = 1 \wedge (M_k(x') \in \mathbb{S}_k)] + \mathsf{negl}(k)$ where we write $D_k(y)$ for $D(1^k, z_k, y)$ and the probability is taken over the randomness of mechanism M_k and distinguisher D_k.

▶ **Definition 4** (Two-Party Differential Privacy)**.** Let $\pi : \langle A, B\rangle$ be a protocol with inputs of A and B in $\{0,1\}^n$. Then π provides ϵ-DP if: (1) for every $x \in \{0,1\}^n$ the mechanism represented by the function $\mathsf{view}^A_\pi(x, \cdot)$ over the inputs $y \in \{0,1\}^n$ is ϵ-DP, and (2) for every $y \in \{0,1\}^n$ the mechanism represented by $\mathsf{view}^B_\pi(\cdot, y)$ over the inputs $x \in \{0,1\}^n$ is ϵ-DP.

In the two-party computational setting, ϵ_k-IND-CDP is defined analogously. Formally, let $\{\pi_k := \langle A, B\rangle(1^k)\}_{k\in\mathbb{N}}$ be an ensemble of interactive functions where the inputs of A and B are in $\{0,1\}^n$. We say that $\{\pi_k\}_{k\in\mathbb{N}}$ provides ϵ_k-IND-CDP if: (1) for every $x \in \{0,1\}^n$ $\{\mathsf{view}^A_\pi(k, x, \cdot)\}_k$ provides ϵ_k-IND-CDP over the inputs $y \in \{0,1\}^n$, and (2) for every $y \in \{0,1\}^n$ $\{\mathsf{view}^A_\pi(k, \cdot, y)\}_k$ provides ϵ_k-IND-CDP over the inputs $x \in \{0,1\}^n$.

▶ **Definition 5** (Accuracy in Differential Privacy [19])**.** The *accuracy* of a randomized Boolean mechanism $M : \{0,1\}^n \mapsto \{0,1\}$ with respect to a Boolean function $f : \{0,1\}^n \mapsto \{0,1\}$ is defined as: $\mathsf{Acc}_f(M) = \min_x\{\Pr[M(x) = f(x)]\}$, where the probability is taken over the randomness of M.

The accuracy of a *symmetric two-party protocol* $\pi := \langle A, B\rangle$ w.r.t. $f : \{0,1\}^n \times \{0,1\}^n \mapsto \{0,1\}$ is the accuracy of the (Boolean) mechanism $\mathsf{out}_\pi : \{0,1\}^n \times \{0,1\}^n \mapsto \{0,1\}$; where out_π returns the official output. Accuracy in the computational setting is defined analogously.

- For every Boolean mechanism $M : \{0,1\}^n \mapsto \{0,1\}$ and Boolean function $f : \{0,1\}^n \mapsto \{0,1\}$, if M is ϵ-DP then: $\mathsf{Acc}_f(M) \leq \frac{\lambda}{1+\lambda}$ where $\lambda = e^\epsilon$.[3] We call the bound $\rho = \frac{\lambda}{1+\lambda}$, the *optimal* accuracy, achieved by setting $M(x) = f(x) \oplus e$ such that $\Pr[e = 0] = \frac{\lambda}{1+\lambda}$.
- If M satisfies ϵ-IND-CDP, then $\mathsf{Acc}_f(M) \leq \frac{\lambda}{1+\lambda} + \mathsf{negl}(k)$ for a negligible function $\mathsf{negl}(\cdot)$.
- If a symmetric protocol ensemble $\{\pi_k\}_{k\in\mathbb{N}}$ provides ϵ-IND-CDP for a constant $\epsilon > 0$, then the accuracy of this ensemble w.r.t. the XOR function is at most $\frac{\lambda+\mathsf{negl}(k)}{1+\lambda} = \rho + \mathsf{negl}'(k)$ for constant ϵ. The accuracy ρ can be achieved using secure two-party computation [37].

3 Noisy Channels Reduce to Optimal Two-Party IND-CDP

▶ **Theorem 6.** *If there exists a two-party ϵ_k-IND-CDP protocol with accuracy $\rho_k(> 1/2)$ such that $\rho_k \geq \frac{e^{\epsilon_k}}{1+e^{\epsilon_k}}$ with respect to the* exclusive-or *function for a constant $\epsilon_k > 0$, then there exists a protocol implementing the ρ_k-noisy-channel functionality.*

[3] Informally, if this is not the case, there exists a distinguisher such that the ratio between the probability that it guesses the input correctly versus incorrectly is greater than e^ϵ, thereby violating ϵ-DP.

Proof. Let $\{\pi_k\}_k$ where $\pi_k = \langle A, B\rangle(1^k)$ be an ensemble of ϵ_k-IND-CDP protocols for computing the XOR function with accuracy $\rho_k \geq \frac{\lambda}{1+\lambda}$ where $\lambda = e^{\epsilon_k}$, and $\epsilon_k > 0$ is a constant. Note that since the protocol is ϵ_k-IND-CDP and $\epsilon_k > 0$, we have that $\rho_k \leq \frac{\lambda}{1+\lambda} + \mathsf{negl}(k)$ for some negligible function $\mathsf{negl}(k)$. For the rest of the proof, we denote ϵ_k by ϵ, and ρ_k by ρ.

The following protocol ensemble $\{\pi_k := \langle S, R\rangle(1^k)\}_k$ implements a ρ-noisy-channel: S receives bit x as input, and R has no input. R samples a random bit y and the parties execute the ϵ-IND-CDP protocol $\langle A(x), B(y)\rangle(1^k)$ and obtain the (same) bit z as official output of this protocol. R outputs $\tilde{x} = z \oplus y$ and S outputs $\perp$. The correctness of this protocol follows directly from the accuracy of the ϵ-IND-CDP protocol. We now show that it satisfies sender-security.

Sender security. Assume to the contrary, that the protocol does not satisfy sender-security. That is, there exists a non-uniform PPT distinguisher $\mathcal{D}_R$, a fixed polynomial $q(\cdot)$, and infinitely many values k for which (there exists a polynomial-sized advice string z_k such that) $\mathsf{Adv}^R_\pi(k) \geq 1/q(k)$. Fix one such k from now on and let:

$$p_k = \Pr[\mathcal{D}_R(z_k, \mathsf{view}^R_{\pi_k}) = 1 | E = 0] - \Pr[\mathcal{D}_R(\mathsf{view}^R_{\pi_k}) = 1 | E = 1]. \tag{2}$$

Note that $\mathsf{Adv}^R_\pi(k) = |p_k|$. Without loss of generality, let $p_k > 0$ for this k, and therefore by assumption $p_k \geq 1/q(k)$. We abuse notation and write $\mathcal{D}_R = 1$ to denote the event that $\mathcal{D}_R(1^k, z_k, \mathsf{view}^R_{\pi'_k}) = 1$.[4] Since $p_k \neq 0$ we must have that $0 < \Pr[\mathcal{D}_R = 1] < 1$.

Let E be the random variable denoting the *error bit* for the ϵ-IND-CDP protocol. That is, for the ϵ-IND-CDP protocol, $E = \tilde{x} \oplus x$. Since we are in the computational setting, the accuracy of the protocol may be different for each input, denoted by: $\rho_{00}, \rho_{01}, \rho_{10}, \rho_{11}$. However, they must all be within a negligible distance from each other and therefore lie within the interval $[\rho - \mathsf{negl}(k), \rho + \mathsf{negl}(k)]$, where ρ denotes ρ_{00}. Since a correct output is equivalent to $E = 0$, and each input is selected with equal probability, $\Pr[E = 0]$ (which is equivalent to "average" accuracy) also lies in the same interval. We show that if p_k is noticeable then differential privacy is violated on the set of transcripts where $\mathcal{D}_R$ outputs 1.

▶ **Claim 7.** $\Pr[E = 0 \wedge \mathcal{D}_R = 1] > e^\epsilon \times \Pr[E = 1 \wedge \mathcal{D}_R = 1] + \frac{p_k}{2}$.

Proof. Let $\Pr[E = 0] = \rho^*$, and $\mu(k)$ be a negligible function so that $\rho^* = \frac{\lambda}{1+\lambda} + \mu(k) > 1/2$. Also, $\Pr[E = 0]/\Pr[E = 1]$ is equal to $\rho^*/(1-\rho^*) = \lambda + \mu'(k)$ for some negligible function μ'. Now, since $\Pr[\mathcal{D}_R = 1] \neq 0$, we can write (using Bayes' rule):

$$\begin{aligned}
&\Pr[E = 0 \wedge \mathcal{D}_R = 1] = \Pr[\mathcal{D}_R = 1 | E = 0] \times \Pr[E = 0] \\
&= \big(p_k + \Pr[\mathcal{D}_R = 1 | E = 1]\big) \times \Pr[E = 0] && \text{(By equation 2)} \\
&= \left(p_k + \frac{\Pr[E = 1 | \mathcal{D}_R = 1] \times \Pr[\mathcal{D}_R = 1]}{\Pr[E = 1]}\right) \times \Pr[E = 0] && \text{(Bayes' rule)} \\
&= p_k \cdot \Pr[E = 0] + \Pr[E = 1 \wedge \mathcal{D}_R = 1] \times \frac{\Pr[E = 0]}{\Pr[E = 1]}
\end{aligned}$$

Note that: $p_k \cdot \Pr[E = 0] = p_k \rho^* > p_k/2$, and $\frac{\Pr[E=0]}{\Pr[E=1]} = \frac{\rho^*}{1-\rho^*} = \lambda + \mu'(k) > \lambda$. Therefore, $\Pr[E = 0 \wedge \mathcal{D}_R = 1] > \frac{p_k}{2} + \lambda \cdot \Pr[E = 1 \wedge \mathcal{D}_R = 1]$. ◀

[4] Note that the input of the sender in sampling view $\mathsf{view}^R_{\pi'_k}$ is uniformly chosen by definition of sender-security; and further, since k has been fixed, letting $\mathcal{D}_R := \mathcal{D}_R(1^k, z_k, \mathsf{view}^R_{\pi'_k})$ is unambiguous and well defined. Note that now, $p_k = \Pr[\mathcal{D}_R = 1 | e = 0] - \Pr[\mathcal{D}_R = 1 | e = 1]$.

- Obtain inputs $M_k(x)$, S_k, D'_k
- If $S_k(M_k(x)) = 1$, $D_k(M_k(x)) = D'_k(M_k(x))$
- If $S_k(M_k(x)) \neq 1$, $D_k(M_k(x)) = 0$

Figure 1 Algorithm for ϵ-IND-CDP Distinguisher D_k.

We say that a subset $\mathbb{S}$ of transcripts is PPT-checkable, if there exists a probabilistic poly-time "checking" algorithm for deciding membership of a transcript in $\mathbb{S}$.

▶ **Claim 8.** *If* $\Pr[E = 0 \wedge \mathcal{D}_R = 1] > e^\epsilon \times \Pr[E = 1 \wedge \mathcal{D}_R = 1] + \frac{p_k}{2}$ *is such that* $\frac{p_k}{2}$ *is non-negligible over uniformly chosen sender input, then the protocol ensemble* $\{\pi_k\}_k$ *does not preserve* ϵ*-IND-CDP on the PPT-checkable subset of transcripts satisfying* $\mathcal{D}_R = 1$.

Proof. From $\Pr[E = 0 \wedge \mathcal{D}_R = 1] > e^\epsilon \Pr[E = 1 \wedge \mathcal{D}_R = 1] + \frac{p_k}{2}$ it follows that $\Pr[\tilde{x} = x \wedge \mathcal{D}_R = 1] > e^\epsilon \Pr[\tilde{x} \neq x \wedge \mathcal{D}_R = 1] + \frac{p_k}{2}$, over the randomness of x where $\tilde{x}$ denotes the output of the receiver. Since x is *uniformly chosen* in $\{0, 1\}$,

$$\Pr[\tilde{x} = 1 \wedge \mathcal{D}_R = 1 | x = 1] + \Pr[\tilde{x} = 0 \wedge \mathcal{D}_R = 1 | x = 0]$$
$$> e^\epsilon \left(\Pr[\tilde{x} = 0 \wedge \mathcal{D}_R = 1 | x = 1]\right) + e^\epsilon \left(\Pr[\tilde{x} = 1 \wedge \mathcal{D}_R = 1 | x = 0]\right) + \frac{p_k}{2}$$

Now, it is easy to observe that *either* of the following statements are true.

1. $\Pr[\tilde{x} = 1 \wedge \mathcal{D}_R = 1 | x = 1] > e^\epsilon \times \Pr[\tilde{x} = 1 \wedge \mathcal{D}_R = 1 | x = 0] + \frac{p_k}{4}$ OR,
2. $\Pr[\tilde{x} = 0 \wedge \mathcal{D}_R = 1 | x = 0] > e^\epsilon \times \Pr[\tilde{x} = 0 \wedge \mathcal{D}_R = 1 | x = 1] + \frac{p_k}{4}$

In either case, it is possible to claim the existence of a distinguisher. If p_k is noticeable and statement 1 holds, then there exists a distinguisher $D_k^{1\prime}$ with output equal to receiver output $\tilde{x}$, which violates IND-CDP over the PPT checkable subset corresponding to $\mathcal{D}_R = 1$. On the other hand, if p_k is noticeable and statement 2 is true, then there exists a distinguisher $D_k^{2\prime}$ with output equal to $1 - \tilde{x}$, which violates IND-CDP over the PPT checkable subset corresponding to $\mathcal{D}_R = 1$.

It follows from this claim that if p_k is noticeable, then the protocol ensemble $\{\pi_k\}_k$ does not preserve ϵ-IND-CDP on the PPT-checkable subset of transcripts on which $\mathcal{D}_R = 1$, because there exists distinguisher $D'_k \in \{D_k^{1\prime}, D_k^{2\prime}\}$ and a corresponding pair of inputs $(x^*, x^{*\prime}) \in (\{0, 1\} \times \{0, 1\})$ such that $\Pr[D'_k = 1 \wedge \mathcal{D}_R = 1 | x = x^*] > e^\epsilon \times \Pr[D'_k = 0 \wedge \mathcal{D}_R = 1 | x = x^{*\prime}] + \frac{p_k}{4}$. In other words, there exists a non-uniform distinguisher that violates ϵ-IND-CDP on this subset. This proves the claim. ◀

▶ **Claim 9.** *A two-party protocol ensemble that provides* ϵ*-IND-CDP over all executions also provides* ϵ*-IND-CDP over any PPT-checkable subset of executions.*

Proof. Assume to the contrary that there exists a two-party ϵ-IND-CDP protocol for which there is a non-uniform PPT distinguisher D'_k that violates ϵ-IND-CDP over some PPT-checkable subset of executions (denoted by $\mathbb{S}_k$). Let S_k denote the code of a PPT-checking algorithm that returns 1 if some execution $M_k(x) \in \mathbb{S}_k$, and 0 otherwise.

Then, we construct a non-uniform PPT distinguisher D_k (Figure 1) that accepts S_k, D'_k as advice z_k, and violates ϵ-IND-CDP for the protocol.

We know that for some polynomial $p(\cdot)$, some sufficiently large $k \in \mathbb{N}$, some $(x^*, x^{*\prime}) \in \{0, 1\} \times \{0, 1\}$, some advice string z'_k of size at most $p(k)$ and all functions $\mathsf{negl} : \mathbb{N} \mapsto \mathbb{R}$, it holds that: $\Pr[D'_k(M_k(x^*)) = 1 \wedge (M_k(x^*) \in \mathbb{S}_k)] > e^{\epsilon_k} \Pr[D'_k(M_k(x^{*\prime})) = 1 \wedge (M_k(x^{*\prime}) \in$

$\mathbb{S}_k)] + \mathsf{negl}(k)$, where the probability is taken over the randomness of mechanism M_k and distinguisher D'_k, and $D'_k(y)$ represents $D'(1^k, z_k, y)$. Then, by a simple manipulation:

$$\begin{aligned}
&\Pr[D_k(M_k(x^*)) = 1] = \Pr[D_k(M_k(x^*)) = 1 \wedge (M_k(x^*) \in \mathbb{S}_k)] \\
&> e^{\epsilon} \Pr[D'_k(M_k(x^{*\prime})) = 1 \wedge (M_k(x^{*\prime}) \in \mathbb{S}_k)] + \mathsf{negl}(k) \\
&= e^{\epsilon} \big(\Pr[D_k(M_k(x^{*\prime})) = 1 \wedge (M_k(x^{*\prime}) \in \mathbb{S}_k)] + \Pr[D_k(M_k(x^{*\prime})) = 1 \wedge (M_k(x^{*\prime}) \notin \mathbb{S}_k)] \big) \\
&+ \mathsf{negl}(k), = e^{\epsilon} \Pr[D_k(M_k(x^{*\prime})) = 1] + \mathsf{negl}(k).
\end{aligned}$$

Therefore, we have a non-uniform PPT distinguisher D_k such that for some polynomial $p(\cdot)$, some sufficiently large $k \in \mathbb{N}$, for the same $(x^*, x^{*\prime}) \in (\{0,1\} \times \{0,1\})$, some advice string z_k of size at most $p(k)$ and all functions $\mathsf{negl} : \mathbb{N} \mapsto \mathbb{R}$ it holds that $\Pr[D'_k(M_k(x^*)) = 1] > e^{\epsilon_k} \times \Pr[D'_k(M_k(x^{*\prime})) = 1] + \mathsf{negl}(k)$. This completes the proof of this claim. ◀

From these claims, it follows that if p_k is noticeable, then $\{\pi_k\}_k$ does not preserve ϵ-IND-CDP. This is a contradiction, therefore $p_k = \mathsf{negl}(k)$, and the noisy channel is sender-secure.

Receiver security. The output z of the ϵ-IND-CDP-protocol, obtained by both parties, is symmetric with respect to the input of each party. Moreover, since the inputs of both parties are chosen uniformly at random, the security of the receiver follows in a manner similar to sender security. This completes the proof of the theorem. ◀

Combining this with Crépeau-Kilian's reduction [5] of OT to noisy channels, we obtain:

▶ **Corollary 10.** *If there exists a two-party ϵ_k-IND-CDP protocol with accuracy ρ_k such that $\rho_k \geq \frac{e^{\epsilon_k}}{1+e^{\epsilon_k}}$ with respect to the* exclusive-or *function for a constant $\epsilon_k > 0$, then there exists an ensemble of protocols implementing the semi-honest oblivious-transfer functionality in the computational setting.*

4 Noisy Channels Reduce to Non-Optimal Two-Party IND-CDP

▶ **Theorem 11.** *If there exists a two-party ϵ_k-IND-CDP protocol with non-optimal accuracy $\rho^1_k \leq \frac{e^{\epsilon_k}}{1+e^{\epsilon_k}}$ with respect to the* exclusive-or *function for a constant $\epsilon_k > 0$, then there exists a protocol implementing the $(\rho^1_k, \frac{\lambda}{m} - 1, \frac{\lambda}{m} - 1)$-passive weak binary symmetric channel functionality where $\rho^1_k > 1/2$, $\lambda = e^{\epsilon_k}$ and $m = \frac{\rho^1_k}{1-\rho^1_k}$.*

The proof of this theorem follows in a similar manner as Theorem 6, and can be found in the full version of our paper. While our reduction to weak noisy channels holds for all parameters $\epsilon > 0$ and accuracies ρ^1_k, the range of parameters for which such channels give OT is small. The following corollary follows from Theorem 11, and Corollary 1.

▶ **Corollary 12.** *If there exists a two-party ϵ_k-IND-CDP protocol with non-optimal accuracy $\rho^1_k \leq \frac{e^{\epsilon_k}}{1+e^{\epsilon_k}}$ with respect to the* exclusive-or *function for a constant $\epsilon > 0$, then there exist constants $c_1, \left\{c_2 < \frac{e^{c_1}}{1+e^{c_1}}\right\}$, such that for all $\epsilon_k > c_1$ and $\rho^1_k > c_2$, there is a protocol implementing the semi-honest oblivious transfer functionality.*

5 Conclusion and Open Problems

5.1 Extension to Functionalities with an Embedded XOR

Recall that we say that a function f contains an embedded XOR on *adjacent* inputs if there exist adjacent inputs x_0, x_1, y_0, y_1 and outputs z_0, z_1 such that $f(x_1, y_b) = z_{\mathsf{XOR}(a,b)}$ for all

$a, b \in \{0, 1\}$. It is easy to observe that any finite functionality f with an embedded XOR, which can be computed with optimal accuracy restricted to its embedded XOR on adjacent inputs, can be used to obtain a differentially private optimally accurate XOR functionality over boolean inputs. Accuracy of XOR follows from the accuracy of the original functionality f, and privacy of XOR follows because differential privacy is a worst-case guarantee which must be maintained even when restricted to a single bit of the adjacent inputs. The resulting differentially private optimally accurate XOR protocol can then be used to obtain a secure noisy channel and therefore, perform oblivious transfer.

5.2 Open Problems

Characterizing All Functionalities. It remains an intriguing open problem to obtain a complete characterization of functionalities whose differentially private evaluation with optimal accuracy in a distributed setting, is cryptographically complete. It is interesting to obtain a complete characterization even for boolean functionalities, since the differentially private evaluation of any non-trivial functionality with optimal accuracy (such as the inner product and hamming distance functionalities considered by McGregor et al. [36]) implies the differentially private evaluation of a non-trivial boolean functionality with optimal accuracy.

Consider, the case of boolean AND. This functionality is interesting, because any non-trivial boolean functionality must contain embedded AND or XOR on adjacent inputs [3]. Therefore, for instance, showing that any (possibly polynomial round) protocol that gives a differentially private protocol for the boolean AND functionality with optimal accuracy, is cryptographically complete – would imply the completeness of an optimally accurate distributed differentially private protocol for any non-trivial boolean functionality. However, unlike XOR, the AND functionality is not completely informative about the other party's input. In case the input of a party is 0, even a non-noisy output of the ideal AND functionality conveys absolutely no information about the input of the other party. In case the input is 1, the output allows to exactly compute the other party's input. Therefore, if a party has input 0, the differentially-private output would be completely useless for this party, while there could be additional leakage from the transcript (allowed by differential privacy) that we do not know how to use. Such functionalities appear to have interesting connections to weak oblivious transfer, from which it is not completely known how to obtain oblivious transfer.

Characterizing non-optimal accuracies. From the work of McGregor et al. [36] and Goyal et al. [19] in the information theoretic setting, it is clear that for any privacy parameter ϵ, there is a constant gap in the maximal achievable accuracies of any ϵ differentially private protocol in the client-server and distributed settings. Goyal et al. [19] additionally showed that any hope of bridging this gap would imply the existence of one-way functions. The black box separation results of [21, 25] also hold for differentially private protocols with any accuracy in this range. Yet, it is unclear whether all protocols with accuracies in this range must imply the existence of oblivious transfer.

Our techniques for non-optimal accuracies give rise to weak noisy channels and weak versions of oblivious transfer, which for a constant range of parameters, do imply full-fledged oblivious transfer. Yet, there is a large gap between the upper and lower bounds for weak oblivious transfer amplification, and since our reductions go via noisy channels – this gap lends itself to our setting. We believe that this provides additional motivation to revive (and continue) research on the characterization of weak noisy channels.

Abstract

We formalize a cryptographic primitive called functional commitment (FC) which can be viewed as a generalization of vector commitments (VCs), polynomial commitments and many other special kinds of commitment schemes. A non-interactive functional commitment allows committing to a message in such a way that the committer has the flexibility of only revealing a function of the committed message during the opening phase. We provide constructions for the functionality of linear functions, where messages consist of vectors over some domain and commitments can later be opened to a specific linear function of the vector coordinates. An opening for a function thus generates a witness for the fact that the function indeed evaluates to a given value for the committed message. One security requirement is called *function binding* and requires that no adversary be able to open a commitment to two different evaluations for the same function.

We propose a construction of functional commitment for linear functions based on constant-size assumptions in composite order groups endowed with a bilinear map. The construction has commitments and openings of constant size (i.e., independent of n or function description) and is *perfectly hiding* – the underlying message is information theoretically hidden. Our security proofs build on the Déjà Q framework of Chase and Meiklejohn (Eurocrypt 2014) and its extension by Wee (TCC 2016) to encryption primitives, thus relying on constant-size subgroup decisional assumptions. We show that FC for linear functions are sufficiently powerful to solve four open problems. They, first, imply polynomial commitments, and, then, give cryptographic accumulators (i.e., an algebraic hash function which makes it possible to efficiently prove that some input belongs to a hashed set). In particular, specializing our FC construction leads to the first pairing-based polynomial commitments and accumulators for large universes known to achieve security under simple assumptions. We also substantially extend our pairing-based accumulator to handle subset queries which requires a non-trivial extension of the Déjà Q framework.

1 Introduction

Commitment schemes are fundamental primitives used as building blocks in a number of cryptographic protocols. A commitment scheme emulates a publicly observed safe; it allows a party to commit to a message m so that this message is not revealed until a later moment when the commitment is opened and the receiver gets convinced that the message was indeed m. Two important security properties are called hiding and binding. The former requires that no information about the message is revealed to an observer. The latter property means that the committing party cannot change the message after committing to it.

Several works considered commitment schemes where the committer has the flexibility of only revealing some partial information about the message (rather than the entire message) during the opening phase. In vector commitments [22, 10], messages are *vectors* and commitments are only opened with respect to specific positions. Another example is polynomial commitments, where users commit to a polynomial and only reveal evaluations of this polynomial on certain inputs.

In this work, we consider functional commitments (FC) for linear functions. Namely, messages consist of vectors $(m_1, \ldots, m_n)$ and commitments can be partially opened by having the sender verifiably reveal a linear combination $\sum_{i=1}^{n} x_i \cdot m_i$, for public coefficients $\{x_i\}_{i=1}^{n}$. We show that this functionality implies many other natural functionalities, including vector commitments, polynomial commitments and cryptographic accumulators. We provide an efficient FC realization for linear functions based on well-studied assumptions in groups with a bilinear map. In turn, our scheme implies solutions to past natural questions. We give the first constructions under constant-size assumptions of two important primitives: polynomial commitments and cryptographic accumulators. In both cases, earlier solutions were based on non-standard assumptions where the number of input elements (and thus the strength of the assumption) depended on specific features of the schemes (like the maximal degree of committed polynomials). Our third result is a solution to an accumulator supporting subset queries, which is also based on constant size assumptions.

1.1 Related Works and the Open Problems

Functional commitments. Functional commitments can be seen as the natural commitment analogue of functional encryption [31, 6]. The latter primitive allows restricting what the receiver learns about encrypted data: when decrypting using a secret key SK_F for the function F, the decryptor learns $F(x)$ and nothing else. Likewise, FC schemes allow the committer to accurately control what the opening phase can reveal about the message.

Functional commitments were implicitly suggested by Gorbunov, Vaikuntanathan and Wichs [17] who described a statistically-hiding commitment scheme for which the sender is able to only reveal a circuit evaluation $C(x)$ when x is the committed input. While their solution supports arbitrary circuits and relies on well-studied lattice assumptions, its input x must be committed to in a bit-by-bit manner (or at least by splitting x into small blocks). We remark that, assuming a common reference string, non-interactive FC for general functionalities can be realized by combining ordinary statistically-hiding commitments with non-interactive zero-knowledge (NIZK) proofs [3]. Here, we focus on the problem of achieving

a better efficiency for more restricted (yet, sufficiently powerful for many applications) functionalities. Assuming a common reference string (as in all non-interactive perfectly hiding commitments), we aim at efficient constructions supporting short witnesses without resorting to the machinery of NIZK proofs. In particular, we aim at constant-size commitment strings (regardless of how long the message is) supporting concise witnesses.

In the literature, a number of earlier works consider settings where a sender is given the flexibility of revealing only a partial information about committed data. A verifiable random function [25], for example, can be seen as a perfectly binding commitment to a pseudo-random function key for which the committer can convince a verifier about the correct function evaluation for the committed key on a given input. Selective-opening security [16] addresses the problem of proving the security of un-opened commitments when an adversary gets to see the opening of other commitments to possibly correlated messages.

Zero-knowledge sets, as introduced by Micali, Rabin and Kilian [24], are another prominent example where users commit to a set S or an elementary database and subsequently prove the (non-)membership of some elements without revealing any further information (not even the cardinality of the committed set S). Ostrovsky, Rackoff and Smith [27] envisioned committed databases for which the sender can demonstrate more general statements than just membership and non-membership.

Vector commitments. Concise vector commitments were first suggested by Libert and Yung [22] and further developed by Catalano and Fiore [10]. They basically consist of Pedersen-like [30] commitments to vectors $(m_1, \ldots, m_n)$ where a constant-size opening (where "constant" means independent of n) allows the sender to open the commitment for only one coordinate m_i without revealing anything on other coordinates. The initial motivation of vector commitments was the design of zero-knowledge databases with short proofs [11, 22] via mercurial commitments [12] supporting short coordinate-wise openings [22]. While concise vector commitments can be based on long-lived hardness assumptions like RSA or Computational Diffie-Hellman [10], they either require groups of hidden order or public keys of size $O(n^2)$ if n is the dimension of committed vectors. In contrast, solutions based on variable-size assumptions allow for public keys of size $O(n)$, which leaves open the following problem.

Problem 1: *Is there a concise vector commitment scheme achieving linear-size public keys under constant-size assumptions in groups with a bilinear map?*

Polynomial commitments. As introduced by Kate, Zaverucha and Goldberg [19], polynomial commitments are a mechanism whereby a sender can generate a constant-size commitment to a polynomial $P[Z]$ (where "constant" means independent of the degree) in such a way that a constant-size witness can convince a verifier that the committed $P[Z]$ indeed evaluates to $P(i)$ for a given i. Polynomial commitments find natural applications in the context of verifiable secret sharing [14], anonymous credentials with attributes [7] or in optimized flavors of zero-knowledge databases which do not seek to hide the size of the committed set. They also imply vector commitments, as observed in [7]. Camenisch *et al.* [7] used vector commitments in a modular design of anonymous credentials where users' credentials are associated with descriptive attributes. While the commitments in [19, 7] were based on parameterized assumptions, the problem described below has been open.

Problem 2: *Design a polynomial commitment based on constant-size assumptions.*

Accumulators. Cryptographic accumulators can be interpreted as commitments, especially when the hashing algorithm is randomized. Accumulators [2] are closely related to zero-knowledge sets in that they make it possible to hash a set S while efficiently generating witnesses guaranteeing the inclusion of certain elements in the hashed set. Unlike zero-knowledge sets, they do not hide the cardinality of the underlying set but usually achieve a better efficiency via short membership witnesses. The first family of accumulators based on number theoretic techniques relies on groups of hidden order [2, 1, 23, 4] and includes proposals based on the Strong RSA assumption [1, 21]. The second family [26, 8], which was first explored by Nguyen [26], appeals to bilinear maps (a.k.a. pairings) and assumptions whose hardness depends on a parameter q determined by features of the scheme or the number of adversarial queries.

Solutions based on the Strong RSA assumption feature short public parameters and readily extend into universal accumulators [21] (where non-membership witnesses can show that a given input was not accumulated) or dynamic accumulators [9] (where witnesses can be autonomously updated when the hashed set is modified). On the other hand, they usually require expensive operations to injectively encode set elements as prime numbers. While pairing-based schemes [26, 8] do not need such a prime-number-encoding, they require linear-size public parameters in the maximal number of accumulated elements. On the positive side, they are useful in applications where the number of hashed elements cannot exceed a pre-determined bound. Pairing-based accumulators also proved useful in the context of authenticated data structures. Papamanthou *et al.* [29] used them to authenticate set operations and notably prove (using a constant-size witness) the inclusion of a given set in the accumulated set. The same technique was extended [29] to provide evidence that two accumulated sets have a given intersection.

A third family of accumulators [28, 4] builds on hash trees rather than number theoretic assumptions. Its disadvantage is that witnesses have size $O(\log N)$ (where N denote the cardinality of hashed sets) whereas number-theoretic solutions enable $O(1)$-size witnesses.

The security properties of accumulators were recently re-formalized by Derler *et al.* [15] who showed connections with other primitives. It was notably showed that, when endowed with an indistinguishability property, accumulators imply non-interactive commitment schemes and are implied by zero-knowledge sets.

Despite their numerous applications, cryptographic accumulators still have relatively few assumptions to rely on. So far, known candidates based on standard assumption arise from a generic construction from vector commitments [10]. While implying solutions based on RSA or Diffie-Hellman, the generic construction of [10] only supports inputs living in a small domain: the public key size is indeed linear in the size of the input universe, which prevents from hashing elements consisting of arbitrary strings. This leaves open Problem 3.

Problem 3: *Does there exist a pairing-based accumulator for large input universes secure under constant-size assumptions?*

As mentioned earlier, accumulators are applicable in authenticating set operations ([29]) and a useful extension would allow creating witnesses for set inclusion and intersection that are of constant size. Namely, a short witness can serve as evidence that some set X is a subset of the accumulated set or that two sets X_1, X_2 have a particular intersection I. In this domain, the following problem still remains open.

Problem 4: *Construct a pairing-based accumulator supporting set operations with constant-size witnesses achieving security under simple assumptions.*

1.2 Our Contributions

We formalize the notion of *functional commitments* (FCs) for linear functions, a generalization of vector commitments (VCs). Similar to VCs, such a commitment scheme allows committing to vectors of messages which can later be opened to specific function evaluations. While possible [17], the design of FCs for arbitrary functionalities seems unlikely to lead to truly efficient solutions. Instead, we aim at FCs for linear function families $\{F_{\vec{x}} : \mathcal{D}^n \times \mathcal{D}^n \to \mathcal{D}\}_{\vec{x}\in\mathcal{D}^n}$ defined by $F_{\vec{x}}(\vec{m}) = \langle \vec{x}, \vec{m}\rangle = \sum_{i=1}^n x_i m_i$ for $\vec{m} \in \mathcal{D}^n$ that suffice for many important applications. An FC scheme for a family of linear functions $\{F_{\vec{x}} : \mathcal{D}^n \to \mathcal{D}\}_{\vec{x}\in\mathcal{D}^n}$ produces commitments to messages of the form $\vec{m} = (m_1, \ldots, m_n) \in \mathcal{D}^n$ over the domain $\mathcal{D}$. Fixing a specific $\vec{x} \in \mathcal{D}^n$, such that $y = \sum_{i=1}^n x_i m_i \in \mathcal{D}$, an opening for $F_{\vec{x}}$ demonstrates that $F_{\vec{x}}(\vec{m})$ indeed evaluates to y. The security notions of hiding and binding extend to our setting in a natural way. In addition, we require the commitments and witnesses to be *concise* i.e., their size should be independent of the length of messages or function description.

Our first contribution is a construction of functional commitment for linear functions based on well-studied assumptions in composite order bilinear groups. The scheme is perfectly hiding and computationally binding under subgroup decision assumptions. The construction can be seen as a variant of the vector commitment scheme of Izabachène *et al.* [18] which was only proved secure under a non-standard variable-size assumption. We show that the composite-order setting makes it possible to use the Déjà Q framework of [13] so as to obtain security from constant size assumptions. As FC for linear functions implies vector commitments, our construction provides a positive answer to *Problem 1*.

As a second contribution, we show that our FC scheme implies polynomial commitments and large-universe accumulators supporting subset queries. The resulting schemes are secure under subgroup decision assumptions of constant-size thus settling *Problem 2* and *Problem 3*. We finally extend our accumulator into a scheme supporting subset queries while retaining security from constant size assumptions, partially answering *Problem 4* in the affirmative.

Overview of our Construction. Let $e : \mathbb{G} \times \mathbb{G} \to \mathbb{G}_T$ be a bilinear map with common group order $N = p_1p_2p_3$ and let $\mathbb{G}_q$ denote the subgroup of $\mathbb{G}$ of order q (here q would be of the form $p_1^{e_1}p_2^{e_2}p_3^{e_3}$ for $e_1, e_2, e_3 \in \{0, 1\}$). The linear functions will be defined over $\mathbb{Z}_N$. The commitment key consists of $\{g^{\alpha^j}\}_{j=1}^n$, $\{U_j = u^{\alpha^j}\}_{j\in[1,2n]\setminus\{n+1\}}$ for some $g, u \in \mathbb{G}_{p_1}$. The trapdoor is $U_{n+1} = u^{\alpha^{n+1}}$. A commitment to $\vec{m}$ consists of $C = g^\gamma \cdot \prod_{j=1}^n g^{\alpha^j m_j}$. Witness for a function evaluation $\langle \vec{x}, \vec{m}\rangle = y$ is defined as $W_y = \prod_{i=1}^n W_i^{x_i}$ with the $\mathbb{G}_{p_1}$ component of W_i being $u^{\alpha^{n-i+1}\gamma} \cdot \prod_{j=1, j\neq i}^n u^{\alpha^{n+1+j-i}m_j}$ for each $i = 1, \ldots, n$. The absence of U_{n+1} in the witness allows verifying that $y = \langle \vec{x}, \vec{m}\rangle$ by testing if $e(C, \prod_{i=1}^n u^{\alpha^{n-i+1}x_i}) = e(g^\alpha, u^{\alpha^n})^y \cdot e(g, W_y)$. The u-components are randomized with elements of $\mathbb{G}_{p_3}$. This modification does not affect verification since the $\mathbb{G}_{p_3}$ components get cancelled upon pairing with $\mathbb{G}_{p_1}$ elements. The scheme is a composite-order analogue of the one proposed in [22].

Proof Idea. A $(q_1 \to q_2)$ subgroup decision assumption requires random elements of $\mathbb{G}_{q_1}$ to be indistinguishable from random elements of $\mathbb{G}_{q_2}$. Using Wee's adaptation [32] of the Déjà Q framework [13], we prove that our FC scheme is computationally binding based on $(p_1 \to p_1p_2)$ and $(p_1p_3 \to p_1p_2p_3)$ subgroup decision assumptions. An adversary breaking the binding property is successful if it can produce a commitment C and two conflicting witnesses W_y and $W_{y'}$ for evaluation of a function $\vec{x}$. Given that both witnesses satisfy the verification equations, one can say that the adversary can essentially produce $\Delta W = \left(W_{y'}/W_y\right)^{1/(y-y')}$ which is of the form $u^{(\alpha^{n+1})} \cdot g_2^{r_2} \cdot g_3^{r_3}$ for some $r_2, r_3 \in \mathbb{Z}_N$ and generators $g_2 \in \mathbb{G}_{p_2}$ and

$g_3 \in \mathbb{G}_{p_3}$. The $\mathbb{G}_{p_1}$ component of ΔW is identical to that of the trapdoor key. Define two types of keys (resp. attacks) according to $\{U_j\}_{j=1}^{2n}$ (resp. ΔW) containing a $\mathbb{G}_{p_2}$ component or not. We argue that the attacker cannot mount an attack of a type different from that of the key based on the $(p_1 \to p_1 p_2)$. The distribution of $\mathbb{G}_{p_2}$ components for the keys are changed gradually via the transition described below.

$$u^{\alpha^i} R_{3,i} \xrightarrow{\text{subgroup}} u^{\alpha^i} g_2^{r_1 \alpha^i} R_{3,i} \xrightarrow{\text{CRT}} u^{\alpha^i} g_2^{r_1 \alpha_1^i} R_{3,i},$$

where α_1 is uniformly distributed over $\mathbb{Z}_N$. The first transition uses the $p_1 p_3 \to p_1 p_2 p_3$ subgroup decision assumptions and the second transition is based on the Chinese remainder theorem (CRT) that states that $\alpha \bmod p_1$ and $\alpha \bmod p_2$ are uncorrelated. We can thus replace $\alpha \bmod p_2$ by $\alpha_1 \bmod p_2$ as long as the former is unconditionally hidden from the attacker. By repeating the transition $2n$ times, we obtain the transformation: $u^{\alpha^i} \to u^{\alpha^i} g_2^{\sum_{j=1}^{2n} r_j \alpha_j^i} R'_{3,i}$.

The exponent of g_2 is a pseudorandom function [13, 32] and hence can be replaced by a random exponent, $RF(i)$ for U_i in particular. After the final transition, creating ΔW consistent with these keys amounts to predicting the value of the random function evaluated at $n+1$ (for the trapdoor U_{n+1}), which is statistically infeasible.

Polynomial Commitments from Simple Assumptions. We wish to commit to a polynomial $P[Z] = a_0 + a_1 Z + \cdots + a_{n-1} Z^{n-1}$ of degree n over $\mathcal{D}$ and reveal an opening for $P(x)$ for $x \in \mathcal{D}$. Using the FC scheme for linear functions, we can commit to $(a_0, \ldots, a_{n-1}) \in \mathcal{D}^n$ so that an opening to $P(x)$ is a witness for $\langle \vec{x}, \vec{m} \rangle = P(x)$ where $\vec{x} = (1, x, \ldots, x^{n-1})$.

Accumulators for Large Universes. An accumulator allows hashing a set to a single element so that one can prove the membership of a value in the set. Vector commitments are known to imply accumulators [10], but via a construction that only supports a small universe of values. Our polynomial commitment naturally leads to an accumulator for large universes (i.e., the domain size can be exponential in the security parameter). To accumulate a set of values $S = \{y_1, \ldots, y_{n-1}\}$, use a polynomial commitment to $P[Z] = \prod_{i=1}^{n-1} (Z - y_i)$. A witness for $x \in S$ (or $x \notin S$) is generated based on the fact $P[x] = 0$ if and only if $x \in S$.

Tackling Subset Queries. Polynomial commitments and universal accumulators can be seen as direct consequences of the FC for linear functions. On the other hand, proving security for accumulators with concise subset witnesses requires a novel extension of the Déjà Q framework. We now provide a brief outline of the same.

Let n be the maximal number of accumulated values and let d be the maximal size of "provable" subsets. In the commitment scheme, keys consisted of powers of α in the exponent over the interval $[1, 2n]$ with a hole at position $n+1$. We extend this interval to $[1, (d+1)n]$ keeping $n+1, 2n+1, \ldots, (d+1)n$ powers of α as part of the trapdoor. The witness component for a specific position i of the linear function was defined as $W_i = u^{\alpha^{n-i+1}\gamma} \cdot \prod_{j=1, j\neq i}^{n} u^{\alpha^{n+1+j-i} m_j}$. To combine witnesses for several (at most d) values into a constant-size witness, we define the witness for the i-th position of the ℓ-th element as a "shift" of W_i by n. More precisely, $W_{\ell,i}$ is defined to have $u^{\alpha^{\ell n - i + 1}\gamma} \cdot \prod_{j=1, j\neq i}^{n} u^{\alpha^{\ell n + 1 + j - i} m_j}$ as its $\mathbb{G}_{p_1}$ component.

Security for accumulators is captured by the notion of *collision-freeness* which asserts that it is computationally infeasible for an attacker to produce a set S and a witness W_X for a subset $X = \{x_1, \ldots, x_k\} \not\subseteq S$ that verifies correctly with an accumulated value for S (generated using randomness specified by the adversary). Given the randomness, the

reduction can compute valid witnesses of membership and non-membership for individual values in X (as in the normal accumulator scheme). Combining appropriate "shifts" of these witnesses gives us $W_{X\cap S}$ (combined membership witness) and $W_{X\setminus S}$ (combined non-membership witness). We then observe that $W/(W_{X\cap S}W_{X\setminus S})$ has a $\mathbb{G}_{p_1}$-component of the form $u^{\sum_{\ell\in[1,k],x_\ell\notin S} w_\ell \alpha^{\ell n+1}}$ ($w_\ell \neq 0$) which means that the attacker essentially produces a linear combination of the discrete logarithms of trapdoor keys in the exponent. The rest of the reduction proceeds similar to the FC scheme with the pseudorandom function now extending to the larger interval. Using this pseudorandom function, the distribution of the keys is gradually modified until the $\mathbb{G}_{p_2}$ components of all U_i's are truly random. We argue that generating such a witness requires the adversary to predict a linear combination of at most d specific evaluations of a random function which is clearly infeasible.

2 Background

2.1 Bilinear Maps and Complexity Assumptions

We use groups $(\mathbb{G}, \mathbb{G}_T)$ of composite order $N = p_1p_2p_3$ endowed with an efficiently computable map (a.k.a. pairing) $e : \mathbb{G}\times\mathbb{G} \to \mathbb{G}_T$ such that: (1) $e(g^a, h^b) = e(g, h)^{ab}$ for any $(g, h) \in \mathbb{G}\times\mathbb{G}$ and $a, b \in \mathbb{Z}$; (2) if $e(g, h) = 1_{\mathbb{G}_T}$ for each $h \in \mathbb{G}$, then $g = 1_{\mathbb{G}}$. Also, pairing two elements of order p_i and p_j, with $i \neq j$, always gives the identity element $1_{\mathbb{G}_T}$.

In the following, for each $i \in \{1, 2, 3\}$, we denote by $\mathbb{G}_{p_i}$ the subgroup of order p_i. For all distinct $i, j \in \{1, 2, 3\}$, we call $\mathbb{G}_{p_ip_j}$ the subgroup of order p_ip_j. We rely on the following assumptions introduced in [20], which are non-interactive, falsifiable. In both of them, the number of input elements is constant (regardless of the number of adversarial queries).

Assumption 1. Given a description of $(\mathbb{G}, \mathbb{G}_T)$ as well as $g \xleftarrow{R} \mathbb{G}_{p_1}, X_3 \xleftarrow{R} \mathbb{G}_{p_3}$ and $T \in \mathbb{G}$, it is infeasible to efficiently decide if $T \in \mathbb{G}_{p_1p_2}$ or $T \in \mathbb{G}_{p_1}$.

Assumption 2. Let $g, X_1 \xleftarrow{R} \mathbb{G}_{p_1}, X_2, Y_2 \xleftarrow{R} \mathbb{G}_{p_2}, Y_3, Z_3 \xleftarrow{R} \mathbb{G}_{p_3}$. Given a description of $(\mathbb{G}, \mathbb{G}_T)$, (g, X_1X_2, Z_3, Y_2Y_3) and T, it is hard to decide if $T \in_R \mathbb{G}_{p_1p_3}$ or $T \in_R \mathbb{G}$.

2.2 Vector Commitment Schemes

In prime order groups, Libert and Yung [22] introduced concise vector commitment schemes, which are commitments that can be opened with a short de-commitment string for each individual coordinate. Such commitments were described in [22, 10]. In [22], the commitment key is $CK = (g, g_1, \ldots, g_n, g_{n+2}, \ldots, g_{2n}) \in \mathbb{G}^{2n}$, where $g_i = g^{(\alpha^i)}$ for each i. The trapdoor is g_{n+1}. To commit to $\vec{m} = (m_1, \ldots, m_n)$, one picks $r \xleftarrow{R} \mathbb{Z}_p$ and computes $C = g^r \cdot \prod_{j=1}^{n} g_{n+1-j}^{m_\kappa}$. A single element $W_i = g_i^r \cdot \prod_{j=1, j\neq i}^{n} g_{n+1-j+i}^{m_j}$ provides evidence that m_i is the i-th component of $\vec{m}$ as it satisfies $e(g_i, C) = e(g, W_i) \cdot e(g_1, g_n)^{m_i}$. The infeasibility of opening C to two distinct messages for some i relies on a parametrized assumption [5].

2.3 Functional Commitments for Linear Functions: Definitions

In [18], Izabachène *et al.* implicitly showed that the vector commitment scheme of [22] can be generalized into a commitment scheme allowing to commit to a vector $\vec{m}$ while proving – via a partial opening made of a short piece of information – that the committed vector $\vec{m}$ satisfies $\langle\vec{m}, \vec{x}\rangle = y$, for some public $\vec{m}$ and y. We call such a primitive *functional* commitment for *linear* functions. In this section, we formally define this primitive and its security.

▶ **Definition 1** (Functional Commitments)**.** Let $\mathcal{D}$ be a domain and consider linear functions $\langle\cdot,\cdot\rangle : \mathcal{D}^n \times \mathcal{D}^n \to \mathcal{D}$ defined by $\langle \vec{x}, \vec{m}\rangle = \sum_{i=1}^{n} x_i m_i$ for $\vec{x}, \vec{m} \in \mathcal{D}^n$ with $\vec{x} = (x_1, \ldots, x_n), \vec{m} = (m_1, \ldots, m_n)$. A functional commitment scheme FC for $(\mathcal{D}, n, \langle\cdot,\cdot\rangle)$ is a tuple of four (possibly probabilistic) polynomial time algorithms – (Setup,Commit,Open,Verify).

Setup$(1^\lambda, 1^n)$: takes in a security parameter $\lambda \in \mathbb{N}$, a desired message length $n \in \mathsf{poly}(\lambda)$ and outputs a commitment key CK and, optionally, a trapdoor TK.

Commit$(CK, \vec{m})$: takes as input the commitment key CK, a message vector $\vec{m} \in \mathcal{D}^n$ and outputs a commitment C for $\vec{m}$ and auxiliary information denotes aux.

Open$(CK, C, \mathsf{aux}, \vec{x})$: takes as input the commitment key CK, a commitment C (to $\vec{m}$), auxiliary information (possibly containing $\vec{m}$) and a vector $\vec{x} \in \mathcal{D}^n$; computes a witness W_y for $y = \langle \vec{x}, \vec{m}\rangle$ *i.e.,* W_y is a witness for the fact that the linear function defined by $\vec{x}$ when evaluated on $\vec{m}$ gives y.

Verify$(CK, C, W_y, \vec{x}, y)$: takes as input the commitment key CK, a commitment C, a witness W_y, a vector $\vec{x} \in \mathcal{D}^n$ and $y \in \mathcal{D}$; outputs 1 if W_y is a witness for C being a commitment for some $\vec{m} \in \mathcal{D}^n$ such that $\langle \vec{x}, \vec{y}\rangle = y$ and outputs 0 otherwise.

The correctness condition for a functional commitment scheme requires that for every $(CK, TK) \leftarrow \mathsf{Setup}(\lambda, n)$, for all $\vec{m}, \vec{x} \in \mathcal{D}^n$, if $(C, \mathsf{aux}) \leftarrow \mathsf{Commit}(CK, \vec{m})$ and $W_y \leftarrow \mathsf{Open}(CK, C, \mathsf{aux}, \vec{x})$, then $\mathsf{Verify}(CK, C, W_y, \vec{x}, y) = 1$ with probability 1.

The security requirements of functional commitments are formalized as follows. The perfect hiding property mandates that the distribution of the commitment string $\mathsf{Commit}(CK, \vec{m})$ be independent of the message $\vec{m}$.

▶ **Definition 2** (Perfectly Hiding)**.** A commitment scheme is perfectly hiding if for a key CK generated by an honest setup, for all $\vec{m}_1, \vec{m}_2 \in \mathcal{D}^n$ with $\vec{m}_1 \neq \vec{m}_2$, the two distributions $\{CK, \mathsf{Commit}(CK, \vec{m}_1)\}$ and $\{CK, \mathsf{Commit}(CK, \vec{m}_2)\}$ are identical given that the random coins of Commit are chosen according to the uniform distribution from the respective domain.

The binding property requires the infeasibility of generating a commitment C and accepting witnesses for two distinct values y, y' without knowing the trapdoor TK.

▶ **Definition 3** (Function Binding)**.** A functional commitment scheme $\mathsf{FC} = (\mathsf{Setup}, \mathsf{Commit}, \mathsf{Open}, \mathsf{Verify})$ for $(\mathcal{D}, n, \langle\cdot,\cdot\rangle)$ is said to be computationally binding if any PPT adversary $\mathcal{A}$ has negligible advantage in winning the following game.

1. The challenger generates (CK, TK) by running $\mathsf{Setup}(\lambda, n)$ and gives CK to $\mathcal{A}$.
2. The adversary $\mathcal{A}$ outputs a commitment C, a vector $\vec{x} \in \mathcal{D}^n$, two values $y, y' \in \mathcal{D}$ and two witnesses $W_y, W_{y'}$. We say that $\mathcal{A}$ wins the game if the following conditions hold.
   - **(i)** $y \neq y'$;
   - **(ii)** $\mathsf{Verify}(CK, C, W_y, \vec{x}, y) = \mathsf{Verify}(CK, C, W_{y'}, \vec{x}, y') = 1$.

2.4 Cryptographic Accumulators

The basic functionality of an accumulator is to combine a set S of values into a single value V so that for any $x \in S$ it is possible to prove that x is accumulated in V.

▶ **Definition 4** (Accumulator)**.** Let $\mathcal{D}$ be a domain. An accumulator scheme Acc for $\mathcal{D}$ is a tuple $(\mathsf{Setup}, \mathsf{Eval}, \mathsf{WitCreate}, \mathsf{Verify})$ of PPT algorithms defined as follows.

Setup$(1^\lambda, 1^n)$: takes as input a security parameter λ and an integer $n \in \mathbb{N}$ upper bounding the number of elements that can be accumulated; outputs a pair of keys (PK, SK).

Eval(PK, S): inputs a key PK, a set $S \subset \mathcal{D}$ of elements (with $|S| \leq n$) to be accumulated and outputs an accumulated value V along with some auxiliary information aux.

WitCreate$(PK, S, V, \mathsf{aux}, x, \mathsf{type})$**:** inputs a public key PK, a set S, a pair of accumulated value and state information (V, aux) generated by $\mathsf{Eval}(PK, S)$, an element $x \in \mathcal{D}$ and a boolean value $\mathsf{type} \in \{0, 1\}$ indicating whether the output should be membership or non-membership witness according as its value is 1 or 0 respectively.
Case type $= 1$**:** If $x \notin S$, it returns $\perp$. Otherwise, a membership witness W is returned.
Case type $= 0$**:** It returns $\perp$ if $x \in S$ and a non-membership witness W otherwise.

Verify$(PK, V, W, x, \mathsf{type})$**:** takes as input the public key PK, an accumulator V for set S, a witness W, an element $x \in \mathcal{D}$ and a boolean value type. Returns 1 if and only if either
- W is a valid witness for $x \in S$ and $\mathsf{type} = 1$
- W is a valid witness for $x \notin S$ and $\mathsf{type} = 0$.

The above definition consider static accumulators. In dynamic accumulators, the accumulated value as well as witnesses can be publicly updated whenever an element is added to or deleted from the set. In this work, we only consider static accumulators.

The correctness condition requires that for all honestly generated keys, all honestly computed accumulators and witnesses, the Verify algorithm always accepts. An accumulator scheme is deemed secure if it is at least *collision-free*. Collision-freeness ensures the computational infeasibility of producing either a membership witness for a non-accumulated value or a non-membership witness for an accumulated value.

In accumulators supporting subset queries, witnesses can be generated for a subset of the accumulated set rather than individual elements. While accumulators have been defined in the universal setting, i.e., both membership and non-membership witnesses can be generated, here we only consider the non-universal setting.

▶ **Definition 5** (Accumulator with subset queries)**.** Let $\mathcal{D}$ be a domain. An accumulator scheme Acc for $\mathcal{D}$ is defined by a tuple (Setup, Eval, WitCreate, Verify) of probabilistic polynomial time algorithms defined as follows.

Setup$(1^\lambda, 1^n, 1^d)$**:** takes as input a security parameter λ, an upper bound $n \in \mathbb{N}$ on the number of elements that can be accumulated and an integer $d \in \mathbb{N}$ denoting the maximum size of a set for which a witness can be created; outputs a pair of keys (PK, SK).

Eval(PK, S)**:** takes in a public key PK, a set $S \subset \mathcal{D}$ of elements (with $|S| \leq n$) to be accumulated and outputs an accumulated value V with some auxiliary information aux.

WitCreate$(PK, S, V, \mathsf{aux}, X)$**:** inputs a public key PK, a set S, a pair of accumulated value and state information (V, aux) generated by $\mathsf{Eval}(PK, S)$, a set $X \subseteq S$ with $|X| \leq d$ and outputs a witness W_X.

Verify(PK, V, W_X, X)**:** takes as input the public key PK, an accumulator V for set S, a witness W_X, a set $X \subseteq S$. Returns 1 if W_X is a witness for $X \subseteq S$ and $\perp$ otherwise.

In the above syntax, we assume that the auxiliary information aux includes the randomness that was used to compute V when Eval is a probabilistic algorithm.

3 A Functional Commitment from Subgroup Decision Assumptions

Here, we prove that the Déjà Q framework [13] allows proving the security of the functional commitment of [18] under constant size assumptions by switching to composite order groups.

Setup$(1^\lambda, 1^n)$**:** Choose bilinear groups $(\mathbb{G}, \mathbb{G}_T)$ of composite order $N = p_1p_2p_3$, where $p_i > 2^{l(\lambda)}$ for each $i \in \{1, 2, 3\}$, for a suitable polynomial $l : \mathbb{N} \to \mathbb{N}$. Choose $g, u \xleftarrow{R} \mathbb{G}_{p1}$, $R_3 \xleftarrow{R} \mathbb{G}_{p_3}$ and $\alpha \xleftarrow{R} \mathbb{Z}_N$ at random in order to define $G_j = g^{\alpha^j}$ for each $j \in [1, n]$ and

$$U_1 = u^\alpha \cdot R_{3,1}, \quad \ldots \quad U_n = u^{(\alpha^n)} \cdot R_{3,n},$$
$$U_{n+2} = u^{(\alpha^{n+2})} \cdot R_{3,n+2}, \quad \ldots \quad U_{2n} = u^{(\alpha^{2n})} \cdot R_{3,2n},$$

where $R_{3,j} \overset{R}{\leftarrow} \mathbb{G}_{p_3}$ for each $j \in [1, 2n]\backslash\{n+1\}$. Define the commitment key to consist of $CK := \big(g,\ \{G_j\}_{j=1}^n,\ \{U_j\}_{j\in[1,2n]\backslash\{n+1\}},\ R_3\big)$. The trapdoor consists of $TK := U_{n+1} = u^{(\alpha^{n+1})} \cdot R_{3,n+1}$, where $R_{3,n+1} \overset{R}{\leftarrow} \mathbb{G}_{p_3}$.

Commit($CK, \vec{m}$): Given $\vec{m} = (m_1, \ldots, m_n) \in \mathbb{Z}_N^n$, compute $C = g^\gamma \cdot \prod_{j=1}^n G_j^{m_j}$ for a random choice of $\gamma \overset{R}{\leftarrow} \mathbb{Z}_N$ and output C with the auxiliary information $\mathsf{aux} = (m_1, \ldots, m_n, \gamma)$.

Open($CK, C, \mathsf{aux}, \vec{x}$): Given $\vec{x} = (x_1, \ldots, x_n) \in \mathbb{Z}_N^n$, the auxiliary information $\mathsf{aux} = (m_1, \ldots, m_n, \gamma)$ allows generating a witness for the function $\langle \vec{m}, \vec{x} \rangle = \sum_{i=1}^n m_i \cdot x_i$ by computing

$$W_i = U_{n-i+1}^\gamma \cdot \prod_{j=1, j\neq i}^{n} U_{n+1+j-i}^{m_j} \qquad \forall i \in \{1, \ldots, n\}, \tag{1}$$

and outputting $W_y = \prod_{i=1}^n W_i^{x_i}$.

Verify($CK, C, W_y, \vec{x}, y$): Given $C \in \mathbb{G}$ and $\vec{x} = (x_1, \ldots, x_n) \in \mathbb{Z}_N^n$, accept $W_y \in \mathbb{G}$ as evidence that C is a commitment to $\vec{m} \in \mathbb{Z}_N^n$ such that $y = \langle \vec{m}, \vec{x} \rangle$ if and only if it holds that $e(C, \prod_{i=1}^n U_{n-i+1}^{x_i}) = e(G_1, U_n)^y \cdot e(g, W_y)$. If so, output 1. Otherwise, return 0.

The correctness is verified by observing that, for each $i \in \{1, \ldots, n\}$, (1) implies that

$$e(C, U_{n-i+1}) = e(g,u)^{(\alpha^{n+1})m_i} \cdot e\big(g, U_{n-i+1}^\gamma \prod_{j=1, j\neq i}^{n} U_{n+j-i+1}^{m_j}\big) = e(G_1, U_n)^{m_i} \cdot e(g, W_i).$$

By raising both members of the above equality to the power $x_i \in \mathbb{Z}_N$ and taking the product over all $i \in [1, n]$, we find that W_y satisfies $e(C, \prod_{i=1}^n U_{n-i+1}^{x_i}) = e(G_1, U_n)^{\langle \vec{m}, \vec{x} \rangle} \cdot e(g, W_y)$.

It is clear that that the commitment is perfectly hiding: since C lives in the cyclic subgroup $\mathbb{G}_{p_1}$, any vector $(m_1, \ldots, m_n) \in \mathbb{Z}_N^n$ has a corresponding opening $\gamma \in \mathbb{Z}_N$ (and even $p_2 p_3$ openings since only $\gamma \bmod p_1$ is fixed by $\vec{m}$).

We now prove it computationally binding under subgroup assumptions. While this property can be proved via a reduction from the one-wayness of Wee's broadcast encryption [32, Section 4], we found it interesting to give a direct proof under the underlying assumptions for two reasons. First, this proof allows relying on a computational (rather than decisional) analogue of Assumption 1. Second, the proof provides insights allowing to prove the security of variants of this commitment or the other primitives it implies. For example, by adapting the proof of Theorem 6, we design an accumulator supporting subset queries in section 5. Since the latter scheme has a public key containing more elements than in [32], it can hardly be proved secure via a reduction from the security of Wee's broadcast encryption [32].

The proof involves two computationally indistinguishable distributions of parameters (CK, TK). The normal distribution is as in the real scheme whereas the semi-functional distribution allows CK and TK to have a $\mathbb{G}_{p_2}$ component. As in [32, Theorem 2], we use the Déjà Q framework so as to gradually move to a game where the $\{U_i\}_{i=1}^{2n}$ all contain a $\mathbb{G}_{p_2}$ component $g_2^{R(i)}$ which is determined by a random function $R : [1, 2n] \to \mathbb{Z}_{p_2}$. As in [22, 18], we rely on the fact that any attack against the binding property publicly reveals a value U_{n+1} which contains $u^{(\alpha^{n+1})}$ as its $\mathbb{G}_{p_1}$ component. Depending on whether U_{n+1} contains a $\mathbb{G}_{p_2}$ component or not, we speak of Type B or Type A attacks. The proof uses a subsequence of $2n$ games where, in the k-th game, the $\mathbb{G}_{p_2}$ component of U_i is of the form $g_2^{F_k(i)}$, where $F_k : [1, 2n] \to \mathbb{Z}_{p_2}$ is a k-wise independent function. The strategy of the proof is to show that, unless either Assumption 1 or Assumption 2 can broken, the attack on the binding property also reveals a U_{n+1} of the form $U_{n+1} = u^{(\alpha^{n+1})} \cdot g_2^{F_k(n+1)} \cdot \mathcal{R}_3$, for some $R_3 \in \mathbb{G}_{p_3}$ in the k-th game. Said otherwise, the attack reveals a trapdoor U_{n+1} which mimics the distribution of the commitment key CK. When we reach the $2n$-th game, the $\mathbb{G}_{p_2}$ component of each U_i is determined by $F_{2n}(i)$. Since $F_{2n}(.)$ is a $2n$-wise independent function, the $\mathbb{G}_{p_2}$ of U_{n+1}

is thus statistically independent of those of $\{U_i\}_{i\in[1,2n]\setminus\{i\}}$, which appear in the public key. The proof of Theorem 6 is given in the full version of the paper.

▶ **Theorem 6.** *The scheme is binding if Assumption 1 and Assumption 2 both hold.*

4 Further Constructions

4.1 Polynomial Commitments from Constant-Size Assumptions

It is easy to see that any functional commitment for linear functions implies a polynomial commitment. Indeed, in order to commit to a polynomial $P[Z] = a_0 + a_1 Z + \cdots + a_{n-1}Z^{n-1}$ of degree $n-1$, we can simply commit to the vector of coefficients $\vec{m} = (a_0, a_1, \ldots, a_{n-1}) \in \mathbb{Z}_N^n$. When the sender wants to convince a verifier that $P(x) = y$, for some public $x, y \in \mathbb{Z}_N$, it is sufficient to generate a witness W_y showing that $\langle \vec{m}, \vec{x} \rangle = y$, where $\vec{x} = (1, x, x^2, \ldots, x^{n-1})$. Our construction of Section 3 thus implies the first polynomial commitment based on constant-size assumptions. Indeed, the schemes of [19, 7] rely on q-type assumptions where q is proportional to the maximal degree of committed polynomials.

4.2 Large-Universe Pairing-Based (Universal) Accumulators from Constant-Size Assumptions

Catalano and Fiore [10] designed cryptographic accumulators from vector commitments. While their construction yields an accumulator based on the Diffie-Hellman assumption, it only supports small universes. Namely, accumulated values should come from a polynomial-size domain since the public key has linear size in the cardinality of this domain.

It is easy to see that polynomial commitments imply accumulators for exponential-size universes. While the size of the public key is linear in the maximal number of accumulated values (as in Nguyen's accumulator [26]), it does not depend of the universe size. As a result, we can accumulate inputs consisting of arbitrary strings of polynomial length.

In order to accumulate a set $S = \{x_1, \ldots, x_{n-1}\}$, one can commit to the vector $(a_0, a_1, \ldots, a_{n-2}, 1)$ that contains the coefficients of the polynomial $P[Z] = \prod_{j=1}^{n-1}(Z - x_j)$ and rely on the fact that $x \in S$ if and only if $P(x) = 0$. A witness that $x_i \in S$ (resp. $x_i \notin S$) is obtained by generating a witness that the committed polynomial satisfies $P(x_i) = 0$ (resp. $P(x_i) \neq 0$)). A concrete construction based on Assumptions 1 and 2 is described in the the full version.

5 Accumulators Supporting Subset Queries

We now generalize the accumulator of Section 4.2 so that a constant-size witness $W \in \mathbb{G}$ can provide evidence that a purported set X is contained in the hashed set S. Such a commitment was previously designed by Papamanthou *et al.* [29] under a non-standard q-type assumption. Our construction is thus the first realization based on fixed-size assumptions.

Gen$(1^\lambda, 1^n)$: Choose bilinear groups $(\mathbb{G}, \mathbb{G}_T)$ of composite order $N = p_1p_2p_3$, where $p_i > 2^{l(\lambda)}$ for each $i \in \{1,2,3\}$, for a suitable polynomial $l : \mathbb{N} \to \mathbb{N}$. Choose $g, u \xleftarrow{R} \mathbb{G}_{p_1}$, $R_3 \xleftarrow{R} \mathbb{G}_{p_3}$ and $\alpha \xleftarrow{R} \mathbb{Z}_N$ at random. Let $d \leq n$ be the bound placed on size of a subset (also polynomial in the security parameter). Define $G_i = g^{(\alpha^i)}$ for each $i \in [1, n]$ and $U_j = u^{(\alpha^j)} \cdot R_{3,j}$, where $R_{3,j} \xleftarrow{R} \mathbb{G}_{p_3}$ for each $j \in [1, (d+1)n] \setminus \{n+1, 2n+1, \ldots, dn+1\}$.

The secret key is $SK := \{U_{\ell n+1}\}_{\ell=1}^{d}$, where $U_{\ell n+1} = u^{(\alpha^{\ell n+1})} \cdot R_{3,\ell n+1}$ with $R_{3,\ell n+1} \xleftarrow{R} \mathbb{G}_{p_3}$ for all $\ell \in [1, d]$. The public key is

$$PK := \big(g, \{G_j\}_{j=1}^{n}, \{U_j\}_{j\in[1,(d+1)n]\setminus\{n+1,2n+1,\ldots,dn+1\}}, R_3\big).$$

Eval(PK, S): To hash a set $S = \{y_1, \ldots, y_{n'}\}$ of cardinality $n' \leq n-1$, expand the polynomial $P_S[Z] = \prod_{j=1}^{n'}(Z - y_j) = \sum_{j=0}^{n'} m_j \cdot Z^j$. Choose $\gamma \xleftarrow{R} \mathbb{Z}_N$ to compute and output

$$V = g^{\gamma} \cdot \prod_{j=1}^{n'+1} G_j^{m_{j-1}} = g^{\gamma+\alpha\cdot P_S(\alpha)}, \qquad \mathsf{aux} = (S, \gamma) \tag{2}$$

WitCreate($PK, V, S, \mathsf{aux}, X$): Given a set $S = \{y_1, \ldots, y_{n'}\}$, a subset $X = \{x_1, \ldots, x_k\} \subseteq S$ of size $k \leq d$ (we assume w.l.o.g. that $x_1, \ldots, x_k$ are arranged in some pre-determined lexicographical order), and the state information $\mathsf{aux} = (S, \gamma)$ such that (V, aux) was produced by $\mathsf{Acc}(PK, S)$, compute $P_S[Z] = \prod_{j=1}^{n'}(Z - y_j) = \sum_{j=0}^{n'} m_j \cdot Z^j$ and define the corresponding vector $\vec{m} = (m_0, m_1, \ldots, m_{n'}, 0, \ldots, 0) \in \mathbb{Z}_N^n$. For each $\ell \in [1, k]$, define $\vec{x}_\ell = (x_{\ell,1}, \ldots, x_{\ell,n}) = (1, x_\ell, x_\ell^2, \ldots, x_\ell^n) \in \mathbb{Z}_N^n$ which satisfies $P_S(x_\ell) = \vec{m} \cdot \vec{x}_\ell = 0$. For $\ell \in [1, k]$, generate a witness that $\langle \vec{m}, \vec{x}_\ell \rangle = 0$ by first using $\{U_{\ell n+1+j-i}\}_{j\neq i}$ to compute

$$W_{\ell,i} = U_{\ell n-i+1}^{\gamma} \cdot \prod_{j=1, j\neq i}^{n} U_{\ell n+1+j-i}^{m_j} \qquad \forall i \in \{1, \ldots, n\}, \tag{3}$$

which satisfies $e(V, \prod_{i=1}^{n} U_{\ell n+1-i}^{x_{\ell,i}}) = e(g, W_{\ell,i})$ for all $\ell \in [1, k]$ since $\vec{m} \cdot \vec{x}_\ell = 0$. Then, compute and output the witness $W_X = \prod_{\ell=1}^{k} \prod_{i=1}^{n} W_{\ell,i}^{x_{\ell,i}}$.

Verify(PK, V, W_X, X): Given an accumulator value $V \in \mathbb{G}$, a subset $X = \{x_1, \ldots, x_k\}$, where $x_i \in \mathbb{Z}_N$ for each $i \in [1, k]$, and a candidate a witness W_X, do the following.

1. For each $\ell \in [1, k]$, define $\vec{x}_\ell = (x_{\ell,1}, \ldots, x_{\ell,n}) = (1, x_\ell, \ldots, x_\ell^n) \in \mathbb{Z}_N^n$.
2. Return 1 if and only if $e(V, \prod_{\ell=1}^{k} \prod_{i=1}^{n} U_{\ell n+1-i}^{x_{\ell,i}}) = e(g, W_X)$.

From an efficiency standpoint, the size of PK is quadratic in n when $d \approx n$ so as to handle queries for arbitrary subsets of size $\leq n$. In comparison with [29], we thus achieve security under simple assumptions at the expense of a somewhat larger public key. We see it as an interesting open problem to retain $O(n)$-size public keys under simple assumptions.

We prove that the scheme provides collision-freeness (a detailed definition is given in the full version) in that no PPT adversary can output a set S (of size $\leq n$) along with a verifying witness W_X for another set X which is *not* contained in S. We thus use a natural analogue of the definition of collision-freeness used in [15]: since our evaluation algorithm is randomized, we assume that the adversary outputs the set S and the random coins γ of the evaluation algorithm that lead to the accumulator value for which W_X verifies.

The proof relies on the fact that the adversary outputs both the hashed set S and the random coins γ of the hashing algorithm. It allows the reduction to use W_X in order to extract a membership witness for the difference $X \setminus S$ using the homomorphic properties of the underlying commitment. Having obtained $W_{X\setminus S}$, the reduction is also able to compute an aggregation of non-membership witnesses for the same difference $X \setminus S$. From these two conflicting witnesses, it is possible to extract some linear combination of the secret key components $\{U_{\ell n+1}\}_{\ell=1}^{d}$. In turn, this forces the adversary to predict a linear combination of random function evaluations in the final step of the sequence of games. The proof is given in the full version of the paper.

▶ **Theorem 7.** *The scheme is collision-free if Assumption 1 and Assumption 2 hold.*

Abstract

Non-malleable codes, introduced by Dziembowski, Pietrzak, and Wichs (ICS '10) provide the guarantee that if a codeword c of a message m, is modified by a tampering function f to c', then c' either decodes to m or to "something unrelated" to m. In recent literature, a lot of focus has been on explicitly constructing such codes against a large and natural class of tampering functions such as *split-state* model in which the tampering function operates on different parts of the codeword *independently*.

In this work, we consider a stronger adversarial model called *block-wise tampering* model, in which we allow tampering to depend on more than one block: if a codeword consists of two blocks $c = (c_1, c_2)$, then the first tampering function f_1 could produce a tampered part $c'_1 = f_1(c_1)$ and the second tampering function f_2 could produce $c'_2 = f_2(c_1, c_2)$ depending on *both* c_2 and c_1. The notion similarly extends to multiple blocks where tampering of block c_i could happen with the knowledge of all c_j for $j \leq i$. We argue this is a natural notion where, for example, the blocks are sent one by one and the adversary must send the tampered block before it gets the next block.

A little thought reveals that it is impossible to construct such codes that are non-malleable (in the standard sense) against such a powerful adversary: indeed, upon receiving the last block, an adversary could decode the entire codeword and then can tamper depending on the message. In light of this impossibility, we consider a natural relaxation called *non-malleable codes with replacement* which requires the adversary to produce not only related but also a valid codeword in order to succeed. Unfortunately, we show that even this relaxed definition is not achievable in the information-theoretic setting (i.e., when the tampering functions can be unbounded) which implies that we must turn our attention towards computationally bounded adversaries.

As our main result, we show how to construct a block-wise non-malleable code (BNMC) from sub-exponentially hard one-way permutations. We provide an interesting connection between BNMC and non-malleable commitments. We show that any BNMC can be converted into a non-malleable (w.r.t. opening) commitment scheme. Our techniques, quite surprisingly, give rise to a

non-malleable commitment scheme (secure against so-called synchronizing adversaries), in which *only* the committer sends messages. We believe this result to be of independent interest. In the other direction, we show that any non-interactive non-malleable (w.r.t. opening) commitment can be used to construct BNMC only with 2 blocks. Unfortunately, such commitment scheme exists only under highly non-standard assumptions (adaptive one-way functions) and hence can not substitute our main construction.

1 Introduction

Non-malleable codes. Error correcting codes allow a message m to be encoded into a codeword c, such that m can always recovered even from a tampered codeword c', only if the tampering is done in a specific way. More formally, the class of tampering functions, $\mathcal{F}_{\mathsf{frac}}$, tolerated by traditional error correction codes are ones that erase or modify only a constant fraction of the codeword c. In particular, no guarantees are provided on the output of the decoding algorithm when the tampering function $f \notin \mathcal{F}_{\mathsf{frac}}$. A more relaxed notion, error detecting codes, allow the decoder to also output a special symbol $\perp$, when m is unrecoverable from c', but here too, the codes can not tolerate simple tampering functions $f \in \mathcal{F}_{\mathsf{const}}$ where $\mathcal{F}_{\mathsf{const}}$ contains all constant functions[1]. To address this shortcoming of error correction/detection codes, Dziembowski, Pietrzak, and Wichs [12], introduced a more flexible notion of *non-malleable codes* (NMC). Informally, an encoding scheme $\mathsf{Code} := (\mathsf{Enc}, \mathsf{Dec})$ is a NMC against a class of tampering functions, $\mathcal{F}$, if the following holds: the decoded message $m' = \mathsf{Dec}(c')$ is either equal to the original message m or is completely unrelated to m, when $c' = f(\mathsf{Enc}(m))$ for some $f \in \mathcal{F}$. In general, NMC cannot exist for the set of all tampering functions $\mathcal{F}_{\mathsf{all}}$. To see this, observe that a tampering function that simply runs the decode algorithm to retrieve m, and then encodes a message related to m, trivially defeats the requirement above. However, somewhat surprisingly, Dziembowski *et al.* [12] showed the (probabilistic) existence of a NMC against a function family, $\mathcal{F}_{\mathsf{almost}}$, that is only slightly smaller than the set of all functions. They also constructed an efficient NMC against the class of tampering functions, $\mathcal{F}_{\mathsf{bit}}$, that can tamper each bit of the codeword independently. NMC has found important applications in tamper-resilient cryptography [12, 21, 13, 14].

Split-state Tampering. Arguably, one of the strongest class of tampering functions for which explicit constructions of NMC are known, is in the so called *split-state model*. Informally, a split-state model with ℓ states has the following attributes: (i) the codeword is assumed to be partitioned into ℓ-disjoint blocks $(c_1, \cdots, c_\ell)$, and (ii) the class of tampering functions, $\mathcal{F}^{\ell}_{\mathsf{split}}$, consists of all the functions $(f_1, \cdots, f_\ell)$ where f_i operates *independently* on c_i[2]. Dziembowski *et al.* [12] gave a construction of a NMC against the tampering class $\mathcal{F}^{2}_{\mathsf{split}}$ in the random oracle

[1] In particular if f always outputs some valid codeword c', then it is impossible to detect the error. For some cryptographic application like protecting against memory tampering attack this is too restrictive.
[2] Note that the class $\mathcal{F}_{\mathsf{bit}}$ can be viewed as $\mathcal{F}^{n}_{\mathsf{split}}$, where n is the length of the codeword c.

model. Constructions of NMC against $\mathcal{F}^2_{\mathsf{split}}$ are now known both in the computational [21][3] and information-theoretic settings [2, 7, 11]. Recently, Chattopadhyay and Zuckerman [6] gave an explicit information-theoretic NMC against $\mathcal{F}^{10}_{\mathsf{split}}$ and Aggarwal *et al.* [1] showed how to construct explicit information-theoretic NMC against $\mathcal{F}^2_{\mathsf{split}}$.

Going beyond split-state: Block-wise Tampering. A severe restriction of the split-state model is that every block of the codeword can only be tampered *independently* of all other blocks. In particular f_i modifies c_i with absolutely no knowledge about c_j, for any $j \neq i$. In this work, we address this restriction by allowing modification of *each* block *depending* on more than one-block. In particular, each c_i can be modified in any arbitrary way based on the first i blocks $(c_1, \ldots, c_i)$. Such a code is called *block-wise* NMC. More formally a code is called a *block-wise* NMC if it is a NMC against the class of tampering functions $\mathcal{F}^\ell_{\mathsf{block}}$: a set of functions $(f_1, \cdots, f_\ell) \in \mathcal{F}^\ell_{\mathsf{block}}$ if each f_i modify c_i to some c'_i depending on the first i-blocks. We also consider a stronger class of functions where the tampering can be done in *any* order. In particular f_i can modify any c_j depending on any i blocks. A natural scenario is a synchronous streaming model when the blocks are coming in one by one and the adversary on the channel sends across each modified blocks before the next block arrives.

NMC for $\mathcal{F}^\ell_{\mathsf{block}}$ is impossible. One can see that it is impossible to construct NMC against $\mathcal{F}^\ell_{\mathsf{block}}$ (for any ℓ): consider a tampering function, where the first $\ell - 1$ functions, $(f_1, \ldots, f_{\ell-1})$ are identity functions and the function f_ℓ (which gets the entire codeword as input) simply decodes the message and depending on the message, keeps it the same or overwrites it to something "invalid" (i.e., the modified codeword decodes to $\perp$). Note that, in this case the distribution of the (decoding of the) tampered codeword will indeed depend on the message, thereby violating non-malleability. In particular, such a tampering attack makes the decoder output $\perp$ with a probability distribution that depends on the input message. Therefore, we seek for a natural relaxation of the traditional definition of NMC such that it is achievable for the class $\mathcal{F}^\ell_{\mathsf{block}}$ and at the same time sufficient for interesting applications. In particular, we show that such relaxed NMC is sufficient to construct a simple non-malleable commitment scheme in a black-box manner. We note that the traditional application to tamper-resilient cryptography does not work with the relaxed version for obvious reason..

NMC with replacement (NMCwR). Essentially in the above attack the adversary breaks non-malleability by making the codeword "invalid". So, we take the most natural direction to relax the definition, in that the adversary is considered to be successful only if it produces some *valid and related* codeword via tampering. In particular, the adversary may selectively "destroy" a codeword depending upon the message we encode, however we show that in some sense, this is the "only attack" it can perform. Intuitively the guarantee provided by such an encoding scheme is that any adversary, by tampering with some encoded data can not produce a related encoded data without destroying it. However, formalizing such intuition turns out to be non-trivial. We take inspiration from the literature of non-malleable commitment w.r.t. replacement (introduced by Goyal [16]) and formalize such a relaxation by introducing an algorithm (possibly inefficient) called *replacer* which comes into play only when the tampered codeword is invalid, and in that case it replaces the $\perp$ by "anything" of his choice. Essentially, the idea is that if the invalidity depends on the input message (like

[3] In the computational setting, the functions f_i are assumed to run in polynomial time.

described in the above attack) then the replacer would rectify the output to remove such dependency. We call the new notion *non-malleable codes with replacement (NMCwR).*

1.1 Our results

In this paper we explore the properties, constructions and applications of NMCwR with respect to the class of block-wise tampering functions $\mathcal{F}^{\ell}_{\mathsf{block}}$. We call such code *block-wise non-malleable codes* (BNMC). Below we provide an overview of the results presented in this paper.

Information theoretic impossibility. Similar to the notion of continuous non-malleable codes [13](CNMC), any BNMC must possess a *uniqueness* property (a slightly different one than CNMC). For two blocks, uniqueness means that there can not exists two different valid codewords of the form (c_1, c_2) and (c_1, c_2') which decodes to different messages, i.e., for every valid code c_1, there is a unique decoding. If not, then an attack similar to the CNMC is possible without making the codeword invalid – the adversary can always tampers the first block to c_1 and depending on the message (since f_2 gets the entire codeword) tampers to one of c_2 or c_2' hence making the output distribution depend on the message. Consequently, just like CNMC, an information theoretic impossibility is evident with the only difference that in the setting of CNMC, the functions are unbounded, and, therefore (for two blocks) the function f_1 can derive the unique message corresponding to c_1 by brute-force and thus break the scheme. We show the following in the full version [4].

▶ **Theorem 1.** *It is impossible to construct an information-theoretic BNMC.*

Henceforth, in this paper we focus on constructing BNMC based on computational assumptions. We stress that even we are in the computationally bounded setting, we do not put any restriction on the efficiency of the replacer. In particular, the replacer is allowed to run in super-polynomial (or even exponential) time. In fact, later in this paper, we often encounter a replacer which runs in exponential time. Nonetheless, we must restrict the reduction to be probabilistic polynomial time (PPT). We are indeed able to overcome this technical hurdle by constructing such "efficient" reductions which can correctly simulate behavior of "highly inefficient" replacers.

Connection to Non-malleable Commitment. Since BNMC satisfies a definition weaker (that is NMC with replacement) than the traditional NMC, it is not possible to use such a code to build a tamper-resilient compiler as described in [12, 21] for obvious reason. In fact, it is nevertheless impossible to protect a system against memory tampering attack (see [8, 15, 18] for formal expositions on such attack) against any block-wise tampering. However we are able to show connections with non-malleable commitment with respect to opening (NMCom). To the best of our knowledge this is the first attempt to bridge these two non-malleability notions[4].

[4] In a recent work, Agrawal et al. [3] showed how to use NMC to construct non-malleable string-commitment from non-malleable bit-commitment. In their work, NMC is used as a tool, and, no relations are shown between non-malleable commitments and NMC. Recently, another work by Goyal et al. [17] constructs round-optimal NMCom from split-state NMC, the full version of which appears after the first version of this work.

1. Given an ℓ-block BNMC we can construct (in a black-box way) a simple $(\ell-1)$ round commitment protocol which is non-malleable with respect to opening (against synchronizing adversaries) as follows: the committer sends the block c_i in the i-th round and sends the last block c_ℓ as the opening. The receiver sends only acknowledgements after receiving each message. The non-malleability essentially follows from the non-malleability of the underlying BNMC and the perfect binding follows from the uniqueness property described above. To best of our knowledge, this is the first NMCom protocol where the receiver is not required to send any message (e.g. challenge) except for acknowledgement.

▶ **Theorem 2.** *Suppose there is an ℓ-block BNMC. Then there is a $(\ell-1)$ round perfectly binding non-malleable commitment scheme with respect to opening against a synchronizing man-in-the-middle adversary.*

2. We also show that from any non-interactive NMCom one can easily construct an BNMC even for only $\ell = 2$ blocks (i.e. optimal for $\mathcal{F}^{\ell}_{\mathsf{block}}$). Unfortunately, the only assumptions under which we know how to construct such commitments are either in the (non-tamperable) CRS model [9] or under the highly non-standard assumption of *adaptive* one-way functions [22]. Evidently this construction can not substitute our main construction which is based on much more standard assumption like sub-exponentially hard OWP.

▶ **Theorem 3.** *Suppose there is a perfectly binding non-interactive non-malleable commitment scheme (w.r.t. opening) whose input is a k-bit message and output is an n-bit commitment. Then there is a 2-block BNMC.*

Combining Theorem 2 and Theorem 3, we can conclude that when $\ell = 2$ the NMCom and BNMC are equivalent. The details of these results are elaborated in the full version [4].

Constructing BNMC. As the main result we provide a construction of BNMC from a standard assumption in the plain model. Precisely, we show that, for any arbitrary constant $\varphi > 0$, how to construct a BNMC against $\mathcal{F}^{\ell}_{\mathsf{block}}$ for $\ell = O(\kappa^{2+\varphi})$ (where κ is the security parameter). The security (i.e. non-malleability) of the construction is based on "sub-exponentially" hard one-way permutations which says that there exists one-way permutations (OWP) which are "hard-to-invert" even against an adversary running in sub-exponential time, precisely in time $O(2^{\kappa_{\mathsf{s}}})$ such that $\kappa_{\mathsf{s}} = O(\kappa^{\epsilon}/2)$ for some $0 < \epsilon < 1$. In particular, our construction uses any perfectly binding commitment scheme that is computationally hiding against such sub-exponential adversary (and this primitive can be constructed from the above assumption). The key technical challenge, as remarked earlier, is that BNMC is *not* an interactive primitive that allows bi-directional communication. This limitation renders the previously proposed techniques for designing non-malleable protocols inherently unusable. This is because these previous techniques are based on having "challenge-response" rounds similar to the type also used in designing zero-knowledge protocols. Thus, techniques like rewinding the sender are not useful in this setting at all: since there are no receiver messages, one would end up with the same transcript every time. Thus, apriori, it seems unclear what advantage one could get by having multiple blocks. Our final construction is quite clean and in fact, also gives arguably one of the simplest known constructions of non-malleable commitments. We show the following theorem.

▶ **Theorem 4.** *Assume the existence of sub-exponentially hard one-way permutations. Then for any $\varphi > 0$ of our choice, and any message length $k \in \mathbb{N}$, there exists an explicit construction of ℓ-block* BNMC *of codeword length $n = O(k\kappa^{6+\varphi})$, where $\ell = O(\kappa^{2+\varphi})$.*

We give an overview of the construction used to prove Theorem 4 in Section 1.2.

Strong BNMC. Additionally, we also consider a strictly stronger model of tampering: assume any permutation $\pi : [\ell] \to [\ell]$ chosen by the adversary. Then each function f_i takes i blocks $(c_{\pi(1)}, \ldots, c_{\pi(i)})$ as input and modifies the $\pi(i)$-th block. We call this family of function strong block-wise and denote it by $\mathcal{F}^{\ell}_{\mathsf{s\text{-}block}}$. We also provide a definition of strong BNMC which is essentially an explicit presentation of NMCwR for $\mathcal{F}^{\ell}_{\mathsf{s\text{-}block}}$. We provide an unconditional generic transformation to construct strong BNMC from any BNMC which, along with the earlier results imply that any construction of BNMC can be transformed to a strong BNMC (with some blow up in the length of codeword). We show the following, the details of which appears in the full version [4].

▶ **Theorem 5.** *If there is an ℓ-block BNMC with codeword length n, then there is an (ℓ)-block SBNMC with codeword length $\Theta(\ell n)$.*

1.2 Overview of our techniques

We now give a brief overview of our main construction of BNMC along with intuition as to why it works. The detailed construction is provided in Sec. 3.

First fix a parameter μ (such that $\mu = O(\kappa^{2+\varphi})$ for any arbitrary constant $\varphi > 0$ of our choice where κ is the security parameter) such that we encode a message m using $\ell = (2\mu + 1)$-blocks of codeword for some parameter μ . At a very high level, our encoding is as follows. Let us first fix some index (or *tag*) for the encoder $i \in [\mu]$. The encoder then chooses a *perfectly binding* commitment scheme COM.

Let $\mathsf{COM}_{\kappa_{\mathsf{s}}}(\cdot)$ and $\mathsf{COM}_{\kappa}(\cdot)$ denote that COM is computationally hidden with respect to security parameters κ_{s} and κ respectively, where κ_{s} is as mentioned above. The encoder then computes commitments to the message using $\mathsf{COM}_{\kappa_{\mathsf{s}}}$ and COM_{κ}. The first 2μ blocks of the encoding of m are blocks of all zeroes, except for block i and block $(2\mu - i)$ which are the commitments COM_{κ} and $\mathsf{COM}_{\kappa_{\mathsf{s}}}$, respectively. The $(2\mu + 1)^{\text{th}}$ block of the encoding contains the openings to $\mathsf{COM}_{\kappa_{\mathsf{s}}}$ and COM_{κ}. The decoding algorithm checks if (i) all the openings are consistent with the commitments and (ii) the messages committed are equal. Now, for a moment, assume that adversary's index i' is not equal to i (this can be removed later on). Then if $i' < i$, then the adversary has to output its first commitment without seeing the first commitment in the input codeword (rather only seeing on the string of zeros). Thus, the first commitment in the output is independent of the first commitment in the input. Moreover, our definition (NMCwR) puts the additional restriction that the adversary has to output a valid codeword in order to succeed. Combining one can see that the output codeword, if valid, must contain a message independent of the message encoded in the input. On the other hand, if $i' > i$, then the second commitment of the adversary has to be independent of the second commitment in the input. In this case, we rely on complexity leveraging to prove non-malleability. Using this key-observation one can prove the non-malleability except in one case: when the index chosen by the adversary i' is equal to i. To prevent mauling in this case we use one-time signatures. The encoder signs the entire codeword using i as a public-key and thus leaving the adversary either to forge the signature or change the index. However, one problem still remains. To use i as a public-key we need it to be sufficiently long, in particular for a concrete instance of such OTS (we consider variant of Lamport [19]) the length needed to be $O(\kappa^{2+\varphi})$ for any arbitrary constant $\varphi > 0$ of our choice. But note that, we have $i \in [\mu]$ and $\ell = 2\mu + 1$. Trying to set the size of the index $|i| = \log(\mu)$ to even $\Omega(k)$ would result in an "inefficient" construction with $\ell = 2^{\Omega(k)}$ blocks which is not acceptable. We solve this problem by using a "well-known" technique from non-malleable commitment, so-called DDN-XOR trick. Through that, it is possible to use a long tag of

size $t = O(\kappa^{2+\varphi})$ keeping the number of blocks also $O(\kappa^{2+\varphi})$ just by computing t shares (XOR's) of messages and and applying the above construction independently on the shares. So, our final construction would require a one-time signature which works with a public-key of bit-length $\mu = O(\kappa^{2+\varphi})$.

2 Definitions

We introduce the "relaxed" definition of non-malleable codes which is same as the NMC except there is a so-called *replacer* $\mathbf{R_f}$ which is an "all powerful" algorithm and comes into play only when the modified codeword is invalid (i.e. decodes to $\perp$). In that case, the replacer may replace the $\perp$ by any message in the message space or the symbol $\mathsf{same}^\star$. (The replacer can also keep the $\perp$ in case when it not harmful (i.e. does not depend on the input) e.g. when the tampering function always tampers to something invalid). Since the idea of replacer is similar in spirit with the notion of *non-malleable commitment with replacement* as introduced in [16] we call this relaxed version *non-malleable codes with replacement* (NMCwR in short). We present the formal definition below.

▶ **Definition 6** (Non-malleable codes with replacement)**.** Let $\mathsf{Code} = (\mathsf{Enc}, \mathsf{Dec})$ be an (k, n)-encoding scheme. Let $\mathcal{F}$ be some family of tampering functions. Then Code is called (k, n)-non-malleable code with replacement (NMCwR) if for every $f \in \mathcal{F}$ there exists an algorithm called the replacer $\mathbf{R_f}$ such that for any pair of messages $m_0, m_1 \in \{0,1\}^k$, $\mathsf{TampWR}^f_{m_0} \approx \mathsf{TampWR}^f_{m_1}$, where for any $m \in \{0,1\}^k$, TampWR^f_m is defined as

$$\mathsf{TampWR}^f_m \equiv \left\{ \begin{array}{c} c \leftarrow \mathsf{Enc}(m); c' \leftarrow f(c); \\ \text{If } c' = c \text{ set } m' := \mathsf{same}^\star \text{ else } m' \leftarrow \mathsf{Dec}(c') \\ \text{If } m' = \perp \text{ then } m' := \mathbf{R_f}(c) \ ; \ \text{Output: } m' \end{array} \right\},$$

where the randomness is over the encoding function Enc.

▶ Remark. Here, and everywhere in this section, the indistinguishability depends on the setting (information theoretic or computational). However, we emphasize that even if we are in the computationally bounded scenario, where the adversary is PPT, we do not restrict the replacer to be a PPT algorithm. This assumption is justified because the replacer is required only to establish the meaningfulness of the definition without affecting the natural intuition. Intuitively the purpose of the replacer is to relax the traditional notion in a way such that the tampering function is allowed to distinguish the tampering experiments, albeit only by making the codeword invalid. Nonetheless in the computational setting all the other algorithms involved as well as the the tampering functions are required to be PPT.

Some intuitions. We first provide some intuition behind why the above definition is meaningful. For every adversary, there is guaranteed to exist another adversary which always tampers in the same way as the original adversary, except, when the original adversary were to output an invalid codeword. In that case, the new adversary may employ any other (PPT) strategy. However when the original adversary outputs an invalid codeword, (in many applications) it could be considered as aborting or failing in those cases. Hence, our new adversary could be seen as strictly more powerful than the original one. However as the definition guarantee, the new adversary actually obeys the standard non-malleable code guarantee. Thus, in many scenarios, we believe the above weaker notion may be sufficient. Indeed, as shown in [16], the corresponding weaker notion for non-malleable commitments

(called non-malleability w.r.t. replacement) turns out to be sufficient for several applications including for obtaining constant round multi-party computation.

We now give the syntactic definition of *block-wise encoding scheme*.

▶ **Definition 7** (Block-wise encoding scheme)**.** Let $\mathsf{Code} = (\mathsf{Enc}, \mathsf{Dec})$ be an (k, n)-encoding scheme. Then it is called an (ℓ, k, n)-*block-wise encoding scheme* if each string output by Enc is an ℓ-tuple: $(c_1, \ldots, c_\ell)$ where $|c_i| = n_i$, with $\sum_{i=1}^{\ell} n_i = n$. Also let $\nu_i = \sum_{j=1}^{i} n_i$.

Next we define a property of such block-wise encoding scheme called *reveal index*, that will be useful later on.

▶ **Definition 8** (Reveal Index)**.** Let $\mathsf{Code} = (\mathsf{Enc}, \mathsf{Dec})$ be an (ℓ, k, n)-block-wise encoding scheme. Then Code is said to have reveal index η if $\eta - 1 \in [\ell]$ is the largest index for which the following condition holds: For all pair of messages $m_0, m_1 \in \{0,1\}^k$ if $(c_1^{(0)}, \ldots, c_\ell^{(0)}) \leftarrow \mathsf{Enc}(m_0)$ and $(c_1^{(1)}, \ldots, c_\ell^{(1)}) \leftarrow \mathsf{Enc}(m_1)$ then $(c_1^{(1)}, \ldots, c_{\eta-1}^{(1)}) \approx (c_1^{(1)}, \ldots, c_{\eta-1}^{(1)})$.

▶ Remark. This definition formalizes the fact that, for any encoding scheme, there is an index η which reveals some information about the encoded message for the first time in the sequence and the sequence $(c_1, \ldots, c_{\eta-1})$ before that does not reveal anything about the encoded message. Obviously $\eta \leq \ell$ for any block-wise encoding scheme.

Finally, we present our main definition of a *block-wise non-malleable encoding scheme* which is essentially an explicit presentation of NMCwR for the class $\mathcal{F}^{\ell}_{\mathsf{block}}$.

▶ **Definition 9** (Block-wise non-malleable codes)**.** Let $\mathsf{Code} = (\mathsf{Enc}, \mathsf{Dec})$ be an (ℓ, k, n)-block-wise encoding scheme. Let $\mathbf{f} = (f_1, \ldots, f_\ell)$ be any tuple of functions specified as follows: $\forall i \in [\ell], f_i : \{0,1\}^{\nu_i} \to \{0,1\}^{n_i}$. Then Code is called an (ℓ, k, n)-*block-wise non-malleable code* (BNMC in short) if, for any such tuple $\mathbf{f}$, there exists a replacer $\mathbf{R}_{\mathbf{f}}$, such that, for any pair of messages $(m_0, m_1) \in \{0,1\}^k$, the following holds: $\mathsf{BLTamp}^{\mathbf{f}}_{m_0} \approx \mathsf{BLTamp}^{\mathbf{f}}_{m_1}$. where $\mathsf{BLTamp}^{\mathbf{f}}_{m}$ for any $m \in \{0,1\}^k$ is defined as:

$$\mathsf{BLTamp}^{\mathbf{f}}_{m} = \left\{ \begin{array}{c} \mathbf{c} = (c_1, \ldots, c_\ell) \leftarrow \mathsf{Enc}(m); \\ \forall i \in [\ell] : c'_i = f_i(c_1, \cdots, c_i);\ \text{Let } \mathbf{c}' = (c'_1, \ldots, c'_\ell); \\ \text{If } \mathbf{c}' = \mathbf{c} \text{ then set } m' := \mathsf{same}^\star; \text{Else decode } m' \leftarrow \mathsf{Dec}(c'_1, \ldots, c'_\ell); \\ \text{If } m' = \perp \text{ then } m' \leftarrow \mathbf{R}_{\mathbf{f}}(c_1, \ldots, c_\ell);\ \text{Output } m' \end{array} \right\}.$$

▶ Remark. Our notion of block-wise non-malleable codes is identical to the notion of *look-ahead non-malleable codes* defined in the concurrent and independent work of Aggarwal *et al.* [1]. We choose to use the term block-wise as it is more appropriate in our setting.

3 Our Construction

In this section, we provide our main construction of a BNMC based on *sub-exponentially hard one-way permutations*. We construct the encoding scheme in three steps:

(i) In Sec 3.1 we begin by constructing a weaker BNMC that we call *tag-based block-wise non-malleable encoding scheme* (TBNMC). In such a code, every codeword has a *tag* associated with it and the tampering function must change the tag of a codeword in order to successfully maul a codeword. In other words, we allow an adversary to create a related codeword only when the tag remains the same. The tag used here is an index of the block and hence is only of size $\log(\kappa)$.

(ii) Then in Sec. 3.2 we use a technique, commonly known as the DDN-XOR trick [10], to construct a tag-based BNMC with tags of length $poly(\kappa)$.

(iii) Finally in Sec. 3.3 we construct an BNMC which achieves Def. 9, by using the public key of a *one-time signature scheme* as the tag of the above code, and by signing the entire codeword using the corresponding signing key.

3.1 Tag-based non-malleability

In this section we diverge from our original definition and construct an encoding scheme which meets a weaker definition of non-malleability, called tag-based non-malleability.

We define the tag to be always the first block of any codeword. A tag-based BNMC (TBNMC for short) is defined exactly as the same way as BNMC with the only difference that whenever the tag of the tampered codeword is equal to the tag of the original codeword, then the tampering experiment outputs $\mathsf{same}^\star$ even if there is any other modification. Clearly this is strictly weaker than BNMC. Please see the full version [4] for a formal definition.

Now we construct an encoding scheme which satisfies this weaker definition based on sub-exponentially hard OWP. The proof uses complexity leveraging which essentially forces us to assume sub-exponential hardness as opposed to standard (super-poly) hardness.

We assume that sub-exponentially hard OWP exist that are considered to be hard to break even if the adversary is allowed to run in sub-exponential time, namely in $O(2^{\kappa_{\mathsf{s}}})$ such that $\kappa_{\mathsf{s}} = \kappa^{\epsilon}/2$ (recall that κ is the security parameter) for some constant $\epsilon \in (0, 1)$. The proof crucially relies on this as it uses one level of complexity leveraging. In particular, while reducing to such OWP, we assume that the adversary (the reduction in this case) is unable to break the one-way permutation (the hiding of a commitment scheme in this case) even when it is allowed to run in time $O(2^{\kappa_{\mathsf{s}}})$ (but in time $o(2^{\kappa})$).

We use a *non-interactive commitment*, Com, that is *perfectly binding*. We write $\mathsf{Com}_{\kappa_{\mathsf{s}}}$ and Com_{κ} to denote the commitment scheme has *computational hiding* with the security parameters κ_{s} and κ, respectively. In particular, Com_{κ} is a computationally hiding commitment scheme even against an adversary running in $O(2^{\kappa_{\mathsf{s}}})$ time. Suppose that such commitment scheme, on input some bit-string of length $k \in \mathbb{N}$, outputs commitments of length $\mathsf{p}(\kappa, k)$ where $\mathsf{p}(\cdot) : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ is a fixed polynomial (determined by the specifications of the commitment scheme) in security parameter. We stress that such commitments can be constructed from *sub-exponentially hard one-way permutations*.

First we give a brief overview of the construction. Let $\mu \in \mathbb{N}$ be a parameter. We will now construct a TBNMC with ℓ blocks where $\ell = 2\mu + 2$. For now, assume ℓ to be a even number. Now for any tag $\mathsf{tg} \in [\mu]$ we construct the encoding scheme as follows: we put strings of 0 in all the blocks except the four "special" blocks: the first block is set to tg, the $(\mathsf{tg}+1)$-th block is set to the "bigger" commitment $\mathsf{Com}_{\kappa}(m)$, the $(\ell - \mathsf{tg})$-th block is set to the "smaller" commitment $\mathsf{Com}_{\kappa_{\mathsf{s}}}(m)$ and the ℓ-th (and final) block is set to the openings of the commitments. Now, for odd ℓ, one can just append one dummy block (string of 0's) right before the final block. So, without loss of generality we would assume ℓ to be even in this section. The detail construction is presented in Fig. 1. Note that here the blocks are of different length. However, it is easy to convert the code with equal block-length by padding additional zeros. We keep it without such padding for simplicity. Also, note that, from the computational hiding property of the commitment scheme, it follows that the construction has reveal index $\ell = 2\mu + 2$ for any PPT adversary.

The following theorem states that the construction is a TBNMC. The proof can be found in the full version [4].

▶ **Theorem 10.** *Let $\mu \in \mathbb{N}$ be some parameter. Assume that sub-exponentially hard one-way-permutations exists. Then, for any tag $\mathsf{tg} \in [\mu]$ and any $k \in \mathbb{N}$, the encoding scheme*

$\mathsf{TCode} = (\mathsf{TEnc}, \mathsf{TDec})$ *described in Fig. 1 is a* $(\mathsf{tg}, \ell, k, n)$-TBNMC *against all* PPT *adversary such that* $n = O(k + \mu \cdot \mathsf{p})$ *and* $\ell = 2\mu + 2$.

3.2 Non-malleability amplification

In this section we extend our construction to an efficient construction which can support larger tags. This extension is similar to a well-known phenomenon, namely *non-malleability amplification* [20], in the non-malleable commitment literature using the DDN-XOR trick [10].

3.2.1 One-many non-malleability

Towards that, we first show that the construction given in Fig. 1 already satisfies a stronger notion, which we call *one-many* tag-based non-malleability (OMTBC). This definition (we refer to the full version [4] for a formal definition), informally states that an adversary that is able to tamper a single codeword of m, cannot even come up with a set of codewords such that one of them is related to m. In particular, each function f_i in the tuple $\mathbf{f} = (f_1, \ldots, f_\ell)$ has much larger range than the domain and produces many c_i's together with the knowledge of the first i blocks of the input codeword.[5] Our next theorem shows that our construction (Fig. 1) achieves this stronger definition.

▶ **Theorem 11.** *Let* $\mu, t \in \mathbb{N}$ *be some parameter. Assume that sub-exponentially hard one-way-permutations exists. Then, for any tag* $\mathsf{tg} \in [\mu]$ *and any* $k \in \mathbb{N}$ *the* $(\mathsf{tg}, \ell, k, n)$-TBC $\mathsf{TCode} = (\mathsf{TEnc}, \mathsf{TDec})$ *described in Fig. 1 is an* $(t, \mathsf{tg}, \ell, k, n)$*-one-many tag-based BNMC against all* PPT *adversary such that* $n = O(k + \mu \cdot \mathsf{p})$ *and* $\ell = 2\mu + 2$.

3.2.2 Using DDN-XOR trick

In this section we use the DDN-XOR trick to construct an "efficient" TBNMC with "large" tags. Let us start with some intuitions. The construction uses any OMTBC (called "inner code" in the following) with "small" tag in a black-box way. The basic idea is as follows: let the "big" tag TG be t-bit long. Then compute t shares of message m just using XOR's i.e. $(m_1, \ldots, m_t)$ which is nothing but a t-out-of-t secret sharing. Then encode each m_j with the inner code using $j \| \mathsf{TG}[j]$ (which is of $O(\log(t))$-size) as tag. Finally put the encodings in increasing order of j (from 1 to t). The first block of the final codeword is, by definition the tag TG. the second block would consist of the first t blocks of inner codes in order and so on. The key-intuitions why the construction works are as follows. In order to break the tag-based non-malleability of the final encoding (called "outer code" within this sub-section), the adversary must produce a valid codeword with different"big" tag $\widetilde{\mathsf{TG}} \neq \mathsf{TG}$. In that case, evidently, there must exist at least one index $j \in [t]$ where the "small" tags differ $\widetilde{\mathsf{tg}}_j \neq \mathsf{tg}_j$. Moreover notice that, the adversary can't copy tg_j to any other position than j as that would result in an invalid codeword. Therefore $\mathsf{tg}_j = j \| \mathsf{TG}[j]$ is different from *all* the "small tags" of the tampered inner codewords. Then we reduce to the one-many non-malleability of the inner code in first such position (say $j^\star$). In particular, if the adversary tampers with the $j^\star$-th inner code, then by one-many non-malleability of the "inner code" no tampering

[5] We note that Chattopadhyay et al. [5] introduced the notion of one-many non-malleable code which is in turn built on continuous non-malleable code [13](CNMC). It is important not to confuse this notion with CNMC where the adversary chooses each subsequent tampering function after observing the result of the previous tamperings.

Parameters: Let Com_{κ_s} takes a k-bit message as input and u_s-bit randomness to produce a v_s-bit commitment and Com_{κ} takes a message of the same length, but randomness of u-bit to produce a v-bit commitment[a]. Let $\mathsf{tg} \in [\mu]$ be the tag of the encoding scheme for some $\mu \in \mathbb{N}$. We define a $(\mathsf{tg}, \ell, k, n)$-block-wise encoding scheme where $\ell = 2\mu + 2$ and $n = k + u_s + u + \mu(v_s + v) + \lfloor \log \mu \rfloor + 1$ as follows:

Encoding $\mathsf{TEnc}(m)$**:** The encoder gets a message $m \in \{0,1\}^k$ as input and do as follows:

1. Initialize: Choose randomnesses $r_s \xleftarrow{\$} \{0,1\}^{u_s}$ and $r \xleftarrow{\$} \{0,1\}^u$ for commitment scheme. Set the first block $c_1 := \mathsf{tg}$.
2. Stage-1: For all $i \in \{2, \ldots, \mu + 1\}$, define the i-th block of codeword c_i as follows:

$$c_i := \begin{cases} 0^v & i \neq \mathsf{tg} + 1 \\ \mathsf{Com}_{\kappa}(m, r) & i = \mathsf{tg} + 1 \end{cases}$$

3. Stage-2: For all $i \in \{\mu + 2, \ldots, 2\mu + 1\}$, define the i-th block of codeword c_i as follows:

$$c_i := \begin{cases} 0^{v_s} & i \neq 2\mu + 2 - \mathsf{tg} \\ \mathsf{Com}_{\kappa_s}(m, r_s) & i = 2\mu + 2 - \mathsf{tg} \end{cases}$$

4. Final stage: Define the last block as the decommitments i.e. the message and the randomnesses in the order of commitments are sent: $c_{2\mu+1} := (m, r, r_s)$.

Decoding $\mathsf{TDec}(\mathbf{c})$**:** On receiving a codeword $\mathbf{c}$ parse it as $\mathbf{c} = (c_1, \ldots, c_{2\mu+2})$ such that $|c_1| = \lfloor \mu \rfloor + 1$, for $i \in \{2, \ldots, \mu + 1\}$, $|c_i| = v$, for $i \in \{\mu + 2, \ldots, 2\mu + 1\}$, $|c_i| = v_s$ and for $i = 2\mu + 2$, $|c_i| = k + u_s + u$. Then do as follows:

1. Correctness of Structure: First check if the structure is correct: that is if $c_1 \neq 0$ and there are exactly two indexes $i_1 \in \{2, \ldots, \mu + 1\}$, $i_2 \in \{\mu + 2, 2\mu + 1\}$ such that:
   - **a.** $c_{i_1} \neq 0^v$ and $c_{i_2} \neq 0^{v_s}$.
   - **b.** for all other indexes $i \in \{2, \ldots, \mu+1\} \backslash \{i_1\}$, $c_i = 0^v$ and $i \in \{\mu+2, \ldots, 2\mu+1\} \backslash \{i_2\}$, $c_i = 0^{v_s}$.
   - **c.** $i_1 + i_2 = 2\mu + 1$.

   if any of them fails, then the structure of the tampered codeword is incorrect and therefore output $\perp$, else go to the next step.
2. Consistency of commitment: Parse $c_{2\mu+2}$ as $(m, r, r_s) := c_{2\mu+2}$ such that $|m| = k$, $|r| = u$ and $|r_s| = u_s$. Then check the validity of the commitment-decommitment pair $(c_{i_1}, (m, r))$ and $(c_{i_2}, (m, r_s))$, if any of them are invalid output $\perp$, otherwise output the committed message m.

[a] We assume $|v_s|, |v| = poly(\kappa)$

Figure 1 The construction of $(\mathsf{tg}, \ell, k, n)$-TBNMC for tag size $\log \kappa$.

function would not be able to succeed in producing any valid inner codeword that encodes a value which is "related" to the $j^\star$-th original share. Clearly, this implies the entire tampered outer codeword would have no information about $j^\star$-th share which makes the encoded massage (if valid) completely unrelated to the original message by the property of secret sharing.

For any tag $\mathsf{TG} \in \{0,1\}^t$ we construct a $(\mathsf{TG}, \ell', k', n')$-TBNMC $\mathsf{LCode} = (\mathsf{LEnc}, \mathsf{LDec})$ from a $(t, \mathsf{tg}, \ell, k, n)$-OMTBC $\mathsf{TCode} = (\mathsf{TEnc}, \mathsf{TDec})$ for any $\mathsf{tg} \in \{0,1\}^\alpha$ such that $t = 2^{\alpha-1} - 1$, $\ell' = \ell + 1$, $k' = k$ and $n' = nt$ as follows.

- **Encode** $\mathsf{LEnc}(m)$:
  1. Secret-sharing: On receiving an input message $m \in \{0,1\}^{k'}$, first choose $(t-1)$ random k'-bit strings $(m_1, \ldots, m_{t-1})$ and then compute $m_t = m \oplus m_1 \oplus \cdots \oplus m_{t-1}$. Note that the tuple $(m_1, \ldots, m_t)$ represents a (t,t)-secret sharing of m.
  2. Encode using smaller tag: Then for each $j \in t$, let the j-th "smaller" tag be $\mathsf{tg}_j = \mathtt{BIT}(j) \| \mathsf{TG}[j]$. Then compute the encoding of m_j as: $(c_{1,j}, \ldots, c_{\ell,j}) \leftarrow \mathsf{TEnc}_{\mathsf{tg}_j}(m_j)$.
  3. Constructing blocks: Define the tag-block $c_0 := \mathsf{TG}$. For all $i \in [\ell]$ define the i-th block as $c_i := (c_{i,1}, \ldots, c_{i,t})$. Output the codeword $\mathbf{c} = (c_0, \ldots, c_\ell)$.
- **Decode** $\mathsf{LDec}(\mathbf{c})$:
  1. Parsing: On receiving a codeword $\mathbf{c}$, parse it as $(c_0, \ldots, c_\ell) := \mathbf{c}$ such that $|c_0| = t$ and for all $i \in [\ell]$ $|c_i| = tn_i$. Then, for all $i \in [\ell]$ parse c_i as $(c_{i,1}, \ldots, c_{i,t})$ such that for all $j \in [t]$, $|c_{i,j}| = n_i$.
  2. Checking Tag consistency: Check if the "bigger" tag is consistent with the "smaller" tag: $c_0 = c_{1,1}[\alpha] \| c_{1,2}[\alpha] \| \cdots \| c_{1,t}[\alpha]$. Also check if the positions of the smaller tags are correct: $\forall\ j \in [t]$, $c_{1,j}[1 \ldots (\alpha-1)] = \mathtt{BIT}(j)$. If any of these fail output $\perp$, otherwise go to the next step.
  3. Decoding with smaller tag: For each $j \in [t]$ decode each value $v_j \leftarrow \mathsf{TDec}_{\mathsf{tg}_j}(c_{1,j}, \ldots, c_{\ell,j})$. If any of them is $\perp$ then output $\perp$. Otherwise, parse each v_j as m_j and finally output $m = m_1 \oplus \cdots \oplus m_t$.

Formally we show the following theorem. The proof can be found in the full version [4].

▶ **Theorem 12.** *Let* $\mathsf{TCode} = (\mathsf{TEnc}, \mathsf{TDec})$ *be a* $(t, \mathsf{tg}, \ell, k, n)$-OMTBC *for any tag* $\mathsf{tg} \in \{0,1\}^\alpha$, $t = 2^{\alpha-1} - 1$ *and* $k \in \mathbb{N}$. *Then for any tag* $\mathsf{TG} \in \{0,1\}^t$ *the above construction* $\mathsf{LCode} = (\mathsf{LEnc}, \mathsf{LDec})$ *is a* $(\mathsf{TG}, \ell', k', n')$-TBNMC *for* $\ell' = \ell + 1$, $k' = k$ *and* $n' = nt$.

3.3 The full construction by removing tags

Finally we present a transformation to remove tags using one-time signature scheme and a tag-based code with "large tag" (will be referred to as "inner code" in this section). This is similar to a standard trick [10] used in the area of non-malleable commitment for the same purpose. The main idea is to sign the entire codeword and set the public-key as the tag. This forces the tampering function either to keep the tag same and forge the signature in order to tamper, otherwise change the tag by producing its own key-pairs and then tamper. But the "inner code" guarantees that whenever the tag is changed, the tampering would result in an "unrelated" codeword.

Let $\mathsf{TCode} = (\mathsf{TEnc}, \mathsf{TDec})$ be an $(\mathsf{tg}, \ell, k, n)$-TBNMC for any tag $\mathsf{tg} \in \{0,1\}^t$. Let $\mathsf{OTSig} = (\mathsf{KGen}, \mathsf{Sign}, \mathsf{Verify})$ be a one-time signature scheme with public key $pk \in \{0,1\}^t$ which takes any $k_m = n - t$-bit message to produce a n_s-bit signature. Then we construct an $(\ell, k, n + n_\mathsf{s})$-BNMC $\mathsf{Code} = (\mathsf{Enc}, \mathsf{Dec})$ as follows:

- **Encode** $\mathsf{Enc}(m)$:
  1. GENERATE SIGNATURE KEYS: On input message $m \in \{0,1\}^k$ first run the key-generation algorithm of the signature scheme OTSig to generate a key pair: $(pk, sk) \leftarrow \mathsf{KGen}(1^\kappa)$.
  2. ENCODE WITH TAG: Run the tag-based encoding scheme with pk as the tag on the input message m to produce the codeword $(\tilde{c}_1, \ldots, \tilde{c}_\ell) \leftarrow \mathsf{TEnc}(m)$. Note that $\tilde{c}_1 = pk$.
  3. SIGN THE CODEWORD: Sign the codeword (except the tag) $(\tilde{c}_2, \ldots, \tilde{c}_\ell)$ to compute the signature $\sigma \leftarrow \mathsf{Sign}(sk, (\tilde{c}_2, \ldots, \tilde{c}_\ell))$.
  4. OUTPUT: Set for all $i \in [\ell - 1]$, $c_i = \tilde{c}_i$ and $c_\ell = \tilde{c}_\ell \| \sigma$. Output the codeword $\mathbf{c} = (c_1, \ldots, c_\ell)$
- **Decode** $\mathsf{Dec}(c_1, \ldots, c_\ell)$:
  1. PARSE: On input the codeword $(c_1, \ldots, c_\ell)$, set $\forall i \in [\ell - 1]$, $\tilde{c}_i := c_i$ and parse c_ℓ as $(\tilde{c}_\ell \| \sigma) := c_\ell$ such that $|\tilde{c}_\ell| = n_\ell$ and $|\sigma| = n_{\mathsf{s}}$.
  2. VERIFY SIGNATURE: Then verify the signature $d \leftarrow \mathsf{Verify}\,(\tilde{c}_1, (\tilde{c}_2, \ldots, \tilde{c}_\ell), \sigma)$. If $d = 0$ (i.e. verification fails) then output $\perp$. Otherwise go to the next step.
  3. DECODE WITH TAG: Decode the codeword as $\widetilde{m} \leftarrow \mathsf{TDec}(\tilde{c}_1, \ldots, \tilde{c}_\ell)$. Output $\widetilde{m}$.

Formally, we have the following theorem (see the full version [4] for a formal proof).

▶ **Theorem 13.** *Let* $\mathsf{TCode} = (\mathsf{TEnc}, \mathsf{TDec})$ *be a* $(\mathsf{tg}, \ell, k, n)$*-TBNMC for any tag* $\mathsf{tg} \in \{0,1\}^t$ *and* $\mathsf{OTSig} = (\mathsf{KGen}, \mathsf{Sign}, \mathsf{Verify})$ *be a one-time signature scheme with public key* $pk \in \{0,1\}^t$ *which takes any* $k_m = n - t$*-bit message to produce a* n_{s}*-bit signature.Then the above construction* $\mathsf{Code} = (\mathsf{Enc}, \mathsf{Dec})$ *is a* (ℓ', k', n')*-BNMC for* $\ell' = \ell$, $k' = k$ *and* $n' = n + n_{\mathsf{s}}$.

Theorem 4 now follows by combining Theorem 11, Theorem 12 and Theorem 13 and instantiating with appropriate parameters.

Abstract

Protecting software from malware injection is one of the biggest challenges of modern computer science. Despite intensive efforts by the scientific and engineering community, the number of successful attacks continues to increase.

This work sets first footsteps towards a provably secure investigation of malware detection. We provide a formal model and cryptographic security definitions of attestation for systems with dynamic memory, and suggest novel provably secure attestation schemes. The key idea underlying our schemes is to use the very insertion of the malware itself to allow for the systems to detect it. This is, in our opinion, close in spirit to the quantum Observer Effect. The attackers, no matter how clever, no matter when they insert their malware, change the state of the system they are attacking. This fundamental idea can be a game changer. And our system does not rely on heuristics; instead, our scheme enjoys the unique property that it is proved secure in a formal and precise mathematical sense and with minimal and realistic CPU modification achieves strong provable security guarantees. We envision such systems with a formal mathematical security treatment as a venue for new directions in software protection.

1 Introduction

Protecting software from malware injection is a major goal of computer security. Nonetheless, the problem of basing solutions on strong theoretical foundations does not seem to have received sufficient attention in the malware protection literature. In this work we suggest a novel provably secure and practically efficient paradigm for software protection against

arbitrary malicious code injection. We provide the first formal cryptographic model tailored to detect malware injection in modern computers, which we envision as the basis for fruitful research on provable secure detection and prevention of malware leading into the next generation of secure systems. Importantly, we provide first matching solutions that are accompanied by mathematical proofs that any memory oblivious injection will be caught with arbitrary high probability. Our solutions are practically efficient, demonstrating that provable security does not come at a too high price.

Our proposed system has the following desirable properties: 1) it requires minor to no changes to the CPU specification to provably defend against injection attacks that can not read the code before they inject their malware; 2) it only affects the performance of the program by a modest amount. The first property implies that it can be used on today's computers. The second property means that it can be practical, since performance is critical in most applications; this is obvious even in its simplified form presented here, where various optimizations have been avoided for the sake of clarity in the presentation. Finally, we allow attacks both spatial and temporal freedom: the attack can occur at any time during the execution and on any part of the memory. It can attack code as well as data.

1.1 Overview of our Contributions

We put forward and formally define the notion of a *virus detection scheme* (in short, VDS) which compiles any given program W (and its data) into a new secured program $\widetilde{W}$ that performs the same computation as W but allows us to detect any virus injected in the memory at any point of the execution path. The detection is done via a provably secure challenge-response mechanism between the machine executing the (compiled) software and a verifying external device. Importantly, we insist that the verification algorithm be very simple, and in particular that it be executed by a very lightweight device (Our constructions require that the verifier only does an encryption and compares strings for equality.) Thus, the role of the verifier can be, for example, played by the user with a smartphone, or by a compact and simple, intrusion-free hardware module that could even be part of the CPU.[1] Moreover, the verification uses public key techniques, where the verifier needs only the public key. This restricts the attack surface to the machine executing the secured code, as compromising the verifier's privacy gives an attacker no advantage in breaking our scheme.

We provide our formal cryptographic definitions of VDS security based on the well-studied Random Access Machine (RAM) model, slightly adapted to be closer to an abstract version of a modern computer following the *von Neumann architecture*. The suggested model corresponds to a simplistic *closed-system* abstraction of software execution: The code to be executed along with its associated data is loaded initially on the random access memory (RMEM,) which, through the execution, only communicates with the CPU.[2]

In more detail, a secure VDS is described as follows. The software to be executed is compiled, prior to being loaded onto the memory, to a secure version. Importantly, this compilation does not necessarily need the source code but for a wide class of software (non-self-modifying code) can be applied on the binary (machine-language) code of the program; thus, the compilation can be performed by the program vendor (this might allow for further

[1] Unlike software-based attestation techniques (cf. Section 1.2), the verification in our scheme can be done even over an insecure network, e.g. the Internet.

[2] In particular, the current theoretical model does not address how the data is exchanged with secondary storage devices, e.g., flash memory. It is part of ongoing research to extend this model to more complicated architectures.

efficiency optimizations) or by the user without requiring any reverse engineering. The compiler, in addition to the (binary code) of the program and its data, uses a randomly chosen *compilation key* K.

To check/verify that the software running on a system has not been attacked by a virus (or to detect such an attack in case it has occurred), the following *detection process* is executed. The user issues a challenge c that depends on the compilation key K and the system is required to produce a reply which passes a specified verification test. As already discussed, we arrange things in such a way that the verifier does not need to know the compilation key, and he can just know some public information on it. Formally, this is done by the use of public key cryptography, where the compilation key is the secret key, and the information held by the verifier, which we refer to as the *verification key*, is the corresponding public key. The security of the VDS requires that if the RAM has not been attacked then it can always reply to the challenge in an accepting manner (verification correctness); otherwise, any reply will be rejected with high probability (security).

We provide concrete instantiations of practical VDSs which, depending on the assumptions about the CPU they are executed on, achieve from a reasonably strong security (namely protection against continuous injection of moderate-sized virus) to security against arbitrary small viruses injected on locations that might depend on key-share locations. Informally, we prove the following result for our VDSs.

▶ **Theorem** (informal). *Under standard complexity assumptions our VDSs compile any non-self-modifying software into a secure version that detects any malware injection with very high probability.*

Our schemes are independent of the virus code, are platform-independent, and might require only small modifications to the common CPU architecture (in particular, they do not assume tamper-resilient hardware); and, with appropriate optimizations we can make it that they only affect the performance of the executed software by a practically acceptable amount. As a useful side effect, our scheme is even able to detect hardware errors, e.g., random bit-flips in the memory; as demonstrated in [5], such errors might have important consequences on the security of the executed software.

To construct our VDS we start by constructing a scheme satisfying a weak(er) notion of security, which (1) catches only injections of continuous and sufficiently long viruses, and (2) assumes that the response is computed by an external (trusted) device that is given access to the state of the attacked system. We give a formal definition of this weaker notion which depending on the application and the desired security level might already be satisfactory. We then proceed and gradually modify (strengthen) our scheme. The first modification ensures that the compiled program can compute the response by itself, i.e., without the help of an external trusted device. We note that the security of our weakest scheme is information theoretic (it is based on the perfect privacy of one-time pad encryption), whereas the proof of the more secure scheme requires a leakage-resilient encryption algorithm [9].

The second modification uses a simple *message authentication code* (in short, MAC) to remove the limitation to sufficiently long and continuous virus injection. A MAC authenticates a value using a random key, so that an attacker without access to the key cannot change the value without being detected. More concretely, to authenticate a word w our scheme relies on the standard MAC [16] that uses two keys K_1 and K_2, and compute a MAC tag as $t = w \cdot K_1 + K_2$, where w, K_1, and K_2 are interpreted as elements of an appropriate large arithmetic field. Observe that such arithmetic operations are implemented in hardware in existing CPUs. We assume, however, that the executing CPU has a slightly extended instruction-set which, informally, has each "load" instruction, i.e., read-from-memory instruction, check that the

MAC is correct before it loads the word on the CPU registers. We stress that this only needs the architecture to provide us with a very simple extra piece of microcode. By engineering the CPU's hardware in a smart way so that these operations are done on the circuit level, we expect to be able to reduce the effect of our compiler to a barely noticeable slowdown. Fortunately, the new architecture that Intel recently announced promises to embed such microcode in its next-generation microchips [24].

Overview of our VDS Construction. So how can we detect an intrusion that we have never seen before? How can we arrange that any injection of malware into our program by an attacker who does not know the compilation-key will be detected? The answer is that we will hide the compilation-key/secret in our program in a way that ensures that with very high probability, any injection by an adversary must destroy the secret. Once this secret is destroyed, the adversary may indeed be able to take over the program, but will be quickly detected. We note that current systems may fail to detect such an attack forever – for the type of injection we protect against, we are able to detect it in seconds.

A point: We can imagine situations where even such a swift detection of an attack is not sufficient to stop potential harm. An attacker could, in some situations, do immense damage even if he is in control of a program for only a fraction of a second. Furthermore, our approach is not targeted towards fixing buggy software or detecting malware-including software which might be (unknowingly) installed by the user. Rather, our method offers protection against "unauthorized" injection of malicious code, e.g., direct injection to the memory or radiation attacks. But we view the ability to provably detect any such attack, new, old, clever, or not, as a big improvement over the current state of the art.

So how can we do this? Let W be a program that we wish to protect from malware. We recompile W to $\widetilde{W}$. The idea is that W and $\widetilde{W}$ must compute the same thing, run in about the same time, and yet $\widetilde{W}$ must be able to detect itself against the insertion of malware. An obvious idea is to have $\widetilde{W}$ periodically check to see if its code or data have been maliciously changed. The trouble with this approach is that the attacker could easily inject his own code, take over the checker, and thereby disable the checking. In short: who checks the checker?

Here is how we proceed. The protected program $\widetilde{W}$ operates normally most of the time. Periodically it is challenged by another machine to prove that it has a secret key K. This key is known only to $\widetilde{W}$ and not to the attacker. If $\widetilde{W}$ has not been attacked, then it simply uses the key K to answer the challenge and thus proves that it is still operating properly.

The issue is what happens if $\widetilde{W}$ has been attacked and some code has been injected into it. We can arrange $\widetilde{W}$ so that no matter how the injection of code has happened the key K is lost. The attacker's very injection will have changed the state of $\widetilde{W}$ so that it is now in a state that no longer knows the key K. This is the analog of the quantum observer effect, often referred to as the Heisenberg Uncertainty Principle: the attacker has damaged the state of $\widetilde{W}$ so that the key has been destroyed.

Making the attack destroy the key is the central idea here. If $\widetilde{W}$ simply stores K somewhere in memory, the attacker will take over the program, look around for the key, and likely find the key;[3] this defeats the protection, since now it can answer the periodic challenges just like $\widetilde{W}$ could. To resolve the above issue we distribute the key K all through memory by using what is called *secret sharing* [30]. This is a standard method in cryptography that breaks a small key, like K, into many small pieces, called shares. These pieces are cleverly placed throughout all of $\widetilde{W}$'s memory. Our secret sharing allows K to be reconstructed only

[3] Note that we do not assume private memory, i.e., memory which the CPU cannot read.

if all the pieces are left untouched – if any are changed in any way, then it is impossible to reconstruct the key. Obviously, if there has been no attack, then in normal operation $\widetilde{W}$ can reconstruct the key from the pieces and answer the challenges. However, if the pieces are not all intact, then $\widetilde{W}$ will be unable to answer the next challenge.

This is the high-level idea of our method: hide the key via secret sharing, and rely on the attacker to destroy at least one share of the key. This destruction is irreversible and makes the attack fail the next challenge.

There is one additional point that we must mention. We must arrange that $\widetilde{W}$ can be attacked at anytime, including when the system has collected all the shares and reconstructed the key K on its CPU. This is a very dangerous time, since if $\widetilde{W}$ is attacked at this moment the fact that shares are destroyed does not matter. The attacker can simply use the reconstructed key K. We avoid such *time-of-check-time-of-use* (TOCTOU) attacks [25] by actually using two keys K_1 and K_2 in tandem. Both are stored via secret sharing as before, but now one must have both in order to answer the challenges. We arrange that $\widetilde{W}$ only reconstructs one key at a time and this means that an attacker must destroy either or both of the keys. This handles the above dangerous situation and makes our method provably secure.

Tying up the last loose end, we treat the case of very small viruses – i.e., ones that consist of a single bit or just a few bits – and viruses that know (or guess) the exact memory locations of key-shares in advance and therefore might not need to overwrite them. We armor our system to defend even against such tiny/informed viruses by employing an additional lightweight cryptographic primitive, namely a MAC. We use the MACs in a straightforward and efficient manner: we authenticate each word in W using the key-shares (also) as MAC keys, and require that for any word that is loaded from the random access memory, the CPU verifies the corresponding MAC before further processing the word. Thus, if the MAC does not check out we detect it (and immediately destroy the share), and if the adversary changes the MAC key, he loses one of the shares of one of the two secrets, and we detect that as well.

We enforce the above checks by assuming a modified CPU architecture (with only very small amount of additional computation, so the CPU power consumption is not affected). More specifically, to get the most out of the MAC functionality we need that when the CPU executes the program, it verifies authenticity of the words it loads from the memory. That is, the load operation of the CPU loads a block of several (in our case, five) words – this is already the case in most modern CPUs – including the program word, the MAC-tag and the corresponding keys, and check with every load instruction that the MAC verifies before further processing the word. Importantly, our MAC uses just one field addition and one field multiplication per authentication/verification; the circuits required to perform these operation are actually trivial compared to the modern CPU complexity and are part of many existing CPU specifications.

But to obtain security against any injection, we need one more trick: instead of using the actual key-shares in the generation/verification of the MAC tag, we use their hash-values. This ensures that the virus cannot manipulate the keys and forge a consistent MAC unless he overwrites a large part of them. We anticipate that given our goal's potential impact on security, such functionality might be included in the next generations of CPUs [24].

1.2 Related Literature

The literature on defense mechanisms against malware-injection attacks is vast. Due to its urgency and importance, the problem has been intensively researched. In what follows we provide a brief overview of the directions most related to our approach.

Closest related to our goals is the literature on verifying the authenticity/integrity of the internal state of computing devices to confirm that they have not been attacked by malware,

a mechanism usually referred to as *attestation*. A rough taxonomy divides this literature in three general categories, namely *hardware-based attestation* [2, 6, 11, 21], *software-based attestation* [20, 29, 28, 1, 17, 18], and *remote attestation* [6, 11, 21, 14, 4]. Due to the similarity in the goals of attestation with our system, we present a detailed overview of the corresponding literature in the full version of this work [23]. As a general note, we stress that similarly to other practical defense mechanisms, attestation schemes do not come with a formal proof of security or even a theoretical security model.[4] In contrast, our scheme is not only backed by a formal mathematical proof, but has several additional advantages with respect to existing attestation schemes, which are highlighted in the full version of this work [23]. We note, however, that much of the attestation literature allows the system to leak its entire state; although our schemes do not account for such leakage (in particular, the key shares should not leak), one can use sharing-refreshing techniques, e.g., [26, 3], to add protection against periodic leakage. The details of such a scheme are subject of future work.

On the most theoretical side of cybersecurity, cryptography provides solutions whose security is backed by rigorous mathematical proofs that typically reduce hardness of breaking the scheme to hardness of solving a mathematical problem, e.g., factoring. But with only a few exceptions, e.g., [7, 13, 10, 19, 15, 27], the cryptographic literature has not, to the best of our knowledge, targeted the problem of malicious code injection. And in contrast to the security-engineering research, cryptographic solutions that do target this problem are often inefficient and/or adopt a too-abstract model of computation which makes them inapplicable or impractical for today's systems.

1.3 Organization of the Paper

In Section 2 we describe the model of computation and the virus injection model, and in Section 3 we provide our security definitions for VDSs. Our VDS constructions are then described in Sections 4 and 5. Due to limited space, some of the formal definitions and proofs have been moved to [23].

2 The Model

In this section we provide an abstract specification of our model of computation. We use as our basis the well known Random Access Machine (RAM) model but slightly adapt it to be closer to an abstract version of a modern computer following the *von Neumann architecture*. In a nutshell, this modification consist of assuming that both the program and its data are written on the RAM's random access memory[5] which is polynomially bounded. A RAM $\mathcal{R}$ consist of two components: A *Random Access Memory (in short RMEM)* and a *Central Processing Unit (in short CPU)*. The RMEM and the CPU communicate in *fetch-and-execute cycles, aka CPU cycles*, where the number of CPU cycles is the default complexity measure of a RAM. We will refer to a CPU cycle as a *round* in the RAM execution.

The memory RMEM is modeled as a vector $\texttt{MEM}$ of $m = |\texttt{MEM}| = poly(k)$ *words*, where k is the, often implicit, security parameter. Each word is an L-bit string, where we assume that L is linear in k. (Wlog, in the following we will assume that $L = k$.) For $i \in \{0, 1, \ldots, m-1\}$ we denote by $\texttt{MEM}[i]$ the ith word, i.e., the contents of the i-th RMEM register. The CPU

[4] An exception here is [4] which uses an idea similar in spirit to ours – i.e., sharing a secret through the memory – for provably protecting against a class of heap overflow attacks (cf. [23] for a comparison).

[5] In the literature, a RAM with this modification is usually called a *Random Access Stored-Program* machine [12] (in short, RASP).

consists of a much smaller number of L-bit registers – in this work we assume that the total amount of storage of the CPU is linear in the security parameter k – and an instruction set $\mathcal{I}$ that defines which operations can be performed on the registers, and how data are loaded-to/output-from the CPU. The CPU registers include a read-only input-register and an output register which correspond to its interface with its environment (the user). The CPU registers are modeled as an array $\texttt{REG}$ of words, where we denote by $\texttt{REG}[i]$ the content of the ith CPU register. We denote a CPU by the pair $\mathcal{C} = (\texttt{REG}, \mathcal{I})$ of the vector $\texttt{REG}$ of registers and the instruction set $\mathcal{I}$. We denote a RAM with CPU $\mathcal{C}_k$ and RMEM $\texttt{MEM}_k$ as $\mathcal{R}_k = (\mathcal{C}_k, \texttt{MEM}_k)$.[6] The *state* of $\mathcal{R}_k$ at any point in the protocol execution is the vector $(\texttt{REG}_k, \texttt{MEM}_k)$ including the current contents of all its CPU and RMEM registers. Details of the model and formal definitions can be found in [23].

To allow for asymptotic security definitions – where the word size, the size of the CPU (i.e., number of its registers), and the size of the memory depend on the security parameter – we often consider a family of RAMs, $\mathcal{R} = \{\mathcal{R}_k\}_{k\in\mathbb{N}}$ with $\mathcal{R}_k = (\mathcal{C}_k = (\texttt{REG}_k, \mathcal{I}_k), \{\texttt{MEM}_k\})$. (The size of each word processed by $\mathcal{R}_k$ is $L = k$.) The RAM families considered in this work have the following property: The instruction set $\mathcal{I}_k$ is the same for all values of the security parameter k. In particular, we assume that all elements of a RAM family, have the same constant number $c = \mathcal{O}(1)$ of CPU registers, where each register of $\mathcal{R}_k$ is of size k, and there is some set of instructions $\mathcal{I}$ that includes operations defined over strings of arbitrary size such that $\mathcal{I}_k = \mathcal{I}$ for every $k \in \mathbb{N}$. (Of course for each value of k, $\mathcal{I}_k$ corresponds to the restriction of $\mathcal{I}$ on k-bit strings.)

Software Execution and Virus Injection. A program to be executed on a RAM $\mathcal{R} = (\mathcal{C}, \texttt{MEM})$ is described as a vector $W = (w_0, \ldots, w_{n-1}) \in (\{0,1\}^L)^n$ of words that might be instructions, addresses, or program data. To avoid confusion, we refer to such a vector including the (binary of a) software and its corresponding data as *code for* $\mathcal{R}$. By convention, whenever, for a RAM family $\mathcal{R}$ we say that W is code for $\mathcal{R}$, we mean that W is code for the element $\mathcal{R}_k \in \mathcal{R}$ with register size as long as the word size of W and instruction set that includes all the instructions used by W. The execution of a program proceeds as follows: The code W is loaded onto the memory $\texttt{MEM}$. Unless stated otherwise, we assume that W is loaded sequentially on the first $n = |W|$ locations of $\texttt{MEM}$, where all remainder locations are filled with ($\texttt{no\_op}$) instructions. The user might give input(s) to $\mathcal{R}$ by writing them on its input register. The RAM starts its execution by fetching the word of the RMEM which the program counter points to, i.e., $\texttt{MEM}[\texttt{pc}]$ (wlog, initially $\texttt{pc} = 0$). We assume that the RAM is reactive, i.e., any new input written on its input register, makes the RAM resume its computation even if it had halted with output (cf. [23]).

A CPU is *complete* (also referred to as *universal*) if given sufficient (but polynomial) random access memory it can perform any efficient deterministic computation (for a formal definition see [23]). We at times refer to a RAM (family) with a complete CPU as a complete RAM (family).

Modeling Virus Attacks. In our model, a virus attacks a RAM by injecting its code on selected locations of the memory RMEM. More formally, an ℓ-bit virus is modeled as a tuple $\mathbf{v} = (\vec{\alpha}, V) = ((\alpha_0, \ldots, \alpha_{\ell-1}), (b_0, \ldots, b_{\ell-1}))$, where each $\alpha_i \in \vec{\alpha}$ is a location in the memory and each b_i is a bit. The effect of injecting a virus $\mathbf{v}$ into a RAM $\mathcal{R} = (\mathcal{C}, \texttt{MEM})$, is to have, for each $\alpha_i \in \vec{\alpha}$, the α_i-th bit on the memory – i.e., the $(\alpha_i \mod L)$-th bit of the word written

[6] In slight abuse of notation we at times drop the security parameter whenever it is clear from the context.

on register $\texttt{MEM}[\lfloor \frac{\alpha_i}{L} \rfloor]$ – (over)written with b_i. We say that $\mathbf{v}$ is valid for $\mathcal{R}$ if the following properties hold: (1) $\alpha_i \neq \alpha_j$ for every $\alpha_i, \alpha_j \in \vec{\alpha}$, and (2) $\alpha_i \in \{0, \ldots, L(|\texttt{MEM}| - 1)\}$ for every $\alpha_i \in \vec{\alpha}$. Furthermore, we say that $\mathbf{v}$ is *non-empty* if $|\vec{\alpha}| > 0$. Note that in this work we do not consider viruses which inject themselves on the CPU registers.

3 Virus Detection Schemes

We next formalize our notion of provably secure virus detection. More concretely, we introduce the notion of a *virus detection scheme* (in short VDS) which demonstrates how to compile a given program (and its data) into a new program which allows us to detect any virus injection. The detection is done via a challenge-response mechanism.

▶ **Definition 1.** A *virus detection scheme (VDS)* $\mathcal{V}$ consists of five (potentially) randomized algorithms, i.e., $\mathcal{V} = (\texttt{Gen}, \texttt{Comp}, \texttt{Chal}, \texttt{Resp}, \texttt{Ver})$, defined as follows:[7]

- $\texttt{Gen}$ is a key-generation algorithm; it computes a pair (compilation-key, verification-key), i.e., $(K_c, K_v) \xleftarrow{\$} \texttt{Gen}$.[8]
- $\texttt{Comp}$ on input the description $\mathcal{R} = \{(\mathcal{C}_k, \texttt{MEM}_k)\}_{k \in \mathbb{N}}$ of a RAM family,[9] some code W for $\mathcal{R}_k$, and a compilation key K_c, $\texttt{Comp}$ outputs a new code $\widetilde{W}$ for $\mathcal{R}_k$ (which we will refer to as *secure code*) ; i.e., $\widetilde{W} \xleftarrow{\$} \texttt{Comp}(\mathcal{R}_k, W, K_c)$.
- $\texttt{Chal}$ on input a verification key K_v, and a string $z \in \text{INP}_{\texttt{Chal}} \subseteq \{0,1\}^{poly(k)}$, $\texttt{Chal}$ outputs $poly(k)$-bit string c called the *challenge*; i.e., $c \xleftarrow{\$} \texttt{Chal}(z, K_v)$.
- $\texttt{Resp}$ on input a string $c \in \text{OUT}_{\texttt{Chal}}$ and some code $\widetilde{W}$, $\texttt{Resp}$ outputs a $poly(k)$-bit string y called the *response*; i.e., $y \xleftarrow{\$} \texttt{Resp}(c, \widetilde{W})$.
- $\texttt{Ver}$ on input a verification key K_v, a message $z \in \text{INP}_{\texttt{Chal}}$, a challenge c and a response y, $\texttt{Ver}$ outputs a bit b; i.e., $b \xleftarrow{\$} \texttt{Ver}(K_v, z, c, y)$. We say that $\texttt{Ver}$ accepts iff $b = 1$.

A VDS should satisfy the following four security properties (see [23] for formal definitions).[10] The first property is *verification correctness* which, intuitively, guarantees that if the RAM has not been attacked, then the reply to the challenge is accepting. The second property is *compilation correctness*, which intuitively ensures that the compiled code $\widetilde{W}$ performs the same computation (on $\mathcal{R}$) as the original code W. In an application of a VDS, the verifier inputs the challenge at a point of his choice and checks that the reply verifies according to the predicate $\texttt{Ver}$. Thus, the third property of a VDS is *self-responsiveness*: the secured code $\widetilde{W}$ includes code that on some special input emulates algorithm $\texttt{Resp}$ on the RAM it executes. Finally, the fourth property requires *detection accuracy* which states that if some non-empty malware gets injected onto the RAM, then it is detected with high probability. This is one of the most challenging properties to ensure and is the heart of any VDS. We next specify this property by means of a security game between an adversary $\texttt{Adv}$ who aims to inject a virus on a RAM, and a challenger $\texttt{Ch}$ who aims to detect it.

---

[7] All five algorithms below take as an additional input the security parameter k, which is omitted for compactness.

[8] Note that if we instantiate the VDS with symmetric-key cryptography then $K_c = K_v$.

[9] This description of the family includes the word-size, the size and addresses of the CPU and RMEM registers and (an encoding) of the instruction set $\mathcal{I}$.

[10] Without loss of generality, whenever we refer to the secure (i.e., compiled by $\texttt{Comp}$) version $\widetilde{W}$ of some code W for a RAM family $\mathcal{R}$ we will implicitly assume that $\mathcal{R}$ has enough memory for writing $\widetilde{W}$ on it, i.e., if the word size of $\widetilde{W}$ is k then $|\texttt{MEM}_k| > |\widetilde{W}|$.

3.1 Detection Accuracy as a Security Game

At a high-level, the security game, denoted by $\mathcal{G}_{\mathtt{VDS}}^{\mathcal{R},\mathcal{V},W}$, proceeds as follows: The challenger `Ch` runs the key-generation algorithm to obtain a key-pair (K_c, K_v), and compiles some code W for RAM $\mathcal{R} = (\mathcal{C}, \mathtt{MEM})$ onto a new code $\widetilde{W}$ for $\mathcal{R}$ by invocation of algorithm `Comp`; `Ch` then emulates an execution of $\widetilde{W}$ on $\mathcal{R}$, i.e., emulates its CPU cycles and stores its entire state at any given point. The adversary is allowed to inject a virus of his choice on any location in the memory `MEM`. Eventually, the challenger executes the *(virus) detection procedure*: It computes a challenge c by invocation of algorithm $\mathtt{Chal}(z, K_v)$, and then feeds input $(\mathtt{check}, c)$ to the emulated RAM and lets it compute the response y. The adversary wins if the output b of the verification algorithm with this response y equals 1. To capture worst case attack scenarios, we allow the adversary to inject his virus at any point during the RAM emulation and make no assumption as to how many rounds the RAM executes after the virus has been injected and before it receives the challenge. Furthermore, we make no assumptions on how much information the adversary holds on the original code W or on the inputs/outputs of $\mathcal{R}$. The formal description of the security game $\mathcal{G}_{\mathtt{VDS}}^{\mathcal{R},\mathcal{V},W}$ can be found in [23].

▶ **Definition 2.** We say that a virus detection scheme $\mathcal{V}$ =(`Gen`,`Comp`,`Chal`,`Resp`,`Ver`) is secure for RAM family $\mathcal{R}$ if it satisfies the following properties:

1. $\mathcal{V}$ is verification correct, compilation correct, and self-responsive.
2. For sufficiently large k for any code W for $\mathcal{R}_k$ and any polynomial adversary `Adv` in the game $\mathcal{G}_{\mathtt{VDS}}^{\mathcal{R}_k,\mathcal{V},W}$ who injects a valid non-empty virus the following holds: $\Pr[b = 1]$ is negligible, where the probability is taken over the random coins of `Adv` and `Ch`.

In our constructions we restrict our statements to a certain class of code that satisfies some desirable properties making the compilation easier. We will then say that the corresponding VDS is *secure with respect to the given class of code*.

The Repeated Detection Game $\tau\mathcal{G}_{\mathtt{VDS}}^{\mathcal{R},\mathcal{V}_1,W}$. Definition 2 requires that the adversary is caught even when he injects its virus while the RAM is executing the `Resp` algorithm. We next describe a relaxed security game, which provides a useful guarantee for practical purposes. In this game the virus detection (challenge/response) procedure is executed multiple times periodically (on the same compiled code); the requirement is that if the adversary injects its virus to the RAM at round ρ, then he will be caught by the first invocation of the virus detection procedure which starts *after round* ρ. Note that all executions use *the same* compiled RAM program and therefore the same key K. The corresponding security game $\tau\mathcal{G}_{\mathtt{VDS}}^{\mathcal{R},\mathcal{V},W}$ which involves τ executions of the detections procedure is detailed in [23]. The security definition is similar to Definition 2 but requires that any virus that is injected in the RAM will be caught *in the first virus detection attempt performed after the injection* . Our VDSs will be proven secure in this repeated detection game. In [23] we describe a simple trick which transforms our VDSs to ones that are secure in the standard game using a secure hash function.

4 A Software-based VDS for Continuous Moderate-size Virus

In this section we provide a VDS which is secure assuming the virus is linear in the security parameter and that it is injected in continuous memory locations, i.e., if $\mathbf{v} = ((\alpha_0, \ldots, \alpha_{|V|-1}), V)$, then $\alpha_i = \alpha_{i-1} + 1$ for all $i \in [|V| - 1]$. This captures the entire class of tampering accounted for in [4]. In Section 5 we will show how to get rid of these restrictions. Our construction proceeds in two steps. First, we show how to construct a VDS $\mathcal{V}_1$ which

achieves a weaker notion of security that, roughly, does not have self-responsiveness. In a second step, we show how to transform $\mathcal{V}_1$ into a VDS $\mathcal{V}_2$ which is secure in the repeated detection game.

A VDS without self-responsiveness. We start by describing a VDS $\mathcal{V}_1 = (\mathtt{Gen}_1, \mathtt{Comp}_1, \mathtt{Chal}_1, \mathtt{Resp}_1, \mathtt{Ver}_1)$ which achieves security without self-responsiveness: The corresponding attack-game $\mathcal{G}^{\mathcal{R},\mathcal{V},W}_{\mathtt{VDS}-}$ is derived from the standard attack-game $\mathcal{G}^{\mathcal{R},\mathcal{V},W}_{\mathtt{VDS}}$ by modifying the detection procedure so that instead of emulating $\mathcal{R}$ on the compiled code $\widetilde{W}$ and input $(\mathtt{check}, c)$ to compute $y = \mathtt{Resp}(c, \widetilde{W})$, the challenger evaluates $y \xleftarrow{\$} \mathtt{Resp}(c, \widetilde{W})$ himself on the current contents $\widetilde{W}$ of the memory of the emulated RAM.

At a high level, the idea of our construction is as follows: The key generation algorithm $\mathtt{Gen}_1$ samples a k-bit key K for a symmetric-key cryptosystem, i.e., $K_c = K_v = K \xleftarrow{\$} \{0,1\}^k$. Given key K, the algorithm $\mathtt{Comp}_1$ computes an additive sharing $\langle K \rangle$ of K and fills the entire memory $\mathtt{MEM}$ by interleaving a different share of $\langle K \rangle$ between every two words in the original code. Concretely, $\mathtt{Comp}$ compiles some code W for a RAM $\mathcal{R}$ into some new code $\widetilde{W}$ for $\mathcal{R}$ constructed as follows: Between any two consecutive words w_i and w_{i+1} of W the compiler interleaves a uniformly chosen k-bit string $K^{i,i+1} = K_1^{i,i+1} || \ldots || K_{\frac{k}{L}}^{i,i+1}$, where each $K_j^{i,i+1} \in \{0,1\}^L$. In the last k bits of the compiled code (i.e., after the last word $w_{|W|-1}$) the string $K^{last} = K \oplus \bigoplus_{i=0}^{|W|-2} K^{i,i+1}$ is written.[11]

To ensure that the compiled code $\widetilde{W}$ executes the same computation as W we need that while being executed it "jumps over" the key-share locations. For this purpose, we do the following modification: After each word w_j of W we insert a $(\mathtt{jumpby}, n)$ instruction where n is the number of key-shares between this and the next W-word in the compiled code. Similarly, we modify any "jump" instructions of the original code W to point to the correct locations in $\widetilde{W}$. Note that this modification is not necessarily applicable to arbitrary code, e.g., for certain self-modifying code it might even be infeasible. However, it is possible for a complete class of code, which we refer to as *non-self-modifying structured code,* – roughly, this includes code that does not modify its instructions and might only jump by a fixed amount in each operation.

In the following we provide the description of our compiler. The first step to this direction is a process, called $\mathtt{Spread}$, which spreads such a code to allow for enough space between the words to fit the key-shares and adds the extra "jump" instructions to preserve the right program flow. The compiler $\mathtt{Comp}_1$ uses the process $\mathtt{Spread}$ to translate, as sketched above, some non-self-modifying structured code W for a RAM $\mathcal{R} = (\mathcal{C}, \mathtt{MEM})$ into (secured) code $\widetilde{W}$ for $\mathcal{R}$. The algorithm $\mathtt{Chal}_1$ chooses random string $x \in \{0,1\}^k$, and computes the challenge as an encryption of x with key K; i.e., $c \leftarrow \mathtt{Chal}(x, K) = \mathtt{Enc}_K(x)$. For achieving security without self-responsiveness, we can take $\mathtt{Enc}$ to be the one-time pad, i.e., $\mathtt{Enc}_K(x) = x \oplus K$. The corresponding algorithm $\mathtt{Resp}_1$ works as follows: On input the challenge $c = \mathtt{Enc}_K(r)$ and the compiled code $\widetilde{W}$, it reconstructs K by summing up all its shares as retrieved from $\widetilde{W}$, and outputs a decryption of the challenge under the reconstructed key, i.e., outputs $y = c \oplus K$. The corresponding verification algorithm $\mathtt{Ver}_1$ simply verifies that $y = x$.

The security of the above scheme follows from the fact that an injection of a sufficiently long continuous virus will have to overwrite a substantial number of bits of a key-share, which will make it infeasible to correctly decrypt the challenge and thus pass the VDS check. The formal security proof of the statement can be found in [23].

[11] Wlog, here we implicitly assume that $(|\mathtt{MEM}| - |W|) = 0 \mod k$ so that the keys fit exactly in the memory. The general case can also be easily treated.

▶ **Theorem 3.** *Assuming $\mathcal{R}$ is a complete RAM family the VDS $\mathcal{V}_1$ is secure for $\mathcal{R}$ without self-responsiveness with respect to the class of all non-self-modifying structured codes and the class of adversaries who injects a virus $\mathbf{v}$ with $|\mathbf{v}| \geq 2L + \ell$ where $\ell = \omega(\log k)$ on consecutive memory locations.*

Adding Self-Responsiveness. We next modify $\mathcal{V}_1$ so that it is secure (with self-responsiveness) in the repeated detection game. Due to space limitation, the detailed transformation has been moved to [23]; here we restrict to an overview of the basic technical ideas. The first step is to devise a code $W_{\texttt{Resp}}$ for computing a given VDS response algorithm `Resp` and then combine it with W via a threading mechanism: When executing, the combined code $\text{Emb}(W, W_{\texttt{Resp}})$ (periodically) checks if a verification request-input with challenge c is handed to $\mathcal{R}$; if so, it stores the CPU state on free memory locations – namely, locations at the end of the memory that are occupied by (`no_op`) – and changes the program counter to point to the location where $W_{\texttt{Resp}}$ is stored; once `Resp` has produced output, it restores the CPU to its prior state and continues the execution of W.

But the above modification applied on $\mathcal{V}_1$ does not yield a secure VDS, as it only detects attacks (virus injections) that occur *outside* the virus verification procedure, i.e., has the TOCTOU vulnerability discussed in the introduction. To solve this, instead of using a single compilation-key K of length k we use a $2k$-bit key K which is parsed as two k-bit keys $K_{\texttt{od}}$ and $K_{\texttt{ev}}$ via the following transformation: Let $K = x_1 || \dots || x_{\frac{2k}{L}}$, where each x_i is a word.[12] Then $K_{\texttt{od}}$ is a concatenation of the odd-indexed words, i.e., x_i's with $i = 1 \mod 2$, and $K_{\texttt{ev}}$ is a concatenation of the even indexed words. Now the challenge algorithm outputs a double encryption of z with keys $K_{\texttt{od}}$ and $K_{\texttt{ev}}$, i.e., $c = \texttt{Enc}_{K_{\texttt{od}}}(\texttt{Enc}_{K_{\texttt{ev}}}(z))$. In order to decrypt, the response algorithm does the following: First it reconstructs $K_{\texttt{od}}$ by XOR-ing the appropriate shares, and uses it to decrypt c, thus computing $\texttt{Enc}_{K_{\texttt{ev}}}(z)$. Subsequently, it erases $K_{\texttt{od}}$ from the CPU register (e.g., by filling the register where $K_{\texttt{od}}$ is stored with 0's) and *after the erasure completes* it starts reconstructing $K_{\texttt{ev}}$ and uses it (as above) to decrypt $\texttt{Enc}_{K_{\texttt{ev}}}(z)$ and output $y = z$.

The above modification ensures that in order to correctly answer the challenge, the virus needs both $K_{\texttt{od}}$ and $K_{\texttt{ev}}$. However, the keys are never simultaneously written in the CPU. Thus if the adversary injects the virus before $K_{\texttt{od}}$ is erased he will overwrite bits from a share of $K_{\texttt{ev}}$ (which at that point exists only in the memory RMEM); thus he will not be able to decrypt the challenge. Otherwise, if the adversary injects the virus after $K_{\texttt{od}}$ has been erased from the CPU, he will overwrite bits from a share of $K_{\texttt{od}}$; in this case he might successfully pass this detection attempt, but will fail the next detection attempt.

But we are still not done, because the above argument cannot work with any encryption scheme, e.g., it fails if we instantiate $\texttt{Enc}(\cdot)$ with one-time-pad encryption as in VDS $\mathcal{V}_1$. The reason is that once inside the system, the adversary might be able to use the key material it has not destroyed to answer the challenge with non-negligible probability. To avoid this, we make use of a public-key leakage-resilient encryption scheme, e.g., [8], which is secure as long as the adversary's probability of guessing the key is negligible even when one leaks a big part of the key.

The above tricks are the heart of our modified VDS, but a few more low level hacks are employed to ensure that the modified protocols compose well with the ones from the previous section. For example, we need to make sure that the part of the code $\text{Emb}(W, W_{\texttt{Resp}})$ that

[12] We provide the general solution for $k = Lq$ for some q; with the simplification that $L = k$, we get that $K = x_1 || x_2 = K_{\texttt{od}} || K_{\texttt{ev}}$.

performs the verification accesses the correct key-share locations. We refer to [23] for the details and the security proof of the resulting VDS $\mathcal{V}_2 = (\mathtt{Gen}_2, \mathtt{Comp}_2, \mathtt{Chal}_2, \mathtt{Resp}_2, \mathtt{Ver}_2)$.

On the performance of our VDS. It is easy to verify that the above VDS induces a moderate slowdown, i.e., a factor two, due to processing the newly inserted jump instructions plus whatever slowdown the periodically checking for inputs might impose, on the execution of the code on the RAM (while the code is not being verified). Both slowdowns can be reduced. E.g., the factor two is an overestimate as several instructions are already "jumps" plus reading data does not execute "jumps"; similarly, the check for the input can be executed periodically (or explicitly assumed as being part of any CPU-cycle). On the other hand, verification is quite heavy as it needs to traverse almost the entire memory but this is not our main consideration as (1) we believe that our scheme's provable security guarantee makes the waiting acceptable, and (2) unlike existing attestation methods the verification does not need to stop the normal execution of the program – e.g., in a RAM with parallel processors it could be done by a single designated processor.

In terms of memory usage, the secured code requires a linear (concretely, a factor four) amount of memory with respect to the original code. Although we are less concerned about memory needs – memory is an inexpensive expandable resource the capacities of which increase faster than computation speed – improving the memory usage is an interesting research direction.

5 Detecting Arbitrary Injection

The above VDSs are secure only against (sufficiently) long and consecutive viruses. In this section we describe a construction which is secure independently of the virus length even if the virus bits are not injected continuously, and in particular even when the virus targets non-key-share locations. To achieve this ultimate security guarantees we use a compiler similar to $\mathtt{Comp}_2$, but we include, for each code word and pair of key-shares, message-authentication-code tags (MACs) which we verify every time we load a code word to the CPU. Concretely, the difference with $\mathtt{Comp}_2$ is that $\mathtt{Comp}_3$ appends a MAC tag t^i to each word, keyed with the (concatenation of the) key-shares $K_{\mathtt{od}}^{i,i+1}||K_{\mathtt{ev}}^{i,i+1}$ that follow this word. We use a MAC with a special leakage-resilient property that ensures that the adversary cannot forge a tag even when he knows a large portion of the key. Thus, if the malware overwrites only a few bits of some of the key-shares it will be unable to guess an appropriate manipulation of the MAC key. And if it overwrites a large portion it will be unable to answer decryption challenges.

To use the power of the MACs we need to make sure that during the program execution, before loading any word to the CPU we first verify its MAC. To this direction, we assume that, by default, the CPU loads values from the memory RMEM to its registers via a special load instruction $(\mathtt{read\_auth}, i, j)$, which fetches five consecutive words (corresponding to $\widetilde{w}_i$ and its MAC key and tag), verifies the MAC with the corresponding keys, and only if the MAC verifies, it keeps the word on the CPU to process. If the MAC verification fails, then $(\mathtt{read\_auth}, i, j)$ deletes at least one of the key-shares from the memory, thus introducing an inconsistency that will be caught by the detection procedure. Furthermore, to ensure that the compiled program will not introduce inconsistencies, our compiler replaces every $(\mathtt{write}, j, i)$ instruction (which writes the contents of register j in RMEM location i) with microcode, denoted as `write_auth`, which, when writing a word in the memory it also updates the corresponding MAC tag. We stress that, unlike `read_auth` which we need the CPU to support as an atomic instruction, the instruction `write_auth` does *not* require any

change in the architecture or additional assumptions as it can be implemented in code itself. The details of the corresponding VDS $\mathcal{V}_3$ along with its security proof can be found in [23].

▶ **Theorem 4.** *Let $\mathcal{R}$ be a complete RAM. If the encryption scheme used in $\mathcal{V}_3$ is CPA secure even against an adversary who learns all but $\omega(\log k)$ bits of the secret key, then $\mathcal{V}_3$ is secure for $\mathcal{R}$ in the repeated-detection mode with respect to the class of all non-self-modifying structured codes and adversaries in the bit-by-bit (non-continuous) injection model.*

Abstract

We show an almost cubic lower bound on the size of any depth three arithmetic circuit computing an explicit multilinear polynomial in n variables over any field. This improves upon the previously known quadratic lower bound by Shpilka and Wigderson [CCC, 1999].

1 Introduction

An arithmetic circuit is a directed acyclic graph with leaves (nodes with in-degree zero) labeled by formal variables and other nodes labeled by addition ($+$) or multiplication ($\times$) operations. Nodes with out-degree zero are the output nodes; for simplicity and without losing generality we will assume that there is only one output node in a circuit. Non-leaf nodes are also referred to as addition or multiplication *gates*. Such a circuit naturally represents a multivariate polynomial; we say this polynomial is *computed* at the output node of the circuit (or simply computed by the circuit). Two parameters that determine the complexity of a circuit are its *size* and *depth*, which are respectively the number of edges and the length of the longest path from any input node to the output node of the circuit. Computations involving arithmetic operations can be naturally modeled by arithmetic circuits and hence study of these objects forms a fundamental aspect of complexity theory.

Research on arithmetic circuits received a great impetus from the seminal paper by Valiant [42] who defined two non-uniform complexity classes that are algebraic analogues of classes P and NP. These algebraic complexity classes are known as VP and VNP in the literature. Class VP consists of families of polynomials $\{g_n\}_{n\geq 1}$ such that the number of variables and the degree of g_n are $n^{O(1)}$, and there is an arithmetic circuit of size $n^{O(1)}$ computing g_n. A family of polynomials $\{f_n\}_{n\geq 1}$ is in VNP if there is another family of polynomials $\{g_n(\mathbf{x},\mathbf{y})\}_{n\geq 1}$ in VP such that $f_n = \sum_{\mathbf{y}\in\{0,1\}^{|\mathbf{y}|}} g_n(\mathbf{x},\mathbf{y})$. Valiant defined a notion of completeness for the classes VNP and VP, and showed that the family of permanent polynomials is VNP-complete whereas the family of determinant polynomials is *almost* complete for VP. This gave rise

to the famous 'determinantal complexity of the permanent' problem, a suitable resolution of which would imply $\mathsf{VP} \neq \mathsf{VNP}$ or equivalently a super-polynomial size lower bound for arithmetic circuits. We refer the reader to the surveys [26, 39], the book [4] and the paper [27] for more on these and other related algebraic complexity classes, their inter-relationships and their associations with Boolean complexity classes. Throughout this article, whenever we use the term 'circuit(s)' we will mean 'arithmetic circuit(s)'.

Starting with Valiant's work there has been significant progress in proving lower bounds for several restricted models of arithmetic circuits. Multilinear [31, 30, 34], noncommutative [28, 25], monotone [13] and special low-depth circuits [29, 8, 36, 35, 32, 1, 15, 16, 21, 19] are examples of such interesting circuit classes. But still, our knowledge of general circuit lower bound is rather limited. The best known lower bound for general circuits is Baur and Strassen's $\Omega(n \log d)$ bound [40, 3] for circuits computing the simple polynomial $\sum_{i\in[n]} x_i^d$. A recent line of work on depth reduction, starting with [2, 43] and culminating with [20, 10, 41], has shown that a moderately strong lower bound for circuits of *depth three*[1] implies a super-polynomial lower bound for general circuits. Also, Raz [33] showed that a strong enough lower bound for a special kind of (namely, set-multilinear) depth three circuits implies a super-polynomial lower bound for general arithmetic formulas[2]. These depth reduction results have opened up the possibility of proving a super-polynomial lower bound for general circuits/formulas by first proving strong lower bounds for low-depth, in particular depth three, circuits. The hope is depth three circuits, which have an apparent simple structure, might be more amenable to lower bound proofs. But, unfortunately, even at depth three we do not know of any super-polynomial lower bound over fields of characteristic zero!

Depth three circuits. In this paper, whenever we mention a depth three circuit we will mean a $\Sigma\Pi\Sigma$ circuit that has an addition gate at the top, followed by a layer of multiplication gates and finally a bottom layer of sum gates. Such a circuit is a "sum of product of linear polynomials" representation of the computed polynomial. The fan-in of the top addition gate is called the top fan-in, and that of the bottom layer of addition gates the bottom fan-in of the circuit. Observe that bottom fan-in can be at most $n+1$ where n is the number of variables. The *multiplicative complexity* of a depth three circuit $\mathtt{C}$ is the sum of the fan-ins of the multiplication gates of the circuit, i.e. if $\mathtt{C} = \sum_{i=1}^{s} l_{i1} \cdots l_{id_i}$ where l_{ij}'s are linear polynomials then multiplicative complexity of $\mathtt{C}$ is $\sum_i^s d_i$. It is easy to see that multiplicative complexity is less than the size of a depth three circuit. Circuit $\mathtt{C}$ is *homogeneous* if l_{ij}'s are homogeneous linear polynomials (a.k.a. linear forms).

Previous works on depth three circuit lower bound. In [38, 36], Shpilka and Wigderson proved an $\Omega(n^2)$ lower bound on the multiplicative complexity of depth three circuits computing the elementary symmetric polynomial

$$\text{ESym}_n^d(x_1, \ldots, x_n) \stackrel{\text{def}}{=} \sum_{S\subseteq[n],|S|=d} \prod_{i\in S} x_i$$

on n-variables and degree $d = \Theta(n)$. This bound is essentially optimal for fields of size more than n, as n-variate elementary symmetric polynomials can be computed by depth three

[1] over fields of characteristic zero
[2] a *formula* is a circuit whose underlying directed acyclic graph is a tree

circuits with multiplicative complexity $O(n^2)$ [3]. A similar tight quadratic lower bound but for the power symmetric polynomial $\sum_{i\in[n]} x_i^n$ was shown in [12]. Also, a near quadratic lower bound is known for the determinant polynomial [38, 36]. The situation is a lot better over small fields or under the restriction of homogeneity. An exponential lower bound was shown by [8] (and by [9]) for depth three circuits over any fixed finite field computing the determinant polynomial (even if the circuit and the determinant are treated in the algebra of functions over the finite field). It was shown in [29] that any homogeneous depth three circuit computing ESym_n^{2d} has size $\Omega((n/4d)^d)$. Recently, [16] showed a lower bound of $n^{\Omega(\sqrt{d})}$ for depth three circuits, with bottom fan-in bounded by n^ε for any fixed $\varepsilon < 1$, computing an explicit n-variate polynomial of degree d.

1.1 Our results

▶ **Theorem 1** (Depth-3 circuit lower bound). *There is a family of homogeneous multilinear polynomials $\{f_n\}_{n\geq 1}$ in* VNP*, where f_n is a $\Theta(n)$-variate polynomial of degree $\Theta(n)$ such that any depth-3 circuit computing f_n has multiplicative complexity (and hence size) $\Omega\left(\frac{n^3}{(\ln n)^2}\right)$.*

Theorem 1 can be seen as an improvement in the state of the art of the long-standing quadratic lower bound for depth three circuits [38, 36], although our target polynomial family is harder – it is in VNP and not known to be in VP. Also, from our analysis, we arrive at a near quadratic lower bound for the *symmetric model* defined in [37] thereby improving upon the linear bound therein (Theorem 2).

Let ESym_m^d be an elementary symmetric polynomial in m variables and of degree d. Borrowing terminologies from [37], a *symmetric circuit* has a bottom layer of plus gates computing linear polynomials, and a top gate that computes some elementary symmetric polynomial on the linear polynomials computed at the bottom level gates. Thus, a symmetric circuit with m bottom level gates outputs a polynomial of the form $\text{ESym}_m^d(l_1, \ldots, l_m)$ for some d, where $l_1, \ldots, l_m$ are linear polynomials computed by the m bottom level gates. The parameter m is defined as the *size* of the symmetric circuit. This model was shown to be complete or universal in [37] (i.e. every polynomial can be computed in this model), and linear lower bounds were shown on the size of the smallest symmetric circuit computing the determinant polynomial and the polynomial $\prod_{i=1}^{n/2} x_i + \prod_{i=n/2+1}^{n} x_i$. The following theorem improves this lower bound but once again the target polynomial family is likely harder than the ones studied in [37].

▶ **Theorem 2** (Symmetric circuit lower bound). *Let $\{f_n\}_{n\geq 1}$ be the polynomial family of Theorem 1. The size of the smallest symmetric circuit computing f_n is $\Omega\left(\frac{n^2}{(\ln n)^2}\right)$ over any infinite field.*

In an attempt to make progress in understanding lower bounds for circuit models where formal degree of the circuit is much higher than the number of variables (as might be the case for a depth three circuit), [17] posed the problem of proving lower bounds for homogeneous depth three circuits with formal degree much larger than the number of variables. The following theorem gives a solution to this problem.

▶ **Theorem 3** (Homogeneous depth three circuits with high degree). *For any positive integer $d = d(n) \geq n$, there exists an explicit family $\{f_{n,d}\}$ of n-variate polynomials of degree d*

[3] this follows from an interpolation trick attributed to Michael Ben-Or in [29]

such that any homogeneous depth three circuit computing $f_{n,d}$ must have size at least $2^{\Omega(n)}$. Moreover, one can even choose such a family $f_{n,d}$ so that it can in fact be computed by a $(nd)^{O(1)}$-sized algebraic branching program[4].

The above theorem can be viewed as a generalization of the lower bound by [29] for homogeneous depth three circuits. Since elementary symmetric polynomials in n-variables have degree at most n, the lower bound in [29] holds for homogeneous depth three circuits with degree less than the number of variables. To the best of our knowledge, a lower bound of $(nd)^{\omega(1)}$ for homogeneous depth three circuits with degree d much greater than the number of variables n was not known. Theorem 3 fills in this gap in our understanding as long as $d = 2^{o(n)}$. However, note that the lower bound in the above theorem is independent of d, ideally one should get $d^{\Omega(n)}$ instead of $2^{\Omega(n)}$.

1.2 Proof ideas

Like in many of the previous works, we use a measure $\mu : \mathbb{F}[\mathbf{x}] \to \mathbb{N}$ to capture some 'weakness' of a circuit family as opposed to a 'hard' family of polynomials which leads to a lower bound for the circuit family. In both Theorem 1 and 3, the improvements are achieved by applying the *dimension of the shifted partials* measure, introduced in [14], and used subsequently (at times with certain crucial alterations) in many other recent lower bound results [11, 18, 7, 15, 22, 16, 24, 21, 19, 23]. The shifted partials measure is a generalization of the dimension of the partial derivatives measure used previously in [29, 36]. It is quite effective in proving lower bounds for the model of depth four ($\Sigma\Pi\Sigma\Pi$) circuits with formal degree close to the actual degree of the computed polynomial, and somewhat low bottom fan-in [11, 18]. In fact, all the recent lower bounds (for restricted depth 3 and 4 circuits) obtained using shifted partials 'reduce' to this case of depth four circuits one way or the other. We take a similar route here, but make the crucial observation that a simple "grouping" step in the analysis with shifted partials gives some *leeway to the formal degree* of the circuit and allows it to grow over the actual degree of the computed polynomial. This observation and a careful construction of the target family of polynomials to take advantage of this leeway are the primary sources of improvement of the depth three lower bound.

An immediate hurdle in proving lower bounds for depth three circuits is that the formal degree of the circuit can be much larger than the degree and number of variables of the computed polynomial. The existing proof techniques and measures have had limited success in handling high formal degree circuits [16, 23]. To get around this first hurdle, we begin by following the same approach as in [36] of pruning the circuit of high degree product gates by going modulo some linear polynomials picked from among the factors of such 'heavy' product gates. This step is exactly (borrowing terminologies from [36]) satisfying some affine linear constraints and restricting the circuit to an affine subspace. However, the degree threshold used to define 'heavy' product gates can now be chosen higher than that in [36] because of the 'leeway to formal degree' provided by shifted partials. In the pruned circuit, a simple "grouping" of linear polynomials in every product term of a depth three circuit turns out to be surprisingly effective in handling the remaining product gates. The grouping step transforms a depth three circuit to a depth four circuit with bottom fan-in more than 1, but at the same time brings down the number of factors in every product term. The tradeoff between the bottom fan-in and the number of factors per product term is then analyzed to obtain a suitable upper bound on the shifted partials dimension of a depth three circuit.

[4] The definition of an algebraic branching program can be found, for example, in [39].

Finally, in order to maximize the gain and obtain a near cubic bound we need an explicit multilinear polynomial with *degree linear in the number of variables*, and that has close to the maximum possible shifted partials dimension even when restricted to an affine subspace. The polynomial family $\{f_n\}_{n\geq 1}$ in Theorem 1 is a variant of the family of Nisan-Wigderson polynomials used in [18, 15]. A notable difference between the Nisan-Wigderson families used in earlier works and the one used here is that the degree of f_n is linearly related to its number of variables, unlike $d = n^{o(1)}$ in previous works. Although, a greedy construction of a Nisan-Wigderson family can make degree $\Theta(n)$, it is not clear if such a family is in VNP. To ensure both – a VNP family and linear degree – we construct a family by 'composing' two smaller families of Nisan-Wigderson polynomials, one is obtained by a greedy algorithm and the other explicitly defined in [18, 15]. A detailed description of the polynomial family is given in Section 6.

Few more details on the polynomial families. Polynomial f_n in Theorem 1 is homogeneous with three sets of variables $\mathbf{u}, \mathbf{y}, \mathbf{x}$ such that $|\mathbf{u}| = |\mathbf{y}| = |\mathbf{x}| = \frac{10n}{9}$. (To avoid a few ceil and floor notations in the analysis, we shall assume without any loss of generality that n is divisible by $1872 = 9 \cdot 13 \cdot 16$.) Let $\mathbf{u} = \{u_1, \ldots, u_{\frac{10n}{9}}\}, \mathbf{y} = \{y_1, \ldots, y_{\frac{10n}{9}}\}$ and $\mathbf{x} = \{x_1, \ldots, x_{\frac{10n}{9}}\}$. Every monomial of f_n is a product of a $\mathbf{u}$-monomial of degree $d_{\mathbf{u}} = n$, a $\mathbf{y}$-monomial of degree $d_{\mathbf{y}} = \lfloor \ln n \rfloor$, and an $\mathbf{x}$-monomial of degree $d_{\mathbf{x}} \in \left[\frac{2n}{13}, \frac{n}{3}\right]$. Thus the number of variables and the degree of f_n are both $\Theta(n)$. The $\mathbf{x}$ and the $\mathbf{y}$ variables are the primary variables; derivatives of f_n of order $\lfloor \ln n \rfloor$ with respect to the $\mathbf{y}$-variables give rise to $\mathbf{x}$-monomials with large 'pairwise distance' that help estimate the shifted partials dimension of the target polynomial. The $\mathbf{u}$-variables are auxiliary variables which ensure that the measure remains high for the target polynomial even when restricted to an affine subspace.

The polynomial family $\{f_{n,d}\}$ used in Theorem 3 is a simple variant of the multi-r-ic iterated matrix multiplication polynomial family used in [19].

1.3 Organization

Sections 3 to 6 are devoted to the proofs of Theorem 1 and 2. We prove Theorem 3 in Section 7.

2 Preliminaries

2.1 Basic notations

For any $m \in \mathbb{N}$, the set of natural numbers, the set $\{1, \ldots, m\}$ is denoted by $[m]$. We use upper-case letters (like A or S) to denote sets of numbers, calligraphic upper-case letters (like $\mathcal{B}, \mathcal{D}$ or $\mathcal{L}$) to denote sets of polynomials, and bold lower-case letters (like $\mathbf{x}$ or $\mathbf{y}$) to denote sets of variables. When the base ring of polynomials is clear from the context, the ideal generated by a set of polynomials of the ring, say $\mathcal{L}$, is denoted by $\langle \mathcal{L} \rangle$. A circuit is denoted using typewriter font, as in `C` or `D`. For a set of numbers $S \subseteq [m]$, $\bar{S}$ denote the complement of S. Sometimes, we use the notation $\mathsf{poly}(n)$ to mean $n^{O(1)}$.

2.2 The measure

Although, the results in this paper can be derived using the shifted partials measure as it is in [14], we choose to work with a variant of this measure for better clarity in the analysis. This variant is similar in outlook to the *shifted skewed partials* measure used recently in [19],

although for our application there is no difference (or skew) between the number of $\mathbf{x}$ and $\mathbf{y}$ variables. Such a skew between $|\mathbf{y}|$ and $|\mathbf{x}|$ was important for the results in [19].

Let $A \subset \left[\frac{10n}{9}\right]$ of size $|A| = n$. Let $\mathbf{x}_A = \{x_i : i \in A\}$ and $g(\mathbf{y}, \mathbf{x}_A) \in \mathbb{F}[\mathbf{y}, \mathbf{x}_A]$. For $k, \ell \in \mathbb{N}$, define the measure $\mathrm{SP}_{k,\ell,A} : \mathbb{F}[\mathbf{y}, \mathbf{x}_A] \to \mathbb{N}$ as follows.

$$\mathrm{SP}_{k,\ell,A}(g) \stackrel{\text{def}}{=} \dim(\mathbf{x}_A^{\leq \ell} \cdot \sigma_{\mathbf{y}}(\boldsymbol{\partial}_{\mathbf{y}}^{=k} g)),$$

where $\boldsymbol{\partial}_{\mathbf{y}}^{=k} g$ is the set of all k-th order partial derivatives of g with respect to the $\mathbf{y}$-variables, and $\sigma_{\mathbf{y}} : \mathbb{F}[\mathbf{y}, \mathbf{x}_A] \to \mathbb{F}[\mathbf{x}_A]$ is a map that sets all the $\mathbf{y}$-variables to zero. Naturally, $\sigma_{\mathbf{y}}$ is a homomorphism from $\mathbb{F}[\mathbf{y}, \mathbf{x}_A]$ to $\mathbb{F}[\mathbf{x}_A]$, and $\sigma_{\mathbf{y}}(\mathcal{D})$ is defined by $\{\sigma_{\mathbf{y}}(h) : h \in \mathcal{D}\}$ for any set of polynomials $\mathcal{D} \subseteq \mathbb{F}[\mathbf{y}, \mathbf{x}_A]$. $\mathbf{x}_A^{\leq \ell}$ is the set of all monomials in the $\mathbf{x}_A$-variables of degree ℓ or less. For two sets of polynomials $\mathcal{B}$ and $\mathcal{D}$, $\mathcal{B}.\mathcal{D} \stackrel{\text{def}}{=} \{h_1.h_2 : h_1 \in \mathcal{B} \text{ and } h_2 \in \mathcal{D}\}$, and the dimension of a set of polynomials $\mathcal{D}$ (denoted by $\dim(\mathcal{D})$) is the dimension of the vector space spanned by the polynomials in $\mathcal{D}$ over the field $\mathbb{F}$.

It is worth noting that the above measure (as in [19]) can be thought of as a hybrid of the *rank of the partial derivatives matrix* measure of [28] and the shifted partials measure of [14]. The former measure has been refined and used in several other subsequent work, most notably in [31, 35], and is also identified with the *evaluation dimension* measure in [6] over fields of characteristic zero. The following proposition is easy to verify.

▶ **Proposition 4** (Sub-additivity). *For any $k, \ell \in \mathbb{N}$, $\mathbf{x}_A \subseteq \mathbf{x}$ and $g_1, g_2 \in \mathbb{F}[\mathbf{y}, \mathbf{x}_A]$,*

$$\mathrm{SP}_{k,\ell,A}(g_1 + g_2) \leq \mathrm{SP}_{k,\ell,A}(g_1) + \mathrm{SP}_{k,\ell,A}(g_2).$$

3 Lower bounding the measure for the target polynomial family

We will show that the measure SP (from Section 2.2) is considerably large when applied suitably to the polynomial family $\{f_n\}_{n \geq 1}$. The precise statement is given in the theorem below.

Polynomials restricted to an affine subspace. Let $S \subseteq \left[\frac{10n}{9}\right]$ be a set of size $\frac{n}{9}$ and

$$\mathcal{L}_S = \{x_i - h_i\}_{i \in S} \tag{1}$$

be a set of $|\mathcal{L}_S| = |S| = \frac{n}{9}$ linear polynomials in $\mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}]$ such that $h_i \in \mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}_{\bar{S}}]$ for every $i \in S$, where $\bar{S} = \left[\frac{10n}{9}\right] \setminus S$.

Denote the ideal of $\mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}]$ generated by the linear polynomials of $\mathcal{L}_S$ by $\langle \mathcal{L}_S \rangle$. For any polynomial $f \in \mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}]$, let

$$f_{\langle \mathcal{L}_S \rangle} \stackrel{\text{def}}{=} f \mod \langle \mathcal{L}_S \rangle$$

be the image of the polynomial f in the ring $\mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}]/\langle \mathcal{L}_S \rangle$. Since $\mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}]/\langle \mathcal{L}_S \rangle$ is isomorphic to $\mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}_{\bar{S}}]$, $f_{\langle \mathcal{L}_S \rangle}$ can be represented by a polynomial in the ring $\mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}_{\bar{S}}]$; this polynomial is obtained from f by replacing x_i by h_i for all $i \in S$. So, we will treat $f_{\langle \mathcal{L}_S \rangle}$ as an element of $\mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}_{\bar{S}}]$.

Finally, let $f_{\langle \mathcal{L}_S \rangle, \mathbf{u}_S = 0}$ be the polynomial obtained from $f_{\langle \mathcal{L}_S \rangle} \in \mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}_{\bar{S}}]$ by setting the $\mathbf{u}$-variables to 0/1-values as follows: $u_i = 0$ if $i \in S$, else $u_i = 1$. We will describe the family $\{f_n\}_{n \geq 1}$ and prove the following theorem in Section 6.

▶ **Theorem 5.** *Let n be the parameter that defines the polynomial family $\{f_n\}_{n\geq 1}$. Let $k = \lfloor \ln n \rfloor$, q be the smallest prime greater or equal to $\lceil \frac{n}{1000\cdot \ln n} \rceil$, $\ell = \left\lfloor \frac{n^2}{32\cdot k \cdot \ln q} \right\rfloor$. Then for every set $S \subseteq \left[\frac{10n}{9}\right]$ of size $|S| = \frac{n}{9}$, and every set of linear polynomials $\mathcal{L}_S$ as in Equation (1), and $f = f_n$,*

$$\mathrm{SP}_{k,\ell,\bar{S}}(f_{\langle \mathcal{L}_S\rangle, \mathbf{u}_S=0}) \geq \frac{1}{2}\cdot q^k \cdot \binom{n+\ell}{n}.$$

Next, we show an upperbound of the measure for a depth-3 circuit and prove Theorem 1.

4 Upper bounding the measure for a depth three circuit

Pruning 'heavy' product gates from a depth three circuit. Let $\mathtt{C} = \sum_{i=1}^{s} T_i$ be a depth three circuit computing $f = f_n$, where T_i is a product term[5] of $\mathtt{C}$. Let c_0 be a constant to be fixed later in the analysis. Then either of the following two cases is obviously true.

Case 1: The number of product terms of $\mathtt{C}$, with $\mathbf{x}$-degree greater or equal to $\left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$, is greater than $\frac{n}{9}$.

Case 2: The number of product terms of $\mathtt{C}$, with $\mathbf{x}$-degree greater or equal to $\left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$, is less than or equal to $\frac{n}{9}$.

If Case 1 is true then the multiplicative complexity of $\mathtt{C}$ is at least $\left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor \cdot \frac{n}{9} = \Omega(\frac{n^3}{(\ln n)^2})$ as $d_{\mathbf{x}} \in \left[\frac{2n}{13}, \frac{n}{3}\right]$ and we have nothing to prove in this case. If Case 2 is true then we can find a 'few' linear polynomials such that modulo these the circuit is free of 'heavy' product terms. This is stated formally in the lemma below and the corollary thereafter, and is directly inspired by a similar argument in [38, 36]. However, the threshold chosen to define 'heavy' product gates in [38, 36] is linear in n, whereas the one here has an extra $\frac{d_{\mathbf{x}}}{(\ln n)^2}$ factor that finally accounts for the improvement in the lower bound. As mentioned in Section 1, this is the leeway to the formal degree of the circuit provided by the analysis with shifted partials.

▶ **Lemma 6.** *Suppose the number of product terms of $\mathtt{C}$, with $\mathbf{x}$-degree greater or equal to $\left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$, is bounded by $\frac{n}{9}$. Then, there is a set $S \subseteq \left[\frac{10n}{9}\right]$ of size $\frac{n}{9}$ and a set of linear polynomials,*

$$\mathcal{L}_S = \{x_i - h_i\}_{i\in S}, \text{ where } h_i \text{ is a linear polynomial in } \mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}_{\bar{S}}] \text{ for every } i \in S,$$

such that $f_{\langle \mathcal{L}_S\rangle} \in \mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}_{\bar{S}}]$ is computed by a depth three circuit, say $\mathtt{C}_{\langle \mathcal{L}_S\rangle}$, satisfying the following:

1. *top fan-in of $\mathtt{C}_{\langle \mathcal{L}_S\rangle}$ is upper bounded by the top fan-in of $\mathtt{C}$,*
2. *every product term of $\mathtt{C}_{\langle \mathcal{L}_S\rangle}$ has $\mathbf{x}$-degree upper bounded by $\left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$.*

The proof of the lemma is relatively straightforward and and can be found in the full version paper.

▶ **Corollary 7.** *Polynomial $f_{\langle \mathcal{L}_S\rangle, \mathbf{u}_S=0} \in \mathbb{F}[\mathbf{y}, \mathbf{x}_{\bar{S}}]$ is computed by a depth three circuit, say $\mathtt{C}_{\langle \mathcal{L}_S\rangle, \mathbf{u}_S=0}$, with top fan-in bounded by the top fan-in of $\mathtt{C}$ and every product term of $\mathtt{C}_{\langle \mathcal{L}_S\rangle, \mathbf{u}_S=0}$ has $\mathbf{x}$-degree bounded by $\left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$.*

[5] a product term corresponds to a multiplication gate of $\mathtt{C}$

Let us denote the circuit $\mathtt{C}_{\langle\mathcal{L}_S\rangle,\mathbf{u}_S=0}$ by $\mathtt{D}$. Let $\mathtt{D} = \sum_{i=1}^{s} P_i$, where a term P_i is a product of linear polynomials in $\mathbb{F}[\mathbf{y}, \mathbf{x}_{\bar{S}}]$. Note that the pruned circuit $\mathtt{D}$ has only $\mathbf{y}$ and $\mathbf{x}_{\bar{S}}$ variables. Now, as the degrees of the intermediate gates are bounded, we can upperbound the shifted partial measure for $\mathtt{D}$ by using a grouping argument (as it was done in [19]). We get then the next lemma.

▶ **Lemma 8.** *Let $k, \ell \in \mathbb{N}$ be as in Theorem 5. Then*

$$\mathrm{SP}_{k,\ell,\bar{S}}(\mathtt{D}) \leq s \cdot \binom{\lceil 32c_0 d_{\mathbf{x}} \rceil}{k} \cdot \binom{n+\ell+kt}{n}, \text{ where } t = \left\lceil \frac{n}{32 \cdot (\ln n)^2} \right\rceil.$$

5 Putting together: Proof of Theorem 1

Let $\mathtt{C}$ be a depth three circuit computing f_n. Then, as explained in Section 4, we have two cases to handle. In Case 1, the multiplicative complexity of $\mathtt{C}$ is already $\Omega(\frac{n^3}{(\ln n)^2})$ and we have nothing to prove. Whereas, in Case 2, the circuit can be pruned of heavy product gates so that the polynomial $f_{\langle\mathcal{L}_S\rangle,\mathbf{u}_S=0} \in \mathbb{F}[\mathbf{y}, \mathbf{x}_{\bar{S}}]$ is computed by a depth three circuit, say $\mathtt{D}$, whose top fan-in is upper bounded by the top fan-in of $\mathtt{C}$ (by Corollary 7). Moreover, every product term of $\mathtt{D}$ has $\mathbf{x}$-degree bounded by $\left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$ so that Lemma 8 is applicable now. The computations of the next lemma can be found in the full version paper.

▶ **Lemma 9.** *In Case 2, the top fan-in of $\mathtt{D}$ (hence also the top fan-in of $\mathtt{C}$) is $\omega(n^3)$.*

Proof. By Theorem 5 and Lemma 8, the top fan-in s of $\mathtt{D}$ can be lower bounded as follows:

$$s \geq \frac{1}{2} \cdot \frac{q^k \cdot \binom{n+\ell}{n}}{\binom{\lceil 32c_0 d_{\mathbf{x}} \rceil}{k} \cdot \binom{n+\ell+kt}{n}},$$

which will imply after some computations that $s = \omega(n^3)$. ◀

Thus, in Case 2, the top fan-in of $\mathtt{D}$ (and hence $\mathtt{C}$) must be $\omega(n^3)$ and therefore putting Case 1 and 2 together, the multiplicative complexity of $\mathtt{C}$ is $\min\{\Omega(\frac{n^3}{(\ln n)^2}), \omega(n^3)\} = \Omega(\frac{n^3}{(\ln n)^2})$ for sufficiently large n.

5.1 Proof of Theorem 2

The proof follows from Lemma 9. Suppose $f = f_n$ is computed by a symmetric circuit where $l_1, \ldots, l_m$ are the bottom level linear polynomials. Naturally, $f = \mathrm{ESym}_m^d(l_1, \ldots, l_m)$ for some d, and hence (by Ben-Or's interpolation trick over any field of size more than m) f is also computed by a depth three circuit $\mathtt{C}$ with top fan-in $m+1$ and degree of every product term bounded by m. If $m \geq \left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$ then we have nothing to prove. Suppose $m < \left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$. Then the condition of Case 2 (in Section 4) is satisfied as *every* product term of $\mathtt{C}$ has $\mathbf{x}$-degree (in fact, total degree) bounded by $m < \left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor$. But then, Lemma 9 tells us that $\mathtt{C}$ has top fan-in $\omega(n^3)$ which contradicts with the fact that the top fan-in is $m+1 = O(n^2)$. So, it must be that $m \geq \left\lfloor \frac{c_0 n d_{\mathbf{x}}}{(\ln n)^2} \right\rfloor = \Omega\left(\frac{n^2}{(\ln n)^2}\right)$.

6 The polynomial family and proof of Theorem 5

6.1 Construction of the Nisan-Wigderson polynomial family

Let $\mathbf{z} = \{z_1, \ldots, z_n\}$ be a set of n formal variables. For any two multilinear monomials m_1 and m_2 in the $\mathbf{z}$-variables of degree $d_{\mathbf{z}}$ each, let $|m_1 \cap m_2|$ be the number of variables common

between m_1 and m_2. Define *distance* between the monomials m_1, m_2 as,

$$\Delta(m_1, m_2) \stackrel{\text{def}}{=} d_{\mathbf{z}} - |m_1 \cap m_2|.$$

As in the statement of Theorem 5, let q be the smallest prime greater or equal to $\left\lceil \frac{n}{1000 \ln n} \right\rceil$ and $k = \lfloor \ln n \rfloor$. The following lemma plays a central role in the construction of the polynomial family $\{f_n\}_{n \geq 1}$.

▶ **Lemma 10.** *There is a family $\{g_n(\mathbf{z})\}_{n \geq 1}$ in* VNP *such that $g_n(\mathbf{z})$ is a homogeneous multilinear polynomial of degree $d_{\mathbf{z}} \in \left[\frac{2n}{13}, \frac{n}{3}\right]$ in n $\mathbf{z}$-variables, and $\Delta(m_1, m_2) \geq \frac{n}{16}$ for any pair of distinct monomials m_1 and m_2 of g_n. Further, g_n is a sum of q^k distinct monomials.*

In the previous lemma, we need to find a family whose monomials are pairwise distant, such that the degree is linear in the number of variables and the family is in VNP. The Nisan-Wigderson polynomial family in [18] is in VNP but its degree is not linear. On the other hand, one can greedily get a family such that the degree is linear but which is not known to be in VNP. We show in the full version paper that by 'composing' these two families one can get both the desired properties.

The family $\{f_n\}_{n \geq 1}$. Let $(m_1, \ldots, m_{q^k})$ be an ordered sequence of monomials of the polynomial $g_n(\mathbf{z})$ from the above lemma under lexicographic monomial ordering $z_1 \succ \ldots \succ z_n$. Let $\mathbf{w} = \{w_1, \ldots, w_n\}$ be n formal variables different from $\mathbf{z}$. The number of multilinear monomials in $\mathbf{w}$-variables of degree k is $\binom{n}{k} \geq (\frac{n}{k})^k = \left(\frac{n}{\lfloor \ln n \rfloor}\right)^k \geq q^k$. Under lexicographic monomial ordering $w_1 \succ \ldots \succ w_n$, let $(\beta_1, \ldots, \beta_{q^k})$ be the ordered sequence of the first q^k monomials among all multilinear monomials in the $\mathbf{w}$-variables of degree k. Define the polynomial $F_n(\mathbf{w}, \mathbf{z})$ as,

$$F_n(\mathbf{w}, \mathbf{z}) \stackrel{\text{def}}{=} \sum_{j=1}^{q^k} \beta_j m_j. \tag{2}$$

Now let $\mathbf{u} = \{u_1, \ldots, u_{\frac{10n}{9}}\}$, $\mathbf{y} = \{y_1, \ldots, y_{\frac{10n}{9}}\}$ and $\mathbf{x} = \{x_1, \ldots, x_{\frac{10n}{9}}\}$ be the sets of variables on which $f_n(\mathbf{u}, \mathbf{y}, \mathbf{x})$ is defined as follows.

$$f_n(\mathbf{u}, \mathbf{y}, \mathbf{x}) \stackrel{\text{def}}{=} \sum_{\substack{A \subseteq \left[\frac{10n}{9}\right] \\ |A| = n}} \prod_{i \in A} u_i \cdot F_n(\mathbf{y}_A, \mathbf{x}_A). \tag{3}$$

We assume the lexicographic order $x_1 \succ \ldots \succ x_{\frac{10n}{9}}$ and $y_1 \succ \ldots \succ y_{\frac{10n}{9}}$. The polynomial $F_n(\mathbf{y}_A, \mathbf{x}_A)$ is obtained by substituting the $\mathbf{y}_A$-variables $\{y_i : i \in A\}$ in place of the $\mathbf{w}$-variables and $\mathbf{x}_A$-variables $\{x_i : i \in A\}$ in place of the $\mathbf{z}$-variables such that the underlying lexicographic orders, $z_1 \succ \ldots \succ z_n$ and $w_1 \succ \ldots \succ w_n$, are obeyed. Note that $d_{\mathbf{y}} = \deg_{\mathbf{y}} f_n = k$, $d_{\mathbf{u}} = \deg_{\mathbf{u}} f_n = n$ and $d_{\mathbf{x}} = \deg_{\mathbf{x}} f_n = \deg_{\mathbf{z}} g_n = d_{\mathbf{z}} \in \left[\frac{2n}{13}, \frac{n}{3}\right]$. Further, the polynomial family $\{f_n\}_{n \geq 1}$ is in VNP: It would be clear from the proof of Lemma 10 that the computational problem of finding the 'index' of a given monomial in g_n can be solved in $\mathsf{poly}(n)$ time, which in turn implies the coefficient of a given monomial in f_n can be found in $\mathsf{poly}(n)$ time. The *index* of a monomial m in g_n is the position of m in the lexicographically ordered list of q^k monomials of g_n.

6.2 Proof of Theorem 5: The measure on the polynomial family

In this section, we show that the relevant measure is high for the family of polynomials (defined in Equation 3) even when restricted to an affine subspace. As in Section 3 (Equation

1), let $S \subseteq \left[\frac{10n}{9}\right]$ be a set of size $\frac{n}{9}$. Let $\mathcal{L}_S = \{x_i - h_i\}_{i \in S}$ be any set of $\frac{n}{9}$ linear polynomials in $\mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}]$ such that $h_i \in \mathbb{F}[\mathbf{u}, \mathbf{y}, \mathbf{x}_{\bar{S}}]$ for every $i \in S$, where $\bar{S} = \left[\frac{10n}{9}\right] \setminus S$. Let $f = f_n(\mathbf{u}, \mathbf{y}, \mathbf{x})$ (as defined in Equation 3).

▶ **Observation 11.** $f_{\langle \mathcal{L}_S \rangle, \mathbf{u}_S = 0} = F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}}) \in \mathbb{F}[\mathbf{y}, \mathbf{x}_{\bar{S}}]$.

Proof. The polynomial $f_{\langle \mathcal{L}_S \rangle, \mathbf{u}_S = 0}$ is obtained from f by substituting every x_i by h_i for every $i \in S$, and then setting $u_j = 0$ for every $j \in S$ and $u_j = 1$ otherwise. Since the only $\mathbf{x}$-variables occurring in $F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}})$ are from $\mathbf{x}_{\bar{S}}$, it remains untouched by the above substitutions. Finally, the setting of the $\mathbf{u}$-variables retains only $F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}})$ from the sum in Equation 3. ◀

So, we need to show that

$$\mathrm{SP}_{k,\ell,\bar{S}}(F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}})) \geq \frac{1}{2} \cdot q^k \cdot \binom{n+\ell}{n}.$$

This part of the argument bears close resemblance to and is inspired by similar arguments in [7, 5]. We begin with the following observation.

▶ **Observation 12.** *The set $\boldsymbol{\partial}_{\mathbf{y}}^{=k} F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}})$ consists of exactly the monomials of $g_n(\mathbf{x}_{\bar{S}})$. Hence, $\sigma_{\mathbf{y}}(\boldsymbol{\partial}_{\mathbf{y}}^{=k} F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}}))$ also consists of exactly the monomials of $g_n(\mathbf{x}_{\bar{S}})$.*

Proof. Follows easily from the definition of the polynomial F_n in Equation 2. ◀

Reusing notation, let the monomials of $g_n(\mathbf{x}_{\bar{S}})$ be $\{m_1, \ldots, m_{q^k}\}$ – these are monomials in $\mathbf{x}_{\bar{S}}$-variables. By Lemma 10, $\Delta(m_i, m_j) \geq \frac{n}{16}$ for every $i \neq j$ and $\frac{2n}{13} \leq \deg(m_i) \leq \frac{n}{3}$ for every $i \in [q^k]$. Let

$$B_i \stackrel{\text{def}}{=} \mathbf{x}_{\bar{S}}^{\leq \ell} \cdot m_i, \qquad \text{for } i \in [q^k].$$

Then,

$$\begin{aligned} \dim(\mathbf{x}_{\bar{S}}^{\leq \ell} \cdot \sigma_{\mathbf{y}}(\boldsymbol{\partial}_{\mathbf{y}}^{=k} F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}}))) &= |B_1 \cup \ldots \cup B_{q^k}| \\ \Rightarrow \mathrm{SP}_{k,\ell,\bar{S}}(F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}})) &\geq \sum_{i=1}^{q^k} |B_i| - \frac{1}{2} \cdot \sum_{\substack{i,j \\ i \neq j}} |B_i \cap B_j| \\ &= q^k \cdot \binom{n+\ell}{n} - \frac{1}{2} \cdot \sum_{\substack{i,j \\ i \neq j}} |B_i \cap B_j|, \end{aligned} \tag{4}$$

as $|\bar{S}| = n$ and $|B_i| = \binom{n+\ell}{n}$.

▶ **Proposition 13.** *For every $i, j \in [q^k]$ and $i \neq j$, $|B_i \cap B_j| \leq \binom{n+\ell-n/16}{n}$.*

Proof. If a monomial m belongs to both B_i and B_j then $m = s_1 \cdot m_i = s_2 \cdot m_j$ where $\deg(s_1), \deg(s_2) \leq \ell$. Since $\Delta(m_i, m_j) \geq n/16$,

$$m = s' \cdot \frac{m_j}{\gcd(m_i, m_j)} \cdot m_i, \qquad \text{where } \deg(s') \leq \ell - \frac{n}{16}.$$

Hence, the number of such monomials m is bounded by $\binom{n+\ell-n/16}{n}$. ◀

Therefore, by Equation (4), after some computations.

▶ **Claim 14.** $\mathrm{SP}_{k,\ell,\bar{S}}(F_n(\mathbf{y}_{\bar{S}}, \mathbf{x}_{\bar{S}})) \geq \frac{1}{2} \cdot q^k \cdot \binom{n+\ell}{n}$.

This completes the proof of Theorem 5.

7 Homogeneous depth three circuits with large degree

We prove Theorem 3 in this section. The measure remains the same as before, but the notation is simplified a little bit (as we do not need to include a subset of variables in the definition of the measure). For any $g \in \mathbb{F}[\mathbf{y}, \mathbf{x}]$, define the measure $\mathrm{SP}_{k,\ell} : \mathbb{F}[\mathbf{y}, \mathbf{x}] \to \mathbb{N}$ as

$$\mathrm{SP}_{k,\ell}(g) \stackrel{\text{def}}{=} \dim(\mathbf{x}^{\leq \ell} \cdot \sigma_{\mathbf{y}}(\boldsymbol{\partial}_{\mathbf{y}}^{=k} g)).$$

Like before, the measure is sub-additive, i.e. for $g_1, g_2 \in \mathbb{F}[\mathbf{y}, \mathbf{x}]$ and $k, \ell \in \mathbb{N}$,

$$\mathrm{SP}_{k,\ell}(g_1 + g_2) \leq \mathrm{SP}_{k,\ell}(g_1) + \mathrm{SP}_{k,\ell}(g_2).$$

Moreover, the measure is invariant under multiplication by any fixed polynomial from $\mathbb{F}[\mathbf{x}]$ (the proof of the following lemma is very simple and appears in the full version paper):

▶ **Lemma 15.** *For any $g \in \mathbb{F}[\mathbf{y}, \mathbf{x}]$, $h \in \mathbb{F}[\mathbf{x}]$ and $k, \ell \in \mathbb{N}$, $\mathrm{SP}_{k,\ell}(h \cdot g) = \mathrm{SP}_{k,\ell}(g)$.*

The outline of the proof of Theorem 3 also remains the same: we show a suitable upper bound on the measure for the circuit, and a lower bound for the target family of polynomials. The target family of polynomials is basically a *multi-r-ic* variant of the iterated matrix multiplication polynomial defined and analysed in [19] – we will recall some parts of the analysis from there to lower bound the measure for the family of polynomials. Furthermore, this polynomial can be computed by an algebraic branching program of size polynomial in the number of variables and degree of the polynomial.

7.1 Upper bound for the circuit

Let $\mathtt{C}$ be any homogeneous depth three circuit computing a polynomial in n variables $\mathbf{y} \uplus \mathbf{x}$ and of degree d. More precisely, by identifying the circuit with the polynomial it computes, $\mathtt{C} = T_1 + T_2 + \ldots + T_s$, where the T_i's are products of d homogeneous linear polynomials i.e. $T_i = l_{i1} \cdot l_{i2} \cdot \ldots \cdot l_{id}$, where every l_{ij} is a linear form. Let us consider any one product term, say T. By grouping t linear forms together and multiplying the linear forms within each group, we obtain $T = Q_1 \cdot \ldots \cdot Q_{\lceil \frac{d}{t} \rceil}$, where $\deg(Q_j) \leq t$ for every $j \in \left[\lceil \frac{d}{t} \rceil\right]$. By sub-additivity of the measure and following a similar argument as in the proof of Lemma 8, we get the following lemma.

▶ **Lemma 16.** *For any $k, \ell \in \mathbb{N}$ and $t \leq d$,*

$$\mathrm{SP}_{k,\ell}(\mathtt{C}) \leq s \cdot \binom{\lceil \frac{d}{t} \rceil}{k} \cdot \binom{|\mathbf{x}| + \ell + kt}{|\mathbf{x}|}. \tag{5}$$

7.2 Lower bound for the polynomial family

The polynomial family. We define a polynomial on n variables $\mathbf{y} \uplus \mathbf{x}$ and of degree d, where d is any integer greater or equal to n.

For $w, k, r, \alpha \in \mathbb{N}$, consider the following polynomial.

$$F_{w,k,r,\alpha}(\mathbf{y}, \mathbf{x}) \stackrel{\text{def}}{=} g_1(\mathbf{y}_1, \mathbf{x}_1) \cdot g_2(\mathbf{y}_2, \mathbf{x}_2) \cdot \ldots \cdot g_k(\mathbf{y}_k, \mathbf{x}_k),$$

where the g_i's are polynomials over the indicated (disjoint) subsets of variables $\mathbf{y} = \mathbf{y}_1 \uplus \ldots \uplus \mathbf{y}_k$ and $\mathbf{x} = \mathbf{x}_1 \uplus \ldots \uplus \mathbf{x}_k$, and defined as,

$$g_i(\mathbf{y}_i, \mathbf{x}_i) \stackrel{\text{def}}{=} \sum_{a,b \in [w]} y_{i,a,b} \cdot \prod_{c \in [\alpha]} x_{i,c,a}^r \cdot x_{i,c+\alpha,b}^r.$$

The number of $\mathbf{y}$-variables is $|\mathbf{y}| = kw^2$ and the number of $\mathbf{x}$-variables is $|\mathbf{x}| = 2k\alpha w$. The total number of variables in $F_{w,k,r,\alpha}$ is $(w^2 + 2\alpha w) \cdot k$, and it has degree $\tilde{d} = (2\alpha r + 1) \cdot k$. Our target polynomial is almost $F_{w,k,r,\alpha}$, except that we multiply it with a suitable power of a variable just to match its degree with the given degree parameter d which is any number more than the number of variables.

Let $n = (w^2 + 2\alpha w) \cdot k$ and $d \geq n$ be a given degree parameter. In the analysis, we eventually fix α and w to integer constants so that $n = \Theta(k)$. Set $r = \lceil \frac{d}{3\alpha k} \rceil$ and x be any arbitrarily fixed variable in $\mathbf{x}$. Our polynomial family $\{f_{n,d}\}$ is defined by

$$f_{n,d} \stackrel{\text{def}}{=} x^{d-\tilde{d}} \cdot F_{w,k,r,\alpha}. \tag{6}$$

This polynomial is well defined, i.e. $d \geq \tilde{d}$, as soon as $w \geq 3$. Observe that $f_{n,d}$ has the same set of n variables as $F_{w,k,r,\alpha}$ and has degree d. Let us record the values for k and r for the analysis later $k = \frac{n}{w^2+2\alpha w}$ and $r = \lceil \frac{d}{3\alpha k} \rceil$. Also, note that $f_{n,d}$ can be computed by a $\mathsf{poly}(n, d)$-size ABP.

The measure on the polynomial family. The following lemma was essentially proved in [19] (see Section 7.5 in there) with slightly different notations.

▶ **Lemma 17.** *Let $0 < \delta \leq 1/5$ be a constant and $w \geq 3$.*

1. *Then*

$$\mathrm{SP}_{k,\ell}(F_{w,k,r,\alpha}) \geq M \cdot \binom{|\mathbf{x}| + \ell}{|\mathbf{x}|} - \frac{M^2}{2} \cdot \binom{|\mathbf{x}| + \ell - \lceil \delta k \rceil \cdot \alpha r}{|\mathbf{x}|} \text{ with } M = \left(\left\lfloor \frac{w^{2-\delta}}{2} \right\rfloor \right)^k.$$

2. *Moreover, if $\ell \geq |\mathbf{x}|$ and $2 \cdot |\mathbf{x}| \cdot \alpha r \geq \ell\beta \cdot \ln w$ where $\beta \geq 4(2-\delta)/\delta$ is a constant then we can also conclude that $\mathrm{SP}_{k,\ell}(F_{w,k,r,\alpha})$ is lower bounded by $M \cdot \binom{|\mathbf{x}|+\ell}{|\mathbf{x}|}/2$.*

For the choice of parameters below, $\frac{w^{2-\delta}}{2}$ is an integer. Hence, $M = \left(\frac{w^{2-\delta}}{2}\right)^k$.

▶ **Corollary 18.** *If the conditions of Lemma 17 are satisfied then it follows from Lemma 15*

$$\mathrm{SP}_{k,\ell}(f_{n,d}) \geq \frac{M}{2} \cdot \binom{|\mathbf{x}| + \ell}{|\mathbf{x}|}.$$

7.3 Putting together: Proof of Theorem 3

Let us choose $t = \lfloor 2\varepsilon\alpha r \rfloor$, and $\ell = \left\lfloor \frac{|\mathbf{x}| \cdot t}{\varepsilon\beta \cdot \ln w} \right\rfloor$ with the following parameters $\alpha = 18$, $\delta = \frac{1}{5}$, $\beta = 36$, $\varepsilon = \frac{1}{200}$, and $w = 2^{10}$.

We can notice that $t > 0$ and $\lceil d/t \rceil \leq (2k)/\varepsilon$. Furthermore, the conditions $\ell \geq |\mathbf{x}|$, $2 \cdot |\mathbf{x}| \cdot \alpha r \geq \ell\beta \cdot \ln w$, and $\beta \geq 4(2-\delta)/\delta$ are satisfied. Hence, if $\mathtt{C}$ is a homogeneous depth three circuit computing $f_{n,d}$, then by Lemma 16 and Corollary 18,

$$s \cdot \binom{\lceil \frac{d}{t} \rceil}{k} \cdot \binom{|\mathbf{x}| + \ell + kt}{|\mathbf{x}|} \geq \mathrm{SP}_{k,\ell}(f_{n,d}) \geq \frac{M}{2} \cdot \binom{|\mathbf{x}| + \ell}{|\mathbf{x}|}.$$

It implies, after some computations that $s \geq 2^{\Omega(n)}$.

Abstract

One fundamental question in the context of the geometric complexity theory approach to the VP vs. VNP conjecture is whether VP = $\overline{\text{VP}}$, where VP is the class of families of polynomials that can be computed by arithmetic circuits of polynomial degree and size, and $\overline{\text{VP}}$ is the class of families of polynomials that can be approximated infinitesimally closely by arithmetic circuits of polynomial degree and size. The goal of this article is to study the conjecture in (Mulmuley, FOCS 2012) that $\overline{\text{VP}}$ is not contained in VP.

Towards that end, we introduce three degenerations of VP (i.e., sets of points in $\overline{\text{VP}}$), namely the stable degeneration Stable-VP, the Newton degeneration Newton-VP, and the p-definable one-parameter degeneration VP*. We also introduce analogous degenerations of VNP. We show that Stable-VP $\subseteq$ Newton-VP $\subseteq$ VP* $\subseteq$ VNP, and Stable-VNP = Newton-VNP = VNP* = VNP. The three notions of degenerations and the proof of this result shed light on the problem of separating $\overline{\text{VP}}$ from VP.

Although we do not yet construct explicit candidates for the polynomial families in $\overline{\text{VP}} \setminus$VP, we prove results which tell us where not to look for such families. Specifically, we demonstrate that the families in Newton-VP $\setminus$VP based on semi-invariants of quivers would have to be non-generic by showing that, for many finite quivers (including some wild ones), Newton degeneration of any generic semi-invariant can be computed by a circuit of polynomial size. We also show that the Newton degenerations of perfect matching Pfaffians, monotone arithmetic circuits over the reals, and Schur polynomials have polynomial-size circuits.

1 Introduction

One fundamental question in the context of the geometric complexity theory (GCT) approach (cf. [22, 23], [5], and [21]) to the VP vs. VNP conjecture in Valiant [27] is whether VP = $\overline{\text{VP}}$, where VP is the class of families of polynomials that computed by arithmetic circuits of polynomial degree and size, VNP is the class of p-definable families of polynomials, and $\overline{\text{VP}}$ is the class of families of polynomials that can be approximated infinitesimally closely by arithmetic circuits of polynomial degree and size. We assume in what follows that the

circuits are over an algebraically closed field $\mathbb{F}$. We call $\overline{\text{VP}}$ the *closure* of VP, and $\overline{\text{VP}} \setminus \text{VP}$ the *boundary* of VP. So the question is whether this boundary is non-empty. At present, it is not even known if $\overline{\text{VP}}$ is contained in VNP.

The VP vs. $\overline{\text{VP}}$ question is important for two reasons. First, all known algebraic lower bounds for the exact computation of the permanent also hold for its infinitesimally close approximation. For example, the known quadratic lower bound for the permanent [20] also holds for its infinitesimally closely approximation [18], and so also the known lower bounds in the algebraic depth-three circuit models [14]; cf. App. B in [11] for a survey of the known lower bounds which emphasizes this point. These lower bounds hold because some algebraic, polynomial property that is satisfied by the coefficients of the polynomials computed by the circuits in the restricted class under consideration is not satisfied by the coefficients of the permanent. Since a polynomial property is a closed condition,[1] the same property is also satisfied by the coefficients of the polynomials that can be approximated infinitesimally closely[2] by circuits in the restricted class under consideration. This is why the same lower bound also holds for infinitesimally close approximation. We expect the same phenomenon to hold in the unrestricted algebraic circuit model as well. Hence, it is natural to expect that any realistic proof of the VP $\neq$ VNP conjecture will also show that VNP $\not\subseteq \overline{\text{VP}}$, as conjectured in [22] (note that if VNP $\not\subseteq \overline{\text{VP}}$ then there exists a polynomial property showing this lower bound). This is, in fact, the underlying thesis of geometric complexity theory that is implicit in [21]. But, if $\overline{\text{VP}} \neq \text{VP}$, as conjectured in [21], this would mean that any realistic approach to the VP vs. VNP conjecture would even have to separate the permanent from the families in $\overline{\text{VP}} \setminus \text{VP}$ with high circuit complexity.[3]

Second, it is shown in [21] that, assuming a stronger form of the VNP $\not\subseteq \overline{\text{VP}}$ conjecture, the problem NNL (short for Noether's Normalization Lemma) of computing Noether normalization of explicit varieties can be brought down from EXPSPACE, where it is currently, to P, ignoring a quasi-prefix. The existing EXPSPACE vs. P gap,[4] called the geometric complexity theory (GCT) chasm [21], in the complexity of NNL may be viewed as the common cause and measure of the difficulty of the fundamental problems in geometry (NNL) and complexity theory (Hardness). If $\overline{\text{VP}} = \text{VP}$, then it follows [21] that NNL is in PSPACE. Thus the conjectural inequality between $\overline{\text{VP}}$ and VP is the main difficulty that needs to be overcome to bring NNL from EXPSPACE to PSPACE unconditionally, and is the main reason why the standard techniques in complexity theory may not be expected to work in the context of the VP $\neq$ VNP conjecture.

The goal of this article is to study the conjecture in [21] that $\overline{\text{VP}}$ is not contained in VP.

1.1 Degenerations of VP and VNP

Towards that end, we introduce three notions of degenerations of VP and VNP; "degeneration" is the standard term in algebraic geometry for a limit point or infinitesimal approximation. These are subclasses of $\overline{\text{VP}}$ and $\overline{\text{VNP}}$, respectively; cf. Sec. 3 for formal definitions.

---

[1] It is defined by the vanishing of a continuous function, namely, a (meta) polynomial.

[2] This means the polynomials are the limits of the polynomials computed by the circuits in the restricted class under consideration.

[3] Although some lower bounds techniques in the restricted models do distinguish between different polynomials with high circuit complexity (e.g., [25]), we need a better understanding of the families in $\overline{\text{VP}} \setminus \text{VP}$ in order to know which techniques in this spirit could even potentially be useful in the setting of the VNP versus $\overline{\text{VP}}$ problem.

[4] Or, the EXPH vs. P gap, assuming the Generalized Riemann Hypothesis.

The first notion is that of a stable degeneration. Recall [24] that a polynomial f in $\mathbb{F}[x_1, \ldots, x_n]$ is called *stable* with respect to the natural action of $G = \mathrm{SL}(n, \mathbb{F})$ on $\mathbb{F}[x_1, \ldots, x_n]$ if the G-orbit of f is closed (in the Zariski topology). We say that a polynomial f is a *stable degeneration* of $g \in \mathbb{F}[x_1, \ldots, x_n]$ if f lies in a closed G-orbit (which is unique [24]) in the closure of the G-orbit of g. The degeneration is called stable since f in this case is stable. For any class of polynomials $\mathcal{C}$, the class Stable-$\mathcal{C}$ is defined to be the class of families of polynomials that are either in $\mathcal{C}$ or are stable degenerations thereof.

The second notion is that of a Newton degeneration. We say that a polynomial f is a *Newton degeneration* of g if it is obtained from g by keeping only those terms whose associated monomial-exponents lie in some specified face of the Newton polytope of g. For any class of polynomial families $\mathcal{C}$, the class Newton-$\mathcal{C}$ is defined to be the class of families of polynomials that are Newton degenerations of the polynomials in $\mathcal{C}$, or are linear projections of such Newton degenerations.[5]

The third notion, motivated by the notion of p-definability in Valiant [27], is that of a p-definable one-parameter degeneration. We say that a family $\{f_n\}$ of polynomials is a *p-definable one-parameter degeneration* of a family $\{g_n\}$ of polynomials, if $f_n = \lim_{t \to 0} g_n(t)$, where $g_n(t)$ is obtained from g_n by transforming its variables linearly such that (1) the entries of the linear transformation matrix are Laurent polynomials in t of possibly exponential degree (in n), and (2) there exists a small circuit C_n of size polynomial in n such that any coefficient of the Laurent polynomial in any entry of the transformation matrix can be obtained by evaluating C_n at the indices of that entry and the index of the coefficient.[6] Thus a p-definable one-parameter degeneration is a one-parameter degeneration of exponential degree that can be encoded by a small circuit. For any class $\mathcal{C}$, the class $\mathcal{C}^*$ is then defined to be the class of families of polynomials that are p-definable one-parameter degenerations of the families in $\mathcal{C}$.

$\overline{\mathrm{VP}}$ and $\overline{\mathrm{VNP}}$ are closed under these three types of degenerations (cf. Propositions 6, 8, 11). Since we want to compare $\overline{\mathrm{VP}}$ with VP, and $\overline{\mathrm{VNP}}$ with VNP, we ask how VP and VNP behave under these three degenerations. This is addressed in the following result.

▶ **Theorem 1.**
(a) *Stable-VNP = Newton-VNP = VNP* = VNP, and*
(b) *Stable-VP ⊆ Newton-VP ⊆ VP* ⊆ VNP.*

The statement of this result tells us nothing as to whether any of the inclusions in the sequence Stable-VP ⊆ Newton-VP ⊆ VP* ⊆ $\overline{\mathrm{VP}}$ can be expected to be strict or not. But its proof, as discussed below, does shed light on this subject.

Theorem 1 is proved by combining the Hilbert–Mumford–Kempf criterion for stability [15] with the ideas and results in Valiant [27]. The Hilbert–Mumford–Kempf criterion [15] shows that, for any polynomial f_n in the unique closed G-orbit in the G-orbit-closure of any $g_n \in \mathbb{F}[x_1, \ldots, x_n]$, with $G = \mathrm{SL}_n(\mathbb{F})$, there exists a one-parameter subgroup of G that drives g_n to f_n. Furthermore, by Kempf [15], such a subgroup can be chosen in a canonical manner. As a byproduct of the proof of Theorem 1, we get a complexity-theoretic form of this criterion (cf. Theorem 18), which shows that such a one-parameter group can be chosen

[5] Taking a Newton degeneration and a linear projection need not commute, so the set of Newton degenerations alone will not in general be closed under linear projections. For example, any polynomial f is a linear projection of a sufficiently large determinant, but the Newton degenerations of the determinant only consist of polynomials of the form $\det(X')$ where X' is matrix consisting only of variables and 0s.

[6] It is assumed here that the indices are encoded as the lists of 0-1 variables.

so that the resulting one-parameter degeneration of any $\{g_n\} \in \text{VP}$ to $\{f_n\} \in \text{Stable-VP}$ is p-definable. Thus the inclusion of Stable-VP in VNP ultimately depends on the existence of a very special type of one parameter degeneration of $\{g_n\}$ to $\{f_n\}$, as provided by the Hilbert–Mumford–Kempf criterion, which can be encoded by a small circuit. However, no such degeneration scheme, which can be encoded by a small circuit, is known if f_n is allowed to be any polynomial in the $\text{GL}(n, \mathbb{F})$-orbit-closure of g_n.

If such a scheme exists for every f_n in the $\text{GL}(n, \mathbb{F})$-orbit-closure of g_n, then it would follow that $\overline{\text{VP}} \subseteq \text{VP}^*$, and in conjunction with Theorem 1, that $\overline{\text{VP}} \subseteq \text{VNP}$. This is one plausible approach to show that $\overline{\text{VP}} \subseteq \text{VNP}$, if this is true. If, on the other hand, no such special scheme akin to the Hilbert–Mumford–Kempf criterion for stability exists for every f_n in the $\text{GL}(n, \mathbb{F})$-orbit-closure of g_n, as the extensive research in geometric invariant theory [24] in the last century since the work of Hilbert [12] suggests, then this may be taken as an indication that $\overline{\text{VP}}$ is not contained in VP^*, and hence, also not in VP.

The complexity-theoretic form of the Hilbert-Mumford criterion mentioned above (Theorem 18) also provides an exponential (in n) upper bound on the degree of the canonical Kempf-one-parameter subgroup that drives g_n to f_n, with $\{g_n\} \in \text{VP}$ and $\{f_n\} \in \text{Stable-VP}$. This canonical Kempf-one-parameter subgroup is known to be the fastest way to approach a closed orbit [16]. If one could prove a polynomial upper bound on this degree, then it would follow that Stable-VP = VP (cf. Lemma 17). On the other hand, if a worst-case superpolynomial lower bound on this degree can be proved, then it would be an indication that Stable-VP, and hence $\overline{\text{VP}}$, are different from VP. In other words, this suggests a possible route to formally separate VP and $\overline{\text{VP}}$.

An analogue of Theorem 1 also holds for VP_{ws}, the class of families of polynomials that can be computed by symbolic determinants of polynomial size.

Next we ask if one can construct an *explicit* family in Newton-VP_{ws} that can reasonably be conjectured to be not in VP_{ws} or even VP. With this mind, we first construct an explicit family $\{f_n\}$ of polynomials that can be approximated infinitesimally closely by symbolic determinants of size $\leq n$, but conjecturally cannot be computed exactly by symbolic determinants of $\Omega(n^{2+\delta})$ size, for a small enough positive constant $\delta < 1$; cf. Section 5. This construction follows a suggestion made in [22, Section 4.2]. The family $\{f_n\}$ is a Newton degeneration of the family of perfect matching Pfaffians of graphs. However, this family $\{f_n\}$ turns out to be in VP_{ws}. So we need to extend this idea much further to construct an explicit family in Newton-VP_{ws} that can be conjectured to be not in VP.

To see how, note that perfect matching Pfaffians are derived from a semi-invariant of the symmetric quiver with two vertices and one arrow. This suggests that to upgrade the conjectural $\Omega(n^{2+\delta})$ lower bound to obtain a candidate for a superpolynomial lower bound a possible route is to replace perfect matching Pfaffians by appropriate representation-theoretic invariants. This leads to the second line of investigation, which we now discuss.

1.2 On Newton degeneration of generic semi-invariants

Our next result suggests that these invariants should be non-generic by showing that, for many finite quivers, including some wild ones, Newton degeneration of any generic semi-invariant can be computed by a symbolic determinant of polynomial size.

A quiver $Q = (Q_0, Q_1)$ [6, 8] is a directed graph (allowing multiple edges) with the set of vertices Q_0 and the set of arrows Q_1. A linear representation V of a quiver associates to each vertex $x \in Q_0$ a vector space V^x, and to each arrow $\alpha \in Q_1$ a linear map V^α from $V^{s\alpha}$ to $V^{t\alpha}$, where $s\alpha$ denotes the start (tail) of α and $t\alpha$ its target (head). The dimension vector of V is the tuple of non-negative integers that associates $\dim(V^x)$ to

each vertex $x \in Q_0$. Given a dimension vector $\beta \in \mathbb{N}^{|Q_0|}$, let $\mathrm{Rep}(Q, \beta)$ denote the space of all representations of Q with the dimension vector β. We have the natural action of $\mathrm{SL}(\beta) := \prod_{x \in Q_0} \mathrm{SL}(\beta(x), \mathbb{F})$ on $\mathrm{Rep}(Q, \beta)$ by change of basis. Let $\mathrm{SI}(Q, \beta) = \mathrm{Rep}(Q, \beta)^{\mathrm{SL}(\beta)}$ denote the ring of semi-invariants. The *generic* semi-invariants in this ring (see [6]) will be recalled in Section 6.

We will be specifically interested in the following well-known types of quivers, cf. [7]. The m-Kronecker quiver is the quiver with two vertices, and m arrows between the two vertices with the same direction. It is wild if $m \geq 3$; wildness is a universality property in representation theory, analogous to NP-completeness (see, e.g., [1]). The k-subspace quiver is the quiver with $k+1$ vertices $\{x_1, \ldots, x_k, y\}$ and k arrows $(x_1, y), \ldots, (x_k, y)$. It is wild if $k \geq 5$. The A-D-E Dynkin quivers are the only quivers of finite representation type – they have only finitely many indecomposable representations.

The following result tells us where *not* to look for explicit candidate families in $\overline{\mathrm{VP}} \setminus \mathrm{VP}$.

▶ **Theorem 2.** *Let Q be an m-Kronecker quiver, or a k-subspace quiver, or an A-D-E Dynkin quiver. Then any Newton degeneration of a generic semi-invariant of Q with dimension vector β and degree d can be computed by a weakly skew circuit (or equivalently a symbolic determinant) of* $\mathsf{poly}(|\beta|, d)$ *size, where $|\beta| = \sum_{x \in Q_0} \beta(x)$.*

The proof strategy for Theorem 2 is as follows. Define the coefficient complexity $\mathrm{coeff}(E)$ of a set E of integral linear equalities in $\mathbb{R}^m$ as the sum of the absolute values of the coefficients of the equalities. Define the coefficient complexity of a face of a polytope in $\mathbb{R}^m$ as the minimum of $\mathrm{coeff}(E)$, where E ranges over all integral linear equality sets that define the face, in conjunction with the description of the polytope; cf. Section 6.1.

Theorem 2 is proved by showing that the coefficient complexity of every face of the Newton polytope of a generic semi-invariant of any quiver as above is polynomial in $|\beta|$ and d, though the number of vertices on a face can be exponential.

In view of this result and its proof, to construct an explicit family in $\text{Newton-VP}_{\mathrm{ws}} \setminus \mathrm{VP}_{\mathrm{ws}}$, we should look for appropriate *non-generic* invariants of representations of finitely generated algebras whose Newton polytopes have faces with *superpolynomial coefficient complexity* and *superpolynomial number of vertices*.

Of course, we do not have to confine ourselves to Newton-VP in the search of an explicit candidate family in $\overline{\mathrm{VP}} \setminus \mathrm{VP}$. We may search within VP^*, or even outside VP^*.

Organization. The rest of this article is organized as follows. In Section 2 we cover the preliminaries. In Section 3, we formally define the three degenerations of VP and VNP. In Section 4, we prove Theorem 1. In Section 5 we construct an explicit family $\{f_n\}$ that can be approximated infinitesimally closely by symbolic determinants of size $\leq n$, but conjecturally cannot be computed exactly by symbolic determinants of $\Omega(n^{2+\delta})$ size, for a small enough positive constant $\delta < 1$. In Section 6, we prove Theorem 2 for generalized Kronecker quivers. Due to page constraints, some proofs are deferred to the full version. In particular, there we give additional examples of representation-theoretic symbolic determinants whose Newton degenerations have small circuits. All these examples suggest that explicit families in $\text{Newton-VP}_{\mathrm{ws}} \setminus \mathrm{VP}_{\mathrm{ws}}$ have to be rather delicate.

2 Preliminaries

For $n \in \mathbb{N}$, let $[n] := \{1, \ldots, n\}$. We denote by $\mathbf{x} = (x_1, \ldots, x_n)$ a tuple of variables; $\mathbf{x}$ may also denote $\{x_1, \ldots, x_n\}$. Let $\mathbf{e} = (e_1, \ldots, e_n)$ be a tuple of nonnegative integers. We usually

use $\mathbf{e}$ as the exponent vector of a monomial in $\mathbb{F}[x_1, \ldots, x_n]$. Thus, $\mathbf{x}^{\mathbf{e}}$ denotes the monomial with the exponent vector $\mathbf{e}$. Let $|\mathbf{e}| := \sum_{i=1}^{n} e_i$.

For a field $\mathbb{F}$, $\mathrm{char}(\mathbb{F})$ denotes the characteristic of $\mathbb{F}$. Throughout this paper, we assume that $\mathbb{F}$ is algebraically closed. S_n denotes the symmetric group consisting of permutations of n objects.

We say that a polynomial $g = g(x_1, \ldots, x_n)$ is a *linear projection* of $f = f(y_1, \ldots, y_m)$ if g can be obtained from f by letting y_j's be some (possibly non-homogeneous) linear combinations of x_i's with coefficients in the base field $\mathbb{F}$.

A family of polynomials $\{f_n\}_{n\in\mathbb{N}}$ is p-bounded if f_n is a polynomial in $\mathsf{poly}(n)$ variables of $\mathsf{poly}(n)$ degree. The class VP [27] consists of p-bounded polynomial families $\{f_n\}_{n\in\mathbb{N}}$ over $\mathbb{F}$ such that f_n can be computed by an arithmetic circuit over $\mathbb{F}$ of $\mathsf{poly}(n)$ size.

Convention: We call a class $\mathcal{C}$ of families of polynomials *standard* if it contains only p-bounded families, and is closed under linear projections.

By a symbolic determinant of size m over the variables $x_1, \ldots, x_n$, we mean the determinant of an $m \times m$ matrix, whose each entry is a possibly non-homogeneous linear function of $x_1, \ldots, x_n$ with coefficients in the base field $\mathbb{F}$. The class $\mathrm{VP}_{\mathrm{ws}}$ is the class of families of polynomials that can be computed by weakly skew circuits of polynomial size, or equivalently, by symbolic determinants of polynomial size [19].

The class VNP is the class of p-definable families of polynomials [27], that is, those families (f_n) such that f_n has $\mathsf{poly}(n)$ variables and $\mathsf{poly}(n)$ degree, and there exists a family $(g_n(x, y)) \in \mathrm{VP}$ such that $f_n(x) = \sum_{e\in\{0,1\}^{\mathsf{poly}(n)}} g_n(x, e)$.

The class $\overline{\mathrm{VP}}$ is defined as follows [22, 5]. Over $\mathbb{F} = \mathbb{C}$, we say that a polynomial family $\{f_n\}_{n\in\mathbb{N}}$ is in $\overline{\mathrm{VP}}$, if there exists a family of sequences of polynomials $\{f_n^{(i)}\}_{n\in\mathbb{N}}$ in VP, $i = 1, 2, \ldots$, s.t. for every n, the sequence of polynomials $f_n^{(i)}$, $i = 1, 2, \ldots$, goes infinitesimally close to f_n, in the usual complex topology. Here, polynomials are viewed as points in the linear space of polynomials. There is a more general definition that works over arbitrary algebraically closed fields – including in positive characteristic – using the Zariski topology. For a direct treatment, see, e.g. [4, App. 20.6]. The operational version of this definition we use is as follows: $\{f_n(x_1, \ldots, x_m)\} \in \overline{\mathrm{VP}}$ if there exist polynomials $f_{n,t}(x_1, \ldots, x_m) \in \mathrm{VP}_{\mathbb{C}((t))}$ – $f_{n,t}$ is a polynomial in the x_i whose coefficients are Laurent series in t – such that $f_n(x)$ is the coefficient of the term in $f_{n,t}(x)$ of lowest degree in t.

The classes $\overline{\mathrm{VP}_{\mathrm{ws}}}$, $\overline{\mathrm{VNP}}$, and $\overline{\mathcal{C}}$, for any standard class $\mathcal{C}$, are defined similarly.

By the determinantal complexity $\mathrm{dc}(f)$ of a polynomial $f(x_1, \ldots, x_n)$, we mean the smallest integer m s.t. f can be expressed as a symbolic determinant of size m over $x_1, \ldots, x_n$. By the approximative determinantal complexity $\overline{\mathrm{dc}}(f)$, we mean the smallest integer m s.t. f can be approximated infinitesimally closely by symbolic determinants of size m.

Thus the $\mathrm{VP}_{\mathrm{ws}} \neq \mathrm{VNP}$ conjecture in Valiant [27] is equivalent to saying that $\mathrm{dc}(\mathrm{perm}_n)$ is not $\mathsf{poly}(n)$, where perm_n denotes the permanent of an $n \times n$ variable matrix. The $\mathrm{VNP} \not\subseteq \overline{\mathrm{VP}_{\mathrm{ws}}}$ conjecture in [22] is equivalent to saying that $\overline{\mathrm{dc}}(\mathrm{perm}_n)$ is not $\mathsf{poly}(n)$.

A priori, it is not at all obvious that dc and $\overline{\mathrm{dc}}$ are different complexity measures. The following two examples should make this clear.

▶ **Example 3** (Example 9 in [17]). Let $f = x_1^3 + x_2^2 x_3 + x_2 x_4^2$. Then $\mathrm{dc}(f) \geq 5$, but $\overline{\mathrm{dc}}(f) = 3$.

▶ **Example 4** (Proposition 3.5.1 in [18]). Let n be odd. Given an $n \times n$ complex matrix M, let M_{ss} and M_s denote its skew-symmetric and symmetric parts. Since n is odd, $\det(M_{ss})$=0. Hence, for a variable t, $\det(M_{ss} + tM_s) = tf(M) + O(t^2)$, for some polynomial function

$f(M)$. Clearly, $\overline{\mathrm{dc}}(f) = n$, since $\det(M_{ss} + tM_s)/t$ goes infinitisimally close to $f(M)$ when t goes to 0. But $\mathrm{dc}(f) > n$.

The $\mathrm{VP}_{\mathrm{ws}} \neq \overline{\mathrm{VP}_{\mathrm{ws}}}$ conjecture in [21] is equivalent to saying that there exists a polynomial family $\{f_n\}$ such that $\overline{\mathrm{dc}}(f_n) = \mathsf{poly}(n)$, but $\mathrm{dc}(f_n)$ is not $\mathsf{poly}(n)$. Instead of this conjecture, we will focus on the $\mathrm{VP} \neq \overline{\mathrm{VP}}$ conjecture in [21], since the considerations for the former conjecture are entirely similar.

A (convex – we will only consider convex ones here) *polytope* is the convex hull in $\mathbb{R}^n$ of a finite set of points. A *face* of a polytope P is the intersection of P with linear halfspace $H = \{v \in \mathbb{R}^n | \ell(v) \geq c\}$ for some linear function ℓ and constant c such that H contains no points of the (topological) interior of P. Equivalently, a polytope is the intersection of finitely many half-spaces, a half-space $H_{\ell,c} = \{v | \ell(v) \geq c\}$ is tight for P if $P \subseteq H_{\ell,c}$ and $P \nsubseteq H_{\ell,c'}$ for any $c' > c$, and a face of P is the intersection of P with a half-space of the form $H_{-\ell,-c}$ where $H_{\ell,c}$ is tight for P.

3 Degenerations of VP and VNP

To understand the relationship between VP, VNP, and their closures $\overline{\mathrm{VP}}$ and $\overline{\mathrm{VNP}}$, we now introduce three degenerations of VP and VNP. The considerations for $\mathrm{VP}_{\mathrm{ws}}$ and $\overline{\mathrm{VP}_{\mathrm{ws}}}$ are entirely similar.

3.1 Stable degeneration

First we define stable degenerations of VP and VNP.

Consider the natural action of $G = \mathrm{SL}(n, \mathbb{F})$ on $\mathbb{F}[\mathbf{x}] = \mathbb{F}[x_1, \ldots, x_n]$ that maps $f(\mathbf{x})$ to $f(\sigma^{-1}\mathbf{x})$ for any $\sigma \in G$. Following Mumford et al. [24], call $f = f(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]$ *stable* (with respect to the G-action) if the G-orbit of f is Zariski-closed. It is known [24] that the closure of the G-orbit of any $g \in \mathbb{F}[\mathbf{x}]$ contains a unique closed G-orbit. We say that f is a *stable degeneration* of g if f lies in the unique closed G-orbit in the G-orbit-closure of g. (If the G-orbit of g is already closed then this just means that f lies in the G-orbit of g.)

We now define the class Stable-$\mathcal{C}$, the stable degeneration of any standard class $\mathcal{C}$, as follows. We say that $\{f_n\}_{n\in\mathbb{N}}$ is in Stable-$\mathcal{C}$ if (1) $\{f_n\} \in \mathcal{C}$, or (2) there exists $\{g_n\}_{n\in\mathbb{N}}$ in $\mathcal{C}$ such that each f_n is a stable degeneration of g_n with respect to the action of $G = \mathrm{SL}(m_n, \mathbb{F})$, where $m_n = \mathsf{poly}(n)$ denotes the number of variables in f_n and g_n.

▶ **Proposition 5.** *For any class $\mathcal{C}$ of p-bounded families of polynomials, Stable-$\mathcal{C} \subseteq \overline{\mathcal{C}}$. In particular, Stable-VP $\subseteq \overline{VP}$ and Stable-VNP $\subseteq \overline{VNP}$.*

▶ **Proposition 6.** *Stable-$\overline{\mathcal{C}} = \overline{\mathcal{C}}$, in particular Stable-$\overline{VP} = \overline{VP}$, and Stable-$\overline{VNP} = \overline{VNP}$.*

This is a direct consequence of the definitions.

3.2 Newton degeneration

Next we define Newton degenerations of VP and VNP.

Given a polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$, suppose $f = \sum_{\mathbf{e}} \alpha_{\mathbf{e}} \mathbf{x}^{\mathbf{e}}$. We collect the exponent vectors of f and form the convex hull of these exponent vectors in $\mathbb{R}^n$. The resulting polytope is called the *Newton polytope* of f, denoted $\mathrm{NPT}(f)$. Given an arbitrary face Q of $\mathrm{NPT}(f)$, the Newton degeneration of f to Q, denoted $f|_Q$, is the polynomial $\sum_{\mathbf{e}\in Q} \alpha_{\mathbf{e}} \mathbf{x}^{\mathbf{e}}$.

We now define the class Newton-$\mathcal{C}$, the Newton degeneration of any class $\mathcal{C}$, as follows: $\{f_n\}_{n\in\mathbb{N}}$ is in Newton-$\mathcal{C}$, if there exists $\{g_n\}_{n\in\mathbb{N}}$ in $\mathcal{C}$ such that each f_n is the Newton

degeneration of g_n to some face of $\mathrm{NPT}(g_n)$, or a linear projection of such a Newton degeneration.

▶ **Theorem 7.** *Let $\mathcal{C}$ be any standard class (cf. Section 2). Then Newton-$\mathcal{C} \subseteq \overline{\mathcal{C}}$. In particular, Newton-VP $\subseteq \overline{VP}$ and Newton-VNP $\subseteq \overline{VNP}$.*

Proof. Let $\{f_n\}_{n\in\mathbb{N}}$ be in Newton-$\mathcal{C}$, and suppose $f_n \in \mathbb{F}[x_1, \ldots, x_{m(n)}]$.Then there exists $\{g_n\}_{n\in\mathbb{N}} \in \mathcal{C}$, such that $g_n \in \mathbb{F}[x_1, \ldots, x_m]$, $m = m(n)$, and $f_n = g_n|_Q$, where Q is a face of $\mathrm{NPT}(g_n)$. Suppose the supporting hyperplane of Q is defined by $\langle \mathbf{a}, \mathbf{x}\rangle = b$, where $\mathbf{a} = (a_1, \ldots, a_m)$. If necessary, by replacing $(\mathbf{a}, b)$ with $(-\mathbf{a}, -b)$, we make sure that for an arbitrary exponent vector $\mathbf{e}$ in g_n, $\langle \mathbf{a}, \mathbf{e}\rangle \geq b$. That is, among all exponent vectors, exponent vectors on Q achieve the minimum value b in the direction $\mathbf{a}$.

Now introduce a new variable t, and replace x_i with $t^{a_i}x_i$ to obtain a polynomial $g'_n(x_1, \ldots, x_m, t) = g_n(t^{a_1}x_1, \ldots, t^{a_m}x_m) \in \mathbb{F}[x_1, \ldots, x_m, t]$. By the definition of f_n, $g'_n = t^b \cdot f_n +$ higher order terms in t. Therefore, $\{f_n\} \in \overline{\mathcal{C}}$. ◀

Noting that if $\mathcal{C}$ is closed under linear projections, then so is $\overline{\mathcal{C}}$, we have:

▶ **Corollary 8.** *For any standard class $\mathcal{C}$, Newton-$\overline{\mathcal{C}} = \overline{\mathcal{C}}$. In particular, Newton-$\overline{VP} = \overline{VP}$ and Newton-$\overline{VNP} = \overline{VNP}$.*

3.3 P-definable one-parameter degeneration

Finally, we define p-definable one-parameter degenerations of VP and VNP. We say a family $\{f_n(x_1, \ldots, x_{m_n})\}$, $m_n = \mathsf{poly}(n)$, is a *one-parameter degeneration* of $\{g_n(y_1, \ldots, y_{l_n})\}$, for $l_n = \mathsf{poly}(n)$, of *exponential degree*, if, for some positive integral function $K(n) = O(2^{\mathsf{poly}(n)})$, there exist $c_n(i, j, k) \in \mathbb{F}$, $1 \leq i \leq l_n$, $0 \leq j \leq m_n$, $-K(n) \leq k \leq K(n)$, such that $f_n = \lim_{t\to 0} g_n(t)$, where $g_n(t)$ is obtained from g_n by substitutions of the form

$$y_i = a_0^i + \sum_{j=1}^{m_n} a_j^i x_j, \quad 1 \leq i \leq l_n, \text{ where } a_j^i = \sum_{k=-K(n)}^{K(n)} c_n(i, j, k)t^k, \quad 1 \leq i \leq l_n,\ 0 \leq j \leq m_n.$$

Note that by [3], $\overline{\mathrm{VP}}$ consists exactly of those one-parameter degenerations of VP of exponential degree.

We say that the family $\{f_n(x_1, \ldots, x_{m_n})\}$, $m_n = \mathsf{poly}(n)$, is a *one-parameter degeneration* of $\{g_n(y_1, \ldots, y_{l_n})\}$, $l_n = \mathsf{poly}(n)$, of *polynomial degree* if $K(n)$ above is $O(\mathsf{poly}(n))$ (instead of $O(2^{\mathsf{poly}(n)})$).

We say that a family $\{f_n(x_1, \ldots, x_{m_n})\}$, $m_n = \mathsf{poly}(n)$, is a *p-definable one-parameter degeneration* of $\{g_n(y_1, \ldots, y_{l_n})\}$, $l_n = \mathsf{poly}(n)$, if, for some $K(n) = O(2^{\mathsf{poly}(n)})$, there exists a $\mathsf{poly}(n)$-size circuit family $\{C_n\}$ over $\mathbb{F}$ such that $f_n = \lim_{t\to 0} g_n(t)$, where $g_n(t)$ is obtained from g_n by substitutions of the form

$$y_i = a_0^i + \sum_{j=1}^{m_n} a_j^i x_j, \quad 1 \leq i \leq l_n, \text{ where } a_j^i = \sum_{k=-K(n)}^{K(n)} C_n(i, j, k)t^k, \quad 1 \leq i \leq l_n,\ 0 \leq j \leq m_n.$$

Here it is assumed that the circuit C_n takes as input $\lceil \log_2 l_n \rceil + \lceil \log_2 m_n \rceil + \lceil \log_2(K(n)+1) \rceil$ many 0-1 variables, which are intended to encode three integers (i, j, k) satisfying $1 \leq i \leq l = l_n$, $0 \leq j \leq m = m_n$, and $|k| \leq K(n)$, treating 0 and 1 as elements of $\mathbb{F}$.

Thus a p-definable one-parameter degeneration is a one-parameter degeneration of exponential degree that can be specified by a circuit of polynomial size.

For any class $\mathcal{C}$ we now define $\mathcal{C}^*$, called the p-definable one-parameter degeneration of $\mathcal{C}$, as follows. We say that $\{f_n\} \in \mathcal{C}^*$ if there exists $\{g_n\} \in \mathcal{C}$ such that $\{f_n\}$ is a p-definable one-parameter degeneration of $\{g_n\}$.

▶ **Lemma 9.** *For any standard class $\mathcal{C}$ (cf. Section 2), Newton-$\mathcal{C} \subseteq \mathcal{C}^*$. In particular, Newton-VP $\subseteq$ VP* and Newton-VNP $\subseteq$ VNP*.*

This follows from the proof of Theorem 7, noting that we may always take the coefficients of a face to have size at most $2^{\mathsf{poly}(n)}$. The following are easy consequences of the definitions:

▶ **Proposition 10.** *VP* $\subseteq \overline{\text{VP}}$, and VNP* $\subseteq \overline{\text{VNP}}$.*

▶ **Proposition 11.** *$\overline{\text{VP}}^*$ $= \overline{\text{VP}}$, and $\overline{\text{VNP}}^*$ $= \overline{\text{VNP}}$.*

4 Stable-VNP = Newton-VNP = VNP* = VNP

We now prove Theorem 1, by a circular sequence of inclusions.

Proof of Theorem 1. Since VNP $\subseteq$ Stable-VNP by definition, Theorem 1(a) follows from the facts that Stable-VNP $\subseteq$ Newton-VNP (cf. Theorem 12 below), Newton-VNP $\subseteq$ VNP* (Lemma 9), and VNP* $\subseteq$ VNP (cf. Theorem 15 below).

Theorem 1(b) follows from the facts that Stable-VP $\subseteq$ Newton-VP (cf. Theorem 12 below), Newton-VP $\subseteq$ VP* (Lemma 9), and VP* $\subseteq$ VNP (cf. Corollary 16 below). ◀

▶ **Theorem 12.** *For any class $\mathcal{C}$ of families of p-bounded polynomials, Stable-$\mathcal{C} \subseteq$ Newton-$\mathcal{C}$. In particular, Stable-VP $\subseteq$ Newton-VP and Stable-VNP $\subseteq$ Newton-VNP.*

Proof. Suppose $\{f_n\} \in$ Stable-$\mathcal{C}$. If $\{f_n\} \in \mathcal{C}$ then there is nothing to show. Otherwise, there exists $\{g_n\}_{n\in\mathbb{N}}$ in $\mathcal{C}$ s.t. each f_n is a stable degeneration of g_n with respect to the action of $G = SL_{m_n}(\mathbb{F})$, where m_n denotes the number of variables in f_n and g_n.

It suffices to show that $f = f_n(x_1, \ldots, x_m)$, $m = m_n$, is a Newton degeneration of $g = g_n(x_1, \ldots, x_m)$. Let $\mathbf{x} = (x_1, \ldots, x_m)$.

By the Hilbert–Mumford–Kempf criterion for stability [15], there exists a one-parameter subgroup $\lambda(t) \subseteq G$ such that $\lim_{t\to 0} \lambda(t).g = f$. Let T be the canonical maximal torus in G such that the monomials in x_i's are eigenvectors for the action of T. After a linear change of coordinates (which is allowed since Newton-$\mathcal{C}$ is closed under linear transformations by definition), we can assume that $\lambda(t)$ is contained in T. Thus $\lambda(t) = \text{diag}(t^{k_1}, \ldots, t^{k_m})$ (the diagonal matrix with t^{k_j}'s on the diagonal), $k_j \in \mathbb{Z}$, such that $\sum k_j = 1$.

It follows that f is the Newton degeneration of g to the face of NPT(g) where the linear function $\sum_j k_j x_j$ achieves the minimum value (which has to be zero). ◀

The following result is subsumed by Theorem 15; we include its proof here both for expository clarity (it is somewhat simpler but still gives the flavor) and brevity.

▶ **Theorem 13.** *Newton-VNP $\subseteq$ VNP.*

Proof. Suppose $\{f_n\} \in$ Newton-VNP. If $\{f_n\} \in$ VNP, then there is nothing to show. Otherwise, there exists $\{g_n\}_{n\in\mathbb{N}}$ in VNP such that each f_n is the Newton degeneration of g_n to some face of NPT(g_n), or a linear projection of such a Newton degeneration. Since VNP is closed under linear projections, we can assume, without loss of generality, that f_n is the Newton degeneration of g_n to some face of NPT(g_n).

By Valiant [27], we can assume that $g = g_n(x_1, \ldots, x_m)$, $m = m_n = \mathsf{poly}(n)$, is a projection of $\mathrm{perm}(X)$,[7] where X is a $k \times k$ variable matrix, with $k = \mathsf{poly}(n)$. This means $g = \mathrm{perm}(X')$, where each entry of X' is some variable x_i or a constant from the base field F. Since $f = f_n$ is a Newton degeneration of g, it follows that there is some substitution, as in the proof of Theorem 7, $x_j \to x_j t^{k_j}$, $k_j \in \mathbb{Z}$, such that $f = \lim_{t\to 0} \mathrm{perm}(X'(t))$, where $X'(t)$ denotes the matrix obtained from X' after this substitution.

It is easy to ensure that $|k_j| \leq O(2^{\mathsf{poly}(n)})$. Then, given any permutation $\sigma \in \mathrm{S}_k$, whether the corresponding monomial $\prod_i X'_{i\sigma(i)}$ contributes to f can be decided in $\mathsf{poly}(n)$ time. It follows that the coefficient of a monomial can be computed by an algebraic circuit summed over polynomially many Boolean inputs (convert the implicit $\mathsf{poly}(n)$-time Turing machine into a Boolean circuit, then convert it into an algebraic circuit (as in [27, Remark 1]) that incorporates the constants appearing in the projection). Hence $\{f_n\} \in \mathrm{VNP}$. ◀

Since $\mathrm{VP} \subseteq \mathrm{VNP}$, the preceding result implies:

▶ **Corollary 14.** *Newton-VP $\subseteq$ VNP.*

The following result can proved similarly to Theorem 13; see the full version for its proof.

▶ **Theorem 15.** *$\mathrm{VNP}^* \subseteq$ VNP.*

▶ **Corollary 16.** *$\mathrm{VP}^* \subseteq$ VNP.*

In contrast, using the interpolation technique of Strassen [26] and Bini [2] we have:

▶ **Lemma 17** (cf. also [3], [5, §9.4], [10, Prop. 3.5.4])**.** *If $\{f_n\}$ is a one-parameter degeneration of $\{g_n\} \in$ VP of polynomial degree, then $\{f_n\} \in$ VP.*

A complexity-theoretic form of the Hilbert–Mumford–Kempf criterion. As a byproduct of the proof of Theorem 1, we get the following complexity-theoretic form of the Hilbert–Mumford–Kempf criterion [15] for stability with respect to the action of $G = \mathrm{SL}(m, \mathbb{F})$ on $\mathbb{F}[x_1, \ldots, x_m]$. Given a one-parameter subgroup $\lambda(t) \subseteq G$, we can express it as $A \cdot \mathrm{diag}(t^{k_1}, \ldots, t^{k_m}) \cdot A^{-1}$, for some $A \in G$ and $k_j \in \mathbb{Z}$, $1 \leq j \leq m$. We call $\sum_i |k_i|$ the total degree of $\lambda(t)$. The following theorem is implicit in the proofs of Theorems 12 and 13.

▶ **Theorem 18.** *Suppose $f = f(x_1, \ldots, x_m)$ belongs to the unique closed G-orbit in the G-orbit-closure of $g = g(x_1, \ldots, x_m) \in \mathbb{F}[x_1, \ldots, x_m]$. Then there exists a one-parameter subgroup $\lambda(t) \subseteq G$ such that (1) $\lim_{t\to 0} \lambda(t) \cdot g = f$, and (2) the total degree of λ is $O(exp(m, \langle \deg(g) \rangle))$, where $\langle \deg(g) \rangle$ denotes the bitlength of the degree of g.*

It follows that if $\{f_n\}$ is a stable degeneration of $\{g_n\} \in$ VP, then $\{f_n\}$ is a p-definable one-parameter degeneration of $\{g_n\}$.

See the full version for an analogous result for reductive algebraic groups. We formally propose a question that has ramifications on the Stable-VP vs. VP question (cf. Section 1).

▶ **Question 19.** For some positive constant a, does there exist a stable degeneration $\{f_n\}$ of some $\{g_n\} \in$ VP, with an $\Omega(2^{n^a})$ lower bound on the degree of the canonical Kempf-one-parameter subgroup [15] λ_n driving $\{g_n\}$ to $\{f_n\}$?

[7] To get the proof to work in characteristic 2 as well, simply use the Hamilton cycle polynomial $HC(X) = \sum_{\text{k-cycles } \sigma \in S_k} \prod_{i\in[k]} x_{i,\sigma(i)}$ instead, which is VNP-complete in any characteristic [27].

5 Newton degeneration of perfect matching Pfaffians

In this section, we construct an explicit family $\{f_n\}$ of polynomials such that f_n can be approximated infinitesimally closely by symbolic determinants of size n, but conjecturally requires size $\Omega(n^{2+\delta})$ to be computed by a symbolic determinant, for a small enough positive constant δ. However, the family $\{f_n\}$ turns out to be in $\mathrm{VP}_{\mathrm{ws}}$.

Suppose we have a simple undirected graph $G = (V, E)$ where $V = [n]$. Let $\{x_e \mid e \in E\}$ be a set of variables. The Tutte matrix of G is the $n \times n$ skew-symmetric matrix T_G such that, if $(i, j) = e \in E$, with $i < j$, then $T_G(i, j) = x_e$ and $T_G(j, i) = -x_e$; otherwise $T_G(i, j) = 0$. For a skew-symmetric matrix T, the determinant of T is a perfect square, and the square root of $\det(T)$ is called the Pfaffian of T, denoted $\mathrm{pf}(T)$. We call $\mathrm{pf}(T_G)$ the *perfect matching Pfaffian* of the graph G, and $\mathrm{pf}(T_G) = \sum_P \mathrm{sgn}(P) \prod_{e \in P} x_e$, where the sum is over all perfect matchings P of G, and $\mathrm{sgn}(P)$ takes ± 1 in a suitable manner. It is well-known that $\mathrm{pf}(T_G) \in \mathrm{VP}_{\mathrm{ws}}$.

Note that $\mathrm{NPT}(\mathrm{pf}(T_G))$ is the perfect matching polytope of G, which has the following description by Edmonds. For any $S \subseteq V$, we use $e \sim S$ to denote that e lies at the border of S. When $S = \{i\}$, we may write $e \sim i$ instead of $e \sim \{i\}$.

▶ **Theorem 20** (Edmonds, [9]). *The perfect matching polytope of a graph G is characterized by the following constraints:*

$$
\begin{aligned}
&(a) \quad \forall e \in E, x_e \geq 0; \\
&(b) \quad \forall i \in V, \sum_{e \in E, e \sim i} x_e = 1; \\
&(c) \quad \forall C \subseteq V, |C| > 1 \text{ is odd}, \sum_{e \in E, e \sim C} x_e \geq 1.
\end{aligned} \tag{1}
$$

We shall refer to constraints of type (c) in Equation (1) as "odd-size constraints."

▶ **Theorem 21** (Kaltofen and Koiran, [13, Corollary 1]). *Given $f, g, h \in \mathbb{F}[\mathbf{x}]$, suppose $h = f/g$, and f and g are in VP_{ws}. Then $h \in VP_{ws}$.*

▶ **Theorem 22.** *For any graph G and any face Q of $\mathrm{NPT}(\mathrm{pf}(T_G))$, $\mathrm{pf}(T_G)|_Q \in VP_{ws}$.*

Proof. Thanks to Edmonds' description, any face of $\mathrm{NPT}(\mathrm{pf}(T_G))$ is obtained by setting some of the inequalities in Equation (1) to equalities. As setting $x_e = 0$ amounts to consider some graph G' with e deleted from G, the bottleneck is to deal with the odd-size constraints.

Suppose the face Q is obtained via setting the odd-size constraints corresponding to $C_1, \ldots, C_s$ to equalities, where $C_i \subseteq V$. Note that $s = \mathsf{poly}(n)$, because the dimension of $\mathrm{NPT}(\mathrm{pf}(T_G))$ is polynomially bounded, thus any face can be obtained by setting polynomially many constraints to equalities. Let y be a new variable. For any edge $e \in E$, let the number of $i \in [s]$ s.t. e lies at the border of C_i be k_e. Then transform x_e to $x_e y^{k_e}$. Let the skew-symmetric matrix after the transformation be $\widetilde{T_G}$. Since each perfect matching touches the border of every C_i at least once, y^s divides $\mathrm{pf}(\widetilde{T_G})$, so $f := \frac{\mathrm{pf}(\widetilde{T_G})}{y^s}$ is a polynomial. Furthermore, the y-free terms in f corresponds to those perfect matchings that touch each border exactly once. Thus, setting y to zero in f gives $\mathrm{pf}(T_G)|_Q$.

f is in $\mathrm{VP}_{\mathrm{ws}}$, because $\mathrm{pf}(\widetilde{T_G})$ and y^s are in $\mathrm{VP}_{\mathrm{ws}}$, and use Theorem 21. ◀

Construction of an explicit family. Now we turn to the construction of an explicit family $\{f_n\}$ mentioned in the beginning of this section. We assume that the base field $\mathbb{F} = \mathbb{C}$.

First, we give a randomized procedure for constructing f_n:

1. Fix a small enough constant $a > 0$, and let l be the nearest odd integer to n^a. Fix odd-size disjoint subsets $C_1, \ldots, C_k \subseteq [n]$, $k = \lfloor n^{1-a} \rfloor$, of size l. For example, we can let $C_1 = \{1, \ldots, l\}$, $C_2 = \{l+1, \ldots, 2l+1\}$, etc.
2. Choose a random regular non-bipartite graph G_n on n nodes with degree (say) $\sqrt{n}$.
3. Let Q be the face of $\mathrm{NPT}(\mathrm{pf}(T_G))$ obtained by setting the odd-size constraints corresponding $C_1, \ldots, C_k$ to equalities.
4. Let $f_n = \det(T_G)|_Q$.

Then, f_n can be approximated infinitesimally closely by symbolic determinants of size n; cf. the proof of Theorem 7. By Theorem 22, f_n can be expressed as a symbolic determinant of $\mathsf{poly}(n)$ size. But:

▶ **Conjecture 23.** If $a > 0$ is small enough, then, with a high probability, f_n cannot be expressed as a symbolic determinant of size $\leq n^{2+\delta}$, for a small enough positive constant δ.

This is because, with high probability, the coefficient complexity of Q is $\Omega(n^{1-a+1/2})$, and hence interpolation, which lies at the heart of the algorithm in Theorem 22, can be expected to incur $\Omega(n^{1+\delta})$ blow-up in the determinantal size, for a small enough constant $\delta > 0$. Specifically, if we unwind Strassen's proof of division gate elimination, the number of terms in the interpolation is the degree of the polynomial times the degree of the denomenator. The former number gets increased by a multiplicative factor of the sum of absolute values of variable coefficients in the equations, and the latter number is the sum of absolute values of constant terms. It follows that the coefficient complexity determines the blow-up factor.

To get an explicit family $\{f_n\}$, we let G_n be a pseudo-random graph, instead of a random graph. Some suggestions can be found in the full version.

6 Newton degenerations of generic semi-invariants of quivers

In this section we prove Theorem 2 for the generalized Kronecker quivers. Due to page constraints, proofs for k-subspace quivers and A-D-E Dynkin quivers are in the full version. We assume familiarity with the basic notions of the representation theory of quivers; cf. [6, 8].

6.1 Newton degeneration to faces with small coefficient complexity

We begin by observing that the technique used to prove Theorem 22 can be generalized further. In the proof of Theorem 22, due to Edmonds' description of the perfect matching polytope, every face has a "small" description, by a set of linear equalities whose coefficients are polynomially bounded in magnitude.

For a face Q of a polytope P, we say that a set of linear equalities E characterizes Q with respect to P, if the description of P together with that of E characterizes Q. For E, let $\mathrm{coeff}(E)$ be the sum of the absolute values of the coefficients of the linear equalities in E. We define the *coefficient complexity* of Q as the minimum of $\mathrm{coeff}(E)$ over the linear equality sets E that characterize Q with respect to P. Adapting the proof of Theorem 22 we easily get the following; see the full version for a proof.

▶ **Theorem 24.** *Suppose $f \in \mathbb{F}[x_1, \ldots, x_n]$ can be computed by a (weakly skew) arithmetic circuit of size s. Let Q be a face of $\mathrm{NPT}(f)$ whose coefficient complexity is $\mathsf{poly}(n)$. Then $f|_Q$ can be computed by a (weakly skew) arithmetic circuit of size $\mathsf{poly}(s, n)$.*

▶ Remark. If Q has $\mathsf{poly}(n)$ coefficient complexity, then it can be shown that $f|_Q$ is a one-parameter degeneration of f of $\mathsf{poly}(n)$ degree. Hence, Thm. 24 also follows from Lem. 17.

6.2 Generic semi-invariants of generalized Kronecker quivers

We now discuss Theorem 2 for the m-Kronecker quiver; the proof is deferred to the full version. The m-Kronecker quiver is the graph with two vertices s and t, with m arrows pointing from s to t. When $m \geq 3$, this quiver is wild.

Any tuple of m $n \times n$ matrices is a linear representation of the m-Kronecker quiver of dimension vector (n, n). Let $\mathbb{F}[x_{i,j}^{(k)}]$ denote the ring of polynomials in the variables $x_{i,j}^{(k)}$, where $i, j \in [n]$, and $k \in [m]$. For $k \in [m]$, let $X_k = (x_{i,j}^{(k)})$ denote the variable $n \times n$ matrix, whose (i, j)-th entry is $x_{i,j}^{(k)}$. Let $R(n, m)$ consist of those polynomials in $\mathbb{F}[x_{i,j}^{(k)}]$ that are invariant under the action of every $(A, C) \in \mathrm{SL}(n, \mathbb{F}) \times \mathrm{SL}(n, \mathbb{F})$, which sends $(X_1, \ldots, X_m)$ to $(AX_1C^{-1}, \ldots, AX_mC^{-1})$. $R(n, m)$ is the ring of semi-invariants for the m-Kronecker quiver for dimension vector (n, n) or "*matrix semi-invariants*" due to their similarity with the well-known matrix invariants. The following is proved using Theorem 24:

▶ **Theorem 25.** *The Newton degeneration of a generic semi-invariant of the m-Kronecker quiver with dimension vector (n, n) and degree dn to an arbitrary face can be computed by a weakly skew arithmetic circuit of size* $\mathsf{poly}(d, n)$.

Acknowledgment. We thank the anonymous reviewers for careful reading and suggestions that greatly help to improve the writing of the paper.

Abstract

$AC^0 \circ MOD_2$ circuits are AC^0 circuits augmented with a layer of parity gates just above the input layer. We study $AC^0 \circ MOD_2$ circuit lower bounds for computing the Boolean Inner Product functions. Recent works by Servedio and Viola (ECCC TR12-144) and Akavia et al. (ITCS 2014) have highlighted this problem as a frontier problem in circuit complexity that arose both as a first step towards solving natural special cases of the matrix rigidity problem and as a candidate for constructing pseudorandom generators of minimal complexity. We give the first superlinear lower bound for the Boolean Inner Product function against $AC^0 \circ MOD_2$ of depth four or greater. Specifically, we prove a superlinear lower bound for circuits of arbitrary constant depth, and an $\tilde{\Omega}(n^2)$ lower bound for the special case of depth-4 $AC^0 \circ MOD_2$. Our proof of the depth-4 lower bound employs a new "moment-matching" inequality for bounded, nonnegative integer-valued random variables that may be of independent interest: we prove an optimal bound on the maximum difference between two discrete distributions' values at 0, given that their first d moments match.

1 Introduction

We study lower bounds for computing the inner product function by AC^0 circuits with parity gates on the level just above the input gates ($AC^0 \circ MOD_2$). As we will review, this problem has emerged as a common, particularly simple special case of several major open problems in Computational Complexity, about which we know surprisingly little. We therefore view progress on this special case as a benchmark for new techniques in circuit complexity for these larger questions.

A core program in Computational Complexity is to understand the power of restricted circuit families. One facet of such understanding is to identify functions that these circuits cannot compute. In practice, it turns out that once we can prove such lower bounds, then we become surprisingly facile with the class, gaining the ability to learn the functions computed by such circuits [14] (and this is necessary in some form [10, 11, 29]), the ability to generate inputs that are pseudorandom for the class [16, 18] (again necessary in some form [7, 24, 27]), and more. As a consequence, "understanding" the class is often identified with proving such lower bounds. It is therefore interesting when this intuition *fails* to hold.

Shaltiel and Viola [25] noticed such a gap: although we can prove that, e.g., the MOD_3 function has constant hardness for $AC^0[2]$ circuits [21, 26] (where $AC^0[2]$ is AC^0 equipped with parity gates), we still *do not* have pseudorandom generators for $AC^0[2]$. The trouble is that known constructions of pseudorandom generators require strongly hard on average functions [18], and proofs of hardness amplification require the class in question to compute the majority function, which $AC^0[2]$ cannot even approximate [21]. Shaltiel and Viola therefore highlight the problem of establishing such strong average case hardness against $AC^0[2]$ circuits as a challenge in circuit complexity. Servedio and Viola [23] pointed out that such strong hardness is not even known for $AC^0 \circ MOD_2$, and suggest the problem as a natural special case. In particular, they conjecture that, for this special case, the Inner Product function (IP), defined below, is an example of such a function (although it is trivially computable by $AC^0[2]$).

▶ **Definition 1.** $\mathrm{IP}(x, y)\colon \{0,1\}^{2n} \to \{0,1\}$ is the function $\sum_{i=1}^{n} x_i y_i \pmod 2$.

Thus, showing that IP cannot be computed by small $AC^0 \circ MOD_2$ circuits is a natural step towards a better understanding of $AC^0[2]$.

On the other hand, a better understanding of the class $AC^0 \circ MOD_2$ turns out to be of interest to practical cryptography as well. Along similar lines, Akavia et al. [1], in the course of proposing a candidate weak pseudorandom function of minimal complexity (computable in $AC^0 \circ MOD_2$ in this case), made a strong conjecture; namely that every $AC^0 \circ MOD_2$ circuit has a quasipolynomially heavy Fourier coefficient. Since IP only has small Fourier coefficients, this conjecture also entails the same consequence considered by Servedio and Viola, and simply showing that IP cannot be computed by small $AC^0 \circ MOD_2$ circuits is again a special case of this problem.

Finally, Servedio and Viola [23] note that a special case of Valiant's matrix rigidity problem [28] is to exhibit a function that has low correlation with all sparse polynomials. $AC^0 \circ MOD_2$ circuits are in turn well-approximated by such sparse polynomials, so giving explicit functions that are not correlated with any $AC^0 \circ MOD_2$ functions is again a natural special case; and IP is again the natural candidate for such a function.

Proving lower bounds for $AC^0 \circ MOD_2$ circuits computing IP is challenging since the usual techniques from the literature do not immediately apply. Specifically, although Razborov's technique [21] establishes strong lower bounds against $AC^0[2]$, we note that IP *does* have small $AC^0[2]$ circuits. There is thus no hope in using Razborov's technique directly to prove

lower bounds for IP. And of course, techniques based on random restrictions are helpless against the input layer parity gates.

Servedio and Viola noted that it follows from Jackson's work [8, Fact 8] that depth-3 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuits (i.e., a DNF of parities) cannot approximate IP. Also, Jukna [9] has shown that such circuits computing IP must have exponential size (a bound recently optimized by Cohen and Shinkar [4]). And yet, as Servedio and Viola noted, nothing is known about depth-4 circuits, let alone $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuits of arbitrary depth.

1.1 Our results

In this work, we give the first nontrivial (superlinear) lower bound for IP against (arbitrary depth) $\mathrm{AC}^0 \circ \mathrm{MOD}_2$. In fact, our result is slightly stronger and applies to the broader class of *bent* functions (i.e., functions whose Fourier coefficients are all equal in magnitude, IP being a special case).

▶ **Theorem 2.** *If C is an $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit of depth k and size S that computes the* IP *function on n variables, then $S = \Omega(n^{1+4^{-k}})$.*

The proof of this theorem follows by an adaptation of the results of Chaudhuri and Radhakrishnan [3] who showed a similar bound for AC^0 circuits; a similar adaptation for $\mathrm{AC}^0[2]$ circuits was previously given by Kopparty and Srinivasan [13].

Our main theorem is an $\tilde{\Omega}(n^2)$ $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ lower bound for IP:

▶ **Theorem 3.** *Any depth-4 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit computing the* IP *function on n variables must have size $s = \Omega(n^2/\log^6 n)$.*

An intuitive interpretation of the above results is the following. IP is a means to "generate" all possible parities on n bits. $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuits are merely AC^0 circuits that are given access to an arbitrary but fixed set of parity functions, bounded in number by the size of the circuit. Our results address the question of how much these few parities can aid the computation of most remaining parities.

1.2 Our technique: a moment-matching bound

At the heart of this second lower bound is a lemma that may be of independent interest:

▶ **Lemma 4** (Moment-matching bound)**.** *Let X and Y be random variables taking values in $\{0, 1, 2, \ldots, s\}$. Suppose that the first d moments of X and Y are equal. Then,* $\Pr(Y = 0) \leq \Pr(X = 0) + e^{-\Omega(d/\sqrt{s})}$.

Several other "moment-matching" bounds appear in the literature, and here we briefly discuss the relationship of our work to these bounds. First, the classical *"truncated moments" problem* concerns the conditions for the existence of a probability distribution on a given set with a given sequence of moments [2, 5]. But, as noted by Rashkodnikova et al. [20], the solutions generated by these techniques do not necessarily lie on integers, and so the conditions refer to a different class of random variables. Klivans and Meka [12] likewise considered bounds on the difference in probability of general events that may be induced by distributions with d matching moments. Their bounds apply to much more general properties (than simply the event $X = 0$) and much more general distributions; as such, in spite of some

similarities in the techniques employed in their work[1], they do not obtain bounds in a useful form for our purposes. Rashkodnikova et al. [20] in turn consider nonnegative, bounded, and integer-valued random variables as we do, but they consider a different property; namely, given that the first d moments are *proportional* (not necessarily identical), they maximize their ratio.

Interestingly, it turns out that the moment-matching bound we obtain has a close technical relationship to the *approximate inclusion-exclusion* bounds obtained by Linial and Nisan [15].[2] Indeed, the technique we use to prove Lemma 4 is essentially the same as the core technique underlying Linial and Nisan's work, and in fact, we can show that our moment-matching lemma is essentially equivalent to Linial and Nisan's approximate inclusion-exclusion bounds (details of this equivalence appear in the full version of the paper). In view of the naturalness of the statement of our moment-matching bound, we believe that this lemma may be of interest, even if one is familiar with the approximate inclusion-exclusion bounds.

1.3 Overview of the depth-4 lower bound

Our argument consists of two main steps: (1) We show that any depth-4 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit (without loss of generality, with an AND top gate) of size $s \leq n^2$ computing the Inner Product function must have a one-sided approximation by a DNF of parities in which the terms are all small: It is correct when it outputs 0, and the circuit outputs zero on at least a $1/n^2$ fraction of inputs. (2) We then show that such one-sided approximators for the Inner Product function can only output 0 with small probability, which can be made smaller than $1/n^2$ for some $s = O(n^2/\mathrm{poly}\log n)$.

The first part is relatively straightforward. We let a candidate circuit for the inner product function of size $s \leq n^2$ be given. We first obtain a one-sided approximation to our circuit by invoking the Discriminator Lemma of Hajnal et al. [6] to obtain a depth-3 circuit (eliminating the top AND layer) that is correct whenever it reports 0, and reports 0 on a large ($\geq 1/n^2$) fraction of the inputs. We then reduce the fan-in of the second (from bottom) layer of AND gates by trimming the AND gates with large fan-in at a slight cost in the approximation error (asymptotically smaller than $1/n^2$).

Towards the second part of our argument, we consider the *degree* of an arbitrary parity in the $\{\pm 1\}$-representation in terms of the original variables as well as the bottom layer parities. That is, the degree of a parity χ is now defined as the minimum number of variables and/or bottom layer parities that need to be added together (over $\mathbb{F}_2$) to obtain χ: e.g., a single parity gate (new variable) has degree 1, and a parity of k new variables (parity gates or old variables) has degree $\leq k$. Given the size of the circuit s, we obtain that w.h.p. over the setting of the input y variables, the inner product function $\mathrm{IP}(x, y)$ is a parity in the x variables that remains of high degree (at least $\Omega(n/\log s)$) over these new variables.

We show that, for a $1 - o(1)$ fraction of fixings of the y variables, the probability that our circuit outputs 0 when $\mathrm{IP}(x, y) = 0$ is small as follows. We apply the above-mentioned moment-matching bound (Lemma 12) to the random variable $N(x)$ (over a random x) that counts the number of the AND gates in the depth-3 approximator obtained by the Discriminator Lemma that output 1. We can then show that the first $m = \tilde{\Omega}(n)$ moments of $(N(x) \mid \mathrm{IP}(x, y) = 0)$ and $(N(x) \mid \mathrm{IP}(x, y) = 1)$ are identical and $\Pr_x(N(x) = 0 \mid \mathrm{IP}(x, y) = 1) = 0$ since $N(x) = 0$

[1] Indeed, although like us, Klivans and Meka related this problem to the existence of some polynomials via LP duality, for Klivans and Meka, constructing these (sandwiching) polynomials was the *problem*, not the *solution*.

[2] We are indebted to Johan Håstad for pointing out to us the similarity in the underlying technique.

precisely when the OR gate at the output of the depth-3 one-sided approximator outputs 0, in which case the circuit is correct. Using this information in a linear-programming based proof, we show that $\Pr_x(N(x) = 0 \mid \mathrm{IP}(x, y) = 0) \lesssim e^{-\tilde{\Omega}(m/\sqrt{s})}$. For our m, if $s \leq n^2/\operatorname{poly}\log n$, the upper bound becomes smaller than $1/n^2$, completing the second part and finishing the proof.

To see that the low-degree moments match, we note that $N(x)$ is represented by a low-degree polynomial: In the $\{0,1\}$-representation, it is simply the summation of monomials of degree $O(\log n)$ corresponding to the second-level AND gates (recall that the degree remains the same in the $\{\pm 1\}$-representation). In the $\{\pm 1\}$-representation, however, it is then clear that the parity in x that we obtain from our setting of the y variables in $\mathrm{IP}(x, y)$ is (w.h.p. over y) uncorrelated with $N(x)$. In other words, $\mathbf{E}_x(N(x) \mid \mathrm{IP}(x, y) = 0) = \mathbf{E}_x(N(x) \mid \mathrm{IP}(x, y) = 1)$. This argument can be seen to hold for larger moments as well.

We prove the moment-matching bound by writing a linear program for the probability distribution satisfying the given moment constraints over $\{0, \ldots, s\}$ that maximizes the probability of obtaining 0. We bound the value of this LP by giving an explicit dual-feasible solution; It turns out that the dual can be rewritten as maximizing the lower bound on the values a bounded degree polynomial attains at the integer points in $[0, s]$, given that it takes value 0 at the origin and is also upper bounded by 1 at these integer points. This is quite similar to the conditions for approximators for the OR function sought by Nisan and Szegedy [17], and our solution follows theirs, using Chebyshev polynomials to construct the desired (essentially optimal, cf. Paturi [19]) polynomial.

Alternative proof. There is also an alternative way of completing the proof of our lower bound that uses approximate inclusion-exclusion directly. We believe that the main proof we describe here, using moment-matching, is more natural. This alternative proof appears in the full version of the paper.

1.4 Preliminaries and notation

All logarithms in this paper are to the base 2. Let $n \geq 1$ be a natural number. We use $[n]$ to denote the set $\{1, \ldots, n\}$. We use $\mathbb{F}_2$ for the field with 2 elements $\{0, 1\}$, where addition and multiplication are performed modulo 2. We view elements in $\mathbb{F}_2^n$ as n-bit binary strings – that is elements of $\{0,1\}^n$ – alternatively. If x and y are two n-bit strings, then $x + y$ (or $x - y$) denotes bitwise addition (i.e. XOR) of x and y. We view $\mathbb{F}_2^n$ as a vector space equipped with an inner product $\langle x, y\rangle$, which we take to be the standard dot product: $\langle x, y\rangle = \sum_{i=1}^n x_i y_i$, where all operations are performed in $\mathbb{F}_2$.

Often times, it is convenient to switch the range of Boolean functions between $\{0, 1\}$ and $\{-1, 1\}$. We use $f^{\pm}$ to denote the $\{-1, 1\}$-valued Boolean function corresponding to f. They are related by $f^{\pm} = (-1)^f = 1 - 2f$ and $f = (1 - f^{\pm})/2$.

A *linear threshold* gate $T_k^{\mathbf{a}}(x_1, \ldots, x_t)$ of fan-in t outputs 1 if and only if $\sum_{i=1}^t a_i x_i \geq k$, where $\mathbf{a} = (a_1, \ldots, a_t)$ is vector of weights. The Discriminator Lemma of Hajnal et al. is a powerful tool for proving lower bounds of threshold circuits.

▶ **Lemma 5** (Discriminator lemma, Lemma 3.3 in [6]). *Let $C = T_k^{\mathbf{a}}(C_1, \ldots, C_m)$ be a circuit on n inputs with a threshold gate at the top level, and write $a = \sum_{i=1}^m |a_i|$. Let $A, B \subseteq \{0,1\}^n$ be any two disjoint sets of inputs such that the circuit C accepts A and rejects B. Then there exists a subcircuit C_i, $i \in [m]$, such that $|\Pr_A(C_i(x) = 1) - \Pr_B(C_i(x) = 1)| \geq 1/a$, where $\Pr_A(C_i(x))$ (resp., $\Pr_B(C_i(x))$) denotes the uniform probability over the set A (resp., B).*

2 Lower bound for depth-4 circuit

In this section we will show an $\tilde{\Omega}(n^2)$ lower bound for any depth-4 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit that computes $\mathrm{IP}(x, y)$. Note that all circuits here are allowed to have negations below the XOR gates; these negations are not counted in the depth of the circuit.

2.1 Depth-3 discriminator

Let C be any depth-4 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit that computes $\mathrm{IP}(x, y)$. First, without loss of generality, we may assume the top layer gate of C is an AND gate; the case that top layer gate is an OR gate follows a similar argument[3]. Second, suppose $C = \mathrm{AND}(C_1, \ldots, C_m)$, where each subcircuit C_i is a parity-DNF circuit; then because $C(x, y) = \mathrm{IP}(x, y)$ for *every* input, each subcircuit C_i must compute IP with *one-sided* error only. Specifically, for every input (x, y) with $\mathrm{IP}(x, y) = 1$ and every i, $C_i(x, y) = 1$.

We invoke a consequence of the Discriminator Lemma of Hajnal et al. [6].

▶ **Claim 6** (Consequence of Lemma 5). *There is a subcircuit C_i, $i \in [m]$, such that $\Pr_{(x,y):\, \mathrm{IP}(x,y)=1}(C_i(x, y) = 1) = 1$, and $\Pr_{(x,y):\, \mathrm{IP}(x,y)=0}(C_i(x, y) = 1) \leq 1 - 1/m$.*

We call such a depth-3 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit C_i a *one-sided $1/m$-discriminator* for IP. Our main lemma is an upper bound on the discriminator parameter $1/m$ of such discriminators in terms of its size.

▶ **Lemma 7** (Main). *Suppose that a depth-3 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit of size s is a one-sided ϵ-discriminator for IP. Then ϵ satisfies*

$$\epsilon \leq 4 \exp\left(-\sqrt{\frac{n^2}{128 s \log^2 n \log^2 s}}\right) + \frac{4s}{n^4} + 2^{-n/2}.$$

The proof of Lemma 7 is discussed in Section 2.3. Assuming Lemma 7, the proof of Theorem 3 is straightforward. If $m \geq n^2$, then we are done already. Suppose otherwise, so $\epsilon \geq 1/n^2$. Then by Lemma 7, the size of discriminator subcircuit C_i is of size at least $s = \Omega(\frac{n^2}{\log^6 n}) = \tilde{\Omega}(n^2)$.

2.2 Random y-restrictions

Let C' be a size-s depth-3 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit which is a one-sided ϵ-discriminator for IP. So $\Pr_{(x,y):\, \mathrm{IP}(x,y)=0}(C'(x, y) = 0) \geq \epsilon$, and $C' = \mathrm{OR}(f_1, f_2, \ldots, f_{s'})$, where each f_i is an AND of parities and $s' < s$. Without loss of generality, we can assume that none of these AND gates are constant (i.e., always 0 or 1).

Reducing the fan-in of AND gates

Define the *codimension* of f_i (each of which is an AND of parities) to be the codimension of the subspace corresponding to the coset of inputs on which f_i evaluates to 1.

For example, if $f_1 = \mathrm{AND}(x_1 + x_2, x_1 + x_3, \neg(x_2 + x_3))$, then $x_1 + x_2$ and $x_1 + x_3$ both evaluating to 1 necessarily implies that $\neg(x_2 + x_3)$ evaluates to 1. Hence, the set of inputs for

[3] One way to see this is to notice that our proof also shows the same lower bound for the negation of the Inner Product function (since negating only incurs an affine shift that our methods are not sensitive to). Thus it suffices to note that when the top gate is an OR one can just negate the layers and get a circuit in which the top gate is AND that computes the negation of the Inner Product.

which $f_1(x) = 1$ is the affine subspace specified by $\{x_1 + x_2 = 1 \wedge x_2 + x_3 = 1\}$; consequently, the codimension of f_1 is 2.

The codimension of f_i measures the "effective" fan-in of the AND gate in C'. It is straightforward that without loss of generality one can assume the co-dimension of each AND gate to be equal to its fan-in (one can simply eliminate linearly dependent inputs to each AND gate). From now on, we assume that all redundant parity inputs have already been removed and each AND gate in C' has its fan-in equal to its codimension. Our next step is trim those AND gates of C' whose fan-in is large.

Call an AND gate in C' "bad" if its fan-in is larger than $4 \log n$. We reduce C' to a circuit C'' by trimming all "bad" AND gates to an arbitrary set of $4 \log n$ inputs in their fan-in. Note that each trimmed AND gate may cause an error, only from 0 to 1, and only when all its (non-trimmed) inputs evaluate to 1 (an event that happens with probability at most $2^{-4 \log n}$, since the inputs of each gate are uniform and independent). Define $\tau = \Pr_{x,y}(C'(x, y) \neq C''(x, y))$. By the union bound, $\tau \leq s2^{-4 \log n} = s/n^4$. Further, if $C'(x, y) \neq C''(x, y)$ then we must have $C'(x, y) = 0$ and $C''(x, y) = 1$. In other words, if $\epsilon' := \Pr_{(x,y):\, \mathrm{IP}(x,y)=0}(C''(x, y) = 0)$, then $\epsilon' \geq \epsilon - \tau$, and moreover, if C' approximates IP with a one-sided error (i.e., $C' = 1$ whenever IP $= 1$), then so does C''.

▶ **Definition 8.** For a function $F(x, y)$ (resp., a circuit $C(x, y)$) that maps $\{0, 1\}^n \times \{0, 1\}^n$ to $\{0, 1\}$, a *y-restriction* $\rho \in \{0, 1\}^n$ is an assignment of all the y variables in the input according to ρ. Denote the resulting function F (resp., circuit C) after applying restriction ρ by $F|_\rho$ (resp., $C|_\rho$).

A simple fact exploited in the proof is that, for any y-restriction ρ, $\mathrm{IP}|_\rho$ is a parity over the x variables, which we denote by ℓ_ρ. Note that $\ell_\rho(x) = \sum_{i:\rho_i=1} x_i \bmod 2$. We next argue that for *any* fixed depth-3 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit C'', the parity function ℓ_ρ resulting from a random y-restriction ρ is of "high degree" with respect to the parity inputs of C'', and thus "hard" for the circuit.

Fix an arbitrary depth-3 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit C'', of which the fan-in of each AND gates is at most $4 \log n$. Let the parity inputs for C'' be $\ell_{(a_1, S_1^x, S_1^y)}, \ldots, \ell_{(a_{s'}, S_{s'}^x, S_{s'}^y)}$, where $a_i \in \{0, 1\}$, $S_i^x, S_i^y \subseteq [n]$, $\ell_{S_i^x, S_i^y}(x, y) = a_i + \sum_{j \in S_i^x} x_j + \sum_{j \in S_i^y} y_j$, and $s' < s$.

Observe that after applying a y-restriction ρ to C'', the inputs to $C''|_\rho$ become the x-part of the original parities or their negations, namely $\ell_{(a_i, S_i^x, S_i^y)}|_\rho = a_i' + \sum_{j \in S_i^x} x_j$ and $a_i' = a_i$ or $a_i' = 1 - a_i$. Since there is a natural one-to-one correspondence between subsets of $[n]$ and vectors in $\mathbb{F}_2^n$, we may use a set of vectors $S \subseteq \mathbb{F}_2^n$ to identify the set of parities (or their negations), namely $\{S_i^x\}_{i \in [s']}$, that are fed into $C''|_\rho$. A key point is that the subset S depends only on the circuit C'', and is essentially independent of the choice of y-restriction ρ. Note also that $|S| \leq s' < s$. In the following, we will slightly abuse notation and use a parity and the subset of $[n]$ corresponding to that parity interchangeably.

IP results in high degree parity under random restriction

Following standard additive combinatorial notation, for a subset $S \subseteq \mathbb{F}_2^n$ and a positive integer k, let $kS = \{x_1 + \cdots + x_k \colon x_1, \ldots, x_k \in S\}$. Clearly we have $|S \cup 2S \cup \cdots \cup kS| \leq (|S| + 1)^k$.

▶ **Definition 9.** For any $S \subseteq \mathbb{F}_2^n$ and $z \in \mathbb{F}_2^n$, the *S-degree* of z is the smallest integer d such that $z \in dS$, or ∞ if no such d exists. Further, the S-degree of a parity function $\langle \alpha, x \rangle$ for $\alpha \in \mathbb{F}_2^n$ is the S-degree of α.

Our next claim shows that for any fixed size-s depth-3 $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit C'', after applying a random y-restriction, then almost surely, the resulting parity function ℓ_ρ is of

high degree with respect to the parity inputs of $C''|_\rho$.

▶ **Claim 10.** *Let $S \subseteq \mathbb{F}_2^n$ be the set of input parities (or their negations) of $C''|_\rho$. Then with probability at least $1 - 2^{-n/2}$ over the choice of ρ, ℓ_ρ has S-degree larger than $n/(2\log s)$.*

Proof. Set $k = n/(2\log s)$. We have $|S \cup 2S \cup \cdots \cup kS| \leq (|S|+1)^k \leq s^k = s^{n/(2\log s)} = 2^{n/2}$, so the probability that the S-degree of ℓ_ρ being at most k is no more than $2^{n/2}/2^n = 2^{-n/2}$. ◀

We will call a y-restriction ρ *good* (for circuit C'') if the S-degree of ℓ_ρ is larger than $n/(2\log s)$ and *bad* otherwise. Therefore a random ρ is bad with probability at most $2^{-n/2}$. Let $N_\rho : \{0,1\}^n \to \mathbb{N}$ be the function that counts the number of AND gates of $C''|_\rho$ that are 1.

▶ **Lemma 11.** *Let $S \subseteq \mathbb{F}_2^n$ be the set of input parities (or their negations) of $C''|_\rho$. Suppose ℓ_ρ has S-degree larger than k and each* AND *gate in $C''|_\rho$ has fan-in at most w, then N_ρ^i is uncorrelated with ℓ_ρ for $i = 1, 2, \ldots, k/w$. In other words, $\mathbf{E}_x(N_\rho^i(x) \mid \ell_\rho(x) = 0) = \mathbf{E}_x(N_\rho^i(x) \mid \ell_\rho(x) = 1)$ for $i = 1, 2, \ldots, k/w$.*

Proof. For convenience, we switch to the $\{-1, 1\}$ representation of Boolean values for parities, i.e. $\chi(x) = (-1)^{\ell(x)}$. Let $\chi_1, \ldots, \chi_{s'}$ be the input parities of $C''|_\rho$, and let $f_1', f_2', \ldots, f_{t'}'$ (each still taking value in $\{0,1\}$) be the functions computed by the AND gates in $C''|_\rho$. Then $N_\rho(x) = f_1'(x) + f_2'(x) + \cdots + f_{t'}'(x)$. Note that since each $f_j'(x)$ is the AND of at most w parities from $\{\chi_1, \ldots, \chi_{s'}\}$, $f_j'(x)$ can be expressed as a polynomial of degree at most w with $\chi_1, \ldots, \chi_{s'}$ as variables (indeed, if $f_1'(x) = \mathrm{AND}(\chi_1(x), \ldots, \chi_w(x))$, then $f_1' = (\frac{1-\chi_1}{2}) \cdots (\frac{1-\chi_w}{2})$). Consequently, N_ρ^i is a polynomial of degree at most $i \cdot w$ in $\chi_1, \ldots, \chi_{s'}$. Now because ℓ_ρ is of S-degree larger than $k \geq i \cdot w$ for $i = 1, 2, \ldots, k/w$, we have that ℓ_ρ is not in the support of the polynomial representation of N_ρ^i. Finally, by the orthogonality of parities, letting $\chi_\rho(x) := (-1)^{\ell_\rho(x)}$, we have

$$0 = \langle N_\rho^i, \ell_\rho \rangle = \mathbf{E}_x(N_\rho^i(x) \cdot \ell_\rho(x)) = \frac{1}{2}\left(\mathbf{E}_x(N_\rho^i(x) \mid \chi_\rho(x) = 0) - \mathbf{E}_x(N_\rho^i(x) \mid \chi_\rho(x) = 1)\right). \quad \blacktriangleleft$$

Since each of the AND gates in C'' has fan-in at most $4\log n$ and the S-degree of ℓ_ρ is larger than $n/(2\log s)$ for every good ρ, Lemma 11 implies that N_ρ^i is uncorrelated with ℓ_ρ for i up to $d := n/(8\log n \log s)$ for every good y-restriction.

2.3 Linear programming and feasible solutions based on Chebyshev polynomials (Proof of Lemma 7)

In this section we prove Lemma 7. Let X_ρ (resp. Y_ρ) be the (conditional) random variable of $N_\rho(x) \mid (\ell_\rho(x) = 1)$ (resp., $N_\rho(x) \mid (\ell_\rho(x) = 0)$). Our key observation is that, by Lemma 11, these two random variables both take values in $\{0, 1, \ldots, s'\}$ and their moments match up to $n/8\log n \log s$. So intuitively, if s' is not too large, these two random variables should have close to identical distributions; in particular, we should have $\Pr(X_\rho = 0) \approx \Pr(Y_\rho = 0)$. Since C' (and thus, C'') computes IP with only one-sided error, we have that for *every* y-restriction ρ, $\Pr(C''|_\rho(x) = 1 \mid \ell_\rho(x) = 1) = 1$ and consequently $\Pr(X_\rho = 0) = 0$. Combining this with the consequence of moment-matching condition between X_ρ and Y_ρ implies that $\Pr(Y_\rho = 0) \approx 0$ for every good ρ.

Fix a good y-restriction ρ. The following key lemma provides the desired upper bound on $\Pr(Y_\rho = 0) = \Pr_x(C''|_\rho(x) = 0 \mid \ell_\rho(x) = 0)$. The lemma allows an additional parameter ξ_ρ which in our application is set to zero (since we have $\Pr_x(C''|_\rho(x) = 0 \mid \ell_\rho(x) = 1) = 0$). However, since the lemma applies to general random variables with matching moments and may be of independent interest, it is stated in the more general form.

$$
\begin{array}{lll}
\text{Max} & y_0 & \text{(primal LP)} \\
\text{s.t.} & \sum_{i=0}^{s'} i^j x_i - \sum_{i=0}^{s'} i^j y_i = 0, \quad j = 1, \ldots, d & \\
& \sum_{i=0}^{s'} x_i = 1 & \\
& \sum_{i=0}^{s'} y_i = 1 & \\
& x_0 = \xi_\rho & \\
& x_i, y_i \geq 0, \quad i = 0, \ldots, s' &
\end{array}
$$

$$
\begin{array}{lll}
\text{Min} & 1 - (1 - \xi_\rho)z & \text{(dual LP)} \\
\text{s.t.} & p \text{ is a polynomial of degree at most } d & \\
& p(0) = 0 & \\
& z \leq p(i) \leq 1 \quad i = 1, \ldots, s' &
\end{array}
$$

Figure 1 Primal LP for finding maximum $\Pr(Y = 0)$ (top), and the final dual LP for finding maximum $\Pr(Y = 0)$ (bottom).

▶ **Lemma 12.** *Let X_ρ and Y_ρ be random variables supported on $\{0, 1, \ldots, s'\}$ such that*
(i) $\mathbf{E}(X_\rho^i) = \mathbf{E}(Y_\rho^i)$ *for $i = 1, \ldots, d$; and*
(ii) $\Pr(X_\rho = 0) = \xi_\rho$.
Then $\Pr(Y_\rho = 0) \leq \xi_\rho + 4(1 - \xi_\rho)e^{-d/\sqrt{2s'}}$.

Proof. We set up a linear program to maximize $\Pr(Y_\rho = 0)$ over the choices of random variables X_ρ and Y_ρ. The variables in the LP are x_i and y_i where $x_i = \Pr(X_\rho = i)$ and $y_i = \Pr(Y_\rho = i)$. Aside from nonnegativity and an upper bound constraint for x_0, we have $d+2$ equality constraints; 2 of them to force X_ρ and Y_ρ to have probability distributions, and the other d for the moment matching condition. The linear program and the corresponding dual are listed in Figure 1. In order to upper bound the value of the primal program (i.e., $\Pr(Y_\rho = 0)$) and prove Lemma 12, it suffices to find a feasible solution to the corresponding dual program. We show that by choosing the polynomial p in the dual to be a Chebyshev polynomial (appropriately shifted and scaled), an essentially optimal bound on the primal value can be found.

Denote by P_ρ the value of the primal LP in Figure 1. The dual linear program is

$$
\begin{array}{ll}
\text{minimize} & z_{d+1} + z_{d+2} + \xi_\rho z_{d+3} \\
\text{such that} & z_{d+1} + z_{d+3} \geq 0 \\
& z_{d+2} \geq 1 \\
& (\sum_{j=1}^{d} i^j z_j) + z_{d+1} \geq 0 \qquad i = 1, \ldots, s' \\
& (\sum_{j=1}^{d} -i^j z_j) + z_{d+2} \geq 0 \qquad i = 1, \ldots, s'
\end{array}
$$

We can interpret the dual as a problem involving polynomials. The feasible solutions correspond to coefficients of degree-d polynomials $p(x) = \sum_{j=1}^{d} z_j x^j$ with $p(0) = 0$. By duality, the objective value of the dual is nonnegative for any feasible solution. Thus, by scaling, we can assume $z_{d+2} = 1$. Further, since z_{d+3} only appears in the first constraint in this minimization problem, we can always take $z_{d+3} = -z_{d+1}$.

Rearranging the last two constraints of this problem yields that $p(1), p(2), \ldots, p(s')$ must all lie in the interval $[-z_{d+1}, z_{d+2}]$. Setting $z = -z_{d+1}$, the dual problem can be rephrased

as the final Dual LP showed in Figure 1.

Denote by D_ρ the value of this dual LP. By the Strong Duality Theorem, $P_\rho = D_\rho$, and therefore if $V(p)$ is the value of any feasible solution corresponding to a polynomial p to the dual LP, we have $\Pr(Y_\rho = 0) \le P_\rho = D_\rho \le V(p)$.

The above modified problem about polynomials is strikingly similar to the problem of approximating OR functions by low-degree polynomials, for which Nisan and Szegedy gave an optimal solution based on Chebyshev polynomials [17]. Recall that Chebyshev polynomial (of the first kind) $T_k(x)$ is a degree k polynomial defined by $T_k(x) = \cos(k \arccos(x))$, or more explicitly

$$T_k(x) = \frac{1}{2}\left[\left(x + \sqrt{x^2-1}\right)^k + \left(x - \sqrt{x^2-1}\right)^k\right].$$

It is well-known that $-1 \le T_k(x) \le 1$ for all $x \in [-1,1]$ and $T_k(x) > 1$ when $x > 1$. For a detailed treatment of Chebyshev polynomials see e.g. [22].

We now construct a dual feasible polynomial p based on Chebyshev polynomials. Define

$$q(x) := 1 - \frac{T_d(\frac{s'-x}{s'-1})}{T_d(\frac{s'}{s'-1})}, \qquad p(x) := \frac{q(x)}{\max_{i\in\{1,\ldots,s'\}} q(i)}.$$

Clearly $p(x)$ is a degree d polynomial, $p(0) = 0$ and $p(i) \le 1$ for $i = 1, \ldots, s'$, hence a feasible solution to the dual LP.

▶ **Claim 13.** *The value of $p(x)$ with respect to the dual LP satisfies that $D(p) \le \xi_\rho + \frac{2(1-\xi_\rho)}{T_d(1+\frac{1}{s'})}$.*

Proof. Since $-1 \le T_d(w) \le 1$ for all $-1 \le w \le 1$, then for $i = 1, \ldots, s'$,

$$\begin{aligned} p(i) &= \frac{q(x)}{\max_{i\in\{1,\ldots,s'\}} q(i)} = \frac{T_d(1+\frac{1}{s'-1}) - T_d(\frac{s'-i}{s'-1})}{T_d(1+\frac{1}{s'-1}) - \min_{j\in[s']} T_d(\frac{s'-j}{s'-1})} \\ &\ge \frac{T_d(1+\frac{1}{s'-1}) - 1}{T_d(1+\frac{1}{s'-1}) + 1} = \frac{1 - 1/T_d(1+\frac{1}{s'-1})}{1 + 1/T_d(1+\frac{1}{s'-1})} \ge 1 - \frac{2}{T_d(1+\frac{1}{s'-1})} \ge 1 - \frac{2}{T_d(1+\frac{1}{s'})}. \end{aligned}$$

Therefore the value z in the objective function of dual LP is at least $z \ge 1 - \frac{2}{T_d(1+\frac{1}{s'})}$ and the claim follows. ◀

We will need the following two inequalities bounding $T_k(x)$'s growth when $x \ge 1$.

▶ **Claim 14.** *For any nonnegative integer k, we have*[4]

1. *$T_k(1+\mu) \ge \frac{1}{2} e^{(\sqrt{2\mu+\mu^2})k/2}$ for all real number $0 \le \mu \le 1$.*
2. *$T_k(1+\mu) \le e^{2(\sqrt{2\mu+\mu^2})k}$ for all $\mu \ge 0$.*

Proof. For the first part, using that $1 + x \ge e^{x/2}$ for $0 \le x \le 2$, we obtain

$$T_k(1+\mu) \ge \frac{1}{2}(1 + \mu + \sqrt{2\mu+\mu^2})^k \ge \frac{1}{2}(1 + \sqrt{2\mu+\mu^2})^k \ge \frac{1}{2} e^{(\sqrt{2\mu+\mu^2})k/2},$$

for all $0 \le \mu \le 1$.

For the second part, by the standard inequality $(1 + t/n)^n \le e^t$ for all nonnegative t and n,

$$T_k(1+\mu) \le (1 + \mu + \sqrt{2\mu+\mu^2})^k \le (1 + 2\sqrt{2\mu+\mu^2})^k \le e^{2(\sqrt{2\mu+\mu^2})k}.$$ ◀

[4] The second inequality also appeared in [19].

Finally, by setting $\mu = 1/s'$ in the first inequality of Claim 14, we have $T_d(1+1/s') \geq \frac{1}{2}e^{(\sqrt{2/s'+1/s'^2})d/2} \geq \frac{1}{2}e^{\sqrt{d^2/2s'}}$. Combining this with Claim 13, we get $\Pr(Y_\rho = 0) \leq \xi_\rho + 4(1-\xi_\rho)e^{-d/\sqrt{2s'}}$, which completes the proof of Lemma 12. ◀

In order to complete the proof of Lemma 7, recall that X_ρ (resp. Y_ρ) is the (conditional) random variable of $N_\rho(x) \mid (\ell_\rho(x) = 1)$ (resp., $N_\rho(x) \mid (\ell_\rho(x) = 0)$), where $N_\rho(x)$ counts the number of AND gates in $C''|_\rho$ that evaluate to 1. Since $C''|_\rho$ provides a one-sided approximation of the function ℓ_ρ, we have that $\xi_\rho := \Pr_x(N_\rho(x) = 0 \mid \ell_\rho(x) = 1) = 0$.

Taking $d = \frac{n}{8 \log n \log s}$ and $s' < s$ into Lemma 12, we have that for any good y-restriction ρ,

$$\begin{aligned}\Pr_x(C''|_\rho(x) = 0 \mid \ell_\rho(x) = 0) = \Pr(Y_\rho = 0) &\leq \xi_\rho + 4(1-\xi_\rho)\exp(-d/2\sqrt{s}) \\ &= 4\exp(-d/2\sqrt{s}). \end{aligned} \tag{1}$$

Taking into account bad ρ's, which happens with probability at most $2^{-n/2}$ (according to Claim 10), the discriminator parameter ϵ' for $C''(x,y)$ can now be upper bounded as

$$\begin{aligned}\epsilon' &= \Pr_{x,\rho}(C''|_\rho(x) = 0 \mid \ell_\rho(x) = 0) = \mathbf{E}_\rho(\Pr_x(C''|_\rho(x) = 0 \mid \ell_\rho(x) = 0)) = \mathbf{E}_\rho(Y_\rho) \\ &= \mathbf{E}_{\text{good }\rho}(Y_\rho)\Pr(\rho \text{ is good}) + \mathbf{E}_{\text{bad }\rho}(Y_\rho)\Pr(\rho \text{ is bad}) \leq 4\exp(-d/2\sqrt{s}) + 2^{-n/2}.\end{aligned}$$

Finally, since $\epsilon' \geq \epsilon - \tau$, where we recall that $\tau = \Pr_{x,y}(C'(x,y) \neq C''(x,y)) \leq s/n^4$, the proof of Lemma 7 is complete.

2.4 Limitations of our approach

We remark that the $\tilde{\Omega}(n^2)$ lower bound is optimal (up to a polylogarithmic factor) for our current approach. This follows from a theorem of Paturi [19], which states that if $p(x)$ is a degree d polynomial such that $0 \leq p(i) \leq 1$ for $i = 0, 1, \ldots, s$ and $|p(1) - p(0)| \geq c$ for some constant c, then $d = \Omega(\sqrt{s})$, or equivalently $s = O(d^2)$. Since in our setting $d = \Theta(n/\log n \log s)$, the best lower bound one can show in the current framework is $\tilde{O}(n^2)$.

3 Superlinear Lower Bound for General Circuits

In this section we prove the following superlinear lower bound for $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuits of arbitrary depth. Throughout this section we find it more convenient to use $(x_1, \ldots, x_n)$ as the entire input to IP rather than the two-input notation $(x_1, \ldots, x_n, y_1, \ldots, y_n)$ used previously. We remark that the results of this section hold for a more general class of functions than IP, namely *bent functions*[5]. We state the results here for IP, and prove them for bent functions in the appendix.

▶ **Theorem 15.** *If C is an $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit of depth k and size S that computes $\mathrm{IP}\colon \{0,1\}^n \to \{0,1\}$, then $S = \Omega(n^{1+4^{-k}})$.*

[5] A Boolean function is bent if all its Fourier coefficients are equal in magnitude. The Inner Product function (IP) is a special case. In fact, our result holds for any function whose Fourier coefficients are all exponentially small in magnitude.

Deterministic restrictions

The high level idea of the proof is to adapt the technique of "deterministic restrictions" [3] to $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuits. In contrast to *random restrictions* which simplify circuits probabilistically, deterministic restrictions aim to show that, if the circuit size is small, then one can find a (small) set of input variables *deterministically* based on the structure of the circuit, such that fixing them forces the circuit to output a constant. This implies that small circuits fail to compute functions that cannot be made constant without setting a large number of input variables. The only twist when applying this framework to $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuits is, instead of fixing independent input variables, one now fixes linear functions which in general are no longer independent. We use a folklore result (called the *Folk Lemma* below) that IP can not be made constant by imposing less than $n/2$ linear constraints on the inputs; i.e., IP is not constant on a linear subspace of dimension more than $n/2$.

The main ingredient of the proof is the following lemma, which is the exact analogue of a result of Chaudhuri and Radhakrishnan [3] for AC^0 circuits.

▶ **Lemma 16.** *Let $C(x)$ be an $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuit of depth k and size S, with variable inputs $x_1, \ldots, x_n$ and bottom parity gates $p_1(x), \ldots, p_r(x)$. Then there exists a set of t linearly independent linear restrictions, $t < 5S^{1-4^{-k}}$, such that imposing them on $x_1, \ldots, x_n$ makes $C(x)$ constant (on the restricted space).*

Proof. We will adapt the argument of [3]. The algorithm of [3] constructs a partial assignment to the inputs of an AC^0 circuits so that the output is fixed and the number of fixed variables is small. In particular, it fixes the values of gates at each level (by fixing the bottom variables and propagating the values up the circuit), starting at level 0 (the input level), and proceeding successively up to the output gate at level k. The specific way of fixing these gates ensures that after level i is fixed, all gates at levels $j \leq i$ have both small fan-in and small fan-out (fan-ins and fan-outs are defined with respect to the current partial restriction and gates that are not fixed yet). At the end of such fixing, a so-called "regular" circuit is obtained. Then it is straightforward to show that one can fix an additional small number of variables of such regular circuit to make it output a constant. Our argument proceeds in an almost identical way. However, we fix *parities* in addition to input variables, and once a new parity gate is fixed, we need to fix the free parity gates which linearly depend on the fixed parity gates. This can only possibly reduce the number of parity gates needed to be fixed in the process, thus the original proof works in the setting of $\mathrm{AC}^0 \circ \mathrm{MOD}_2$ circuits as well. We defer the details to the full version of the paper. ◀

Now we are ready to prove the main theorem of this section.

Proof of Theorem 15. Suppose C has size $S < \frac{1}{5}n^{1+4^{-k}}$ (hence, it has at most that many parity gates) and computes the IP function. By Lemma 16, there exists a set of linearly independent linear restrictions of size at most $5S^{1-4^{-k}} < (n^{1+4^{-k}})^{1-4^{-k}} = n^{1-16^{-k}} < n/2$ (for large enough n), under which C becomes a constant function. But by the Folk Lemma, we must impose at least $n/2$ linear restrictions to make IP a constant; a contradiction. ◀

Abstract

We prove exponential lower bounds on the size of semantic read-once 3-ary nondeterministic branching programs. Prior to our result the best that was known was for D-ary branching programs with $|D| \geq 2^{13}$.

1 Introduction

A major question in complexity theory is whether polynomial-time is the same as log-space or nondeterministic log-space. One approach to this problem is to study time/space tradeoffs for problems in P. For example, for natural problems in P, does the addition of a space restriction prevent a polynomial time solution? In the uniform setting, time-space tradeoffs for SAT were achieved in a series of papers [7, 15, 8, 9]. Fortnow-Lipton-Viglas-Van Melkebeek [9] shows that any algorithm for SAT running in space $n^{o(1)}$ requires time at least $\Omega(n^{\phi-\epsilon})$ where ϕ is the golden ratio $((\sqrt{5}+1)/2)$ and $\epsilon > 0$. Subsequent works [18, 6] improved the time lower bound to greater than $n^{1.759}$.

In the nonuniform setting, the standard model for studying time/space tradeoffs is the *branching program*. In this model, a program for computing a function $f(x_1, \ldots, x_n)$ (where the variables take values from a finite domain D) is represented by a directed acyclic graph with a unique source node called the start node. Each nonsink node is labelled by a variable and the edges out of a node correspond to the possible values of the variable. Each sink node is labelled by an output value. For Boolean functions, there is one sink node called the accept node (or 1-node), and all other sink nodes are rejecting nodes. Executing the program on an input corresponds to following a path from the start node, using the values of the input variables to determine which edges to follow. The output of the program is the value labelling the sink node reached. A D-ary branching program is deterministic if each non-sink node has exactly D edges, one for every value in D.

The length of a branching program is the number of edges in the longest path. It is clear that length of a branching program can be seen as a measure of computation time. The size of a branching program is the number of nodes in the program. For a boolean function f_n of n variables, let $BP(f_n)$ denote the minimum size of a branching program computing f_n. $BP(f_n)$ is closely related to the space complexity $S(f_n)$ of a non-uniform Turing machine computing f_n: $S(f_n) = O(\log(\max\{BP(f_n), n\}))$ and $BP(f_n) = 2^{O(\max\{S(f_n), \log n\})}$ [5, 17]. This motivates the study of branching program size lower bounds. In particular, size lower bounds on length restricted branching programs translate to time/space tradeoffs.

The state of the art time/space tradeoffs for branching programs were proven in the remarkable papers by Ajtai [1] and Beame-et-al [3]. In the first paper, Ajtai exhibited a polynomial-time computable Boolean function such that any sub-exponential size deterministic branching program requires superlinear length. This result was significantly improved and extended by Beame-et-al who showed that any sub-exponential size randomized branching program requires length $\Omega(n\frac{\log n}{\log\log n})$.

Lower bounds for nondeterministic branching programs have been more difficult to obtain. In this model, there can be several arcs (or no arcs) out of a node with the same value for the variable associated with the node. An input is accepted if there exists at least one path consistent with the input from the source to the 1-node. A nondeterministic branching program computes a function f if its accepted inputs are exactly equal to $f^{-1}(1)$. From here on, we shall restrict our attention to non-deterministic branching programs.

Length-restricted nondeterministic branching programs come in two flavors: *syntactic* and *semantic*. A length l syntactic model requires that every path in the branching program has length at most l, and similarly a read-k syntactic model requires that every path in the branching program reads every variable at most k times. In the less restricted semantic model, the requirement is only for *consistent* accepting paths from the source to the 1-node; that is, accepting paths along which no two tests $x_i = d_1$ and $x_i = d_2$, $d_1 \neq d_2$ are made. This is equivalent to requiring that for every accepting path, each variable is read at most k times. Thus for a nondeterminsitic read-k semantic branching program, the overall length of the program can be unbounded.

Note that any syntactic read-once branching program is also a semantic read-once branching program, but the the opposite direction does not hold. In fact, Jukna [11] proved that semantic read-once branching programs are exponentially more powerful than syntactic read-once branching programs, via the "Exact Perfect Matching"(EPM) problem. The input is a (Boolean) matrix A, and A is accepted if and only if every row and column of A has exactly one 1 and rest of the entries are 0's i.e if it's a permutation matrix. Jukna gave a polynomial-size semantic read-once branching program for EPM, while it was known that syntactic read-once branching programs require exponential size [14, 13].

Lower bounds for syntactic read-k (nondeterministic) branching programs have been known for some time [16, 4]. However, for *semantic* nondeterministic branching programs, even for read-once, no lower bounds are known for polynomial time computable functions for the $|D| = 2$ case. The best lower bound known prior to our work is an exponential lower bound for semantic read-once (nondeterministic) $|D|$-way branching programs, where $|D| = 2^{13}$ [10]. In fact this lower bound actually holds more generally for semantic read-k but where $|D| = 2^{3k+10}$.

Jukna obtains his result by showing that any time restricted semantic branching program of small size has a large rectangle in $f^{-1}(1)$. He uses the explicit function of computing the characteristic function of a linear code having minimum distance $m + 1$ defined over $GF(q)$. Given a parity matrix Y,the function $g(Y, x) = 1$ iff x is a codeword. Since codewords in a

linear code of minimum distance $m+1$ can only have an m-rectangle of size 1 he argues that a time restricted branching program of length kn computing g requires a size of $2^{\Omega(n/k^2 4^k)}$. This exponential lower bound can be obtained whenever D is sufficiently large in comparison to k, specifically for $|D| = q \geq 2^{3k+10}$.

Jukna's result is an improvement over exponential lower bounds with a domain requirement of $2^{2^{ck}}$ obtained in [2]. Beame et.al [2] obtain their result by characterizing the function computed by a time restricted branching program of small size as a union of shallow decision forests where the size of the union depends on the size of the branching program. Each shallow forest is then shown to be representable by a collection of *small* number of βn-pseudo-rectangles in $f^{-1}(1)$. (Pseudo-rectangles are a generalization of what we call embedded rectangles later). This gives a representation of the branching program as a union of small (in the size 's') number of βn-pseudo-rectangles. Now, if for some function f the maximum size of a βn-pseudo-rectangle is $|D|^{(1-\psi_f(\beta))n}$ and the number of *yes*-instances $|f^{-1}(1)| \geq |D|^{(1-\eta(f))n}$ then the number of βn-pseudo-rectangles will be at least $|D|^{(\psi_f(\beta)-\eta(f))n}$. This yields an exponential lower bound on s for sufficiently large $|D|$ whenever $(\psi_f(\beta)-\eta(f))$ is bounded away from 0 by some $\epsilon > 0$. They then exhibit an explicit function with this property. Their function $QF_M : GF(q^n) \to \{0,1\}$ is based on quadratic forms using a modified Generalized Fourier Transform matrix. They show that there exists a constant $c > 0$ such that for all k and $\epsilon \in (0,1)$, if $D \geq 2^{2^{\frac{c}{\epsilon}k}}$ then a non-deterministic BP of length kn computing QF_M needs size at least $S = 2^{n \log^{1-\epsilon}|D|}$. For the specific case of $k = 1$, it can be shown that if their analysis of maximum size of βn-pseudo-rectangles in QF_M is tight, a domain size of at least $|D| \geq 2^{64}$ is needed.

Our main result is an exponential lower bound on the size of semantic read-once non-deterministic branching programs for a polynomial time decision problem f for 3-ary inputs. Similar in spirit to these previous results [10, 2] we show that a small sized semantic read once branching program is bound to have a large rectangle in $f^{-1}(1)$.

($\star$) However in addition, we show that one can always find a *balanced* rectangle in $f^{-1}(1)$ of size r^2 where r is some large constant.

A balanced rectangle is one which is reasonably close to being a square.

The particular polynomial time decision problem we use to prove the lower bound is: to decide if a polynomial over a finite field K evaluates to a value less than a certain threshold at a given input. The input is a pair (u, x) where u is the description of a degree $d-1$ polynomial over $[K]$ and $x \in [K]$, and we want to accept if and only if $u(x) < K^{1-\delta}$. We actually prove a stronger theorem: with high probability over all polynomials u, any nondeterministic semantic read-once branching program for what we shall call $Poly_u$ (along with a hyperplane constraint) requires exponential size. That is, even if the branching program knows the polynomial u, for a typical u it cannot efficiently do polynomial evaluation. The main properties of polynomials over finite fields we are using are polynomial interpolation, and Lemma 7, which might be interpreted to mean something like: the spread of values of a typical random polynomial of degree d over a field K is roughly close to being uniform over K, provided K is sufficiently large.

Continuing with the above observation ($\star$) that we can find a balanced rectangle in $f^{-1}(1)$ for a function with a small semantic read once branching program, since the number of balanced rectangles of a certain size $d = r^2$ is *small* and since each one of them can be a rectangle in $f^{-1}(1)$ for a relatively *small* number of degree d polynomials over K as a consequence of polynomial interpolation, we argue that there must be a polynomial with no balanced rectangle of this size in $f^{-1}(1)$ and hence the branching program computing it

should be *large*. A key idea of this argument is that for a balanced rectangle the sum of the lengths of the rectangle can be at most a *small* fraction of its area.

By a simple padding argument, we can modify our problem $Poly_u$ and actually achieve the lower bound for domain size $2+\epsilon$ for arbitrarily small $\epsilon > 0$. In this model, we can define the problem to have $N = n + M$ variables, $M = \Theta(N)$ of them with domain size 3 and the rest, with domain size 2, do not affect the output. In section 5, we show why it might be harder to prove lower bounds for semantic read-once branching programs when $|D| = 2$ by showing how these branching programs can altogether evade having an exponential number of states in many purported choices of bottleneck layer by giving polynomial upper bounds.

2 Definitions

Throughout this article, D denotes a finite set. For finite set N, D^N is the set of maps from N to D. An element of N is called a *variable index* or simply an *index*. We normally take N to be $[n]$ for some integer n, and write D^N for $D^{[n]}$. If $A \subseteq N$, a point $\sigma \in D^A$ is a *partial input* on A. For a partial input σ, $fixed(\sigma)$ denotes the index set A on which it is defined and $unfixed(\sigma)$ denote the set $N - A$. If σ and π are partial inputs with $fixed(\sigma) \cap fixed(\pi) = \emptyset$, then $\sigma\pi$ denote the partial input on $fixed(\sigma) \cup fixed(\pi)$ that agrees with σ on $fixed(\sigma)$ and with π on $fixed(\pi)$.

For $x \in D^N$ and $A \subseteq N$, the *projection* x_A of x onto A is the partial input on A that agrees with x. For $S \subseteq D^N$, $S_A = \{x_A \mid x \in S\}$.

2.1 Nondeterministic Semantic Read-Once Branching Programs

Let $f : D^N \to \{0, 1\}$ be a boolean function whose input is given in $|D|$-ary. Let the input variables be $x_1, \ldots, x_n$ where $x_i \in D$ for all $i \leq n$. A $|D|$-way nondeterministic branching program (for f) is an acyclic directed graph G with a distinguished source node q_{start} and a distinguished sink node (the accept node) q_{accept}. We refer to nodes as *states*. Each non-sink state is labeled with some input variable x_i, and each edge directed out of a state is labeled with some value $b \in D$ for x_i. For each $Z \in D^N$, the branching program accepts Z if and only if there exists at least one (directed) path starting at the q_{start} and leading to the accepting state q_{accept}, and such that all labels along this path are consistent with Z. The size of a branching program is the number states (i.e. nodes) in the graph.

A branching program is *semantic read-k* if for every path from q_{start} to q_{accept} that is consistent with some input, each variable occurs at most k times along the path. For the read-once case, a semantic branching program allows variables to be read more than once, but each accepting path may only query each variable at most once.

2.2 Polynomial Evaluation Problem

Our hard computational problem is the polynomial evaluation problem, $Poly$, with parameters K, d, δ, where $0 < \delta < 1$. The input is a pair (u, x) where $u \in [K]^d$ specifies a degree $d-1$ polynomial over the field $[K]$ (K a prime power), and $x \in [K]$ specifies a field value. $Poly(u, x) = 1$ if and only if the polynomial specified by u on input x evaluates to a number less than $K^{1-\delta}$. (We compare two field elements by comparing them using the natural ordering on ternary strings.)

We will work with $|D|$-ary branching programs (with $|D|$ prime), and let $K = |D|^n$. The input will be given as a vector in $D^{(d+1)n}$. The first dn coordinates specify u and the last n coordinates specify x. Thus the total input length is $(d+1)n$. In the remainder of the

paper, $|D| = 3$, and thus the parameters of $Poly$ are d, δ, n. Both d and δ will be fixed constants. Let $Poly_u$ denote the polynomial evaluation problem with parameters d, δ, n where the polynomial u is fixed.

The actual lower bounds we show will be for a *sensitive* function f_u obtained from $Poly_u$ as follows. Let $a \in GF(q)$ where $q = |D|$ is a prime number. Let $h : D^n \to \{0, 1\}$ be the characteristic function of the hyperplane at a:

$$h_a(x) = 1 \quad \text{iff} \quad x_1 + x_2 + ... + x_n = a \mod q\,.$$

Fix an element $a(u)$ for which h_a accepts the largest number of vectors accepted by $Poly_u$ and define the function

$$f_u(x) = Poly_u(x) \wedge h_{a(u)}(x)\,.$$

We call f_u sensitive because it has the property that changing the value of exactly one variable in a yes input always gives an input vector that is a no instance. As a result any two accepted inputs differ in the value of at least two variables. Similarly for the polynomial evaluation problem $Poly$, where the coefficient vector u is part of the input, we define $f(u, x) = Poly(u, x) \wedge h_{a(u)}(x)$, which is sensitive in x.

2.3 Rectangles and Embedded Rectangles

We use the same definitions and conventions as in [3]. A product $U \times V$ is called a (combinatorial) rectangle. If $A \subseteq N$ is an index subset and $Y \subseteq D^A$ and $Z \subseteq D^{N-A}$, then the product set $Y \times Z$ is naturally identified with the subset $R = \{\sigma\rho \mid \sigma \in Y,\ \rho \in Z\}$ of D^N, and a set of this form is called a *rectangle* in D^N.

An *embedded rectangle* R in D^N is a triple $(\pi_{red}, \pi_{white}, C)$ where π_{red}, π_{white} are disjoint subsets of N, and $C \subseteq D^N$ satisfies: (i) The projection $C_{N-\pi_{red}-\pi_{white}}$ consists of a single partial input w, (ii) if $\tau_1 \in C_{\pi_{red}}$ and $\tau_2 \in C_{\pi_{white}}$, then the point $\tau_1\tau_2 w \in C$. C is called the *body* of R. The sets π_{red}, π_{white} are called the *feet* of the rectangle; the sets $C_{\pi_{red}}$ and $C_{\pi_{white}}$ are the *legs*, and w is the *spine*. We can also specify an embedded rectangle by its feet, legs and spine: $(\pi_{red}, \pi_{white}, A, B, w)$ where π_{red}, π_{white} are the feet, $A = C_{\pi_{red}}, B = C_{\pi_{white}}$ are the legs, and w is the spine.

We will sometimes refer to A as the *red* side of the rectangle and to B as the *white* side of the rectangle. The *size* of the rectangle is $|A| \cdot |B|$, and the dimension of the rectangle is m_r-by-m_w where $m_r = |\pi_{red}|$ and $m_w = |\pi_{white}|$.

3 Lower Bound for $|D| = 3$

▶ **Theorem 1.** *There exists constants d, δ such that for sufficiently large n, for a random u, with probability greater than 1/4, any 3-ary nondeterministic semantic read-once branching program for f_u requires size at least $2^{\Omega(n)}$.*

▶ **Corollary 2.** *There exists constants d, δ such that for sufficiently large n, any 3-ary nondeterministic semantic read-once branching program for $f(u, x)$ with parameters d, δ, n requires size at least $2^{\Omega(n)}$.*

Overview of Proof. Call a degree $d - 1$ polynomial "good" if the fraction of accepting instances is roughly what you would expect from a random function; that is, the fraction of yes instances is at least $\frac{1}{2}K^{-\delta}$. Lemma 7 shows that at least half of all degree $d - 1$ polynomials are good.

The main lemma (Lemma 3) shows that for all good polynomials $Poly_u$ to their corresponding sensitive function f_u, we can associate with every size $s = 2^{o(n)}$ branching program $\mathcal{P}$ computing f_u, an m_r-by-m_w embedded rectangle $R_{\mathcal{P}}$ of size r^2, where r will be a large constant, and m_r and m_w will be roughly equal, and will each be a constant fraction of n. For simplicity of calculations for now, assume that $m_r = m_w = m$. The rectangle will have the property that $\mathcal{P}$ accepts every input in $R_{\mathcal{P}}$; in other words, $R_{\mathcal{P}}$ is a 1-rectangle of $\mathcal{P}$. Choosing $d = r^2$, each rectangle of size r^2 can be a 1-rectangle for very few degree $d-1$ polynomials – at most a $|D|^{-n\delta r^2}$ fraction of all degree $d-1$ polynomials. (This is Lemma 6.) Secondly, the total number of such rectangles is fairly small – of size roughly $|D|^{O(rm)}$ (Lemma 5). The key point is that the *number* of rectangles is roughly $|D|^{2rm}$ – the exponent grows linearly in r. (More precisely it grows linearly in the sum of the lengths of the sides of the rectangle, $|A| + |B|$). But on the other hand, the probability that a degree $d = r^2$ polynomial takes on values less than $K^{1-\delta}$ within the rectangle is roughly $|D|^{-mr^2}$ – that is, the exponent grows *quadratically* with r. (More precisely it grows linearly in the size of the rectangle $|A|.|B|$). Because $|D|^{-n\delta r^2}|D|^{O(rn)}$ is less than $1/4$, this implies that many good degree $d-1$ polynomials have no size r^2 1-rectangle, thus proving the theorem.

Note that we set our parameters so that the area of the rectangle $R_{\mathcal{P}}$ is at least the degree d of the polynomial u. (Thus $r^2 \geq d$.) A crucial point in the above argument is that the sum of the lengths of the sides of $R_{\mathcal{P}}$ must be at most a fraction of its area. This requires that the rectangle is reasonably close to being square. We put extra effort into making sure that the rectangle is square (without compromising too much of its size in order to make it square). This enables us to achieve domain size 3; a somewhat simpler argument achieves domain size 5.

▶ **Lemma 3** (Main Lemma). *Let $f : D^n \to \{0,1\}$ be any sensitive boolean function such that the density of 1's is at least $\frac{1}{2|D|}K^{-\delta}$. Suppose that the following inequalities are satisfied for our parameters:*

(1) $m_w = 4m_r = \gamma n$;
(2) $|D|^{m_r} \leq |D|^{m_w}(1/2 - 2\gamma)^{m_w}$;
(3) $r \leq \frac{1}{4|D|s}(1/2 - \gamma)^{m_r}|D|^{m_r - \delta n}$.

Then if $\mathcal{P}$ is a $|D|$-way nondeterministic semantic read-once branching program of size s for f then there is an m_r-by-m_w embedded rectangle $R = (\pi_{red}, \pi_{white}, A, B, w)$ such that every input in R is accepted by $\mathcal{P}$, and where $|A|, |B| = r$.

Proof. Let f be a sensitive function such that the density of 1's is at least $\frac{1}{2|D|}K^{-\delta}$. Suppose there is a size s nondeterministic semantic read-once branching program, $\mathcal{P}$ for f. Let S_0 be the set of inputs that are accepted by $\mathcal{P}$; since $\mathcal{P}$ is assumed to be correct for all inputs of f, we have $|S_0| \geq \frac{1}{2|D|}K^{-\delta}|D|^n$. For each accepted instance $I \in S_0$, fix one accepting path, p_I, in the branching program. Since the function is sensitive each of the n variables must be read along any accepting path. For if some variable is not read along a computation path then changing the value of that variable alone would produce an accepting instance. However, this can't be the case for a sensitive function since any two accepted inputs will have to differ in at least two positions. So each of the n variables must be read along this path exactly once and thus each accepting instance I has an associated permutation π_I of the n variables associated with its accepting path p_I. Designate state q_I as the state in p_I which occurs just after the first half of the variables in π_I. Now define q to be the most common designated state (over all accepting inputs $I \in S_0$), and let $S_1 \subseteq S_0$ denote the corresponding set of inputs whose designated state is q. Thus for each input I in S_1, there is an accepting path

p_I that passes through state q. Because $\mathcal{P}$ has size s, it follows that

$$|S_1| \geq |S_0|/s \geq \frac{1}{2|D|s} K^{-\delta} |D|^n = \frac{1}{2|D|s} |D|^{n-\delta n} \tag{1}$$

We now want to pick two subsets of coordinates $\pi_{red} \subseteq N$ and $\pi_{white} \subseteq N$, of size m_r and m_w respectively, and a set $S^* \subseteq S_1$ of inputs with the property that for every input $I \in S^*$, and associated accepting path p_I, not only does it pass through state q, but every coordinate in π_{red} is read before state q, and every coordinate in π_{white} read at or after state q.

We will first pick π_{red} greedily. For each $I \in S_1$, at least $n/2$ of the n coordinates in p_I occur in π_I before reaching state q, and thus there is some coordinate i such that for at least half of the inputs $I \in S_1$, i occurs in π_I before reaching state q. After choosing the first coordinate, there are at least $|S_1|/2$ inputs remaining. Continue greedily until we pick m_r coordinates, π_{red}, always choosing the most popular coordinate that occurs in π_I before reaching state q. By averaging, when the i^{th} coordinate, $i \leq m_r < \gamma n$ is chosen, the fraction of inputs that remain is at least $\frac{(n/2-i)}{(n-i)} \geq \frac{(n/2-\gamma n)}{(n-\gamma n)} \geq \frac{(n/2-\gamma n)}{n} = (1/2-\gamma)$. Let $S_2 \subseteq S_1$ denote the set of inputs such that all coordinates in π_{red} are read before reaching q. It follows that

$$|S_2| \geq (1/2-\gamma)^{m_r} |S_1| \tag{2}$$

By assumption (3) in the statement of the Lemma, we have

$$r \leq \frac{1}{4|D|s} (1/2-\gamma)^{m_r} |D|^{m_r - \delta n} \tag{3}$$

Then from (1), (2), and (3) we have

$$|S_2| \geq 2r|D|^{n-m_r} \tag{4}$$

For each $w \in D^{n-\pi_{red}}$, the average number of extensions of w in S_2 is $2r$. We want to prune S_2 such that every $w \in D^{n-\pi_{red}}$ has at least r extensions. To do this, define $S_3 \subseteq S_2$, where we remove all inputs $(w, *)$ from S_2 such that w has less than r extensions in S_2. Since we delete at most $r|D|^{n-m_r}$ elements from S_2, and $|S_2| \geq 2r|D|^{n-m_r}$, it follows that

$$|S_3| \geq r|D|^{n-m_r} \tag{5}$$

Next we will choose m_w coordinates, π_{white} in the same greedy fashion, and let S_4 denote the set of all inputs in S_3 such that all coordinates in π_{white} are read after reaching q. Again by averaging,

$$|S_4| \geq (1/2-2\gamma)^{m_w} |S_3| \tag{6}$$

We will express S_4 as the disjoint union of sets R_w: choose a value w for the coordinates outside of $\pi_{red} \cup \pi_{white}$. The corresponding set $R_w \subseteq S_4$ consists of all inputs (α, w, β) such that α is an assignment to the variables in π_{red}, β is an assignment to the variables in π_{white}, and $(\alpha, w, \beta) \in S_4$.

▶ **Lemma 4.** *For each w: (i) R_w is an embedded rectangle and (ii) as long as R_w is not empty, the size of its red leg is at least r.*

Proof. We will first show that R_w is an embedded rectangle. Let $S_{red} \subseteq D^{\pi_{red}}$ be the projection of R_w onto the coordinates of π_{red} and let $S_{white} \in D^{\pi_{white}}$ be the projection of R_w onto the coordinates of π_{white}. Setting $A = S_{red}$, $B = S_{white}$ and $w = w$, we claim

that R_w is equal to the embedded rectangle defined by $(\pi_{red}, \pi_{white}, A, B, w)$. To see this, consider $x, x' \in A$ and $y, y' \in B$ such that $xyw \in R_w$, and $x'y'w \in R_w$. Let I be the input corresponding to xyw and let p_I be the corresponding path going through state q. Note that in p_I the x-variables are all read prior to reaching q, and the y-variables are read after reaching q, and there is some split of the w variables into w_1, w_2 where the w_1 variables are read prior to q and the w_2 variables are read after q. Similarly, let I' be the input corresponding to $x'y'w$ and let $p_{I'}$ be the corresponding path. There is now a possibly different split of w into w_1', w_2', so x', w_1' are read before q and y', w_2' are read after q. We claim that $xy'w \in R_w$: consider the path (x, w_1) (the first half of p_I) and (y', w_2') (the second half of $p_{I'}$). This path must be consistent since w_1 and w_2' are consistent and x, y' are on disjoint variables. Thus there is an input consistent with this path; it is an accepting path going through q and consistent with w; the variables in π_{red} are all read before q, and the variables in π_{white} are all read after q. Thus it is in R_w. An analogous argument shows that $x'yw \in R_w$. Thus R_w is an embedded rectangle.

Secondly we will show (ii) for each $R_w \subseteq S_4$, the size of the red leg is at least r. (That is, $|A| \geq r$.) Consider a nonempty rectangle R_w with red leg A, white leg B and spine w. Recall that the inputs in S_3 consist of a partial input $w+ \in D^{N-\pi_{red}}$ together with a set $A \subseteq D^{\pi_{red}}$ such that $|A| \geq r$. We obtain S_4 from S_3 by selecting m_w coordinates from $N - \pi_{red}$, one at a time, choosing each coordinate greedily, where a coordinate is chosen if it is read *after* state q in the most inputs. Consider a block of inputs $(A, w+) \in S_3$. If some input $(\alpha, w+) \in (A, w+)$ survives, then all coordinates in π_{white} that were chosen must all be read after state q on input $(\alpha, w+)$. But this means that for every input $(\alpha', w+) \in (A, w+)$, all coordinates in π_{white} are also read after q. (Otherwise, some coordinate would be read twice along this accepting input, violating the read-once condition.) Thus, either the entire block $(A, w+)$ is in S_4, or the entire block is removed from S_4.

Now let $R_w = (\pi_{red}, \pi_{white}, A, B, w) \subseteq S_4$ be a nonempty rectangle, $w \in D^{N-\pi_{red}-\pi_{white}}$. R_w is obtained by taking the union of (nonempty) blocks $(A', w+) \in S_4$, $w+ \in D^{N-\pi_{white}}$. Since as we argued above, for each such block, $|A'| \geq r$, it follows that $|A| \geq r$ as well. ◀

Let r_{avg} denote the average size of the white leg of the rectangle over all rectangles $R_w \subseteq S_4$. It is easy to see that $|D|^{n-m_w} r_{avg} \geq r|D|^{n-m_r}(1/2 - 2\gamma)^{m_w}$. It follows that $r_{avg} \geq r$ if $|D|^{m_w - m_r}(1/2 - 2\gamma)^{m_w} \geq 1$. The latter inequality follows from condition (2). Thus, by condition (2) assumed in the hypothesis of Lemma 3, we can pick some setting w^* to the remaining $n - m_r - m_w$ uncoloured coordinates (the coordinates that are not in π_{red} or π_{white}) such that the white leg of the rectangle R_{w^*} has size at least $r_{avg} = r$. Let S^* equal R_{w^*}. By construction, both the red leg of $S^* = R_{w^*}$ and the white leg of R_{w^*} have size at least r. Prune S^* so that each leg has size exactly r, thus completing the proof of the lemma. ◀

▶ **Lemma 5.** *Let $\mathcal{R}$ be the set of all m_r-by-m_w embedded rectangles over D^N such that $|A| = |B| = r$, where $m_w = \gamma n$ and $m_r = m_w/4$. Then $|\mathcal{R}| \leq (e/\gamma)^{\frac{5}{4}m_w} |D|^{\frac{5}{4}rm_w + m_w/\gamma}$.*

Proof. The number of choices for π_{red}, the coordinates of A, is $\binom{n}{m_r}$. Given π_{red}, we choose r vectors from the $|D|^{m_r}$ possible values for the elements of A. Thus the total number of possible sets A is at most $\binom{n}{m_r}|D|^{rm_r}$. Similarly the number of choices for the set B is at most $\binom{n}{m_w}|D|^{rm_w}$. The number of choices for $w \in D^{N-\pi_{red}-\pi_{white}}$ is $|D|^{n-m_r-m_w}$. Thus $|\mathcal{R}|$ is at most $\binom{n}{m_r}\binom{n}{m_w}|D|^{rm_r}|D|^{rm_w}|D|^{n-\frac{5}{4}m_w}$. Using the inequality $\binom{n}{k} \leq (\frac{en}{k})^k$ we conclude the number of choices for $|\mathcal{R}|$ is at most $(en/m_w)^{m_w}(4en/m_w)^{\frac{1}{4}m_w}|D|^{n-\frac{5}{4}m_w}|D|^{\frac{5}{4}rm_w} \leq (e/\gamma)^{\frac{5}{4}m_w}|D|^{\frac{5}{4}rm_w + m_w/\gamma}$ ◀

▶ **Lemma 6.** *Define the predicate $Good(R,u)$ to be true if for every input x in the rectangle R, the polynomial u on input x is less than $K^{1-\delta}$ (i.e. $Poly_u(x)$ is true). Then for all embedded rectangles R of size d, $Pr_u[Good(R,u)] \leq p$ where $p = |D|^{-\delta nd}$.*

Proof. Assume $Good(R,u)$. Suppose that $|R| = d$ and let $B' \in [K^{1-\delta}]^d$ specify a vector of d accepting values. Let $Good_{B'}(R,u)$ to be the event that for all $x \in R$, $Poly_u(x) = B'(x)$. Then $Pr_u[Good(R,u)] = K^{(1-\delta)d} \cdot Pr_u[Good_{B'}(R,u)]$.

To bound $Pr_u[Good_{B'}(R,u)]$, suppose that it is true that $\forall x \in R$, $F_u(x) = \sum_{i<d} u_i x^i = B'(x)$. Note that this fixes the output of the degree $d-1$ polynomial for d values of x. By interpolation, this uniquely determines the polynomial, u'. Thus, $Pr_u[Good_{B'}(R,u)] = Pr_u[u = u'] = K^{-d} = |D|^{-nd}$. Overall, $Pr_u[Good(R,u)] \leq K^{(1-\delta)d}|D|^{-nd} = |D|^{n(1-\delta)d}|D|^{-nd} = |D|^{-\delta nd}$. This completes the proof of Lemma 6. ◀

▶ **Lemma 7.** *For a random u,for fixed parameters d, δ the probability that $Poly_u(x)$ does not accept a $(1 \pm o(1))K^{-\delta}$ fraction of all the inputs is at most $o(1)$. (Here both $o(1)$ are $K^{-(1-\delta)/3}$.)*

Proof. Randomly choose the coefficients $u \in [K]^d$ of the $d-1$ degree polynomial. For each instance $x \in [K]$ (and value $b \in [K]$), let $A_{\langle x,b\rangle}$ denote the event that the output of this polynomial on input x is b. Let a_x denote the event that this value is less than $K^{1-\delta}$ so that x is a yes instance. Let $Y = \sum_{x\in K} a_x$ denote the number of yes instances for the chosen u. Note $p = \Pr_u[a_x] = K^{1-\delta}/K = K^{-\delta}$ because just choosing the constant coefficient u_0 of the polynomial randomly makes the polynomial's output on x uniformly random in $[K]$. Hence, by linearity of expectation $\overline{Y} = \text{Exp}[Y] = K \cdot \Pr_u[a_x] = K^{1-\delta}$. We show that the $A_{\langle x,b\rangle}$ events for different x are d-wise independent as follows. Consider any subset $\{x_1, x_2, \ldots, x_d\} \subset [K]$ of the instances. Knowing the value of the polynomial at each of these instances, by interpolation, uniquely determines the coefficients u of the polynomial. Hence, if all you know about u is the values on $d-1$ of these instances, then the value on the remaining is still uniformly random within $[K]$. Formally stated, $\Pr_u[A_{\langle x_d,b_d\rangle} \mid A_{\langle x_1,b_1\rangle}, \ldots, A_{\langle x_{d-1},b_{d-1}\rangle}] = \Pr_u[A_{\langle x_d,b_d\rangle}]$. Not fully knowing the value of the first $d-1$ of the instances, but only that their value is small, give you even less information. Hence, $\Pr_u[a_{x_d} \mid a_{x_1}, \ldots, a_{x_{d-1}}] = \Pr_u[a_{x_d}]$. It follows that $\Pr_u[a_{x_1} \wedge \ldots \wedge a_{x_d}] = \Pr_u[a_{x_1}] \cdot \ldots \cdot \Pr_u[a_{x_d}]$. Because the a_x events are d-wise independent, it follows that the d^{th} order standard deviation of their sum Y is the same as it would be if they were completely independent events. We, however, only need to consider the variance. More formally, for each x, let a'_x be an independent event with probability $K^{-\delta}$ of success and $Y' = \sum_{x\in K} a'_x$. The variance is $\text{Var}[Y] = \text{Exp}_u[(Y-\overline{Y})^2] = \text{Exp}_u[(\sum_x a_x - \overline{Y})^2]$. The non-linear part of this is $\text{Exp}_u[(\sum_x a_x)^2] = \sum_{x,x'} \text{Exp}_u[a_x \cdot a_{x'}]$, which we know from pair-wise independence is $\sum_{x,x'} \text{Exp}_u[a_x] \cdot \text{Exp}_u[a_{x'}] = \sum_{x,x'} \text{Exp}_u[a'_x] \cdot \text{Exp}_u[a'_{x'}]$. The same computation for the a'_x, gives that $\sigma^2 = \text{Var}[Y] = \text{Var}[Y'] = K \cdot p(1–p) \approx K\dot{K}^{-\delta} = K^{1-\delta} = \overline{Y}$. By Chebycheff's inequality, $\forall \eta > 0$ we have $Pr_u(|Y - \overline{Y})| \geq \eta\sigma) < \frac{1}{\eta^2}$. Setting $\eta = \overline{Y}^{\frac{1}{6}}$, gives $Pr_u(Y \notin (1 \pm \overline{Y}^{-\frac{1}{3}})\overline{Y}) \leq \overline{Y}^{-\frac{1}{3}}$. ◀

We are now ready to complete the proof of the theorem. Call a polynomial u "good" if $Poly_u$ accepts at least a $\frac{1}{2}K^{-\delta}$ fraction of all inputs. By Lemma 7, we know that at least half of all u's are good. For each good u, the corresponding sensitive function f_u has density at least $\frac{1}{2|D|}K^{-\delta}$. Since f_u is sensitive and has sufficient density Lemma 3 tells us that any small branching program for f_u implies that there exists an m_r-by-m_w embedded rectangle size r^2 that is accepted (assuming that conditions (1), (2), and (3) are satisfied).

On the other hand, by union bound Lemmas 5 and 6 together tell us that at most a $p|\mathcal{R}|$ fraction of degree $d-1$ polynomials u have such m_r-by-m_w embedded rectangles of size r^2

that are accepted. Suppose we can choose a setting of the parameters so that $p|\mathcal{R}| < 1/4$. If follows that for at least $\frac{1}{4}^{th}$ of all good polynomials the corresponding sensitive functions f_u do not have such m_r-by-m_w embedded rectangles of size r^2 that are accepted since the hyperplane constraint $h_{a(u)}(x)$ can only shrink an accepting rectangle. Then by Lemma 3 this implies that at least as many f_u cannot have small branching programs, and thus the theorem is proven.

It is left to show that we can set the parameters such that $p|\mathcal{R}| < 1/4$, and properties (1), (2), and (3) of Lemma 3 are satisfied. We will set the parameters as follows: $|D| = 3$, $m_w = 4m_r = \gamma n$, $\gamma = .01$, $\delta = \gamma/300$, $r = 3000$, and $d = r^2$. To achieve $p|\mathcal{R}| < 1/4$, we require $|D|^{\delta m_w r^2/\gamma - m_w/\gamma - \frac{5}{4}rm_w} > 4(e/\gamma)^{\frac{5}{4}m_w}$. Using $|D| = 3$ and factoring out m_w, it is sufficient if we have $3^{\delta r^2/\gamma - 1/\gamma - \frac{5}{4}r} > 4(e/\gamma)^{\frac{5}{4}}$. With our choice of parameters, this is satisfied for $r \geq 3000$.

For Lemma 3, we also require assumptions (2) and (3). First for (2): $|D|^{m_r} \leq |D|^{m_w}(1/2 - 2\gamma)^{m_w}$. For $|D| = 3$ and $m_w = 4m_r$, this is satisfied. For (3) we require: $r \leq \frac{1}{4|D|}(1/2 - \gamma)^{m_r}|D|^{m_r - \delta n} = \frac{1}{4|D|}(1/2 - \gamma)^{m_r}|D|^{m_r(1-4\delta/\gamma)}$. For $|D| = 3$, $\gamma = .01$, $\delta = \gamma/300$, we have $(1/2 - \gamma)|D|^{(1-4\delta/\gamma)} \geq 1.44$ and thus it suffices to show $r \leq \frac{1}{12}(1.44)^{m_r}/s$. This holds for our choice $r = 3000$ when $s \leq 2^{cm_r} = 2^{cn/(4\gamma)}$ for some $c > 0$ and sufficiently large n. Note that $|D| > 2$ helps us in ensuring assumptions (2) and (3) hold.

4 Conclusion

We have proved an exponential lower bound on the size of non-deterministic semantic read once branching programs computing a polynomial time computable function $f : D^n \to \{0, 1\}$ when $D = \{0, 1, 2\}$ with just three elements. Our contribution is that we bring down the size of the domain required to achieve this. Prior to our result the best that was known was for D-ary branching programs with $|D| \geq 2^{13}$. The explicit function f for which we show the lower bound is the decision problem of determining whether a certain degree d polynomial over a finite field K evaluates to a value less than a certain threshold at a given input (along with a hyperplane constraint). This result brings down the focus to the first non-boolean case, $|D| = 3$ vs the boolean case, $|D| = 2$, since, interestingly the case where D is boolean $\{0, 1\}$ still remains open and no non-trivial lower bounds are known for binary non-deterministic semantic read once branching programs [12]. In the next section we explore the Booelan case.

5 Semantic Branching Programs with $|D| = 2$ can evade Large Bottleneck Rectangles

In this section we show how binary non-deterministic semantic read once branching programs can behave differently by evading lower bounds in certain bottleneck layers by having a small number of states in those layers irrespective of what function $f : \{0, 1\}^n \to \{0, 1\}$ they are computing. The example upper bounds we give demonstrate why it is likely harder to prove lower bounds for semantic read once branching programs with domain size $|D| = 2$.

When the domain size is $|D| > 2$, the technique is to prove that the set of yes instances handled by any one state of the branching program contains a rectangle and then identify a computational problem that has no large rectangle of yes instances. Hence, the rectangle for each state must be small. Because there are exponentially many yes instances and each must be handled by at least one state at a selected *bottle neck* level of the branching program, there must be an exponential number of states at that level. We show here that for domain

size $|D| = 2$, the set of yes instances handled by one state can be quite arbitrary and quite large. This does not mean that the total number of branching program states can necessarily be small. But it does mean that at the one level of the branching program that the prover is hoping to use for a bottleneck, the number of states might be quite small.

A lower bound that attempts to prove that a selected bottleneck level of the branching program must have many states, must start by selecting which level of the branching program will be the level in question. It might do this by specifying how many or which variables have been read so far. Given *any boolean computational problem* with input from $\{0,1\}^n$ and a criteria for choosing the bottle neck level chosen from a wide (but not exhaustive) range of possible choices, we now show how to fool such a lower bound, by giving a branching program that gives a polynomial upper bound on the number states at the selected layer.

The branching program is constructed as follows. For each yes instance $A \in \{0,1\}^n$, we form an accepting branching program path $\langle C_1(A), q(A), C_2(A)\rangle$ where $q(A)$ denotes the state A passes through at the bottleneck level, $C_1(A)$ the path before this level and $C_2(A)$ that after. Note that to get a counter example to a lower bound technique using some bottleneck layer, we don't need to give a full poly-size branching program. We only need the number of states $q(A)$ to be small. It can have exponential number of states before and after this layer. Hence, we will have all of these paths $C_1(A)$ for different yes instances A be completely disjoint from each other. Similarly for $C_2(A)$. These paths only come together and interact at the special layer of states $q(A)$. In order to make the properties of this level more arbitrary, let $A_1, A_2 \subset [n]$ be any partition of the input variables into two parts. Let $C_1(A)$ read all the ones in A_1 and all the zeros in A_2. Let $C_2(A)$ read all the zeros in A_1 and all the ones in A_2. Let $q(A) = \langle u, v\rangle$ be the state, where $u \in [n]$ is the number of ones in A_1 and $v \in [n]$ is the number of the zeros in A_2. Hence only n^2 states are needed in the layer. Note that because we have allowed the computational problem to be arbitrary, other than partitioning its yes instances based on their hamming weights, the sets of instances handled by a state $q(A)$ is completely arbitrary.

Note that as long as A_1, A_2 are comparable in size, for most of the inputs, the incoming path $C_1(A)$ and $C_2(A)$ are of comparable length. However, the purported bottleneck layer for which we give the above upperbound is not identical to the one we use for our lower bound for $|D| \geq 3$ in the sense that the bottleneck states like $q(A)$ do not appear exactly midway through the accepting paths at length $n/2$ on all the paths as is required in Lemma 3. Nevertheless, the upper bound is interesting because for most inputs A the incoming and outgoing paths through a state in the layer are of comparable length.

We will now in two ways, prove that this branching program solves the given computational problem. We will start with a *communication game interpretation.* Think about the algorithm as a game between two players C_1 and C_2 and Charlie who they don't trust. Charlie shows C_1 the ones in the first part A_1 of the input and the zeros in the second part A_2. Assuming he trusts Charlie, this lets C_1 know the entire input. Hence, he can answer *any* question about the input. The only way that Charlie can cheat is to not show all of the entries. In order to verify that he is not lying, C_1 sends to C_2 the number of ones in A_1 and the number of zeros in A_2. C_2 can then check that they have both been shown all of what they were supposed to see.

Now lets consider the *branching program interpretation.* Clearly, the branching program described accepts all yes instances of the given problem, because it has a separate accepting path $\langle C_1(A), q(A), C_2(A)\rangle$ for each yes instance A. What remains is to prove 1) the branching program is semantic read once and 2) that no no instances are accepted. We do this by showing for every pair $\langle A, B\rangle$ of different yes instances that pass through the same bottleneck

states $q(A) = q(B) = \langle u, v \rangle = q$, that the cross path $\langle C_1(A), q, C_2(B) \rangle$ is inconsistent in that it reads some variable twice with different values. Hence, by the definition of *semantic*, it does not matter that this path is not read once and because it is inconsistent, it cannot be accepting a no instance. Because A and B are different, either A_1 and B_1 are different and/or A_2 and B_2 are different. Assume A_1 and B_1 are different. Because A_1 and B_1 have the same number u of ones, there is an element that is one in A_1 and zero in B_1. Hence $C_1(A)$ and $C_2(B)$ both read it. This element is read twice in $\langle C_1(A), q, C_2(B) \rangle$ with different values and so is inconsistent.

So for $D = 2$, presence of a small number of states in a supposed bottleneck layer of a branching program need not imply that there exists a balanced embedded rectangle of accepting instances. In particular, our lower bound finds a rectangle within the set of yes instances handled by narrowing the set down to a subset within which for many variables it is fixed whether it is read before or after the state. However in this upper bound, whether a variable is read before or after the state $q(A)$ is completely determined by whether its value is 0 or 1. Hence, fixing this fixes its value. If this is done for every variable, the set of inputs left in the eventual rectangle identified by this lower bound method is narrowed down to a singleton.

Abstract

The *sign-rank* of a matrix A with entries in $\{-1,+1\}$ is the least rank of a real matrix B with $A_{ij} \cdot B_{ij} > 0$ for all i,j. Razborov and Sherstov (2008) gave the first exponential lower bounds on the sign-rank of a function in AC^0, answering an old question of Babai, Frankl, and Simon (1986). Specifically, they exhibited a matrix $A = [F(x,y)]_{x,y}$ for a specific function $F\colon \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$ in AC^0, such that A has sign-rank $\exp(\Omega(n^{1/3}))$.

We prove a generalization of Razborov and Sherstov's result, yielding exponential sign-rank lower bounds for a non-trivial class of functions (that includes the function used by Razborov and Sherstov). As a corollary of our general result, we improve Razborov and Sherstov's lower bound on the sign-rank of AC^0 from $\exp(\Omega(n^{1/3}))$ to $\exp(\tilde{\Omega}(n^{2/5}))$. We also describe several applications to communication complexity, learning theory, and circuit complexity.

1 Introduction

The *sign-rank* of a matrix A with entries in $\{-1,+1\}$ is the least rank of a real matrix B with $A_{ij} \cdot B_{ij} > 0$ for all i,j. This fundamental matrix-theoretic complexity measure has diverse applications in theoretical computer science. For example:

- Upper bounds on sign-rank underly many state of the art learning algorithms, including the fastest known algorithms for PAC learning DNF and read-once formulas. Algorithms based on sign-rank are additionally robust to random classification noise, a property not satisfied by the handful of known PAC learning algorithms that cannot be captured in the sign-rank framework (all of which are based on Gaussian Elimination) [12].
- In communication complexity, sign-rank is known to characterize *unbounded error communication*. Introduced by Paturi and Simon [16] and captured by the communication complexity class $\mathbf{UPP}^{cc}$, this is a powerful communication model that lies at the frontier of our understanding. It is essentially the most powerful communication model against which we know how to prove lower bounds. In fact, the only known communication models that $\mathbf{UPP}^{cc}$ cannot efficiently simulate are the communication analogues of the polynomial hierarchy introduced by Babai, Frankl, and Simon [4]. We direct the interested reader to the recent paper of Göös et al. [11] for a detailed overview of communication complexity classes and their relationships.

- In circuit complexity, sign-rank lower bounds on a matrix $A = [F(x,y)]_{x,y}$ imply lower bounds on the size of threshold-of-majority circuits computing F.

Despite the importance of these applications, our understanding of sign-rank remains rather limited, and it is possible to summarize relevant prior work in a single paragraph. Alon et al. [2] proved lower bounds on the sign-rank of random matrices. The first nontrivial lower bounds for explicit matrix families was obtained in a breakthrough work of Forster [8], who proved strong lower bounds on the sign-rank of Hadamard matrices, and more generally of any sign matrix with small spectral norm. Several subsequent works improved and generalized Forster's method [9, 10, 14, 3]. Nearly tight estimates of the sign-rank were obtained by Sherstov in [20] for all symmetric predicates, i.e., matrices of the form $[D(\sum_i x_i \vee y_i)]_{x,y}$ where $D : \{0,1,\ldots,n\} \to \{0,1\}$ is a given predicate and x, y range over $\{0,1\}^n$. Razborov and Sherstov [17] answered an old question of Babai, Frankl, and Simon [4] by giving the first exponential sign-rank lower bounds on a function in AC^0. Specifically, they gave a matrix $A = [F(x,y)]_{x,y}$ for a function $F\colon \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$ in AC^0, such that A has sign-rank $\exp(\Omega(n^{1/3}))$.

Our work strengthens and generalizes the results of Razborov and Sherstov on the sign-rank of AC^0.

1.1 Our Results

The *threshold degree* of a function $h\colon \{-1,1\}^n \to \{-1,1\}$, denoted $\deg_\pm(h)$, is the least degree of a real polynomial that agrees in sign with h at all inputs. Minsky and Papert [15] famously showed that the threshold degree of the DNF formula $\mathrm{MP}_n(x) = \vee_{i=1}^{n^{1/3}} \wedge_{j=1}^{n^{2/3}} x_{ij}$ – now known as the Minsky-Papert DNF – is $\Omega(n^{1/3})$. This is the same function that Razborov and Sherstov used to prove their sign-rank lower bounds, and their analysis is highly tailored to the Minsky-Papert DNF. We generalize their result as follows.

For any $d > 0$, we identify a class $\mathcal{C}_d$ of functions $f : \{-1,1\}^k \to \{-1,1\}$ such that any $f \in \mathcal{C}_d$ can be transformed into a function $F : \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$, where $n = O(dk)$, for which $A = [F(x,y)]_{x,y}$ has sign rank $\exp(\Omega(d))$. Crucially, this transformation is simple in the sense that if f is computed by a polynomial-size circuit of depth t, then F is computed by a polynomial-size circuit of depth at most $t+1$ (and in some cases, F may be shallower).

In particular, the k-variate AND_k function is in $\mathcal{C}_d$ for some $d = \Omega(k^{1/2})$. Our transformation of AND_k into a function $F : \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$ for $n = O(k^{3/2})$ recovers Razborov and Sherstov's function, with the same sign-rank bound of $\exp(\Omega(k^{1/2})) = \exp(\Omega(n^{1/3}))$. We also identify a k-variate AC^0 function that is in $\mathcal{C}_d$ for some $d = \tilde{\Omega}(k^{2/3})$, which in turn yields new sign-rank lower bounds for AC^0.

The precise definition of $\mathcal{C}_d$ is rather technical, so for expository purposes, we restrict ourselves to an informal statement of this result in this introduction. We define $\mathcal{C}_d$ formally in Section 2.2.

Informal description of the class $\mathcal{C}_d$. Our class $\mathcal{C}_d$ consists of all functions of the form $f : \{-1,1\}^k \to \{-1,1\}$, where f satisfies the following (informally stated) property: there exists a "small" set $S \subseteq f^{-1}(+1)$ such that f cannot be uniformly approximated to error $1/2$ by degree d polynomials, even under the promise that the input x is in $f^{-1}(-1) \cup S$. The precise definition of $\mathcal{C}_d$ is based on a *dual* (in the sense of linear programming duality) interpretation of this property.

Transforming functions in $\mathcal{C}_d$ to functions with high sign-rank. For $g : \{-1,1\}^m \to \{-1,1\}$ and $f : \{-1,1\}^k \to \{-1,1\}$, the notation $g \circ f = g(f,\ldots,f)$ denotes the function on $n = mk$ bits obtained by block-composing g with f. Let OR_m and AND_m denote the logical OR and AND functions on m bits, respectively. Let C be a sufficiently large universal constant. Given a function $f : \{-1,1\}^k \to \{-1,1\}$, let $F : \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$ be defined by

$$F = \mathrm{OR}_{2d} \circ f \circ \mathrm{AND}_C \circ \mathrm{OR}_2,$$

and hence $n = 2Cdk = O(dk)$.

▶ **Theorem 1** (Informal). *For any $f \in \mathcal{C}_d$, the matrix $A = [F(x,y)]_{x,y}$ has sign-rank* $\exp(\Omega(d))$.

Examples of functions in $\mathcal{C}_d$. We consider two prominent examples of functions in $\mathcal{C}_d$. As mentioned above, the first is the function $\mathrm{AND}_k : \{-1,1\}^k \to \{-1,1\}$, which we show is in $\mathcal{C}_d$ for $d = \Omega(k^{1/2})$. Hence, we recover a new proof of Razborov and Sherstov's lower bound.

▶ **Corollary 2.** *Let $\mathrm{MP}_n = \mathrm{OR}_{n^{1/3}} \circ \mathrm{AND}_{n^{2/3}}$ be the Minsky-Papert DNF. Then $A = [\mathrm{MP}_n(x \vee y)]_{x,y}$ has sign-rank* $\exp(\Omega(n^{1/3}))$.

Let $\mathrm{ED}_k \colon \{-1,1\}^k \to \{-1,1\}$ denote the well-known Element Distinctness function (defined in Section 2.6). As we will show, the function ED_k is in $\mathcal{C}_d$ for some $d = \tilde{\Omega}(k^{2/3})$. Hence, we obtain the following corollary, which improves Razborov and Sherstov's lower bound on the sign-rank of AC^0 from $\exp(\Omega(n^{1/3}))$ to $\exp(\tilde{\Omega}(n^{2/5}))$.

▶ **Corollary 3.** *Let $F_n^{\mathrm{ED}} = \mathrm{OR}_{n^{2/5}} \circ \mathrm{ED}_{n^{3/5}} \circ \mathrm{AND}_C \circ \mathrm{OR}_2$. Then $A = [F_n^{\mathrm{ED}}(x,y)]_{x,y}$ has sign-rank* $\exp(\tilde{\Omega}(n^{2/5}))$.

As discussed in Section 2.6, the function F_n^{ED} is computed by a depth-3 AC^0 circuit with logarithmic bottom fan-in.

1.2 Applications

We describe applications of Corollary 3 to communication complexity, learning theory, and circuit complexity in detail in the full version of this work. Here, we briefly describe these applications.

- Razborov and Sherstov's result yielded a function in the communication complexity class $\mathbf{PH}^{\mathbf{cc}}$ (the communication analog of the polynomial hierarchy) that requires unbounded error communication complexity $\Omega(n^{1/3})$. This was the first separation between the communication complexity classes $\mathbf{PH}^{\mathbf{cc}}$ and $\mathbf{UPP}^{\mathbf{cc}}$, answering a longstanding open problem of Babai, Frankl, and Simon [4]. We improve this separation, giving a function in the communication complexity class $\mathbf{PH}^{\mathbf{cc}}$ (indeed, in $\mathbf{\Sigma_2^{cc}}$) that requires unbounded error communication complexity $\tilde{\Omega}(n^{2/5})$.
- Razborov and Sherstov's result implied that learning algorithms in the sign-rank framework cannot PAC learn DNF formulae in time less than $\exp(O(n^{1/3}))$. This essentially matches the $\exp(\tilde{O}(n^{1/3}))$ runtime of the sign-rank based algorithm of Klivans and Servedio [13]. It is reasonable to ask whether the sign-rank framework can be used to learn depth-3 (or deeper) AC^0 circuits in the same $\exp(\tilde{O}(n^{1/3}))$ time bound. Our results rule this out, showing that sign-rank based learning algorithms require time $\exp(\tilde{\Omega}(n^{2/5}))$ to learn depth-3 AC^0 circuits, even when the bottom fan-in is $O(\log n)$.

- Razborov and Sherstov's result implied an exponential (specifically, $\exp(\Omega(n^{1/3}))$) lower bound on the size of threshold-of-majority circuits computing a function in AC^0. We improve their lower bound to $\exp\left(\tilde{\Omega}(n^{2/5})\right)$.

1.3 Our Techniques

It is well-known that the threshold degree of any function $h\colon \{-1,1\}^n \to \{-1,1\}$ is characterized by an (exponentially large) linear program. Using this formulation, if $\deg_{\pm}(h) = d$, then strong LP duality guarantees the existence of a dual solution μ that *witnesses* the fact that $\deg_{\pm}(h) \geq d$. Specifically, μ takes the form of a distribution on $\{-1,1\}^n$ such that h is uncorrelated under μ with all polynomials of degree at most d, i.e., $\sum_{x\in\{-1,1\}^n} \mu(x)\cdot h(x)\cdot p(x) = 0$ for all polynomials p of degree at most d. Razborov and Sherstov refer to μ as a *d-orthogonalizing distribution* for h (see Section 2.5 below for details).

In order to establish sign-rank lower bounds for the matrix $A = [(h \circ \mathrm{AND}_C)(x \vee y)]_{x,y}$, Razborov and Sherstov extended a lemma of Forster to show that it is enough to give an orthogonalizing distribution μ for h that additionally satisfies a *smoothness* property (cf. Theorem 18 in Section 4 for details). Specifically, a d-orthogonalizing distribution for h is said to be smooth if $\mu(x) = \exp(-O(d))$ for all but an $\exp(-\Omega(d))$ fraction of inputs $x \in \{-1,1\}^n$. Intuitively, this means that μ is smooth if it places "noticeable" mass on "almost all" inputs.

Razborov and Sherstov proved (non-constructively) that there exists a smooth d-orthogonalizing distribution for the Minsky-Papert DNF, for $d = n^{1/3}$. To generalize their result, for any $d > 0$ and any function $f \in \mathcal{C}_d$, we explicitly construct a smooth d-orthogonalizing distribution for the function $\mathrm{OR}_d \circ f$. Our construction combines new ideas with insights of Razborov and Sherstov, and ideas from prior works by the authors and Sherstov [7, 23] that constructed (non-smooth) orthogonalizing distributions for functions of the form $\mathrm{OR} \circ f$.

2 Preliminaries

2.1 Notation

We work with Boolean functions $f : \{-1,1\}^k \to \{-1,1\}$, where -1 corresponds to logical TRUE and $+1$ corresponds to logical FALSE. For $x \in \{-1,1\}^k$, let $|x| = \#\{i : x_i = -1\}$ denote the Hamming weight of x. Note that $|x|$ is computed by the linear function $|x| = \frac{k}{2} - \frac{1}{2}\sum_{i=1}^{k} x_i$.

2.2 Symmetrization

▶ **Definition 4.** Let $T : \{-1,1\}^k \to D$, where D is a finite subset of $\mathbb{R}^n$ for some $n \in \mathbb{N}$. The map T is *degree non-increasing* if for every polynomial $p : \{-1,1\}^k \to \mathbb{R}$, there exists a polynomial $q : D \to \mathbb{R}$ with $\deg q \leq \deg p$ such that

$$q(T(x)) = \mathop{\mathbb{E}}_{y \text{ s.t. } T(y)=T(x)} [p(y)]$$

for every $x \in \{-1,1\}^k$. We say that a degree non-increasing map T *symmetrizes* a function $f : \{-1,1\}^k \to \mathbb{R}$ if $f(x) = f(y)$ whenever $T(x) = T(y)$, and in this case we say that T is a *symmetrization* for f.

The canonical example of a degree non-increasing map is that which computes the Hamming weight.

▶ **Lemma 5** (Minsky and Papert [15]). *The map $T : \{-1,1\}^k \to \{0,1,\ldots,k\}$ defined by $T(x) = |x|$ is degree non-increasing. Hence, T is a symmetrization for any symmetric Boolean function.*

For any function $\psi\colon \{-1,1\}^k \to \mathbb{R}$, a symmetrization $T\colon \{-1,1\}^k \to D$ for ψ induces a symmetrized function $\widetilde{\psi}\colon D \to \mathbb{R}$ defined via $\widetilde{\psi}(z) := \mathbb{E}_{x \in T^{-1}(z)} \psi(x)$. (If $T^{-1}(z)$ is empty, then we define $\widetilde{\psi}(z) = 0$). It will also be convenient to define an "unnormalized" version $\hat{\psi}$ of $\widetilde{\psi}$, defined via $\hat{\psi}(z) := \sum_{x \in T^{-1}(z)} \psi(x)$. Observe that if μ is a distribution on $\{-1,1\}^k$, then $\hat{\mu}$ is a distribution on D.

Similarly, let $T\colon \{-1,1\}^k \to D$ be a degree non-increasing map. A function $\hat{\psi} : D \to \mathbb{R}$ naturally induces an un-symmetrized function $\psi : \{-1,1\}^k \to \mathbb{R}$ by setting $\psi(x) = \frac{1}{|T^{-1}(z)|}\hat{\psi}(z)$ where $z = T(x)$. That is, ψ spreads the mass of $\hat{\psi}(z)$ out evenly over points $x \in T^{-1}(z)$. Observe that, for any $\hat{\psi}$ and any degree non-increasing map T, the induced function ψ is symmetrized by T.

We will often pass back and forth between a function ψ on $\{-1,1\}^k$ and its symmetrized versions $\widetilde{\psi}$ and $\hat{\psi}$ on D, when the underlying symmetrization $T\colon \{-1,1\}^k \to D$ is understood.

2.3 Norms and Inner Products

For a function $\psi : \{-1,1\}^k \to \mathbb{R}$, define the ℓ_1 norm of ψ by $\|\psi\|_1 = \sum_{x \in \{-1,1\}^k} |\psi(x)|$. For functions $\psi, \varphi : \{-1,1\}^k \to \mathbb{R}$, denote the inner product $\langle \psi, \varphi \rangle = \sum_{x \in \{-1,1\}^k} \psi(x)\varphi(x)$. We say a function $\psi : \{-1,1\}^k \to \mathbb{R}$ has *pure high degree d* if $\langle \psi, p \rangle = 0$ for every polynomial $p : \{-1,1\}^k \to \mathbb{R}$ of degree less than d.

2.4 Dual Objects and the Class $\mathcal{C}_d$

Central to our work is the following definition of a "dual object." We show that whenever a Boolean function f can be associated with such a dual object, then f can be transformed into a function F such that $[F(x,y)]_{x,y}$ has high sign-rank.

▶ **Definition 6.** Let $f : \{-1,1\}^k \to \{-1,1\}$, and let $T : \{-1,1\}^k \to D$ be a (degree non-increasing) symmetrization for f. Let $\hat{\psi}\colon D \to \mathbb{R}$ be any function, and let ψ be the associated function on $\{-1,1\}^k$ induced by T. We say that $\hat{\psi}$ is a (d, ε, η)-*dual object* for f (with respect to T) if:

$$\langle \psi, f \rangle \geq \varepsilon \tag{1}$$

$$\|\psi\|_1 = 1 \tag{2}$$

$$\langle \psi, p \rangle = 0 \text{ for every polynomial } p : \{-1,1\}^k \to \mathbb{R} \text{ with } \deg p < d \tag{3}$$

$$f(x) = -1 \implies \psi(x) < 0 \tag{4}$$

$$\hat{\psi}(z_+) \geq \eta \text{ for some } z_+ \in D \text{ satisfying } \widetilde{f}(z_+) = 1 \tag{5}$$

Definition 6 is motivated by a recent line of work establishing lower bounds for polynomial approximations via linear programming duality. We direct the reader to [21, 5, 25, 7, 23, 22, 19, 18, 6] for thorough discussions of this technique and its applications to longstanding open questions in complexity theory. In short, one can use linear programming duality to show that the existence of a $(d, 2\eta, \eta)$-dual object for a function f is implied by the *non-existence* of a degree d polynomial that approximates f in a certain precise sense. In a bit more detail (and still simplifying a little), a $(d, 2\eta, \eta)$-dual object for f always exists if f cannot be uniformly approximated to error 2η by any degree d polynomial, even under the promise

that the input x is in $f^{-1}(-1) \cup T^{-1}(z_+)$. We will not use this *primal* interpretation of dual objects in our analysis, but we spell out this implication in the full version of this work for completeness and intuition.

Motivated by the study of uniform approximation of Boolean functions by polynomials, several works [24, 5, 6] have constructed dual objects directly. In particular, work of Špalek [24] and the authors [5] explicitly constructed an appropriate dual object for the AND function.

▶ **Lemma 7** (cf. [24, 5]). *Let $T : \{-1,1\}^k \to \{0,1,\ldots,k\}$ be the degree non-increasing map $T(x) = |x|$ that computes the Hamming weight. The function AND_k has a $(d, 1/2, 1/4)$-dual object with respect to T for $d = \Omega(\sqrt{k})$.*

We are now ready to define the class $\mathcal{C}_d$ of functions to which our techniques can be applied to yield sign-rank lower bounds.

▶ **Definition 8.** Let $f : \{-1,1\}^k \to \{-1,1\}$ be a Boolean function, and let $d > 0$. Then f is in the class $\mathcal{C}_d$ if there exists a symmetrization $T : \{-1,1\}^k \to D$ for f such that:

- there exists a $(d, 1/2, 1/4)$-dual object for f with respect to T, and
- the function f evaluates to TRUE (i.e. $f(x) = -1$) for at most a 2^{-d} fraction of inputs $x \in \{-1,1\}^k$.

2.5 Orthogonalizing Distributions

As indicated in Section 1.3, our analysis will make essential use of orthogonalizing distributions, which represent a dual formulation of the notion of threshold degree.

▶ **Definition 9.** A distribution $\mu : \{-1,1\}^n \to [0,1]$ is *d-orthogonalizing* for a function $h : \{-1,1\}^n \to \{-1,1\}$ if

$$\mathop{\mathbb{E}}_{x \sim \mu} [h(x)p(x)] = 0$$

for every polynomial $p : \{-1,1\}^n \to \mathbb{R}$ with $\deg p < d$. In other words, μ is d-orthogonalizing for h if the function $\mu(x)h(x)$ has pure high degree d.

2.6 The Element Distinctness Function

The Boolean function $\mathrm{ED}_k : \{-1,1\}^k \to \{-1,1\}$ is defined as follows. For simplicity, assume that $k = K \log_2 K$, where K is a power of 2. The function interprets its input x as blocks $x_1, \ldots, x_K$, where each $x_i \in \{-1,1\}^{\log_2 K}$. Each x_i is interpreted as the binary representation of $g_x(i)$ for a function $g_x : [K] \to [K]$. $\mathrm{ED}_k(x)$ is defined to equal -1 iff the function g_x is 1-to-1.

Observe that ED_k is symmetric with respect to permutations of the domain and range of g_x. That is, if $x, y \in \{-1,1\}^k$ are such that there exist permutations π, σ of $[K]$ with $g_x = \pi \circ g_y \circ \sigma$, then $\mathrm{ED}_k(x) = \mathrm{ED}_k(y)$.

In the full version of this work, we show that these symmetries imply the existence of a symmetrization T for ED_k and an associated dual object.

▶ **Lemma 10.** *There exists a symmetrization $T : \{-1,1\}^k \to [K]^K$ for the* Element Distinctness *function $\mathrm{ED}_k : \{-1,1\}^k \to \{-1,1\}$ such that ED_k has a $(d, 1/2, 1/4)$-dual object (with respect to the map T), for some $d = \Omega(K^{2/3}/\log K)$.*

▶ Remark. In fact, an explicit dual object for ED_k was constructed in our prior work [6]. In the full version of this work, we give an alternative *primal*-based proof of the existence of a dual object for ED_k. The proof is based on Aaronson and Shi's [1] influential lower bound of $\Omega(K^{2/3})$ on the *approximate degree*[1] of ED_k.

The Element Distinctness function is computed by a natural CNF formula:

$$\mathrm{ED}_k(x_1, \ldots, x_K) = \bigwedge_{r=1}^{K} \bigwedge_{i \neq j} ((x_i \neq r) \vee (x_j \neq r)).$$

Notice that the fan-in of each bottom OR gate is only $2K \leq 2\log_2 k$. Recall (cf. Corollary 3) that our aim is to prove a sign-rank lower bound for the function $F_n^{\mathrm{ED}}(x, y) = (\mathrm{OR}_{n^{2/5}} \circ \mathrm{ED}_{n^{3/5}} \circ \mathrm{AND}_C)(x \vee y)$. Using the CNF for Element Distinctness described above, the function F_n^{ED} is naturally computed by an AC^0 circuit Γ of depth 5, with an OR gate at the top. However, as we now explain, F_n^{ED} is actually computable by a *depth-3* AC^0 circuit with logarithmic bottom fan-in.

Number the layers of Γ from 1 to 5, with layer 1 corresponding to the OR gate at the top. Since each OR gate at layer 3 of Γ has fan-in $O(\log n)$ (and the gates at layers 4 and 5 have constant fan-in), the sub-circuits rooted at each gate at layer 3 of Γ are functions of only $O(\log n)$ bits of x. Since any function on $O(\log n)$ inputs can be computed by a $\mathrm{poly}(n)$ size CNF with logarithmic bottom fan-in, we can replace each sub-tree rooted at layer 3 of Γ with such a CNF, to obtain a circuit Γ' of depth 4, in which layers 2 and 3 of Γ' both consist of AND gates. Collapsing layers 3 and 4 into a single layer yields a polynomial size depth 3 circuit with logarithmic bottom fan-in that computes F_n^{ED}.

3 Constructing a Smooth Orthogonalizing Distribution

Sherstov [23] showed that whenever f has a $(d_1, 1/2, 0)$-dual object[2], the function $h_m := \mathrm{OR}_m \circ f$ has a d-orthogonalizing distribution for $d = \min\{m, d_1\}$. The goal of this section, and the main technical contribution of the paper, is to prove that whenever f has a $(d_1, 1/2, \eta)$-dual object for $\eta > 0$, the function h_m has a d-orthogonalizing distribution that places significant mass on each input $x \in h_m^{-1}(1)$. More precisely, we show:

▶ **Theorem 11.** *Suppose that $f : \{-1,1\}^k \to \{-1,1\}$ has a $(d_1, 1/2, \eta)$-dual object, and let $h_m = \mathrm{OR}_m \circ f$. Then there exists a d-orthogonalizing distribution $\mu : \{-1,1\}^{mk} \to [0,1]$ for h_m such that $\mu(x) \geq 4^{-(m+d+1)} \eta^{-m/2} 2^{-mk}$ for every $x \in h_m^{-1}(1)$, where $d = \min\{m/2, d_1\}$.*

Combining this theorem with Lemmas 7 and 10 yields smooth orthogonalizing distributions for the functions $\mathrm{OR}_{n^{1/3}} \circ \mathrm{AND}_{n^{2/3}}$ and $\mathrm{OR}_{n^{2/5}} \circ \mathrm{ED}_{n^{3/5}}$.

▶ **Corollary 12.** *There exists a d-orthogonalizing distribution μ for $h = \mathrm{OR}_{n^{1/3}} \circ \mathrm{AND}_{n^{2/3}}$ such that $\mu(x) \geq 2^{-O(d)} 2^{-n}$ on each $x \in h^{-1}(1)$, for some $d = \Omega(n^{1/3})$.*

▶ **Corollary 13.** *There exists a d-orthogonalizing distribution μ for $h = \mathrm{OR}_{n^{2/5}} \circ \mathrm{ED}_{n^{3/5}}$ such that $\mu(x) \geq 2^{-O(d)} 2^{-n}$ on each $x \in h^{-1}(1)$, for some $d = \tilde{\Omega}(n^{2/5})$.*

---

[1] The approximate degree of a Boolean function f is the minimum degree of a real polynomial for which $|p(x) - f(x)| \leq 1/3$ for all Boolean inputs x.

[2] The existence of a $(d_1, 1/2, 0)$-dual object for f is in fact a dual formulation of the property that f has *one-sided approximate degree* at least d_1. See [5, 23] for the definition of one-sided approximate degree.

3.1 Proof of Theorem 11

3.1.1 Notation

Let $f : \{-1,1\}^k \to \{-1,1\}$ be as in the statement of Theorem 11, and let $T : \{-1,1\}^k \to D$ be the symmetrization for f associated with the assumed $(d_1, 1/2, \eta)$-dual object for f. Define $T^m \colon \{-1,1\}^{mk} \to D^m$ by $T^m(x_1, \ldots, x_m) := (T(x_1), \ldots, T(x_m))$. Since T is degree non-increasing, it is easy to see that T^m is also degree non-increasing. Moreover, T^m is a symmetrization for h_m. The map T^m induces a symmetrized version $\widetilde{h}_m \colon D^M \to \mathbb{R}$ of h_m given by $\widetilde{h}_m = \mathrm{OR}_m \circ \widetilde{f}$.

3.1.2 Proof Outline

Let $Z^+ := \widetilde{h}_m^{-1}(1) \subseteq D^m$. At a high level, our proof will produce, for every $z \in Z^+$, a d-orthogonalizing distribution μ_z that is targeted to z, in the sense that

$$\hat{\mu}_z(z) \geq 2^{-O(m+d)} \cdot \eta^{-O(m)}.$$

Since the property of d-orthogonalization is preserved under averaging, the distribution $\mu = \frac{1}{|Z^+|} \sum_{z \in Z^+} \mu_z$ remains d-orthogonalizing, and places the required amount of probability mass on each input $x \in T^{-1}(Z^+) = h_m^{-1}(1)$. The goal therefore becomes to construct these targeted distributions μ_z. We do this in two stages.

Stage 1. In the first stage (see Claim 15 below), we construct distributions μ_z for every z belonging to a highly structured subset $G \subset Z^+$ that we now describe. Let $c \in \widetilde{f}^{-1}(1)$ denote the point on which the dual object $\hat{\psi}$ for f has $\hat{\psi}(c) \geq \eta$ (cf. Condition (5) within Definition 6). The set G consists of inputs in Z^+ for which $c \in D$ is repeated many times (specifically, at least $m/2$ times).

Stage 2. In the second stage (see Claim 16 below), we show that given the family of distributions $\{\mu_z : z \in G\}$ constructed in Stage 1, we can construct appropriate distributions μ_z for z belonging to the entire set Z^+.

Both stages can be viewed as generalized dual counterparts to analogous statements in the work of Razborov and Sherstov (cf. [17, Lemma 3.4] and [17, Theorem 3.6] respectively). Taking a dual perspective allows us to identify general properties (Definition 6) of a dual object for f that enable the construction of a smooth orthogonalizing distribution. This results in a much more general and modular framework for proving the existence of these distributions. Our framework also has the advantage of constructing smooth orthogonalizing distributions explicitly.

3.1.3 Proof Details

We begin with a relatively simple lemma that shows that the function $\mathrm{OR}_{m/2} \circ f$ has a d-orthogonalizing distribution μ such that $\hat{\mu}$ places a lot of probability mass on a particular highly structured input, where $d = \min\{d_1, m/2\}$. This distribution is an important building block in the proof of Claim 15 below.

▶ **Lemma 14.** *Let $\ell = m/2$, and let f, T, and T^ℓ be as above. Consider the function $h_\ell : \{-1,1\}^{k\ell} \to \{-1,1\}$ defined by $h_\ell(x_1, \ldots, x_\ell) = \mathrm{OR}_\ell(f(x_1), \ldots, f(x_\ell))$. There exists a*

function $\psi : \{-1,1\}^{k\ell} \to [0,1]$ *symmetrized by* T^ℓ *with the following properties.*

$$\psi \text{ agrees in sign with } h_\ell. \text{ That is, } \psi(x) \cdot h_\ell(x) \geq 0 \text{ for all } x \in \{-1,1\}^{k\ell} \tag{6}$$

$$\|\psi\|_1 = 1 \tag{7}$$

$$\psi \text{ has pure high degree at least } d = \min\{\ell, d_1\} \tag{8}$$

$$\text{There exists a } c \in D \text{ such that } \widetilde{f}(c) = 1 \text{ and } \hat{\psi}(\underbrace{c, \ldots, c}_{\ell \text{ times}}) \geq \eta^{-\ell}/2 \tag{9}$$

We remark that Conditions (6)–(8) are equivalent to requiring that $\mu := \psi \cdot h_\ell$ is a d-orthogonalizing distribution for h_ℓ, where $d = \min\{\ell, d_1\}$.

Proof Sketch. Sherstov [23] showed that when the function f has a $(d_1, 1/2, 0)$-dual witness, then there is a function ψ satisfying Conditions (6)–(8). In the full version of this work, we show that if f additionally has a $(d_1, 1/2, \eta)$-dual witness with $\eta > 0$, then Sherstov's construction yields a function $\hat{\psi}$ that also satisfies Condition (9). ◀

To complete Stage 1 of our proof, we show that for every input $w \in D^m$ that is close in Hamming distance to the special point $(\underbrace{c, \ldots, c}_{m \text{ times}})$, there is an orthogonalizing distribution for h_m that places substantial weight on w. Let $G \subset Z^+ = \widetilde{h}_m^{-1}(1)$ denote the set of inputs in $\widetilde{h}_m^{-1}(1)$ that take the value c on at least $m/2$ coordinates. That is,

$$G = \{z \in Z^+ : \exists i_1, \ldots, i_{m/2} \text{ s.t. } z_{i_1} = \cdots = z_{i_{m/2}} = c\}.$$

▶ **Claim 15.** *Let* G *be as above. For every* $w = (w_1, \ldots, w_m) \in G$*, there exists a* d*-orthogonalizing distribution* $\nu_w : \{-1,1\}^{km} \to [0,1]$ *for* h_m *such that* ν_w *is symmetrized by* T^m *and* $\hat{\nu}_w(w) \geq \eta^{m/2}/2$*.*

Proof Sketch. Let $I = \{i_1, \ldots, i_{m/2}\}$ denote the first $m/2$ coordinates on which w takes the value c. Define the distribution $\hat{\nu}_w$ by

$$\hat{\nu}_w(z) = \begin{cases} |\hat{\psi}(z_{i_1}, \ldots, z_{i_{m/2}})| & \text{if } z_i = w_i \text{ for all } i \notin I \\ 0 & \text{otherwise} \end{cases}$$

where $\hat{\psi}$ is the function from Lemma 14 for $\ell = m/2$. It is immediate from the definition that $\hat{\nu}_w$ is a distribution on D^m, and hence ν_w is a distribution on $\{-1,1\}^{km}$. Moreover, $\hat{\nu}_w(w) \geq \eta^{m/2}/2$. The fact that ν_w is d-orthogonalizing follows from the fact that ψ has pure high degree at least d. This calculation appears in the full version of this work. ◀

We now proceed to Stage 2 of our proof, in which we use the distributions constructed in Claim 15 to give orthogonalizing distributions that place significant weight on *any* input $x \in h_m^{-1}(1)$.

▶ **Claim 16.** *Let* G *be as before, and suppose that for every* $w \in G$ *there exists a* d*-orthogonalizing distribution* $\nu_w : \{-1,1\}^{km} \to [0,1]$ *for* h_m *that is symmetrized by* T^m*, and satisfies* $\hat{\nu}_w(w) \geq \delta$*. Then for every* $v \in (Z^+ \setminus G)$*, there exists a* d*-orthogonalizing distribution* ρ_v *that is symmetrized by* T^m*, and* $\hat{\rho}_v(v) \geq \delta/4^{m+d}$*.*

The main technical ingredient in the proof of Claim 16 is the construction of a function $\varphi : \{0,1\}^m \to \mathbb{R}$ of pure high degree d for which $\varphi(1^m)$ is "large". This can be viewed as a dual formulation of a bound on the growth of low-degree polynomials. The construction of φ appears as part of the proof of such a bound in [17].

▶ Remark. We choose to state Lemma 17 below for a function $\varphi : \{0,1\}^m \to \mathbb{R}$, rather than applying our usual convention of working with functions over $\{-1,1\}^m$, because it makes various statements in the proof of Claim 16 cleaner. To clarify the terminology below, we say a function $\varphi : \{0,1\}^m \to \mathbb{R}$ has *pure high degree* d if $\sum_{x\in\{0,1\}^m} \varphi(x) \cdot p(x) = 0$ for every polynomial $p : \{0,1\}^m \to \mathbb{R}$ of degree less than d. The Hamming weight function $|\cdot| : \{0,1\}^m \to [m]$ counts the number of 1's in its input, i.e. $|s| = s_1 + s_2 + \cdots + s_m$.

▶ **Lemma 17** (cf. [17, Proof of Lemma 3.2]). *Let d be an integer with $0 \le d \le m-1$. Then there exists a function $\varphi : \{0,1\}^m \to \mathbb{R}$ such that*

$$\varphi(1^m) = 1 \tag{10}$$

$$\varphi(x) = 0 \text{ for all } d \le |x| < m \tag{11}$$

$$\varphi \text{ has pure high degree at least } d \tag{12}$$

$$\sum_{|x|\le d} |\varphi(x)| \le 2^d \binom{m}{d} \tag{13}$$

Proof of Claim 16. Fix $v \in (Z^+ \setminus G)$. Define an auxiliary function $\hat{\varphi}_v : D^m \to [0,1]$ as follows. For any $z = (z_1, \ldots, z_m)$, let

$$\hat{\varphi}_v(z) := \sum_{\substack{s\in\{0,1\}^m \text{ s.t.} \\ \forall i\ z_i = s_i c + (1-s_i)v_i}} \varphi(s),$$

where φ is as in Lemma 17, with d set as in the conclusion of Claim 15 (observe that if there is some z_i such that $z_i \neq c$ and $z_i \neq v_i$, then $\hat{\varphi}_v(z) = 0$).

Letting φ_v denote the function on $\{-1,1\}^{km}$ induced from $\hat{\varphi}_v$ by T^m, we record some properties of φ_v and $\hat{\varphi}_v$.

$$\hat{\varphi}_v(v) = \varphi(1^m) = 1 \tag{14}$$

$$\operatorname{supp} \hat{\varphi}_v \subset G \cup \{v\} \tag{15}$$

$$\varphi_v \text{ has pure high degree at least } d \tag{16}$$

$$\|\varphi_v\|_1 \le 2^d \binom{m}{d} + 1 \tag{17}$$

$$\hat{\varphi}_v \text{ is supported on at most } \frac{1}{2}2^m + 1 \text{ points in } D^m \tag{18}$$

Verifying Conditions (14)–(18). Conditions (14), (15), and (18) are immediate from the definition of $\hat{\varphi}_v$, combined with Conditions (10) and (11) of Lemma 17. For Condition (16), it is enough to show that if $p_1, \ldots, p_m$ are polynomials over $\{-1,1\}^k$ whose degrees sum to less than d, then $\sum_{x=(x_1,\ldots,x_m)\in\{-1,1\}^{km}} \varphi_v(x) \prod_{i=1}^m p_i(x_i) = 0$. To establish this, let $q_1, \ldots, q_m \colon D \to \mathbb{R}$ denote polynomials satisfying $\deg(q_i) \le \deg(p_i)$, and such that for all i and all z_i in the image of T, $q_i(z_i) := \mathbb{E}_{x\in T^{-1}(z_i)}[p_i(z_i)]$. Such polynomials are guaranteed

to exist, since T is degree non-increasing. Then:

$$\begin{aligned}\sum_{x=(x_1,\ldots,x_m)\in\{-1,1\}^{km}} \varphi_v(x)\prod_{i=1}^m p_i(x_i) &= \sum_{z=(z_1,\ldots,z_m)\in D^m} \hat{\varphi}_v(z)\prod_{i=1}^m q_i(z_i)\\ &= \sum_{z=(z_1,\ldots,z_m)\in D^m}\left(\sum_{\substack{s\in\{0,1\}^m \text{ s.t.}\\ \forall i\ z_i=s_ic+(1-s_i)v_i}}\varphi(s)\right)\prod_{i=1}^m q_i(z_i)\\ &= \sum_{s\in\{0,1\}^m}\varphi(s)\prod_{i=1}^m q_i(s_ic+(1-s_i)v_i)\\ &= 0,\end{aligned}$$

To see that the final equality holds, recall that that degrees of the polynomials q_i sum to strictly less than d. Hence, $p(s_1,\ldots,s_m) := \prod_{i=1}^m q_i(s_ic+(1-s_i)v_i)$ is a polynomial of degree strictly less than d over $\{-1,1\}^m$. The final equality then follows from the fact that φ has pure high degree at least d.

To establish Condition (17), we check that

$$\sum_{z\in D^m, z\neq v}|\hat{\varphi}_v(z)| \le \sum_{s\in\{0,1\}^m, s\neq 1^m}|\varphi(s)| \le 2^d\binom{m}{d},$$

where the final inequality holds by Condition (13).

Construction and analysis of ρ_v. Up to normalization, the function $\varphi_v\cdot h_m$ has all of the properties that we need to establish Claim 16, except that there are locations where it may be negative. We obtain our desired orthogonalizing distribution ρ_v by adding correction terms to $\hat{\varphi}_v$ in the locations where $\hat{\varphi}_v$ may disagree with $\widetilde{h}_m$ in sign. These correction terms are derived from the distributions $\hat{\nu}_w$ whose existence are hypothesized in the statement of Claim 16. We start by defining

$$\hat{P}_v(z) = \frac{\delta}{2^d\binom{m}{d}+1}\widetilde{h}_m(z)\hat{\varphi}_v(z) + \sum_{w\in(\operatorname{supp}\hat{\varphi}_v\setminus\{v\})}\hat{\nu}_w(z). \tag{19}$$

Observe that each w appearing in the sum on the right hand side of Eq. (19) is in the set G, owing to Condition (15). This guarantees that each term $\hat{\nu}_w$ in the sum is well-defined.

Now we check that $\hat{P}_v$ is nonnegative. Since each term $\hat{\nu}_w$ appearing in the sum on the right hand side of Eq. (19) is a distribution (and hence non-negative), it suffices to check that $\hat{P}_v(z)\ge 0$ for each point $z\in\operatorname{supp}\hat{\varphi}_v$. On each such point with $z\neq v$, Condition (17) guarantees that $\frac{\delta}{2^d\binom{m}{d}+1}\widetilde{h}_m(z)\hat{\varphi}_v(z)\ge -\delta$. Moreover, the contribution of the sum is at least $\hat{\nu}_z(z)\ge\delta$ by hypothesis. Hence, $\hat{P}_v$ is a non-negative function.

Next, we check that normalizing $\hat{P}_v$ yields a distribution $\hat{\rho}_v := \hat{P}_v/\|P_v\|_1$ for which $\hat{\rho}_v(v)\ge\delta/4^{m+d}$ as required. By construction, $\hat{P}_v(v) = \delta/\left(2^d\binom{m}{d}+1\right)$. Moreover, Conditions (14), (17), and (18) together show that $\|\hat{P}_v\|_1\le\delta+\frac{1}{2}2^m\le 2^m$. Hence, $\hat{P}_v(v)\ge\delta/\left(2^m\cdot\left(2^d\binom{m}{d}+1\right)\right)\ge\delta/\left(2^{m+d+1}\binom{m}{d}\right)\ge\delta/2^{2m+d+1}\ge\delta/4^{m+d}$.

Finally, we must check that $\rho_v = P_v/\|P_v\|_1$ is d-orthogonalizing for h_m. To see this, observe that $P_v\cdot h_m$ is a linear combination of the functions φ_v and $\nu_w\cdot h_m$ for $w\in(\operatorname{supp}\hat{\varphi}_v\setminus\{v\})$. Moreover, each of these functions has pure high degree at least d (φ_v does so by Condition (16), while $\nu_w\cdot h_m$ does by the fact that ν_w is d-orthogonalizing for h_m). By

linearity, it follows that $P_v \cdot h_m$ has pure high degree at least d, so ρ_v is d-orthogonalizing for h_m as desired.

This completes the proof of Claim 16. ◀

We are now ready to combine the claims above to prove Theorem 11.

Proof of Theorem 11. By Claim 15, for every $w \in G$ there exists a d-orthogonalizing distribution $\nu_w : \{-1,1\}^{km} \to [0,1]$ for h_m that is symmetrized by T^m, with $\hat{\nu}_w(w) \geq \eta^{m/2}/2$. Thus, by Claim 16, it is also true that for every $v \in (Z^+ \setminus G)$, there is a d-orthogonalizing distribution $\rho_v : \{-1,1\}^{km} \to [0,1]$ that is symmetrized by T^m, with $\hat{\rho}_v(v) \geq \eta^{m/2} 4^{-(m+d+1)}$. Now consider the distribution

$$\hat{\mu}(z) = \frac{1}{|Z^+|} \left(\sum_{w \in G} \hat{\nu}_w(z) + \sum_{v \in (Z^+ \setminus G)} \hat{\rho}_v(z) \right).$$

The (un-symmetrized) distribution $\mu : (\{-1,1\}^k)^m \to [0,1]$ satisfies $\mu(x) \geq \eta^{m/2} 4^{-(m+d+1)} 2^{-km}$ for every point $x \in T^{-1}(Z^+) = h_m^{-1}(1)$. Moreover, μ remains d-orthogonalizing for h_m, as it is a sum of d-orthogonalizing distributions for h_m. ◀

4 Sign Rank Lower Bounds for AC^0

We now use the machinery developed by Razborov and Sherstov to translate our construction of a smooth orthogonalizing distribution into a sign-rank lower bound.

▶ **Theorem 18** (Implicit in [17, Theorem 1.1])**.** *Let $h\colon \{-1,1\}^n \to \{-1,1\}$ be a Boolean function, and suppose there exists a d-orthogonalizing distribution μ for h such that $\mu(x) \geq 2^{-cd} 2^{-n}$ for all but a 2^{-cd} fraction of inputs $x \in \{-1,1\}^n$. Then there exists a constant C (depending only on c) such that if $F(x,y) := h(\ldots, \wedge_{j=1}^{C}(x_{ij} \vee y_{ij}), \ldots)$, then the matrix $[F(x,y)]_{x,y}$ has sign-rank $\exp(\Omega(d))$.*

Combining Theorem 18 with Theorem 11 yields the main result of this work.

▶ **Theorem 19.** *Let $f : \{-1,1\}^k \to \{-1,1\}$ be a Boolean function in the class $\mathcal{C}_d$. Let $F : \{-1,1\}^n \to \{-1,1\}^n$ be defined by*

$$F = \mathrm{OR}_{2d} \circ f \circ \mathrm{AND}_C \circ \mathrm{OR}_2,$$

where C is the universal constant of Theorem 18 (and hence $n = O(dk)$). The sign-rank of the matrix $[F(x,y)]_{x,y}$ is $\exp(\Omega(d))$.

Proof. Let $h_{2d} : \{-1,1\}^{2dk} \to \{-1,1\}$ denote the function $h_{2d} = \mathrm{OR}_{2d} \circ f$. By Theorem 11, there exists a d-orthogonalizing distribution μ for h_{2d} such that $\mu(x) \geq 2^{-9d} 2^{-2dk}$ for every $x \in h_{2d}^{-1}(1)$. Since $f \in \mathcal{C}_d$, we have by a union bound that $h_{2d}^{-1}(1)$ contains all but a $(2d) \cdot 2^{-d} \leq 2^{-d/2}$ fraction of the points in $\{-1,1\}^{2dk}$. Thus, by Theorem 18, there is a universal constant C for which $[F(x,y)]_{x,y}$ has sign-rank $\exp(\Omega(d))$. ◀

▶ **Corollary 20.** *Let $\mathrm{MP}_n = \mathrm{OR}_{n^{1/3}} \circ \mathrm{AND}_{n^{2/3}}$ be the Minsky-Papert DNF. Then $[\mathrm{MP}_n(x \vee y)]_{x,y}$ has sign-rank $\exp(\Omega(n^{1/3}))$*

Proof. The function AND_k evaluates to TRUE on exactly 1 out of 2^k inputs. Hence, by Lemma 7, we have $\mathrm{AND}_k \in \mathcal{C}_d$ for $d = \Omega(k^{1/2})$. Let $F = \mathrm{MP}_n \circ \mathrm{AND}_C \circ \mathrm{OR}_2$. Applying Theorem 19 implies that the sign-rank of $[F(x,y)]_{x,y} = \exp(\Omega(n^{1/3}))$. Merging the two adjacent layers of AND gates in the natural circuit computing F yields the desired result. ◀

▶ **Corollary 21.** *Let* $F_n^{\mathrm{ED}} = \mathrm{OR}_{n^{2/5}} \circ \mathrm{ED}_{n^{3/5}} \circ \mathrm{AND}_C$. *Then* $[F_n^{\mathrm{ED}}(x \vee y)]_{x,y}$ *has sign-rank* $\exp(\tilde{\Omega}(n^{2/5}))$

Proof. Assume for simplicity that $k = K \log K$. The function ED_k evaluates to TRUE on exactly $K!$ inputs, which is an $\exp(-O(K))$ fraction of the $2^k = K^K$ total inputs. Hence, by Lemma 10, we have $\mathrm{ED}_k \in \mathcal{C}_d$ for $d = \Omega(K^{2/3}/\log K)$. The result follows by applying Theorem 19. ◀

On the Sensitivity Conjecture

Avishay Tal*

Institute for Advanced Study, Princeton, USA
avishay.tal@gmail.com

Abstract

The sensitivity of a Boolean function $f : \{0,1\}^n \to \{0,1\}$ is the maximal number of neighbors a point in the Boolean hypercube has with different f-value. Roughly speaking, the block sensitivity allows to flip a set of bits (called a block) rather than just one bit, in order to change the value of f. The sensitivity conjecture, posed by Nisan and Szegedy (CC, 1994), states that the block sensitivity, $bs(f)$, is at most polynomial in the sensitivity, $s(f)$, for any Boolean function f. A positive answer to the conjecture will have many consequences, as the block sensitivity is polynomially related to many other complexity measures such as the certificate complexity, the decision tree complexity and the degree. The conjecture is far from being understood, as there is an exponential gap between the known upper and lower bounds relating $bs(f)$ and $s(f)$.

We continue a line of work started by Kenyon and Kutin (Inf. Comput., 2004), studying the ℓ-block sensitivity, $bs_\ell(f)$, where ℓ bounds the size of sensitive blocks. While for $bs_2(f)$ the picture is well understood with almost matching upper and lower bounds, for $bs_3(f)$ it is not. We show that any development in understanding $bs_3(f)$ in terms of $s(f)$ will have great implications on the original question. Namely, we show that either $bs(f)$ is at most sub-exponential in $s(f)$ (which improves the state of the art upper bounds) or that $bs_3(f) \geq s(f)^{3-\varepsilon}$ for some Boolean functions (which improves the state of the art separations).

We generalize the question of $bs(f)$ versus $s(f)$ to bounded functions $f : \{0,1\}^n \to [0,1]$ and show an analog result to that of Kenyon and Kutin: $bs_\ell(f) = O(s(f))^\ell$. Surprisingly, in this case, the bounds are close to being tight. In particular, we construct a bounded function $f : \{0,1\}^n \to [0,1]$ with $bs(f) \geq n/\log n$ and $s(f) = O(\log n)$, a clear counterexample to the sensitivity conjecture for bounded functions.

Finally, we give a new super-quadratic separation between sensitivity and decision tree complexity by constructing Boolean functions with $\mathrm{DT}(f) \geq s(f)^{2.115}$. Prior to this work, only quadratic separations, $\mathrm{DT}(f) = s(f)^2$, were known.

1 Introduction

A long-standing open problem in complexity and combinatorics asks what is the relationship between two complexity measures of Boolean functions: the sensitivity and block-sensitivity. We first recall the definition of the two complexity measures.

▶ **Definition 1.** Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function and $x \in \{0,1\}^n$ be a point. The sensitivity of f at x is the number of neighbors y of x in the Hamming cube such that $f(y) \neq f(x)$, i.e., $s(f,x) \triangleq |\{i \in [n] : f(x) \neq f(x \oplus e_i)\}|$.[1] The (maximal) sensitivity of f is defined as $s(f) \triangleq \max_{x \in \{0,1\}^n} s(f,x)$.

▶ **Definition 2.** Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function and $x \in \{0,1\}^n$ be a point. For a block $B \subseteq [n]$, denote by $\mathbb{1}_B \in \{0,1\}^n$ its characteristic vector, i.e., $(\mathbb{1}_B)_i = 1$ iff $i \in B$. We say that a block B is sensitive for f on x if $f(x) \neq f(x \oplus \mathbb{1}_B)$. The block-sensitivity of f at x $x \in \{0,1\}^n$ is the maximal number of disjoint sensitive blocks for f at x, i.e.,

$$bs(f,x) = \max\{r : \exists \text{ disjoint } B_1, B_2, \ldots, B_r \subseteq [n] \ , f(x) \neq f(x \oplus \mathbb{1}_{B_i})\} \ .$$

The (maximal) block-sensitivity of f is defined as $bs(f) \triangleq \max_{x \in \{0,1\}^n} bs(f,x)$.

For shorthand, we will denote $(x \oplus e_i)$ and $(x \oplus \mathbb{1}_B)$ by $(x + e_i)$ and $(x + B)$ respectively. By definition, the block-sensitivity is at least the sensitivity by considering only blocks of size 1. The sensitivity conjecture, posed by Nisan and Szegedy [14], asks if a relation in the other direction holds as well.

▶ **Conjecture 3** (The Sensitivity Conjecture). $\exists d \ \forall f : \ bs(f) \leq s(f)^d$.

A stronger variant of the conjecture states that d can be taken to be 2. Despite much work on the problem [13, 14, 15, 12, 8, 20, 4, 11, 6, 1, 2, 5, 3, 9, 17, 10] there is still an exponential gap between the best known separations and the best known relations connecting the two complexity measures.

Known Separations. An interesting example due to Rubinstein [15] shows a quadratic separation between the two measures: $bs(f) = \frac{1}{2} \cdot s(f)^2$. This example was improved by [20] and then by [4] to $bs(f) = \frac{2}{3} \cdot s(f)^2 \cdot (1 - o(1))$ which is current state of the art.

Known Relations. Simon [16] proved (implicitly) that $bs(f)$ is at most $4^{s(f)} \cdot s(f)$. The upper bound was improved by Kenyon and Kutin [12] who showed that $bs(f) \leq O(e^{s(f)} \cdot \sqrt{s(f)})$. Recently, Ambainis et al. [1] improved this bound to $bs(f) \leq 2^{s(f)-1} \cdot s(f)$. Even more recently, Ambainis et al. [3] improved this bound slightly to $bs(f) \leq 2^{s(f)-1} \cdot (s(f) - 1/3)$.

To sum up, while the best known upper bound on the block-sensitivity in terms of sensitivity is exponential, the best known lower bound is quadratic. Indeed, we seem far from understanding the right relation between the two complexity measures.

1.1 ℓ-block sensitivity

All mentioned examples that exhibit quadratic separations between the sensitivity and block sensitivity ([15, 20, 4]) have the property that the maximal block sensitivity is achieved on blocks of size at most 2. For this special case, Kenyon and Kutin [12] showed that the block sensitivity is at most $2 \cdot s(f)^2$. Hence, these examples are essentially tight for this subcase.

Kenyon and Kutin introduced the notion of ℓ-block sensitivity (denoted $bs_\ell(f)$): the maximal number of disjoint sensitive blocks where each block is of size at most ℓ. Note that without loss of generality we may consider only sensitive blocks that are minimal with respect to set-inclusion (since otherwise we could of picked smaller blocks that are still disjoint). A

[1] e_i is the vector whose i-th entry equals 1 and all other entries equal 0.

well-known fact (cf. [7, Lemma 3]) asserts that any minimal sensitive block for f is of size at most $s(f)$, thus $bs(f) = bs_{s(f)}(f)$. Kenyon and Kutin proved the following inequalities relating the ℓ-block sensitivity of different ℓ-s:

$$bs_\ell(f) \leq \frac{4}{\ell} \cdot s(f) \cdot bs_{\ell-1}(f) \tag{1}$$

$$bs_\ell(f) \leq \frac{e}{(\ell-1)!} \cdot s(f)^\ell \tag{2}$$

for all $2 \leq \ell \leq s(f)$. Plugging $\ell = s(f)$ gives the aforementioned bound $bs(f) \leq O(e^{s(f)} \cdot \sqrt{s(f)})$.

1.2 Our Results

1. In the full version [19], we refine the argument of Kenyon and Kutin giving a better upper bound on the ℓ-block sensitivity in terms of $(\ell-1)$-block sensitivity. We show that

$$bs_\ell(f) \leq \frac{e}{\ell} \cdot s(f) \cdot bs_{\ell-1}(f) \tag{3}$$

   improving the bound in Eq. (1). On the other hand, Kenyon and Kutin gave examples with $bs_\ell(f) \geq \frac{1}{\ell} \cdot s(f) \cdot bs_{\ell-1}(f)$. Hence, Eq. (3) (and in fact, also Eq. (1)) is tight up to a constant. Interestingly, our analysis uses (a very simple) ordinary differential equation.
2. In Section 2, we put focus on understanding $bs_3(f)$ in terms of the sensitivity. We show that an upper bound of the form $bs_3(f) \leq s(f)^{3-\varepsilon}$ for some constant ε implies a sub-exponential upper bound for the sensitivity conjecture: $\forall f : bs(f) \leq 2^{s(f)^{1-\delta}}$, for $\delta > 0$. On the other hand, the best known separation (i.e., the aforementioned example by [4]) gives examples with $bs_3(f) \geq bs_2(f) \geq \Omega(s(f)^2)$. Thus, improving either the upper or lower bound for $bs_3(f)$ in terms of $s(f)$ will imply a breakthrough in our understanding of the sensitivity conjecture.
3. In Section 3, we consider an extension of the sensitivity conjecture to bounded functions $f : \{0,1\}^n \to [0,1]$. We show that while Kenyon and Kutin's approach works in this model, it is almost tight, i.e., we give functions for which $bs_\ell(f) = \Omega((s(f)/\ell)^\ell)$. In particular, we give a function with sensitivity $O(\log n)$ and block sensitivity $\Omega(n/\log n)$ – a clear counterexample for the sensitivity conjecture in this model.
4. In Section 4, we find better-than-quadratic separations between the sensitivity and the decision tree complexity. We construct functions based on minterm cyclic functions (as coined by Chakraborty [8]), that were found using computer search. In particular, we give an infinite family of functions $\{f_n\}_{n \in I}$ with $\mathrm{DT}(f_n) = n$ and $s(f_n) = O(n^{0.48})$. In addition, we give an infinite family of functions $\{g_n\}_{n \in I}$ with $s(g_n) = O(\mathrm{DT}(g_n)^{0.473})$.

2 Understanding $bs_3(f)$ is Important

As the upper and lower bounds for $bs_2(f)$ are almost matching, it seems that the next challenge is understanding the asymptotic behavior of $bs_3(f)$. A more modest challenge is the following.

▶ **Open Problem 4.** *Improve either the upper or lower bound on $bs_3(f)$.*

Recall that the upper bound on $bs_3(f)$ is $O(s(f)^3)$ (see Eq. (2)) and the lower bound is $(2/3) \cdot s(f)^2 \cdot (1 - o(1))$. It is somewhat surprising that any slight improvement on either the lower or upper bound on bs_3 would be a significant step forward in our understanding of the general question. The following claim shows that a slightly better than quadratic gap on a single example implies a better than quadratic gap on an infinite family of examples.

▶ **Claim 5.** *If there exists a function such that $bs_3(f) > s(f)^2$ then there exists a family of functions $\{f_n\}_{n\in\mathbb{N}}$ with $bs(f_n) > s(f_n)^{2+\varepsilon}$ for some constant $\varepsilon > 0$ (dependant on f).*

This family is simply $f_1 = f$, $f_n = f \circ f_{n-1}$ where $\circ$ stands for Boolean function composition as in [18]. Next, we prove a theorem exhibiting the self-reducibility nature of the problem.

▶ **Theorem 6.** *Let $k, \ell, a \in \mathbb{N}$ such that $\ell > k$ and let $T : \mathbb{N} \to \mathbb{R}$ be a monotone function. If $\forall f : bs_\ell(f) \leq T(bs_k(f))$, then $\forall f' : bs_{\ell a}(f') \leq T(bs_{ka}(f'))$.*

Proof. Assume by contradiction that there exists a function f' such that $bs_{\ell a}(f') > T(bs_{ka}(f'))$. We will show that there exists a function f such that $bs_\ell(f) > T(bs_k(f))$. We shall assume WLOG that the maximal $bs_{\ell a}$ of f' is achieved on $\vec{0}$. Let $B_1, B_2, \ldots, B_m$ be a family of disjoint sensitive blocks for f at $\vec{0}$, each B_i of size at most ℓa. Split every block B_i to ℓ sets $B_{i,1}, \ldots, B_{i,\ell}$ of size at most a. The function f will have a variable $x_{i,j}$ corresponding to every set $B_{i,j}$ of size at most a. The value of $f(x_{1,1}, \ldots, x_{m,\ell})$ is defined to be the value of f' where the variable in each $B_{i,j}$ equal $x_{i,j}$, and all other variables equal 0. $bs_\ell(f, \vec{0}) \geq bs_{\ell a}(f', \vec{0})$, since for any sensitive block $B_1, \ldots, B_m$ for f', there exists a corresponding sensitive block $B'_1, \ldots, B'_m$ for f of size ℓ, where $B'_i = \{x_{i,j} : j \in [\ell]\}$.

On the other hand, any set of disjoint sensitive blocks of size at most k for f corresponds to a disjoint set of sensitive blocks of size at most ka for f'. Thus $bs_k(f) \leq bs_{ka}(f')$, giving

$$T(bs_k(f)) \leq T(bs_{ka}(f')) < bs_{\ell a}(f') \leq bs_\ell(f) \ ,$$

where we used the monotonicity of T in the first inequality. ◀

Using Theorem 6 we get that any upper bound of the form $bs_\ell(f) \leq s(f)^{\ell-\varepsilon}$ implies a sub-exponential upper bound on $bs(f)$ in terms of $s(f)$.

▶ **Theorem 7.** *Let $k \in \mathbb{N}, \varepsilon > 0$ be constants. If for all Boolean functions $bs_k(f) \leq s(f)^{k-\epsilon}$, then for the constant $\gamma = \frac{\log(k-\varepsilon)}{\log(k)} < 1$ it holds that $bs(f) \leq 2^{O(s(f)^\gamma \cdot \log s(f))}$ for all f.*

For example, Theorem 7 shows that if $\forall f : bs_3(f) \leq s(f)^2$, then $\forall f : bs(f) \leq 2^{O(s^{0.631}\cdot\log(s))}$.

Proof. Using the hypothesis and Theorem 6 one can show by induction on t that

$$\forall f : bs_{k^t}(f) \leq s(f)^{(k-\epsilon)^t} \ . \tag{4}$$

The base case $t = 1$ is simply the hypothesis. We assume the claim is true for $1, \ldots, t-1$, and show the claim is true for t. Using Theorem 6 with $T(x) = x^{k-\epsilon}$ and $a = k^{t-1}$ we get $bs_{k^t}(f) \leq T(bs_{k^{t-1}}(f)) = (bs_{k^{t-1}}(f))^{k-\epsilon}$. By induction $bs_{k^{t-1}}(f) \leq s(f)^{(k-\epsilon)^{t-1}}$. Hence, we get $bs_{k^t}(f) \leq s(f)^{(k-\epsilon)^t}$, which finishes the induction proof.

Fix f and let $s = s(f)$. Recall that $bs(f) = bs_s(f)$ since each minimal block that flips the value of f is of size at most s. Hence,

$$\begin{aligned} bs(f) &= bs_s(f) = bs_{k^{\lceil \log_k(s) \rceil}}(f) \\ &\leq s^{(k-\epsilon)^{\lceil \log_k(s) \rceil}} \leq s^{(k-\epsilon)^{\log_k(s)+1}} = 2^{\log(s)\cdot s^{\log(k-\epsilon)/\log(k)}\cdot(k-\epsilon)} = 2^{O(s^\gamma \cdot \log(s))} \ . \end{aligned}$$ ◀

3 The Sensitivity Conjecture for Bounded Functions

In this section, we generalize the definitions of sensitivity and block sensitivity to bounded functions $f : \{0,1\}^n \to [0,1]$, extending the definitions for Boolean functions. We generalize the result of Kenyon and Kutin to this setting (after removing some trivial obstucles). Given

that, one may hope that the sensitivity conjecture holds also for bounded functions, i.e., that the block-sensitivity is at most polynomial in the sensitivity. However, we give a counterexample to this question, by constructing functions on n variables with sensitivity $O(\log n)$ and block sensitivity $n/\log(n)$. In fact, we show that the result of Kenyon and Kutin is essentially tight by giving examples for which $bs_\ell(f) = n/\ell$ and $s(f) = O(\ell \cdot n^{1/\ell})$ for any $\ell \leq \log n$.

We begin by generalizing the definitions of sensitivity and block-sensitivity. For $f : \{0,1\}^n \to [0,1]$ and $x \in \{0,1\}^n$, we denote the sensitivity of f at a point x by

$$s(f,x) = \sum_{i=1}^{n} |f(x) - f(x \oplus e_i)|. \tag{5}$$

Similarly we define the block sensitivity and ℓ-block sensitivity as

$$bs(f,x) = \max \left\{ \sum_i |f(x) - f(x + B_i)| \ : \ B_1, \ldots, B_k \subseteq [n] \text{ are disjoint} \right\} . \tag{6}$$

and

$$bs_\ell(f,x) = \max \left\{ \sum_i |f(x) - f(x + B_i)| \ : \ B_1, \ldots, B_k \subseteq [n] \text{ are disjoint and } \forall i. |B_i| \leq \ell \right\} .$$

Naturally we denote by $s(f) = \max_x s(f,x)$, by $bs(f) = \max_x bs(f,x)$ and by $bs_\ell(f) = \max_x bs_\ell(f,x)$. It is easy to see that for a Boolean function these definitions match the standard definitions of sensitivity, block sensitivity and ℓ-block sensitivity.

We wish to prove an analog of Kenyon-Kutin result, showing that $bs_\ell(f) \leq c_\ell \cdot s(f)^\ell$. However, stated as is the claim is false for a "silly" reason. Take any Boolean function f with a gap between the sensitivity and the ℓ-block sensitivity and take $g(x) = f(x)/s(f)$. Then, we get $s(g) = 1$ and $bs_\ell(g) = bs_\ell(f)/s(f)$. As there are examples with $bs_2(f) = n/2$ and $s(f) = \sqrt{n}$, we get that $bs_2(g) = \sqrt{n}/2$ while $s(g) = 1$, where n grows to infinity. This seems to rule out any relation between the sensitivity and block sensitivity (and even 2-block sensitivity) in the case of bounded functions. To overcome this triviality, we insist that the block sensitivity is close to n, or alternatively that changing each block dramatically changes the value of the function. Surprisingly, under this requirement we are able to retrieve known relations between sensitivity and block sensitivity that were established in the Boolean setting by Kenyon and Kutin [12].

▶ **Theorem 8.** *Let $c > 0$ and $f : \{0,1\}^n \to [0,1]$. Assume that there exists a point $x_0 \in \{0,1\}^n$ and disjoint blocks $B_1, \ldots, B_k$ of size at most ℓ such that $|f(x_0) - f(x_0 + B_i)| \geq c$ for all $i \in k$. Furthermore, assume that $2 \leq \ell \leq \log(k)$. Then, $s(f) \geq \Omega(k^{1/\ell} \cdot c)$.*

We get the following corollary, whose proof is deferred to Appendix A.

▶ **Corollary 9.** *Let $f : \{0,1\}^n \to [0,1]$ with $bs(f) \geq n/\ell$. Then, $s(f) \geq \Omega(n^{1/2\ell}/\ell)$.*

Unlike in the Boolean case, we are able to show that Theorem 8 is essentially tight! That is, for any ℓ and n we have a construction with $bs_\ell(f) \geq n/\ell$ and $s(f) = O(\ell \cdot n^{1/\ell})$. In particular, picking $\ell = \log(n)$ gives an exponential separation between block sensitivity (which is at least $n/\log n$) and sensitivity (which is $O(\log n)$).

▶ **Theorem 10.** *Let $\ell, n \in \mathbb{N}$ with $2 \leq \ell \leq n$. Then, there exists a function $h : \{0,1\}^n \to [0,1]$ with $bs_\ell(h) \geq \lfloor n/\ell \rfloor$ and $s(h) \leq 3 \cdot \ell \cdot n^{1/\ell}$.*

3.1 Proof of Kenyon-Kutin Result for Bounded Functions

Proof Overview. We start by giving a new proof for Kenyon-Kutin result, based on random walks on the hypercube. We assume by contradiction that $f(x_0) = 0$ and $f(x_0 + B_i) = 1$ for all $i \in [k]$ and that the sensitivity is $o(k^{1/\ell})$. Taking a random walk of length $r = n/k^{1/\ell}$ starting from x_0 will end up in point y where with high probability $f(y) = f(x_0)$. This is true since in each step with probability at least $1 - s(f)/n$ we are maintaining the value of f, hence by union bound with probability at least $1 - r \cdot s(f)/n$ we maintain the value of f in the entire walk. On the contrast, choosing a random $i \in [k]$ and starting a random walk of length $r - |B_i|$ starting from $(x_0 + B_i)$ will lead to a point y' where with high probability $f(y') = f(x_0 + B_i) = 1$. However, as we show in the proof below, the distributions of y and y' are similar (close in statistical distance). This leads to a contradiction as $f(y)$ tends to be equal to 0 and $f(y')$ tends to be equal to 1.

A simple observation, which allows us to generalize the argument above to bounded functions, is that for a given point $x \in \{0,1\}^n$ and a random neighbor in the hypercube, $y \sim x$, the expected value of $f(y)$ is close to $f(x)$. This follows from Eq. (5). Thus, the only difference in the argument for bounded functions will be that $\mathbf{E}[f(y)]$ is close to 0 and $\mathbf{E}[f(y')]$ is close to 1, leading to a contradiction as well.

Proof of Theorem 8. First, we make a few assumptions that are without loss of generality, in order to make the argument later clearer. We assume $x_0 = 0^n$ and $f(x_0) = 0$. We assume $n = k \cdot \ell$ and that the blocks are given by $B_i = \{(i-1)\ell + 1, \ldots, i\ell\}$ for $i \in [k]$. We assume that $c = 1$, since for $c < 1$ one can take $f'(x) = \min\{f(x)/c, 1\}$, and note that f' is a bounded function with $f'(x_0 + B_i) = 1$. Proving the theorem for f' gives $s(f) \geq s(f') \cdot c \geq \Omega(c \cdot k^{1/\ell})$.

Let $r = \lfloor \frac{n}{(2k)^{1/\ell}} \rfloor$, by the assumption $2 \leq \ell \leq \log(k)$ we have $\sqrt{n} \leq r \leq n/2$. Assume by contradiction that $s(f) \leq \varepsilon \cdot k^{1/\ell}$ for some sufficiently small constant $\varepsilon > 0$ to be determined later. Consider the following two random processes.

Algorithm 1 Process A

1: $X_0 \leftarrow 0^n$
2: **for** $t = 1, \ldots, r$ **do**
3: Select a random $i \in [n]$ among the coordinates for which X_{t-1} is 0 and let $X_t \leftarrow X_{t-1} + e_i$.
4: **end for**

Algorithm 2 Process B

1: Select uniformly $i \in [k]$ and let $Y_0 \leftarrow B_i$
2: **for** $t = 1, \ldots, r - \ell$ **do**
3: Select a random $i \in [n]$ among the coordinates for which Y_{t-1} is 0 and let $Y_t \leftarrow Y_{t-1} + e_i$.
4: **end for**

For each $t \in \{0, \ldots, r-1\}$, we claim that

$$\mathbf{E}[f(X_{t+1}) - f(X_t)] = \mathbf{E}\left[\frac{1}{n-t} \cdot \sum_{i:(X_t)_i=0} f(X_t + e_i) - f(X_t)\right]$$
$$\leq \frac{1}{n-t} \cdot \mathbf{E}[s(f(X_t))] \leq \frac{s(f)}{n-t} .$$

By telescoping this implies that

$$\mathbf{E}[f(X_r)] = \mathbf{E}[f(X_0)] + \sum_{t=0}^{r-1} \mathbf{E}[f(X_{t+1}) - f(X_t)] \leq 0 + \frac{r \cdot s(f)}{n-r} \leq O(\varepsilon) \ .$$

In a symmetric fashion, for each $t \in \{1, \ldots, r-\ell\}$ we have $\mathbf{E}[f(Y_{t+1}) - f(Y_t)] \geq -\frac{s(f)}{n-t-\ell}$. Again, telescoping implies that

$$\mathbf{E}[f(Y_{r-\ell})] \geq \mathbf{E}[f(Y_0)] - \frac{(r-\ell) \cdot s(f)}{n-r} \geq 1 - \frac{r \cdot s(f)}{n-r} \geq 1 - O(\varepsilon) \ .$$

So it seems that the distribution of X_r and $Y_{r-\ell}$ are very different from one another. However, we shall show that conditioned on a probable event, X_r and $Y_{r-\ell}$ are identically distributed. To define the event, consider the sets

$$U_i = \{\mathbb{1}_A \ \mid \ A \subseteq [n], |A| = r, B_i \subseteq A, \forall j \neq i : B_j \nsubseteq A\}$$

for $i \in [k]$ and their union

$$U = \bigcup_{i=1}^{k} U_i = \{\mathbb{1}_A \ \mid \ A \subseteq [n], |A| = r, \exists! i \in [k] : B_i \subseteq A\} \ .$$

Let E_X be the event that $X_r \in U$, and E_Y be the event that $Y_{r-\ell} \in U$. We show that

▶ **Claim 11.** *The following hold:*

1. $X_r|E_X$ *is identically distributed as* $Y_{r-\ell}|E_Y$.
2. $\mathbf{Pr}[E_Y] = \Omega(1)$
3. $\mathbf{Pr}[E_X] = \Omega(1)$

We defer the proof of Claim 11 for later. We derive a contradiction from all of the above by showing that $\mathbf{E}[f(X_r)|E_X] < \mathbf{E}[f(Y_{r-\ell})|E_Y]$ (this is indeed a contradiction because by the claim $X_r|E_X$ and $Y_{r-\ell}|E_Y$ should be identically distributed and hence the expected values of $f(\cdot)$ on each of them should be the same). To show this, we note that

$$\begin{aligned}\mathbf{E}[f(X_r)|E_X] &= \mathbf{E}[f(X_r) \cdot \mathbb{1}_{E_X}]/\mathbf{Pr}[E_X] \\ &\leq \mathbf{E}[f(X_r)]/\mathbf{Pr}[E_X] = O(\mathbf{E}[f(X_r)]) = O(\varepsilon) \ .\end{aligned}$$

On the other hand

$$\begin{aligned}\mathbf{E}[f(Y_{r-\ell})|E_Y] &= 1 - \mathbf{E}[1 - f(Y_{r-\ell})|E_Y] \\ &\geq 1 - \mathbf{E}[1 - f(Y_{r-\ell})]/\mathbf{Pr}[E_Y] = 1 - O(\mathbf{E}[1 - f(Y_{r-\ell})]) = 1 - O(\varepsilon) \ .\end{aligned}$$

Choosing ε to be a small enough constant implies that $\mathbf{E}[f(X_r)|E_X] < \mathbf{E}[f(Y_{r-\ell})|E_Y]$, which completes the proof. ◀

Proof of Claim 11. We shall use in the proof of Items 2 and 3 the fact that $1/3 \leq \frac{r^\ell k}{n^\ell} \leq 1/2$ which follows from the choice of $r = \lfloor \frac{n}{(2k)^{1/\ell}} \rfloor$ (for large enough n and k).

1. First note that X_r is distributed uniformly over the set of vectors in $\{0,1\}^n$ with hamming weight r. In particular, conditioning that X_r is in a set U of such vectors, makes it uniform over U. We are left to show that $Y_{r-\ell}|E_Y$ is distributed uniformly over U. Given that $Y_0 = B_i$, we have that $Y_{r-\ell}$ is the OR of $\mathbb{1}_{B_i}$ with a random vector of weight $r-\ell$ on $[n] \setminus B_i$. Conditioned on E_Y the only way to reach U_i is if $Y_0 = B_i$, hence, by the above, all points in U_i are attained with the same probability. Using symmetry, all points in $U = \bigcup_i U_i$ are attained with the same probability.

2. Let B_i be the block selected in the first step of Process B. We analyze the probability that all indices in B_j for some $j \neq i$ are chosen in the $r - \ell$ iterations of Process B.

$$\begin{aligned}\mathbf{Pr}[B_j \text{ is selected}] &= \frac{(\#\text{ of sequences where } B_j \text{ is selected})}{(\#\text{ of sequences})} \\ &= \frac{(r-\ell)^{\underline{\ell}} \cdot (n-2\ell)^{\underline{r-2\ell}}}{(n-\ell)^{\underline{r-\ell}}} = \frac{(r-\ell)!(n-2\ell)!(n-r)!}{(r-2\ell)!(n-r)!(n-\ell)!} \\ &= \frac{(r-\ell)!(n-2\ell)!}{(r-2\ell)!(n-\ell)!} = \frac{(r-\ell)\cdots(r-2\ell+1)}{(n-\ell)\cdots(n-2\ell+1)} \leq \left(\frac{r}{n}\right)^{\ell}\end{aligned}$$

(recall that $n^{\underline{k}} \triangleq \frac{n!}{(n-k)!}$). Hence, $\mathbf{Pr}[\exists j \neq i : B_j \text{ is selected}] \leq k \cdot (r/n)^{\ell} \leq 1/2$ and we have $\mathbf{Pr}[E_Y] \geq 1/2$.

3. Let $\pi_1, \ldots, \pi_r \in [n]$ be the sequence of choices made by Process A. For $i \in [k]$, let $E_{X,i}$ be the event that $X_r \in U_i$. By the uniqueness of the block contained in X_r the events $E_{X,i}$ are disjoint, hence $\mathbf{Pr}[E_X] = \sum_{i=1}^{k} \mathbf{Pr}[E_{X,i}]$. By symmetry, $\mathbf{Pr}[E_X] = k \cdot \mathbf{Pr}[E_{X,1}]$. The event $E_{X,1}$ is simply the event that there exists a set $S \subseteq [r]$ of size ℓ such that $\{\pi_j\}_{j \in S} = B_1$ and the sequence $\{\pi_j : j \in [r] \setminus S\}$ is a sequence of choices for which E_Y holds, when starting Process B from $Y_0 = B_1$. This shows that $\mathbf{Pr}[E_{X,1}] = \mathbf{Pr}[E_Y | Y_0 = B_1] \cdot \mathbf{Pr}[B_1 \subseteq \{\pi_1, \ldots, \pi_r\}]$. By Symmetry, $\mathbf{Pr}[E_Y | Y_0 = B_i] = \mathbf{Pr}[E_Y] = \Omega(1)$ from the previous item. In addition,

$$\begin{aligned}\mathbf{Pr}[B_1 \subseteq \{\pi_1, \ldots, \pi_r\}] &= \frac{r^{\underline{\ell}} \cdot (n-\ell)^{\underline{r-\ell}}}{n^{\underline{r}}} = \frac{r!(n-\ell)!(n-r)!}{(r-\ell)!(n-r)!n!} \\ &= \frac{r!(n-\ell)!}{(r-\ell)!n!} = \frac{r \cdots (r-\ell+1)}{n \cdots (n-\ell+1)} \geq \left(\frac{r-\ell}{n}\right)^{\ell} \\ &= \left(\frac{r}{n}\right)^{\ell} \cdot (1-\ell/r)^{\ell} = \left(\frac{r}{n}\right)^{\ell} \cdot (1-o(1))\end{aligned}$$

where $(1-\ell/r)^{\ell} = 1 - o(1)$ follows from $\ell \leq \log(k)$ and $r \geq \sqrt{n} \geq \sqrt{k}$. Thus,

$$\begin{aligned}\mathbf{Pr}[E_X] = k \cdot \mathbf{Pr}[E_{X,1}] &= k \cdot \mathbf{Pr}[B_1 \text{ is selected}] \cdot \mathbf{Pr}[E_Y | Y_0 = B_1] \\ &\geq k \cdot \left(\frac{r}{n}\right)^{\ell} \cdot (1-o(1)) \cdot \frac{1}{2} \geq \frac{1}{3} \cdot (1 - o(1) \cdot \frac{1}{2} = \Omega(1)\,.\end{aligned}$$

◀

3.2 Separating Sensitivity and Block Sensitivity of Bounded Functions

The Lattice Variant of The Sensitivity Conjecture

The proof of Theorem 10 is more natural in the lattice-variant of the sensitivity conjecture as suggested by Aaronson (see [6]). In this variant, instead of talking about functions over $\{0,1\}^n$ we are considering functions over $\{0,1,\ldots,\ell\}^k$ for $\ell, k \in \mathbb{N}$. Given a function $g : \{0,1,\ldots,\ell\}^k \to \mathbb{R}$ one can define a Boolean function $f : \{0,1\}^{\ell \cdot k} \to \mathbb{R}$ by the following equation:

$$f(x_{1,1}, \ldots, x_{k,\ell}) = g\left(\sum_{i=1}^{\ell} x_{1,i}, \ldots, \sum_{i=1}^{\ell} x_{k,i}\right). \tag{7}$$

For a point $y \in \{0,1,\ldots,\ell\}^k$ and function $g : \{0,\ldots,\ell\}^k \to \mathbb{R}$ one can define the sensitivity of g at y as

$$s(g,y) = \sum_{y' \sim y} |g(y') - g(y)|$$

where $y' \sim y$ if $y' \in \{0,\ldots,\ell\}^k$ is a neighbor of y in the grid $\{0,\ldots,\ell\}^k$, i.e., if y and y' agree on all coordinates except for one coordinate, say $j \in [k]$, on which $|y_j - y'_j| = 1$. The following claim relates the sensitivity of f to that of g.

▶ **Claim 12.** *Let $g : \{0,\ldots,\ell\}^k \to \mathbb{R}$ and let f be the function defined by Eq. (7). Then $s(f) \leq \ell \cdot s(g)$.*

Proof. Let $x = (x_{1,1},\ldots,x_{k,\ell}) \in \{0,1\}^{kl}$ and and let $x' \in \{0,1\}^{kl}$ be a neighbor of x, obtained by flipping the (i,j)-th coordinate. Let $y = (\sum_{i=1}^{\ell} x_{1,i},\ldots,\sum_{i=1}^{\ell} x_{k,i})$ and similarly let $y' = (\sum_{i=1}^{\ell} x'_{1,i},\ldots,\sum_{i=1}^{\ell} x'_{k,i})$. Then y and y' differ only on the i-th coordinate, and on this coordinate they differ by a ± 1. If $y'_i = y_i + 1$, then the number of neighbors $x' \sim x$ that are mapped to y' by $y' = (\sum_i x'_{1,i},\ldots,\sum_i x'_{k,i})$ equals the number of zeros in the i-th block of x, i.e., it equals $\ell - y_i$. Similarly, in the case $y'_i = y_i - 1$ the number of $x' \sim x$ that are mapped to y' equals y_i. In both cases, there are between 1 to ℓ points $x' \sim x$ that are mapped to each neighbor $y' \sim y$. Thus,

$$\sum_{x' \sim x} |f(x') - f(x)| = \sum_{x' \sim x} |g(y') - g(y)| \leq \ell \cdot \sum_{y' \sim y} |g(y') - g(y)| \,. \qquad \blacktriangleleft$$

Construction of a Separation. Let k, ℓ be integers. We construct $f : \{0,1,\ldots,\ell\}^k \to [0,1]$ such that $f(0) = 0$, $f(e_i \cdot \ell) = 1$ for all $i \in [k]$ and $s(f) \leq O(k^{1/\ell})$.

Define a weight function $w : \{0,1,\ldots,\ell\} \to [0,1]$ as follows: $w(a) = k^{a/\ell}/k$ for $a \in \{1,\ldots,\ell\}$ and $w(0) = 0$. Take $g : \{0,\ldots,\ell\}^k \to \mathbb{R}^+$ to be the function $g(x_1,\ldots,x_n) = \sum_{i=1}^{k} w(x_i)$ and take $f : \{0,\ldots,\ell\}^k \to [0,1]$ to be $f(x) = \min\{1, g(x)\}$. Then $f(0^k) = 0$ and $f(\ell \cdot e_i) = 1$ for all $i \in [k]$.

▶ **Theorem 13.** *$s(f) \leq 3 \cdot k^{1/\ell}$.*

Proof. Let $x \in \{0,1,\ldots,\ell\}^k$ be a point in the lattice. We distinguish between two cases $g(x) \geq 2$ and $g(x) < 2$. In the first case, all neighbors $x' \sim x$ have $g(x') \geq 1$ since the sums $\sum_i w(x_i)$ and $\sum_i w(x'_i)$ differ by at most 1. Since both $g(x)$ and $g(x')$ are at least 1 we get that $f(x) = f(x') = 1$ and the sensitivity of f at x is 0.

In the latter case, $g(x) < 2$, we bound the sensitivity as well. For ease of notation we extend w to be defined over $\{-1,\ldots,\ell+1\}$ by taking $w(\ell+1) = w(\ell)$ and $w(-1) = w(0)$. We extend also g to $\{-1,0,\ldots,\ell+1\} \to \mathbb{R}^+$ by taking $g(x_1,\ldots,x_n) = \sum_i w(x_i)$. We have

$$\begin{aligned}
s(f,x) \leq s(g,x) &= \sum_{i=1}^{k} |g(x+e_i) - g(x)| + |g(x) - g(x-e_i)| \\
&= \sum_{i=1}^{k} |w(x_i+1) - w(x_i)| + |w(x_i) - w(x_i-1)| \\
&= \sum_{i=1}^{k} w(x_i+1) - w(x_i-1) && (w \text{ is monotone}) \\
&\leq \sum_{i=1}^{k} w(x_i+1) && (w \text{ is non-negative}) \\
&\leq \sum_{i:x_i=0} w(1) + \sum_{i:x_i>0} w(x_i) \cdot k^{1/\ell} \\
&\leq k \cdot \frac{k^{1/\ell}}{k} + \sum_i w(x_i) \cdot k^{1/\ell} \\
&= k^{1/\ell} + g(x) \cdot k^{1/\ell} \leq 3k^{1/\ell}.
\end{aligned}$$ ◀

We show that Theorem 10 is a corollary of Theorem 13.

Proof of Theorem 10. Let $k = n/\ell$. Let $f : \{0,1,\ldots,\ell\}^k \to [0,1]$ be the function in Theorem 13. Take $h(x_{1,1},\ldots,x_{k,\ell}) = f\left(\sum_{i=1}^{\ell} x_{1,i},\ldots,\sum_{i=1}^{\ell} x_{n,i}\right)$. For $x = 0^n$, there are k disjoint blocks $B_1,\ldots,B_k$ of size ℓ each such that $h(x+B_i) = 1$. Hence, $bs_\ell(h) \geq k = n/\ell$. By Claim 12, the sensitivity of h is at most $s(f)\cdot\ell \leq 3\cdot k^{1/\ell}\cdot\ell \leq 3\cdot n^{1/\ell}\cdot\ell$ which completes the proof. ◀

4 New Separations between Decision Tree Complexity and Sensitivity

We report a new separation between the decision tree complexity and the sensitivity of Boolean functions. We construct an infinite family of Boolean functions with

$$\mathrm{DT}(f_n) \geq s(f_n)^{1+\log_{14}(19)} \geq s(f_n)^{2.115}.$$

Our functions are transitive functions, and are inspired by the work of Chakraborty [8].

Our construction is based on finding a "gadget" Boolean function f, defined over a constant number of variables, such that $s^0(f) = 1$, $s^1(f) = k$ and $\mathrm{DT}(f) = \ell$ for $\ell > k$ (recall that $s^0(f) = \max_{x:f(x)=0} s(f,x)$ and similarly $s^1(f) = \max_{x:f(x)=1} s(f,x)$). Given the gadget f, we construct an infinite family of functions with super-quadratic gap between the sensitivity and the decision tree complexity using compositions (which is a well-used trick in query complexity separations, cf. [18]).

▶ **Lemma 14.** *Let $f : \{0,1\}^c \to \{0,1\}$ such that $s^0(f) = 1$, $s^1(f) = k$ and $\mathrm{DT}(f) = \ell > k$. Then, there exists an infinite family of functions $\{g_i\}_{i\in\mathbb{N}}$ such that $s(g_i) = k^i$ and $\mathrm{DT}(g_i) = (k\ell)^i = s(g_i)^{1+\log(k)/\log(\ell)}$.*

Proof. Take $g = \mathrm{OR}_k \circ f$. It is easy to verify that $s(g) = k$, and that $\mathrm{DT}(g) = \mathrm{DT}(\mathrm{OR}_k)\cdot \mathrm{DT}(f) = k\ell$ (for the latter, one can use [18, Lemma 3.1]). For $i \in \mathbb{N}$, we take $g_i = g^i$. It is well-known (cf. [18, Lemma 3.1]) that $s(g^i) \leq s(g)^i$ and that $\mathrm{DT}(g^i) = \mathrm{DT}(g)^i$, which completes the proof. ◀

4.1 Finding a Good Gadget

The gadget f will be a minterm-cyclic function. Roughly speaking, a function $f : \{0,1\}^n \to \{0,1\}$ is minterm-cyclic if there exists pattern $p \in \{0,1,*\}^n$ such that the function f simply checks if x matches one of the cyclic shifts of p. The formal definition follows

▶ **Definition 15.** A pattern $p \in \{0,1,*\}^n$ is a partial assignment to the variables $x_1,\ldots,x_n$. We say that a point $x \in \{0,1\}^n$ matches the pattern p, denoted by $p \subseteq x$, if for all $i \in [n]$ such that $p_i \in \{0,1\}$ we have $p_i = x_i$. Given a pattern p, let $CS(p) = \{p^1,\ldots,p^n\}$ be the set of cyclic shifts of p, where the i-th cyclic shift of p is given by $p^i = (p_i, p_{i+1},\ldots,p_n,p_1,\ldots,p_{i-1})$. For a pattern $p \in \{0,1,*\}^n$ we denote by $f_p : \{0,1\}^n \to \{0,1\}$ the function defined by

$$f_p(x) = 1 \quad \Leftrightarrow \quad \exists p^i \in CS(p) : p^i \subseteq x$$

and call f_p the minterm cyclic function defined by p.

For example, the pattern $p = \texttt{0011**}$ defines a function f_p that checks if there's a sequence of two zeros followed by two ones in x, when x is viewed as a cyclic string. We say that two patterns $p, q \in \{0,1,*\}^n$ disagree on a coordinate i if both p_i and q_i are in $\{0,1\}$ and $p_i \neq q_i$.

▶ **Claim 16.** *Let $p \in \{0,1,*\}^n$ be a pattern defining $f_p : \{0,1\}^n \to \{0,1\}$. Assume that any two different cyclic-shifts of p disagree on at least 3 coordinates. Then, $s^0(f_p) = 1$.*

Proof. Let $x \in \{0,1\}^n$ with $f_p(x) = 0$ and assume by contradiction that $s(f_p, x) \geq 2$. In such a case, there are two indices i and j such that $f_p(x + e_i) = 1$ and $f_p(x + e_j) = 1$. Let q and q' be the patterns among $CS(p)$ that $x + e_i$ and $x + e_j$ satisfy respectively. If $q = q'$, then since both $x + e_i$ and $x + e_j$ satisfy q and they differ on coordinates i and j, it must be the case that $q_i = q_j = *$. However, this implies that x satisfy q as well, which is a contradiction. If $q \neq q'$, then we get that q and q' may disagree only on coordinates i and j, which is also a contradiction. ◀

The following fact is easy to verify.

▶ **Fact 17.** *Let $p \in \{0,1,*\}^n$ be a pattern defining $f_p : \{0,1\}^n \to \{0,1\}$. Then, $s^0(f_p) \leq c^0(f_p) \leq |\{i \in [n] : p_i \in \{0,1\}\}|$.*

Next, we demonstrate a simple example with better-than-quadratic separation between $\mathrm{DT}(f)$ and $s(f)$. Take the pattern $p = *001011$. Denote by $p^1, \ldots, p^7$ all the cyclic shifts of p, where in p^i the i-th coordinate equals $*$. It is easy to verify that any p^i and p^j for $i \neq j$ disagree on at least 3 coordinates. Hence, $s^0(f_p) = 1$ and $s^1(f_p) \leq 6$. We wish to show that any decision tree T for f_p is of depth 7. Let x_i be the first coordinate read by a decision tree T for f_p. Our adversary will answer 0, and will continue to answer as if x matches p^i. Assume the decision tree made a decision before reading the entire input. The decision tree must decide 1 since the adversary answered according to x which satisfies p^i. However, if the decision tree hasn't read the entire input, there is still an unread coordinate j, where $j \neq i$. Let $x' = x + e_j$. Then, the decision tree answers 1 on x' as well. However x' does not match pattern p^i as $(p^i)_j \in \{0,1\}$ and it must be the case that $x_j = (p^i)_j \neq x'_j$.

We also need to rule out that x' matches some other pattern. Indeed, if x' matches some other pattern p^k it means that p^k and p^i disagree only on at most one coordinate, which as discussed above cannot happen.

Using Lemma 14 the function f_p can be turned into an infinite family of functions g_i with $\mathrm{DT}(g_i) = (6 \cdot 7)^i$ and $s(g_i) \leq 6^i$. This gives a super-quadratic separation since

$$\mathrm{DT}(g_i) \geq s(g_i)^{1+\log(7)/\log(6)} \geq s(g_i)^{2.086}.$$

In a similar fashion, one can show that for the pattern $p = \texttt{**0*10000*101}$ after reading any two input bits from the input there exists a cyclic shift p^i of the pattern from which no $\{0,1\}$ coordinate has been read yet. However, to verify that the input x matches p^i we must read all $\{0,1\}$ positions in p^i, which gives $\mathrm{DT}(f_p) \geq 9 + 2$ where 9 is the number of $\{0,1\}$-s in the pattern p.

The decision tree complexity analysis for the other patterns written below is more involved. We computed it using a computer program written to calculate the decision tree complexity in this special case. In the list below, we report several patterns yielding super-quadaratic separations. For each pattern p we report its length n, the decision tree complexity of f_p, the maximal sensitivity of f_p (which equals the number of $\{0,1\}$-s in p) and the resulting exponent one get by using Lemma 14 (i.e., $1 + \frac{\log \mathrm{DT}(f_p)}{\log s(f_p)}$).

```
p = *001011,                          n = 7,  DT = 7,  s = 6,  exp = 2.086
p = **0*10000*101,                    n = 13, DT = 11, s = 9,  exp = 2.091
p = ******01*1*01100000,              n = 19, DT = 14, s = 11, exp = 2.100
p = ******00*0*0010**1*00*011,        n = 25, DT = 17, s = 13, exp = 2.104
p = ******1**0**0**1**0**00*0*10*1011, n = 33, DT = 19, s = 14, exp = 2.115
```

A Proof of Corollary 9

Proof. Let $x \in \{0,1\}^n$ and $B_1, \ldots, B_m$ be the blocks that achieve $bs(f)$. Assume without loss of generality that $B_1, \ldots, B_{m'}$ are of size at most 2ℓ and that $B_{m'+1}, \ldots, B_m$ are of size larger than 2ℓ. Then, by the disjointness of $B_{m'+1}, \ldots, B_m$ we have that $m - m' \leq \frac{n}{2\ell}$. Thus,

$$\begin{aligned} bs_\ell(f,x) &\geq \sum_{i=1}^{m'} |f(x) - f(x+B_i)| = \sum_{i=1}^{m} |f(x) - f(x+B_i)| - \sum_{i=m'+1}^{m} |f(x) - f(x+B_i)| \\ &\geq bs(f,x) - (m-m') \geq bs(f,x) - \frac{n}{2\ell} \geq \frac{n}{2\ell} \,. \end{aligned}$$

Assume without loss of generality that $B_1, \ldots, B_{m''}$ are blocks such that $|f(x) - f(x+B_i)| \geq \frac{1}{4\ell}$ and that $B_{m''+1}, \ldots, B_{m'}$ are not. Then, $\sum_{i=m''+1}^{m'} |f(x) - f(x+B_i)| \leq \frac{m''-m'}{4\ell} \leq \frac{n}{4\ell}$. This implies that $\sum_{i=1}^{m''} |f(x) - f(x+B_i)| \geq \frac{n}{4\ell}$, and in particular that $m'' \geq \frac{n}{4\ell}$. Thus, there are $m'' \geq n/4\ell$ disjoint blocks of size at most 2ℓ which change the value of f by at least $\frac{1}{4\ell}$. Theorem 8 gives that $s(f) \geq \Omega((m'')^{1/2\ell}/\ell) \geq \Omega(n^{1/2\ell}/\ell)$. ◀

Randomization Can Be as Helpful as a Glimpse of the Future in Online Computation*

Abstract

We provide simple but surprisingly useful direct product theorems for proving lower bounds on online algorithms with a limited amount of advice about the future. Intuitively, our direct product theorems say that if b bits of advice are needed to ensure a cost of at most t for some problem, then $r \cdot b$ bits of advice are needed to ensure a total cost of at most $r \cdot t$ when solving r independent instances of the problem. Using our direct product theorems, we are able to translate decades of research on randomized online algorithms to the advice complexity model. Doing so improves significantly on the previous best advice complexity lower bounds for many online problems, or provides the first known lower bounds. For example, we show that

- A paging algorithm needs $\Omega(n)$ bits of advice to achieve a competitive ratio better than $H_k = \Omega(\log k)$, where k is the cache size. Previously, it was only known that $\Omega(n)$ bits of advice were necessary to achieve a constant competitive ratio smaller than $5/4$.
- Every $O(n^{1-\varepsilon})$-competitive vertex coloring algorithm must use $\Omega(n \log n)$ bits of advice. Previously, it was only known that $\Omega(n \log n)$ bits of advice were necessary to be optimal.

For certain online problems, including the MTS, k-server, metric matching, paging, list update, and dynamic binary search tree problem, we prove that randomization and sublinear advice are equally powerful (if the underlying metric space or node set is finite). This means that several long-standing open questions regarding randomized online algorithms can be equivalently stated as questions regarding online algorithms with sublinear advice. For example, we show that there exists a deterministic $O(\log k)$-competitive k-server algorithm with sublinear advice if and only if there exists a randomized $O(\log k)$-competitive k-server algorithm without advice.

Technically, our main direct product theorem is obtained by extending an information theoretical lower bound technique due to Emek, Fraigniaud, Korman, and Rosén [ICALP'09].

1 Introduction

The model of online computation deals with optimization problems where the input arrives sequentially over time. Usually, it is assumed that an online algorithm has no knowledge of future parts of the input. While this is a natural assumption, it leaves open the possibility that a tiny amount of information about the future (which might be available in practical applications) could dramatically improve the performance guarantee of an online algorithm.

* Most proofs have been omitted due to space restrictions. A full version of the paper containing all proofs and technical details is available at http://arxiv.org/abs/1511.05886.

Recently, the notion of advice complexity [17, 29, 34, 28] was introduced in an attempt to provide a quantitative and problem-independent framework for studying *semi-online* algorithms with limited (instead of non-existing) knowledge of the future. In this framework, the limited knowledge is modeled as a number of advice bits provided to the algorithm by an oracle (see Definition 7). The goal is to determine how much advice (measured in the length, n, of the input) is needed to achieve a certain competitive ratio. In particular, one of the most important questions is how much advice is needed to break the lower bounds for (randomized) online algorithms without advice. It has been shown that for e.g. bin packing and makespan minimization on identical machines, $O(1)$ bits of advice suffice to achieve a better competitive ratio than what is possible using only randomization [5, 3]. On the other hand, for a problem such as edge coloring, it is known that $\Omega(n)$ bits of advice are needed to achieve a competitive ratio better than that of the best deterministic online algorithm without advice [41]. However, for many online problems, determining the power of a small amount of advice has remained an open problem.

With a few notable exceptions (e.g. [15, 29, 16, 20]), most of the previous research on advice complexity has been problem specific. In this paper, we take a more complexity-theoretic approach and focus on developing techniques that are applicable to many different problems. Our main conceptual contribution is a better understanding of the connection between advice and randomization. Before explaining our results in details, we briefly review the most relevant previous work.

Standard derandomization techniques imply that a randomized algorithm can be converted (maintaining its competitiveness) into a deterministic algorithm with advice complexity $O(\log\log I(n) + \log n)$, where $I(n)$ is the number of inputs of length n [16]. Clearly, there are problems where even a single bit of advice is much more powerful than randomization, and so we cannot in general hope to convert an algorithm with advice into a randomized algorithm. However, using machine learning techniques, Blum and Burch have shown that a metrical task system algorithm with advice complexity $O(1)$ can be converted into a randomized algorithm without advice [12]. Problems such as paging, k-server, and list update can be modeled as metrical task systems (see e.g. [18]).

2 Overview of results and techniques

We will give a high-level description of the results and techniques introduced in this paper. For simplicity, we restrict ourselves to the case of minimization problems[1].

Direct product theorems. Central to our work is the concept of an *r-round input distribution*. Informally, this is a distribution over inputs that are made up of r rounds such that the requests revealed in each round are selected independently of all previous rounds. Furthermore, there must be a fixed upper bound on the length of each round (see Definition 8).

As the main technical contribution of the paper, we prove direct product theorems for r-round input distributions. Intuitively, a direct product theorem says that if b bits of advice are needed to ensure a cost of at most t for each individual round, then rb bits of advice are needed to ensure a cost of at most rt for the entire input. This gives rise to a useful technique for proving advice complexity lower bounds. In particular, it follows that a linear number of advice bits are needed to get a (non-trivial) improvement over algorithms without any advice at all.

[1] All of our results (and their proofs) are easily adapted to maximization problems. See [42] for details.

We provide two different theorems formalizing the above intuitive statement in different ways: Our main direct product theorem (Theorem 10) is based on an information theoretical argument similar to that of [29]. In the full paper [42], we also provide an alternative direct product theorem based on martingale theory. In this extended abstract, we will only consider the information theoretical version.

Repeatable online problems. We combine our direct product theorems with the following very simple idea: Suppose that we have a lower bound on the competitive ratio of randomized online algorithms without advice. Often, such a lower bound is proved by constructing a hard input distribution and then appealing to Yao's principle. For some online problems, it is always possible to combine (in a meaningful way) a set of input sequences $\{\sigma_1, \ldots, \sigma_r\}$ into one long input sequence $\sigma = g(\sigma_1, \ldots, \sigma_r)$ such that serving σ essentially amounts to serving the r smaller inputs individually and adding the costs incurred for serving each of them. We say that such problems are Σ-*repeatable* (see Definition 12). For a Σ-repeatable online problem, an adversary can draw r input sequences independently at random according to some hard input distribution. This gives rise to an r-round input distribution. By our direct product theorem, an online algorithm needs linear advice (in the length of the input) to do better against this r-round input distribution than an online algorithm without advice. Thus, for Σ-repeatable online problems, we get that it is possible to translate lower bounds for randomized algorithms without advice into lower bounds for algorithms with sublinear advice. More precisely, we obtain the following theorem.

▶ **Theorem 1.** *Let* P *be a* Σ*-repeatable online minimization problem and let* c *be a constant. Suppose that for every* $\varepsilon > 0$ *and every* α*, there exists an input distribution* $p_{\alpha,\varepsilon} : I \to [0,1]$ *with finite support such that* $\mathbb{E}_{p_{\alpha,\varepsilon}}[D(\sigma)] \geq (c-\varepsilon)\,\mathbb{E}_{p_{\alpha,\varepsilon}}[OPT(\sigma)] + \alpha$ *for every deterministic algorithm* D *without advice. Then, every randomized algorithm reading at most* $o(n)$ *bits of advice on inputs of length* n *has a competitive ratio of at least* c*.*

Much research has been devoted to obtaining lower bounds for randomized algorithms without advice. Theorem 1 makes it possible to translate many of these lower bounds into advice complexity lower bounds, often resulting in a significant improvement over the previous best lower bounds (see Table 1).

For a Σ-repeatable problem, the total cost has to be the sum of costs incurred in each individual round. It is also possible to consider another kind of repeatable problems, where the total cost is the *maximum cost* incurred in a single round. We call such problems $\vee$-repeatable. Many online coloring problems are $\vee$-repeatable. For $\vee$-repeatable problems, we show in the full version of the paper [42] that under certain conditions, a constant lower bound on the competitive ratio of *deterministic* algorithms without advice carries over to randomized algorithms, even if the randomized algorithms have advice complexity $o(n)$. The proof of this result is straightforward and does not rely on our direct product theorems for Σ-repeatable problems. However, the result improves or simplifies a number of previously known advice complexity lower bounds for $\vee$-repeatable problems.

In Table 1, we have listed most of the repeatable online problems for which lower bounds on algorithms with sublinear advice existed prior to our work, and compared those previous lower bounds with the lower bounds that we obtain in this paper. We have also included two examples of repeatable online problems for which Theorem 1 provides the first known advice complexity lower bounds.

It is evident from Table 1 that there are many repeatable online problems. On the other hand, let us mention that e.g. bin packing and makespan minimization are examples of problems which are provably not repeatable.

Table 1 New and previously best lower bounds on the competitive ratio for algorithms reading $o(n)$ bits of advice on inputs of length n. For the Σ-repeatable problems, the lower bounds in this table are obtained by combining Theorem 1 with known lower bounds for randomized online algorithms without advice. For the $\vee$-repeatable problems, the lower bounds are obtained by combining our general result on $\vee$-repeatable problems with known lower bounds for *deterministic* algorithms without advice. In both cases, references to these previously known lower bounds for online algorithms without advice are provided in the second column of the table. We refer to the full paper [42] for a more detailed explanation of the entries in Table 1, and for a comparison with the current upper bounds.
Bipartite matching and Max-SAT are maximization problems, and hence the lower bound is obtained via the maximization version of Theorem 1. For paging and reordering buffer management, k denotes the cache/buffer size. For metrical task systems, N is the number of states. For the metrical task system problem and the k-server problem, the bounds are for a worst-case metric. It is also possible to use Theorem 1 together with known lower bounds for specific metric spaces. The lower bound for unit clustering is for the one-dimensional case.

Compact online problems. Note that when translating a lower bound on randomized algorithms without advice to a lower bound on algorithms with $o(n)$ bits of advice via Theorem 1, we had to make some assumptions on the lower bound. This begs the following question: Are there online problems where every lower bound (after suitable modifications) satisfies these assumptions? In order to formally answer this question, we make the following definition.

▶ **Definition 2.** Let P be a minimization problem and let $c > 1$ be a constant such that the expected competitive ratio of every randomized P-algorithm is at least c. We say that P is *compact* if for every $\varepsilon > 0$ and every $\alpha \geq 0$, there exists an input distribution $p_{\alpha,\varepsilon}$ with finite support such that if $\mathtt{D}$ is a deterministic online algorithm (without advice), then $\mathbb{E}_{p_{\alpha,\varepsilon}}[\mathtt{D}(\sigma)] \geq (c-\varepsilon) \cdot \mathbb{E}_{p_{\alpha,\varepsilon}}[\mathtt{OPT}(\sigma)] + \alpha$.

If an online problem is both Σ-repeatable and compact, we get the following result: Let c be a constant and let $\varepsilon > 0$. If c is a lower bound on the competitive ratio of randomized online algorithms without advice, then $c - \varepsilon$ is also a lower bound on the competitive ratio of online algorithms with sublinear advice. Equivalently, by contraposition, the existence of a c-competitive algorithm with sublinear advice implies the existence of a $(c + \varepsilon)$-competitive randomized algorithm without advice. Combining this with existing derandomization results [16] (see also [42]) yields the following complexity theoretic equivalence between randomization and sublinear advice (previously, only the forward implication was known [16]):

▶ **Theorem 3.** *Let* P *be a compact and* Σ*-repeatable minimization problem with at most* $2^{n^{O(1)}}$ *inputs of length* n*, and let* c *be a constant independent of* n*. The following are equivalent:*

1. *For every* $\varepsilon > 0$*, there exists a randomized* $(c + \varepsilon)$*-competitive* P*-algorithm without advice.*
2. *For every* $\varepsilon > 0$*, there exists a deterministic* $(c + \varepsilon)$*-competitive* P*-algorithm with advice complexity* $o(n)$*.*

In this paper, we use a technique due to Ambühl [4] and Mömke [44] to show that the class of compact and Σ-repeatable problems contains all problems which can be modeled as a metrical task system (MTS) with a finite number of states and tasks. This means that e.g. the k-server, list update, paging, and dynamic binary search tree problem are all compact and Σ-repeatable, assuming that the underlying metric space or node set is finite. For all these problems, it is known that it is possible to achieve a constant competitive ratio with respect to the length of the input [42]. Also, the number of inputs of length n for each of these problems is at most $2^{n^{O(1)}}$ (this bound holds since when we apply Theorem 3 to e.g. the k-server problem, the metric space will be fixed and not a part of the input). Thus, for each of these problems, Theorem 3 applies. Furthermore, for all the problems just mentioned (except paging), determining the best possible competitive ratio of a randomized algorithm without advice is regarded as important open problems [18, 27]. For example, the randomized k-server conjecture says that there exists a randomized $O(\log k)$-competitive k-server algorithm [39]. Theorem 3 shows that this conjecture is equivalent to the conjecture that there exists a deterministic $O(\log k)$-competitive k-server algorithm with advice complexity $o(n)$. Currently, it is only known how to achieve a competitive ratio of $O(\log k)$ using $2n$ bits of advice [16, 45].

We also show that there are compact and Σ-repeatable problems which cannot be modeled as a MTS. One such example is the metric matching problem (on finite metric spaces) [35].

Pessimistically, Theorem 3 may be seen as a barrier result which says that (for compact and Σ-repeatable online problems) designing an algorithm with sublinear advice complexity and a better competitive ratio than the currently best randomized algorithm without advice might be very difficult. Optimistically, one could hope that this equivalence might be useful in trying to narrow the gap between upper and lower bounds on the best possible competitive ratio of randomized algorithms without advice. In all cases, Theorem 3 shows that understanding better the exact power of (sublinear) advice in online computation would be very useful.

2.1 Other applications of our direct product theorem

The previously mentioned applications of our direct product theorem treat the hard input distribution as a black-box. However, it is also possible to apply our direct product theorem to explicit input distributions. Doing so yields some interesting lower bounds which cannot be obtained via Theorem 1. In what follows, we will state and briefly discuss three such lower bounds. We refer to the full paper [42] for details and for the proofs of Theorems 4 to 6.

Repeated matrix games. Let $q \in \mathbb{N}$ and let $A \in \mathbb{R}_+^{q \times q}$ be a matrix defining a two-player zero-sum game. Let V denote the value of the game defined by A. The *repeated matrix game (RMG)* with cost matrix A is an online problem where the algorithm and adversary repeatedly plays the game defined by A. The adversary is the row-player, the algorithm is the column-player, and the matrix A specifies the cost incurred by the online algorithm in each round. This generalizes the string guessing problem [15] and the generalized matching pennies problem [29] (both of these essentially corresponds to the RMG with a $q \times q$ matrix A where $A(i,j) = 1$ if $i \neq j$ and $A(i,i) = 0$). Using our direct product theorem, we easily get that for every $\varepsilon > 0$, an online algorithm which on inputs of length n is guaranteed to incur a cost of at most $(V - \varepsilon)n$ must read $\Omega(n)$ bits of advice.

▶ **Theorem 4.** *Let* `ALG` *be an algorithm for the RMG with cost matrix A. Furthermore, let V be the value of the (one-shot) two-person zero-sum game defined by A and let $0 < \varepsilon \leq V$ be a constant. If $\mathbb{E}[\texttt{ALG}(\sigma)] \leq (V - \varepsilon)n$ for every input σ of length n, then* `ALG` *must read at least*

$$b \geq \frac{\varepsilon^2}{2\ln(2) \cdot \|A\|_\infty^2} n = \Omega(n) \tag{1}$$

bits of advice.

Furthermore, we also show how a more careful application of our direct product theorem to some particular repeated matrix games yields good trade-off results for the exact amount of advice needed to ensure a cost of at most αn for $0 < \alpha < V$.

A better bin packing lower bound via repeated matrix games. We use our results on repeated matrix games to prove the following advice complexity lower bound for bin packing:

▶ **Theorem 5.** *Let $c < 4 - 2\sqrt{2}$ be a constant. A randomized c-competitive bin packing algorithm must read at least $\Omega(n)$ bits of advice.*

Previously, Angelopoulos et al. showed that a bin packing algorithm with a competitive ratio of $c < 7/6$ had to use $\Omega(n)$ bits of advice by a reduction from the binary string guessing problem [5, 23]. From our results on repeated matrix games, we obtain a lower bound for *weighted* binary string guessing. Using the same reduction as in [5], but reducing from weighted binary string guessing instead, we improve the lower bound for bin packing algorithms with sublinear advice to $4 - 2\sqrt{2}$. Thus, even though bin packing itself is not repeatable, we can obtain a better lower bound via a reduction from a repeated matrix game.

Superlinear lower bounds for graph coloring. We obtain the following superlinear lower bound for online graph coloring by applying our direct product theorem to an ingenious hard input distribution due to Halldórsson and Szegedy [33] (they show that a randomized graph coloring algorithm *without* advice must have a competitive ratio of at least $\Omega(n/\log^2 n)$):

▶ **Theorem 6.** *Let $\varepsilon > 0$ be a constant. A randomized $O(n^{1-\varepsilon})$-competitive online graph coloring algorithm must read at least $\Omega(n \log n)$ bits of advice.*

Previously, it was only known that $\Omega(n \log n)$ bits of advice were necessary to be 1-competitive [32]. Note that $O(n \log n)$ bits of advice trivially suffice to achieve optimality for graph coloring. Furthermore, it is not hard to prove that for every $c = n^{1-o(1)}$, there exists a c-competitive graph coloring algorithm reading $o(n \log n)$ bits of advice. Thus, our lower bound saying that $\Omega(n \log n)$ bits are needed to be $O(n^{1-\varepsilon})$-competitive for every constant $\varepsilon > 0$ is essentially tight.

3 Relation to machine learning

Theorem 3 is very closely related to previous work on combining online algorithms [12, 31, 6]. Let $A_1, \ldots, A_m$ be m algorithms for a MTS of finite diameter Δ. Based on a variant of the celebrated machine learning algorithm Randomized Weighted Majority (RWM) [40], Blum and Burch obtained the following result [12, 24]: For every $\varepsilon > 0$, it is possible to combine the m algorithms into a single randomized MTS-algorithm, R, such that

$$\mathbb{E}[R(\sigma)] = (1 + 2\varepsilon) \cdot \min_{1 \leq i \leq m} A_i(\sigma) + \left(\frac{7}{6} + \frac{1}{\varepsilon}\right) \Delta \ln m, \tag{2}$$

for every input σ. An algorithm with b bits of advice corresponds to an algorithm which runs $m = 2^b$ algorithms in parallel (and selects the best one at the end). Thus, equation (2) immediately implies that given a c-competitive MTS-algorithm with advice complexity $b = O(1)$, we can convert it to a randomized $(c + \varepsilon)$-competitive algorithm without advice.

Theorem 3 improves on the result of Blum and Burch in two ways. First of all, it allows us to convert algorithms with sublinear instead of only constant advice complexity. Furthermore, Theorem 3 applies to all compact and Σ-repeatable online problems, not just those which can be modeled as a MTS.

It is natural to ask if it is possible to use the technique of Blum and Burch in order to obtain a constructive proof of Theorem 3. To this end, we remark that the result of Blum and Burch relies fundamentally on the fact that the cost incurred by RWM when switching from the state of algorithm A_i to the state of algorithm A_j for $i \neq j$ is bounded by a constant. Thus, it does not seem possible to extend the result to those compact and Σ-repeatable problems which does not satisfy this requirement (such as the metric matching problem). On the other hand, in the full paper [42], we show that by combining the result of Blum and Burch with the ideas that we use to prove that the MTS problem is compact, it is possible to use a variant of RWM to algorithmically convert a c-competitive MTS-algorithm with advice complexity $o(n)$ (instead of just $O(1)$) into a randomized $(c + \varepsilon)$-competitive algorithm without advice. This yields a constructive version of Theorem 3 for problems that can be modeled as a MTS.

Finally, we note that very shortly after and independently of our work, Böckenhauer et al. considered applications of machine learning algorithms to the advice complexity model [14]. In [14], the authors present and analyze an algorithm called Shrinking Dartboard which is similar to the algorithm of Blum and Burch (both algorithms are based on RWM).

4 The computational model

We start by formally defining competitive analysis and advice complexity. Since we are very much interested in sublinear advice, we will use the *advice-on-tape model* [17, 34]. In this model, the algorithm is allowed to read an arbitrary number of advice bits from an advice tape. There is an alternative model, the *advice-with-request model* [29], where a fixed number of advice bits is provided along with each request.

▶ **Definition 7** (Advice complexity [17, 34] and competitive ratio [18])**.** The input to an online problem, P, is a sequence $\sigma = (s, x_1, \ldots, x_n)$. We say that s is the *initial state* and $x_1, \ldots, x_n$ are the *requests*. A *deterministic online algorithm with advice*, `ALG`, computes the output $\gamma = (y_1, \ldots, y_n)$, under the constraint that y_i is computed from $\varphi, s, x_1, \ldots, x_i$, where φ is the content of the advice tape. The *advice complexity*, $b(n)$, of `ALG` is the largest number of bits of φ read by `ALG` over all possible inputs of length at most n.

For an input σ, $\texttt{ALG}(\sigma)$ ($\texttt{OPT}(\sigma)$) denotes the non-negative real *cost* of the output computed by $\texttt{ALG}$ ($\texttt{OPT}$) when serving σ. We say that $\texttt{ALG}$ is *c-competitive* if there exists a constant α such that $\texttt{ALG}(\sigma) \leq c \cdot \texttt{OPT}(\sigma) + \alpha$ for all inputs σ.

A *randomized online algorithm* $\texttt{R}$ *with advice complexity* $b(n)$ is a probability distribution over deterministic online algorithms with advice complexity at most $b(n)$. We say that $\texttt{R}$ is c-competitive if there exists a constant α such that $\mathbb{E}[\texttt{R}(\sigma)] \leq c \cdot \texttt{OPT}(\sigma) + \alpha$ for all inputs σ. △

5 An information theoretical direct product theorem

In this section, we formally state (and sketch how to prove) our direct product theorem upon which all of our results rely. Given P-inputs $\sigma_1, \ldots, \sigma_r$, we define $\sigma = \sigma_1 \ldots \sigma_r$ to be the P-input obtained by concatenating the requests of the r inputs and using the same initial state as σ_1. For example, if $\sigma_1 = (s, x_1, \ldots, x_n)$ and $\sigma_2 = (s', x'_1, \ldots, x'_{n'})$, then $\sigma_1\sigma_2 = (s, x_1, \ldots, x_n, x'_1, \ldots, x'_{n'})$.

▶ **Definition 8** (r-round input distribution)**.** Let P be a minimization problem and let $r \in \mathbb{N}$. For each $1 \leq i \leq r$, let I_i be a finite set of P-inputs such that the following holds: If $\sigma_1, \ldots, \sigma_r$ are such that $\sigma_i \in I_i$ for $1 \leq i \leq r$, then $\sigma = \sigma_1\sigma_2 \ldots \sigma_r$ is a valid P-input. Furthermore, let $I^r = I_1 \times \cdots \times I_r = \{\sigma_1 \ldots \sigma_i \ldots \sigma_r \mid \sigma_i \in I_i \text{ for } 1 \leq i \leq r\}$.

For each $1 \leq i \leq r$, let cost_i be a function which maps an output γ computed for an input $\sigma \in I^r$ to a non-negative real number $\text{cost}_i(\gamma, \sigma)$. We say that cost_i is the ith round *cost function.*

Let $p_i : I_i \to [0, 1]$ be a probability distribution over I_i and let $p^r : I^r \to [0, 1]$ be the (product) probability distribution which maps $\sigma_1\sigma_2 \ldots \sigma_r \in I^r$ into $p_1(\sigma_1)p_2(\sigma_2) \cdots p_r(\sigma_r)$. We say that p^r (together with the associated cost functions cost_i) is an *r-round input distribution.* For $1 \leq i \leq r$, we say that p_i is the ith round input distribution of p^r. △

▶ **Definition 9.** Let P be a minimization problem and let $r \in \mathbb{N}$. Let $p^r : I^r \to [0, 1]$ be an r-round input distribution with associated cost functions cost_i and with ith round input distributions p_i. Let $\texttt{ALG}$ be a deterministic P-algorithm with advice. We define the following random variables: Let X be the entire input and Y the output computed by $\texttt{ALG}$. For $1 \leq i \leq r$, let X_i be the requests revealed in round i, and let $\text{cost}_i(\texttt{ALG}) = \text{cost}_i(Y, X)$ be the ith round cost function applied to the output computed by $\texttt{ALG}$. Also, let $\text{cost}(\texttt{ALG}) = \sum_{i=1}^{r} \text{cost}_i(\texttt{ALG})$, let B be the advice bits read by $\texttt{ALG}$, and let $W_i = (X_1, \ldots, X_{i-1}, B)$. Random variables are always denoted by capital letters and their support by the calligraphic version of that letter[2].

Finally, for every $1 \leq i \leq r$ and every $w \in \mathcal{W}_i$, we define the conditional ith round input distribution $p_{i|w} : I_i \to [0, 1]$ as follows:

$$p_{i|w}(x) = p_i(x|W_i = w) = \frac{\Pr(X_i = x, W_i = w)}{\Pr(W_i = w)}.$$

△

We prove our information theoretical direct product theorem by extending an entropy based lower bound technique due to Emek et al. [29]. The statement and proof of the theorem relies on basic notions and results from information theory (see [42] or [26]). In particular, given two distributions $\mu, \nu : \Omega \to [0, 1]$ such that $\text{supp}(\mu) \subseteq \text{supp}(\nu)$, the *Kullback-Leibler*

[2] For example, the support of W_i is denoted $\mathcal{W}_i$, where $\mathcal{W}_i = \{w\colon \Pr[W_i = w] > 0\}$.

divergence $D_{KL}(\mu\|\nu)$ between μ and ν is defined as $D_{KL}(\mu\|\nu) = \sum_{\omega\in\Omega} \mu(\omega)\log(\mu(\omega)/\nu(\omega))$. Also, we heavily use the notation of Definitions 8 and 9.

▶ **Theorem 10.** *Let* P *be a minimization problem and let* p^r *be an* r*-round input distribution with associated cost-functions* cost_i*. Furthermore, let* ALG *be a deterministic algorithm reading at most* b *bits of advice on every input in the support of* p^r*. Assume that there exists a convex and decreasing function* $f : [0,\infty] \to \mathbb{R}$ *such that for every* $1 \leq i \leq r$ *and* $w \in \mathcal{W}_i$*, the following holds:*

$$\mathbb{E}[\text{cost}_i(\texttt{ALG})|W_i = w] \geq f\left(D_{KL}(p_{i|w}\|p_i)\right). \tag{3}$$

Then, $\mathbb{E}[\text{cost}(\texttt{ALG})] \geq rf(b/r)$.

Before sketching the proof of Theorem 10, we informally discuss the theorem. Recall that W_i is the information available to the algorithm when round i begins (the advice read and the history of previous requests). Without any advice or knowledge of the history, the probability of $x \in \mathcal{X}_i$ being selected as the round i request sequence is $p_i(x)$. However, this probability may change given that the algorithm knows W_i (in the most extreme case, the advice could specify exactly the request sequence in round i). For any fixed $w \in \mathcal{W}_i$, the probability of x being selected in round i given that $W_i = w$ is denoted $p_{i|w}(x)$. Assumption (3) informally means that the closer $p_{i|w}$ and p_i are to each other, the better a lower bound we must have on the expected cost incurred by ALG in round i given that ALG knows w. We remark that the convexity assumption on f is automatically satisfied in most applications. The conclusion of Theorem 10 essentially says that under these assumptions, an algorithm with b bits of advice for the entire input can do no better than an algorithm with b/r bits of advice for each individual round. In particular, this will allow us to conclude that $\Omega(r)$ bits of advice are needed to get a non-trivial improvement over having no advice at all. The complete proof of Theorem 10 can be found in the full version of the paper [42].

Proof Sketch (of Theorem 10). Fix i such that $1 \leq i \leq r$. Using first the law of total expectation and then combining assumption (3) with Jensen's inequality, we get that

$$\mathbb{E}[\text{cost}_i(\texttt{ALG})] = \mathbb{E}_w[\mathbb{E}[\text{cost}_i(\texttt{ALG})|W_i = w]] \geq f\left(\mathbb{E}_w[D_{\text{KL}}(p_{i|w}\|p_i)]\right). \tag{4}$$

A simple calculation shows that the expected Kullback-Leibler divergence $\mathbb{E}_w[D_{\text{KL}}(p_{i|w}\|p_i)]$ equals the mutual information $I(X_i;W_i)$ between X_i and W_i. Thus,

$$\mathbb{E}[\text{cost}(\texttt{ALG})] = \sum_{i=1}^{r} \mathbb{E}[\text{cost}_i(\texttt{ALG})] \geq \sum_{i=1}^{r} f(I(X_i;W_i))$$

The mutual information $I(X;B)$ between the input X and the advice B is at most b simply because the entropy $H(B)$ of B is at most b (since ALG reads at most b bits of advice). On the other hand, using that the r rounds are independent and the chain rule of conditional entropy, we get that $I(X;B) = \sum_{i=1}^{r} I(X_i;W_i)$. Combining these two observations, we see that $I(X_1;W_1),\ldots,I(X_r,W_r)$ are non-negative real numbers which sums to at most b. Since f is convex and decreasing, Jensen's inequality then implies that $\sum_{i=1}^{r} f(I(X_i;W_i)) \geq rf(b/r)$. ◀

6 Application: Repeatable online problems

In this section we will present the main ingredients of the proof of Theorem 1. Before we begin, we need to formally define the repeated version, P^*_Σ, of an online problem P, and

we need to define precisely what it means to be Σ-repeatable. To this end, given P-inputs $\sigma_1, \ldots, \sigma_r$ with the same initial state s, we define $(\sigma_1; \ldots; \sigma_r)$ to be a sequence with the requests of the r inputs concatenated and such that the initial state s arrives together with the first request of each σ_i. For example, if $\sigma_1 = (s, x_1, \ldots, x_n)$ and $\sigma_2 = (s, x'_1, \ldots, x'_{n'})$, then $(\sigma_1; \sigma_2) = (s, \{s, x_1\}, x_2, \ldots, x_n, \{s, x'_1\}, x'_2, \ldots, x'_{n'})$.

▶ **Definition 11.** Let P be an online problem, let S be the set of initial states for P, and let I (I_s) be the set of all possible request sequences for P (with initial state s). Define P^*_Σ to be the online problem with inputs $I^* = \{\sigma^* = (\sigma_1; \sigma_2; \ldots; \sigma_r) \mid r \geq 1, s \in S, \sigma_i \in I_s\}$. An algorithm for P^*_Σ must produce an output $\gamma^* = (\gamma_1, \ldots, \gamma_r)$ where $\gamma_i = (y_1, \ldots, y_{n_i})$ is a valid sequence of answers for the P-input $\sigma_i = (s, x_1, \ldots, x_{n_i}) \in I_s$. The score of the output γ^* is $\mathrm{score}(\gamma^*, \sigma^*) = \sum_{i=1}^{r} \mathrm{score}_P(\gamma_i, \sigma_i)$, where $\mathrm{score}_P(\gamma_i, \sigma_i)$ is the score of the P-output γ_i with respect to the P-input σ_i. The optimal offline algorithm for P^*_Σ is denoted $\mathtt{OPT}^*_\Sigma$. △

$\mathrm{P}^*_\vee$ is defined similarly, except that $\mathrm{score}(\sigma^*, \gamma^*) = \max\{\mathrm{score}_P(\sigma_1, \gamma_1), \ldots, \mathrm{score}_P(\sigma_r, \gamma_r)\}$.

In order to better understand the definition of P^*_Σ, it is useful to imagine that after serving the last request of round $i-1$ but before serving the first request of round i, the current state is changed to the initial state s (note that the algorithm knows when this happens since in $(\sigma_1; \ldots; \sigma_r)$, the first request of each σ_i is special). For instance, if P is the k-server problem, then an initial state s is a placement of the k servers in the metric space. Thus, in P^*_Σ, after serving the last request of round $i-1$ and before serving the first request of round i, the k servers automatically return to their initial position specified by s. Note that when P is the k-server problem, we can concatenate P-inputs $\sigma_1, \sigma_2, \ldots, \sigma_r$ into one long P-input $\sigma = \sigma_1\sigma_2 \ldots \sigma_r$. The only difference between serving the P-input σ and serving the P^*_Σ-input $\sigma^* = (\sigma_1; \ldots; \sigma_r)$ is that for the P-input σ, the k servers are not returned to the initial state s when a round ends. However, if the underlying metric space has finite diameter, this difference in the placement of servers when a new round begins cannot invalidate a lower bound. In fact, it turns out that for many online problems, there is a natural reduction from P^*_Σ to P that essentially preserves all lower bounds. This is formalized in Definition 12.

▶ **Definition 12.** Let P be an online minimization problem such that for every fixed P-input, there is only a finite number of valid outputs. Furthermore, let $k_1, k_2, k_3 \geq 0$. We say that P is Σ-*repeatable with parameters* (k_1, k_2, k_3) if there exists a mapping $g : I^* \to I$ with the following properties:

Σ1. $|g(\sigma^*)| \leq |\sigma^*| + k_1 r$ for every $\sigma^* \in I^*$ consisting of r rounds.

Σ2. For every deterministic P-algorithm ALG, there exists a deterministic P^*_Σ-algorithm $\mathtt{ALG}^*$ such that $\mathtt{ALG}^*(\sigma^*) \leq \mathtt{ALG}(g(\sigma^*)) + k_2 r$ for every $\sigma^* \in I^*$ consisting of r rounds.

Σ3. $\mathtt{OPT}^*_\Sigma(\sigma^*) \geq \mathtt{OPT}(g(\sigma^*)) - k_3 r$ for every $\sigma^* \in I^*$ consisting of r rounds. △

The definition of $\vee$-repeatable is identical to that of Σ-repeatable, except that P^*_Σ and $\mathtt{OPT}^*_\Sigma$ are replaced by $\mathrm{P}^*_\vee$ and $\mathtt{OPT}^*_\vee$. The k-server problem on a metric space of diameter Δ is Σ-repeatable with parameters $(0, k\Delta, k\Delta)$.

We will now sketch the proof of Theorem 1. The complete proof is in the full paper [42].

Proof Sketch (of Theorem 1). We prove the desired lower bound for P^*_Σ. Let ε and α be arbitrary. Without loss of generality, we may assume that all inputs in the support of $p_{\alpha,\varepsilon}$ have the same initial state. Draw r inputs independently from $p_{\alpha,\varepsilon}$. This gives rise to an r-round input distribution $p^r_{\alpha,\varepsilon}$ for P^*_Σ. Note that the ith round input distribution, p_i, of $p^r_{\alpha,\varepsilon}$ is simply $p_i = p_{\alpha,\varepsilon}$, and that a round of $p^r_{\alpha,\varepsilon}$ corresponds to a round of P^*_Σ.

Let $\texttt{ALG}^*$ be a deterministic P^*_Σ-algorithm reading at most b bits of advice on inputs in $\mathrm{supp}(p^r_{\alpha,\varepsilon})$. Fix a round $1 \leq i \leq r$ and let $w \in \mathcal{W}_i$. We need to give a lower bound on the expected cost $\mathbb{E}[\mathrm{cost}_i(\texttt{ALG}^*)|W_i = w]$ in terms of the Kullback-Leibler divergence between $p_{i|w}$ and p_i. To this end, we use *Pinsker's inequality*. Pinsker's inequality ([26, Lemma 11.6.1]) says this if the Kullback-Leibler divergence between $p_{i|w}$ and p_i is small, then $p_{i|w}$ and p_i must be close in L_1-norm: $\|p_{i|w} - p_i\|_1 \leq \sqrt{\ln 4 \cdot D_{\mathrm{KL}}(p_{i|w}\|p_i)}$. Thus, it suffices to bound $\mathbb{E}[\mathrm{cost}_i(\texttt{ALG}^*)|W_i = w]$ in terms of the L_1-distance between $p_{i|w}$ and p_i.

To this end, we construct a P-algorithm, $\texttt{ALG}_w$, without advice by hard-wiring w (i.e., the advice and the requests in rounds 1 to $i-1$) into the P^*_Σ-algorithm $\texttt{ALG}^*$. That is, for an input sequence $\sigma \in \mathrm{supp}(p_{i|w})$, the new algorithm $\texttt{ALG}_w$ simulates the computation of $\texttt{ALG}^*$ on σ when $W_i = w$ and $\texttt{ALG}^*$ is given the requests σ in round i. Note that this is possible since w is fixed, and hence the output of $\texttt{ALG}^*$ in round i given σ as input in this round is completely determined. For all other input sequences, $\texttt{ALG}_w$ behaves arbitrarily (but does compute some valid output). It follows that $\texttt{ALG}_w$ is well-defined for all input sequences in $\mathrm{supp}(p_i)$. Thus, $\texttt{ALG}_w$ defines a mapping $\sigma \mapsto \texttt{ALG}_w(\sigma)$ on $\mathrm{supp}(p_i)$ such that $\|\texttt{ALG}_w\|_\infty = \max_{\sigma \in \mathrm{supp}(p_i)} |\texttt{ALG}_w(\sigma)| \leq M$ and such that if $\sigma \in \mathrm{supp}(p_{i|w}) \subseteq \mathrm{supp}(p_i)$, then $\texttt{ALG}_w(\sigma)$ is equal to the cost incurred by $\texttt{ALG}^*$ if $W_i = w$ and σ is given as input in round i. It follows that

$$\begin{aligned}\mathbb{E}[\mathrm{cost}_i(\texttt{ALG})|W_i = w] &= \mathbb{E}_{\sigma \sim p_{i|w}}[\texttt{ALG}_w(\sigma)] \geq \mathbb{E}_{\sigma \sim p_i}[\texttt{ALG}_w(\sigma)] - \|\texttt{ALG}_w\|_\infty \cdot \|p_{i|w} - p_i\|_1 \\ &\geq (c-\varepsilon)\,\mathbb{E}_{\sigma \sim p_i}[\texttt{OPT}(\sigma)] + \alpha - M \cdot \sqrt{\ln 4 \cdot D_{\mathrm{KL}}(p_{i|w}\|p_i)}.\end{aligned}$$

Let $f(d) = (c-\varepsilon)\,\mathbb{E}_{\sigma \sim p_i}[\texttt{OPT}(\sigma)] + \alpha - M \cdot \sqrt{\ln 4 \cdot d}$. Note that f is convex. Our direct product theorem (Theorem 10) therefore yields (remember that $p_i = p_{\alpha,\varepsilon}$).

$$\mathbb{E}[\mathrm{cost}(\texttt{ALG}^*)] \geq r f(b/r) \geq r\left((c-\varepsilon)\,\mathbb{E}_{\sigma \sim p_{\alpha,\varepsilon}}[\texttt{OPT}(\sigma)] + \alpha - 2M\sqrt{\frac{b}{r}}\right). \tag{5}$$

Assume that $\texttt{ALG}^*$ uses sublinear advice, i.e., $b = o(n)$. Note that $n = \Theta(r)$ since $\mathrm{supp}(p_{\alpha,\varepsilon})$ is finite. Thus, we can make $2M\sqrt{b/r}$ arbitrarily small by choosing the number of rounds r sufficiently large. Furthermore, by linearity of expectation, $r\,\mathbb{E}_{\sigma \sim p_{\alpha,\varepsilon}}[\texttt{OPT}(\sigma)] = \mathbb{E}[\mathrm{cost}(\texttt{OPT}^*_\Sigma)]$. Thus, since ε and α was arbitrary, it follows from (5) and Yao's principle that a randomized P^*_Σ-algorithm with sublinear advice must have a competitive ratio of at least c. Using that P is Σ-repeatable, it is possible to convert this lower bound into a lower bound for P. ◀

7 Application: Compact online problems

Recall (Definition 2) that we defined compact online problems to be those for which Theorem 1 could be used to obtain tight lower bounds. Theorem 3 follows trivially by combining Definition 2 with Theorem 1 (and using previously known derandomization results). In this section, we will sketch how to prove that several important Σ-repeatable online problems are compact. Interestingly, our proof will rely on the "upper bound part" of Yao's principle [48] which is (much) less frequently used than the lower bound part.

Fix a Σ-repeatable problem P such that for every n (and every fixed initial state), the number of inputs of length at most n is finite[3]. Let $c > 1$ be a constant such that the expected

[3] Since P is Σ-repeatable, this assumption automatically implies that there is only finitely many P-algorithms for inputs of length at most n.

competitive ratio of every randomized P-algorithm is at least c. What does it mean for P to *not* be compact? It means that there exists an $\varepsilon > 0$ and $\alpha \geq 0$ such that the following holds: For every $n' \in \mathbb{N}$ and for every probability distribution p over P-inputs of length at most n', there exists a deterministic algorithm $\mathtt{D}$ such that $\mathbb{E}_{\sigma\sim p}[\mathtt{D}(\sigma)] < (c-\varepsilon)\,\mathbb{E}_{\sigma\sim p}[\mathtt{OPT}(\sigma)] + \alpha$. Recall that, by assumption, there is only a finite number of inputs and outputs for P of length at most n'. This makes it possible to view the problem as a *finite* two-player zero-sum game between an algorithm and adversary. Thus (see the full paper [42] for a formal proof), by Yao's principle, we get that there exists a randomized P-algorithm $\mathtt{R}_{n'}$ such that $\mathbb{E}[\mathtt{R}_{n'}(\sigma)] < (c-\varepsilon)\mathtt{OPT}(\sigma)+\alpha$ for every P-input of length at most n'. Now, if we can somehow show that it is possible to use the algorithms $\mathtt{R}_1, \mathtt{R}_2, \ldots$ to obtain a single algorithm $\mathtt{R}$ which is better than c-competitive (on all possible inputs), then the problem at hand must, by contradiction, be compact.

From the above discussion, it is easy to see that the metric matching problem is compact (on finite metric spaces). Indeed, in this problem, there are k servers placed in a metric space. Each server can be matched to at most one request (and vice versa). But this means that for every fixed metric space and fixed set of k servers, the length of the input never exceeds k. This allow us to construct a single algorithm $\mathtt{R}$ which on inputs with k servers run the appropriate algorithm $\mathtt{R}_k$. The algorithm $\mathtt{R}$ will be $(c-\varepsilon)$-competitive. This argument extends to all Σ-repeatable problems for which an online algorithm knows a priori some upper bound on the number of requests.

Another important example is the k-server problem on a finite metric space. In this problem, we also have a metric space and a set of k servers. However, for the k-server problem, there is no bound on the number of times we may use a single server. Thus, the length of the input is unbounded, even if we fix the metric space and the set of servers. This means that we cannot just trivially run the appropriate algorithm $\mathtt{R}_{n'}$, since we do not know an upper bound n' on the length of the input. However, what we can do is the following (see the full paper and [4, 44]): Choose n' to be some sufficiently large number. If the number of requests exceeds n', we *restart* $\mathtt{R}_{n'}$. That is, we use a new instantiation of $\mathtt{R}_{n'}$ which pretends that the $(n'+1)$'th request is in fact the very first request of the input sequence. By appropriately handling some technical issues, we can make sure that the price of performing these restarts is sufficiently small compared to the cost of an optimal solution. This gives a single algorithm $\mathtt{R}$ which is better than c-competitive on inputs of arbitrary length. Thus, the k-server problem is compact. This technique works for all problems that can be modeled as a MTS. We refer to the full version of the paper for more details.

8 Further work and open problems

We have attempted to make the results and techniques introduced in this paper as easy as possible to apply and build on. Komm et al. have used our results on repeated matrix games to prove lower bounds for certain online hereditary graph problems with preemption [38]. Also, in Boyar et al. [21], we have applied Theorem 1 to online weighted matching.

Currently, the equivalence between advice and randomization stated in Theorem 3 is mainly being used to obtain knowledge about algorithms with advice using techniques and results for randomized algorithms. It is an interesting open problem to what extent the equivalence is also useful in the other direction.

Abstract

We consider semidefinite programming through the lens of online algorithms – what happens if not all input is given at once, but rather iteratively? In what way does it make sense for a semidefinite program to be revealed? We answer these questions by defining a model for online semidefinite programming. This model can be viewed as a generalization of online covering-packing linear programs, and it also captures interesting problems from quantum information theory. We design an online algorithm for semidefinite programming, utilizing the online primal-dual method, achieving a competitive ratio of $O(\log n)$, where n is the number of matrices in the primal semidefinite program. We also design an algorithm for semidefinite programming with box constraints, achieving a competitive ratio of $O(\log F^*)$, where F^* is a sparsity measure of the semidefinite program. We conclude with an online randomized rounding procedure.

1 Introduction

The study of online algorithms is a major theme in computer science. In contrast to an algorithm that receives all its input at once, an online algorithm receives its input in an iterative manner, and must make irrevocable decisions after receiving each part of the input. An online algorithm is evaluated based on the ratio between its cost and the optimal offline cost, that is, the cost which could have been achieved had the entire input sequence been known in advance. The worst-case bound on this ratio is called the *competitive ratio* of the algorithm. Competitive analysis of online algorithms is a very active area of research and the last twenty five years have witnessed many exciting new results. For a broad study of online algorithms, see [2, 3].

Online set cover is a classical online problem; elements arrive one by one, specifying which sets they belong to, and each element must be covered upon arrival. Once a set is chosen to the cover it cannot be removed later on, and its cost is accumulated into the final cost. The objective is to minimize the total cost of the chosen sets. A natural extension is online fractional set cover, where sets are associated with fractional values, and for each element the sum of the fractions of the sets containing it is at least 1. Irrevocability is expressed by requiring the fractional values to be monotonically non-decreasing during the online steps.

* This work was partially supported by ISF grant 1585/15 and BSF grant 2014414.

Set cover further generalizes into general *covering* problems. In this setting, an element is not simply contained in a set, but rather a non-negative weight $a_{e,S}$ is associated with each element-set pair. This is actually equivalent to a linear program where the entries of the constraint matrix are all non-negative. The objective function is also non-negative. Covering problems arise naturally in many settings, e.g., graph optimization problems, facility location and paging. The dual problem of covering is *packing* which also captures an important family of combinatorial problems, e.g., flow, routing, matchings, and combinatorial auctions.

The online primal-dual method is a powerful algorithmic technique that has proved to be extremely useful for a wide variety of problems in the area of online algorithms, serving as an important unifying design methodology. In general, suppose that an online problem can be formulated as a linear program, such that requests correspond to linear constraints. The online nature of the problem translates into the constraint matrix being exposed row by row, while the dual program is updated by adding a new dual variable. The idea behind the primal-dual method is to use both primal and dual programs and construct (simultaneously) feasible solutions for both of them, while maintaining some relationship between their corresponding objective functions. Then, using weak duality, it is easy to bound the competitive factor of the primal solution.

For online covering-packing linear programs, the non-negativity of the constraint matrix facilitates the design of elegant online primal-dual algorithms. This approach has been amazingly successful in both unifying previously known results, as well as resolving several important open questions in competitive analysis. This includes, among others, the classic ski rental problem, the online set-cover problem, paging and weighted paging, graph optimization problems, the dynamic TCP-acknowledgement problem, various routing problems, load balancing, machine scheduling, ad auctions, and more. Please refer for more details to a survey on the covering-packing approach to online algorithms [3].

We explore in this work semidefinite programming in the context of online problems. A symmetric matrix $A \in \mathbb{R}^{m \times m}$ is said to be positive semidefinite, i.e., $A \succcurlyeq 0$, if for every vector $v \in \mathbb{R}^m$, it holds that $v^t A v \geq 0$. A semidefinite program has a constraint requiring that a matrix of variables $X = (x_{i,j})$ is positive semidefinite. Such constraints correspond to an unbounded number of linear constraints, since $X \succcurlyeq 0$ is equivalent to a family of linear constraints: $\forall v \in \mathbb{R}^n \; v^t X v = \sum v_i v_j x_{ij} \geq 0$. This greatly extends our ability to express complex problems, since semidefinite programs can be tailored more specifically, thus decreasing integrality gaps of linear relaxations of combinatorial problems and yielding tighter approximation factors. In their seminal work, Goemans and Williamson [4] used a semidefinite programming relaxation for max cut in undirected graphs, obtaining an approximation factor of 0.878, dramatically improving over the straightforward factor of 0.5.

1.1 Results

We study here further extensions of the successful online primal-dual method and linear programming relaxations for online problems to the realm of semidefinite programming. We define the problem of semidefinite covering-packing, which is a semidefinite program in which all coefficients are non-negative. For matrix coefficients, such as those in constraints of the form $A \bullet X \leq c$, the coefficient matrix A is positive-semidefinite. This problem arises in several natural settings, e.g., quantum hypergraph covering, studied by [1], is a semidefinite covering problem with all matrices restricted to the range $[0, I]$. Our work extends semidefinite covering-packing to an online setting. For example, our extension captures the online covering problem as a special case, in which all matrices are diagonal.

We design an online primal-dual algorithm with competitive ratio $O(\log n)$ for the semidefinite covering-packing setting, where n denotes the number of matrices (e.g., corresponding

to sets in the case of set cover). This is called our *general algorithm* (Section 3). We then consider in Section 4 a class of semidefinite covering-packing problems with *box constraints* on the variables. We design a primal-dual algorithm with an improved bound of $O(\log F^*)$, where F^* is a sparsity parameter coinciding with the maximum row-sparsity D of the constraint matrix in the linear case. This bound can be compared to the $O(\log D)$-competitive algorithm known for covering in the linear case [3, 5].

In Section 5 we design an online randomized rounding procedure, which is applicable to both of our algorithms, while adding a factor of $O(R(\log m + \log n))$ to the solution, where m is the dimension of the matrices and R is a bound on the largest eigenvalue of each matrix. Our randomized rounding uses a general matrix Chernoff bound due to Tropp [6], which is based on and improves slightly the novel matrix Chernoff bound developed by Ahlswede and Winter [1]. In a way, our algorithm is an online variation to Wigderson and Xiaos's [7] randomized rounding algorithm for integer semidefinite programming.

Techniques. Our algorithms and proofs strongly utilize the online primal-dual technique, thus taking advantage of semidefinite weak duality and the fact that semidefinite programming is defined over a cone. Additionally, we use the fact that a semidefinite constraint of the form $A \succcurlyeq B$ can be expressed as an infinite number of linear constraints, each corresponding to a projection onto a vector v satisfying $v^T A v \geq v^T B v$.

The heart of our general algorithm is an update step: when considering a primal semidefinite constraint, it is either already satisfied (and then we are done), or there exists a matrix (in fact, many) which is a witness to the violation of the primal constraint, also inducing a linear constraint which is violated. The witness matrix is then used for updating the primal constraint, and for the direction in which we are going to make dual progress. Once the witness matrix is determined, our update rule becomes quite similar to the update rule in the linear case [3]. An important difference though is that, while only a finite number of (linear) constraints needs to be satisfied in the linear case, now we need to satisfy a semidefinite constraint, equivalent to infinitely many linear constraints. We address this issue by over-satisfying constraints, so as to ensure that we make enough progress for our choice of witness matrix, thus bounding the number of steps needed. Without this over-satisfaction, we might only make infinitesimal progress, and it is not clear if the algorithm ever terminates.

For box constraints, we define the *sparsity* of an online semidefinite program, a measure capturing the potential to overshoot when solving a sub-problem of a semidefinite program. While the definition also coincides with the notion of row-sparsity for linear programs, it is not a simple extension, but rather one which is tailored to a very specific observation about our update rule; each subset of the variables defines such a subproblem when those variables are saturated (i.e. their value equals the upper bound). In this situation we want to choose a good progress direction, so that we do not over-satisfy the semidefinite constraint. The progress direction turns out to have the property that, when projecting the problem onto that direction, minimizes the ratio between the uncovered coefficients and the remainder which is left to cover. This proves to be very useful in bounding the primal-dual ratio, and also in allowing the algorithm to make meaningful progress.

2 Our Model and Definitions

Throughout this paper, all matrices are square, symmetric, real, and have dimension m. Given two matrices A, B, their *Frobenius product*, denoted $A \bullet B$, is defined as $A \bullet B = \sum_{i,j} A_{i,j} B_{i,j} = tr\left(A^T B\right)$. This is equivalent to standard inner product if the matrices are

treated as vectors in $\mathbb{R}^{m^2}$. For any vector $v \in R^n$, it is easy to check that the following useful identity holds: $A \bullet \left(vv^T\right) = v^T A v = \sum_{i,j} v_i v_j A_{i,j}$.

The eigenvalues of a matrix A are $\lambda_1(A) \geq \lambda_2(A) \geq \cdots \geq \lambda_m(A)$. For a matrix A and vector v, the *Rayleigh quotient* is defined as $\frac{v^T A v}{v^T v}$ and has the property $\lambda_m(A) \leq \frac{v^T A v}{v^T v} \leq \lambda_1(A)$. A symmetric matrix A is said to be *positive-semidefinite* (p.s.d.), denoted $A \succcurlyeq 0$, if all its eigenvalues are non-negative. This induces a partial order over $\mathbb{R}^{m \times m}$, where $A \succcurlyeq B$ if and only if $A - B \succcurlyeq 0$.

A*semidefinite* minimization program in standard form and its dual program are:

$$\begin{array}{c} \min \sum_{i=1}^n c_i x_i \\ s.t.\ \sum_{i=1}^n A_i x_i \succcurlyeq B \\ \forall i \in [n]\ \ x_i \geq 0 \end{array} \qquad \begin{array}{c} \max B \bullet Y \\ s.t.\ \forall i \in [n]\ A_i \bullet Y \leq c_i \\ Y \succcurlyeq 0 \end{array} .$$

This pair of programs satisfies weak duality, e.g. every feasible solution of the primal problem is an upper bound on the dual problem and vice versa. This can readily be seen as follows. Let x and Y be feasible solutions for the primal and dual problems, respectively. Then

$$\sum_{i=1}^n c_i x_i \geq \sum_{i=1}^n (A_i \bullet Y) x_i = \left(\sum_{i=1}^n A_i x_i\right) \bullet Y \geq B \bullet Y.$$

The first inequality follows since $x_i \geq 0$ for all $i \in [n]$, and $A_i \bullet Y \leq c_i$. The second inequality is due to $\sum_{i=1}^n A_i x_i \succcurlyeq B$ and $Y \succcurlyeq 0$.

We sometimes use the shorthand $\mathcal{A}x$ to denote the matrix $\sum_{i=1}^n A_i x_i$, that is, $\mathcal{A} : \mathbb{R}^n \to \mathbb{R}^{m \times m}$ is a linear function defined as $\mathcal{A}(x) = \sum_{i=1}^n A_i x_i$.

2.1 Our Model

We define a *semidefinite covering problem* as a semidefinite program in which all scalar coefficients are non-negative ($c_i \geq 0$), and all matrix coefficients are positive semidefinite ($A_i \succcurlyeq 0$, $B \succcurlyeq 0$). We can view the matrix B as being "covered", and the matrices A_i as the "covering" matrices. The variable x_i specifies "how much" of A_i is used to cover B.

We further define as *online semidefinite covering problem* as a semidefinite covering problem in which the covered matrix B is revealed in an online fashion, i.e., in each online step t a new matrix B_t is revealed as the matrix which must be covered, and the following relation holds: $B_t \succcurlyeq B_{t-1}$. The irrevocability property is expressed by the requirement that each variable x_i cannot be decreased at any point of time, and is only allowed to increase (or stay unchanged). In each step t the semidefinite constraint $\mathcal{A}x \succcurlyeq B_t$ must be satisfied.

In the dual *online semidefinite packing problem*, the objective function $B \bullet Y$ is revealed online, while the constraints $A_i \bullet Y \leq c_i$ are known in advance. The monotonicity is captured by allowing the variable matrix Y to only increase, e.g. $Y_t \succcurlyeq Y_{t-1}$.

Set Cover and Linear Covering-Packing as a Special Case. When all matrices A_i and B_t are diagonal, the constraint $\sum_{i=1}^n A_i x_i \succcurlyeq B_t$ defines m linear constraints – one for every diagonal element $\sum_{i=1}^n (A_i)_{j,j} x_i \geq (B_t)_{j,j}$. This is because a diagonal matrix D is p.s.d. if and only if all of its diagonal entries are non-negative. Thus, revealing parts of the matrix B is equivalent to revealing new linear constraints. We assume without loss of generality that the linear constraints are revealed one row at a time, meaning that we reduced the primal problem to an instance of online fractional covering. Specifically, if all the diagonal entries are either 0 or 1, the problem then becomes online set cover. In the dual problem, since Y is only multiplied by diagonal matrices, only its diagonal is taking a part in the program, therefore the dual problem also becomes equivalent to online fractional packing.

3 The General Algorithm

In this section we provide an algorithm for the problem of *online semidefinite covering*, as defined in the previous section:

$$\begin{array}{cc} \min \sum_{i=1}^{n} c_i x_i & \max B_t \bullet Y \\ s.t.\ \sum_{i=1}^{n} A_i x_i \succcurlyeq B_t & s.t.\ \forall i \in [n]\ A_i \bullet Y \leq c_i \\ \forall i \in [n]\ \ x_i \geq 0 & Y \succcurlyeq 0 \end{array} .$$

In each online step t a new matrix B_t is revealed, satisfying $B_t \succcurlyeq B_{t-1}$. Our algorithm must then increase the variables x_i, incurring an additional cost of $c_i \Delta x_i$, such that the updated covering constraint $\sum_{i=1}^{n} A_i x_i \succcurlyeq B_t$ is satisfied.

3.1 Intuition

Our algorithm performs a sort of binary search on the optimal value of the primal problem. For a certain guess α, we either find a primal solution whose value does not exceed α, or find a dual solution whose value is at least $\alpha / O(\log n)$. By doubling our guess each time, we are able to mitigate the cost of failed guesses and only lose a factor of 2 in total. Each guess α defines a phase, which may extend over many online steps. During a phase, the primal solution's value is always less than α, and when the phase ends, the dual solution's value is at least $\alpha / O(\log n)$.

We maintain monotonicity within each phase by only increasing the primal and dual variables. Monotonicity is maintained between phases by setting each variable to be the sum (or the maximum) of its values in the previous phases. We note that the optimal value of the primal problem in each online step can only increase (or at least not change).

The idea behind the algorithm's update step is the following. Either the primal constraint $\mathcal{A}x \succcurlyeq B_t$ is already satisfied (and then we are done), or there exists a matrix $V \succcurlyeq 0$ such that $\mathcal{A}x \bullet V < B_t \bullet V$ (by observing that $C \succcurlyeq 0$ if and only if for every matrix $V \succcurlyeq 0$, $C \bullet V \geq 0$). The requirement that $trV = 1$ is a simple scaling constraint, which can be achieved by setting $V' = V / tr(V)$. We can think of the matrix V as a witness to the violation of the primal constraint; it induces a linear constraint $\mathcal{A}x \bullet V \geq B_t \bullet V$ which is violated. We use the witness as the direction in which we make dual progress, and increase the primal according to the relation we wish to maintain between the primal and dual solutions, until the linear constraint $\mathcal{A}x \bullet V \geq B_t \bullet V$ is satisfied. Specifically, the rate at which x_i is increased is proportional to $A_i \bullet V$, which makes sense, since this is the coefficient of x_i in the linear constraint $\mathcal{A}x \bullet V = \sum_{i=1}^{n} A_i \bullet V x_i \geq B_t \bullet V$.

We note that for technical reasons that help simplify the analysis we actually over-satisfy the above linear constraint, i.e. we continue increasing until $\mathcal{A}x \bullet V \geq \mathbf{2} B_t \bullet V$. This is necessary to ensure that we make enough progress for each choice of V, thus bounding the number of steps needed. Without this requirement, we might make infinitesimal progress for each V, and it is not clear if the algorithm will finish its execution, since there are infinitely many choice of V possible. It turns our that this over-satisfaction only contributes a factor of 2 to the competitive ratio.

There are many possible choices of progress direction V. One natural choice is $V = vv^T$, where v is a unit eigenvector corresponding to the smallest eigenvalue of $(\mathcal{A}x - B_t)$. Since $\mathcal{A}x - B_t \not\succcurlyeq 0$, its smallest eigenvalue λ_n is negative, therefore $(\mathcal{A}x - B_t) \bullet V = v^T (\mathcal{A}x - B_t) v = \lambda_n < 0$ as required.

3.2 Algorithm Description

In each phase r we search for a primal solution with cost at most $\alpha(r)$. Whenever the primal cost exceeds $\alpha(r)$, a new phase starts and $\alpha(r+1) \leftarrow 2\alpha(r)$ is doubled. In each new phase we "forget" about the values of the primal and dual variables from the previous phase, but we do account for their cost in the analysis. That is, in each phase r, new variables $x_{r,i}$, Y_r are introduced; however, since the variables are required to be monotonically non-decreasing, each variable x_i is actually set to $\sum_r x_{r,i}$, and the dual variable is also set to $\sum_r Y_r$.

Let OPT_t be the optimal value of the primal problem in phase t. After the first constraint matrix B_1 is introduced, we set the first lower-bound: $\alpha(1) \leftarrow \min_{i=1}^{n} \frac{c_i tr B_1}{tr A_i}$. Note that $\alpha(1) \leq OPT_1 \leq OPT_t$, for all t, because the matrix $Y_0 = \left(\min_{i=1}^{n} \frac{c_i}{tr A_i}\right) I$ is a feasible solution for the dual problem and its cost is $Y_0 \bullet B_1 = \alpha(1)$. In the beginning of each phase, we initialize $Y = 0$, $x_i = \frac{\alpha(r)}{2nc_i}$. Algorithm 2 describes the phase scheme. Algorithm 1 describes the execution during a single online step t, within a single phase r. Algorithm 1 uses an auxiliary variable δ, the measure of progress by which we update all other variables.

Algorithm 1 Primal-Dual Algorithm for step t within phase r

Input: current solutions x, Y, current limit α. Output: updated values for x, Y.
While $\mathcal{A}x \not\succcurlyeq B_t$:

1. Let V be a density matrix ($V \succcurlyeq 0$, $trV = 1$) such that $\mathcal{A}x \bullet V < B_t \bullet V$.
2. While $\mathcal{A}x \bullet V < 2B_t \bullet V$ and $\sum_{i=1}^{n} c_i x_i < \alpha$:
   a. Set $\delta = 0$ initially, and increase it in a continuous manner.
   b. Increase Y continuously by adding $V\delta$ to it.
   c. Increase x continuously by setting:

$$x_i = \frac{\alpha}{2nc_i} \exp\left(\frac{\log 2n}{c_i} A_i \bullet Y\right).$$

Algorithm 2 Phase Scheme

Initialize $r = 1$, $\alpha(0) = \min_{i=1}^{n} \frac{c_i tr B_1}{2tr A_i}$.
For $t = 1, 2, \ldots$:

1. Let $\alpha(r) = 2\alpha(r-1)$, $Y_r = 0$, $x_{r,i} = \frac{\alpha(r)}{2nc_i}$ for $i = 1, \ldots, n$.
2. Run Algorithm 1 on x_r, Y_r, $\alpha(r)$.
3. If $\sum c_i x_{r,i} \geq \alpha(r)$, then update $r \leftarrow r+1$ and go to step 1.
4. Return solutions $\sum_r x_{r,i}$, $\sum_r Y_r$.

▶ **Theorem 1.**

- *The scheme generates a feasible primal solution with a competitive ratio of* $O(\log n)$.
- *The scheme generates a dual solution with competitive ratio of* $O(\log n)$*, and each constraint is violated by a factor of at most* $O\left(\log\log n + \log \frac{OPT_t}{\alpha(1)}\right)$.
- *The scheme terminates, and its runtime is* $O\left(n\left(\log\log n + \log \frac{OPT_t}{\alpha(1)}\right)\right)$

Before we prove the theorem, we establish some assisting claims. Let $X(r)$ and $Y(r)$ be the values of the primal and dual solutions, respectively, generated in the r-th phase. We say that the r-th phase is *finished* if the condition in step 3 of Algorithm 2 holds, i.e. $\sum c_i x_{r,i} \geq \alpha(r)$.

▶ **Lemma 2.** *For each* finished *phase* r, $Y(r) \geq \alpha(r)/4\log 2n$.

Proof. In the beginning of phase r, we have $x_i = \frac{\alpha(r)}{2nc_i}$, therefore $X(r) = \frac{\alpha(r)}{2}$. The dual cost is zero. When the phase ends, $X(r) \geq \alpha(r)$. The proof is completed by showing that at every point in Algorithm 1, we have $\frac{\partial X(r)}{\partial \delta} \leq 2\log 2n \frac{\partial Y(r)}{\partial \delta}$. To show this, we have

$$\begin{aligned}
\frac{\partial X(r)}{\partial \delta} &= \frac{\partial}{\partial \delta}\left(\sum_{i=1}^{n} c_i x_i\right) = \sum_{i=1}^{n} c_i \frac{\partial x_i}{\partial \delta} = \sum_{i=1}^{n} c_i \frac{\partial}{\partial \delta}\left(\frac{\alpha(r)}{2nc_i}\exp\left(\frac{\log 2n}{c_i} A_i \bullet (Y+\delta V)\right)\right) \\
&= \sum_{i=1}^{n} c_i \frac{\log 2n}{c_i}(A_i \bullet V)\frac{\alpha(r)}{2nc_i}\exp\left(\frac{\log 2n}{c_i} A_i \bullet (Y+\delta V)\right) \\
&= \sum_{i=1}^{n} \log 2n\,(A_i \bullet V)\,x_i = \log 2n\left(\sum_{i=1}^{n} A_i x_i\right) \bullet V \\
&= \log 2n \mathcal{A}x \bullet V \leq 2\log 2n B_t \bullet V = 2\log 2n \frac{\partial Y(r)}{\partial \delta}.
\end{aligned}$$

The last inequality holds since we only increase δ while $\mathcal{A}x \bullet V < 2B_t \bullet V$. ◀

▶ **Lemma 3.** *The dual solution generated during each phase is feasible.*

Proof. Consider the i-th dual constraint of the form $A_i \bullet Y \leq c_i$. Since we are in the r-th phase, the current primal solution's value is at most $\alpha(r)$, therefore the value of x_i can be at most $\frac{\alpha(r)}{c_i}$. Thus:

$$\frac{\alpha(r)}{2nc_i}\exp\left(\frac{\log 2n}{c_i} A_i \bullet Y\right) = x_i \leq \frac{\alpha(r)}{c_i}.$$

Simplifying, we get that $A_i \bullet Y \leq c_i$. The final dual constraint $Y \succcurlyeq 0$ is satisfied since Y is the sum of p.s.d matrices δV. ◀

▶ **Lemma 4.** *The total cost of the primal solutions generated from the first phase until the r-th phase is less than $2\alpha(r)$.*

Proof. We bound the total cost paid by the online algorithm. The total primal cost in the r-th phase is at most $\alpha(r)$. Since the ratio between $\alpha(k)$ and $\alpha(k-1)$ is 2, we get that the total cost until the r-th phase is at most $\sum_{k=1}^{r}\alpha(k) = \alpha(r)\sum_{k=1}^{r}\frac{1}{2^{k-1}} \leq 2\alpha(r)$. ◀

▶ **Lemma 5.** *If the algorithm stops during a certain phase, then x is feasible.*

Proof. The algorithm stops only when $\mathcal{A}x \succcurlyeq B_t$. Also, $x \geq 0$ throughout the entire run of the algorithm, since we only increase each x_i from an initially positive value $\frac{\alpha(r)}{2nc_i} > 0$. ◀

▶ **Lemma 6.** *The number of iterations (= choices of V) in each phase is at most $n+1$.*

Proof. Consider any iteration in Algorithm 1 for which the while loop terminates because $\mathcal{A}x \bullet V \geq 2B_t \bullet V$. In the beginning of the while loop, we have $\mathcal{A}x \bullet V < B_t \bullet V$. This implies that at least one x_i was doubled during the iteration. Now, $x_i \geq \frac{\alpha(r)}{2nc_i}$, therefore each iteration increases the primal value by at least $c_i x_i \geq \frac{\alpha(r)}{2n}$. Since the primal value is $\frac{\alpha(r)}{2}$ in the beginning of the phase, after n such choices of V it must reach $\alpha(r)$ and the phase will be finished. Accounting for the possibly one extra iteration when the while loop terminates because the condition $\sum_i c_i x_i \geq \alpha$ is satisfied, the number of iterations is bounded by $n+1$. ◀

▶ **Lemma 7.** *The number of phases reached by step t is bounded by* $O\left(\log\log n + \log\frac{OPT_t}{\alpha(1)}\right)$.

Proof. Let $\mathcal{R} > 1$ be the current phase. Then

$$\alpha(1)\,2^{\mathcal{R}-2} = \alpha(\mathcal{R}-1) \le 4\log(2n)\,Y(\mathcal{R}-1) \le 4\log(2n)\,OPT_t$$

$$\Rightarrow \mathcal{R} \le 2 + \log\left(2\log(2n)\,\frac{OPT_t}{\alpha(1)}\right) = O\left(\log\log n + \log\frac{OPT_t}{\alpha(1)}\right).$$

The first inequality above follows by Lemma 2, and the second because $Y(\mathcal{R}-1)$ is a feasible solution by Lemma 3. ◀

Proof of Theorem 1. Suppose the online scheme terminates within $\mathcal{R}$ phases. Note that if $\mathcal{R} = 1$ then since $X(1) \le \alpha(1) \le OPT_1$ and x is feasible (from Lemma 5)), we must have exactly reached the end of the phase, i.e. $X = \alpha(1) = OPT_1$, $Y \ge \frac{OPT_1}{\log 2n}$, and Y is also feasible (from Lemma 3). From now on assume $\mathcal{R} > 1$.

- By Lemma 5, the primal solution is feasible. The total primal cost is bounded by:

$$\text{total primal cost} \ \le 2\alpha(\mathcal{R}) = 4\alpha(\mathcal{R}-1) \le 16\log 2nY(\mathcal{R}-1) \le 16\log(2n)\,OPT_t.$$

  The first inequality is by Lemma 4, the second by Lemma 2, and the last one by Lemma 3.
- By Lemma 3, the dual solution in each phase is feasible. Summing up over $\mathcal{R}$ phases and using the bound for $\mathcal{R}$ from Lemma 7, we get that the dual solution is violated up to $\mathcal{R} \le O\left(\log\log n + \log\frac{OPT_t}{\alpha(1)}\right)$. The total dual cost is bounded by:

$$\text{total dual cost} = \sum_{r=1}^{\mathcal{R}} Y(r) \ge Y(\mathcal{R}-1) \ge \frac{\alpha(\mathcal{R}-1)}{4\log 2n} = \frac{\alpha(\mathcal{R})}{8\log 2n} \ge \frac{X(\mathcal{R})}{8\log 2n} \ge \frac{OPT_t}{8\log 2n}.$$

  The second inequality is by Lemma 2 and the last one by Lemma 5.
- The runtime and termination of the scheme follow immediately from Lemmas 6 and 7.

◀

4 Box Constraints

In this section we introduce box constraints to our program, i.e. every variable x_i is now limited to a bounded range $0 \le x_i \le u_i$. Surprisingly, these bounds allows us to achieve approximation factors which do not depend on n, the number of matrices in the primal problem, but rather on a natural property of the program which we call the *sparsity*. Without loss of generality, we can assume $u_i = 1$ by replacing A_i with $A'_i = u_i A_i$, and c_i with $c'_i = u_i c_i$. We note that this assumption does alter the sparsity of the program. Our primal-dual problems with box constraints are the following:

$$\begin{array}{cc} \min \sum_{i=1}^n c_i x_i & \max B_t \bullet Y - \sum_{i=1}^n z_i \\ s.t.\ \sum_{i=1}^n A_i x_i \succcurlyeq B_t & s.t.\ \forall i \in [n]\ A_i \bullet Y - z_i \le c_i \\ \forall i \in [n]\ \ 0 \le x_i \le 1 & Y \succcurlyeq 0,\ z \ge 0 \end{array}.$$

4.1 Sparsity

The sparsity of a semidefinite program is defined as:

$$F^* = \max_t \max_{S \subseteq [n]} \min_{V \succcurlyeq 0:\ \left(B_t - \sum_{i \in S} A_i\right) \bullet V > 0} \frac{\sum_{i \notin S} A_i \bullet V}{\left(B_t - \sum_{i \in S} A_i\right) \bullet V}.$$

This quantity can be viewed as follows. If we saturate all variables in S, then $\sum_{i\in S} A_i$ is the coverage we get from the saturated variables, and $B_t - \sum_{i\in S} A_i$ is the remainder that we still need to cover. $\sum_{i\notin S} A_i$ is the total coverage potential of the unsaturated variables. We project both of these matrices, $\sum_{i\notin S} A_i$ and $B_t - \sum_{i\in S} A_i$, onto some witness V, and take the ratio $\frac{\sum_{i\notin S} A_i \bullet V}{\left(B_t - \sum_{i\in S} A_i\right)\bullet V}$. This is the ratio by which we "over-cover" the remainder $B_t - \sum_{i\in S} A_i$ if we use up all non-saturated variables. It turns out that $F^* \geq 1$. We actually use a relaxed version of F^* which may yield an even better result:

$$F = \max_{t,S \text{ occuring in the algorithm}} \min_{V\succcurlyeq 0:\ \left(B_t - \sum_{i\in S} A_i\right)\bullet V > 0} \frac{\sum_{i\notin S} A_i \bullet V}{\left(B_t - \sum_{i\in S} A_i\right)\bullet V}.$$

Here, the maximum is taken only over each online step t and the corresponding set of saturated variables S at step t. For fixed t, S, we can compute the minimum value of this ratio (and a minimizer V) very efficiently, see Lemma 8 below for details. Although we show that $F \leq F^*$, we still phrase our results using F^*, since F^* only depends on the given program, while F also depends on the specific choices made by the algorithm. We note that it is not necessarily the case that $F^* \leq n$, thus it would only make sense to use this parameter if the specifics of the problem can guarantee a better bound on F^* than n.

To further illustrate the meaning of F^*, it is useful to consider the set cover problem. As discussed earlier, set cover is obtained when all matrices A_i and B_t are diagonal, and having only entries from $\{0, 1\}$ on the diagonal. To analyze F^* in this case, it is sufficient to observe witness matrices V of the form $E_{j,j}$ (any other witness is simply a convex combination of these). Then $\sum_{i\notin S} A_i \bullet V$ and $\sum_{i\in S} A_i \bullet V$ are equal to the number of non-saturated and saturated sets which contain element j respectively; and $B_t \bullet V$ is 1 if element j needs to be covered and 0 otherwise. Clearly the only way in which $\left(B_t - \sum_{i\in S} A_i\right) \bullet V > 0$, is if element j needs to be covered and none of the sets containing it are saturated. Then, the expression $\frac{\sum_{i\notin S} A_i \bullet V}{\left(B_t - \sum_{i\in S} A_i\right)\bullet V}$ is exactly the number of sets containing j. Thus, F^* in this case is exactly the maximum number of sets that an element is contained in (taken over the elements which the algorithm is required to cover). This matches the notion of *row sparsity* of a linear program, and clearly in this case $F^* \leq n$.

▶ **Lemma 8.** *Let N be a positive semidefinite matrix and D be a symmetric matrix. Then the minimum value of the ratio $\frac{N\bullet V}{D\bullet V}$ such that $V \succeq 0$ and $D \bullet V > 0$ is equal to the smallest non-negative root of the polynomial equation $\det(N - \lambda D) = 0$.*

Proof. Let V be an optimal solution. Since $V \succeq 0$, we can express it as $V = \sum_\ell v_\ell v_\ell^T$ for some vectors v_ℓ. Since $N \succeq 0$, we have $N \bullet v_\ell v_\ell^T \geq 0$. Then we claim that $D \bullet v_\ell v_\ell^T \geq 0$; otherwise, we could drop $v_\ell v_\ell^T$ from the sum forming V and decrease the ratio. Next, note that $\frac{N\bullet V}{D\bullet V} = \frac{\sum_\ell N\bullet v_\ell v_\ell^T}{\sum_\ell D\bullet v_\ell v_\ell^T} \geq \min_\ell \left\{\frac{N\bullet v_\ell v_\ell^T}{D\bullet v_\ell v_\ell^T}\right\}$, and so we conclude that there is a rank 1 minimizer. Let this minimizer be $V = vv^T$ for some vector v. The minimum ratio is then obtained by minimizing $v^T N v$ subject to $v^T D v = 1$. The Karush-Kuhn-Tucker conditions imply that the optimal vector v satisfies the generalized eigenvalue equation, $Nv = \lambda Dv$ for some constant λ (the generalized eigenvalue). Note that $\frac{N\bullet vv^T}{D\bullet vv^T} = \lambda$. Since we require $v^T D v = 1$, and $v^T N v \geq 0$, only non-negative values of λ are admissible. Since the generalized eigenvalues λ are roots of the polynomial equation $\det(N - \lambda D) = 0$, and we conclude that the minimum value of the ratio is the smallest non-negative root of this polynomial equation. ◀

4.2 Algorithm Description

We now describe an algorithm for semidefinite covering-packing with box constraints. We denote by S the set of indices i of *saturated* primal variables x_i, i.e. variables which have reached their upper bound: $S = \{i | x_i = 1\}$. We use the following notations for simplicity: $\mathcal{A}_{\bar{S}} x = \sum_{i \notin S} A_i x_i$, and $\mathcal{A}_S x = \sum_{i \in S} A_i$ (note that in the second notation, we omit the x_i's because they are all saturated, so are equal to 1). We use an auxiliary variable δ, which is the measure of progress by which we update all other variables.

Algorithm 3 Primal-Dual Algorithm For Box Constraints

Initialize $x = 0$, $z = 0$, $Y = 0$.

Upon arrival of a new constraint matrix B_t, while $\mathcal{A}x \not\succcurlyeq B_t$:

1. Let V be a density matrix ($V \succcurlyeq 0$, $trV = 1$) such that $\mathcal{A}x \bullet V < B_t \bullet V$, minimizing the ratio $\frac{\sum_{i \notin S} A_i \bullet V}{B_t \bullet V - \sum_{i \in S} A_i \bullet V}$.
2. Update $F = \max\left\{F, \frac{\sum_{i \notin S} A_i \bullet V}{B_t \bullet V - \sum_{i \in S} A_i \bullet V}\right\}$.
3. While $\mathcal{A}_{\bar{S}} x \bullet V < 2\left[B_t \bullet V - \mathcal{A}_S x \bullet V\right]$:
   a. Set $\delta = 0$ initially, and increase it in a continuous manner.
   b. Increase Y continuously by adding $V\delta$ to it.
   c. For every i such that $x_i = 1$, increase z_i continuously at rate $A_i \bullet V\delta$.
   d. Update x continuously by setting:

$$x_i = \max\left\{x_i, \frac{1}{F}\left(\exp\left(\frac{\log(F+1)}{c_i}\left(A_i \bullet Y - z_i\right)\right) - 1\right)\right\}.$$

▶ **Theorem 9.** *The algorithm produces a feasible primal solution with a competitive ratio of* $O(\log F^*)$*, and a feasible dual solution with a competitive ratio of* $O(\log F^*)$*.*

The proof is omitted due to space constraints.

5 Rounding

In this section, we discuss the integer version of online semidefinite programming, and how our results in the previous sections can be rounded to an integer solution.

5.1 Changing the Framework

An *integer semidefinite program* is the following:

$$\begin{array}{c} \min \sum_{i=1}^{n} c_i \hat{x}_i \\ s.t. \ \sum_{i=1}^{n} A_i \hat{x}_i \succcurlyeq I \\ \forall i \in [n] \ \ \hat{x}_i \in \mathbb{N}^n \end{array}.$$

Note the different notation for integer variables $\hat{x}_i$ as opposed to real-valued variables x_i of the previous sections. Also note that we now restrict the covered matrix to be the identity matrix I. This is a necessity for our rounding scheme. To justify why this is not any different from the general setting, we invoke some linear algebra. First, assume that B is of full rank (and, of course, p.s.d.). Then B is congruent to I, by some invertible matrix X such that

$X^T BX = I$. Now $\sum_{i=1}^n A_i \hat{x}_i \succcurlyeq B$ if and only if $\sum_{i=1}^n X^T A_i X \hat{x}_i \succcurlyeq X^T BX = I$. We can change the matrices $A'_i = X^T A_i X$ so as to arrive at the formulation above.

However, restricting B to be of full rank throughout the entire online algorithm does not make much sense. To overcome this, we change the framework to allow the dimension m of the matrices to increase over time. Let m_t be the dimension of the online problem at step t. Then, in step $t+1$, the dimension of the matrices may increase to $m_t + 1$ (or may stay m_t). The covering matrices $A_i^{(t+1)}$ must contain $A_i^{(t)}$ as their top-left submatrix, and they must be p.s.d., i.e. $A_i^{(t+1)} \succcurlyeq 0$. The covered matrix $B^{(t+1)}$ must also be p.s.d., and its top-left submatrix of dimension m_t must be greater than or equal to $B^{(t)}$ in the p.s.d. partial ordering. The *online integer semidefinite program* is therefore:

$$\begin{array}{c} \min \sum_{i=1}^n c_i \hat{x}_i \\ s.t. \ \sum_{i=1}^n A_i^{(t)} \hat{x}_i \succcurlyeq B^{(t)} \\ \forall i \in [n] \ \ \hat{x}_i \in \mathbb{N}^n \end{array},$$

where $A_i^{(t)}, B^{(t)} \in \mathbb{R}^{m_t \times m_t}$, and $B^{(t)}$ is of full rank for all t.

Under these assumptions, it can be verified that our algorithms from Sections 3 and 4 still work (for real-valued solutions $x_i \in \mathbb{R}^n$). For Section 3, it is important to note that OPT_t indeed increases with t. The proof of the next lemma is omitted due to space constraints.

▶ **Lemma 10.** *With the above assumptions, $OPT_t \leq OPT_{t+1}$.*

Another consideration when discussing rounding is scale – if $A_1 = (M)$ and $B = (1)$ (matrices of dimension 1), then the optimum fractional solution is $x_1 = \frac{1}{M}$ but the optimum integer solution is 1, which costs M times the fractional solution. Therefore we must assume some kind of bound on the covering matrices (we use $\lambda_1(A_i) \leq R$), and we will be paying for this bound in our competitive ratio. As demonstrated by this example, this is unavoidable.

5.2 A Randomized Rounding Algorithm

We use a simple randomized rounding scheme. We run the algorithm described in Section 3[1] to maintain a fractional solution $x^{(t)}$, and we round that solution to an integer solution $\hat{x}^{(t)}$, so that $\mathbb{E}\hat{x}^{(t)} = \rho_t x^{(t)}$, where ρ_t is an approximation factor (see algorithm for exact definition), which we adjust as the dimension of the matrices grows. We then use the feasibility of $x^{(t)}$ to show that w.h.p. $\hat{x}^{(t)}$ is also feasible. The rounding is done as follows: whenever a variable x_i increases from $x_i^{(t-1)}$ to $x_i^{(t)}$, we add 1 to $\hat{x}_i$ with probability $\rho_t x_i^{(t)} - \rho_{t-1} x_i^{(t-1)}$. Since m_t and $x^{(t)}$ can only increase with t, so can ρ_t and thus $\rho_t x_i^{(t)} - \rho_{t-1} x_i^{(t-1)}$ is non-negative. To make sure that this value is always ≤ 1, we can simply break up the increase in x_i into smaller steps. This is expressed formally in algorithm 4.

▶ **Theorem 11.** *The resulting solution's expected cost is at most $O(R(\log m_t + \log n))$ times the cost of the fractional solution.*

The proof is omitted due to space constraints.

[1] If box constraints are given, we can run the algorithm from Section 4 instead. The only modification to the rounding is that each variable is increased at most once. The same analysis holds for both cases.

Algorithm 4 Randomized rounding

- Let $R > 0$ be such that $\lambda_1(A_i) \leq R$ for all i.
- Initialize $\hat{x}^{(0)} = 0$
- For step $t = 1, 2, \ldots$:
  - Let $\rho_t = 1 + \max\{8R(\log 2m_t + \log n), 2\}$.
  - Use Algorithms (2) or (3) to compute the fractional solution $x^{(t)}$.
  - For $i = 1, \ldots, n$:
    - Let $d_{i,t} = \left\lfloor \rho_t x_i^{(t)} - \rho_{t-1} x_i^{(t-1)} \right\rfloor$, and $\delta_{i,t} = \rho_t x_i^{(t)} - \rho_{t-1} x_i^{(t-1)} - d_{i,t}$
    - Let $\hat{x}_{i,1}^{(t)}, \ldots, \hat{x}_{i,d_{i,t}}^{(t)} = 1$.
    - Let $\hat{x}_{i,d_{i,t}+1}^{(t)} = \begin{cases} 1 & \text{with probability } \delta_{i,t} \\ 0 & \text{otherwise} \end{cases}$.
    - return $\hat{x}_i^{(t)} = \hat{x}_i^{(t-1)} + \hat{x}_{i,1}^{(t)} + \cdots + \hat{x}_{i,d_{i,t}+1}^{(t)}$.

5.3 An Application – Quantum Hypergraph Covering

Quantum hypergraphs originate from the field of quantum information theory. A hypergraph is a pair (V, E) where $E \subseteq 2^V$. The hypergraph covering problem (finding a collection of edges covering all vertices) is equivalent to set cover. Let each edge $e \in E$ be represented by a $\{0,1\}$ diagonal matrix A_e, where the i-th diagonal entry is 1 if and only if the i-th element in V belongs to e. The hypergraph covering problem is to find a collection of edges such that $\sum_{e \in cover} A_e \succcurlyeq I$. A *quantum hypergraph* is a pair (V, E), where each $e \in E$ corresponds to a symmetric matrix A_e of dimension $|V|$, such that $0 \preccurlyeq A_e \preccurlyeq I$. The difference is that A_e need not be diagonal or only have $\{0,1\}$ eigenvalues. The *quantum hypergraph covering* problem is thus the problem of finding a minimum collection of edges in E that satisfy $\sum_{e \in cover} A_e \succcurlyeq I$. The *fractional quantum hypergraph covering* problem is the problem of assigning non-negative weights x_e to each $e \in E$ such that $\sum_{e \in E} x_e A_e \succcurlyeq I_{|V|}$, while minimizing $\sum_{e \in E} x_e$.

Ahlswede and Winter [1] used a novel approach to develop a matrix-valued generalization of the Chernoff inequality. They applied this inequality in the analysis of their randomized rounding scheme, which takes a fractional quantum hypergraph cover and rounds it to a quantum hypergraph cover. They showed that this rounding finds a cover which is at most $O(\log m)$ times larger than the minimum cover, where m is the dimension of the matrices involved. Wigderson and Xiao [7] derandomized this result to provide a deterministic algorithm for quantum hypergraph covering. Their result also produces an $O(\log m)$-approximation cover. In addition to the quantum hypergraph covering problem, Wigderson and Xiao also provided a more general algorithm for integer semidefinite programming.

It is easy to see that the fractional quantum hypergraph covering problem is exactly the semidefinite covering problem, with the added requirement that all the covering matrices A_e fall in the range $[0, I]$, and the covered matrix is the identity matrix $B = I$. When translating this into an online setting, the most natural approach is to look at the setting presented in Section 5, where the dimension of the matrices can increase but the covered matrix must have full rank. The *online quantum hypergraph covering problem* is thus the problem of maintaining a monotonically increasing cover while the edges are revealed one dimension at a time. In this setting, combining algorithms 2 and 4 gives an $O(\log n \log m)$-competitive solution to online quantum hypergraph programming ($R = 1$ since $0 \preccurlyeq A_e \preccurlyeq I$).

Abstract

In the online bin packing problem, items of sizes in $(0, 1]$ arrive online to be packed into bins of size 1. The goal is to minimize the number of used bins. Harmonic++ achieves a competitive ratio of 1.58889 and belongs to the Super Harmonic framework [Seiden, J. ACM, 2002]; a lower bound of Ramanan et al. shows that within this framework, no competitive ratio below 1.58333 can be achieved [Ramanan et al., J. Algorithms, 1989]. In this paper, we present an online bin packing algorithm with asymptotic performance ratio of 1.5815, which constitutes the first improvement in fifteen years and reduces the gap to the lower bound by roughly 15%.

We make two crucial changes to the Super Harmonic framework. First, some of the decisions of the algorithm will depend on *exact sizes* of items, instead of only their types. In particular, for item pairs where the size of one item is in $(1/3, 1/2]$ and the other is larger than $1/2$ (a *large* item), when deciding whether to pack such a pair together in one bin, our algorithm does not consider their types, but only checks whether their total size is at most 1.

Second, for items with sizes in $(1/3, 1/2]$ (*medium* items), we try to pack the larger items of every type in pairs, while combining the smallest items with large items whenever possible. To do this, we *postpone* the coloring of medium items (i.e., the decision which items to pack in pairs and which to pack alone) where possible, and later select the smallest ones to be reserved for combining with large items. Additionally, in case such large items arrive early, we pack medium items with them whenever possible. This is a highly unusual idea in the context of Harmonic-like algorithms, which initially seems to preclude analysis (the ratio of items combined with large items is no longer a fixed constant).

For the analysis, we carefully mark medium items depending on how they end up packed, enabling us to add crucial constraints to the linear program used by Seiden. We consider the dual, eliminate all but one variable and then solve it with the ellipsoid method using a separation oracle. Our implementation uses additional algorithmic ideas to determine previously hand set parameters automatically and gives certificates for easy verification of the results.

We give a lower bound of 1.5766 for algorithms like ours. This shows that fundamentally different ideas will be required to make further improvements.

1 Introduction

In the online bin packing problem, a sequence of *items* with sizes in the interval $(0, 1]$ arrive one by one and need to be packed into *bins*, so that each bin contains items of total size at most 1. Each item must be irrevocably assigned to a bin before the next item becomes available. The algorithm has no knowledge about future items. There is an unlimited supply of bins available, and the goal is to minimize the total number of used bins (bins that receive at least one item). Bin packing is a classical and well-studied problem in combinatorial optimization. Extensive research has gone into developing approximation algorithms for this problem, e.g. [5, 7, 6, 12, 17, 9]. Such algorithms have provably good performance for any possible input and work in polynomial time. In fact, the bin packing problem was one of the first for which approximation algorithms were designed [10].

For bin packing, we are typically interested in the long-term behavior of algorithms: how good is the algorithm for large inputs? If we simply compare to the optimal solution, the worst ratio is often determined by some very small inputs. To avoid such pathological instances, the *asymptotic performance ratio* was introduced: For a given input sequence σ, let $\mathcal{A}(\sigma)$ be the number of bins used by algorithm $\mathcal{A}$ on σ. The *asymptotic performance ratio* for an algorithm $\mathcal{A}$ is defined to be

$$\mathcal{R}_{\mathcal{A}}^{\infty} = \limsup_{n\to\infty} \sup_{\sigma} \left\{ \frac{\mathcal{A}(\sigma)}{\mathrm{OPT}(\sigma)} \,\middle|\, \mathrm{OPT}(\sigma) = n \right\}. \tag{1}$$

From now on, we only consider the asymptotic competitive ratio unless otherwise stated.

Lee and Lee [13] presented an algorithm called Harmonic, which partitions the interval $(0, 1]$ into $m > 1$ intervals $(1/2, 1], (1/3, 1/2], \ldots, (0, 1/m]$. The type of an item is defined as the index of the interval which contains its size. Each type of items is packed into separate bins (i items per bin for type i). For any $\varepsilon > 0$, there is a number m such that the Harmonic algorithm that uses m types has a performance ratio of at most $(1 + \varepsilon)\Pi_\infty$ [13], where $\Pi_\infty \approx 1.69103$.

If we consider the bins packed by Harmonic, then it is apparent that in bins with type 1 items, nearly half the space can remain unused. It is better to use this space for items of other types. After a sequence of papers which used this idea to develop ever better algorithms [13, 15, 16], Seiden [18] presented a general framework called Super Harmonic which captures all of these algorithms. Super Harmonic algorithms classify items based on an interval partition of $(0, 1]$ and give each item a color as it arrives, red or blue. For each type of items j, the fraction of red items is some constant denoted by α_j. Blue items are packed as in Harmonic, i.e., for each item type j, every bin with blue items contains a maximal number of blue items. (This may leave some space for smaller red items of different types.) Red items are packed in bins which are only partially filled. The idea is that hopefully, later blue items of other types will arrive that can be placed into the bins with red items. Seiden [18] showed that the Super Harmonic algorithm Harmonic++, which uses 70 intervals for its classification and has about 40 manually set parameters, achieves a performance ratio of at most 1.58889.

Ramanan et al. [15] gave a lower bound of $19/12 \approx 1.58333$ for this type of algorithm. It is based on inputs like the one shown in Figure 1, which contains a *medium* item (size in $(1/3, 1/2]$) and a *large* item (size in $(1/2, 1]$). Both of these items arrive N times for some large number N, and although they fit pairwise into bins, the algorithm never combines them like this. No matter how fine the item classification of an algorithm, pairs of items such as these, that the algorithm does not pack together into one bin, can always be found. (To complete the lower bound construction, we also need to consider inputs containing the

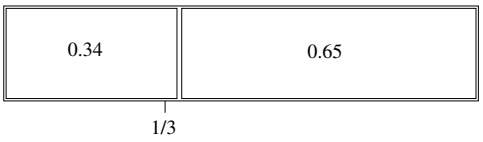

Figure 1 Part of the lower bound construction from Ramanan et al. [15]. The figure shows how one bin is packed in the *optimal* solution. Both of these items arrive many times.

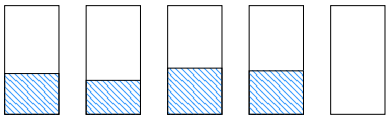
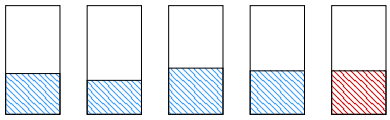
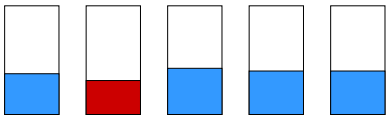


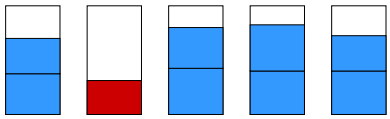
(a) Pack items one per bin with provisional coloring.



(b) A provisional red item arrives.



(c) We fix the colors. The smallest item becomes red.



(d) Additional blue items of the same type are added.

Figure 2 Illustration of the coloring in Extreme Harmonic. In this example, $\alpha = 1/9$. Note that the ratio of 1/9 does not hold (for the bins shown) at the time that the colors are fixed: 1/5 of the items are red at this point. The ratio 1/9 is achieved when all bins with blue items contain two blue items.

sizes $1/3+\varepsilon$, $1/2+\varepsilon$, which can be combined into a single bin, and the input consisting only of items of size $1/3+\varepsilon$.)

We avoid this lower bound construction by defining the algorithm so that it simply combines medium and large items *whenever* they fit together in a single bin. Essentially, we use Any Fit to combine such items into bins (under certain conditions specified below). This is a generalization of the well-known algorithms First Fit and Best Fit [19, 7], which have been used in similar contexts before [2, 1]. Proving formally that this helps to improve the asymptotic performance ratio requires a surprising amount of additional technical modifications to the algorithm and the proof, in particular setting up a complete marking scheme (see below).

As in the Super Harmonic framework, medium items that are packed in pairs are colored blue, and the ones that are packed alone into bins (possibly together with items of other types) are colored red. At this point it is important to note that medium items of any given type are not all exactly the same size, since the type only specifies an interval. This means that the items of any given type could arrive in such an order that all of the red items are slightly larger than the blue ones. Then, when large items arrive later, it could be that they are too large to fit in bins with red medium items, so the online algorithm is forced to pack them into new bins.

In order to benefit from using Any Fit, it is crucial to ensure that for each medium type, as much as possible, *it is the smallest items that are colored red.* We will do this by initially packing each medium item alone into a bin and giving it a provisional color. After several items of the same type have arrived, we will color the smallest one red and start packing additional medium items of the same type together with the other items, that are now colored blue. (See Figure 2.) In this way, we can ensure that at least *half* of the blue

items (namely, the ones that had already arrived at the time when we select the smallest to be red) are at least as large as the smallest red items. The point of this is that if those red items are still alone in bins at the end of the input, OPT cannot pack too many bins as shown in Figure 1, because this can only happen with large items that do not fit with the red items that remain alone in bins (Lemma 6).

We do not postpone the coloring decisions in the following two cases.

1. If a bin with suitable small red items is available, we will pack p into that bin and color it blue, regardless of the precise size of p.[1] In this case, in our analysis we will exploit the fact that these small items exist in the input, meaning that not *all* optimal bins are packed as shown in Figure 1: the small items must be packed somewhere (Lemma 7).
2. If bins with a *large* item are available, and p fits into such a bin, we will pack p in one such bin. This is the best case overall, since finding combinations like this was exactly our goal! However, there is a technical problem with this, which we discuss below.

Overall, we have three different cases: medium items are packed alone initially (in which case we have a guarantee about the sizes of some of the blue items), medium items are combined with smaller red items (so these red items exist and must be packed: Lemma 7), or medium items are combined with larger blue items (which is exactly our goal). The main technical challenge is to quantify these different advantages into one overall analysis. In order to do this (i.e., to prove Lemmas 6 and 7), we introduce - in addition to and separate from the coloring – a marking of the medium items, which we now describe.

$\mathcal{R}$ For any medium type j, a fraction α_j of the items marked $\mathcal{R}$ are red, and all of these **red** items are packed into mixed bins (i.e., together with a large item).

$\mathcal{B}$ For any medium type j, a fraction α_j of the items marked $\mathcal{B}$ are red, and the **blue** items are packed into mixed bins (i.e., together with red items of other (smaller) types)

$\mathcal{N}$ For any medium type j, a fraction α_j of the items marked $\mathcal{N}$ are red, and **none** of the red and blue items marked $\mathcal{N}$ are packed into mixed bins.

Our marking is illustrated in Figure 3. Maintaining the fraction α_j of red items for all marks separately is crucial for the analysis. However, we note here immediately that the fraction α_j of red items is **not** actually maintained continuously throughout the execution for all marks. This can be seen clearly for the items marked $\mathcal{R}$, where the ratio only becomes equal to α_j (ignoring rounding) after all the bins with single blue items in them receive additional blue items (see Figure 2).

Seemingly more problematically, it could happen that many large items arrive first, leading to more than an α_j fraction of the items of type j and mark $\mathcal{B}$ being packed with the large items and colored red. (Potentially, this could even happen to all of them.) While this is in principle exactly what we want to achieve, there is no guarantee that later in the input, sufficiently many additional items of type j will arrive to restore the correct ratio α_j. This is a problem for our analysis, which assumes the ratio α_j is maintained exactly. However, if we insist on maintaining this ratio throughout, i.e., if we color some of these items blue and pack them in pairs even though they could fit with existing large items, we end up with the same worst case instances as for Super Harmonic. We deal with this case by *modifying the input (for the analysis) after it has been packed.* By this and some additional postprocessing, we ensure that for each mark $\mathcal{R}, \mathcal{B}, \mathcal{N}$, an α_j fraction of the medium items of type j are indeed colored red in the end (ignoring rounding) as required. The postprocessing also ensures that

[1] Unless we already have sufficiently many blue items of the type of p, in which case we pack p into a separate bin and color it red to maintain the correct fraction of red items.

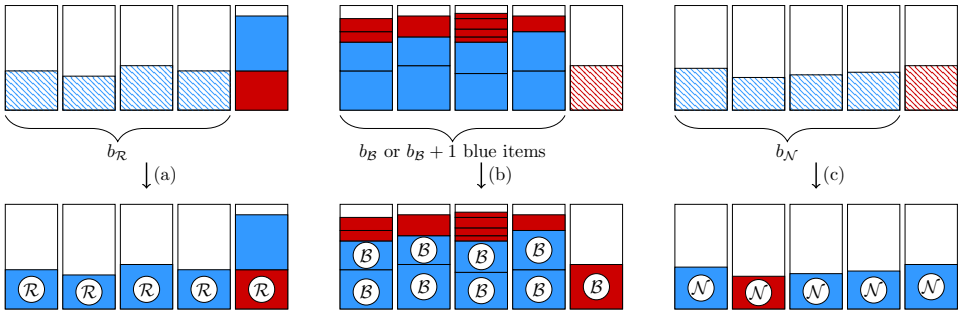


Figure 3 Illustrating the marking of the items. Again we take $\alpha_i = 1/9$. **(a)** Items get mark $\mathcal{R}$: provisionally blue items and a red item in a mixed bin. Bins with blue $\mathcal{R}$-items will receive a second blue item of the same type before a new bin is opened for this type. **(b)** Items get mark $\mathcal{B}$: a provisionally red item and blue items (in pairs) in mixed bins. **(c)** Items get mark $\mathcal{N}$: provisionally blue and provisionally red items. Note that in this step, the colors of items might be fixed to a different color than their provisional color. Bins with blue items will receive a second blue item of the same type before a new bin is opened for this type. See Fig. 2.

the marks are all correct. For instance, if a red item is packed with a blue item marked $\mathcal{N}$, the mark of that blue item gets adjusted in the end.

Like Seiden [18] and many other authors [19, 13, 15], we use weighting functions to analyze our algorithm. A weighting function defines a weight for each item type. By analyzing these, Seiden ended up with a set of mathematical programs that upper bounded the asymptotic performance ratio of Super Harmonic algorithms. These represented a kind of knapsack problems where each item has two different weights. Seiden used heuristics to get exact upper bounds for the solutions of these mathematical programs.

We use a different approach for the Extreme Harmonic framework. First of all we split each mathematical program into two standard linear programs, where both linear programs have a constraint that states its objective value should be smaller than that of the other one (representing for each one that the minimum is achieved for the set of weights it considers). To each linear program, we add two constraints that are based on the marking of the medium items. These constraints essentially state that in the optimal solution for a given input, there cannot be too many bins that are packed as shown in Figure 1 (unless the online algorithm also packs the items like this). This is the key to our improvement of the asymptotic performance ratio. However, after adding these constraints, the heuristic approach by Seiden can no longer be applied. Since each linear program has a very large number of variables but only four constraints, we take the dual and apply the ellipsoid method to solve it. To do this, we construct a separation oracle. This separation oracle solves a standard knapsack problem, making the results much easier to verify.

In order to apply the ellipsoid method, we write the dual in terms of just one variable, by eliminating two variables and assuming a third one to be given. This means that we can now do a straightforward binary search for the final remaining variable. We implemented a computer program which solves the knapsack problems and also does the other necessary work, including the automated setting of many parameters like item sizes and α values. As a result, our algorithm Son Of Harmonic requires far less manual settings than Harmonic++.

Our program uses an exact representation of fractions with arbitrary precision in order to avoid rounding errors. For our final calculations we have set the bound such that every dual LP is feasible; this means that our results do not rely on the correctness of any infeasibility claims (which are generally harder to prove). We provide a certificate and a

verifier program, and we also output the final set of knapsack problems directly to allow independent verification.

Our second main contribution is a new lower bound for all algorithms of this kind. The fundamental property of all these algorithms is that they color a fixed fraction of all items red (for each type). We show that no such algorithm can be better than 1.5766-competitive. Due to space constraints, this result is deferred to the full version.

1.1 Previous Results

The online bin packing problem was first investigated by Ullman [19]. He showed that the First Fit algorithm has performance ratio $\frac{17}{10}$. This result was then published in [7]. Johnson [11] showed that the Next Fit algorithm has performance ratio 2. Yao showed that Revised First Fit has performance ratio $\frac{5}{3}$, and further showed that no online algorithm has performance ratio less than $\frac{3}{2}$ [21]. Brown and Liang independently improved this lower bound to 1.53635 [4, 14]. The lower bound stood for a long time at 1.54014, due to van Vliet [20], until it was improved to $\frac{248}{161} = 1.54037$ by Balogh et al. [3].

The *offline* version, where all the items are given in advance, is well-known to be NP-hard [8]. This version has also received a great deal of attention, for a survey see [5].

2 The Super Harmonic framework [18]

The fundamental idea is to first classify items by size, and then pack an item according to its type. We use numbers $t_1 \geq t_2 \geq \cdots \geq t_N$ to partition the interval $(0, 1]$ into subintervals (N is a parameter). We define $I_j = (t_{j+1}, t_j]$ for $i = 1, \ldots, N$ and $I_{N+1} = (0, t_{N+1}]$. An item of size s has type j if $s \in I_j$. A type j item has size at most t_j.

For each type j, a fraction $\alpha_j \in [0, 1]$ of items are colored red when they arrive, the rest are colored blue. Blue items are packed using Next Fit: we use each bin until exactly $\text{bluefit}_j := \lfloor 1/t_j \rfloor$ items are packed into it. Red items are also packed using Next Fit, but using only some fixed amount of the available space in a bin. This space is not necessarily exactly some value $1 - \text{bluefit}_j t_j$; for any given type j, there may be several other types that the algorithm will potentially pack into a bin together with items of type j. For each type of items that have size at most $1/3$, the algorithm chooses in advance an upper bound for the space that red items may occupy from a fixed set $\mathcal{D} = \{\Delta_i\}_{i=1}^{K}$ of spaces, where $\Delta_1 \leq \cdots \leq \Delta_K$. For *medium* items (i.e., items whose size is in $(1/3, 1/2]$), red items are packed one per bin. The number of red items of type i that are packed in one bin is denoted by redfit_i. In the space not used by blue (resp. red) items, the algorithm may pack red (resp. blue) items. Each bin will contain items of at most two different types.

A Super Harmonic algorithm uses a function $b : \{1, \ldots, N\} \to \{0, \ldots, K\}$ to map each item type to an index of a space in $\mathcal{D}$, indicating how much space for red items it leaves unused in bins with blue items of this type. Here $b(j) = 0$ means that no space is left for red items. The algorithm also uses a function $r : \{1, \ldots, N\} \to \{1, \ldots, K\}$ to map how much space (given by an index of $\mathcal{D}$) red items of each type require.

We say that the *class* of an item of type j is $b(j)$, if it is blue, and $r(j)$ if it is red.[2] Thus, the class of a blue item reflects how much space is left (at least) in a bin with blue items of this type, and the class of a red item indicates how much space red items of this type require (at most) in a bin. There are four kinds of bins.

[2] Seiden used the notation $\phi(j)$ and $\varphi(j)$ for these functions.

- Pure blue: $\{i|b(i) = 0, 1 \leq i \leq N\}$. No red items are ever packed into such bins.
- Unmixed blue: $\{(i, ?)|b(i) \neq 0, 1 \leq i \leq N\}$. There is at least one blue item in the bin, and red items might still be packed into it (in the free space of size $\Delta_{b(i)}$).
- Unmixed red: $\{(?, j)|\alpha_i \neq 0, 1 \leq i \leq N\}$. There is at least one red item in the bin and no blue items, but blue items might still be packed in it (in the free space of size $1 - \Delta_{r(i)}$).
- Mixed bins: $\{(i, j)|b_i \neq 0, \alpha_j \neq 0, t_j \leq \Delta_{b(i)}, 1 \leq i \leq N, 1 \leq j \leq N\}$. There are items of both colors.

An unmixed blue bin is *compatible* with a red item of type i if the bin is in a group $(j, ?)$ and $b(j) \geq r(i)$. An unmixed red bin is compatible with a blue item of type i if the bin is in a group $(?, j)$ and $b(i) \geq r(j)$. In both cases, the condition means that the blue items and the red items together would use at most 1 space in the bin (the blue items leave enough space for the red items).

3 Marking the items and the Extreme Harmonic framework

The heart of our improvement over the Super Harmonic framework is marking the medium items. It enables us to keep track of how they are packed, allowing us to prove the crucial Lemmas 6 and 7 later, which bound how often "bad" patterns of the form shown in Figure 1 (which have weight > 1.5815) can be used in the optimal solution. Mark Items divides the medium items into three sets $\mathcal{N}, \mathcal{B}$ and $\mathcal{R}$ (see Figure 3). Every time an item arrives, after it is packed using the new framework below, Mark Items performs one of the three steps in Figure 3 if possible. This is done to keep the number of provisionally colored items small (a constant). We define Mark Items formally in the full version.

▶ **Theorem 1.** *At all times, there are at most* $5/\alpha_i$ *provisionally colored items of type* i*.*

Once assigned, an item remains in a set until the end of the input. This holds even if e.g. a blue item is packed with a red $\mathcal{N}$-item, meaning that a more appropriate mark for the red item is $\mathcal{B}$. We change marks where needed only after all items have been packed.

Let n^i count the total number of items of type i, and n^i_r count the number of red items of type i. For a given type i and set X, denote the number of red items in set X by $n^i_r(X)$, the number of blue items by $n^i_b(X)$, and the total number of items by $n^i(X)$. After all items have arrived and after some postprocessing, we will have

$$n^i_r(X) = \lfloor \alpha_i n^i(X) \rfloor \text{ for } X \in \{\mathcal{N}, \mathcal{B}, \mathcal{R}\} \text{ and each medium type } i. \tag{2}$$

▶ **Definition 2.** An unmixed bin is *red-compatible* with a newly arriving item if (1) the bin contains (provisionally) blue items of type i, the new item is of type j and will be colored red, and $b(i) \geq r(j)$, *or* (2) the bin contains a large item of size s, the new item is medium and has size at most $1 - s$. The definition for unmixed bins being blue-compatible to new items is completely analogous.

We say that a (mixed or unmixed) bin is *red-open* if it contains some non-provisionally red items but can still receive additional red items. We define *blue-open* analogously.

Like Super Harmonic algorithms, an Extreme Harmonic algorithm first tries to pack a red (blue) item into a red-open (blue-open) bin with items of the same type and color; then it tries to find a unmixed compatible bin; if all else fails, it opens a new bin. Of course, the definition of compatible has been extended compared to Super Harmonic (where this concept was not defined explicitly). Note that the choice of bin depends on the actions of Mark Items, since that algorithm fixes the colors of some items and bins.

1 $n^i \leftarrow n^i + 1$
2 **if** *p is medium, $\alpha_i > 0$, and there exists a red-compatible bin B with a large item* **then**
3 Place p in B and label it as bonus item. `// special case: existing bin`
4 $n^i \leftarrow n^i - 1$ `// we do not count this item for type` i
5 **else**
6 **if** $n_r^i < \lfloor \alpha_i n^i \rfloor$ **then** `// pack a (provisionally) red item`
7 **if** *there is a bin B with a bonus item of type i or there is a bin B with a bonus item of type j and $r(i) \leq b(j)$* **then**
8 Label the medium item in B as type i and color it red. It is no longer a bonus item.
9 $n^i \leftarrow n^i + \text{redfit}_i$ `// count medium item as type` i `item(s)`
10 $n_r^i \leftarrow n_r^i + \text{redfit}_i$
11 Pack(p, blue) `// since we now have` $n_r^i \geq \lfloor \alpha_i n^i \rfloor$ `again`
12 **else** Pack(p, red)
13 **else** `// pack a (provisionally) blue item`
14 **if** $b(i) = 0$ then pack p using Next Fit into pure bins of type i and color p blue.
15 **else** Pack(p, blue)
16 Update the marks and colors using Mark Items.

Algorithm 1: How the Extreme Harmonic framework packs a single item p of type $i < n$. At the beginning, we set $n_r^i \leftarrow 0$ and $n^i \leftarrow 0$ for $1 \leq i \leq n$.

1 Try the following types of bins to place p with (provisional) color c in this order:
2 - a mixed or unmixed c-open bin with items of type i and **definite** color c
3 - a c-compatible unmixed bin (the bin becomes mixed, its items' colors are fixed)
4 - a new unmixed bin
5 If p was packed into a new bin, p is medium and $\alpha_i > 0$, give p provisionally the color c, else give it the definite color c. If p got the definite color red, $n_r^i \leftarrow n_r^i + 1$.

Algorithm 2: The algorithm Pack(p, c) for packing an item p of type i with color $c \in \{\text{blue, red}\}$.

The new framework is formally described in Algorithm 1 and 2. We require $\alpha_i < 1/3$ for all types i. We discuss the changes from Super Harmonic one by one. All the changes stem from our much more careful packing of medium items.

As can be seen in Algorithm 2 (lines 2, 4 and 5), medium items that are packed into new bins are initially packed **one** per bin and given a provisional color. The goal of having provisionally colored items is to try and make sure that the *smallest* items of each type become red in the end. Thus, we wait until some number of these items have arrived, and then color the smallest one red (Figure 2).

When an item arrives, in many cases, we cannot postpone assigning it a color, since a c-open or c-compatible bin is already available (see lines 2–3 of Pack(p, c)). Additionally, we need to check right at the start whether a suitable large item has already arrived. We deal with this case in lines 2–4 of Algorithm 1. In this special case, we *ignore* the value α_i. We pack the medium item with the large item as if it was a red item, but we *do not count* it towards the total number of existing items of its type; instead we label it a **bonus item**. Bonus items do not have a color or mark, at least initially.

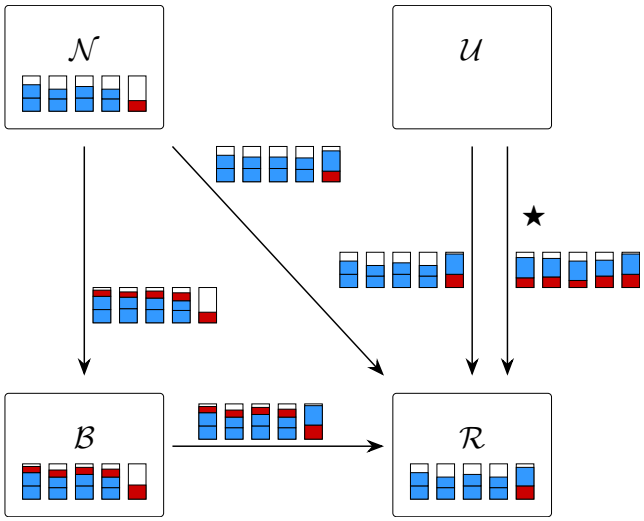

Figure 4 Reassigning marks after the input is complete. Items are sorted into their correct sets whenever possible, updating the marks that they received while the algorithm was running. Some item sizes are reduced. The bins next to the arrows indicate what sets of bins are being reassigned. The step marked with ★ takes place at the end of the postprocessing, after all other steps.

This means that we have (possibly temporarily) too many items of this type that are packed as red items (we do not count them towards the quantities n^i and n^i_r, but we do record that they exist). There are several ways that this can be fixed later on. Either, additional blue items of type i arrive and we can restore the correct ratio of red items. Or, some item of type j and size at most $1/3$ arrives that should be colored red and is compatible with blue items of type i. In this case, for our accounting, we replace the bonus item with redfit_j red items of type j, adjust the counts accordingly in lines 9–10, and color the new type j item blue.[3] Finally, it could also happen that some bonus items remain until the end; in this case we use careful post-processing so that each item does have a type and color at the end, and the ratio α_i is maintained. Note that we only modify item sizes for the analysis, and we only make items smaller, so the value of the optimal solution can only decrease and the implied competitive ratio can only increase as a result. Also note that allowing bonus items (i.e., occasionally packing too many items as red items) is essential to achieve a better competitive ratio; without this, we would get the same lower bound instances as before.

It can be seen that blue items of size at most $1/3$ are packed as in Super Harmonic. For red items of size at most $1/3$, we need to deal with existing bonus items in lines 9–10, and in line 3 of Pack(p, c), the provisional color of an existing item may be made permanent. Otherwise, the packing proceeds as in Super Harmonic. By the order in which existing bins are tried for packing new items, c-open bins always take precedence over other bins.

4 Postprocessing

After the algorithm has packed all items, we perform some postprocessing. For an overview of our changes of marks and sizes, see Figure 4. A formal version is given in the full paper.

[3] Note that the meanings of i and j are switched in the description of the algorithm for reasons of presentation.

▶ **Theorem 3.** *After postprocessing, (2) holds. Each blue item in $\mathcal{N}, \mathcal{R}$ and $\mathcal{B}$ is packed in a bin that contains two blue items. No bins with items in $\mathcal{N}$ or* red *items in $\mathcal{B}$ are mixed.*

In line 3 of Extreme Harmonic, bonus items are created. These are medium items which are packed together with a large blue item. Some of them may still be bonus when the algorithm has finished. Also, some of them may be labeled with a different type than the type they belong to according to their size. We call such items reduced items. In an additional postprocessing step, we split up reduced items into (possibly several) red items of the type with which we labeled the item. If any bonus items remain, we modify the packing that the algorithm outputs (for the analysis) by replacing some number of bins with a large blue item and a red medium item by the same number of bins with two blue medium items. Note that we only make items smaller, so all items still fit in their bins in both the optimal packing and the online packing. We finally achieve the following result.

▶ **Theorem 4.** *For each type i, we have $n_r^i \in [\lfloor \alpha_i n^i \rfloor - 3, \lfloor \alpha_i n^i \rfloor]$.*

5 Analysis using weights

Let $\mathcal{A}$ be an Extreme Harmonic algorithm. For analyzing the asymptotic performance ratio of $\mathcal{A}$, we will use the well-known technique of weighting functions: We assign weights to each item such that the number of bins that our algorithm uses in order to pack a specific input is equal to the sum of the weights of all items in this input. Then, we determine the maximum weight that can be packed in a single bin. Clearly, the offline algorithm cannot pack more weight than this in any of its bins, thus this maximum weight for a single bin gives us an upper bound on the competitive ratio.

Recall that the class of a red item of type i is $r(i)$ and the class of a blue item of type i is $b(i)$. Let $\mathfrak{r}$ be the smallest red item in a bin that has no blue items. Let the type of $\mathfrak{r}$ be ℓ, and $k = r(\ell)$. The weights of a non-large item p will depend on its class relative to k, and on its mark in case its class is k. The value of k (and the marks) become clear by running the algorithm. Note that the algorithm including the postprocessing does not depend on the weight functions in any way. There are $2K$ weighting functions in total, where $K = |\mathcal{D}|$ is the number of different spaces used for red items. For each k, w_k counts all the blue items, and v_k counts all the red items. The two weight functions of an item p of type i and mark m are given by the following table. The marks are only relevant for items of class k.

$w_k(p) = w_k(i,m)$		$v_k(p) = v_k(i,m)$	
$\frac{1-\alpha_i}{\text{bluefit}_i} + \frac{\alpha_i}{\text{redfit}_i}$	if $r(i) > k$	$\frac{1-\alpha_i}{\text{bluefit}_i} + \frac{\alpha_i}{\text{redfit}_i}$	if $b(i) < k$
$\frac{1-\alpha_i}{\text{bluefit}_i} + \frac{\alpha_i}{\text{redfit}_i}$	if $r(i) = k, m \in \{\mathcal{N}, \mathcal{B}, \emptyset\}$	$\frac{\alpha_i}{\text{redfit}_i}$	if $b(i) \geq k$
$\frac{1-\alpha_i}{\text{bluefit}_i}$	if $r(i) = k, m = \mathcal{R}$		
$\frac{1-\alpha_i}{\text{bluefit}_i}$	if $r(i) < k$		

▶ **Theorem 5.** *We have $\mathcal{A}(\sigma) \leq \max_{1 \leq k \leq K+1} \min\{\sum_{i=1}^n w_k(p_i), \sum_{i=1}^n v_k(p_i)\} + O(1)$ for any Extreme Harmonic algorithm $\mathcal{A}$ and any input σ.*

A *pattern* is a tuple $q = \{q_1, \ldots, q_m\}$ such that $\sum_{i=1}^m q_i t_{i+1} < 1$. Intuitively, a pattern describes the contents of a bin in the optimal offline solution. For a given weight function w, the weight of pattern q is $w(q) = w\left(1 - \sum_{i=1}^m q_i t_{i+1}\right) + \sum q_i w(t_i)$.

Denote the (finite) set of patterns by $\mathcal{Q}$. We can define an offline algorithm for a given input by a distribution χ over the patterns, where $\chi(q)$ indicates which fraction of the bins

are packed using pattern q. To show that a given Extreme Harmonic algorithm has performance ratio at most 1.5815 for input sequences with $\mathfrak{r}$ having class k, we must show

$$\frac{\min\{\sum_{i=1}^n w_k(p_i), \sum_{i=1}^n v_k(p_i)\}}{OPT(\sigma)} = \min\left\{\frac{\sum_{i=1}^n w_k(p_i)}{OPT(\sigma)}, \frac{\sum_{i=1}^n v_k(p_i)}{OPT(\sigma)}\right\}$$
$$\leq \min\left\{\sum_{q\in\mathcal{Q}} \chi(q) w_k(q), \sum_{q\in\mathcal{Q}} \chi(q) v_k(q)\right\} \leq 1.5815 \quad (3)$$

for all such inputs σ. As can be seen from this bound, the question now becomes: what is the distribution χ (the mix of patterns) that maximizes the minimum in (3)?

For this χ, the following constraints hold. Consider an input where $\mathfrak{r} > 1/3$. Let $m(q)$ be the number of $\mathcal{N}$-items of type ℓ in pattern q. Let q_1 be the pattern with an $\mathcal{N}$-item of type ℓ and an item of type i where $b(i) = k-1$. (Such an item is larger than $1-\mathfrak{r}$.) The parameters of the algorithm, in particular the type boundaries, must be such that this pattern is unique (i.e., no non-sand item can be added); it is easy to ensure this holds by setting an appropriate upper bound for the sand.

▶ **Lemma 6.** *If $\mathfrak{r} > 1/3$ and the type of $\mathfrak{r}$ is ℓ, then $m(q) \in \{0,1,2\}$ for all q, and $\chi(q_1) \leq \frac{1-\alpha_\ell}{1+\alpha_\ell} \sum_{q\neq q_1} \chi(q) m(q)$.*

For any j and q, let $n_j(q)$ be the number of items of type j in pattern q. Let q_2 be the pattern with a $\mathcal{B}$-item of the type of $\mathfrak{r}$ and an item larger than $1-\mathfrak{r}$. Like q_1, q_2 should be unique (this is easy to guarantee and check). Note that the patterns q_1 and q_2 are versions of the pattern shown in Figure 1.

▶ **Lemma 7.** *If $\mathfrak{r} > 1/3$, and ℓ is the type of $\mathfrak{r}$, $\frac{1-\alpha_\ell}{2}\chi(q_2) \leq \sum_{r(j)\leq b(\ell)} \sum_q \frac{\alpha_j}{\text{redfit}_j} \chi(q) n_j(q)$.*

Maximizing the minimum in (3) is the same as maximizing the first term under the condition that it is not larger than the second term—except that this condition might not be satisfiable, in which case we need to maximize the second term. We are led to consider two linear programs, which we will call LP_w^k and LP_v^k. Let $\mathcal{Q} = \{q_1, \ldots, q_{|Q|}\}$ and let $\chi_i = \chi(q_i), w_{ik} = w_k(q_i), n_{ij} = n_j(q_i), m_i = m(q_i)$. LP_w^k is the following linear program.

$$\begin{aligned}
\max \quad & \sum_{i=1}^{|\mathcal{Q}|} \chi_i w_{ik} && \text{// First term in (3)} && (4)\\
s.t. \quad & \chi_1 - \tfrac{1-\alpha_\ell}{2} \sum_{i=2}^{|\mathcal{Q}|} \chi_i m_i \leq 0 && \text{// Lemma 6} && (5)\\
& \tfrac{1-\alpha_\ell}{2}\chi_2 - \sum_{j:r(j)\leq b(\ell)} \sum_{i=3}^{|\mathcal{Q}|} \tfrac{\alpha_j}{\text{redfit}_j} \chi_i n_{ij} \leq 0 && \text{// Lemma 7} && (6)\\
& \sum_{i=3}^{|\mathcal{Q}|} \chi_i (w_{ik} - v_{ik}) \leq 0 && \text{// Bound on first term} && (7)\\
& \sum_{i=1}^{|\mathcal{Q}|} \chi_i \leq 1 && \text{// } \chi \text{ is a distribution} && (8)\\
& \chi_i \geq 0, 1 \leq i \leq |\mathcal{Q}| && \text{// } \chi \text{ is a distribution} && (9)
\end{aligned}$$

LP_w^k has a very large number of variables but only four constraints (apart from the non-negativity constraints). In (7) we use the following proposition.

▶ **Proposition 8.** $w_{1k} = v_{1k}, w_{2k} = v_{2k}$.

The dual DP_w^k is the following.

$$\begin{aligned}
\min \quad & y_4 && && (10)\\
s.t. \quad & y_1 + y_4 \geq w_{1k} && && (11)\\
& \frac{1-\alpha_\ell}{2} y_2 + y_4 \geq w_{2k} && && (12)\\
& -\tfrac{1-\alpha_\ell}{2} m_i y_1 - y_2 \sum_{j:r(j)\leq b(\ell)} \tfrac{\alpha_j}{\text{redfit}_j} n_{ij} + (w_{ik} - v_{ik}) y_3 + y_4 \geq w_{ik} && i = 3, \ldots, |\mathcal{Q}| && (13)\\
& y_i \geq 0 && i = 1, \ldots, 4 && (14)
\end{aligned}$$

If the objective value of DP_w^k as well as that of DP_v^k is at most some value y_4^* (or if one is infeasible), then y_4^* upper bounds the asymptotic performance ratio of our algorithm for this value of k by duality and by (3). It is easy to see that if for some feasible y^*, constraint (11) or (12) is not tight, then we can decrease y_1^* or y_2^* and still have a feasible solution. We therefore restrict our search to solutions for which (11) and (12) are tight. Given y_4^*, we then know the values of y_1^* and y_2^*. If the constraint (13) does not hold for pattern q_i and a given dual solution y^*, we have the following:

$$(1-y_3^*)w_{ik} + y_3^* v_{ik} + \frac{1-\alpha_\ell}{2} m_i y_1^* + y_2^* \sum_{j:r(j)\le b(\ell)} \alpha_j n_j > y_4^* \tag{15}$$

Note that we get exactly the same condition by considering DP_v^k due to symmetry.

Recall that w_{ik} and v_{ik} are just the sums of the respective weights of all the non-sand items in pattern q_i. Based on (15), we define a new weighting function $\omega(p)$ as follows.

$$\omega(p) = \begin{cases} (1-y_3^*)w_k(p) + y_3^* v_k(p) + \frac{1-\alpha_\ell}{2} y_1^* & \text{type of } p \text{ is } \ell \ (= \text{ type of } e) \\ (1-y_3^*)w_k(p) + y_3^* v_k(p) + y_2^* \alpha_j & \text{type of } p \text{ is } j, r(j) \le b(\ell) \\ (1-y_3^*)w_k(p) + y_3^* v_k(p) & \text{else} \end{cases}$$

The inequality (15) then turns into $\omega(q_i) > y_4^*$. For given y_4^*, we can therefore determine feasibility of (11)–(13) by using the ellipsoid method, fortunately for only one dimension: that is, we do a binary search for $y_3^* \in [0,1]$. For every value y_3^* that we consider, we solve a simple knapsack problem to determine $W = \max_{q\in\mathcal{Q}} \omega(q)$ using a dynamic program.

Summarizing the above discussion, proving that an algorithm is c-competitive can be done by running the described binary search for $k = 1, \ldots, K$ using $y_4^* = c$. Note that for $\mathfrak{r} \le 1/3$, we do not have conditions (5) and (6), and we can define $\omega(p) = (1-y_3^*)w_k(p) + y_3^* v_k(p)$ for all items.

For our algorithm Son Of Harmonic we have set initial values as follows. The last three columns contain item sizes and corresponding α_i values that were set manually, separated by semicolons. Numbers of the form $1/i$ until the value t_N are added automatically by our program if they are not listed below, but only up to 1/50; for very small items, we (automatically) merge some consecutive classes without loss of performance to speed up the binary search.

$c = \frac{15815}{10000}$	Item bounds and α values:	1/4;106/1000	3/20;0
$t_N = \frac{1}{2^{100}}$	33345/100000;0	8/39;8/100	29/200;0
$\gamma = \frac{2}{7}$	33340/100000;0	1/5;93/1000	1/7;16/100
(starting from $\frac{1}{14}$)	5/18;2/100	3/17;3/100	1/13;1/8
Last type before small type generation: $\frac{1}{50}$	7/27;105/1000	1/6;8/100	1/14;1/13

The remaining values α_i are set automatically using heuristics designed to speed up the search and minimize the resulting upper bound. In the range $(1/3, 1/2]$, we automatically generate item sizes (with corresponding α values and Δ_i values) that are less than t_N apart to ensure uniqueness of q_1 and q_2. The value γ specifies how much room is used by red items of size at most 1/14; larger items ($\le 1/3$) use at most 1/3 room. Our computer program and more information is available at `http://people.mpi-inf.mpg.de/~heydrich/extremeHarmonic/index.html`.

Abstract

We design the first online algorithm with poly-logarithmic competitive ratio for the *edge-weighted degree-bounded Steiner forest* (EW-DB-SF) problem and its generalized variant. We obtain our result by demonstrating a new generic approach for solving mixed packing/covering integer programs in the online paradigm. In EW-DB-SF, we are given an edge-weighted graph with a degree bound for every vertex. Given a root vertex in advance, we receive a sequence of terminal vertices in an online manner. Upon the arrival of a terminal, we need to augment our solution subgraph to connect the new terminal to the root. The goal is to minimize the total weight of the solution while respecting the degree bounds on the vertices. In the offline setting, *edge-weighted degree-bounded Steiner tree* (EW-DB-ST) and its many variations have been extensively studied since early eighties. Unfortunately, the recent advancements in the online network design problems are inherently difficult to adapt for degree-bounded problems. In particular, it is not known whether the fractional solution obtained by standard primal-dual techniques for mixed packing/covering LPs can be rounded online. In contrast, in this paper we obtain our result by using structural properties of the optimal solution, and reducing the EW-DB-SF problem to an exponential-size mixed packing/covering integer program in which every variable appears only once in covering constraints. We then design a generic *integral* algorithm for solving this restricted family of IPs.

As mentioned above, we demonstrate a new technique for solving mixed packing/covering integer programs. Define the *covering frequency* k of a program as the maximum number of covering constraints in which a variable can participate. Let m denote the number of packing constraints. We design an online *deterministic integral algorithm* with competitive ratio of $O(k \log m)$ for the mixed packing/covering integer programs. We prove the tightness of our result by providing a matching lower bound for any randomized algorithm. We note that our solution solely depends on m and k. Indeed, there can be exponentially many variables. Furthermore,

our algorithm directly provides an integral solution, even if the integrality gap of the program is unbounded. We believe this technique can be used as an interesting alternative for the standard primal-dual techniques in solving online problems.

1 Introduction

Degree-bounded network design problems comprise an important family of network design problems since the eighties. Aside from various real-world applications such as vehicle routing and communication networks [6, 32, 38], the family of degree-bounded problems has been a testbed for developing new ideas and techniques. The problem of *degree-bounded spanning tree*, introduced in Garey and Johnson's *Black Book* of NP-Completeness [29], was first investigated in the pioneering work of Fürer and Raghavachari [15]. In this problem, we are required to find a spanning tree of a given graph with the goal of minimizing the maximum degree of the vertices in the tree. Let b^* denote the maximum degree in the optimal spanning tree. Fürer and Raghavachari give a parallel approximation algorithm which produces a spanning tree of degree at most $O(\log(n)b^*)$. This result was later generalized by Agrawal, Klein, and Ravi [1] to the case of degree-bounded Steiner tree (DB-ST) and degree bounded Steiner forest (DB-SF) problem. In DB-ST, given a set of terminal vertices, we need to find a subgraph of minimum maximum degree that connects the terminals. In the more generalized DB-SF problem, we are given pairs of terminals and the output subgraph should contain a path connecting each pair. Fürer and Raghavachari [16] significantly improved the result for DB-SF by presenting an algorithm which produces a Steiner forest with maximum degree at most $b^* + 1$.

The study of DB-ST and DB-SF was the starting point of a very popular line of work on various degree-bounded network design problems; e.g. [28, 31, 27, 22, 13] and more recently [14, 13]. One particular variant that has been extensively studied was initiated by Marathe et al. [28]: In the *edge-weighted degree-bounded spanning tree* problem, given a weight function over the edges and a degree bound b, the goal is to find a minimum-weight spanning tree with maximum degree at most b. The initial results for the problem generated much interest in obtaining approximation algorithms for the edge-weighted degree-bounded spanning tree problem [11, 10, 17, 23, 24, 25, 26, 34, 35, 36]. The groundbreaking results obtained by Goemans [18] and Singh and Lau [37] settle the problem by giving an algorithm that computes a minimum-weight spanning tree with degree at most $b+1$. Singh and Lau [27] generalize their result for the *edge-weighted Steiner tree* (EW-DB-ST) and *edge-weighted Steiner forest* (EW-DB-SF) variants. They design an algorithm that finds a Steiner forest with cost at most twice the cost of the optimal solution while violating the degree constraints by at most three.

Despite these achievements in the offline setting, it was not known whether degree-bounded problems are tractable in the *online setting*. The online counterparts of the aforementioned Steiner problems can be defined as follows. The underlying graph and degree bounds are known in advance. The demands arrive one by one in an online manner. At the arrival of a demand, we need to augment the solution subgraph such that the new demand is satisfied. The goal is to be competitive against an offline optimum that knows the demands in advance.

Recently, Dehghani et al. [12] explore the tractability of the Online DB-SF problem by showing that a natural greedy algorithm produces a solution in which the degree bounds are violated by at most a factor of $O(\log n)$, which is asymptotically *tight*. They analyze their algorithm using a dual fitting approach based on the combinatorial structures of the graph such as the toughness[1] factor. Unfortunately, they can also show that greedy methods are not competitive for the edge-weighted variant of the problem. Hence, it seems unlikely that the approach of [12] can be generalized to EW-DB-SF.

The *online edge-weighted Steiner connectivity* problems (with no bound on the degrees) have been extensively studied in the last decades. Imase and Waxman [21] use a dual-fitting argument to show that the greedy algorithm has a competitive ratio of $O(\log n)$, which is also asymptotically tight. Later the result was generalized to the EW SF variant by Awerbuch et al. [4] and Berman and Coulston [7]. In the past few years, various primal-dual techniques have been developed to solve the more general node-weighted variants [2, 30, 19], prize-collecting variants [33, 20], and multicommodity buy-at-bulk [9]. These results are obtained by developing various primal-dual techniques [2, 19] while generalizing the application of combinatorial properties to the online setting [30, 20, 9]. In this paper however, we develop a primal approach for solving *bounded-frequency mixed packing/covering integer programs*. We believe this framework would be proven useful in attacking other online packing and covering problems.

1.1 Our Results and Techniques

In this paper, we consider the online Steiner tree and Steiner forest problems at the presence of both edge weights and degree bounds. In the Online EW-DB-SF problem, we are given a graph $G = (V, E)$ with n vertices, edge-weight function w, degree bound b_v for every $v \in V$, and an online sequence of connectivity demands (s_i, t_i). Let w_{opt} denote the minimum weight subgraph which satisfies the degree bounds and connects all demands. Let $\rho = \frac{\max_e w(e)}{\min_{e:w(e)>0} w(e)}$.

▶ **Theorem 1.** *There exists an online deterministic algorithm which finds a subgraph with total weight at most $O(\log^3 n)w_{opt}$ while the degree bound of a vertex is violated by at most a factor of $O(\log^3(n)\log(n\rho))$.*

If one favors the degree bounds over total weight, one can find a subgraph with degree-bound violation $O(\log^3(n)\frac{\log(n\rho))}{\log\log(n\rho)})$ and total cost $O(\log^3(n)\frac{\log(n\rho))}{\log\log(n\rho)})w_{opt}$.

We note that the logarithmic dependency on ρ is indeed necessary. It follows from the result of [12] that the competitive ratio of any algorithm is either $\Omega(n)$ or $\Omega(\log \rho)$.

Our technical contribution for solving the EW-DB-SF problem is twofold. First by exploiting a structural result and massaging the optimal solution, we show a formulation of the problem that falls in the restricted family of *bounded-frequency mixed packing/cover IPs*, while losing only logarithmic factors in the competitive ratio. We then design a generic online algorithm with a logarithmic competitive ratio that can solve any instance of the bounded-frequency packing/covering IPs. In what follows, we describe our results in detail.

1.1.1 Massaging the optimal solution

Initiated by work of Alon et al. [2] on online set cover, Buchbinder and Naor developed a strong framework for solving packing/covering LPs *fractionally* online. For the applications

[1] The toughness of a graph is defined as $\min_{X \subseteq V} \frac{|X|}{|\text{CC}(G \setminus X)|}$; where for a graph H, $\text{CC}(H)$ denotes the collection of connected components of H.

of their general framework in solving numerous online problems, we refer the reader to the survey in [8]. Azar et al. [5] generalize this method for the fractional *mixed* packing and covering LPs. The natural linear program relaxation for EW-DB-SF, commonly used in the literature, is a special case of mixed packing/covering LPs: one needs to select an edge from every cut that separates the endpoints of a demand (covering constraints), while for a vertex we cannot choose more than a specific number of its adjacent edges (packing constraints). Indeed, one can use the result of Azar et al. [5] to find an online *fractional* solution with polylogarithmic competitive ratio. However, doing the rounding in an online manner seems very hard.

Offline techniques for solving degree-bounded problems often fall in the category of iterative and dependent rounding methods. Unfortunately, these methods are inherently difficult to adapt for an online settings since the underlying fractional solution may change dramatically in between the rounding steps. Indeed, this might be the very reason that despite many advances in the online network design paradigm in the past two decades, the natural family of degree-bounded problems has remained widely open. In this paper, we circumvent this by reducing EW-DB-ST to a novel formulation beyond the scope of standard online packing/covering techniques and solving it using a new online integral approach.

The crux of our IP formulation is the following structural property: Let (s_i, t_i) denote the i^{th} demand. We need to augment the solution Q_{i-1} of previous steps by buying a subgraph that makes s_i and t_i connected. Let G_i denote the graph obtained by contracting the pairs of vertices s_j and t_j for every $j < i$. Note that any $(s_i - t_i)$-path in G_i corresponds to a feasible augmentation for Q_{i-1}. Some edges in G_i might be already in Q_{i-1} and therefore by using them again we can save both on the total weight and the vertex degrees. However, in Section 2 we prove that there always exists a path in G_i such that even without sharing on any of the edges in G_i and therefore paying completely for the increase in the weight and degrees, we can approximate the optimal solution up to a logarithmic factor. This in fact, enables us to have a formulation in which the covering constraints for different demands are *disentangled*. Indeed, we only have one covering constraint for each demand. Unfortunately, this implies that we have exponentially many variables, one for each possible path in G_i. This may look hopeless since the competitive factors obtained by standard fractional packing/covering methods introduced by Buchbinder and Naor [8] and Azar et al. [5], depend on the logarithm of the number of variables. Therefore we come up with a new approach for solving this class of mixed packing/covering integer programs (IP).

1.1.2 Bounded-frequency mixed packing/covering IPs

We derive our result for EW-DB-ST by demonstrating a new technique for solving mixed packing/covering *integer* programs. We believe this approach could be applicable to a broader range of online problems. The integer program $\mathbb{IP}1$ describes a general mixed packing/covering IP with the set of integer variables $\mathbf{x} \in \mathbb{Z}^n_{\geq 0}$ and α. The packing constraints are described by a $m \times n$ non-negative matrix P. Similarly, the $q \times n$ matrix C describes the covering constraints. The *covering frequency* of a variable x_i is defined as the number of covering constraints in which x_i has a positive coefficient. The covering frequency of a mixed packing/covering program is defined as the maximum covering frequency of its variables.

$$\begin{aligned} \text{minimize} \quad & \alpha \ , \\ s.t. \quad & P\mathbf{x} \leq \alpha \ . \\ & C\mathbf{x} \geq 1 \ . \\ & \mathbf{x} \in \mathbb{Z}_{\geq 0}, \alpha \in \mathbb{R}_{>0} \ . \end{aligned} \tag{$\mathbb{IP}1$}$$

In the online variant of mixed packing and covering IP, we are given the packing constraints in advance. However the covering constraints arrive in an online manner. At the arrival of each covering constraint, we should *increase* the solution $\mathbf{x}$ such that it satisfies the new covering constraint. We provide a deterministic algorithm for solving online mixed packing/covering IPs.

▶ **Theorem 2.** *Given an instance of the online mixed packing/covering IP, there exists a deterministic integral algorithm with competitive ratio $O(k \log m)$, where m is the number of packing constraints and k is the covering frequency of the IP.*

We note that the competitive ratio of our algorithm is independent of the number of variables or the number of covering constraints. Indeed, there can be exponentially many variables.

Our result can be thought of as a generalization of the work of Aspnes et al. [3] on virtual circuit routing. Although not explicit, their result can be massaged to solve mixed packing/covering IPs in which all the coefficients are zero or one, and the covering frequency is one. They show that such IPs admit a $O(\log(m))$-competitive algorithms. Theorem 2 generalizes their result to the case with arbitrary non-negative coefficients and any bounded covering frequency.

We complement our result by proving a matching lower bound for the competitive ratio of any *randomized* algorithm. This lower bound holds even if the algorithm is allowed to return fractional solutions.

▶ **Theorem 3.** *Any randomized online algorithm A for integral mixed packing and covering is $\Omega(k \log m)$-competitive, where m denotes the number of packing constraints, and k denotes the covering frequency of the IP. This even holds if A is allowed to return a fractional solution.*

As mentioned before, Azar et al. [5] provide a fractional algorithm for mixed packing/-covering LPs with competitive ratio of $O(\log m \log d)$ where d is the maximum number of variables in a single constraint. They show an almost matching lower bound for deterministic algorithms. We distinguish two advantages of our approach compared to that of Azar et al.:

- The algorithm in [5] outputs a *fractional* competitive solution which then needs to be rounded online. For various problems such as Steiner connectivity problems, rounding a solution online is very challenging, even if offline rounding techniques are known. Moreover, the situation becomes hopeless if the integrality gap is unbounded. However, for bounded-frequency IPs, our algorithm directly produces an integral competitive solution. Thus it does not depend on rounding methods, and is applicable to problems with large integrality gap, or the problems for which it is shown that rounding methods do not preserve any approximation guarantee, and as such, the traditional approach fails.
- Azar et al. find the best competitive ratio with respect to the number of packing constraints and the size of constraints. Although these parameters are shown to be bounded in several problems, in many problems such as connectivity problems and flow problems, formulations with exponentially many variables are very natural. Our techniques provide an alternative solution with a tight competitive ratio, for formulations with bounded covering frequency.

1.2 Preliminaries

Let $G = (V, E)$ be an undirected graph of size n ($|V| = n$). Let $w : E \to \mathbb{Z}_{>0}$ be a function denoting the edge weights. For a subgraph $H \subseteq G$, we define $w(H) := \sum_{e \in E(H)} w(e)$. For every vertex $v \in V$, let $b_v \in \mathbb{Z}_{>0}$ denote the degree bound of v. Let $\deg_H(v)$ denote the degree of vertex v in subgraph H. We define the load $l_H(v)$ of vertex v w.r.t. H as
