BlockQuicksort: Avoiding Branch Mispredictions in Quicksort

Stefan Edelkamp[1] **and Armin Weiß**[2]

1 **TZI, Universität Bremen, Bremen, Germany**
2 **Stevens Institute of Technology, Hoboken, NJ, USA**

Abstract

Since the work of Kaligosi and Sanders (2006), it is well-known that Quicksort – which is commonly considered as one of the fastest in-place sorting algorithms – suffers in an essential way from branch mispredictions. We present a novel approach to address this problem by partially decoupling control from data flow: in order to perform the partitioning, we split the input in blocks of constant size (we propose 128 data elements); then, all elements in one block are compared with the pivot and the outcomes of the comparisons are stored in a buffer. In a second pass, the respective elements are rearranged. By doing so, we avoid conditional branches based on outcomes of comparisons at all (except for the final Insertionsort). Moreover, we prove that for a static branch predictor the average total number of branch mispredictions is at most $\epsilon n \log n + \mathcal{O}(n)$ for some small ϵ depending on the block size when sorting n elements.

Our experimental results are promising: when sorting random integer data, we achieve an increase in speed (number of elements sorted per second) of more than 80% over the GCC implementation of C++ `std::sort`. Also for many other types of data and non-random inputs, there is still a significant speedup over `std::sort`. Only in few special cases like sorted or almost sorted inputs, `std::sort` can beat our implementation. Moreover, even on random input permutations, our implementation is even slightly faster than an implementation of the highly tuned Super Scalar Sample Sort, which uses a linear amount of additional space.

1 Introduction

Sorting a sequence of elements of some totally ordered universe remains one of the most fascinating and well-studied topics in computer science. Moreover, it is an essential part of many practical applications. Thus, efficient sorting algorithms directly transfer to a performance gain for many applications. One of the most widely used sorting algorithms is Quicksort, which has been introduced by Hoare in 1962 [14] and is considered to be one of the most efficient sorting algorithms. For sorting an array, it works as follows: first, it chooses an arbitrary pivot element and then rearranges the array such that all elements smaller than the pivot are moved to the left side and all elements larger than the pivot are moved to the right side of the array – this is called *partitioning*. Then, the left and right side are both sorted recursively. Although its average[1] number of comparisons is not optimal – $1.38n \log n + \mathcal{O}(n)$ vs. $n \log n + \mathcal{O}(n)$ for Mergesort –, its over-all instruction count is very low. Moreover, by

[1] Here and in the following, the average case refers to a uniform distribution of all input permutations assuming all elements are different.

choosing the pivot element as median of some larger sample, the leading term $1.38n \log n$ for the average number of comparisons can be made smaller – even down to $n \log n$ when choosing the pivot as median of some sample of growing size [22]. Other advantages of Quicksort are that it is easy to implement and that it does not need extra memory except the recursion stack of logarithmic size (even in the worst case if properly implemented). A major drawback of Quicksort is its quadratic worst-case running time. Nevertheless, there are efficient ways to circumvent a really bad worst-case. The most prominent is Introsort (introduced by Musser [23]) which is applied in GCC implementation of `std::sort`: as soon as the recursion depth exceeds a certain limit, the algorithm switches to Heapsort.

Another deficiency of Quicksort is that it suffers from branch mispredictions (or branch misses) in an essential way. On modern processors with long pipelines (14 stages for Intel Haswell, Broadwell, Skylake processors – for the older Pentium 4 processors even more than twice as many) every branch misprediction causes a rather long interruption of the execution since the pipeline has to be filled anew. In [16], Kaligosi and Sanders analyzed the number of branch mispredictions incurred by Quicksort. They examined different simple branch prediction schemes (static prediction and 1-bit, 2-bit predictors) and showed that with all of them, Quicksort with a random element as pivot causes on average $cn \log n + \mathcal{O}(n)$ branch mispredictions for some constant $c = 0.34$ (resp. $c = 0.46$, $c = 0.43$). In particular, in Quicksort with random pivot element, every fourth comparison is followed by a mispredicted branch. The reason is that for partitioning, each element is compared with the pivot and depending on the outcome either it is swapped with some other element or not. Since for an optimal pivot (the median), the probability of being smaller the pivot is 50%, there is no way to predict these branches.

Kaligosi and Sanders also established that choosing skewed pivot elements (far off the median) might even decrease the running time because it makes branches more predictable. This also explains why, although theoretically larger samples for pivot selection were shown to be superior, in practice the median-of three variant turned out to be the best. In [5], the skewed pivot phenomenon is confirmed experimentally. Moreover, in [21], precise theoretical bounds on the number of branch misses for Quicksort are given – establishing also theoretical superiority of skewed pivots under the assumption that branch mispredictions are expensive.

In [7] Brodal and Moruz proved a general lower bound on the number of branch mispredictions given that every comparison is followed by a conditional branch which depends on the outcome of the comparison. In this case there are $\Omega(n \log_d n)$ branch mispredictions for a sorting algorithm which performs $\mathcal{O}(dn \log n)$ comparisons. As Elmasry and Katajainen remarked in [10], this theorem does not hold anymore if the results of comparisons are not used for conditional branches. Indeed, they showed that every program can be transformed into a program which induces only a constant number of branch misses and whose running time is linear in the running time of the original program. However, this general transformation introduces a huge constant factor overhead. Still, in [10] and [11] Elmasry, Katajainen and Stenmark showed how to efficiently implement many algorithms related to sorting with only few branch mispredictions. They call such programs *lean*. In particular, they present variants of Mergesort and Quicksort suffering only very little from branch misses. Their Quicksort variant (called Tuned Quicksort, for details on the implementation, see [17]) is very fast for random permutations – however, it does not behave well with duplicate elements because it applies Lomuto's uni-directional partitioner (see e. g. [8]).

Another development in recent years is multi-pivot Quicksort (i. e. several pivots in each partitioning stage [3, 4, 19, 28, 29]). It started with the introduction of Yaroslavskiy's dual-pivot Quicksort [31] – which, surprisingly, was faster than known Quicksort variants and, thus, became the standard sorting implementation in Oracle Java 7 and Java 8. Concerning branch mispredictions all these multi-pivot variants behave essentially like ordinary Quicksort [21]; however, they have one advantage: every data element is accessed only a few times (this is also referred to as the number of *scans*). As outlined in [4], increasing the number of pivot elements further (up to 127 or 255), leads to Super Scalar Sample Sort, which has been introduced by Sanders and Winkel [25]. Super Scalar Sample Sort not only has the advantage of few scans, but also is based on the idea of avoiding conditional branches. Indeed, the correct bucket (the position between two pivot elements) can be found by converting the results of comparisons to integers and then simply performing integer arithmetic. In their experiments Sanders and Winkel show that Super Scalar Sample Sort is approximately twice as fast as Quicksort (`std::sort`) when sorting random integer data. However, Super Scalar Sample Sort has one major draw-back: it uses a linear amount of extra space (for sorting n data elements, it requires space for another n data elements and additionally for more than n integers). In the conclusion of [16], Kaligosi and Sander raised the question:

> *However, an in-place sorting algorithm that is better than Quicksort with skewed pivots is an open problem.*

(Here, in-place means that it needs only a constant or logarithmic amount of extra space.) In this work, we solve the problem by presenting our block partition algorithm, which allows to implement Quicksort without any branch mispredictions incurred by conditional branches based on results of comparisons (except for the final Insertionsort – also there are still conditional branches based on the control-flow, but their amount is relatively small). We call the resulting algorithm BlockQuicksort. Our work is inspired by Tuned Quicksort from [11], from where we also borrow parts of our implementation. The difference is that by doing the partitioning block-wise, we can use Hoare's partitioner, which is far better with duplicate elements than Lomuto's partitioner (although Tuned Quicksort can be made working with duplicates by applying a check for duplicates similar to what we propose for BlockQuicksort as one of the further improvements in Section 3.2). Moreover, BlockQuicksort is also superior to Tuned Quicksort for random permutations of integers.

Our Contributions

- We present a variant of the partition procedure that only incurs few branch mispredictions by storing results of comparisons in constant size buffers.
- We prove an upper bound of $\epsilon n \log n + \mathcal{O}(n)$ branch mispredictions on average, where $\epsilon < \frac{1}{16}$ for our proposed block size (Theorem 1).
- We propose some improvements over the basic version.
- We implemented our algorithm with an `stl`-style interface[2].
- We conduct experiments and compare BlockQuicksort with `std::sort`, Yaroslavskiy's dual-pivot Quicksort and Super Scalar Sample Sort – on random integer data it is faster than all of these and also Katajainen et al.'s Tuned Quicksort.

Outline. Section 2 introduces some general facts on branch predictors and mispredictions, and gives a short account of standard improvements of Quicksort. In Section 3, we give a precise description of our block partition method and establish our main theoretical result – the bound on the number of branch mispredictions. Finally, in Section 4, we

[2] Code available at `https://github.com/weissan/BlockQuicksort`

experimentally evaluate different block sizes, different pivot selection strategies and compare our implementation with other state of the art implementations of Quicksort and Super Scalar Sample Sort.

Further experimental results as well as the C++ Code of the basic version of BlockQuicksort can be found in [9].

2 Preliminaries

Logarithms denoted by log are always base 2. The term *average case* refers to a uniform distribution of all input permutations assuming all elements are different. In the following `std::sort` always refers to its GCC implementation.

Branch Misses. Branch mispredictions can occur when the code contains conditional jumps (i. e. *if* statements, loops, etc.). Whenever the execution flow reaches such a statement, the processor has to decide in advance which branch to follow and decode the subsequent instructions of that branch. Because of the length of the pipeline of modern microprocessors, a wrong predicted branch causes a large delay since, before continuing the execution, the instructions for the other branch have to be decoded.

Branch Prediction Schemes. Precise branch prediction schemes of most modern processors are not disclosed to the public. However, the simplest schemes suffice to make BlockQuicksort induce only few mispredictions.

The easiest branch prediction scheme is the *static predictor*: for every conditional jump the compiler marks the more likely branch. In particular, that means that for every *if* statement, we can assume that there is a misprediction if and only if the *if* branch is not taken; for every *loop* statement, there is precisely one misprediction for every time the execution flow reaches that loop: when the execution leaves the loop. For more information about branch prediction schemes, we refer to [13, Section 3.3].

How to avoid Conditional Branches. The usual implementation of sorting algorithms performs conditional jumps based on the outcome of comparisons of data elements. There are at least two methods how these conditional jumps can be avoided – both are supported by the hardware of modern processors:

- Conditional moves (`CMOVcc` instructions on x86 processors) – or, more general, conditional execution. In C++ compilation to a conditional move can be (often) triggered by

```
i = (x < y) ? j : i;
```

- Cast Boolean variables to integer (`SETcc` instructions x86 processors). In C++:

```
int i = (x < y);
```

Also many other instruction sets support these methods (e. g. ARM [2], MIPS [24]). Still, the Intel Architecture Optimization Reference Manual [15] advises only to use these instructions to avoid unpredictable branches (as it is the case for sorting) since correctly predicted branches are still faster. For more examples how to apply these methods to sorting, see [11].

Quicksort and improvements. The central part of Quicksort is the partitioning procedure. Given some pivot element, it returns a pointer p to an element in the array and rearranges the array such that all elements left of the p are smaller or equal the pivot and all elements on the right are greater or equal the pivot. Quicksort first chooses some pivot element, then performs the partitioning, and, finally, recurses on the elements smaller and larger the pivot – see Algorithm 1. We call the procedure which organizes the calls to the partitioner the *Quicksort main loop*.

Algorithm 1 Quicksort

```
1: procedure QUICKSORT($A[\ell, \dots, r]$)
2:     if $r > \ell$ then
3:         pivot ← choosePivot($A[\ell, \dots, r]$)
4:         cut ← partition($A[\ell, \dots, r]$, pivot)
5:         Quicksort($A[\ell, \dots, \text{cut} - 1]$)
6:         Quicksort($A[\text{cut}, \dots, r]$)
7:     end if
8: end procedure
```

There are many standard improvements for Quicksort. For our optimized Quicksort main loop (which is a modified version of Tuned Quicksort [11, 17]), we implemented the following:

- A very basic optimization due to Sedgewick [27] avoids recursion partially (e. g. `std::sort`) or totally (here – this requires the introduction of an explicit stack).
- Introsort [23]: there is an additional counter for the number of recursion levels. As soon as it exceeds some bound (`std::sort` uses $2 \log n$ – we use $2 \log n + 3$), the algorithms stops Quicksort and switches to Heapsort [12, 30] (only for the respective sub-array). By doing so, a worst-case running time of $\mathcal{O}(n \log n)$ is guaranteed.
- Sedgewick [27] also proposed to switch to Insertionsort (see e. g. [18, Section 5.2.1]) as soon as the array size is less than some fixed small constant (16 for `std::sort` and our implementation). There are two possibilities when to apply Insertionsort: either during the recursion, when the array size becomes too small, or at the very end after Quicksort has finished. We implemented the first possibility (in contrast to `std::sort`) because for sorting integers, it hardly made a difference, but for larger data elements there was a slight speedup (in [20] this was proposed as *memory-tuned Quicksort*).
- After partitioning, the pivot is moved to its correct position and not included in the recursive calls (not applied in `std::sort`).
- The basic version of Quicksort uses a random or fixed element as pivot. A slight improvement is to choose the pivot as median of three elements – typically the first, in the middle and the last. This is applied in `std::sort` and many other Quicksort implementations. Sedgewick [27] already remarked that choosing the pivots from an even larger sample does not provide a significant increase of speed. In view of the experiments with skewed pivots [16], this is no surprise. For BlockQuicksort, a pivot closer to the median turns out to be beneficial (Figure 2 in Section 4). Thus, it makes sense to invest more time to find a better pivot element. In [22], Martinez and Roura show that the number of comparisons incurred by Quicksort is minimal if the pivot element is selected as median of $\Theta(\sqrt{n})$ elements. Another variant is to choose the pivot as median of three (resp. five) elements which themselves are medians of of three (resp. five) elements. We implemented all these variants for our experiments – see Section 4.

Our main contribution is the block partitioner, which we describe in the next section.

3 Block Partitioning

The idea of block partitioning is quite simple. Recall how Hoare's original partition procedure works (Algorithm 2):

Algorithm 2 Hoare's Partitioning

```
1: procedure Partition($A[\ell, \dots, r]$, pivot)
2:     while $\ell < r$ do
3:         while $A[\ell] <$ pivot do $\ell$++ end while
4:         while $A[r] >$ pivot do $r$−− end while
5:         if $\ell < r$ then swap($A[\ell], A[r]$); $\ell$++; $r$−− end if
6:     end while
7:     return $\ell$
8: end procedure
```

Two pointers start at the leftmost and rightmost elements of the array and move towards the middle. In every step the current element is compared to the pivot (Line 3 and 4). If some element on the right side is less or equal the pivot (resp. some element on the left side is greater or equal), the respective pointer stops and the two elements found this way are swapped (Line 5). Then the pointers continue moving towards the middle.

The idea of BlockQuicksort (Algorithm 3) is to separate Lines 3 and 4 of Algorithm 2 from Line 5: fix some block size B; we introduce two buffers $\mathrm{offsets}_L[0, \dots, B-1]$ and $\mathrm{offsets}_R[0, \dots, B-1]$ for storing pointers to elements ($\mathrm{offsets}_L$ will store pointers to elements on the left side of the array which are greater or equal than the pivot element – likewise $\mathrm{offsets}_R$ for the right side). The main loop of Algorithm 3 consists of two stages: the scanning phase (Lines 5 to 18) and the rearrangement phase (Lines 19 to 26).

Like for classical Hoare partition, we also start with two pointers (or indices as in the pseudocode) to the leftmost and rightmost element of the array. First, the scanning phase takes place: the buffers which are empty are refilled. In order to do so, we move the respective pointer towards the middle and compare each element with the pivot. However, instead of stopping at the first element which should be swapped, only a pointer to the element is stored in the respective buffer (Lines 8 and 9 resp. 15 and 16 – actually the pointer is always stored, but depending on the outcome of the comparison a counter holding the number of pointers in the buffer is increased or not) and the pointer continues moving towards the middle. After an entire block of B elements has been scanned (either on both sides of the array or only on one side), the rearranging phase begins: it starts with the first positions of the two buffers and swaps the data elements they point to (Line 21); then it continues until one of the buffers contains no more pointers to elements which should be swapped. Now the scanning phase is restarted and the buffer that has run empty is filled again.

The algorithm continues this way until fewer elements than two times the block size remain. Now, the simplest variant is to switch to the usual Hoare partition method for the remaining elements (in the experiments with suffix `Hoare finish`). But, we also can continue with the idea of block partitioning: the algorithm scans the remaining elements as one or two final blocks (of smaller size) and performs a last rearrangement phase. After that, some elements to swap in one of the two buffers might still remain, while the other buffer is empty. With one run through the buffer, all these elements can be moved to the left resp. right (similar as it is done in the Lomuto partitioning method, but without performing actual comparisons). We do not present the details for this final rearranging here because on one hand it gets a little tedious and on the other hand it does neither provide a lot of insight into the algorithm nor is it necessary to prove our result on branch mispredictions.

Algorithm 3 Block partitioning

```
1: procedure BlockPartition($A[\ell, \dots, r]$, pivot)
2:     integer $\text{offsets}_L[0, \dots, B-1], \text{offsets}_R[0, \dots, B-1]$
3:     integer $\text{start}_L, \text{start}_R, \text{num}_L, \text{num}_R \leftarrow 0$
4:     while $r - \ell + 1 > 2B$ do                                    ▷ start main loop
5:         if $\text{num}_L = 0$ then                          ▷ if left buffer is empty, refill it
6:             $\text{start}_L \leftarrow 0$
7:             for $i = 0, \dots, B-1$ do

27:    compare and rearrange remaining elements
28: end procedure
```

3.1 Analysis

If the input consists of random permutations (all data elements different), the average numbers of comparisons and swaps are the same as for usual Quicksort with median-of-three. This is because both Hoare's partitioner and the block partitioner preserve randomness of the array.

The number of scanned elements (total number of elements loaded to the registers) is increased by two times the number of swaps, because for every swap, the data elements have to be loaded again. However, the idea is that due to the small block size, the data elements still remain in L1 cache when being swapped – so the additional scan has no negative effect on the running time. In Section 4 we see that for larger data types and from a certain threshold on, an increasing size of the blocks has a negative effect on the running time. Therefore, the block size should not be chosen too large – we propose $B = 128$ and fix this constant throughout (thus, already for inputs of moderate size, the buffers also do not require much more space than the stack for Quicksort).

Branch mispredictions. The next theorem is our main theoretical result. For simplicity we assume here that BlockQuicksort is implemented without the worst-case-stopper Heapsort (i. e. there is no limit on the recursion depth). Since there is only a low probability that a high recursion depth is reached while the array is still large, this assumption is not a real restriction. We analyze a static branch predictor: there is a misprediction every time a loop is left and a misprediction every time the *if* branch of an *if* statement is not taken.

▶ **Theorem 1.** *Let $\mathcal{C}$ be the average number of comparisons of Quicksort with constant size pivot sample. Then BlockQuicksort (without limit to the recursion depth and with the same pivot selection method) with blocksize B induces at most $\frac{6}{B} \cdot \mathcal{C} + \mathcal{O}(n)$ branch mispredictions on average. In particular, BlockQuicksort with median-of-three induces less then $\frac{8}{B} n \log n + \mathcal{O}(n)$ branch mispredictions on average.*

Theorem 1 shows that when choosing the block size sufficiently large, the $n \log n$-term becomes very small and – for real-world inputs – we can basically assume a linear number of branch mispredictions. Moreover, Theorem 1 can be generalized to samples of non-constant size for pivot selection. Since the proof might become tedious, we stick to the basic variant here. The constant 6 in Theorem 1 can be replaced by 4 when implementing Lines 19, 24, and 25 of Algorithm 3 with conditional moves.

▶ Remark. The $\mathcal{O}(n)$-term in Theorem 1 can be bounded by $3n$ by taking a closer look to the final rearranging phase. For a heuristic argument see [9].

Proof. First, we show that every execution of the block partitioner Algorithm 3 on an array of length n induces at most $\frac{6}{B} n + c$ branch mispredictions for some constant c. In order to do so, we only need to look at the main loop (Line 4 to 27) of Algorithm 3 because the final scanning and rearrangement phases consider only a constant (at most $2B$) number of elements. Inside the main loop there are three *for* loops (starting Lines 7, 14, 20), four *if* statements (starting Lines 5, 12, 24, 25) and the min calculation (whose straightforward implementation is an *if* statement – Line 19). We know that in every execution of the main loop at least one of the conditions of the *if* statements in Line 5 and 12 is true because in every rearrangement phase at least one buffer runs empty. The same holds for the two *if* statements in Line 24 and 25. Therefore, we obtain at most two branch mispredictions for the *if*s, three for the *for* loops and one for the min in every execution of the main loop.

In every execution of the main loop, there are at least B comparisons of elements with the pivot. Thus, the number of branch misses in the main loop is at most $\frac{6}{B}$ times the number of comparisons. Hence, for every input permutation the total number of branch mispredictions of BlockQuicksort is at most $\frac{6}{B} \cdot \#\text{comparisons} + (c + c') \cdot \#\text{calls to partition} + \mathcal{O}(n)$, where c' it the number of branch mispredictions of one execution of the main loop of Quicksort (including pivot selection, which only needs a constant number of instructions) and the $\mathcal{O}(n)$ term comes from the final Insertionsort. The number of calls to partition is bounded by n because each element can be chosen as pivot only once (since the pivots are not contained in the arrays for the recursive calls). Thus, by taking the average over all input permutations, the first statement follows.

The second statement follows because Quicksort with median-of-three incurs $1.18 n \log n + \mathcal{O}(n)$ comparisons on average [26]. ◀

3.2 Further Tuning of Block Partitioning

We propose and implemented further tunings for our block partitioner:

1. Loop unrolling: since the block size is a power of two, the loops of the scanning phase can be unrolled four or even eight times without causing additional overhead.
2. Cyclic permutations instead of swaps: We replace

```
1: for $j = 0, \dots, \text{num} - 1$ do
2:     swap($A\big[\ell + \text{offsets}_L[\text{start}_L + j]\big], A\big[r - \text{offsets}_R[\text{start}_R + j]\big]$)
3: end for
```

by the following code, which does not perform exactly the same data movements, but still in the end all elements less than the pivot are on the left and all elements greater are on the right:

```
1: temp ← $A\big[\ell + \text{offsets}_L[\text{start}_L]\big]$
2: $A\big[\ell + \text{offsets}_L[\text{start}_L]\big] \leftarrow A\big[r - \text{offsets}_R[\text{start}_R]\big]$
3: for $j = 1, \ldots, \text{num} - 1$ do
4:     $A\big[r - \text{offsets}_R[\text{start}_R + j - 1]\big] \leftarrow A\big[\ell + \text{offsets}_L[\text{start}_L + j]\big]$
5:     $A\big[\ell + \text{offsets}_L[\text{start}_L + j]\big] \leftarrow A\big[r - \text{offsets}_R[\text{start}_R + j]\big]$
6: end for
7: $A\big[r - \text{offsets}_R[\text{start}_R + \text{num} - 1]\big] \leftarrow$ temp
```

Note that this is also a standard improvement for partitioning – see e. g. [1].

In the following, we always assume these two improvements since they are of very basic nature (plus one more small change in the final rearrangement phase). We call the variant without them `block_partition_simple`.

The next improvement is a slight change of the algorithm: in our experiments we noticed that for small arrays with many duplicates the recursion depth becomes often higher than the threshold for switching to Heapsort – a way to circumvent this is an additional check for duplicates equal to the pivot if one of the following two conditions applies:

- the pivot occurs twice in the sample for pivot selection (in the case of median-of-three),
- the partitioning results very unbalanced for an array of small size.

The check for duplicates takes place after the partitioning is completed. Only the larger half of the array is searched for elements equal to the pivot. This check works similar to Lomuto's partitioner (indeed, we used the implementation from [17]): starting from the position of the pivot, the respective half of the array is scanned for elements equal to the pivot (this can be done by one *less than* comparison since elements are already known to be greater or equal (resp. less or equal) the pivot)). Elements which are equal to the pivot are moved to the side of the pivot. The scan continues as long as at least every fourth element is equal to the pivot (instead every fourth one could take any other ratio – this guarantees that the check stops soon if there are only few duplicates).

After this check, all elements which are identified as being equal to the pivot remain in the middle of the array (between the elements larger and the elements smaller than the pivot); thus, they can be excluded from further recursive calls. We denote this version with the suffix `duplicate check` (dc).

4 Experiments

We ran thorough experiments with implementations in C++ on different machines with different types of data and different kinds of input sequences. The experiments are run on an Intel Core i5-2500K CPU (3.30GHz, 4 cores, 32KB L1 instruction and data cache, 256KB L2 cache per core and 6MB L3 shared cache) with 16GB RAM and operating system Ubuntu Linux 64bit version 14.04.4. We used GNU's `g++` (4.8.4); optimized with flags `-O3 -march=native`.

For time measurements, we used `std::chrono::high_resolution_clock`, for generating random inputs, the Mersenne Twister pseudo-random generator `std::mt19937`. All time measurements were repeated with the same 20 deterministically chosen seeds – the displayed numbers are the average of these 20 runs. Moreover, for each time measurement, at least 128MB of data were sorted – if the array size is smaller, then for this time measurement several arrays have been sorted and the total elapsed time measured. Our running time plots all display the actual time divided by the number of elements to sort on the y-axis.

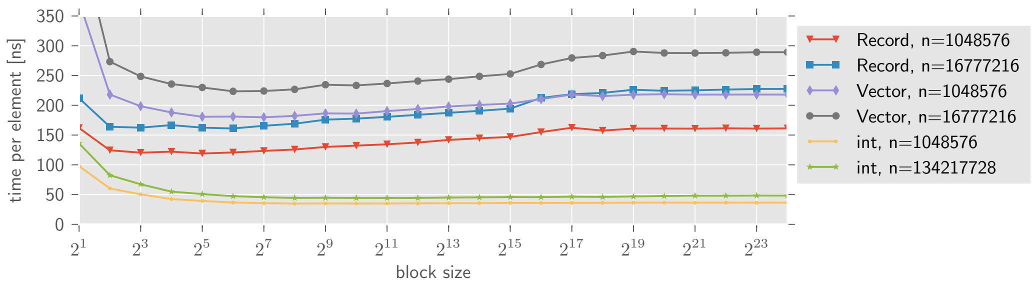

Figure 1 Different block sizes for random permutations.

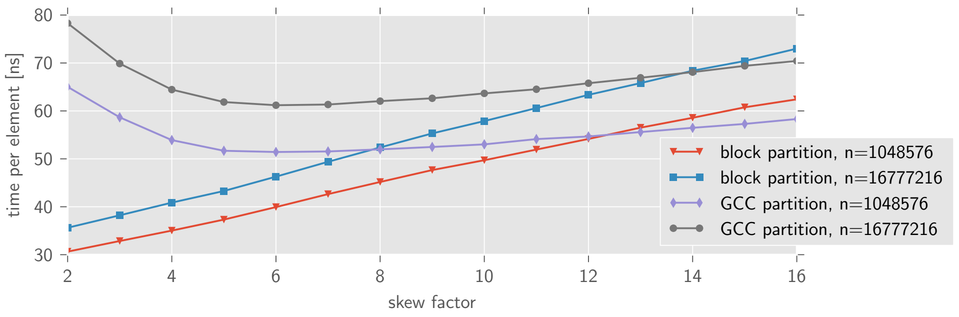

Figure 2 Sorting random permutations of 32-bit integers with skewed pivot. A skew factor k means that $\left\lfloor \frac{n}{k} \right\rfloor$-th element is chosen as pivot of an array of length n.

We performed our running time experiments with three different data types:

- `int`: signed 32-bit integers.
- `Vector`: 10-dimensional array of 64-bit floating-point numbers (`double`). The order is defined via the Euclidean norm – for every comparison the sums of the squares of the components are computed and then compared.
- `Record`: 21-dimensional array of 32-bit integers. Only the first component is compared.

The code of our implementation of BlockQuicksort as well as the other algorithms and our running time experiments is available at `https://github.com/weissan/BlockQuicksort`.

Different Block Sizes. Figure 1 shows experimental results on random permutations for different data types and block sizes ranging from 4 up to 2^{24}.

We see that for integers only at the end there is a slight negative effect when increasing the block size. Presumably this is because up to a block size of 2^{19}, still two blocks fit entirely into the L3 cache of the CPU. On the other hand for `Vector` a block size of 64 and for `Record` of 8 seem to be optimal – with a considerably increasing running time for larger block sizes.

As a compromise we chose to fix the block size to 128 elements for all further experiments. An alternative approach would be to choose a fixed number of bytes for one block and adapt the block size according to the size of the data elements.

Skewed Pivot Experiments. We repeated the experiments from [16] with skewed pivot for both the usual Hoare partitioner (`std::__unguarded_partition`, from the GCC implementation of `std::sort`) and our block partition method. For both partitioners we used our tuned Quicksort loop. The results can be seen in Figure 2: classic Quicksort benefits from skewed pivot, whereas BlockQuicksort works best with the exact median. Therefore, for BlockQuicksort it makes sense to invest more effort to find a good pivot.

Different Pivot Selection Methods. We implemented several strategies for pivot selection:

- median-of-three, median-of-five, median-of-twenty-three,
- median-of-three-medians-of-three, median-of-three-medians-of-five, median-of-five-medians-of-five: first calculate three (resp. five) times the median of three (resp. five) elements, then take the pivot as median of these three (resp. five) medians,
- median-of-$\sqrt{n}$.

All pivot selection strategies switch to median-of-three for small arrays. Moreover, the median-of-$\sqrt{n}$ variant switches to median-of-five-medians-of-five for arrays of length below 20000 (for smaller n even the number of comparisons was better with median-of-five-medians-of-five). The medians of larger samples are computed with `std::nth_element`.

Despite the results on skewed pivots Figure 2, there was no big difference between the different pivot selection strategies (for the results, see [9]). As expected, median-of-three was always the slowest for larger arrays. Median-of-five-medians-of-five was the fastest for `int` and median-of-$\sqrt{n}$ for `Vector`. We think that the small difference between all strategies is due to the large overhead for the calculation of the median of a large sample – and maybe because the array is rearranged in a way that is not favorable for the next recursive calls.

4.1 Comparison with other Sorting Algorithms

We compare variants of BlockQuicksort with the GCC implementation of `std::sort`[3] (which is known to be one of the most efficient Quicksort implementations – see e. g. [6]), Yaroslavskiy's dual-pivot Quicksort [31] (we converted the Java code of [31] to C++) and an implementation of Super Scalar Sample Sort [25] by Hübschle-Schneider[4]. For random permutations and random values modulo $\sqrt{n}$, we also test Tuned Quicksort [17] and three-pivot Quicksort implemented by Aumüller and Bingmann[5] from [4] (which is based on [19]) – for other types of inputs we omit these algorithms because of their poor behavior with duplicate elements.

Branch mispredictions. We experimentally determined the number of branch mispredictions of BlockQuicksort and the other algorithms with the *chachegrind* branch prediction profiler, which is part of the profiling tool *valgrind*[6]. The results of these experiments on random `int` data can be seen in Figure 3 – the y-axis shows the number of branch misprediction

[3] For the source code see e. g. `https://gcc.gnu.org/onlinedocs/gcc-4.7.2/libstdc++/api/a01462_source.html` – be aware that in newer versions of GCC the implementation is slightly different: the old version uses the first, middle and last element as sample for pivot selection, whereas the new version uses the *second*, middle and last element. For decreasingly sorted arrays the newer version works far better – for random permutations and increasingly sorted arrays, the old one is better. We used the old version for our experiment. The new version is included in some plots in [9] (Figures 9 and 10); this reveals a enormous difference between the two versions for particular inputs and underlines the importance of proper pivot selection.

[5] URL: `http://eiche.theoinf.tu-ilmenau.de/Quicksort-experiments/` – retrieved March, 2016

[6] For more information on valgrind, see `http://valgrind.org/`. To perform the measurements we used the same Python script as in [11, 17], which first measures the number of branch mispredictions of the whole program including generation of test cases and then, in a second run, measures the number of branch mispredictions incurred by the generation of test cases.

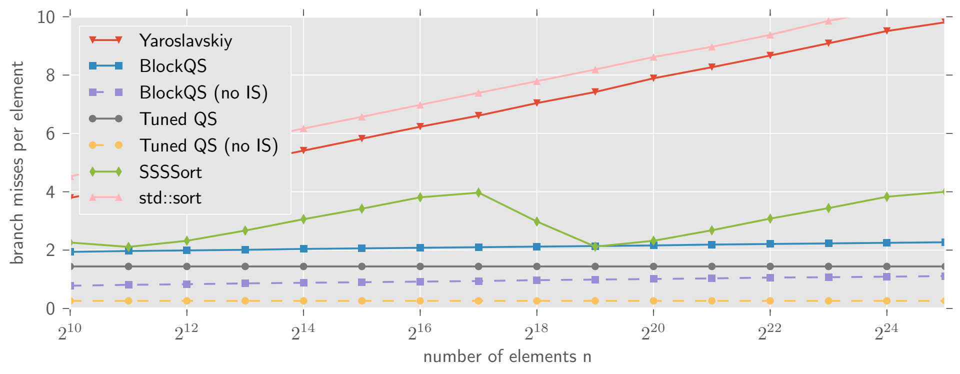

Figure 3 Number of branch mispredictions.

divided the the array size. We only display the median-of-three variant of BlockQuicksort since all the variants are very much alike. We also added plots of BlockQuicksort and Tuned Quicksort skipping final Insertionsort (i. e. the arrays remain partially unsorted).

We see that both `std::sort` and Yaroslavskiy's dual-pivot Quicksort incur $\Theta(n \log n)$ branch mispredictions. The up and down for Super Scalar Sample Sort presumably is because of the variation in the size of the arrays where the base case sorting algorithm `std::sort` is applied to. For BlockQuicksort there is an almost non-visible $n \log n$ term for the number of branch mispredictions. Indeed, we computed an approximation of $0.02n \log n + 1.75n$ branch mispredictions. Thus, the actual number of branch mispredictions is still better then our bounds in Theorem 1. There are two factors which contribute to this discrepancy: our rough estimates in the mentioned results, and that the actual branch predictor of a modern CPU might be much better than a static branch predictor. Also note that approximately one half of the branch mispredictions are incurred by Insertionsort – only the other half by the actual block partitioning and main Quicksort loop.

Finally, Figure 3 shows that Katajainen et al.'s Tuned Quicksort is still more efficient with respect to branch mispredictions (only $\mathcal{O}(n)$). This is no surprise since it does not need any checks whether buffers are empty etc. Moreover, we see that over 80% of the branch misses of Tuned Quicksort come from the final Insertionsort.

Running Time Experiments. In Figure 4 we present running times on random `int` permutations of different BlockQuicksort variants and the other algorithms including Katajainen's Tuned Quicksort and Aumüller and Bingmann's three-pivot Quicksort. The optimized BlockQuicksort variants need around 45ns per element when sorting 2^{28} elements, whereas `std::sort` needs 85ns per element – thus, there is a speed increase of 88% (i. e. the number of elements sorted per second is increased by 88%)[7].

The same algorithms are displayed in Figure 5 for sorting random `ints` between 0 and $\sqrt{n}$. Here, we observe that Tuned Quicksort is much worse than all the other algorithms (already for $n = 2^{12}$ it moves outside the displayed range). All variants of BlockQuicksort are faster than `std::sort` – the `duplicate check` (dc) version is almost twice as fast.

[7] In an earlier version of [9], we presented slightly different outcomes of our experiments. One reason it the usage of another random number generator. Otherwise, we introduced only minor changes in test environment – and no changes at all in the sorting algorithms themselves.

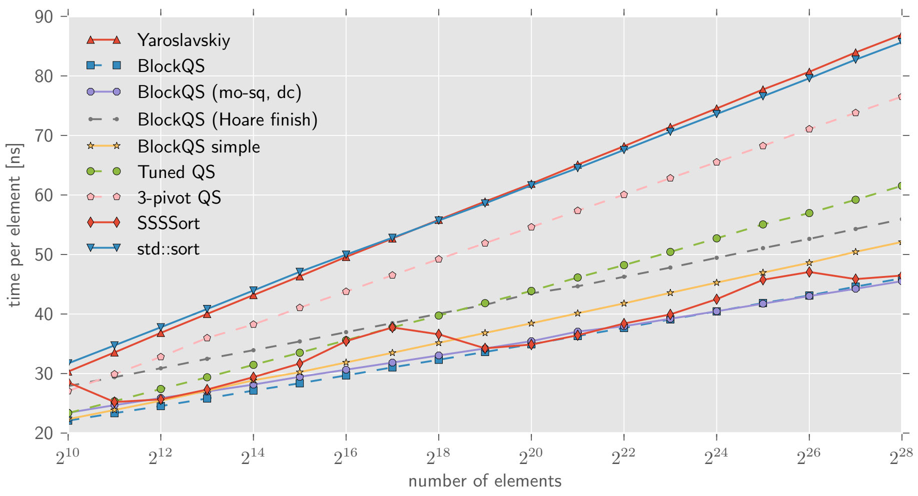

Figure 4 Random permutation of `int`.

Figure 6 presents experiments with data containing a lot of duplicates and having specific structures – thus, maybe coming closer to "real-world" inputs (although it is not clear what that means). Since here Tuned Quicksort and three-pivot Quicksort are much slower than all the other algorithms, we exclude these two algorithms from the plots. The array for the left plot contains long already sorted runs. This is most likely the reason that `std::sort` and Yaroslavskiy's dual-pivot Quicksort have similar running times to BlockQuicksort (for sorted sequences the conditional branches can be easily predicted what explains the fast running time). The arrays for the middle and right plot start with sorted runs and become more and more erratic; the array for the right one also contains a extremely high number of duplicates. Here the advantage of BlockQuicksort – avoiding conditional branches – can be observed again. In all three plots the check for duplicates (dc) established a considerable improvement.

In Figure 7, we show the results of selected algorithms for random permutations of `Vector` and `Record`. We conjecture that the good results of Super Scalar Sample Sort on `Records` are because of its better cache behavior (since `Record` are large data elements with very cheap comparisons). More running time experiments also on other machines and compiler flags can be found in [9].

More Statistics. Table 1 shows the number of branches taken / branch mispredicted as well as the instruction count and cache misses. Although `std::sort` has a much lower instruction count than the other algorithms, it induces most branch misses and (except Tuned Quicksort) most L1 cache misses (= L3 refs since no L2 cache is simulated). BlockQuicksort does not only have a low number of branch mispredictions, but also a good cache behavior – one reason for this is that Insertionsort is applied during the recursion and not at the very end.

5 Conclusions and Future Research

We have established an efficient in-place general purpose sorting algorithm, which avoids branch predictions by converting results of comparisons to integers. In the experiments we have seen that it is competitive on different kinds of data. Moreover, in several benchmarks it is almost twice as fast as `std::sort`. Future research might address the following issues:

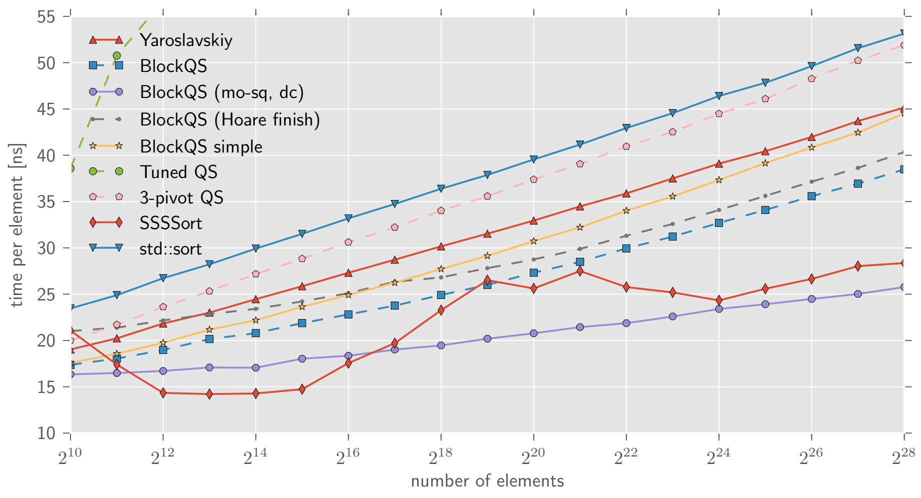

Figure 5 Random `int` values between 0 and $\sqrt{n}$.

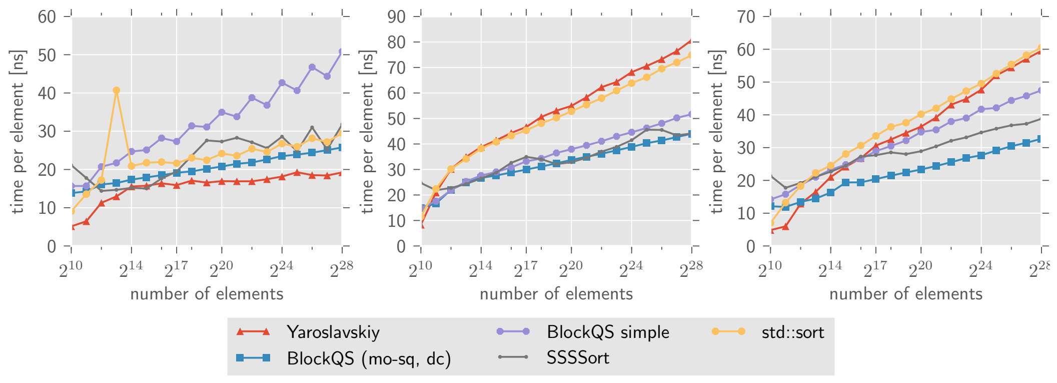

Figure 6 Arrays A of `int` with duplicates: *left*: $A[i] = i \mod \lfloor\sqrt{n}\rfloor$; *middle*: $A[i] = i^2 + n/2 \mod n$; *right*: $A[i] = i^8 + n/2 \mod n$. Since n is always a power of two, the value $n/2$ occurs approximately $n^{7/8}$ times in the last case.

- We used Insertionsort as recursion stopper – inducing a linear number of branch misses. Is there a more efficient recursion stopper that induces fewer branch mispredictions?
- More efficient usage of the buffers: in our implementation the buffers on average are not even filled half. To use the space more efficiently one could address the buffers cyclically and scan until one buffer is filled. By doing so, also both buffers could be filled in the same loop – however, with the cost of introducing additional overhead.
- The final rearrangement of the block partitioner is not optimal: for small arrays the similar problems with duplicates arise as for Lomuto's partitioner.
- Pivot selection strategy: though theoretically optimal, median-of-$\sqrt{n}$ pivot selection is not best in practice. Also we want to emphasize that not only the sample size but also the selection method is important (compare the different behavior of the two versions of `std::sort` observed in [9]). It might be even beneficial to use a fast pseudo-random generator (e. g. a linear congruence generator) for selecting samples for pivot selection.

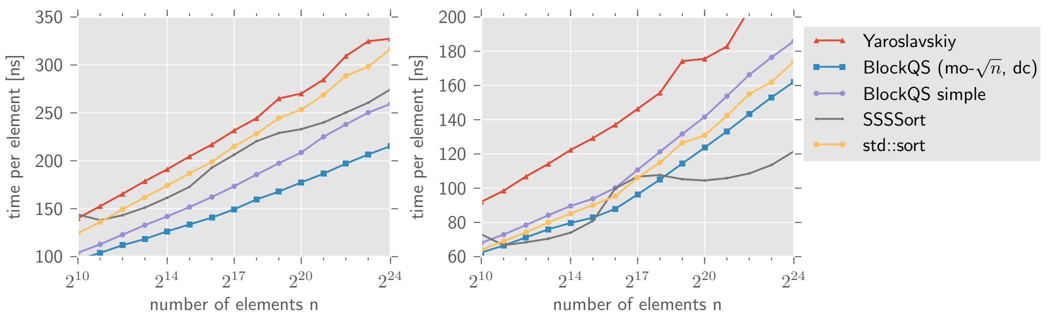

Figure 7 Random permutations – *left:* `Vector`; *right:* `Record`.

Table 1 Instruction count, branch and cache misses when sorting random `int` permutations of size $16777216 = 2^{24}$. All displayed numbers are divided by the number of elements.

algorithm	branches taken	branch misses	instructions	L1 refs	L3 refs	L3 misses
`std::sort`	37.81	10.23	174.82	51.96	1.05	0.41
SSSSort	16.2	3.87	197.06	68.47	0.82	0.5
Yaroslavskiy	52.92	9.51	218.42	59.82	0.79	0.27
BlockQS (mo-$\sqrt{n}$, dc)	20.55	2.39	322.08	89.9	0.77	0.27
BlockQS (mo5-mo5)	20.12	2.31	321.49	88.63	0.78	0.28
BlockQS	20.51	2.25	337.27	92.45	0.88	0.3
BlockQS (no IS)	15.38	1.09	309.85	84.66	0.88	0.3
Tuned QS	29.66	1.44	461.88	105.43	1.23	0.39
Tuned QS (no IS)	24.53	0.26	434.53	97.65	1.22	0.39

- Parallel versions: the block structure is very well suited for parallelism.
- A three-pivot version might be interesting, but efficient multi-pivot variants are not trivial: our first attempt was much slower.

Acknowledgments. Thanks to Jyrki Katajainen and Max Stenmark for allowing us to use their Python scripts for measuring branch mispredictions and cache missses and to Lorenz Hübschle-Schneider for his implementation of Super Scalar Sample Sort. We are also indebted to Jan Philipp Wächter for all his help with creating the plots, to Daniel Bahrdt for answering many C++ questions, and to Christoph Greulich for his help with the experiments.

Abstract

We consider the #P-complete problem of counting the number of linear extensions of a poset (#LE); a fundamental problem in order theory with applications in a variety of distinct areas. In particular, we study the complexity of #LE parameterized by the well-known decompositional parameter treewidth for two natural graphical representations of the input poset, i.e., the cover and the incomparability graph. Our main result shows that #LE is fixed-parameter intractable parameterized by the treewidth of the cover graph. This resolves an open problem recently posed in the Dagstuhl seminar on Exact Algorithms. On the positive side we show that #LE becomes fixed-parameter tractable parameterized by the treewidth of the incomparability graph.

1 Introduction

Counting the number of linear extensions of a poset is a fundamental problem of order theory that has applications in a variety of distinct areas such as sorting [30], sequence analysis [25], convex rank tests [27], sampling schemes of Bayesian networks [28], and preference reasoning [24]. Determining the exact number of linear extensions of a given poset is known to be #P-complete [6] already for posets of height at least 3. Informally, #P-complete problems are as hard as counting the number of accepting paths of any polynomial time nondeterministic Turing machine, implying that such problems are not tractable unless P = NP. The currently fastest known method for counting linear extensions of a general n-element poset is by dynamic programming over the lattice of downsets and runs in time $\mathcal{O}(2^n \cdot n)$ [10]. Polynomial time algorithms have been found for various special cases such as series-parallel posets [26] and posets whose cover graph is a (poly)tree [2]. Fully polynomial time randomized approximation schemes are known for estimating the number of linear extensions [13, 7].

Due to the inherent difficulty of the problem, it is natural to study whether it can be solved efficiently by exploiting the structure of the input poset. In this respect, the

parameterized complexity framework [12, 9] allows a refined view of the interactions between various forms of structure in the input and the running time of algorithms. The idea of the framework is to measure the complexity of problems not only in terms of input sizes, but also with respect to an additional numerical parameter. The goal is then to develop so-called *fpt algorithms*, which are algorithms that run in time $f(k)n^{\mathcal{O}(1)}$ where n is the input size and f is a computable function depending only on the parameter k. A less favorable outcome is a so-called XP algorithm, which runs in time $n^{f(k)}$; the existence of such algorithms then gives rise to the respective complexity classes FPT (*fixed-parameter tractable*) and XP.

The first steps in this general direction have been taken, e.g., in [19], using the decomposition diameter as a parameter, in [15] using a parameter called activity for N-free posets, and very recently in [22], where the treewidth of the so-called cover graph was considered as a parameter. Also the exact dynamic programming algorithm [10] can be shown to run in time $\mathcal{O}(n^w \cdot w)$ for a poset with n elements and width w (the size of the largest anti-chain). Interestingly, none of these efforts has so far led to an fpt algorithm.

We believe that this uncertainty about the exact complexity status of counting linear extensions with respect to these various parameterizations is at least partly due to the fact that we deal with a counting problem whose decision version is trivial, i.e., every poset has at least one linear extension. This fact makes it considerably harder to show that the problem is fixed-parameter intractable; in particular, the usual approach for counting problems based on parsimonious reductions (i.e., polynomial time one-one reductions) fails. On the other hand, the same predicament makes studying the complexity of counting linear extensions significantly more interesting, as noted also by Flum and Grohe [16]:

The theory gets interesting with those counting problems that are harder than their corresponding decision versions.

1.1 Results

In this paper we study the complexity of counting linear extensions when the parameter is the treewidth – a fundamental graph parameter which has already found a plethora applications in many areas of computer science [18, 17, 29]. In particular, we settle the fixed-parameter (in)tractability of the problem when parameterizing by the treewidth of two of the most prominent graphical representations of posets, the cover graph (also called the Hasse diagram) and the incomparability graph.

Our main result then provides the first evidence that the problem does not allow for an fpt algorithm parameterized by the treewidth of the cover graph unless FPT = W[1]. We remark that this complements the XP algorithm of [22] and resolves an open problem recently posed in the Dagstuhl seminar on Exact Algorithms [21]. The result is based on a so-called *fpt turing reduction* from Equitable Coloring parameterized by treewidth [14], and combines a counting argument with a fine-tuned construction to link the number of linear extensions with the existence of an equitable coloring. To the best of our knowledge, this is the first time this technique has been used to show fixed-parameter intractability of a counting problem.

We complement this negative result by obtaining an fpt algorithm for the problem when the parameter is the treewidth of the incomparability graph of the poset. To this end, we use the so-called *combined graph* (also called the cover-incomparability graph [5]) of the poset, which is obtained from the cover graph by adding the edges of the incomparability graph. We employ a special normalization procedure on a decomposition of the incomparability graph to show that the treewidth of the combined graph must be bounded by the treewidth of the incomparability graph. Once this is established, the result follows by giving a formulation of the problem in *Monadic Second Order Logic* and applying an extension of Courcelle's Theorem for counting.

The paper is organized as follows. Section 2 introduces the required preliminaries and notation. Section 3 is then dedicated to proving the fixed-parameter intractability of the problem when parameterized by the treewidth of the cover graph, and the subsequent Section 4 presents our positive results for the problem. Concluding notes are then provided in Section 5.

2 Preliminaries

For standard terminology in graph theory, such as the notions of a graph, digraph, path, etc. we refer readers to [11]. Given a graph G, we let $V(G)$ denote its vertex set and $E(G)$ its edge set. The (open) neighborhood of a vertex $x \in V(G)$ is the set $\{y \in V(G) : (x,y) \in E(G)\}$ and is denoted by $N(x)$. The closed neighborhood $N[v]$ of x is defined as $N(v) \cup \{v\}$. A path between two disjoint vertex sets $A, B \subseteq V(G)$ is a path with one endpoint in A, one endpoint in B, and all internal vertices disjoint from $A \cup B$. A set $X \subseteq V(G)$ is a separator in G if $G - X$ contains at least two connected components.

We use $[i]$ to denote the set $\{0, 1, \ldots, i\}$. The following fact about prime numbers will also be useful later.

▶ **Fact 1** ([6]). *For any $n \geq 4$, the product of primes strictly between n and n^2 is at least $n!2^n$.*

2.1 Treewidth

A *tree-decomposition* of a graph G is a pair $(T, \mathcal{X} = \{X_t\}_{t \in V(T)})$, where T is a rooted tree whose every vertex t is assigned a vertex subset $X_t \subseteq V(G)$, called a *bag*, such that the following properties hold:

(T1) $\cup_{t \in V(T)} X_t = V(G)$,

(T2) for every $u \in V(G)$, the set $T_u = \{t \in V(T) : u \in X_t\}$ induces a connected subtree of T (*monotonicity*), and

(T3) for each $uv \in E(G)$ there exists $t \in V(T)$ such that $u, v \in X_t$.

To distinguish between the vertices of the tree T and the vertices of the graph G, we will refer to the vertices of T as *nodes*. The *width* of the tree-decomposition $\mathcal{T}$ is $\max_{t \in V(T)} |X_t| - 1$. The *treewidth* of G, $\mathrm{tw}(G)$, is the minimum width over all tree-decompositions of G.

A path-decomposition is a tree-decomposition where each node of T has degree at most 2, and the notion of *pathwidth* is then defined analogously to treewidth. A tree-decomposition $\mathcal{T} = (T, \mathcal{X})$ is *nice* if T contains a root r, the root and all leaves have empty bags, and each non-leaf node belongs to one of three categories: **Introduce**, **Forget**, **Join** (see, e.g., [9]). A nice tree-decomposition (path-decomposition) can be obtained from a tree-decomposition (path-decomposition) of the same width in polynomial time [23]. Observe that any path-decomposition can be fully characterized by the order of appearance of its bags along T, and hence we will consider succinct representations of path-decompositions in the form $\mathcal{Q} = (Q_1, \ldots, Q_d)$, where Q_i is the i-th bag in $\mathcal{Q}$.

We list some useful facts about treewidth and pathwidth.

▶ **Fact 2** ([3, 4]). *There exists an algorithm which, given a graph G and an integer k, runs in time $\mathcal{O}(k^{\mathcal{O}(k^3)}n)$ and either outputs a tree-decomposition of G of width at most k or correctly* *identifies that* $\mathrm{tw}(G) > k$*. Furthermore, there exists an algorithm which, given a graph* G *and an integer* k*, runs in time* $\mathcal{O}(k^{\mathcal{O}(k^3)}n)$ *and either outputs a path-decomposition of* G *of width at most* k *or correctly identifies that* $\mathrm{pw}(G) > k$*.*

▶ **Fact 3** (Folklore). *Let* $\mathcal{T}$ *be a tree-decomposition of* G *and* $t \in V(T)$*. Then each connected component of* $G - X_t$ *lies in a single subtree of* $T - t$*. In particular, for each connected component* C *of* $G - X_t$ *there exists a subtree* T' *of* $T - t$ *such that for each vertex* $a \in C$ *there exists* $t_a \in V(T')$ *such that* $a \in X_{t_a}$*.*

We note that if G is a directed graph, then $\mathrm{tw}(G)$ and a tree-decomposition of G refers to the treewidth and a tree-decomposition of the underlying undirected graph of G, i.e., the undirected graph obtained by replacing each directed edge with an edge.

2.2 Monadic Second Order Logic

We consider *Monadic Second Order* (MSO) logic on (edge-)labeled directed graphs in terms of their incidence structure whose universe contains vertices and edges; the incidence between vertices and edges is represented by a binary relation. We assume an infinite supply of *individual variables* $x, x_1, x_2, \dots$ and of *set variables* $X, X_1, X_2, \dots$ The *atomic formulas* are Vx ("x is a vertex"), Ey ("y is an edge"), Ixy ("vertex x is incident with edge y"), Hxy ("vertex x is the head of the edge y"), Txy ("vertex x is the tail of the edge y"), $x = y$ (equality), $x \neq y$ (inequality), $P_a x$ ("vertex or edge x has label a"), and Xx ("vertex or edge x is an element of set X"). *MSO formulas* are built up from atomic formulas using the usual Boolean connectives ($\neg, \wedge, \vee, \rightarrow, \leftrightarrow$), quantification over individual variables ($\forall x$, $\exists x$), and quantification over set variables ($\forall X$, $\exists X$).

Let $\Phi(X)$ be an MSO formula with a free set variable X. For a labeled graph $G = (V, E)$ and a set $S \subseteq E$ we write $G \models \Phi(S)$ if the formula Φ holds true on G whenever X is instantiated with S.

The following result (an extension of the well-known Courcelle's Theorem [8]) shows that if G has bounded treewidth then we can count the number of sets S with $G \models \Phi(S)$.

▶ **Fact 4** ([1]). *Let* $\Phi(X)$ *be an MSO formula with a free set variable* X *and* w *a constant. Then there is a linear-time algorithm that, given a labeled directed graph* $G = (V, E)$ *of treewidth at most* w*, outputs the number of sets* $S \subseteq E$ *such that* $G \models \Phi(S)$*.*

2.3 Posets

A *partially ordered set* (*poset*) $\mathcal{P}$ is a pair $(P, \leq^P)$ where P is a set and $\leq^P$ is a reflexive, antisymmetric, and transitive binary relation over P. The *size* of a poset $\mathcal{P} = (P, \leq^P)$ is $|\mathcal{P}| := |P|$. We say that p *covers* p' for $p, p' \in P$, denoted by $p' \lhd^P p$, if $p' \leq^P p$, $p \neq p'$, and for every p'' with $p' \leq^P p'' \leq^P p$ it holds that $p'' \in \{p, p'\}$. We say that p and p' are *incomparable* (in $\mathcal{P}$), denoted $p \parallel^P p'$, if neither $p \leq^P p'$ nor $p' \leq^P p$.

A *chain* C of $\mathcal{P}$ is a subset of P such that $x \leq^P y$ or $y \leq^P x$ for every $x, y \in C$. An *antichain* A of $\mathcal{P}$ is a subset of P such that for all $x, y \in A$ it is true that $x \parallel^P y$. A family $C_1, \dots, C_\ell$ of pairwise disjoint subsets of P forms a *total order* if for each $i, j \in [\ell]$ and each $a \in C_i$, $b \in C_j$, it holds that $a \leq b$ iff $i < j$. Furthermore, for each $i \in [\ell - 1]$ we say that C_i and C_{i+1} are *consecutive*. We call a poset $\mathcal{P}$ such that every two elements of $\mathcal{P}$ are comparable a *linear order*. A *linear extension* of a poset $\mathcal{P} = (P, \leq^P)$ is a reflexive, antisymmetric, and transitive binary relation $\preceq$ over P such that $x \preceq y$ whenever $x \leq^P y$ and a poset $\mathcal{P}^* = (P, \preceq)$ is a linear order.

We denote the number of linear extensions of $\mathcal{P}$ by $e(\mathcal{P})$. For completeness, we provide a formal definition of the problem of counting the number of linear extensions below.

#LE
Instance: A poset $\mathcal{P}$.
Task: Compute $e(\mathcal{P})$.

We consider the following graph representations of a poset $\mathcal{P} = (P, \leq^{\mathcal{P}})$. The *cover graph* of $\mathcal{P}$, denoted $C(\mathcal{P})$, is the directed graph with vertex set P and edge set $\{(a, b) \mid a \lhd b\}$. The *incomparability graph* of $\mathcal{P}$, denoted $I(\mathcal{P})$, is the undirected graph with vertex set P and edge set $\{\{a, b\} \mid a \parallel b\}$. The *combined graph* of $\mathcal{P}$, denoted $I_C(\mathcal{P})$, is the directed graph with vertex set P and edge set $\{(a, b) \mid (a \lhd b) \vee (a \parallel b)\}$; observe that $I_C(\mathcal{P})$ can be obtained by taking disjoint union of the edge sets of $C(\mathcal{P})$ and $I(\mathcal{P})$ and then replacing undirected edges by two directed ones. Finally, the *poset graph* of $\mathcal{P}$, denoted $P_G(\mathcal{P})$, is the directed graph with vertex set P and edge set $\{(a, b) \mid a \leq b\}$. We will use the following known fact about tree-decompositions and path-decompositions of incomparability graphs.

▶ **Fact 5** ([20, Theorem 2.1]). *Let $\mathcal{P}$ be a poset. Then* $\mathrm{tw}(I(\mathcal{P})) = \mathrm{pw}(I(\mathcal{P}))$.

▶ **Corollary 6** (of Fact 2 and 5). *Let $\mathcal{P}$ be a poset and $k = \mathrm{tw}(I(\mathcal{P}))$. Then it is possible to compute a nice path-decomposition $\mathcal{Q}$ of $I(\mathcal{P})$ of width at most k in time $\mathcal{O}(k^{\mathcal{O}(k^3)}n)$.*

2.4 Parameterized Complexity

We refer the reader to [12, 9, 16] for an in-depth introduction to parameterized complexity. In particular, we will need the notions of *parameterized (decision) problem*, the complexity classes $W[1]$ and *FPT*, *fpt algorithm*, and *fpt turing reduction*. Informally, recall that an fpt turing reduction from problem $\mathcal{A}$ to problem $\mathcal{B}$ is an fpt-algorithm that solves $\mathcal{A}$ using an oracle for $\mathcal{B}$. A *parameterized counting problem* $\mathcal{P}$ is a function $\Sigma^* \times \mathbb{N} \to \mathbb{N}$ for some finite alphabet Σ. We call a parameterized counting problem $\mathcal{P}$ *fixed-parameter tractable* (FPT) if $\mathcal{P}$ can be computed in time $f(k) \cdot |x|^{\mathcal{O}(1)}$ where f is an arbitrary computable function and (x, k) is the instance. To avoid confusion, we remark that there also exists the complexity class #W[1] which is an analog of #P for parameterized counting problems. Our main negative result is based on an fpt turing reduction from the following fairly well-known W[1]-hard decision problem [14].

Equitable Coloring[tw]
Instance: A graph G and an integer r.
Parameter: $\mathrm{tw}(G) + r$.
Question: Does G admit a proper r-coloring such that the number of vertices in any two color classes differ by at most one?

We denote by $\#\mathrm{EC}(G, r)$ the number of equitable colorings of graph G with r colors.

3 Fixed-Parameter Intractability of Counting Linear Extensions

The goal of this section is to prove Theorem 7, stated below.

▶ **Theorem 7.** *#LE parameterized by the treewidth of the cover graph of the input poset does not admit an fpt algorithm unless* W[1]=FPT.

We begin by giving a brief overview of the proof, whose general outline follows the #P-hardness proof of the problem [6]. However, since our parameter is treewidth, we needed to reduce from a problem that is not fixed-parameter tractable parameterized by treewidth. Consequently, instead of reducing from SAT, we will use Equitable Coloring. This made the reduction considerably more complicated and required the introduction of novel gadgets, which allow us to encode the problem without increasing the treewidth too much.

The proof is based on solving an instance (G, r) of Equitable Coloring[tw] in FPT time using an oracle that solves #LE in FPT time parameterized by the treewidth of the cover graph (i.e., an fpt turing reduction). The first step is the construction of an auxiliary poset $\mathcal{P}(G, r)$ of size $2(r-1)|V(G)| + (r^2-1)|E(G)|$. Then, for a given sufficiently large (polynomially larger than $|V(G)|$) prime number p, we show how to construct a poset $\mathcal{P}(G, r, p)$ such that $e(\mathcal{P}(G, r, p)) \equiv e(\mathcal{P}(G, r)) \cdot \#\mathrm{EC}(G, r) \cdot A_p \mod p$, where A_p is a constant that depends on p and is not divisible by p. Therefore, if we choose a prime p that does not divide $e(\mathcal{P}(G, r)) \cdot \#\mathrm{EC}(G, r)$, then $e(\mathcal{P}(G, r, p))$ will not be divisible by p. Using Fact 1 we show that if $\#\mathrm{EC}(G, r) \neq 0$, then there always exists a prime p within a specified polynomial range of $|V(G)|$ such that p does not divide $e(\mathcal{P}(G, r)) \cdot \#\mathrm{EC}(G, r)$.

From the above, it follows that there exists an equitable coloring of G with r colors if and only if, for at least one prime p within a specified (polynomial) number range, the number of linear extensions of $\mathcal{P}(G, r, p)$ is not divisible by p. Moreover, we show that all inputs for the oracle will have size polynomial in the size of G and treewidth bounded by polynomial in $\mathrm{tw}(G) + r$. Before proceeding to a formal proof of Theorem 7, we state two auxiliary lemmas which will be useful for counting linear extensions later in the proof.

▶ **Lemma 8.** *If a poset $\mathcal{P}$ is a disjoint union of posets $\mathcal{P}_1, \dots, \mathcal{P}_k$ for some positive integer k, then*

$$e(\mathcal{P}) = \frac{(\sum_{i=1}^{k} |\mathcal{P}_i|)!}{\prod_{i=1}^{k} |\mathcal{P}_i|!} \prod_{i=1}^{k} e(\mathcal{P}_i)\,.$$

▶ **Lemma 9.** *Let p be a prime number and $\mathcal{Q}$ be a connected component of poset $\mathcal{P}$ such that $|\mathcal{Q}| = p - 1$. If the number of linear extensions of $\mathcal{P}$ is not divisible by p, then the number of elements in each connected component of $\mathcal{P}$ other than $\mathcal{Q}$ is divisible by p.*

We now proceed to the proof of the theorem.

Proof of Theorem 7. The proof is structured into the construction of $\mathcal{P}(G, r)$, the construction of $\mathcal{P}(G, r, p)$, establishing the desired properties of $\mathcal{P}(G, r, p)$ and $\mathcal{P}(G, r)$, and the conclusion.

Construction of $\mathcal{P}(G, r)$ and the main gadget

Let (G, r) be an instance of Equitable Coloring[tw] such that $|V(G)|$ is divisible by r (if this is not the case, then this can be enforced by padding the instance with isolated vertices, see also [14]). We begin by constructing the poset $\mathcal{P}(G, r)$, which will play an important role later on. For every vertex v of $V(G)$ we create $2(r-1)$ elements denoted $v_{i,j}$, where $1 \leq i \leq r-1$ and $j \in \{0, 1\}$, such that the only dependencies in the poset between these elements are $v_{i,1} \leq v_{i,0}$ for all $v \in V(G)$, for all $i \in \{1, \dots, r-1\}$. For every edge $e = uv \in E(G)$ we create $r^2 - 1$ pairwise-incomparable elements $e_{i,j}$, such that $(i, j) \in (\{0, \dots, r-1\}^2 \setminus \{(0, 0)\})$. The dependencies of $e_{i,j}$ are: if $i > 0$ then $u_{i,0} \leq e_{i,j}$, and if $j > 0$ then $v_{j,0} \leq e_{i,j}$ (see also Fig. 1).

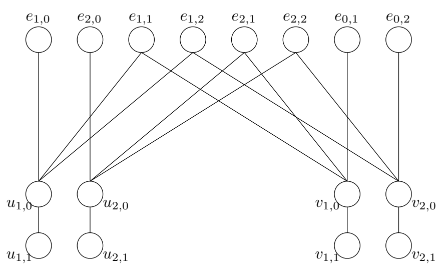

Figure 1 The cover graph for an edge $e = uv$ in $\mathcal{P}(G, 3)$.

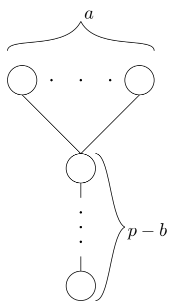

Figure 2 An (a, b)-flower.

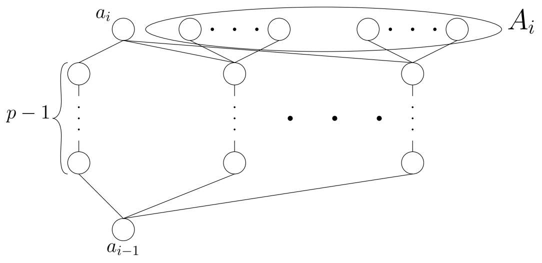

Figure 3 Each level consists of a chain of length $p - 1$ and a few flowers. The set of petals associated with level L_i is denoted by A_i.

Let us now fix a prime number p such that p does not divide $e(\mathcal{P}(G, r))$ and $p > 2r|V(G)| + r^2|E(G)|$. The main gadget in our reduction is a so-called (a, b)-*flower*, which consists of an antichain of a vertices (called the *petals*) covering a chain of $p - b$ elements (called the *stalk*); see Fig. 2. Due to Lemma 9, (a, b)-flowers will later allow us to force a choice of exactly b vertices out of a.

Construction of $\mathcal{P}(G, r)$

Let G be a graph, r be an integer and p be a prime number as above. Recall that $|V(G)|$ is divisible by r and let $s = \frac{|V(G)|}{r}$ (note that this implies that each color in an equitable coloring of G must occur precisely s times in G). We proceed with a description of the poset $\mathcal{P}(G, r, p)$. The poset $\mathcal{P}(G, r, p)$ is split into $r + 3$ "*levels*" $L_1, \ldots, L_{r+3}$ by linearly ordered elements $a_0 \leq a_1 \leq \cdots \leq a_{r+2} \leq a_{r+3}$, called the *anchors*. Each of these levels, besides L_{r+3}, will consist of some flowers and a chain of $p - 1$ elements which we call a *stick*; each of these flowers and the stick will always be pairwise incomparable. The anchors a_0 and a_{r+3} are the unique minimum and maximum elements, respectively. The stick and all the stalks of flowers in level L_i will always lie between two consecutive elements a_{i-1} and a_i, and the petals of these flowers will be incomparable with a_i as well as some anchors above that (as defined later). Observe that while the relative position of any stalk and any anchor is fixed in every linear extension, petals can be placed above a_i.

We say that a flower (or its stalk, petals, or elements) is *associated* with the level in which it is constructed, i.e., with the level L_i such that $a_{i-1} \leq c \leq a_i$ for stalk elements c and $a_{i-1} \leq d$ and $d \parallel a_i$ for petals d. We denote the set of all petals associated with level L_i as A_i (see Fig. 3).

For the construction, it will be useful to keep in mind the following intended goal: whenever an (a, b)-flower is placed in level i, it will force the selection of precisely b petals (from its total of a petals), where selected elements remain on level i (i.e., between a_{i-1} and a_i) in the linear extension and unselected elements are moved to level $r + 2$ (i.e., between

a_{r+2} and a_{r+3}) in the linear extension. We will later show that the total number of linear extensions which violate this goal must be divisible by p, and hence such extensions can all be disregarded modulo p.

The first r levels are so-called *color class* levels, each representing one color class. We use these levels to make sure that every color class contains exactly s vertices. Aside from the stick, each such level contains a single $(|V(G)|, s)$-flower. Recall that the stalk and the stick on level $1 \leq i \leq r$ both lie between anchors a_{i-1} and a_i, and that the stick and the flower are incomparable. We associate each petal of the flower at level L_i with a unique vertex $v \in V(G)$ and denote the petal v_i. Each petal v_i will be incomparable with all anchors above a_{i-1} up to a_{r+3}, i.e., $v_i \parallel a_j$ for $i \leq j \leq r+2$ and $v_i \leq a_{r+3}$. Intuitively, the flower in each color class level will later force a choice of s vertices to be assigned the given color.

Level L_{r+1} is called the *vertex* level and consists of one stick and $|V(G)|$-many $(r,1)$-flowers; the purpose of this level is to ensure that every vertex is assigned exactly one color. Each flower is associated with one vertex $v \in V(G)$ and we denote the petals of the flower associated with vertex v as v^i for $1 \leq i \leq r$. We set $v_i \leq v^i$ for all $v \in V(G)$ and $1 \leq i \leq r$.

Level L_{r+2} is called the *edge* level, and its purpose is to ensure that the endpoints of every edge have a different color. It consists of a stick and $|E(G)|$-many $(r^2, 1)$-flowers. Each flower is associated with one edge $e = uv \in V(G)$ and we denote the petals of the flower associated with e as $e_{i,j}$ for $1 \leq i \leq r$ and $1 \leq j \leq r$. Moreover, for edge $e = uv$ we set $u^i \leq e_{i,j}$, $v^j \leq e_{i,j}$, and we set $a_{r+2} \leq e_{i,j}$ whenever $i = j$. Observe that this forces any petal $e_{i,i}$ to lie between a_{r+2} and a_{r+3} in every linear extension (i.e., prevents $e_{i,i}$ from being "selected").

Level L_{r+3} is called the *trash level.* It does not contain any new elements in the poset, but it plays an important role in the reduction: we will later show that any petals which are interpreted as "not selected" must be located between a_{r+2} and a_{r+3} in any linear extension that is not automatically "canceled out" due to counting modulo p.

A high-level overview of the whole constructed poset $\mathcal{P}(G, r, p)$ is presented in Fig. 4.

Establishing the desired properties of $\mathcal{P}(G, r, p)$ and $\mathcal{P}(G, r)$

We begin by formalizing the notion of selection. Let a *configuration* be a partition ϕ of petals of all flowers into $r+3$ sets $L_1^\phi, \ldots, L_{r+3}^\phi$. Let Φ denote a set of all configurations. We say that a linear extension $\preceq$ of $\mathcal{P}(G, r, p)$ *respects* the configuration ϕ if $L_1^\phi \preceq a_1 \preceq L_2^\phi \preceq a_2 \preceq \cdots \preceq a_{r+2} \preceq L_{r+3}^\phi$ and we denote the set of all linear extensions of $\mathcal{P}(G, r, p)$ that respects ϕ by $\mathcal{L}^\phi$. We say that a configuration ϕ is *consistent* if $\mathcal{L}^\phi$ is non-empty; this merely means that $L_1^\phi \leq a_1 \leq L_2^\phi \leq a_2 \leq \cdots \leq a_{r+2} \leq L_{r+3}^\phi$ does not violate any inequalities in $\mathcal{P}(G, r, p)$. Observe that if ϕ is consistent, then $\mathcal{L}^\phi$ is exactly the set of linear extension of the partial order $\mathcal{P}^\phi(G, r, p)$, where $\mathcal{P}^\phi(G, r, p)$ is obtained by enriching $\mathcal{P}(G, r, p)$ with the relations $L_1^\phi \leq a_1 \leq L_2^\phi \leq a_2 \leq \cdots \leq a_{r+2} \leq L_{r+3}^\phi$ and performing transitive closure (in other words, $\mathcal{P}^\phi(G, r, p)$ is obtained by enforcing ϕ onto $\mathcal{P}(G, r, p)$).

Since every linear extension of $\mathcal{P}(G, r, p)$ respects exactly one configuration, it is easy to see that $e(\mathcal{P}(G, r, p)) = \sum_{\phi \in \Phi} |\mathcal{L}^\phi| = \sum_{\phi \in \Phi} e(\mathcal{P}^\phi(G, r, p))$. Intuitively, a configuration ϕ *contributes* to the above sum modulo p if $e(\mathcal{P}^\phi(G, r, p))$ is not divisible by p. We shall prove that the only configurations which contribute to this sum modulo p are those where from every (a, b)-flower there are exactly b petals in the same level as the stalk, and the remaining $a - b$ petals are in the trash. Furthermore, in each configuration ϕ which contributes to the above sum modulo p, the petals in L_{r+1}^ϕ represent a proper equitable coloring of G with r colors, and each such configuration is respected by the same number of linear extensions.

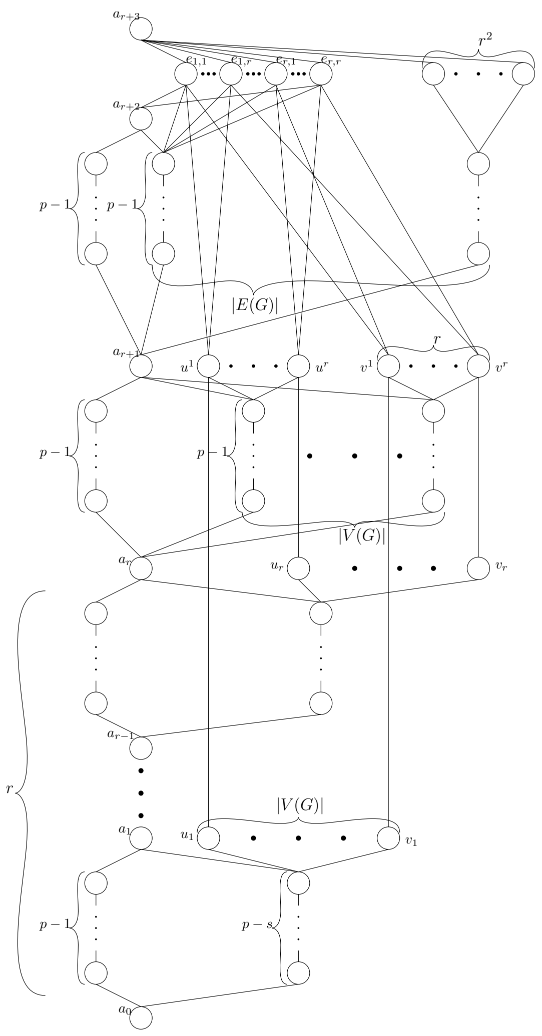

Figure 4 The cover graph of $\mathcal{P}(G,r,p)$. The edge e is the edge in G between vertices u and v.

Let us first remark that for any configuration ϕ, the anchors $a_0, a_1, \dots, a_{r+3}$ are comparable to all elements of $\mathcal{P}^\phi(G,r,p)$. Now, let $\mathcal{P}^\phi_{L_i}$ be the poset induced by all elements $e \in \mathcal{P}^\phi(G,r,p)$ such that $a_{i-1} \le e \le a_i$. It is readily seen that $e(\mathcal{P}^\phi(G,r,p)) = \prod_{i=1}^{r+3} e(\mathcal{P}^\phi_{L_i})$. We proceed by stating a series of claims about our construction.

▶ **Claim 10.** *For each $i \in \{1,\dots,r\}$, it holds that either $e(\mathcal{P}^\phi_{L_i}) \equiv 0 \mod p$, or $e(\mathcal{P}^\phi_{L_i}) = s!\binom{2p-1}{p}$ and L^ϕ_i contains exactly s petals of A_i and no other petals.*

Proof of the claim. Assume that $e(\mathcal{P}^\phi_{L_i}) \not\equiv 0 \mod p$ and recall that level L_i contains a stick, which is a chain of $p-1$ elements that is incomparable with all elements of $\mathcal{P}^\phi_{L_i}$ in every configuration ϕ. By Lemma 9 this implies that every connected component of $\mathcal{P}^\phi_{L_i}$ has size divisible by p. Clearly, L^ϕ_i contains only those stalks that are associated with the level L_i, and it contains all such stalks. It is readily seen from the construction that any petal in $\cup_{j<i} A_j$ would necessarily form a component of size one in $\mathcal{P}^\phi_{L_i}$. Hence, $\mathcal{P}^\phi_{L_i}$ contains only elements associated with level L_i, namely elements of the chain with $p-1$ vertices and elements of a $(|V(G)|, s)$-flower. Moreover, by Lemma 9 and the fact that $|V(G)|+p-s < 2p$, each such flower has exactly p elements in level $\mathcal{P}^{\phi}_{L_i}$. Since the $p-s$ elements of the stalk must be in $\mathcal{P}^{\phi}_{L_i}$, the poset $\mathcal{P}^{\phi}_{L_i}$ contains exactly s elements of A_i. Clearly, the number of linear extensions of the petals of the $(|V(G)|, s)$-flower in $\mathcal{P}^{\phi}_{L_i}$ is $s!$ and hence by Lemma 8 $e(\mathcal{P}^{\phi}_{L_i}) = s!\binom{2p-1}{p}$, which concludes the proof. ◀

▶ **Claim 11.** *Either $e(\mathcal{P}^{\phi}_{L_{r+1}}) \equiv 0 \mod p$, or $e(\mathcal{P}^{\phi}_{L_{r+1}}) = \frac{(|V(G)|p+p-1)!}{(p-1)}!(p!)^{|V(G)|}$ and L^{ϕ}_{r+1} contains exactly $|V(G)|$ elements of A_{r+1}, specifically one petal for each $(r,1)$-flower on level L_{r+1}.*

Proof of the claim. Assume $e(\mathcal{P}^{\phi}_{L_{r+1}}) \not\equiv 0 \mod p$, and let us first examine elements that are not associated with level L_{r+1}. Clearly, no element associated with level L_{r+2} can appear in $\mathcal{P}^{\phi}_{L_{r+1}}$ and the only elements associated with any level $i < r+1$ that can end up in $\mathcal{P}^{\phi}_{L_{r+1}}$ are petals. Each of these elements is smaller then exactly one petal at level L_{r+1} and independent to all other elements associated with this level. It is easy to see that largest possible size of a connected component of $\mathcal{P}^{\phi}_{L_{r+1}}$ is $p-1+2r < 2p$. By Lemma 9, every connected component in $\mathcal{P}^{\phi}_{L_{r+1}}$ (except for the stick) will have size p, and therefore $\mathcal{P}^{\phi}_{L_{r+1}}$ will contain exactly one element for every antichain associated with L_{r+1} and no other elements. Hence, $\mathcal{P}^{\phi}_{L_{r+1}}$ consists of $|V(G)|$ chains of length p and one chain of length $p-1$. Then $e(\mathcal{P}^{\phi}_{L_{r+1}}) = \frac{(|V(G)|p+p-1)!}{(p-1)}!(p!)^{|V(G)|}$ follows from Lemma 8. ◀

▶ **Claim 12.** *Either $e(\mathcal{P}^{\phi}_{L_{r+2}}) \equiv 0 \mod p$, or $e(\mathcal{P}^{\phi}_{L_{r+2}}) = \frac{(|E(G)|p+p-1)!}{(p-1)}!(p!)^{|E(G)|}$ and L^{ϕ}_{r+2} contains exactly $|E(G)|$ elements of A_{r+2}, specifically one petal for each $(r^2,1)$-flower on level L_{r+2}.*

Proof of the claim. The idea of the proof is similar to the proof of the previous claim, with one additional obstacle: that several flowers can be connected with petals from lower levels into one connected component on level L_{r+2} through the petals of flowers on level L_{r+1}. So, assume $e(\mathcal{P}^{\phi}_{L_{r+2}})$ contains a connected component C which contains at least a single stalk. For each stalk in C, there must be at least one petal in the same flower (otherwise the stalk cannot be connected to the rest of C); in other words, the intersection of each flower and C contains at least p vertices. Let a denote the number of flowers which intersect C, b_2 denote $|A_{r+2} \cap C|$, b_1 denote $|A_{r+1} \cap C|$ and b_0 denote $\sum_{i=1}^{r} |A_r \cap C|$. Then it follows that $|C| = p \cdot a + (b_2 - a) + b_1 + b_0 \leq p \cdot a + r^2|E(G)| + r|V(G)| + r|V(G)|$, and recall that $r^2|E(G)| + r|V(G)| + r|V(G)| < p$. Furthermore, if $b_1 > 0$ (and at least one petal from A_{r+1} is required unless C contains only a single flower), we have $a \cdot p < |C| < (a+1) \cdot p$. Hence any such C cannot have size divisible by p and by Lemma 9 we have $e(\mathcal{P}^{\phi}_{L_{r+2}}) \equiv 0 \mod p$. Otherwise, if no two flowers are connected through a petal of a flower associated with level L_{r+1}, then every connected component of $\mathcal{P}^{\phi}_{L_{r+2}}$ of size p must consist of a stalk and exactly one petal and the claim follows analogously as the proof of Claim 11. ◀

▶ **Claim 13.** *If ϕ is a consistent configuration and for all $i \in \{1, \ldots, r+2\}$ it holds that $e(\mathcal{P}^{\phi}_{L_i}) \not\equiv 0 \mod p$, then the petals in L^{ϕ}_{r+1} encode a proper equitable coloring of $V(G)$ where vertex v receives color i iff the petal v_i lies in L^{ϕ}_{i} and $\mathcal{P}^{\phi}_{L_{r+3}}$ is isomorphic with $\mathcal{P}(G, r)$.*

Proof of the claim. From Claims 10, 11 and 12 together with the assumption that $e(\mathcal{P}^{\phi}_{L_i}) \not\equiv 0$ mod p, it follows that each of the levels $L^{\phi}_1, \ldots, L^{\phi}_r$ contains exactly s petals associated with the corresponding level, level L^{ϕ}_{r+1} contains exactly one petal for each vertex of G and level L^{ϕ}_{r+2} contains exactly one petal for each edge of G.

For the first part of this claim, we observe that each pair of petals in $L_1^\phi, \ldots, L_r^\phi$ are associated with distinct vertices of G. If this were not the case, then since $|V(G)| = rs$ there would exist a vertex v such that no element of $L_1^\phi, \ldots, L_r^\phi$ is associated with v. But due to the construction at level $r+1$ there exists some $i \in 1, \ldots, r$ such that $v^i \in L_{r+1}^\phi$. Then, since $v_i \leq v^i$ and v_i can only occur either in level L_i^ϕ or L_{r+3}^ϕ (the latter of which lies above v^i in the linear extension due to the configuration ϕ), this would lead to a contradiction. In particular, we conclude that there is a matching between the petals in level $r+1$ (encoding the color for each vertex) and the union of petals in levels $1, 2, \ldots r$ (encoding the vertices assigned to each color class), and by Claim 10 it follows that there are exactly s petals in L_{r+1} associated with each color class.

We now argue that the coloring is proper. Observe that by the same argument as above, if an edge $e = uv$ satisfies $e_{i,j} \in L_{r+2}^\phi$, then $u_i \in L_{r+1}^\phi$ and $v_j \in L_{r+1}^\phi$. From the construction of $\mathcal{P}(G, r, p)$ it follows that if $i = j$, then $e_{i,j} \notin L_{r+2}$. Combining these two facts we get that the coloring encoded in L_{r+1}^ϕ is indeed proper.

Now let us take a look at level L_{r+3}^ϕ. To prove the claim, we will construct an isomorphism f from elements of $\mathcal{P}_{L_{r+3}}^\phi$ to elements of $\mathcal{P}(G, r)$. For every vertex $v \in V(G)$, precisely one element $v^i \in L_{r+1}^\phi$ and precisely one of the first r levels contains an element associated with v; to be precise, $v_i \in L_i^\phi$ and $v_j \in L_{r+3}^\phi$ and hence also $v^j \in L_{r+3}^\phi$ for all $j \neq i$. We set $f(v^j) = v_{j,0}$ and $f(v_j) = v_{j,1}$, whenever $j \neq i$ and $j < r$. For the last remaining elements, we set $f(v^r) = v_{i,0}$ and $f(v_r) = v_{i,1}$. Next, for every edge $e = uv$ there is exactly one $e_{a,b} \in L_{r+2}^\phi$. Moreover, if $e_{a,b} \in L_{r+2}^\phi$ then $u_a \in L_{r+1}^\phi$ and $v_b \in L_{r+1}^\phi$, and all other petals for this edge e are in L_{r+3}^ϕ. Let $g_i(r) = i$, $g_i(i) = 0$, and $g_i(k) = k$ otherwise. Then we set $f(e_{i,j}) = e_{g_a(i), g_b(j)}$. Observe that, since $e_{a,b}$ does not lie in L_{r+3}^ϕ, no edge is mapped to the non-existent element $e_{0,0}$ in $\mathcal{P}(G, r)$. It is straightforward to verify that f is really bijective mapping between elements of $\mathcal{P}_{L_{r+3}}^\phi$ and $\mathcal{P}(G, r)$. Moreover, $f(u) \leq f(v)$ in $\mathcal{P}(G, r)$ if and only if $u \leq v$ in $\mathcal{P}_{L_{r+3}}^\phi$. Therefore, $\mathcal{P}_{L_{r+3}}^\phi$ is isomorphic with $\mathcal{P}(G, r)$ and the claim holds. ◀

▶ **Claim 14.** *$e(\mathcal{P}(G, r, p)) \not\equiv 0 \mod p$ if and only if $e(\mathcal{P}(G, r)) \cdot \#\mathrm{EC}(G, r) \not\equiv 0 \mod p$.*

▶ **Claim 15.** *If $\#\mathrm{EC}(G, r) \neq 0$, then there is a prime number p greater than $2r|V(G)| + r^2|E(G)|$ and smaller than $(2r|V(G)| + r^2|E(G)|)^2$ such that p does not divide $e(\mathcal{P}(G, r)) \cdot \#\mathrm{EC}(G, r)$.*

▶ **Claim 16.** $\mathrm{tw}(C(\mathcal{P}(G, r, p))) \leq r \cdot (\mathrm{tw}(G) + 3) + 6$.

Concluding the proof

Let us summarize the fpt turing reduction used to prove Theorem 7. Given an instance (G, r) of Equitable Coloring[tw], we loop over all primes p such that $2r|V(G)| + r^2|E(G)| < p < (2r|V(G)| + r^2|E(G)|)^2$, and for each such prime we construct the poset $\mathcal{P}(G, r, p)$; from Claim 15 it follows that if $\#\mathrm{EC}(G, r) \neq 0$, then at least one such prime will not divide $e(\mathcal{P}(G, r)) \cdot \#\mathrm{EC}(G, r)$, and by Claim 16 each of the constructed posets $\mathcal{P}(G, r, p)$ has bounded treewidth of the cover graph. For each such poset $\mathcal{P}(G, r, p)$, we compute $e(\mathcal{P}(G, r, p))$ by the black-box procedure provided as part of the reduction. If for any prime p we get $e(\mathcal{P}(G, r, p)) \not\equiv 0 \mod p$, then we conclude that (G, r) is a yes-instance, and otherwise we reject (G, r), and this is correct by Claim 14. ◀

We remark that the above construction can be extended to also compute the exact number of equitable colorings. However, because Equitable Coloring[tw] is not known to be

#W[1]-hard, this does not immediately imply #W[1]-hardness for counting the number of linear extensions.

4 Fixed-Parameter Tractability of Counting Linear Extensions

This section is dedicated to proving our algorithmic result, stated below.

▶ **Theorem 17.** #LE *is fixed-parameter tractable parameterized by the treewidth of the incomparability graph of the input poset.*

The proof of Theorem 17 is divided into two steps. First, we apply a transformation process to a path-decomposition $\mathcal{Q}$ of small width (the existence of which is guaranteed by Corollary 6) of $I(\mathcal{P})$ which results in a tree-decomposition $\mathcal{T}$ of $I(\mathcal{P})$ satisfying certain special properties. We call these "blocked tree-decompositions" and the construction is given in Lemma 21. The properties of $\mathcal{T}$ are then used to prove that $I_C(\mathcal{P})$ has treewidth bounded by the treewidth of $I(\mathcal{P})$ (Corollary 26). In the second step, we construct an MSO formulation which enumerates all the linear extensions of $\mathcal{P}$ using $I_C(\mathcal{P})$, and apply Fact 4.

4.1 The Treewidth of Combined Graphs

We begin by arguing a useful property of separators in incomparability graphs.

▶ **Lemma 18.** *Let $S \subseteq V(I(\mathcal{P}))$. Then for each pair of distinct connected components C_1, C_2 in $I(\mathcal{P}) - S$, it holds that for any $a_1, b_1 \in C_1$ and any $a_2, b_2 \in C_2$ we have $a_1 \leq a_2$ iff $b_1 \leq b_2$. Namely, the poset contains a total order of all connected components in $I(\mathcal{P}) - S$.*

Proof. We begin by proving the following claim.

▶ **Claim 19.** *Let a, b, c be three distinct elements of $\mathcal{P}$ such that $a \parallel b$ and both pairs a, c and b, c are comparable. Then $a \leq c$ iff $b \leq c$.*

Proof of the claim. Suppose that, w.l.o.g., $a \leq c$ and $c \leq b$. Then by the transitivity of $\leq$, we get $a \leq b$ which contradicts our assumption that $a \parallel b$. ◀

Now to prove Lemma 18, assume for a contradiction that, w.l.o.g., there exist $a_1, b_1 \in C_1$ and $a_2, b_2 \in C_2$ such that $a_1 \leq b_1$ and $b_2 \leq a_2$. Let Q_1 be an a_1-a_2 path in $I[C_1]$. By Claim 19, $a_1 \leq b_1$ implies that every element q on Q_1 satisfies $q \leq b_1$, and in particular $a_2 \leq b_1$. Next, let Q_2 be a b_1-b_2 path in $I[C_2]$. Then Claim 19 also implies that each element q' on Q_2 satisfies $a_2 \leq q'$. Since b_2 lies on Q_2, this would imply that $a_2 \leq b_2$, a contradiction. ◀

To proceed further, we will need some notation. Let $\mathcal{T} = (T, \mathcal{X})$ be a rooted tree-decomposition and $t \in V(T)$. We denote by $L(t)$ the set of all vertices which occur in the "branch" of $T - t$ containing the root r; formally, $L(t) = \{v \in X_{t'} \setminus X_t \mid t'$ lies in the same connected component as r in $T - t\}$. We then set $R(t) = V(G) \setminus (L(t) \cup X_t)$ (the intuition behind L and R is that they represent "left" and "right"). We also let T_t^r denote the connected component of $T - t$ which contains the root r.

Next, recall that each connected component of the graph obtained after deleting X_t must lie in a subtree of $T - t$ (Fact 3). A *block* of a bag X_t in a rooted tree-decomposition $\mathcal{T} = (T, \mathcal{X})$ is a sequence of consecutive connected components in $(I(\mathcal{P}) - X_t) \cap R(t)$. We say that a node $t \in V(T)$ has z blocks if there exist z distinct blocks of X_t. Blocks will play an important role in the tree-decomposition we wish to obtain from our initial path-decomposition of $I(\mathcal{P})$. The following lemma captures the operation we will use to alter our path-decomposition.

▶ **Lemma 20.** *Let $\mathcal{T} = (T, \mathcal{X})$ be a rooted tree-decomposition of a graph G and let $t \in V(T)$ be such that there are z blocks of X_t. Then there is a tree-decomposition $\mathcal{T}'(T', \mathcal{X}')$ satisfying:*

1. *The width of $\mathcal{T}'$ is at most the width of $\mathcal{T}$.*
2. *The tree T' contains T_t^r as a subtree which is separated from the rest of T' by t.*
3. *The degree of t in T' is $z + 1$.*
4. *There exists a bijection α between the z blocks of X_t and the z trees in $T' - t$ other than T_t^r such that for each block B of X_t, we have $\bigcup_{s \in \alpha(B)} X'_s \setminus X_t = B$.*
5. *For each $t' \in N[t] \setminus V(T_t^r)$, we have $X_{t'} = X_t$.*

We proceed by showing how Lemma 20 is applied to transform a given path-decomposition.

▶ **Lemma 21.** *Let $\mathcal{Q}$ be a nice path-decomposition of $I(\mathcal{P})$. Then there is a rooted tree-decomposition $\mathcal{T} = (T, \mathcal{X})$ of $I(\mathcal{P})$ with the following properties. $\mathcal{T}$ is rooted at a leaf r and $X_r = \emptyset$, the width of $\mathcal{T}$ is at most the width of $\mathcal{Q}$, and for any node $t \in V(T)$ with $z > 1$ blocks:*

1. *The degree of t in T is $z + 1$.*
2. *There exists a bijection α between the z blocks of X_t and the z trees in $T' - t$ other than T_t^r such that for each block B of X_t, we have $\bigcup_{s \in \alpha(B)} X_s \setminus X_t = B$.*
3. *For $t' \in N(t) \cap V(T_t^r)$ there exists a vertex v such that $X_{t'} = X_t \setminus \{v\}$, and furthermore t' has degree 2 and 1 block.*
4. *For each pair of neighbors $t, t' \in V(T)$, it holds that $|X_t \setminus X_{t'}| + |X_{t'} \setminus X_t| \leq 1$.*

We call a tree-decomposition rooted at a leaf with $X_r = \emptyset$ which satisfies the properties of Lemma 21 a *blocked tree-decomposition*. The next ingredient we will need for proving that $I_C(\mathcal{P})$ has small treewidth is the notion of *cover-guards*.

Let $\mathcal{T} = (T, \mathcal{X})$ be a tree-decomposition of $I(\mathcal{P})$ rooted at r and let $t \neq r$. Then the *cover-guard* of t, denoted $\mathcal{A}_t$, is the set of vertices in $L(t)$ which are incident to a cover edge whose other endpoint lies in $R(t)$; formally, $\mathcal{A}_t = \{v \in L(t) \mid \exists u \in R(t) : (uv \in E(C(\mathcal{P})) \vee vu \in E(C(\mathcal{P})))\}$. For a vertex $v \in I(\mathcal{P})$, we let $\mathcal{A}^v = \{t \in V(T) \mid v \in \mathcal{A}_t\}$ and $X^v = \{t \in V(T) \mid v \in X_t\}$.

Our next aim is to add all the cover-guards into each bag. The following lemma will allow us to argue that the result is still a tree-decomposition; it is worth noting that the assumption that the decomposition is blocked is essential for the lemma to hold.

▶ **Lemma 22.** *Let $\mathcal{T} = (T, \mathcal{X})$ be a blocked tree-decomposition of $I(\mathcal{P})$ rooted at r and let $v \in I(\mathcal{P})$. Then $T[\mathcal{A}^v \cup X^v]$ is a tree.*

Next we show that the cover-guards in blocked tree-decompositions are never too large.

▶ **Lemma 23.** *Let $\mathcal{T} = (T, \mathcal{X})$ be a blocked tree-decomposition of $I(\mathcal{P})$ of width k. Then for each $t \in V(T)$ it holds that $|\mathcal{A}_t| \leq 2k + 2$.*

Proof. First, observe that if a node $t \in V(T)$ has 0 blocks, then $R(t) = \mathcal{A}_t = \emptyset$. So, consider a node t which has exactly 1 block consisting of connected components $(D_1, \ldots, D_j)$ in $(I(\mathcal{P}) - X_t) \cap R(t)$.

▶ **Claim 24.** $|\mathcal{A}_t| \leq 2k + 2$.

Proof of the claim. Assume for a contradiction that $|\mathcal{A}_t| > 2k+2$. By Lemma 18 we have that $(D_1, \dots, D_j)$ are consecutive connected components in a total order of connected components in $I(\mathcal{P}) - X_t$. Hence any edge in $C(\mathcal{P}) - X_t$ between $R(t)$ and $L(t)$ must necessarily have one endpoint in $D_1 \cup D_j$. Furthermore, an element in $\mathcal{A}_t$ cannot be adjacent to both D_1 and D_j in $C(\mathcal{P}) - X_t$ due to transitivity and acyclicity. So, we may partition $\mathcal{A}_t$ into $\mathcal{A}_t^1 = \{v \in \mathcal{A}_t \mid \exists u \in D_1 : v \lhd^{\mathcal{P}} u\}$ and $\mathcal{A}_t^2 = \{v \in \mathcal{A}_t \mid \exists u \in D_j : u \lhd^{\mathcal{P}} v\}$.

By Lemma 18, it also follows that $\mathcal{A}_t^1$ and $\mathcal{A}_t^2$ must each lie in separate connected components of $I(\mathcal{P}) - X_t$, say C^1 and C^2 respectively. Furthermore, each element in $\mathcal{A}_t^1$ is maximal in C^1 and each element in $\mathcal{A}_t^2$ is minimal in C^2. In particular, each of $\mathcal{A}_t^1$, $\mathcal{A}_t^2$ forms a clique in $I(\mathcal{P})$. But by our assumption on the size of $\mathcal{A}_t$, at least one of $\mathcal{A}_t^2$ and $\mathcal{A}_t^1$ must have size greater than $k+1$, which implies that $I(\mathcal{P})$ contains a clique of size at least $k+2$. It is well-known that each clique must be completely contained in at least one bag of a tree-decomposition, and so we arrive at a contradiction with $\mathrm{tw}(I(\mathcal{P})) \le k$. Hence we conclude that $|\mathcal{A}_t| \le 2k+2$ and the claim holds. ◀

Finally, consider a node t which has at least 2 blocks. By Property **3** of Lemma 21, it holds that t has a neighbor t' in T_t^r such that $X_{t'} = X_t \setminus \{v\}$ and t' has 1 block. By Claim 24 we know that $\mathcal{A}_{t'} \le 2k+2$. Since $L(t) = L(t')$ and $R(t) \subseteq R(t')$, it follows that $\mathcal{A}_t \subseteq \mathcal{A}_{t'}$, and in particular $|\mathcal{A}_t| \le |\mathcal{A}_{t'}|$. We have now proved the desired bound for all nodes in $\mathcal{T}$, and so the lemma holds. ◀

With Lemma 22 and Lemma 23, we have the tools necessary for arguing that there exists a tree-decomposition of the combined graph of small width.

▶ **Lemma 25.** *Let $\mathcal{T} = (T, \mathcal{X})$ be a blocked tree-decomposition of $I(\mathcal{P})$ such that $\mathrm{tw}(\mathcal{T}) \le k$. Then there exists a tree-decomposition $\mathcal{T}'$ of $I_C(\mathcal{P})$ of width at most $3k+2$.*

Proof. Consider the tree-decomposition $\mathcal{T}' = (T, \mathcal{X}')$ where $\mathcal{X}' = \{X'_t \mid t \in V(T)\}$ is defined as follows. For each $t \in V(T)$ such that its unique neighbor s in T_t^r satisfies $|X_t \setminus X_s| = 1$, we set $X'_t = X_t \cup \mathcal{A}_s$; it will be useful to observe that $\mathcal{A}_s \supseteq \mathcal{A}_t$. For all other nodes $t \in V(T)$, we then set $X'_t = X_t \cup \mathcal{A}_t$. We call nodes of the first type *non-standard* and nodes of the second type standard.

First, we note that the size of each bag in $\mathcal{T}'$ is at most $3k+2$, since every node $t \in V(T)$ satisfies $|\mathcal{A}_t| \le 2k+2$ by Lemma 23. Furthermore, $\mathcal{T}'$ satisfies condition (T1) because $\mathcal{T}$ was a tree-decomposition of $I(\mathcal{P})$. $\mathcal{T}'$ also satisfies condition (T2); indeed, for each $v \in \mathcal{P}$ it holds that X'^v restricted to standard nodes is a connected tree by Lemma 22, and by construction every non-standard node t such that $v \in X'_t \setminus X_t$ is adjacent to a standard node containing v. So, it only remains to argue condition (T3).

Obviously, condition (T3) holds for any edge of $I(\mathcal{P})$. So, consider two elements u, v of $\mathcal{P}$ such that $u \lhd^{\mathcal{P}} v$ or $v \lhd^{\mathcal{P}} u$. If there exists a node $t \in V(T)$ such that $u, v \in X_t$, then $u, v \in X'_t$ and the condition also holds for this edge in $I_C(\mathcal{P})$. So, assume that X^v and X^u are disjoint and let Q be the unique X^v-X^u path in T. By Property **4**, the X^v-X^u path Q in T must contain at least one internal node.

Consider the case where one of these subtrees, say w.l.o.g. X^v, lies in the connected component T_t^r of $T - Q$. Then for each internal node $q \in Q$, it holds that $v \in L(q)$ and $u \in R(q)$, which in turn implies that $v \in \mathcal{A}_q$. Let q_u be the endpoint of Q in X^u and let q_0 be the neighbor of q_u in Q. By Property **4** we have $X_{q_u} \setminus X_{q_0} = \{u\}$, which implies that q_u is a non-standard node and in particular $\mathcal{A}_{q_0} \subseteq X'_{q_u}$. Since q_0 is an internal node of Q, it follows that $v \in X'_{q_u}$ which means that condition (T3) also holds for any edge uv in this case.

Finally, consider the case where there exists a node $q \in Q$ of degree at least 3 such that each of X^u, X^v and r occur in different components of $T - q$. Then we reach a contradiction similarly as in the proof of Lemma 22. In particular, since $u, v \in R(q)$ due to the location of the root and there is a cover edge between them, it follows that either u, v occur in the same connected component of X_q or in two consecutive ones, but in either case u, v must lie in the same block of q, say block B. But since $u, v \notin X_q$, this contradicts Property **2** in Lemma 21; indeed, each tree in $T - q$ contains at most one of v, u in its bags, and hence there exists no tree T' in $T - q$ satisfying $\bigcup_{t' \in V(T')} X_{t'} \setminus X_q = B$. Hence this case in fact violates our assumptions and cannot occur.

Summarizing the above arguments, we conclude that each bag in $\mathcal{T}'$ has size at most $3k + 2$ and that $\mathcal{T}'$ satisfies all of the conditions of a tree-decomposition. ◀

▶ **Corollary 26.** *Let $\mathcal{P}$ be a poset such that $\text{tw}(I(\mathcal{P})) \leq k$. Then $\text{tw}(I_C(\mathcal{P})) \leq 3k + 2$.*

Proof. By Corollary 6 we know that there exists a nice path-decomposition of $I(\mathcal{P})$ of width at most k. By Lemma 21, it follows that there exists a blocked tree-decomposition of $I(\mathcal{P})$ of width at most k. The corollary then follows by Lemma 25. ◀

4.2 MSO Formulation

In this subsection, we use Fact 4 to prove the following result, which forms the second ingredient required for our proof of Theorem 17.

▶ **Lemma 27.** *#LE is fixed-parameter tractable parameterized by the treewidth of the combined graph of the input poset.*

Sketch of the Proof. Let $\mathcal{P} := (P, \leq^P)$ be a poset. Let G be the (edge-)labeled directed graph obtained from $I_C(\mathcal{P})$ by directing every bidirectional edge of $I_C(\mathcal{P})$, i.e., every edge of $I(\mathcal{P})$, in an arbitrary way and labeling it with the label $\|$.

For a set of edges $E \subseteq E(G)$ with label $\|$, let $G[E]$ be the graph obtained from G after reversing every edge in E. Moreover, for a linear extension $\preceq$ of $\mathcal{P}$ let $E_G(\preceq)$ be the set of edges (u, v) of G such that $v \preceq u$. Note that because every linear extension of $\mathcal{P}$ has to respect the direction of the edges in G given by C, it holds that every edge in $E_G(\preceq)$ has label $\|$.

▶ **Claim 28.** *$E_G(\preceq)$ defines a bijection between the set of linear extensions of $\mathcal{P}$ and the set of subsets E of edges of G with label $\|$ such that $G[E]$ is acyclic.*

Proof of the claim. Let $\preceq$ be a linear extension of $\mathcal{P}$. Then, as observed above, $E_G(\preceq)$ is a set of edges of G with label $\|$. Moreover, because $G[E_G(\preceq)]$ is a subgraph of $P_G(\preceq)$ and $P_G(\preceq)$ is acyclic so is $G[E_G(\preceq)]$. Hence, $E_G(\preceq)$ is a function from the set of linear extensions of $\mathcal{P}$ to the set of subsets E of edges of G with label $\|$ such that $G[E]$ is acyclic. Towards showing that $E_G(\preceq)$ is injection assume for a contradiction that this is not the case, i.e., there are two distinct linear extensions $\preceq_1$ and $\preceq_2$ of $\mathcal{P}$ such that $E_G(\preceq_1) = E_G(\preceq_2)$ and let u and v be two elements of $\mathcal{P}$ ordered differently by $\preceq_1$ and $\preceq_2$. Then $\{u, v\} \in I(\mathcal{P})$ and hence either $(u, v) \in G$ or $(v, u) \in G$ the label of (u, v) or (v, u) respectively is $\|$. W.l.o.g. assume that $(u, v) \in G$ with label $\|$. But then, because $\preceq_1$ and $\preceq_2$ differ on u and v, either $(u, v) \in E_G(\preceq_1)$ but not $(u, v) \in E_G(\preceq_2)$ or $(u, v) \in E_G(\preceq_2)$ but not $(u, v) \in E_G(\preceq_1)$. In both cases we get a contradiction to our assumption that $E_G(\preceq_1) = E_G(\preceq_2)$. It remains to show that $E_G(\preceq)$ is surjective. To see this let E be a subsets of the edges of G with label $\|$ such that $G[E]$ is acyclic. Because $G[E]$ is acyclic it has a topological ordering, say $\preceq$, of its vertices. Because $G[E]$ contains $C(\mathcal{P})$ as a subgraph and any topological ordering of $C(\mathcal{P})$ is a linear extension of $\mathcal{P}$, we obtain that $\preceq$ is a linear extension and also $E = E_G(\preceq)$. ◀

It follows from the above that instead of counting the number of linear extensions of $\mathcal{P}$ directly, we can count the number of subsets E of the edges of G with label $\|$ such that $G[E]$ is acyclic. It can be shown that there exists an MSO formula Φ (with length independent of G) such that $G \models \Phi(X)$ if and only if X is a subset of the edges of G with label $\|$ such that $G[X]$ is acyclic. Because of Fact 4, this implies that #LE is fixed-parameter tractable when parameterized by $\mathrm{tw}(G)$ and hence also when parameterized by $\mathrm{tw}(I_C(\mathcal{P}))$, concluding the proof of the lemma. Generally speaking, $\Phi(X)$ only needs to check that X is a set of edges of G with label $\|$ and there is no non-empty set of edges C of $G[X]$ that forms a cycle. ◀

We conclude this section by stating the proof of Theorem 17.

Proof of Theorem 17. Let $\mathcal{P}$ be the input poset and let $k = \mathrm{tw}(I(\mathcal{P}))$. Then $\mathrm{tw}(I_C(\mathcal{P})) \leq 3k + 2$ by Corollary 26, and the theorem follows by Lemma 27. ◀

5 Conclusions and Future Work

We have given the first parameterized intractability result for counting linear extensions. We hope that the employed techniques will inspire similar results and expand our knowledge about the parameterized complexity of counting problems. In particular, even for #LE there remain many open questions concerning other very natural parameterizations such as the width of the poset or the treewidth of the poset graph. Moreover, our intractability result for the treewidth of the cover graph poses the question whether there are stronger parameterizations under which #LE becomes tractable, e.g., the treewidth of the poset graph, the treedepth or even vertex cover number of the poset- or cover graph, as well as combinations of these parameters with parameters such as the width, the dimension, or the height of the poset. These numerous examples illustrate that the parameterized complexity of #LE is still largely unexplored. As a side note it would also be interesting to establish whether our hardness result for #LE can be sharpened to #W[1]-hardness and to obtain matching membership results.

Abstract

In this paper we improve the approximation ratio for the problem of scheduling packets on line networks with bounded buffers with the aim of maximizing the throughput. Each node in the network has a local buffer of bounded size B, and each edge (or link) can transmit a limited number c of packets in every time unit. The input to the problem consists of a set of packet requests, each defined by a source node, a destination node, and a release time. We denote by n the size of the network. A solution for this problem is a schedule that delivers (some of the) packets to their destinations without violating the capacity constraints of the network (buffers or edges). Our goal is to design an efficient algorithm that computes a schedule that maximizes the number of packets that arrive to their respective destinations.

We give a randomized approximation algorithm with constant approximation ratio for the case where the buffer-size to link-capacity ratio, B/c, does not depend on the input size. This improves over the previously best result of $O(\log^* n)$ [11]. Our improvement is based on a new combinatorial lemma that we prove, stating, roughly speaking, that if packets are allowed to stay put in buffers only a limited number of time steps, $2d$, where d is the longest source-destination distance, then the optimal solution is decreased by only a constant factor. This claim was not previously known in the integral (unsplitable, zero-one) case, and may find additional applications for routing and scheduling algorithms.

While we are not able to give the same improvement for the related problem when packets have hard deadlines, our algorithm does support "soft deadlines". That is, if packets have deadlines, we achieve a constant approximation ratio when the produced solution is allowed to miss deadlines by at most $\log n$ time units.

1 Introduction

In this paper we give an approximation algorithm with an improved approximation ratio for a network-scheduling problem which has been studied in numerous previous works in a number of variants (cf. [2, 3, 5, 8, 14, 11]). The problem consists of a directed line network

* The full version of this paper can be found in http://arxiv.org/abs/1602.06174.

over nodes $\{0, \ldots, n-1\}$, where each node i can send packets to node $i+1$, and can also store packets in a local buffer. The maximum number of packets that can be sent in a single time unit over a given link is denoted by c, and the number of packets each node can store at any given time is denoted by B. An instance of the problem is further defined by a set of packets $r_i = (a_i, b_i, t_i)$, $1 \leq i \leq M$, where a_i is the source node of the packet, b_i is its destination node, and $t_i \geq 1$ is the release time of the packet at vertex a_i. The goal is that of maximizing the number of packets that reach their respective destinations without violating the links or the buffers capacities. See Section 2 for a formal definition of the problem.

We present a randomized approximation algorithm for that problem, which has a *constant* approximation ratio for the case that the ratio B/c does not depend on the input size, improving upon the previous $O(\log^* n)$ approximation ratio given in [11, Theorem 3]. While this constant approximation result does not hold for the variant of the problem where packets have deadlines, our algorithm does provide a constant-approximation solution that abides to "soft deadlines". That is, in that solution each packet is delivered at most $\log n$ time units past its deadline.

Our algorithm is based on a novel combinatorial lemma 3 which states the following. Consider a set of packets such that all source-destination distances are bounded from above by some d. The throughput of an optimal solution in which every packet r_i must reach its destination no later than time $t_i + 2d$ is an $\Omega(B/c)$-fraction of the unrestricted optimal throughput. This lemma plays a crucial role in our algorithm, and we believe that it may find additional applications for scheduling and routing algorithms in networks. We emphasize that the fractional version of a similar property, i.e., when packets are splitable and one accrues a benefit also from the delivery of partial packets, presented first in [5], does not imply the integral version that we prove here.

We emphasize that the problem studied here, namely, maximizing the throughput on a network with bounded buffers, has resisted substantial efforts in its (more applicable) distributed, online setting, even for the simple network of a directed line. Indeed, even the question whether or not there exists a constant competitive online distributed algorithm for that problem on the line network remains unanswered at this point. We therefore study here the offline setting with the hope that, in addition to its own interest, results and ideas from this setting will contribute to progress on the distributed problem.

Related Work. The problem of scheduling packets so as to maximize the throughput (i.e., maximize the number of packets that reach their destinations) in a network with bounded buffers was first considered in [2], where this problem is studied for various types of networks in the distributed setting. The results in that paper, even for the simple network of a directed line, were far from tight but no substantial progress has been made since on the realistic, distributed and online, setting. This has motivated the study of this problem in easier settings, as a first step towards solving the realistic, possibly applicable, scenario.

Angelov et al. [3] give centralized online randomized algorithms for the line network, achieving an $O(\log^3 n)$-competitive ratio. Azar and Zachut [5] improved the randomized competitive ratio to $O(\log^2 n)$ which was later improved by Even and Medina [6, 8] to $O(\log n)$. A deterministic $O(\log^5 n)$-competitive algorithm was given in [7, 8], which was later improved in [9] to $O(\log n)$ if buffer and link capacities are not very small (not smaller than 5).

The related problem of maximizing the throughput when packets have deadlines (i.e., a packet is counted towards the quality of the solution only if it arrives to its destination before a known deadline) on line network with unbounded input queues is known to be NP-hard [1].

The same problem in a variant of the setting, where the input queues are bounded, is shown in [11] to have a $O(\log^* n)$-approximation randomized algorithm. The setting in the present paper is the same setting as the one of the latter paper, and the results of [11] immediately give an $O(\log^* n)$-approximation randomized algorithm for the problem and setting we study in the present paper.

2 Preliminaries

2.1 Model and problem statement

We consider the standard model of synchronous store-and-forward packet routing networks [2, 3, 5]. The network is modeled by a directed path over n vertices. Namely, the network is a directed graph $G = (V, E)$, where $V = \{0, \ldots, (n-1)\}$ and there is a directed edge from vertex u to vertex v if $v = u + 1$. The network resources are specified by two positive integer parameters B and c that describe, respectively, the local buffer capacity of every vertex and the capacity of every edge. In every time step, at most B packets can be stored in the local buffer of each vertex, and at most c packets can be transmitted along each edge.

The input consists of a set of packet requests $R = \{r_i\}_{i=1}^{M}$. A packet request is specified by a 3-tuple $r_i = (a_i, b_i, t_i)$, where $a_i \in V$ is the *source node* of the packet, $b_i \in V$ is its *destination node*, and $t_i \in \mathbb{N}$ is the release time of the packet at vertex a_i. Note that $b_i > a_i$, and r_i is ready to leave a_i in time step t_i.

A solution is a schedule S. For each request r_i, the schedule S specifies a sequence s_i of transitions that packet r_i undergoes. A *rejected* request r_i is simply discarded at time t_i, and no further treatment is required (i.e., $s_i = \{\mathit{reject}\}$). An *accepted* request r_i is delivered from a_i to b_i by a sequence s_i of actions, where each action is either "store" or "forward". Consider the packet of request r_i. Suppose that in time t the packet is in vertex v. A store action means that the packet is stored in the buffer of v, and will still be in vertex v in time step $t + 1$. A forward action means that the packet is transmitted to vertex $v + 1$, and will be in vertex $v + 1$ in time step $t + 1$. The packet of request r_i reaches its destination b_i after exactly $b_i - a_i$ forward steps. Once a packet reaches its destination, it is removed from the network and it no longer consumes any of the network's resources.

A schedule must satisfy the following constraints:

1. The *buffer capacity constraint* asserts that at any time step t, and in every vertex v, at most B packets are stored in v's buffer.
2. The *link capacity constraint* asserts that at any step t, at most c packets can be transmitted along each edge.

The *throughput* of a schedule S is the number of accepted requests. We denote the throughput of a schedule S by $|S|$. As opposed to online algorithms, there is no point in injecting a packet to the network unless it reaches its destination. Namely, a packet that is not rejected and does not reach its destination only consumes network resources without any benefit. Hence, without loss of generality, we assume that every packet that is dropped before reaching its designation is rejected at its source node at its release time.

We consider the offline optimization problem of finding a schedule that maximizes the throughput. We propose a centralized constant-ratio approximation algorithm. By *offline* we mean that the algorithm receives all requests in advance[1]. By *centralized* we mean that all

[1] The number of requests M is finite and known in the offline setting. This is not the case in the online setting in which the number of requests is not known in advance and may be unbounded.

the requests are known in one location where the algorithm is executed. Let $\mathsf{opt}(R)$ denote a schedule of maximum throughput for the set of requests R. Let $\mathsf{alg}(R)$ denote the schedule computed by alg on input R. We say that the approximation ratio of a scheduling algorithm alg is c if $\forall R : |\mathsf{alg}(R)| \geq c \cdot |\mathsf{opt}(R)|$. For a randomized algorithm we say that the expected approximation ratio is c if $\forall R : \mathbf{E}[|\mathsf{alg}(R)|] \geq c \cdot |\mathsf{opt}(R)|$.

The Max-Pkt-Line Problem. The problem of maximum throughput scheduling of packet requests on directed line (Max-Pkt-Line) is defined as follows. The input consists of: n - the size of the network, B - node buffer capacities, c - link capacities, and M packet requests $\{r_i\}_{i=1}^M$. The output is a schedule S. The goal is to maximize the throughput of S.

2.2 Path Packing in a uni-directed 2D-Grid

In this section we define a problem of maximum cardinality path packing in a two-dimensional uni-directed grid (Max-Path-Grid). This problem is equivalent to Max-Pkt-Line, and was used for that purpose in previous work, where the formal reduction is also presented [4, 1, 5, 11]. As the two problems are equivalent, we use in the sequel terminology from both problems interchangeably.

The grid, denoted by $G^{st} = (V^{st}, E^{st})$, is an infinite directed acyclic graph. The vertex set V^{st} equals $V \times \mathbb{N}$, where $V = \{0, 1, \ldots, (n-1)\}$. Note that we use the first coordinate (that corresponds to vertices in V) for the y-axis and the second coordinate (that corresponds to time steps) for the x-axis. The edge set consists of horizontal edges (also called store edges) directed to the right and vertical edge (also called forward edges) directed upwards. The capacity of vertical edges is c and the capacity of horizontal edges is B. We often refer to G^{st} as the space-time grid (in short, grid) because the x-axis is related to time and the y-axis corresponds to the vertices in V.

A *path request* in the grid is a tuple $r^{st} = (a_i, t_i, b_i)$, where $a_i, b_i \in V$ and $t_i \in \mathbb{N}$. The request is for a path that starts in node (a_i, t_i) and ends in any node in the row of b_i (i.e., the end of the path can be any node (b_i, t), where $t \geq t_i$).

A *packing* is a set of paths S^{st} that abides the capacity constraints. For every grid edge e, the number of paths in S^{st} that contain e is not greater than the capacity of e.

Given a set of path requests $R^{st} = \{r_i^{st}\}_{i=1}^M$, the goal in the Max-Path-Grid problem is to find a packing S^{st} with the largest cardinality. (Each path in S^{st} serves a distinct path request.)

Multi-Commodity Flows (MCFs). Our use of path packing problems gives rise to *fractional* relaxations of that problem, namely to multi-commodity flows (MCFs) with unit demands on uni-directional grids. We deferred the definitions and terminology of MCFs to the full version.

2.3 Tiling, Classification, and Sketch Graphs

To define our algorithm we make use of partitions of the space-time grid described above into sub-grids. We define here the notions we use for this purpose. In this section we focus on the case of unit capacities, namely, $B = c = 1$. An extension to other values of B and c can be found [8].

Tiling. *Tiling* is a partitioning of the two-dimensional space-time grid (in short, grid) into squares, called *tiles*. Two parameters specify a tiling: the side length k, an even integer, of the squares and the shifting (φ_x, φ_y) of the squares. The shifting refers to the x- and y-coordinates of the bottom left corner of the tiles modulo k. Thus, the tile $T_{i,j}$ is the subset of the grid vertices defined by

$$T_{i,j} \triangleq \{(v,t) \in V \times \mathbb{N} \mid ik \leq v - \varphi_y < (i+1)k \text{ and } jk \leq t - \varphi_x < (j+1)k\},$$

where φ_x and φ_y denote the horizontal and vertical shifting, respectively. We consider two possible shifts for each axis, namely, $\varphi_x, \varphi_y \in \{0, k/2\}$.

Quadrants and Classification. Consider a tile T. Let (x', y') denote the lower left corner (i.e., south-west corner) of T. The *south-west quadrant* of T is the set of vertices (x,y) such that $x' \leq x \leq x' + k/2$ and $y' \leq y \leq y' + k/2$.

For every vertex (x,y) in the grid, there exists exactly one shifting $(\varphi_x, \varphi_y) \in \{0, k/2\}^2$ such that (x,y) falls in the south-west (SW) quadrant of a tile. Fix the tile side length k. We define a *class* for every shifting (φ_x, φ_y). The class that corresponds to the shifting (φ_x, φ_y) consists of all the path requests r_i^{st} whose origin (a_i, t_i) belongs to a SW quadrant of a tile in the tiling that uses the shifting (φ_x, φ_y).

Sketch graph and paths. Consider a fixed tiling. The *sketch graph* is the graph obtained from the grid after coalescing each tile into a single node. There is a directed edge (s_1, s_2) between two tiles s_1, s_2 in the sketch graph if there is a directed edge $(\alpha, \beta) \in E^{st}$ such that $\alpha \in s_1$ and $\beta \in s_2$. Let p^s denote the projection of a path p in the grid to the sketch graph. We refer to p^s as the *sketch path* corresponding to p. Note that the length of p^s is at most $\lceil |p|/k \rceil + 1$.

3 Outline of our Algorithm

For the sake of simplicity we focus hereafter on the case of unit capacities, namely $B = c = 1$. Extension to non-unit capacities are discussed in Section 6.1.

Packet requests are categorized into three categories: short, medium, and long, according to the source-destination distance of each packet. A separate approximation algorithm is executed for each category. The algorithm returns a highest throughput solution among the solutions computed for the three categories.

Notation. Two thresholds are used for defining short, medium, and long requests: $\ell_M \triangleq 3 \ln n, \ell_S \triangleq 3 \cdot \ln(\ell_M) = 3 \cdot \ln(3 \ln n)$.

▶ **Definition 1.** A request r_i is a *short* request if $b_i - a_i \leq \ell_S$. A request r_i is a *medium* request if $\ell_S < b_i - a_i \leq \ell_M$. A request r_i is a *long* request if $b_i - a_i > \ell_M$.

We use a deterministic algorithm for the class of short packets, and in Theorem 7 we prove that this deterministic algorithm achieves a constant approximation ratio. We use a randomized algorithm for each of the classes of medium and long packets; in Theorem 15 we prove that this randomized algorithm achieves a constant approximation ratio in expectation for each of these classes. Thus, we obtain the following corollary.

▶ **Corollary 2** (Main Result). *If $B = c = 1$, then there exists a randomized approximation algorithm for the Max-Pkt-Line problem that achieves a constant approximation ratio in expectation.*

In Section 6.1 we discuss non-unit capacities, give the approximation ratio for this case and show that we achieve a constant approximation ratio as long as the ratio B/c does not depend on the input size.

4 Approximation Algorithm for Short Packets

In this section we present a constant ratio deterministic approximation algorithm for short packets. This algorithm, which is key to achieving the results of the present paper, makes use of a new combinatorial lemma that we prove in the next subsection, stating, roughly speaking, that if packets from a given set of packets are allowed to stay put in buffers (i.e., use horizontal edges in the grid) only a limited number of time steps, $2d$ (where d is the longest source-destination distance in the set of packets), then the optimal solution is decreased by only a constant factor. We believe that this lemma may find additional applications in future work on routing and scheduling problems.

4.1 Bounding Path Lengths in the Grid

In this section we prove that bounding, from above, the number of horizontal edges along a path incurs only a small reduction in the throughput. Previously known bounds along these lines hold only for fractional solutions [5], while we present here the first such claim for integral schedules.

Let R_d denote a set of packet requests r_i, $i \geq 1$, such that $b_i - a_i \leq d$ for any i. Consider the paths in the space-time grid that are allocated to the accepted requests. We prove that restricting the path lengths to $2d$ decreases both the optimal fractional and the optimal *integral* throughput only by a multiplicative factor of $O(c/B)$. We note that if the ratio B/c is a constant, then we are guaranteed an optimal solution which is only a constant away from the unrestricted optimal solution.

Notation. For a single commodity acyclic flow f_i, let $p_{\max}(f_i)$ denote the diameter of the support of f_i (i.e., length of longest path[2]). For an MCF $F = \{f_i\}_{i \in I}$, let $p_{\max}(F) \triangleq \max_{i \in I} p_{\max}(f_i)$. Let $F^*_{\mathit{frac}}(R)$ (respectively, $F^*_{\mathit{int}}(R)$) denote a maximum throughput fractional (resp., integral) MCF with respect to the set of requests R. Similarly, let $F^*_{\mathit{frac}}(R \mid p_{\max} < d')$ (respectively, $F^*_{\mathit{int}}(R \mid p_{\max} < d')$) denote a maximum throughput fractional (resp., integral) MCF with respect to the set of requests R subject to the additional constraint that the maximum path length is at most d'.

▶ **Lemma 3.**

$$F^*_{\mathit{frac}}(R_d \mid p_{\max} \leq 2d) \geq \frac{c}{B+2c} \cdot F^*_{\mathit{frac}}(R_d),$$
$$F^*_{\mathit{int}}(R_d \mid p_{\max} \leq 2d) \geq \frac{c}{2(B+c)} \cdot F^*_{\mathit{int}}(R_d).$$

Proof. Partition the space-time grid into *slabs* S_j of "width" d. Slab S_j contains the vertices (v, k), where $k \in [(j-1) \cdot d, j \cdot d]$, $j \geq 1$. We refer to vertices of the form (v, jd) as the *boundary* of S_j. Note that if $v - u \leq d$, then the forward-only vertical path from (u, jd) to $(v, jd + (v-u))$ is contained in slab S_{j+1}.

[2] Without loss of generality, we may assume that each single commodity flow f_i is acyclic.

We begin with the fractional case. Let $f^* = F^*_{frac}(R_d)$ denote an optimal fractional solution for R_d. Consider request r_i and the corresponding single commodity flow f^*_i in f^*. Decompose f^*_i to flow-paths $\{p_\ell\}_\ell$. For each flow-path p_ℓ in f^*_i, let p'_ℓ denote the prefix of p_ℓ till it reaches the boundary of a slab. Note that $p'_\ell = p_\ell$ if p_ℓ is confined to a single slab. If $p'_\ell \subsetneq p_\ell$, then let (v, jd) denote the last vertex of p'_ℓ. Namely, the path p'_ℓ begins in $(a_i, t_i) \in S_j$ and ends in (v, jd). Let q''_ℓ denote the forward-only path from (v, jd) to $(b_i, jd + (b_i - v))$. (If $p'_\ell = p_\ell$, then q''_ℓ is an empty path.) Note that q''_ℓ is confined to the slab S_{j+1}. We refer to the vertex (v, jd) in the intersection of p'_ℓ and q''_ℓ as the *boundary* vertex. Let g_i denote the fractional single commodity flow for request r_i obtained by adding the concatenated flow-paths $q_\ell \triangleq p'_\ell \circ q''_\ell$ each with the flow amount of f^*_i along p_ℓ. Define the MCF g by $g(e) \triangleq \sum_{i \in I} g_i(e)$. For every edge e, part of the flow $g(e)$ is due to prefixes p'_ℓ, and the remaining flow is due to suffixes q''_ℓ. We denote the part due to prefixes by $g_{pre}(e)$ and refer to it as the prefix-flow. We denote the part due to suffixes by $g_{suf}(e)$ and refer to it as the suffix-flow. By definition, $g(e) = g_{pre}(e) + g_{suf}(e)$.

The support of g_i is contained in the union of two consecutive slabs. Hence, the diameter of the support of g_i is bounded by $2d$. Hence $p_{\max}(g) \leq 2d$.

Clearly, $|g_i| = |f^*_i|$ and hence $|g| = |f^*|$. Set $\rho = c/(B + 2c)$. To complete the proof, it suffices to prove that $\rho \cdot g$ satisfies the capacity constraints. Indeed, for a "store" edge $e = (v, t) \to (v, t + 1)$, we have $g_{suf}(e) = 0$ and $g_{pre}(e) \leq f^*(e) \leq B$. For a "forward" edge $e = (v, t) \to (v + 1, t + 1)$ we have: $g_{pre}(e) \leq f^*(e) \leq c$. On the other hand, $g_{suf}(e) \leq B + c$. The reason is as follows. All the suffix-flow along e starts in the same boundary vertex (u, jd) below e. The amount of flow forwarded by (u, jd) is bounded by the amount of incoming flow, which is bounded by $B + c$. This completes the proof of the fractional case.

We now prove the integral case. The proof is a variation of the proof for the fractional case in which the supports of pre-flows and suffix-flows are disjoint. Namely, one alternates between slabs that support prefix-flow and slabs that support suffix-flow.

In the integral case, each accepted request r_i is allocated a single path p_i, and the allocated paths satisfy the capacity constraints. As in the fractional case, let $q_i \triangleq p'_i \circ q''_i$, where p'_i is the prefix of p_i till a boundary vertex (v, jd), and q''_i is a forward-only path. We need to prove that there exists a subset of at least $c/(2(B + c))$ of the paths $\{q_i\}_i$ that satisfy the capacity constraints. This subset is constructed in two steps.

First, partition the requests into "even" and "odd" requests according to the parity of the slab that contains their origin (a_i, t_i). (The parity of request r_i is simply the parity of $\lceil t_i/d \rceil$.) Pick a part that has at least half of the accepted requests in $F^*_{int}(R_d)$; assume w.l.o.g. that such a part is the part of the even slabs. Then, we only keep accepted requests whose origin belong to even slabs.

In the second step, we consider all boundary vertices $(v, j \cdot d)$. For each boundary vertex, we keep up to c paths that traverse it, and delete the remaining paths if such paths exist. In the second step, again, at least a $c/(B + c)$ fraction of the paths survive. It follows that altogether at least $c/(2(B + c))$ of the paths survive.

We claim that the remaining paths satisfy the capacity constraints. Note that prefixes are restricted to even slabs, and suffixes are restricted to odd slabs. Thus, intersections, if any, are between two prefixes or two suffixes. Prefixes satisfy the capacity constraints because they are prefixes of $F^*_{int}(R_d)$. Suffixes satisfy the capacity constraints because if two suffixes intersect, then they start in the same boundary vertex. However, at most c paths emanating from every boundary vertex survive. Hence, the surviving paths satisfy the capacity constraints, as required. This completes the proof of the lemma. ◀

We note that if the ratio B/c is bounded by a constant, then Lemma 3 guarantees an optimal solution which is only a (different) constant away from the unrestricted optimal solution.

4.2 The Algorithm for Short Packets

Short requests are further partitioned into four classes, defined as follows. Consider four tilings each with side length $k \triangleq 4\ell_S$ and horizontal and vertical shifts in $\varphi_x, \varphi_y \in \{0, k/2\}$.[3] The four possible shifts define four classes: The packets of a certain class (shift) are the packets whose source nodes reside in the SW quadrants of the tiles according to a given shift. Observe that each packet request belongs to exactly one class. We say that a path p_i from (a_i, t_i) to the row of b_i is *confined to a tile* if p_i is contained in one tile. We bound from above the path lengths by $2\ell_S$ so

We claim that by exhaustive search, it is possible to efficiently compute a maximum throughput solution for each class, under the restriction that each path is of length at most $2\ell_S$. The algorithm computes an optimal (bounded path length) solution for each class, and returns a highest throughput solution among the four solutions.

The polynomial running time of the exhaustive search algorithm per class is based on the two following observations.

▶ **Observation 4.** *A path of length at most $k/2 = 2\ell_S$ that begins in the SW quadrant of tile T is confined to T.*

Proof. The tile side length equals $k = 4\ell_S$. If the origin of a request is in the SW quadrant of a tile and the path length is at most $2\ell_S = k/2$, then the end of the path belongs to the same tile. ◀

▶ **Observation 5** ([6, 9, 8])**.** *Partition the packets according to their source node. For each node v, order the packets with source node v in increasing order of their target point. There exists an optimal solution that does not include any packet with rank more than 2 in that ordering.*[4]

▶ **Lemma 6.** *If $B = c = 1$, an optimal solution for each class in which paths are confined to their origin tile is computable in time polynomial in n and M.*

Proof. Fix a tile T. Let X denote the set of short requests in T, having rank at most 2 according to the ordering defined in Observation 5. By Observation 5, an optimal solution can be computed out of the set of packets X. Let Y be the set of paths in T. We perform an exhaustive search to find the optimal solution.

It suffices for the exhaustive search to consider all possibly partial functions $f : X \to Y$, and for each such function check that (1) each packet in the domain of f can be served by the path associated with it, and (2) no two path in the image of f intersect. Then pick, among all functions that pass the checks, the one with the largest domain.

The size of X is at most $2(k/2)^2$ since there are at most $(k/2)^2$ possible source nodes. The size of Y is at most $(k/2)^2\binom{2k}{k}$ (there are $(k/2)^2$ possible source nodes, and a path is defined by the steps in which it goes horizontally, and those where it goes vertically).

Therefore the number of possibly partial functions per tile is at most $2^{|X|} \cdot |Y|^{|X|} < 2^{2(k/2)^2} \cdot \left((k/2)^2 2^{2k}\right)^{2(k/2)^2} \leq 2^{poly(k)}$. Furthermore, given a function f the two needed checks

[3] Recall that $\ell_M \triangleq 3\ln n$ and $\ell_S \triangleq 3 \cdot \ln(\ell_M) = 3 \cdot \ln(3\ln n)$.
[4] Rank $B + c$ for non unit capacities.

can be done in time at most $O(|X| + |X|^2 \cdot k^2) = O(|X|^2 \cdot k^2)$. Since $k = O(\log \log n)$ for the case of the short packets, and $|X| \leq 2(k/2)^2$, the total time of the exhaustive search per tile is $poly(n)$.

The number of tiles that contain a request is bounded by the number of requests M. Hence, the running time of the algorithm for short requests is polynomial in n and M. ◀

▶ **Theorem 7.** *The approximation ratio of the algorithm for short requests is* $\frac{1}{16}$.

Proof. The short requests are partitioned to 4 classes. Then, for each class and tile, the exhaustive algorithm computes a solution which with cardinality at least a 1/4 of the optimal one, by the integral version of Lemma 3. ◀

5 Approximation Algorithm for Medium & Long Requests

We use the same algorithm for the two classes of medium and long requests, the only difference being some parameters of the algorithm. As indicated above, we consider at this point the case of unit capacities ($B = c = 1$). We further note that the approximation ratio of the algorithm for these classes is with respect to the optimal *fractional* solution.

Notation. Let $R_{d_{\min},d_{\max}}$ denote the set of packet requests whose source-to-destination distance is greater than $d_{\min}$ and at most $d_{\max}$. Formally, $R_{d_{\min},d_{\max}} \triangleq \{r_i \mid d_{\min} < b_i - a_i \leq d_{\max}\}$.

Parametrization. When applied to medium requests we use the parameter $d_{\max} = \ell_M$ and $d_{\min} = \ell_S$. When applied to long requests the parameters are $d_{\max} = n$ and $d_{\min} = \ell_M$. Note that these parameters satisfy $d_{\min} = 3 \cdot \ln d_{\max}$.

5.1 The Algorithm for $R_{d_{\min},d_{\max}}$

The algorithm for $R_{d_{\min},d_{\max}}$ proceeds as follows. To simplify notation, we abbreviate $R_{d_{\min},d_{\max}}$ by R. The parameters $d_{\min}$ and $d_{\max}$ must satisfy that $d_{\min} = 3 \cdot \ln d_{\max}$. We use the randomized rounding procedure by Raghavan [12, 13]. The description of this randomized rounding procedure is deferred to the full version.

1. Reduce the packet requests in R to path requests R^{st} over the space-time graph G^{st}.
2. Compute a maximum throughput fractional MCF $F \triangleq \{f_i\}_{r_i \in R^{st}}$ with edge capacities $\tilde{c}(e) = \lambda$ (for $\lambda = 1/(\beta(3) \cdot 6)$) [5] and bounded diameter $p_{\max}(F) \leq 2d_{\max}$. We remark that this MCF can be computed in time polynomial in n - the number of nodes and M - the number of requests.[6]

[5] The function $\beta : (-1, \infty) \to \mathbb{R}$ is defined by $\beta(\varepsilon) \triangleq (1 + \varepsilon)\ln(1 + \varepsilon) - \varepsilon$.

[6] Since always $d_{\max} \leq n$, we can consider a space-time grid of size at most $n \times (M \cdot 2n)$, which can be constructed by going over the release times of all M requests, eliminating "unnecessary" time steps. One can then compute a maximum throughput fractional solution with bounded diameter on this grid using linear programming. This is true because the constraint $p_{\max}(f_i) \leq d'$ is a linear constraint and can be imposed by a polynomial number of inequalities (i.e, polynomial in n and d'). For example, one can construct a product network with $(d' + 1)$ layers, and solve the MCF problem over this product graph.

3. Partition R to 4 classes $\{R^j\}_{j=1}^4$ according to the shift that results in the source node being in the SW quadrant of a $k \times k$ tiling, where $k \triangleq 2d_{\min} = 6 \ln d_{\max}$ (see Section 2.3). Pick a class R^j such that the throughput of F restricted to R^j is at least a quarter of the throughput of F, i.e., $|F(R^j)| \geq |F|/4$.
4. For each request $r_i \in R^j$, apply randomized rounding independently to f_i. The outcome of randomized rounding per request $r_i \in R^j$ is either "reject" or a path p_i in G^{st}. Let $R_{rnd} \subseteq R^j$ denote the subset of requests r_i that are assigned a path p_i by the randomized rounding procedure.
5. Let $R_{\mathit{fltr}} \subseteq R_{rnd}$ denote the requests that remain after applying filtering (described in Section 5.2).
6. Let $R_{quad} \subseteq R_{\mathit{fltr}}$ denote the requests for which routing in first quadrant is successful (as described in Section 5.3).
7. Complete the path of each request in R_{quad} by applying crossbar routing (as described in Section 5.4).

5.2 Filtering

Notation. Let e denote an edge in the space-time grid G^{st}. Let e^s denote an edge in the sketch graph (see Section 2.3). We view e^s also as the set of edges in G^{st} that cross the tile boundary that corresponds to the sketch graph edge e^s. The path p_i is a random variable that denotes the path, if any, that is chosen for request r_i by the randomized rounding procedure. For a path p and an edge e let $\mathbb{1}_p(e)$ denote the 0-1 indicator function that equals 1 iff $e \in p$.

The set of filtered requests R_{fltr} is defined as follows (recall that $\lambda = 1/(\beta(3) \cdot 6)$).

▶ **Definition 8.** A request $r_i \in R_{\mathit{fltr}}$ if and only if r_i is accepted by the randomized rounding procedure, and for every sketch-edge e^s in the sketch-path p_i^s it holds that $\sum_i \mathbb{1}_{p_i^s}(e^s) \leq 4\lambda \cdot k$.

▶ **Claim 9.** $\mathbf{E}\left[|R_{\mathit{fltr}}|\right] \geq \left(1 - O(\frac{1}{k})\right) \cdot \mathbf{E}\left[|R_{rnd}|\right]$.

Proof. We begin by bounding the probability that at least $4\lambda k$ sketch paths cross a single sketch edge.

▶ **Lemma 10** (Chernoff Bound). *For every edge e^s in the sketch graph,*[7]

$$\mathbf{Pr}\left[\sum_i \mathbb{1}_{p_i^s}(e^s) > 4\lambda k\right] \leq e^{-k/6}. \tag{1}$$

Proof of lemma. Recall that the edge capacities in the MCF F are λ. The capacity constraint $\sum_i f_i(e) \leq \lambda$ implies that $f_i(e) \leq \lambda$. Each sketch edge e^s corresponds to the grid edges between adjacent tiles. Since the demand of each request is 1, it follows that $f_i(e^s) \leq 1$.

For every edge e and request r_i, we have $\mathbf{E}\left[\mathbb{1}_{p_i^s}(e^s)\right] = \mathbf{Pr}\left[\mathbb{1}_{p_i^s}(e^s) = 1\right] = f_i(e^s) \leq 1$. Fix a sketch edge e^s. The random variables $\{\mathbb{1}_{p_i^s}(e^s)\}_i$ are independent 0-1 variables. Moreover, $\sum_i \mathbf{E}\left[\mathbb{1}_{p_i^s}(e^s)\right] = \sum_i f_i(e^s) = \sum_{e \in e^s} \sum_i f_i(e) \leq \lambda \cdot k$. By Chernoff bound[8]

$$\mathbf{Pr}\left[\sum_i \mathbb{1}_{p_i^s}(e^s) > 4 \cdot \sum_i \mathbf{E}\left[\mathbb{1}_{p_i^s}(e^s)\right]\right] < e^{-\beta(3)\cdot\lambda k} = e^{-k/6}. \quad ◀$$

[7] The e in the RHS is the base of the natural logarithm.

[8] We use the following version of Chernoff Bound [12, 15]. Let $\{X_i\}_i$ denote a sequence of independent random variables attaining values in $[0,1]$. Assume that $\mathbf{E}[X_i] \leq \mu_i$. Let $X \triangleq \sum_i X_i$ and $\mu \triangleq \sum_i \mu_i$. Then, for $\varepsilon > 0$, $\mathbf{Pr}[X \geq (1+\varepsilon) \cdot \mu] \leq e^{-\beta(\varepsilon)\cdot\mu}$.

A request $r_i \in R_{rnd}$ is not in R_{fltr} iff at least one of the edges $e^s \in p_i^s$ has more than $2\lambda k$ paths on it. Hence, by a union bound,

$$\mathbf{Pr}\left[r_i \notin R_{\mathit{fltr}} \mid r_i \in R_{rnd}\right] \leq |p_i^s| \cdot e^{-k/6} \leq \left(\left\lceil \frac{2d_{\max}}{k} \right\rceil + 2\right) \cdot e^{-\ln d_{\max}} = O\left(\frac{1}{k}\right),$$

since $k = 6 \ln d_{\max}$. ◀

5.3 Routing in the First Quadrant

In this section, we deal with the problem of evicting as many requests as possible from their origin quadrant to the boundary of the origin quadrant.

▶ Remark. Because $k/2 \leq d_{\min}$ every request that starts in a SW quadrant of a tile must reach the boundary (i.e., top or right side) of the quadrant before it can reach its destination.

The maximum flow algorithm. Consider a tile T. Let X denote set of requests r_i whose source (a_i, t_i) is in the south-west quadrant of T. We say that a subset $X' \subseteq X$ is *quadrant feasible* (in short, feasible) if it satisfies the following condition: There exists a set of edge disjoint paths $\{q_i \mid r_i \in X'\}$, where each path q_i starts in the source (a_i, t_i) of r_i and ends in the top or right side of the SW quadrant of T.

We employ a maximum-flow algorithm to solve the following problem.
Input: A set of requests X whose source is in the SW quadrant of T.
Goal: Compute a maximum cardinality quadrant-feasible subset $X' \subseteq X$.

The algorithm is simply a maximum-flow algorithm over the following network, denoted by $N(X)$. Augment the quadrant with a super source $\tilde{s}$ and a super sink $\tilde{t}$. The super source $\tilde{s}$ is connected to every source (a_i, t_i) (of a request $r_i \in X$) with a unit capacity directed edge. (If γ requests share the same source, then the capacity of the edge is γ.) There is a unit capacity edge from every vertex in the top side and right side of the SW quadrant of T to the super sink $\tilde{t}$. All the grid edges are assigned unit capacities. Compute an integral maximum flow in the network. Decompose the flow to unit flow paths. These flow paths are the paths that are allocated to the requests in X'.

Analysis. Fix a tile T and let $R_T \subseteq R_{\mathit{fltr}}$ denote the set of requests in R_{fltr} whose source vertex is in the SW quadrant of T. Let $R'_T \subseteq R_T$ denote the quadrant-feasible subset of maximum cardinality computed by the max-flow algorithm. Let $R_{quad} = \bigcup_T R'_T$.

We now prove the following theorem that relates the *expected value* of $|R'_T|$ to the expected value of $|R_T|$. Observe that it is not always true that the same relation holds for any specific R_T that results from a specific random tape used by the randomized rounding procedure.

▶ **Theorem 11.** *[10, 11]* $\mathbf{E}_\tau\left[|R_{quad}|\right] \geq 0.93 \cdot \mathbf{E}_\tau\left[|R_{\mathit{fltr}}|\right]$, *where τ is the probability space induced by the randomized rounding procedure.*

Proof. By linearity of expectation, it suffices to prove that $\mathbf{E}_\tau\left[|R'_T|\right] \geq 0.93 \cdot \mathbf{E}_\tau\left[|R_T|\right]$, for any given tile T.

The proof goes along the following lines. We define a certain capacity constraint over rectangles; this definition makes use of the capacity of the boundary of the rectangles, and the number of requests within them. We define the set $\hat{R}_T \subseteq R_T$ to be a set of requests based on the capacity constraints of the rectangles containing the source of the requests. We prove that: (1) The set $\hat{R}_T$ thus defined is feasible, and (2) $\mathbf{E}_\tau\left[|\hat{R}_T|\right] \geq 0.93 \cdot \mathbf{E}_\tau\left[|R_T|\right]$. By the algorithm, R'_T is of maximum cardinality (maximum flow), therefore, $|R'_T| \geq |\hat{R}_T|$, and the theorem follows.

We now describe how the feasible subset $\hat{R}_T$ is defined. Consider a subset S of the vertices in the SW quadrant of T. Let $\mathsf{dem}(S)$ denote the number of requests in R_T whose origin is in S. Let $\mathsf{cap}(S)$ denote the capacity of the edges in the network $N(X)$ that emanate from S. By the min-cut max-flow theorem, a set of requests $X \subseteq R_T$ is feasible if and only if $\mathsf{dem}(S) \leq \mathsf{cap}(S)$ for every cut $S \cup \{\tilde{s}\}$ in the network $N(X)$.

In fact, it is not necessary to consider all the cuts. It suffices to consider only axis parallel rectangles contained in the quadrant T. The reason is that without loss of generality, the set S is connected in the underlying undirected graph of the grid (i.e., consider each connected components of S separately). Every "connected" set S can be replaced by the smallest rectangle $Z(S)$ that contains S. We claim that $\mathsf{cap}(S) \geq \mathsf{cap}(Z(S))$ and $\mathsf{dem}(S) \leq \mathsf{dem}(Z(S))$. Indeed, there is an injection from the edges in the cut of $Z(S)$ to the edges in the cut of S. For example, a vertical edge e in the cut of $Z(S)$ is mapped to the topmost edge e' in the cut of S that is in the column of e. Hence, $\mathsf{cap}(Z(S)) \leq \mathsf{cap}(S)$. On the other hand, as $S \subseteq Z(S)$, it follows that $\mathsf{dem}(S) \leq \mathsf{dem}(Z(S))$. Hence if $\mathsf{dem}(S) > \mathsf{cap}(S)$, then $\mathsf{dem}(Z(S)) > \mathsf{cap}(Z(S))$.

We say that a rectangle Z is *overloaded* if $\mathsf{dem}(Z) > \mathsf{cap}(Z)$. The set $\hat{R}_T$ is defined to be the set of requests $r_i \in R_T$ such that the source of r_i is not included in an overloaded rectangle. Namely, $\hat{R}_T \triangleq \{r_i \in R_T \mid \forall \text{ rectangles } Z : Z \text{ is overloaded } \Rightarrow (a_i, t_i) \notin Z\}$. Consider an $x \times y$ rectangle Z. We wish to bound from above the probability that $\mathsf{dem}(Z) > \mathsf{cap}(Z)$. Note that $\mathsf{cap}(Z) = x + y$. Since requests in R_T that start in Z must exit the quadrant, it follows that $\mathsf{dem}(Z)$ is bounded by the number of paths in R_T that cross the top or right side of Z (note that there might be additional paths that do not start in Z but cross Z.). The amount of flow that emanates from Z is bounded by $\lambda \cdot (x+y)$ (the initial capacities are λ and there are $x+y$ edges in the cut). By the randomized rounding procedure, $\mathbf{Pr}[e \in p_i] = f_i(e)$. Summing up over all the edges in the cut of Z and the requests in R_T, the expected number of paths in R_T that cross the cut of Z equals the flow of the request in R_T, which, in turn, is bounded by the capacity $\lambda \cdot (x+y)$. As the paths of the requests are independent random variables, we obtain:[9] $\mathbf{Pr}[\mathsf{dem}(Z) > \mathsf{cap}(Z)] \leq \mathbf{Pr}\left[\sum_{i \in R_T} |p_i \cap cut(Z)| > (x+y)\right] \leq (\lambda \cdot e)^{x+y}$.

For each x, y, each source (a_i, t_i) is contained in at most $x \cdot y$ rectangles with side lengths $x \times y$. By applying a union bound, the probability that (a_i, t_i) is contained in an overloaded rectangle is bounded from above by

$$\begin{aligned}\mathbf{Pr}[\exists \text{ overloaded rectangle } Z : (a_i, t_i) \in Z] &\leq \sum_{x=1}^{\infty}\sum_{y=1}^{\infty} xy \cdot (\lambda \cdot e)^{x+y} \\ &\leq \frac{(\lambda \cdot e)^2}{(1 - \lambda \cdot e)^4} \leq 0.07, \qquad (2)\end{aligned}$$

and the theorem follows. ◀

Routing within the first tile (see Section 5.4) requires however a stronger upper bound on the number of requests that emanate from each side of the quadrant, namely that at most $k/3$ paths reach each side of the quadrant. Using a simple procedure (e.g., taking the solution and greedily eliminating paths) one can have a solution for which this condition holds, and with cardinality only a constant fraction smaller.

[9] Using the following version of the Chernoff bound: $\mathbf{Pr}[X \geq \alpha \cdot \mu] \leq \left(\frac{e}{\alpha}\right)^{\alpha \cdot \mu}$.

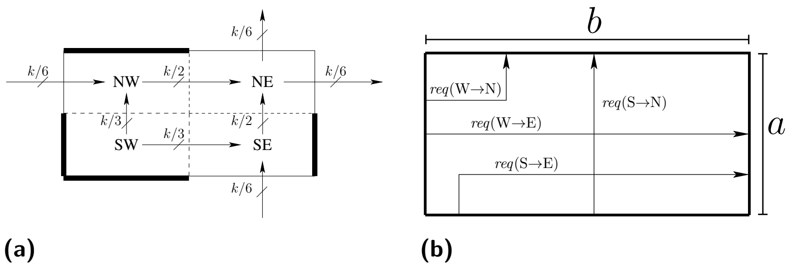

Figure 1 (a) Partitioning of a tile to quadrants [9]. Thick lines represent "walls" that cannot be crosses by paths. Sources may reside only in the SW quadrant of a tile. Maximum flow amounts crossing quadrant sides appears next to each side. Final destinations of paths are assumed (pessimistically) to be in the top row of the NE quadrant. (b) Crossbar routing: flow crossing an $a \times b$ grid [9].

▶ **Corollary 12.** *Let R'_{quad} be the set of quadrant-feasible paths such that at most $k/3$ paths reach each side of each quadrant. Then, $\mathbf{E}_\tau\left[|R'_{quad}|\right] \geq \Omega(1) \cdot \mathbf{E}_\tau\left[|R_{fltr}|\right]$, where τ is the probability space induced by the randomized rounding procedure.*

5.4 Detailed Routing

In this section we deal with computing paths for requests $r_i \in R_{quad}$ starting from the boundary of the SW quadrant that contains the source (a_i, t_i) till the destination row b_i. These paths are concatenated to the paths computed in the first quadrant to obtain the *final* paths of the accepted requests. Detailed routing is based on the following components: (1) The projections of the final path and the path p_i to the sketch graph must coincide. (2) Each tile is partitioned to quadrants and routing rules within a tile are defined. (3) Crossbar routing within each quadrant is applied to determine the final paths (except for routing in SW quadrants in which paths are already assigned).

Sketch paths and routing between tiles. Each path p_i computed by the randomized rounding procedure is projected to a sketch path p^s_i in the sketch graph. The final path $\hat{p}_i$ assigned to request r_i traverses the same sequence of tiles, namely, the projection of $\hat{p}_i$ is also p^s_i.

Routing rules within a tile [6]. Each tile is partitioned to quadrants as depicted in Figure 1a. The bold sides (i.e., "walls") of the quadrants indicate that final paths may not cross these walls. The classification of the requests ensures that source vertices of requests reside only in SW quadrants of tiles. Final paths may not enter the SW quadrants; they may only emanate from them. If the endpoint of a sketch path p^s_i ends in tile T, then the path $\hat{p}_i$ must reach a copy of its destination b_i in T. Reaching the destination is guaranteed by having $\hat{p}_i$ reach the top row of the NE quadrant of T (and thus it must reach the row of b_i along the way).

Crossbar routing. [9]. Routing in each quadrant is simply an instance of routing in a (uni-directional) 2D grid where requests enter from two adjacent sides and exit from the opposite sides. Figure 1b depicts such an instance in which requests arrive from the left and bottom sides and exit from the top and right side. The following claim characterizes when crossbar routing succeeds.

▶ **Claim 13** ([9]). *Consider a 2-dimensional directed $a \times b$ grid. A set of requests can be routed from the bottom and left boundaries of the grid to the opposite boundaries if and only if the number of requests that should exit each side is at most the length of the corresponding side.*

We conclude with the following claim.

▶ **Claim 14.** *Detailed routing succeeds in routing all the requests in R_{quad}.*

Proof sketch. The sketch graph is a directed acyclic graph. Sort the tiles in topological ordering. Within each tile, order the quadrants also in topological order: SW, NW, SE, NE. Prove by induction on the position of the quadrant in the topological ordering that detailed routing up to and including the quadrant succeeds. The claim for all SW quadrants follows because this routing is done along the path that result of the randomized rounding step of the requests in R_{quad}. Now note that filtering ensures that the number of paths between tiles is at most $2\lambda k < k/6$. Routing in the first quadrant ensures that the number of paths emanating from each side of a SW quadrant is at most $k/3$. The induction step follows by applying Claim 13. ◀

5.5 Approximation Ratio

▶ **Theorem 15.** *The approximation ratio of the algorithm for packet requests in $R_{d_{\min},d_{\max}}$, for $d_{\min} = 3 \cdot \ln d_{\max}$, is constant in expectation.*

Proof. We follow the algorithm, as defined in Section 5.1, stage by stage.

Stage 2 computes a fractional maximum multi-commodity flow on a network with reduced edge capacities, and with the requirement that all flows have bounded diameter. By Lemma 3, bounding path lengths in the MCF results in a solution of at least a 1/3 fraction of the unrestricted one, and the scaling of the capacities in the space-time grid results in a solution which is at least a $\lambda = \Omega(1)$ fraction of the latter.

Stage 3 classifies the requests into 4 classes and picks only the one for which the multi-commodity flow solution is the highest, hence resulting in a solution of at least a 1/4 fraction of the solution of the previous stage.

Stage 4 applies a randomized rounding procedure to the flows that are picked in stage 3. The expected size of the solution is equal to the total flow left from the previous stage (but the solution might not be feasible).

Stage 5 applies a filtering procedure to the solution of the previous stage, in order to get a feasible solution on the sketch graph. By Claim 9, the expected size of the feasible solution is at least a $1 - O(1/k)$ fraction of the solution given by stage 4. Observe that $1 - O(1/k) = O(1)$ (in fact $k = \Omega(\log \log n)$ in any relevant invocation of the algorithm).

Stage 6 further reduces the size of the solution when the algorithm selects a subset of the requests that have survived so far, using a maximum flow algorithm applied to each SW quadrant. This is done in order to allow for the solution to be feasible in the original space-time grid. By Corollary 12 the expected size of the solution after this stage is an $\Omega(1)$ fraction of the expected size before this stage.

Stage 7 gives the final routing without further reducing the size of the solution.

We conclude that the algorithm for medium and long requests is a randomized $O(1)$ approximation algorithm (in fact with respect to the fractional optimum). ◀

6 Extensions

6.1 Non-unit Capacities & Buffer Sizes

Our results extend to arbitrary values of B and c, with an (additional) multiplicative penalty in the approximation ratio of $O(B/c)$ in certain cases. In this section we outline the required changes in the algorithm when B/c does not depend on the input size, i.e., $B = \Theta(c)$. For this case, our results will give a randomized approximation algorithm with constant approximation ratio. We now outline the required modifications to handle this case, explaining the modifications in each component of the algorithm, and then the overall structure of the modified algorithm.

Adapting the algorithm for short packets (the exhaustive search algorithm). Exhaustive search for arbitrary B and c can be done in polynomial time provided that the distance of each packet request is at most $\ln(\ell_S)$ (see [11, Lemma 7]). This means that for general B and c there is an additional category of requests, called *very short* requests, on which the exhaustive search will be applied. The remaining packets are divided into short, medium, and long requests, as for the case of $B = c = 1$, and the distance of short requests is lower bounded by $\ln(\ell_S)$.

Adapting the Algorithm for $R_{d_{\min},d_{\max}}$ (for short, medium, and long packets). We adapt the algorithm to the case where $B = c = \gamma$, where $\gamma \in \mathbb{N}^{>0}$. Note that while we consider here non-unit capacities, the flow demands (packets) are not changed, i.e., they remain unit demands. Consider a 3-dimensional view of the grid where there are γ "floors", each floor for a single capacity slice out of γ. This view of the grid partitions the routing problem at hand to γ problems, where at each of them the capacities are unit. Now, apply the algorithm for $R_{d_{\min},d_{\max}}$ on each of these floors. The approximation ratio of the revised algorithm follows from linearity of expectation.

Putting things together. We now describe the general structure of the algorithm for arbitrary B and c. The packets are partitioned into four classes *very short, short, medium,* and *long.* As given above, we have a constant approximation algorithm for very short packets for arbitrary B and c.

For the other three categories, we set both the buffer sizes and link capacities to $\min\{B, c\}$, and apply the (modified) $R_{d_{\min},d_{\max}}$ for the case $B = c$. Observe that the *fractional* optimum incurs a penalty of at most a factor of $O(B/c)$ as a result of this capacity change. Since this algorithm gives a constant approximation compared to the *fractional* optimum, we get an $O(B/c)$-approximation algorithm compared to the optimum on the network with non-modified capacities.

We can now conclude with the following theorem.

▶ **Theorem 16.** *There exists a randomized algorithm for the Max-Pkt-Line problem, such that if $B = O(c)$, then its approximation ratio is a (different) constant.*

6.2 Supporting Soft Deadlines

In this section we argue that if packets have deadlines, we achieve a constant approximation ratio when the produced solution is allowed to miss deadlines by at most $O(\log n)$ time units. This is achieved, simply, by reducing a request with deadlines to a path request which its destination set is a copy of the destination vertex with a time index which is less than the time of the deadline. Since the tiling has "resolution" of at most $O(\log n)$, the detailed routing might "miss" the deadline by the tile's side length.

Note that the algorithm for short requests (or very short for non-unit capacities) can handle requests with deadlines, and achieve the same performance while respecting hard deadlines, because it employs exhaustive search[10].

Abstract

The study of the algorithmic and computational complexity of designing efficient signaling schemes for mechanisms aiming to optimize social welfare or revenue is a recurring theme in recent computer science literature. In reality, however, information is typically not held by a central authority, but is distributed among multiple sources (third-party "mediators"), a fact that dramatically changes the strategic and combinatorial nature of the signaling problem.

In this paper we introduce *distributed signaling games*, while using display advertising as a canonical example for introducing this foundational framework. A distributed signaling game may be a pure coordination game (i.e., a distributed optimization task), or a non-cooperative game. In the context of pure coordination games, we show a wide gap between the computational complexity of the centralized and distributed signaling problems, proving that distributed coordination on revenue-optimal signaling is a much harder problem than its "centralized" counterpart.

In the context of non-cooperative games, the outcome generated by the mediators' signals may have different value to each. The reason for that is typically the desire of the auctioneer to align the incentives of the mediators with his own by a compensation relative to the marginal benefit from their signals. We design a mechanism for this problem via a novel application of Shapley's value, and show that it possesses a few interesting economical properties.

1 Introduction

The topic of signaling has recently received much attention in the computer science literature on mechanism design [2, 4, 6, 5, 7, 12]. A recurring theme of this literature is that proper design of a signaling scheme is crucial for obtaining efficient outcomes, such as social welfare maximization or revenue maximization. In reality, however, sources of information are typically not held by a central authority, but are rather distributed among third party mediators/information providers, a fact which dramatically changes the setup to be studied, making it a game between information providers rather than a more classic mechanism

* This work was done while the authors were at Microsoft Research, Israel.

design problem. Such a game is in the spirit of work on the theory of teams in economics [14], whose computational complexity remained largely unexplored. The goal of this paper is to initiate an algorithmic study of such games, which we term *distributed signaling games*, via what we view as a canonical example: Bayesian auctions; and more specifically, display advertising in the presence of third party external mediators (information providers).

Consider a web-site owner that auctions each user's visit to its site, a.k.a. impression. The impression types are assumed to arrive from a commonly known distribution. The bidders are advertisers who know that distribution, but only the web site owner knows the impression type instantiation, consisting of identifiers such as age, origin, gender and salary of the web-site visitor. As is the practice in existing ad exchanges, we assume the auction is a second price auction. The web-site owner decides on the information (i.e., signal) about the instantiation to be provided to the bidders, which then bid their expected valuations for the impression given the information provided. The selection of the proper signaling by the web-site is a central mechanism design problem. Assume, for example, an impression associated with two attributes: whether the user is male or female on one side, and whether he is located in the US or out of the US on the other side. This gives 4 types of possible users. Assume for simplicity that the probability of arrival of each user type is 1/4, and that there are four advertisers each one of them has value of \$100 for a distinguished user type and \$0 for the other types, where these values are common-knowledge. One can verify that an auctioneer who reveals no information receives an expected payoff of \$25, an auctioneer who reveals all information gets no payoff, while partitioning the impression types into two pairs, revealing only the pair of the impression which was materialized (rather than the exact instantiation) will yield a payoff of \$50, which is much higher revenue.

While the above example illustrates some of the potential benefits of signaling and its natural fit to mechanism design, its major drawback is in the unrealistic manner in which information is manipulated: while some information about the auctioned item is typically published by the ad network [18] (such information is modeled here as a public prior), and despite the advertisers' effort to perform "behavioral targeting" by clever data analysis (e.g., utilizing the browsing history of a specific user to infer her interests), the quantity of available contextual information and market expertise is often way beyond the capabilities of both advertisers and auctioneers. This reality gave rise to "third-party" companies which develop technologies for collecting data and online statistics used to infer the contexts of auctioned impressions (see, e.g., [15] and references therein). Consequently, a new *distributed* ecosystem has emerged, in which many third-party companies operate within the market aiming at maximizing their own utility, while significantly increasing the effectiveness of display advertising, as suggested by the following article recently published by Facebook:

> *"Many businesses today work with third parties such as Acxiom, Datalogix, and Epsilon to help manage and understand their marketing efforts. For example, an auto dealer may want to customize an offer to people who are likely to be in the market for a new car. The dealer also might want to send offers, like discounts for service, to customers that have purchased a car from them. To do this, the auto dealer works with a third-party company to identify and reach those customers with the right offer."*
> (www.facebook.com, "Advertising and our Third-Party Partners", April 10, 2013.)

Hence, in reality sources of information are distributed. Typically, the information is distributed among several mediators or information providers/brokers, and is not held (or mostly not held) by a central authority. In the display advertising example, one information source may know the gender and another may know the location of the web-site visitor, while the web-site itself often lacks the capability to track such information. The information sources need to decide on the communicated information. In this case the information sources become players in a game. To make the situation clearer, assume (as above) that the value of each impression type for each bidder is public-knowledge (as is typically the case in repeated interactions through ad exchanges which share their logs with the participants), and the only unknown entity is the instantiation of the impression type; given the information learned from the information sources each bidder will bid his true expected valuation; hence, the results of this game are determined solely by the information providers. Notice that if, in the aforementioned example, the information provider who knows the gender reveals it while the other reveals nothing, then the auctioneer receives a revenue of \$50 as in the centralized case, while the cases in which both information providers reveal their information or none of them do so result in lower revenues. This shows the subtlety of the situation.

The above suggests that a major issue to tackle is the study of *distributed signaling games*, going beyond the realm of classical mechanism design. We use a model of the above display advertising setting, due to its centrality, as a tool to introduce this novel foundational topic. The distributed signaling games may be pure coordination games (a.k.a. distributed optimization), or non-cooperative games. In the context of pure coordination games each information source has the same utility from the output created by their joint signal. Namely, in the above example if the web-site owner pays each information source proportionally to the revenue obtained by the web-site owner then the aims of the information sources are identical. The main aim of the third parties/mediators is to choose their signals based on their privately observed information in a distributed manner in order to optimize their own payoffs. Notice that in a typical embodiment, which we adapt, due to both technical and legal considerations, the auctioneer does not synthesize reported signals into new ones nor the information providers are allowed to explicitly communicate among them about the signals, but can only broadcast information they individually gathered. The study of the computational complexity of this highly fundamental problem is the major technical challenge tackled in this paper. Interestingly, we show a wide gap between the computational complexity of the centralized and distributed setups, proving that coordinating on optimal signaling is a much harder problem than the one discussed in the context of centralized mechanism design. On the other hand we also show a natural restriction on the way information is distributed among information providers, which allows for an efficient constant approximation scheme.

In the context of non-cooperative games the outcome generated by the information sources' reports may result in a different value for each of them. The reason for that is typically the desire of the auctioneer to align the incentives of the mediators with his own by a compensation relative to the marginal benefit from their signals. In the above example one may compare the revenue obtained without the additional information sources, to what is obtained through their help, and compensate relatively to the Shapley values of their contributions, which is a standard (and rigorously justified) tool to fully divide a gain yielded by the cooperation of several parties. Here we apply such division to distributed signaling games, and show that it possesses some interesting properties: in particular the corresponding game has a pure strategy equilibrium, a property of the Shapley value which is shown for the first time for signaling settings (and is vastly different from previous studies of Shapley mechanisms in non-cooperative settings such as cost-sharing games [16]).

1.1 Model

Our model is a generalization of the one defined in [11]. There is a ground set $I = [n]$ of potential items (contexts) to be sold and a set $B = [k]$ of bidders. The value of item j for bidder i is given as v_{ij}. Following the above discussion (and the previous line of work, e.g., [8, 11]), we assume the valuation matrix $V = \{v_{i,j}\}$ is publicly known. An auctioneer is selling a single random item j_R, distributed according to some publicly known prior distribution μ over I, using a second price auction (a more detailed description of the auction follows). There is an additional set $M = [m]$ of "third-party" mediators. Following standard practice in game theoretic information models [1, 9, 7], we assume each mediator $t \in M$ is equipped with a *partition* (signal-set) $\mathcal{P}_t \in \Omega(I)$[1]. Intuitively, $\mathcal{P}_t$ captures the extra information t has about the item which is about to be sold – he knows the set $S \in \mathcal{P}_t$ to which the item j_R belongs, but has no further knowledge about which item of S it is (except for the a priori distribution μ) – in other words, the distribution t has in mind is $\mu|_S$. For example, if the signal-set partition $\mathcal{P}_t$ partitions the items of I into pairs, then mediator t knows to which pair $\{j_1, j_2\} \in \mathcal{P}_t$ the item j_R belongs, but he has no information whether it is j_1 or j_2, and therefore, from her point of view, $\Pr[j_R = j_1] = \mu(j_1)/\mu(\{j_1, j_2\})$.

Mediators can signal some (or all) of the information they own to the network. Formally, this is represented by allowing each mediator t to report *any* super-partition $\mathcal{P}'_t$, which is obtained by merging partitions in her signal-set partition $\mathcal{P}_t$ (in other words $\mathcal{P}_t$ must be a refinement of $\mathcal{P}'_t$). In other words, a mediator may report any partition $\mathcal{P}'_t$ for which there exists a set $\mathcal{Q}'_t \in \Omega(\mathcal{P}_t)$ such that $\mathcal{P}'_t = \{\cup_{S \in A} S \mid A \in \mathcal{Q}'_t\}$. In particular, a mediator can always report $\{I\}$, in which case we say that he remains silent since he does not contribute any information. The signals $\mathcal{P}'_1, \mathcal{P}'_2, \ldots, \mathcal{P}'_m$ reported by the mediators are *broadcasted*[2] to the bidders, inducing a combined partition $\mathcal{P} \triangleq \times_{t=1}^{m} \mathcal{P}'_t = \{\cap_{i \in M} A_i \mid A_i \in \mathcal{P}'_i\}$, which we call the *joint partition* (or *joint signal*). $\mathcal{P}$ splits the auction into separate "restricted" auctions. For each bundle $S \in \mathcal{P}$, the item j_R belongs to S with probability $\mu(S) = \sum_{j \in S} \mu(j)$, in which case S is signaled to the bidders and a second-price auction is performed over $\mu|_S$. Notice that if the signaled bundle is $S \subseteq I$, then the (expected) value of bidder i for $j_R \sim \mu|_S$ is $v_{i,S} = \frac{1}{\mu(S)} \sum_{j \in S} (\mu(j) \cdot v_{ij})$, and the truthfulness of the second price auction implies that this will also be bidder i's bid for the restricted auction. The winner of the auction is the bidder with the maximum bid $\max_{i \in B} v_{i,S}$, and he is charged the second highest valuation for that bundle $\max^{(2)}_{i \in B} v_{i,S}$. Therefore, the auctioneer's revenue with respect to $\mathcal{P}$ is the expectation (over $S \in_R \mathcal{P}$) of the price paid by the winning bidder: $R(\mathcal{P}) = \sum_{S \in \mathcal{P}} [\mu(S) \cdot \max^{(2)}_{i \in B}(v_{i,S})]$.

The joint partition $\mathcal{P}$ signaled by the mediators can dramatically affect the revenue of the auctioneer. Consider, for example, the case where V is the 4×4 identity matrix, μ is the uniform distribution, and M consists of two mediators associated with the partitions $\mathcal{P}_1 = \{\{1, 2\}\ ,\ \{3, 4\}\}$ and $\mathcal{P}_2 = \{\{1, 3\}\ ,\ \{2, 4\}\}$. If both mediators remain silent, the revenue is $R(\{I\}) = 1/4$ (as this is the average value of all 4 bidders for a random item). However, observe that $\mathcal{P}_1 \times \mathcal{P}_2 = \{\{1\}, \{2\}, \{3\}, \{4\}\}$, and the second highest value in every column of V is 0, thus, if both report their partitions, the revenue drops to $R(\mathcal{P}_1 \times \mathcal{P}_2) = 0$. Finally, if mediator 1 reports $\mathcal{P}_1$, while meditor 2 keeps silent, the revenue increases from 1/4 to $R(\mathcal{P}_1) = 1/2$, as the value of each pair of items is 1/2 for two different bidders (thus, the second highest price for each pair is 1/2). This example can be easily generalized to show

[1] For a set S, $\Omega(S) \triangleq \{\mathcal{A} \subseteq 2^S \mid \bigcup_{A \in \mathcal{A}} A = S, \forall_{A,B \in \mathcal{A}} A \cap B = \varnothing\}$ is the collection of all partitions of S.

[2] By saying that a mediator reports $\mathcal{P}'_t$, we mean that he reports the bundle $S \in \mathcal{P}'_t$ for which $j_R \in S$. The reader may wonder why our model is a broadcast model, and does not allow the mediators to report their information to the auctioneer through private channels, in which case the ad network will be able to manipulate and publish whichever information that best serves its interest. The primary reason for the broadcast assumption is that online advertising is a highly dynamic marketplace in which mediators often "come and go", so implementing "private contracts" is infeasible. The second reason is that real-time bidding environments cannot afford the latency incurred by such a two-phase procedure in which the auctioneer first collects the information, and then selectively publishes it. The auction process is usually treated as a "black box", and modifying it harms the modularity of the system.

that in general the intervention of mediators can increase the revenue by a factor of $n/2$!

Indeed, the purpose of this paper is to understand how mediators' (distributed) signals affect the revenue of the auctioneer. We explore the following two aspects of this question:

1. (Computational) Suppose the auctioneer has control over the signals reported by the mediators. We study the computational complexity of the following problem. *Given a $k \times n$ matrix V of valuations and mediators' partitions $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_m$, what is the revenue maximizing joint partition $\mathcal{P} = \mathcal{P}'_1 \times \ldots \times \mathcal{P}'_m$?* We call this problem the *Distributed Signaling Problem*, and denote it by $\mathbf{DSP}(n, k, m)$.
   We note that the problem studied in [11] is a special case of **DSP**, in which there is a *single* mediator ($m = 1$) with *perfect knowledge* about the item sold and can report any desirable signal (partition).[3]
2. (Strategic) What if the auctioneer cannot control the signals reported by the mediators (as the reality of the problem usually entails)? *Can the auctioneer introduce compensations that will incentivize mediators to report signals leading to increased revenue in the auction, when each mediator is acting selfishly?*
   This is a mechanism design problem: Here the auctioneer's goal is to design a payment rule (i.e., a mechanism) for allocating (part of) his profit from the auction among the mediators, based on their reported signals and the auction's outcome, so that global efficiency (i.e., maximum revenue) emerges from their signals.

Section 1.2 summarizes our findings regarding the two above problems.

1.2 Our Results

Ghosh et al. [11] showed that computing the revenue-maximizing signal in their "perfect-knowledge" setup is NP-hard, but present an efficient algorithm for computing a 2-approximation of the optimal signal (partition). We show that when information is distributed, the problem becomes much harder. More specifically, we present a gap-preserving reduction from the *Maximum Independent Set* problem to **DSP**.

▶ **Theorem 1.1** (Hardness of approximating **DSP**). *If there exists an $O(m^{1/2-\varepsilon})$ approximation (for some constant $\varepsilon > 0$) for instances of $\mathbf{DSP}(2m, m+1, m)$, then there exists a $O(N^{1-2\varepsilon})$ approximation for Maximum Independent Set (MIS$_N$), where N is the number of nodes in the underlying graph of the MIS instance.*

Since the Maximum Independent Set problem is NP-hard to approximate to within a factor of $n^{1-\rho}$ for any fixed $\rho > 0$ [13], Theorem 1.1 indicates that approximating the revenue-maximizing signal, even within a multiplicative factor of $O((\min\{n, k, m\})^{1/2-\varepsilon})$, is NP-hard. In other words, one cannot expect a reasonable approximation ratio for $\mathbf{DSP}(n, k, m)$ when the three parameters of the problem are all "large". The next theorem shows that a "small" value for either one of the parameters n or k indeed implies a better approximation ratio.

▶ **Theorem 1.2** (Approximation algorithm for small n or k). *For $k \geq 2$, there is a polynomial time $\min\{n, k-1\}$-approximation algorithm for $\mathbf{DSP}(n, k, m)$.*[4]

We leave open the problem of determining whether one can get an improved approximation ratio when the parameter m is "small". For $m = 1$, the result of [11] implies immediately

[3] In other words, $\mathcal{P}_1$ is the partition of I into singletons.
[4] For $k = 1$, any algorithm is optimal since the use of a second price auction implies that the revenue of any strategy profile is 0 when there is only one bidder.

a 2-approximation algorithm. However, even for the case of $m = 2$ we are unable to find an algorithm having a non-trivial approximation ratio. We mitigate the above results by proving that for a natural (and realistic) class of mediators called *local experts* (defined in Section 3), there exists a polynomial time 5-approximation algorithm for **DSP**.

▶ **Theorem 1.3** (A 5-approximation algorithm for Local Expert mediators)**.** *If mediators are local experts, there exists a polynomial time* 5*-approximation algorithm for* **DSP***.*

In the strategic setup, we design a fair (symmetric) payment rule $\mathcal{S} : (\mathcal{P}'_1, \mathcal{P}'_2, ..., \mathcal{P}'_m) \to \mathbb{R}^m_+$ for incentivizing mediators to report useful information they own, and refrain from reporting information with negative impact on the revenue. This mechanism is inspired by the *Shapley Value* – it distributes part of the auctioneer's surplus among the mediators according to their expected relative marginal contribution to the revenue, when ordered randomly.[5] We first show that this mechanism always admits a *pure* Nash equilibrium, a property we discovered to hold for arbitrary games where the value of the game is distributed among players according to Shapley's value function.

▶ **Theorem 1.4.** *Let $\mathcal{G}_m$ be a non-cooperative m-player game in which the payoff of each player is set according to $\mathcal{S}$. Then $\mathcal{G}_m$ admits a pure Nash equilibrium. Moreover, best response dynamics are guaranteed to converge to such an equilibrium.*

We then turn to analyze the revenue guarantees of our mechanism $\mathcal{S}$. Our first theorem shows that using the mechanism $\mathcal{S}$ never decreases the revenue of the auctioneer compared to the initial state (i.e., when all mediators are silent).

▶ **Theorem 1.5.** *For every Nash equilibrium $(\mathcal{P}'_1, \mathcal{P}'_2, \ldots, \mathcal{P}'_m)$ of $\mathcal{S}$, $R(\times_{t\in M}\mathcal{P}'_t) \geq R(\{I\})$.*

The next two theorems provide tight bounds on the *price of anarchy* and *price of stability* of $\mathcal{S}$.[6] Unlike in the computational setup, even restricting the mediators to be local experts does not enable us to get improved results here.

▶ **Theorem 1.6.** *For $k \geq 2$, the price of anarchy of $\mathcal{S}$ under any instance* $\mathbf{DSP}(n, k, m)$ *is no more than* $\min\{k - 1, n\}$*.*

▶ **Theorem 1.7.** *For every $n \geq 1$, there is a* $\mathbf{DSP}(3n + 1, n + 2, 2)$ *instance for which the price of stability of $\mathcal{S}$ is at least n. Moreover, all the mediators in this instance are local experts.*

Interestingly, an adaptation of Shapley's uniqueness theorem [17] to our non-cooperative setting asserts that the price of anarchy of our mechanism is inevitable if one insists on a few natural requirements – essentially anonymity and efficiency[7] of the payment rule – and assuming the auctioneer alone can introduce payments. We discuss this further in the full version of this paper [10].

[5] Shapley's value was originally introduced in the context of cooperative games, where there is a well defined notion of a coalition's value. In order to apply this notation to a non-cooperative game, we assume the game has some underlying global function ($v(\cdot)$) assigning a value to every strategy profile of the players, and the Shapley value of each player is defined with respect to $v(\cdot)$. In this setting, a "central planner" (the auctioneer in our case) is the one making the utility transfer to the "coalised" players. For the formal axiomatic definition of a value function and Shapley's value function, see [17].

[6] The price of anarchy (stability) is the ratio between the revenue of the optimum and the worst (best) Nash equilibrium.

[7] I.e., the sum of payments is equal to the total surplus of the auctioneer.

1.3 Additional Related Work

The formal study of internet auctions with contexts was introduced by [8] where the authors studied the impact of contexts in the related Sponsored Search model, and showed that *bundling contexts* may have a significant impact on the revenue of the auctioneer. The subsequent work of Ghosh et al. [11] considered the computational algorithmic problem of computing the revenue maximizing partition of items into bundles, under a second price auction in the full information setting. Recently, Emek et al. [7] and Bro Miltersen and Sheffet [2] studied signaling (which generalizes bundling) in the context of display advertising. They explore the computational complexity of computing a signaling scheme that maximizes the auctioneer's revenue in a Bayesian setting. On the other hand, Guo and Deligkas [12] studied a special case of bundling where only "natural" bundles are allowed. Unlike our distributed setup, all the above models are *centralized*, in the sense that the auctioneer has full control over the bundling process (which in our terms corresponds to having a single mediator with a perfect knowledge about the item sold).

A different model with knowledgeable third parties was recently considered by Cavallo et al. [3]. However, the focus of this model is completely different then ours. More specifically, third parties in this model use their information to estimate the clicks-per-impression ratio, and then use this estimate to bridge between advertisers who would like to pay-by-click and ad networks which use a pay-by-impression payment scheme.

2 Preliminaries

Throughout the paper we use capital letters for sets and calligraphic letters for set families. For example, the partition $\mathcal{P}_t$ representing the knowledge of mediator t is a set of sets, and therefore, should indeed be calligraphic according to this notation. A mechanism $\mathcal{M}$ is a tuple of payment functions $(\Pi_1, \Pi_2, \ldots, \Pi_m)$ determining the compensation of every mediator given a strategy profile (i.e., $\Pi_t : \Omega(\mathcal{P}_1) \times \Omega(\mathcal{P}_2) \times \ldots \times \Omega(\mathcal{P}_m) \longrightarrow \mathbb{R}^+$). Every mechanism $\mathcal{M}$ induces the following game between mediators.

▶ **Definition 2.1** (**DSP** game). Given a mechanism $\mathcal{M} = (\Pi_1, \Pi_2, \ldots, \Pi_m)$ and an instance $\mathbf{DSP}(n, k, m)$, the $\mathbf{DSP}_{\mathcal{M}}(n, k, m)$ game is defined as follows. Every mediator $t \in M$ is a player whose strategy space consists of all partitions $\mathcal{P}'_t$ for which $\mathcal{P}_t$ is a refinement. Given a strategy profile $\mathcal{P}'_1, \mathcal{P}'_2, \ldots, \mathcal{P}'_m$, the payoff of mediator t is $\Pi_t(\mathcal{P}'_1, \mathcal{P}'_2, \ldots, \mathcal{P}'_m)$.

Given a **DSP** instance and a set $S \subseteq I$, we use the shorthand $v(S) := \max^{(2)}_{i \in B}(v_{i,S})$ to denote the second highest bid in the restricted auction $\mu|_S$. Using this notation, the expected revenue $R(\mathcal{P})$ of the auctioneer under the (joint) partition $\mathcal{P}$ of the mediators can be restated as $R(\mathcal{P}) = \sum_{S \in \mathcal{P}} \mu(S) \cdot v(S)$.

For a $\mathbf{DSP}_{\mathcal{M}}$ game, let $\mathcal{E}(\mathcal{M})$ denote the set of Nash equilibria of this game and let $\mathcal{P}^*$ be a maximum revenue strategy profile. The *Price of Anarchy* and *Price of Stability* of $\mathbf{DSP}_{\mathcal{M}}$ are defined as:

$$\mathsf{PoA} := \max_{\mathcal{P} \in \mathcal{E}(\mathcal{M})} \frac{R(\mathcal{P}^*)}{R(\mathcal{P})} \ , \qquad \text{and} \qquad \mathsf{PoS} := \min_{\mathcal{P} \in \mathcal{E}(\mathcal{M})} \frac{R(\mathcal{P}^*)}{R(\mathcal{P})} \ ,$$

respectively. Notice that our definition of the price of anarchy and price of stability differs from the standard one by using revenue instead of social welfare.

Paper Organization. The proofs of our results for the computational and strategic setups are given in Sections 3 and 4, respectively. Unfortunately, due to space constraints, many proof are omitted from these sections, and are deferred to the full version of this paper [10]. Section 5 summarizes our contributions and discusses possible avenues for future research.

3 The Computational Complexity of Distributed Signaling (DSP)

This section explores **DSP** from a pure combinatorial optimization viewpoint. In other words, we assume the auctioneer can control the signals produced by each mediator. The objective of the auctioneer is then to choose a distributed strategy profile $\mathcal{P}'_1, \mathcal{P}'_2, \ldots, \mathcal{P}'_m$ whose combination $\times_t \mathcal{P}'_t$ yields maximum revenue in the resulting auction. In light of Theorem 1.1, an efficient algorithm with a reasonable approximation guarantee for general **DSP** is unlikely to exist when the three parameters of the problem are all "large". Subsection 3.1 gives a trivial algorithm which has a good approximation guarantee when either n or k is small. A more interesting result is given in Subsection 3.2, which proves a 5-approximation algorithm for **DSP** under the assumption that the mediators are *local experts*. Due to space constraints, the proof of our negative result (i.e., Theorem 1.1) is omitted from this extended abstract.

3.1 A Simple $\min\{n, k-1\}$-Approximation Algorithm for DSP

In this section we prove the following theorem:

▶ **Theorem 1.2.** *For $k \geq 2$, there is a polynomial time* $\min\{n, k-1\}$*-approximation algorithm for* $\mathbf{DSP}(n, k, m)$.

Proof. We show that the algorithm that simply returns the partition $\{I\}$, the joint partition corresponding to the case where all mediators are silent, has the promised approximation guarantee. For that purpose we analyze the revenue of $\{I\}$ in two different ways:

- Let $\mathcal{P}' = (\mathcal{P}'_1, \mathcal{P}'_2, \ldots, \mathcal{P}'_m)$ be an arbitrary strategy profile of the instance in question. The revenue of $\mathcal{P}'$ is:

$$\begin{aligned} R(\times_{t=1}^m \mathcal{P}'_t) &= \sum_{S \in \times_{t=1}^m \mathcal{P}'_t} \mu(S) \cdot v(S) \leq |\times_{t=1}^m \mathcal{P}'_t| \cdot \max_{S \in \times_{t=1}^m \mathcal{P}'_t} \mu(S) \cdot v(S) \\ &\leq n \cdot \max_{S \in \times_{t=1}^m \mathcal{P}'_t} \mu(S) \cdot v(S) \leq n \cdot R(\{I\}) \ , \end{aligned}$$

  where the last inequality holds since, for every set S, $R(\{I\}) = v(I) \geq v(S) \cdot \mu(S)$. This shows that the approximation ratio of the trivial strategy profile $\{I\}$ provides an n-approximation to the optimal revenue.

- Let $\mathcal{P}' = (\mathcal{P}'_1, \mathcal{P}'_2, \ldots, \mathcal{P}'_m)$ be an arbitrary strategy profile of the instance in question. The revenue of $\mathcal{P}'$ is:

$$\begin{aligned} R(\times_{t=1}^m \mathcal{P}'_t) &= \sum_{S \in \times_{t=1}^m \mathcal{P}'_t} \mu(S) \cdot v(S) = \sum_{S \in \times_{t=1}^m \mathcal{P}'_t} \mu(S) \cdot \left(\max{}^{(2)}_{i \in B} \frac{\sum_{j \in S} \mu(j) \cdot v_{i,j}}{\mu(S)} \right) \\ &= \sum_{S \in \times_{t=1}^m \mathcal{P}'_t} \left(\max{}^{(2)}_{i \in B} \sum_{j \in S} \mu(j) \cdot v_{i,j} \right) \ . \end{aligned}$$

  For every bidder $i \in B$, let $\Sigma_i = \sum_{j \in I} \mu(j) \cdot v_{ij}$. It is easy to see that $v(I) = \max^{(2)}_{i \in B} \Sigma_i$ (in other words, the second highest Σ_i value is $v(I)$). Let $i^* \in B$ be the index maximizing Σ_{i^*} (breaking ties arbitrary). Consider a set $S \in \times_{t=1}^m \mathcal{P}'_t$. The elements of S contribute at least $\max^{(2)}_{i \in B} \sum_{j \in S} \mu(j) \cdot v_{i,j}$ to at least two of the values: $\Sigma_1, \ldots, \Sigma_n$. Thus, they contribute at least the same quantity to the sum $\sum_{i \in B \setminus \{i^*\}} \Sigma_i$. This means that at least one of the values $\{\Sigma_i\}_{i \in B \setminus \{i^*\}}$ must be at least:

$$\frac{\sum_{S \in \times_{t=1}^m \mathcal{P}'_t} \left(\max^{(2)}_{i \in B} \sum_{j \in S} \mu(j) \cdot v_{i,j} \right)}{k-1} = \frac{R(\times_{t=1}^m \mathcal{P}'_t)}{k-1} .$$

By definition Σ_{i^*} must also be at least that large, and therefore, $R(\{I\}) = v(I) \geq R(\times_{t=1}^m \mathcal{P}'_t)/(k-1)$. ◀

3.2 A 5-Approximation Algorithm for Local Expert Mediators

In this subsection we consider an interesting special case of **DSP** which is henceforth shown to admit a constant factor approximation.

▶ **Definition 3.1** (Local Expert mediators). A mediator t in a **DSP** instance is a *local expert* if there exists a set $I_t \subseteq I$ such that: $\mathcal{P}_t = \{\{j\} \mid j \in I_t\} \cup \{I \setminus I_t\}$.

Informally, a local expert mediator has perfect knowledge about a single set I_t – if the item belongs to I_t, he can tell exactly which item it is. In other words, a local expert mediator specializes in some kind of items to the extent that it knows everything about this kind of items, and nothing at all about other kinds of items. Our objective in the rest of the section is to prove Theorem 1.3, i.e., to describe a 5-approximation algorithm for instances of **DSP** consisting of only local expert mediators.

We begin the proof with an upper bound on the revenue of the optimal joint strategy, which we denote by $\mathcal{P}^*$. To describe this bound, we need some notation. We use $\hat{I}$ to denote the set of items that are within the experty field of some mediator (formally, $\hat{I} = \bigcup_{t \in M} I_t$). Additionally, for every item $j \in I$, h_j and s_j denote $\mu(j)$ times the largest value and second largest value, respectively, of j for any bidder (more formally, $h_j = \mu(j) \cdot \max_{i \in B} v_{i,j}$ and $s_j = \mu(j) \cdot \max^{(2)}_{i \in B} v_{i,j}$).

Next, we need to partition the items into multiple sets. The optimal joint partition $\mathcal{P}^*$ is obtained from partitions $\{\mathcal{P}^*_t\}_{t \in M}$, where $\mathcal{P}^*_t$ is a possible partition for mediator t. Each part of $\mathcal{P}^*$ is the intersection of $|M|$ parts, one from each partition in $\{\mathcal{P}^*_t\}_{t \in M}$. On the other hand, each part of $\mathcal{P}^*_t$ is a subset of I_t, except for maybe a single part. Hence, there exists at most a single part $I_0 \in \mathcal{P}^*$ such that $I_0 \not\subseteq I_t$ for any $t \in M$. For ease of notation, if there is no such part (which can happen when $\hat{I} = I$) we denote $I_0 = \varnothing$. To partition the items of $I \setminus I_0$, we associate each part $S \in \mathcal{P}^* \setminus \{I_0\}$ with an arbitrary mediator t such that $S \subseteq I_t$, and denote by A_t the set of items of all the parts associated with mediator t. Observe that the construction of A_t guarantees that $A_t \subseteq I_t$. Additionally, $\{I_0\} \cup \{A_t\}_{t \in M}$ is a disjoint partition of I.

A different partition of the items partitions them according to the bidder that values them the most. In other words, for every $1 \leq i \leq k$, H_i is the set of items for which bidder i has the largest value. If multiple bidders have the same largest value for an item, we assign it to the set H_i of an arbitrary one of these bidders. Notice that the construction of H_i guarantees that the sets $\{H_i\}_{i \in B}$ are disjoint.

Finally, for every set $S \subseteq I$, we use $\phi(S)$ to denote the sum of the $|B| - 1$ smaller values in $\{\sum_{j \in H_i \cap S} h_j\}_{i \in B}$, i.e., the sum of all the values except the largest one. In other words, we calculate for every bidder i the sum of its values for items in $H_i \cap S$, and then add up the $|B| - 1$ smaller sums. Using all the above notation we can now state our promised upper bound on $R(\mathcal{P}^*)$.

▶ **Lemma 3.2.** $R(\mathcal{P}^*) \leq \mu(I_0) \cdot v(I_0) + \sum_{j \in \hat{I}} s_j + \sum_{t \in M} \phi(A_t)$.

Proof. Fix an arbitrary mediator $t \in M$, and let i be the bidder whose term is not counted by $\phi(A_t)$. For every part $S \in \mathcal{P}^*$ associated with t, let i' be a bidder other than i that has one of the two largest bids for S. By definition:

$$\mu(S) \cdot v(S) = \max^{(2)}_{i'' \in B} \sum_{j \in S} \mu(j) \cdot v_{i'',j} \leq \sum_{j \in S} \mu(j) \cdot v_{i',j} \leq \sum_{j \in S \cap H_i} s_j + \sum_{j \in S \setminus H_i} h_j \ .$$

Summing over all parts associated with t, we get:

$$\sum_{\substack{S \in \mathcal{P}^* \\ S \subseteq A_t}} \mu(S) \cdot v(S) \leq \sum_{j \in A_t \cap H_i} s_j + \sum_{j \in A_t \setminus H_i} h_j \leq \sum_{j \in A_t} s_j + \phi(A_t) \ .$$

Summing over all mediators, we get:

$$R(\mathcal{P}^*) - \mu(I_0) \cdot v(I_0) \leq \sum_{t \in M} \left(\sum_{j \in A_t} s_j + \phi(A_t) \right) \leq \sum_{j \in \hat{I}} s_j + \sum_{t \in M} \phi(A_t) \ . \qquad ◀$$

Our next step is to describe joint partitions that can be found efficiently and upper bound the different terms in the bound given by Lemma 3.2 (up to a constant factor). Finding such partitions for the first two terms is quite straightforward.

▶ **Observation 3.3.** *The joint partitions where all mediators are silent $\{I\} = \times_{i \in B}\{I\}$ obeys: $R(\{I\}) \geq \mu(I_0) \cdot v(I_0)$.*

Proof.

$$R(\{I\}) = \max^{(2)}_{i \in B} \left(\sum_{j \in I} \mu(j) \cdot v_{i,j} \right) \geq \max^{(2)}_{i \in B} \left(\sum_{j \in I_0} \mu(j) \cdot v_{i,j} \right) = \mu(I_0) \cdot v(I_0) \ . \qquad ◀$$

▶ **Observation 3.4.** *The joint partitions $\mathcal{P}_S = \times_{t \in M} \mathcal{P}_t$ where every mediator reports all his information obeys:*

$$R(\mathcal{P}_S) = R(\{\{j\}_{j \in \hat{I}}\} \cup \{I \setminus \hat{I}\}) \geq \sum_{j \in \hat{I}} \mu(j) \cdot \max^{(2)}_{i \in B} v_{i,j} = \sum_{j \in \hat{I}} s_j \ .$$

It remains to find a joint partition that upper bounds, up to a constant factor, the third term in the bound given by Lemma 3.2. If one knows the sets $\{A_t\}_{t \in M}$, then one can easily get such a partition using the method of Ghosh et al. [11]. In this method, one partitions every set A_t into the parts $\{A_t \cap H_i\}_{i=1}^t$ and sort these parts according to the value of $\sum_{j \in A_t \cap H_i} h_j$. Then, with probability $1/2$ every even part is united with the part that appears after it in the above order, and with probability $1/2$ it is united with the part that appears before it in this order. It is not difficult to verify that if the part of bidder i is not the first in the order, then with probability $1/2$ it is unified with the part that appears before it in the order, and then it contributes $\sum_{j \in A_t \cap H_i} h_j$ to the revenue. Hence, the expected contribution to the revenue of the parts produced from A_t is at least $1/2 \cdot \phi(A_t)$.

Algorithm 1 can find a partition that is competitive against $\sum_{t \in M} \phi(A_t)$ without knowing the sets $\{A_t\}_{t \in M}$. The algorithm uses the notation of a *cover*. We say that a set S_j is a cover of an element $j \in I_t \cap H_i$ if $S_j \subseteq I_t \cap H_{i'}$ for some $i \neq i'$.

Notice that the definition of cover guarantees that a part containing both j and S_j contributes to the revenue at least $\min\{h_j, \sum_{j' \in S_j h_{j'}}\}$. Using this observation, each iteration of Algorithm 1 can be viewed as trying to extract revenue from element j. Additionally, observe that the partition $\mathcal{P}$ produced by Algorithm 1 can be presented as a joint partition since every part in it, except for $I \setminus \hat{I}$, contains only items that belong to a single set I_t (for some mediator $t \in M$).

Algorithm 1: Local Experts - Auxiliary Algorithm

```
1 Let $I' \leftarrow \hat{I}$ and $\mathcal{P} \leftarrow \{I \setminus \hat{I}\}$.
2 while $I' \neq \varnothing$ do
3     Let $j$ be the element maximizing $h_j$ in $I'$.
4     Find a cover $S_j \subseteq I'$ of $j$ obeying $h_j \leq \sum_{j' \in S_j} h_{j'} \leq 2h_j$, or maximizing $\sum_{j' \in S_j} h_{j'}$
       if no cover of $j$ makes this expression at least $h_j$.
5     Add the part $S_j \cup \{j\}$ to $\mathcal{P}$, and remove the elements of $S_j \cup \{j\}$ from $I'$.
6 return $\mathcal{P}$
```

▶ **Observation 3.5.** *Algorithm 1 can be implemented in polynomial time.*

Proof. One can find a cover S_j maximizing $\sum_{j' \in S_j} h_{j'}$ in line 4 of the algorithm by considering the set $I_t \cap H_{i'} \cap I'$ for every mediators t and bidder i' obeying $j \in I_t$ and $j \notin H_{i'}$. Moreover, if this cover is of size larger than $2h_j$, then by removing elements from this cover one by one the algorithm must find a cover S'_j obeying $h_j \leq \sum_{j' \in S'_j} h_{j'} \leq 2h_j$ because j is the element maximizing h_j in I'. ◀

The following lemma relates the revenue of the set produced by Algorithm 1 to the sum $\sum_{t \in M} \phi(A_t)$.

▶ **Lemma 3.6.** *No iteration of the loop of Algorithm 1 decreases the value of the expression* $R(\mathcal{P}) + 1/3 \cdot \sum_{t \in M} \phi(A_t \cap I')$.[8]

Proof. Fix an arbitrary iteration. There are two cases to consider. First, assume $h_j \leq \sum_{j' \in S_j} h_{j'} \leq 2h_j$. In this case the increase in $R(\mathcal{P})$ during this iteration is:

$$\mu(S_j \cup \{j\}) \cdot v(S_j \cup \{j\}) \geq \min\left\{h_j, \sum_{j' \in S_j} h_{j'}\right\} = h_j \quad .$$

On the other hand, one can observe that, when removing an element j' from S, the value of $\phi(S)$ can decrease by at most $h_{j'}$. Hence, the decrease in $\sum_{t \in M} \phi(A_t \cap I')$ during this iteration can be upper bounded by: $h_j + \sum_{j' \in S_j} h_{j'} \leq 3h_j$.

Consider now the case $\sum_{j' \in S_j} h_{j'} < h_j$. In this case the increase in $R(\mathcal{P})$ during the iteration is:

$$\mu(S_j \cup \{j\}) \cdot v(S_j \cup \{j\}) \geq \min\left\{h_j, \sum_{j' \in S_j} h_{j'}\right\} = \sum_{j' \in S_j} h_{j'} \quad .$$

If j does not belong to A_t for any mediator t, then by the above argument we can bound the decrease in $\sum_{t \in M} \phi(A_t \cap I')$ by $\sum_{j' \in S_j} h_{j'}$. Hence, assume from now on that there exists a mediator t' and a bidder i such that $j \in A_{t'} \cap H_i$. Let $i' \neq i$ be a bidder maximizing $\sum_{j' \in H_{i'} \cap A_{t'} \cap I'} h_{j'}$. Clearly, the removal of a single element from I' can decrease $\phi(A_{t'} \cap I')$ by no more than $\sum_{j' \in H_{i'} \cap A_{t'} \cap I'} h_{j'}$. Hence, the decrease in $\sum_{t \in M} \phi(A_t \cap I')$ during the iteration of the algorithm can be upper bounded by:

$$\sum_{j' \in H_{i'} \cap A_{t'} \cap I'} h_{j'} + \sum_{j' \in S_j} h_{j'} \quad .$$

[8] Before the algorithm terminates $\mathcal{P}$ is a partial partition in the sense that some items do not belong to any part in it. However, the definition of $R(\mathcal{P})$ naturally extends to such partial partitions.

On the other hand, $H_{i'} \cap A_{t'} \cap I'$ is a possible cover for j, and thus, by the optimality of S_j:

$$\sum_{j' \in H_{i'} \cap A_{t'} \cap I'} h_{j'} \leq \sum_{j' \in S_j} h_{j'} \ . \qquad \blacktriangleleft$$

▶ **Corollary 3.7.** *$R(\mathcal{P}_A) \geq 1/3 \cdot \sum_{t \in M} \phi(A_t)$, where $\mathcal{P}_A$ is the partition produced by Algorithm 1.*

Proof. After the initialization step of Algorithm 1 we have:

$$R(\mathcal{P}) + 1/3 \cdot \sum_{t \in M} \phi(A_t \cap I') \geq 1/3 \cdot \sum_{t \in M} \phi(A_t) \ .$$

On the other hand, when the algorithm terminates:

$$R(\mathcal{P}) + 1/3 \cdot \sum_{t \in M} \phi(A_t \cap I') = R(\mathcal{P}_A)$$

because $I' = \varnothing$. The corollary now follows from Lemma 3.6. ◀

We are now ready to prove Theorem 1.3.

▶ **Theorem 1.3.** *If mediators are local experts, there exists a polynomial time 5-approximation algorithm for* **DSP**.

Proof. Consider an algorithm that outputs the best solution out of $\{I\}$, $\mathcal{P}_S$ and $\mathcal{P}_A$. The following inequality shows that at least one of these joint partitions has a revenue of $R(\mathcal{P}^*)/5$:

$$R(\{I\}) + R(\mathcal{P}_S) + 3R(\mathcal{P}_A) \geq \sum_{j \in \hat{I}} s_j + \mu(I_0) \cdot v(I_0) + \sum_{t \in M} \phi(A_t) \geq R(\mathcal{P}^*) \ ,$$

where the first inequality holds by Observations 3.3 and 3.4 and Corollary 3.7; and the second inequality uses the upper bound on $R(\mathcal{P}^*)$ proved by Lemma 3.2. ◀

4 The Strategic Problem

This section explores the **DSP** problem from a strategic viewpoint, in which the auctioneer *cannot* control the signals produced by each mediator, and is, therefore, trying to solicit information from the mediators that would yield a maximal revenue in the auction. In other words, the objective of the auctioneer is to design a mechanism $\mathcal{M}$ whose equilibria (i.e., the signals $\mathcal{P}'_1, \mathcal{P}'_2, \ldots, \mathcal{P}'_m$ which are now chosen strategically by the mediators) induce maximum revenue. Due to space constraints we are only able to present in this extended abstract only a few of our contributions for the strategic settings. Namely, we introduce the *Shapley mechanism* $\mathcal{S}$ and prove some interesting properties of it (Theorems 1.4 and 1.5).

Our mechanism $\mathcal{S}$ aims to incentivize mediators to report useful information, with the hope that global efficiency emerges despite selfish behavior of each mediator. For the sake of generality, we describe $\mathcal{S}$ for a game generalizing **DSP**. Consider a game $\mathcal{G}_m$ of m players where each player t has a finite set A_t of possible strategies, one of which $\varnothing_t \in A_t$ is called the null strategy of t. The value of a strategy profile in the game $\mathcal{G}_m$ is determined by a value function $v : A_1 \times A_2 \times \ldots \times A_m \to \mathbb{R}$. A mechanism $M = (\Pi_1, \Pi_2, \ldots, \Pi_m)$ for $\mathcal{G}_m$ is a set of payments rules. In other words, if the players choose strategies $a_1 \in A_1, a_2 \in A_2, \ldots, a_m \in A_m$, then the payment to player t under mechanism M is $\Pi_t(v, a_1, a_2, \ldots, a_m)$. Notice that **DSP** fits the definition of $\mathcal{G}_m$ when $A_t = \Omega(\mathcal{P}_t)$ is the set of partitions that t can report for every mediator t, and $\varnothing_t$ is the silence strategy $\{I\}$. The appropriate value function v for **DSP** is the function $R(\times_{t=1}^{m}\mathcal{P}'_t)$, where $\mathcal{P}'_t \in A_t$ is the strategy of mediator t. In other words, the value function v of a **DSP** game is equal to the revenue of the auctioneer.

Given a strategy profile $a = (a_1, a_2, \ldots, a_m)$, and subset $J \in [m]$ of players, we write a_J to denote a strategy profiles where the players of J play their strategy in a, and the other players play their null strategies. We abuse notation and denote by $\varnothing$ the strategy profile $a_\varnothing$ where all players play their null strategies. Additionally, we write (a'_t, a_{-t}) to denote a strategy profile where player t plays a'_t and the rest of the players follow the strategy profile a. The mechanism $\mathcal{S}$ we propose distributes the increase in the value of the game (compared to $v(\varnothing)$) among the players according to their Shapley value: it pays each player his expected marginal contribution to the value according to a uniformly random ordering of the m player. Formally, the payoff for player t given a strategy profile a is

$$\Pi_t(a) = \frac{1}{m!} \cdot \sum_{\sigma \in S_m} \left[v\left(a_{\{\sigma^{-1}(j) | 1 \le j \le \sigma(t)\}}\right) - v\left(a_{\{\sigma^{-1}(j) | 1 \le j < \sigma(t)\}}\right) \right] \quad , \tag{1}$$

which can alternatively be written as

$$\Pi_t(a) = \sum_{J \subseteq [m] \setminus \{t\}} \gamma_J \left(v(a_{J \cup \{t\}}) - v(a_J) \right) \quad , \tag{2}$$

where $\gamma_J = \frac{|J|!(m-|J|-1)!}{m!}$ is the probability that the players of J appear before player t when the players are ordered according to a uniformly random permutation $\sigma \in_R S_m$. We use both definitions (1) and (2) interchangeably, as each one is more convenient in some cases than the other. We remark that the above payoffs can be implemented efficiently.[9]

Clearly, the mechanism $\mathcal{S}$ is anonymous (symmetric). The main feature of the Shapley mechanism is that it is efficient. In other words, the sum of the payoffs is exactly equal to the total increase in value (in the case of **DSP**, the surplus revenue of the auctioneer compared to the initial state).[10]

▶ **Proposition 4.1** (Efficiency property). *For every strategy profile $a = (a_1, a_2, \ldots, a_m)$, $v(a) - v(\varnothing) = \sum_{t=1}^{m} \Pi_t(a)$.*

Proof. Recall that the payoff of mediator t is:

$$\frac{1}{m!} \cdot \sum_{\sigma \in S_m} \left[v\left(a_{\{\sigma^{-1}(j) | 1 \le j \le \sigma(t)\}}\right) - v\left(a_{\{\sigma^{-1}(j) | 1 \le j < \sigma(t)\}}\right) \right] \quad .$$

Summing over all mediators, we get:

$$\sum_{t=1}^{m} \Pi_t(\mathcal{P}'_t, \mathcal{P}'_{-t}) = \sum_{t=1}^{m} \left\{ \frac{1}{m!} \cdot \sum_{\sigma \in S_m} \left[v\left(a_{\{\sigma^{-1}(j) | 1 \le j \le \sigma(t)\}}\right) - v\left(a_{\{\sigma^{-1}(j) | 1 \le j < \sigma(t)\}}\right) \right] \right\}$$

[9] Assuming value queries, we can calculate a payoff for every player by drawing a random permutation σ and paying $v\left(a_{\{\sigma^{-1}(j) | 1 \le j \le \sigma(t)\}}\right) - v\left(a_{\{\sigma^{-1}(j) | 1 \le j < \sigma(t)\}}\right)$ for each mediator t. Clearly this procedure produce the payoffs of our mechanism *in expectation*. Alternatively, the *expected* payoff of each player can be approximated using sampling.

[10] One natural alternative for the Shapley mechanism is a VCG-based mechanism. The main disadvantage of this alternative mechanism is that it is not necessarily efficient. In fact, one can easily design instances where a VCG-based mechanism induces a total payoff which is significantly larger than the increase in the value.

$$= \frac{1}{m!} \cdot \sum_{\sigma \in S_m} \sum_{t=1}^{m} \left[v\left(a_{\{\sigma^{-1}(j) | 1 \leq j \leq \sigma(t)\}}\right) - v\left(a_{\{\sigma^{-1}(j) | 1 \leq j < \sigma(t)\}}\right) \right]$$

$$= \frac{1}{m!} \cdot \sum_{\sigma \in S_m} \left[v\left(a_{\{\sigma^{-1}(j) | 1 \leq j \leq m\}}\right) - v\left(a_{\varnothing}\right) \right] = v(a) - v(\varnothing) \ . \qquad ◀$$

Proposition 4.1 implies the following theorem. Notice that Theorem 1.5 is in fact a restriction of this theorem to the game $\mathbf{DSP}_{\mathcal{S}}$.

▶ **Theorem 4.2.** *For every Nash equilibrium a, $v(a) \geq v(\varnothing)$.*

Proof. A player always has the option of playing his null strategy, which results in a zero payoff for him. Thus, the payoff of a player in a Nash equilibrium can never be negative. Hence, by Proposition 4.1: $v(a) \geq v(\varnothing) + \sum_{i=1}^{m} \Pi_t(a) \geq v(\varnothing)$. ◀

Next, let us prove Theorem 1.4. For convenience, we restate it below.

▶ **Theorem 1.4.** *Let $\mathcal{G}_m$ be a non-cooperative m-player game in which the payoff of each player is set according to $\mathcal{S}$. Then $\mathcal{G}_m$ admits a pure Nash equilibrium. Moreover, best response dynamics are guaranteed to converge to such an equilibrium.*

Proof. We prove the theorem by showing that $\mathcal{G}_m$ is an exact potential game, which in turn implies all the conclusions of the theorem. Recall that an exact potential game is a game for which there exists a potential function $\Phi\colon A_1 \times A_2 \times \cdots \times A_t \to \mathbb{R}$ such that every strategy profile a and possible deviation $a'_t \in A_t$ of a player t obey:

$$\Pi_t(a'_t, a_{-t}) - \Pi_t(a) = \Phi(a'_t, a_{-t}) - \Phi(a) \ . \tag{3}$$

In our case the potential function is $\Phi(a) = \sum_{J \subseteq [m]} \beta_J \cdot v(a_J)$, where $\beta_J = \frac{(|J|-1)!(m-|J|)!}{m!}$. Let us prove that this function obeys (3). It is useful to denote by a' the strategy profile (a'_t, a_{-t}). By definition:

$$\Pi_t(a') - \Pi_t(a) = \sum_{J \subseteq [m] \setminus \{i\}} \gamma_J \left[v(a_{J \cup \{i\}}) - v(a_J) \right] - \sum_{J \subseteq [m] \setminus \{i\}} \gamma_J \left[v(a'_{J \cup \{i\}}) - v(a'_J) \right] \ . \tag{4}$$

For $J \subseteq [m] \setminus \{i\}$, we have $a_J = a'_J$. Plugging this observation into (4), and rearranging, we get:

$$\Pi_t(a') - \Pi_t(a) = \sum_{J \subseteq [m] \setminus \{i\}} \gamma_J \left[v(a_{J \cup \{i\}}) - v(a'_{J \cup \{i\}}) \right] \ . \tag{5}$$

For every J containing i we get: $\alpha_{J \setminus \{i\}} = \beta_J$. Using this observation and the previous observation that $a_J = a'_J$ for $J \subseteq [m] \setminus \{i\}$, (5) can be replaced by:

$$\Pi_t(a') - \Pi_t(a) = \sum_{J \subseteq [m]} \beta_J (v(a'_J) - v(a_J)) = \Phi(a') - \Phi(a) \ . \qquad ◀$$

Before concluding this section, a few remarks regarding the use of $\mathcal{S}$ to **DSP** are in order:

1. The reader may wonder why the auctioneer cannot impose on the mediators any desired outcome $\times_{t \in M} \mathcal{P}'_t$ by offering mediator t a negligible payment if he signals $\mathcal{P}'_t$, and no payment otherwise. However, implementing such a mechanism requires the auctioneer to know the information sets $\mathcal{P}_t$ of each mediator *in advance.* In contrast, our mechanism requires access only to the outputs of the mediators.

2. Proposition 4.1 implies that the auctioneer distributes the entire surplus among the mediators, which seems to defeat the purpose of the mechanism. However, in the target application she can scale the revenue by a factor $\alpha \in (0, 1]$ and only distribute the corresponding fraction of the surplus. As all of our results are invariant under scaling, this trick can be applied in a black box fashion. Thus, we assume, without loss of generality, $\alpha = 1$.
3. We assume mediators never report a signal which is inconsistent with the true identity of the sold element j_R. The main justification for this assumption is that the mediators' signals must be consistent with one another (as they refer to a single element j_R). Thus, given that sufficiently many mediators are honest, "cheaters" can be easily detected.
4. Note that for a particular ordering of the mediators $\sigma \in \mathcal{S}_m$ and a particular joint strategy profile, the marginal payoff of a mediator may be negative (if she is out of luck and contributes negatively to the revenue according to σ). However, we stress that the expected value (over σ) of each mediator is never negative in any equilibrium strategy (by Theorem 4.2). Since in realistic applications the process is assumed to be repeated over time, the probability that a mediator has overall negative payoff is negligible.

5 Discussion

In this paper we have considered computational and strategic aspects of auctions involving third party information mediators. Our main result for the computational point of view shows that it is NP-hard to get a reasonable approximation ratio when the three parameters of the problem are all "large". For the parameters n and k this is tight in the sense that there exists an algorithm whose approximation ratio is good when either one of these parameters is "small". However, we do not know whether a small value for the parameter m allows for a good approximation ratio. More specifically, even understanding the approximation ratio achievable in the case $m = 2$ is an interesting open problem. Observe that the case $m = 2$ already captures (asymptotically) the largest possible price of stability and price of anarchy in the strategic setup,[11] and thus, it is tempting to assume that this case also captures all the complexity of the computational setup.

Unfortunately, most of our results, for both the computational and strategic setups, are quite negative. The class of local experts we describe is a natural mediators class allowing us to bypass one of these negative result and get a constant approximation ratio algorithm for the computational setup. An intriguing potential avenue for future research is finding additional natural classes of mediators that allow for improved results, either under the computational or the strategic setup.

Another possible direction for future research is to study an extension of our distributed setup where bundling is replaced with randomized signaling (similarly to the works of [2] and [7] which introduced randomized signaling into the centralized model of [11]). In the centralized model it turned out that finding the optimal randomized signaling is easier then finding the optimal bundling [2, 7], which is counterintuitive since randomized signaling generalize bundling. Hence, one can hope that randomized signaling might also mitigate some of our inapproximability results.

[11] By Theorem 1.7 the price of stability can be as large as $O(\min\{k, n\})$ even for two mediators, and Theorem 1.6 shows that the price of anarchy cannot be larger than that for any number of mediators.

Abstract

We study the classical NP-hard problems of finding maximum-size subsets from given sets of k terminal pairs that can be routed via edge-disjoint paths (MaxEDP) or node-disjoint paths (MaxNDP) in a given graph. The approximability of MaxEDP/NDP is currently not well understood; the best known lower bound is $\Omega(\log^{1/2-\varepsilon} n)$, assuming $\mathsf{NP} \not\subseteq \mathsf{ZPTIME}(n^{\mathrm{poly}\log n})$. This constitutes a significant gap to the best known approximation upper bound of $\mathcal{O}(\sqrt{n})$ due to Chekuri et al. (2006) and closing this gap is currently one of the big open problems in approximation algorithms. In their seminal paper, Raghavan and Thompson (Combinatorica, 1987) introduce the technique of randomized rounding for LPs; their technique gives an $\mathcal{O}(1)$-approximation when edges (or nodes) may be used by $\mathcal{O}\left(\frac{\log n}{\log\log n}\right)$ paths.

In this paper, we strengthen the above fundamental results. We provide new bounds formulated in terms of the *feedback vertex set number* r of a graph, which measures its vertex deletion distance to a forest. In particular, we obtain the following.

- For MaxEDP, we give an $\mathcal{O}(\sqrt{r}\cdot\log^{1.5} kr)$-approximation algorithm. As $r \leq n$, up to logarithmic factors, our result strengthens the best known ratio $\mathcal{O}(\sqrt{n})$ due to Chekuri et al.
- Further, we show how to route $\Omega(\mathrm{OPT})$ pairs with congestion $\mathcal{O}\left(\frac{\log kr}{\log\log kr}\right)$, strengthening the bound obtained by the classic approach of Raghavan and Thompson.
- For MaxNDP, we give an algorithm that gives the optimal answer in time $(k+r)^{\mathcal{O}(r)}\cdot n$. This is a substantial improvement on the run time of $2^k r^{\mathcal{O}(r)}\cdot n$, which can be obtained via an algorithm by Scheffler.

We complement these positive results by proving that MaxEDP is NP-hard even for $r=1$, and MaxNDP is W[1]-hard for parameter r. This shows that neither problem is fixed-parameter tractable in r unless $\mathsf{FPT} = \mathsf{W}[1]$ and that our approximability results are relevant even for very small constant values of r.

1 Introduction

In this paper, we study disjoint paths routing problems. In this setting, we are given an undirected graph G and a collection of source-destination pairs $\mathcal{M} = \{(s_1,t_1),\ldots,(s_k,t_k)\}$.

* This research was supported by ERC Starting Grant 306465 (BeyondWorstCase).

The goal is to select a maximum-sized subset $\mathcal{M}' \subseteq \mathcal{M}$ of the pairs that can be *routed*, where a routing of $\mathcal{M}'$ is a collection $\mathcal{P}$ of paths such that, for each pair $(s_i, t_i) \in \mathcal{M}'$, there is a path in $\mathcal{P}$ connecting s_i to t_i. In the Maximum Edge Disjoint Paths (MaxEDP) problem, a routing $\mathcal{P}$ is *feasible* if its paths are pairwise edge-disjoint, and in the Maximum Node Disjoint Paths (MaxNDP) problem the paths in $\mathcal{P}$ must be pairwise vertex-disjoint.

Disjoint paths problems are fundamental problems with a long history and significant connections to optimization and structural graph theory. The decision versions EDP of MaxEDP and NDP of MaxNDP ask whether all of the pairs can be routed. Karp [27] showed that, when the number of pairs is part of the input, the decision problem is NP-complete. In undirected graphs, MaxEDP and MaxNDP are solvable in polynomial time when the number of pairs is a fixed constant; this is a very deep result of Robertson and Seymour [40] that builds on several fundamental results in structural graph theory from their graph minors project.

In this paper, we consider the optimization problems MaxEDP and MaxNDP when the number of pairs are part of the input. In this setting, the best approximation ratio for MaxEDP is achieved by an $\mathcal{O}(\sqrt{n})$-approximation algorithm [12, 33], where n is the number of nodes, whereas the best hardness for undirected graphs is only $\Omega(\log^{1/2-\varepsilon} n)$ [3]. Bridging this gap is a fundamental open problem that seems quite challenging at the moment.

Most of the results for routing on disjoint paths use a natural multi-commodity flow relaxation as a starting point. A well-known integrality gap instance due to Garg et al. [24] shows that this relaxation has an integrality gap of $\Omega(\sqrt{n})$, and this is the main obstacle for improving the $\mathcal{O}(\sqrt{n})$-approximation ratio in general graphs. The integrality instance on an $n \times n$ grid (of treewidth $\Theta(\sqrt{n})$) exploits a topological obstruction in the plane that prevents a large integral routing; see Fig. 1. This led Chekuri et al. [15] to studying the approximability of MaxEDP with respect to the *tree-width* of the underlying graph. In particular, they pose the following conjecture:

▶ **Conjecture 1** ([13]). *The integrality gap of the standard multi-commodity flow relaxation for* MaxEDP *is $\Theta(w)$, where w is the treewidth of the graph.*

Recently, Ene et al. [21] showed that MaxEDP admits an $\mathcal{O}(w^3)$-approximation algorithm on graphs of treewidth at most w. Theirs is the best known approximation ratio in terms of w, improving on an earlier $\mathcal{O}(w \cdot 3^w)$-approximation algorithm due to Chekuri et al. This shows that the problem seems more amenable on "tree-like" graphs.

However, for $w = \omega(n^{1/6})$, the bound is weaker than the bound of $\mathcal{O}(\sqrt{n})$. In fact, EDP remains NP-hard even for graphs of *constant* treewidth, namely treewidth $w = 2$ [37]. This further rules out the existence of a fixed-parameter algorithm for MaxEDP parameterized by w, assuming P $\neq$ NP. Therefore, to obtain fixed-parameter tractability results as well as better approximation guarantees, one needs to resort to parameters stronger than treewidth.

Another route to bridge the large gap between approximation lower and upper bounds for MaxEDP is to allow the paths to have *low congestion* c: that is, instead of requiring the routed paths to be pairwise disjoint, at most c paths can use an edge. In their groundbreaking work, Raghavan and Thompson [38] introduced the technique of randomized rounding of LPs to obtain polynomial-time approximation algorithms for combinatorial problems. Their approach allows to route $\Omega(\text{OPT})$ pairs of paths with congestion $\mathcal{O}\left(\frac{\log n}{\log\log n}\right)$. This extensive line of research [2, 18, 28] has culminated in a $\log^{\mathcal{O}(1)} k$-approximation algorithm with congestion 2 for MaxEDP [20]. A slightly weaker result also holds for MaxNDP [11].

1.1 Motivation and Contribution

The goal of this work is to study disjoint paths problems under another natural measure for how "far" a graph is from being a tree. In particular, we propose to examine MaxEDP and MaxNDP under the *feedback vertex set number*, which for a graph G denotes the smallest size r of a set R of G for which $G-R$ is a forest. Note that the treewidth of G is at most $r+1$. Therefore, given the NP-hardness of EDP for $w=2$ and the current gap between the best known upper bound $\mathcal{O}(w^3)$ and the linear upper bound suggested by Conjecture 1, it is interesting to study the stronger restriction of bounding the feedback vertex set number r of the input graph. Our approach is further motivated by the fact that MaxEDP is efficiently solvable on trees by means of the algorithm of Garg, Vazirani and Yannakakis [24]. Similarly, MaxNDP is easy on trees (see Theorem 4).

Our main insight is that one can in fact obtain bounds in terms of r that either strengthen the best known bounds or are almost tight (see Table 1). It therefore seems that parameter r correlates quite well with the "difficulty" of disjoint paths problems.

Our first result allows the paths to have small congestion: in this setting, we strengthen the result, obtained by the classic randomized LP-rounding approach of Raghavan and Thompson [38], that one can always route $\Omega(\mathrm{OPT})$ pairs with congestion $\mathcal{O}\left(\frac{\log n}{\log\log n}\right)$ with constant probability.

▶ **Theorem 2.** *For any instance* $(G,\mathcal{M})$ *of* MaxEDP, *one can efficiently find a routing of* $\Omega(\mathrm{OPT})$ *pairs with congestion* $\mathcal{O}\left(\frac{\log kr}{\log\log kr}\right)$ *with constant probability; in other words, there is an efficient* $\mathcal{O}(1)$*-approximation algorithm for* MaxEDP *with congestion* $\mathcal{O}\left(\frac{\log kr}{\log\log kr}\right)$.

Our second main result builds upon Theorem 2 and uses it as a subroutine. We show how to use a routing for MaxEDP with low congestion to obtain a polynomial-time approximation algorithm for MaxEDP *without congestion* that performs well in terms of r.

▶ **Theorem 3.** *The integrality gap of the multi-commodity flow relaxation for* MaxEDP *with* k *terminal pairs is* $\mathcal{O}(\sqrt{r}\cdot\log^{1.5} rk)$ *for graphs with feedback vertex set number* r. *Moreover, there is a polynomial time algorithm that, given a fractional solution to the relaxation of value* opt, *it constructs an integral routing of size* $\mathsf{opt}/\mathcal{O}(\sqrt{r}\cdot\log^{1.5} rk)$.

In particular, our algorithm strengthens the best known approximation algorithm for MaxEDP on general graphs [12] as always $r\leq n$, and indeed it matches that algorithm's performance up to polylogarithmic factors. Substantially improving upon our bounds would also improve the current state of the art of MaxEDP. Conversely, the result implies that it suffices to study graphs with close to linear feedback vertex set number in order to improve the currently best upper bound of $\mathcal{O}(\sqrt{n})$ on the approximation ratio [12].

Our algorithmic approaches harness the forest structure of $G-R$ for any feedback vertex set R. However, the technical challenge comes from the fact that the edge set running between $G-R$ and R is unrestricted. Therefore, the "interaction" between R and $G-R$ is non-trivial, and flow paths may run between the two parts in an arbitrary manner and multiple times. In fact, we show that MaxEDP is already NP-hard if R consists of a *single node* (Theorem 6); this contrasts the efficient solvability on forests [24].

In order to overcome the technical hurdles we propose several new concepts, which we believe could be of interest in future studies of disjoint paths or routing problems.

In the randomized rounding approach of Raghavan and Thompson [38], it is shown that the probability that the congestion on any fixed edge is larger than $c\frac{\log n}{\log\log n}$ for some constant c is at most $1/n^{O(1)}$. Combining this with the fact that there are at most n^2 edges, yields that every edge has bounded congestion w.h.p. The number of edges in the graph may, however, be unbounded in terms of r and k. Hence, in order to to prove Theorem 2, we propose a non-trivial *pre-processing step* of the optimum LP solution that is applied prior to the randomized rounding. In this step, we aggregate the flow paths by a careful rerouting so that the flow "concentrates" in $O(kr^2)$ nodes (so-called *hot spots*) in the sense that if all edges incident on hot spots have low congestion then so have all edges in the graph. Unfortunately, for any such hot spot the number of incident edges carrying flow may still be unbounded in terms of k and r. We are, however, able to give a refined probabilistic analysis that suitably relates the probability that the congestion bound is exceeded to the amount of flow on that edge. Since the total amount of flow on each hot spot is bounded in terms of k, the probability that *all* edges incident on the same hot spot have bounded congestion is inverse polynomial in r and k.

The known $\mathcal{O}(\sqrt{n})$-approximation algorithm for MaxEDP by Chekuri et al. [12] employs a clever LP-rounding approach. If there are many long paths then there must be a single node carrying a significant fraction of the total flow and a good fraction of this flow can be realized by integral paths by solving a single-source flow problem. If the LP solution contains many short flow paths then greedily routing these short paths yields the bound since each such path blocks a bounded amount of flow. In order to prove Theorem 3, it is natural to consider the case where there are many paths visiting a large number of nodes in R. In this case, we reduce to a single-source flow problem, similarly to the approach of Chekuri et al. The case where a majority of the flow paths visit only a few nodes in R turns out more challenging, since any such path may still visit an unbounded number of edges in terms of k and r. We use two main ingredients to overcome these difficulties. First, we apply our Theorem 2 as a building block to obtain a solution with logarithmic congestion while losing only a constant factor in the approximation ratio. Second, we introduce the concept of *irreducible routings with low congestion* which allows us exploit the structural properties of the graph and the congestion property to identify a sufficiently large number of flow paths blocking only a small amount of flow.

Note that the natural greedy approach of always routing the shortest conflict-free path gives only $\mathcal{O}(\sqrt{m})$ for MaxEDP. We believe that it is non-trivial to obtain our bounds via a more direct or purely combinatorial approach.

Our third result is a fixed-parameter algorithm for MaxNDP in $k + r$.

▶ **Theorem 4.** MaxNDP *can be solved in time* $(8k + 8r)^{2r+2} \cdot \mathcal{O}(n)$ *on graphs with feedback vertex set number* r *and* k *terminal pairs.*

This run time is polynomial for constant r. We also note that for small r, our algorithm is asymptotically significantly faster than the fastest known algorithm for NDP, by Kawarabayashi and Wollan [29], which requires time at least *quadruple-exponential* in k [1]. Namely, if r is at most triple-exponential in k, our algorithm is asymptotically faster than theirs. We achieve this result by the idea of so-called *essential pairs* and *realizations*, which characterizes the "interaction" between the feedback vertex set R and the paths in an optimum solution. Note that in our algorithm of Theorem 4, parameter k does not appear in the exponent of the run time at all. Hence, for small values of r, our algorithm is also faster than reducing MaxNDP to NDP by guessing the subset of pairs to be routed (at an expense of 2^k in the run time) and using Scheffler's [41] algorithm for NDP with run time $2^{O(r \log r)} \cdot \mathcal{O}(n)$.

Once a fixed-parameter algorithm for a problem has been obtained, the existence of a polynomial-size kernel comes up. Here we note that MaxNDP does not admit a polynomial kernel for parameter $k + r$, unless $\mathsf{NP} \subseteq \mathsf{coNP}/poly$ [8].

Table 1 Summary of results obtained in this paper.

const.	param.	EDP	MaxEDP	NDP	MaxNDP
$r = 0$		poly [24]	poly [24]	poly [41]	poly (Thm. 4)
$r = 1$		*open*	NP-hard (Thm. 6)	poly [41]	poly (Thm. 4)
$r \geq 2$		NP-hard (Thm. 6)	NP-hard (Thm. 6)	poly [41]	poly (Thm. 4)
	r	para-NP-hard (Thm. 6)		FPT [41]	W[1]-hard (Thm. 5)
		$\mathcal{O}(\sqrt{r} \cdot \log^{1.5} kr)$-approx (Thm. 3)			exact $(k + r)^{\mathcal{O}(r)}$ (Thm. 4)
		$\mathcal{O}(1)$-approx. w.cg. $\mathcal{O}\left(\frac{\log kr}{\log\log kr}\right)$ (Thm. 2)			

Another natural question is whether the run time $f(k, r) \cdot n$ in Theorem 4 can be improved to $f(r) \cdot n^{\mathcal{O}(1)}$. We answer this question in the negative, ruling out the existence of a fixed-parameter algorithm for MaxNDP parameterized by r (assuming FPT $\neq$ W[1]):

▶ **Theorem 5.** MaxNDP *in unit-capacity graphs is* W[1]*-hard parameterized by* r*.*

This contrasts the known result that NDP is fixed-parameter tractable in r [41]—which further stresses the relevance of understanding this parameter. We prove Theorem 5 in the full version of the paper [22].

For MaxEDP, we prove that the situation is, in a sense, even worse:

▶ **Theorem 6.** MaxEDP *is* NP*-hard for unit-capacity graphs with* $r = 1$ *and* EDP *is* NP*-hard for unit-capacity graphs with* $r = 2$*.*

This theorem also shows that our algorithms are relevant for small values of r, and they nicely complement the NP-hardness for MaxEDP in capacitated trees [24].

Our results are summarized in Table 1.

Related Work. Our study of the feedback vertex set number is in line with the general attempt to obtain bounds for MaxEDP (or related problems) that are independent of the input size. Besides the above-mentioned works that provide bounds in terms of the *tree-width* of the input graph, Günlük [25] and Chekuri et al. [17] give bounds on the *flow-cut gap* for the closely related integer multicommodity flow problem that are logarithmic with respect to the *vertex cover number* of a graph. This improved upon earlier bounds of $\mathcal{O}(\log n)$ [34] and $\mathcal{O}(\log k)$ [5, 35]. As every feedback vertex set is in particular a vertex cover of a graph, our results generalize earlier work for disjoint path problems on graphs with bounded vertex cover number. Bodlaender et al. [8] showed that NDP does not admit a polynomial kernel parameterized by vertex cover number *and* the number k of terminal pairs, unless NP $\subseteq$ coNP/*poly* ; therefore, NDP is unlikely to admit a polynomial kernel in $r + k$ either. Ene et al. [21] showed that MaxNDP is W[1]-hard parameterized by treedepth, which is another restriction of treewidth that is incomparable to the feedback vertex set number.

The basic gap in understanding the approximability of MaxEDP has led to several improved results for special graph classes, and also our results can be seen in this light. For example, polylogarithmic approximation algorithms are known for graphs whose global minimum cut value is $\Omega(\log^5 n)$ [39], for bounded-degree expanders [10, 9, 30, 34, 23], and for Eulerian planar or 4-connected planar graphs [28]. Constant factor approximation algorithms are known for capacitated trees [24, 14], grids and grid-like graphs [4, 6, 31, 32]. For planar graphs, there is a constant-factor approximation algorithm with congestion 2 [42]. Very

(MaxEDP LP)

$$\begin{array}{lll} \max & \displaystyle\sum_{i=1}^{k} x_i & \\ \text{s.t.} & \displaystyle\sum_{P \in \mathcal{P}(s_i,t_i)} f(P) = x_i \leq 1 & i = 1, \dots, k, \\ & \displaystyle\sum_{P\colon e \in P} f(P) \leq 1 & e \in E(G) \\ & f(P) \geq 0 & P \in \mathcal{P} \end{array}$$

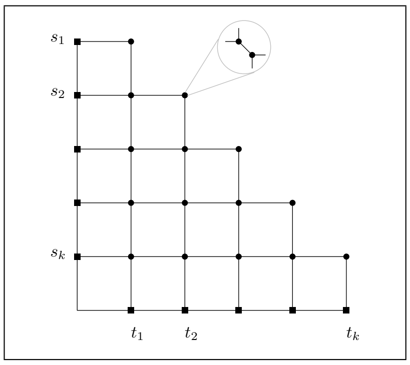

Figure 1 Multi-commodity flow relaxation for MaxEDP. Right: $\Omega(\sqrt{n})$ integrality gap for MaxEDP [24]: any integral routing routes at most one pair, whereas a multi-commodity flow can send 1/2 unit of flow for each pair (s_i, t_i) along the canonical path from s_i to t_i in the grid.

recently, Chuzhoy et al. [19] gave a $\tilde{\mathcal{O}}(n^{9/19})$-approximation algorithm for MaxNDP on *planar* graphs. However, improving the $\mathcal{O}(\sqrt{n})$-approximation algorithm for MaxEDP remains elusive even for *planar* graphs.

2 Preliminaries

We use standard graph theoretic notation. For a graph G, let $V(G)$ denote its vertex set and $E(G)$ its edge set. Let G be a graph. A *feedback vertex set* of G is a set $R \subseteq V(G)$ such that $G - R$ is a forest. A *minor* of G is a graph H that is obtained by successively contracting edges from a subgraph of G (and deleting any occurring loops). A class $\mathcal{G}$ of graphs is *minor-closed* if for any graph in $\mathcal{G}$ also all its minors belong to $\mathcal{G}$.

For an instance $(G, \mathcal{M})$ of MaxEDP/MaxNDP, we refer to the vertices participating in the pairs $\mathcal{M}$ as *terminals*. It is convenient to assume that $\mathcal{M}$ forms a matching on the terminals; this can be ensured by making several copies of a terminal and attaching them as leaves.

Multi-commodity flow relaxation. We use the following standard multi-commodity flow relaxation for MaxEDP (there is an analogous relaxation for MaxNDP). We use $\mathcal{P}(u, v)$ to denote the set of all paths in G from u to v, for each pair (u, v) of nodes. Since the pairs $\mathcal{M}$ form a matching, the sets $\mathcal{P}(s_i, t_i)$ are pairwise disjoint. Let $\mathcal{P} = \bigcup_{i=1}^{k} \mathcal{P}(s_i, t_i)$. The LP has a variable $f(P)$ for each path $P \in \mathcal{P}$ representing the amount of flow on P. For each pair $(s_i, t_i) \in \mathcal{M}$, the LP has a variable x_i denoting the total amount of flow routed for the pair (in the corresponding IP, x_i denotes whether the pair is routed or not). The LP imposes the constraint that there is a flow from s_i to t_i of value x_i. Additionally, the LP has constraints that ensure that the total amount of flow on paths using a given edge (resp. node for MaxNDP) is at most 1.

It is well-known that the relaxation MaxEDP LP can be solved in polynomial time, since there is an efficient separation oracle for the dual LP (alternatively, one can write a compact relaxation). We use $(f, \mathbf{x})$ to denote a feasible solution to MaxEDP LP for an instance $(G, \mathcal{M})$ of MaxEDP. For each terminal v, let $x(v)$ denote the total amount of flow routed for v and we refer to $x(v)$ as the *marginal value* of v in the multi-commodity flow f.

We will use the following result by Chekuri et al. [12, Sect. 3.1]; see also Proposition 3.3 of Chekuri et al. [16].

▶ **Proposition 7.** *Let $(f, \mathbf{x})$ be a fractional solution to the LP relaxation of a* MaxEDP *instance $(G, \mathcal{M})$. If some node v is contained in all flow paths of f, then we can find an integral routing of size at least $\frac{1}{12}\sum_i x_i$ in polynomial time.*

3 Bi-Criteria Approximation for MaxEDP with Low Congestion

We present a randomized rounding algorithm that will lead to the proof of Theorem 2.

3.1 Algorithm

Consider an instance $(G, \mathcal{M})$ of MaxEDP. Let R be a 2-approximate minimum feedback vertex set of G and let $r = |R|$; note that such a set R can be obtained in polynomial time [7].

For the sake of easier presentation, we will assume in this section that the feedback vertex set R contains all terminal nodes from $\mathcal{M}$. This can be achieved by temporarily adding the set of terminals to the feedback vertex set R. Also note that this assumption increases the bound of Theorem 2 by at most a constant factor.

First, solve the corresponding MaxEDP LP. We obtain an optimal extreme point solution $(f, \mathbf{x})$. For each $(s_i, t_i) \in \mathcal{M}$, this gives us a set $\mathcal{P}'(s_i, t_i) = \{P \in \mathcal{P}(s_i, t_i) \mid f(P) > 0\}$ of positive weighted paths that satisfy the LP constraints.

Since we have an extreme point solution, the number of tight constraints is not smaller then the number of variables. As the number of constraints that are not of type $f(P) \geq 0$ is polynomially bounded in the input size, the same holds for the cardinality of the set $\mathcal{P}' = \bigcup_{i=1}^{k} \mathcal{P}'(s_i, t_i)$. In what follows, we will modify $\mathcal{P}'$ and then select an (unweighted) subset $\mathcal{S}$ of $\mathcal{P}'$ that will form our integral solution.

Each $P \in \mathcal{P}'$ has the form $(r_1, \dots, r_2, \dots, r_\ell)$ where $r_1, \dots, r_\ell$ are the nodes in R that are traversed by P in this order. The paths $(r_j, \dots, r_{j+1})$ with $j = 1, \dots, \ell - 1$ are called *subpaths of* P. For every subpath P' of P, we set $f(P') = f(P)$. Let $\mathcal{J}$ be the multi-set of all subpaths of all paths in $\mathcal{P}'$. Let $F = G - R$ be the forest obtained by removing R.

We now modify some paths in $\mathcal{P}'$, one by one, and at the same time construct a subset H_0 of nodes that we will call "hot spots". At the end, every subpath in $\mathcal{J}$ will contain at least one hot spot.

Initially, let $H_0 = \emptyset$. Consider any tree T in F and fix any of its nodes as a root. Then let $\mathcal{J}_T$ be the multi-set of all subpaths in $\mathcal{J}$ that, excluding the endpoints, are contained in T. For each subpath $P \in \mathcal{J}_T$, define its *highest node* $h(P)$ as the node on P closest to the root. Note that $P \cap T = P \cap F$ is a path. Now, pick a subpath $P \in \mathcal{J}_T$ that does not contain any node in H_0 and whose highest node $h(P)$ is *farthest away* from the root. Consider the multi-set $\mathcal{J}[P]$ of all subpaths in $\mathcal{J}_T$ that are identical to P (but may be subpaths of different flow paths in $\mathcal{P}'$). Note that the weight $f(\mathcal{J}[P]) := \sum_{P \in \mathcal{J}[P]} f(P)$ of $\mathcal{J}[P]$ is at most 1 by the constraints of the LP. Let $u, v \in R$ be the endpoints of P. We define $\mathcal{J}_{uv}$ as the set of all subpaths in $\mathcal{J} \setminus \mathcal{J}[P]$ that have u and v as their endpoints and that do not contain any node in H_0.

Intuitively speaking, we now aggregate flow on P by rerouting as much flow as possible from $\mathcal{J}_{uv}$ to P. To this end, we repeatedly perform the following operation as long as $f(\mathcal{J}[P]) < 1$ and $\mathcal{J}_{uv} \neq \emptyset$. We pick a path P' in $\mathcal{J}$ that contains a subpath in $\mathcal{J}_{uv}$. We reroute flow from P' by creating a new path P'' that arises from P' by replacing its subpath between u and v with P, and assign it the weight $f(P'') = \min\{f(P'), 1 - f(\mathcal{J}[P])\}$. Then we set the weight of (the original path) P' to $\max\{0, f(P') + f(\mathcal{J}[P]) - 1\}$. We update the sets $\mathcal{P}'$, $\mathcal{P}'(s_i, t_i)$, $\mathcal{J}$, $\mathcal{J}_T$, $\mathcal{J}[P]$ and $\mathcal{J}_{uv}$ accordingly.

As soon as $f(\mathcal{J}[P]) = 1$ or $\mathcal{J}_{uv} = \emptyset$, we add $h(P)$ to H_0. Then, we proceed with the next $P \in \mathcal{J}_T$ not containing a hot spot and whose highest node $h(P)$ is farthest away from the root. If no such P is left, we consider the next tree T in F.

At the end, we create our solution $\mathcal{S}$ by randomized rounding: We route every terminal pair (s_i, t_i) with probability x_i. In case (s_i, t_i) is routed, we randomly select a path from $\mathcal{P}'(s_i, t_i)$ and add it to $\mathcal{S}$ where the probability that path P is taken is $f(P)/x_i$.

3.2 Analysis

First, observe that $\mathbf{x}$ did not change during our modifications of the paths, as the total flow between any terminal pair did not change. Thus, the expected number of pairs routed in our solution is $\sum_{i=1}^{k} x_i \geq \mathrm{OPT}$. Using the Chernoff bound, the probability that we route less than $\mathrm{OPT}/2$ pairs is at most $e^{-1/8\,\mathrm{OPT}} < 1/2$, assuming that $\mathrm{OPT} > 8$. Secondly, we bound the congestion of our solution—our second criterion.

▶ **Lemma 8.** *The congestion of flow f is at most 2.*

Proof. In our algorithm, we increase the flow only along flow subpaths that are pairwise edge-disjoint. To see this, consider two distinct flow subpaths P and P' on which we increase the flow. Assume, without loss of generality, that P was considered before P' by the algorithm. If there was an edge e lying on P and P', then both subpaths traverse the same tree in forest F. Hence, the path from e to $h(P')$ would visit $h(P)$, and $h(P)$ would be an internal node of P'. This yields a contradiction, as $h(P)$ was already marked as a hot spot when P' was considered. This shows that we increased the flow along any edge by at most one unit, and, hence, f has congestion at most 2. ◀

We now bound the congestion of the integral solution obtained by randomized rounding. In the algorithm, we constructed a set H_0 of hot spots. As a part of the analysis, we will now extend this set to a set H as follows. Initially, $H = H_0$. We build a sub-forest F' of F consisting of all edges of F that lie on a path connecting two hot spots. Then we add to H all nodes that have degree at least 3 in F'. Since the number of nodes of degree 3 in any forest is at most its number of leaves and since every leaf of F' is a hot spot, it follows that this can at most double the size of H to $2|H_0|$. Finally, we add the set R of all feedback vertex nodes to H. In the following, all nodes in H are called hot spots.

▶ **Lemma 9.** *The number $|H|$ of hot spots is $\mathcal{O}(kr^2)$.*

Proof. It suffices to show that $|H_0| \in \mathcal{O}(kr^2)$. To this end, fix two nodes $u, v \in R$ and consider the set of flow subpaths P with end nodes u and v for which we added $h(P)$ to H_0. Due to the aggregation of flows in our algorithm, all except possibly one of the subpaths are saturated, that is, they carry precisely one unit of flow. Since no two of these subpaths are contained in a same flow path of f and since the flow value of f is bounded from above by k, we added only $\mathcal{O}(k)$ hot spots for the pair u, v. Since there are at most r^2 pairs in R, the claim follows. ◀

▶ **Definition 10.** A hot spot $u \in H$ is *good* if the congestion on any edge incident on u is bounded by $c \cdot \frac{\log kr}{\log\log kr}$, where c is a sufficiently large constant; otherwise, u is *bad*.

▶ **Lemma 11.** *Let $u \in H$ be a hot spot. Then the probability that u is bad is at most $1/(k^2r^3)$.*

Proof. Let $e_1 = uv_1, \ldots, e_\ell = uv_\ell$ be the edges incident on u and let f_i be the total flow on edge uv_i for $i = 1, \ldots, \ell$. By Lemma 8, we have that $f_i \leq 2$. Since any flow path visits at most two of the edges incident on u, the total flow $\sum_{i=1}^{\ell} f_i$ on the edges incident on u is at most $2k$.

For any $i = 1, \dots, \ell$, we have that $f_i = \sum_{P\colon P \ni e_i} f(P)$, where P runs over the set of all paths connecting some terminal pair and containing e_i. Let $f_{ij} = \sum_{P \in \mathcal{P}(s_j,t_j)\colon P \ni e_i} f(P)$ be the total amount of flow sent across e_i by terminal pair (s_j, t_j). Recall that x_j is the total flow sent for terminal pair (s_j, t_j). The probability that the randomized rounding procedure picks path P with $P \in \mathcal{P}(s_j, t_j)$ is precisely $x_j \cdot \frac{f(P)}{x_j} = f(P)$. Given the disjointness of the respective events, the probability that pair (s_j, t_j) routes a path across e_i is precisely f_{ij}. Let X_{ij} be the binary random variable indicating whether pair (s_j, t_j) routes a path across e_i. Then $\mathbb{P}[X_{ij} = 1] = f_{ij}$. Let $X_i = \sum_j X_{ij}$ be the number of paths routed across e_i by the algorithm. By linearity of expectation, we have that $\mathbb{E}[X_i] = \sum_j \mathbb{E}[X_{ij}] = \sum_j f_{ij} = f_i$.

Fix any edge e_i. Set $\delta = c \cdot \frac{\log kr}{\log\log kr}$ and $\delta' = 2\frac{\delta}{f_i} - 1$. Note that for fixed i, the variables X_{ij} are independent. Hence, by the Chernoff bound, we have that

$$\mathbb{P}\left[X_i \geq c \cdot \frac{\log kr}{\log\log kr}\right] \leq \mathbb{P}\left[X_i \geq (1+\delta')f_i\right] < \left(\frac{e^{\delta'}}{(1+\delta')^{1+\delta'}}\right)^{f_i}$$
$$\leq \left(\frac{f_i}{2}\right)^{2\delta} \cdot \left(\frac{\delta}{e}\right)^{-2\delta} \leq f_i e^{-c' \log\log kr \cdot \frac{\log kr}{\log\log kr}} \leq \frac{f_i}{2k^3 r^3}\,.$$

Here, we use that $f_i \leq 2$ for the second last inequality and for the last inequality we pick c' sufficiently large by making c and k sufficiently large. (Note that MaxEDP can be solved efficiently for constant k.)

Now, using the union bound, we can infer that the probability that any of the edges incident on u carries more than δ paths is at most $\sum_i f_i/(2k^3r^3) \leq (2k)/(2k^3r^3) = 1/(k^2r^3)$. ◀

▶ **Lemma 12.** *Assume that every hot spot is good. Then the congestion on any edge is bounded by* $2c\frac{\log kr}{\log\log kr}$.

Proof. Consider an arbitrary edge $e = uv$ that is not incident on any hot spot. In particular, this means that e lies in the forest $F = G - R$. A hot spot z in F is called *direct* to e if the path in F from z to e excluding e does not contain any hot spot other than z.

We claim that there can be at most two distinct hot spots z, z' direct to e. If there were a third hot spot z'' direct to e, then consider the unique node $z_0 \in V(F)$ such that no two of the hot spots z, z', z'' are connected in $F - z_0$. Such a node z_0 exists since z, z', z'' cannot lie on a common path in F since they are all direct to e. The node z_0, however, would be added as a hot spot at the latest when H was built. Now, this is a contradiction, because then one of the paths connecting z, z' or z'' to e would contain z_0 and thus one of these hot spots would not be direct to e.

Now let P be an arbitrary path that is routed by our algorithm and that traverses e, and let $P' \in \mathcal{J}$ be the subpath of P in F visiting e. Moreover, let P_z, $P_{z'}$ be the paths in F connecting z, z' to e excluding e, and let e_z, $e_{z'}$ be the edges on these paths incident on z, z', respectively. By our construction, P' must visit a hot spot in F. If P' visited neither z nor z', then P' would contain a hot spot direct to u or to v that is distinct from z and z'—a contradiction. Hence P' and thus also P visit e_z or $e_{z'}$. The claim now follows from the fact that this holds for any path traversing e, that z and z' are good, and that therefore altogether at most $2c\frac{\log kr}{\log\log kr}$ paths visit e_z or e'_z. ◀

▶ **Theorem 13.** *The algorithm from Sect. 3.1 produces—with constant probability—a routing with* $\Omega(\mathrm{OPT})$ *paths, such that the congestion is* $\mathcal{O}\left(\frac{\log kr}{\log\log kr}\right)$.

Proof. As argued above, we route less than OPT $/2$ paths with probability at most $1/2$. By Lemma 9, there are $\mathcal{O}(kr^2)$ hotspots. The probability that at least one of these hot spots is bad is $\mathcal{O}(kr^2/(k^2r^3)) = \mathcal{O}(1/(kr))$, by Lemma 11. Hence, with constant probability, we route at least OPT $/2$ pairs with congestion at most $2c\frac{\log kr}{\log\log kr}$, by Lemma 12. ◀

4 Refined Approximation Bound for MaxEDP

In this section, we provide an improved approximation guarantee for MaxEDP *without* congestion, thereby proving Theorem 3. (In contrast to the previous section, we do not assume here that all terminals are contained in the feedback vertex set.)

4.1 Irreducible Routings with Low Congestion

We first develop the concept of *irreducible routings with low congestion*, which is (besides Theorem 2) a key ingredient of our strengthened bound on the approximability of MaxEDP based on the feedback vertex number.

Consider any multigraph G and any set $\mathcal{P}$ of (not necessarily simple) paths in G with congestion c. We say that an edge e is *redundant in* $\mathcal{P}$ if there is an edge $e' \neq e$ such that the set of paths in $\mathcal{P}$ *covering* (containing) e is a subset of the set of paths in $\mathcal{P}$ covering e'. Thus, any edge that is not covered by any path in $\mathcal{P}$ is redundant in $\mathcal{P}$ if G contains at least two edges.

▶ **Definition 14.** Set $\mathcal{P}$ is called an *irreducible routing with congestion* c if each edge belongs to at most c paths of $\mathcal{P}$ and there is no edge redundant in $\mathcal{P}$.

In contrast to a feasible routing of an MaxEDP instance, we do not require an irreducible routing to connect a set of terminal pairs. If there is an edge e redundant in $\mathcal{P}$, we can apply the following *reduction rule*: We contract e in G and we contract e in every path of $\mathcal{P}$ that covers e. By this, we obtain a minor G' of G and a set $\mathcal{P}'$ of paths that consists of all the contracted paths and of all paths in $\mathcal{P}$ that were not contracted. Thus, there is a one-to-one correspondence between the paths in $\mathcal{P}$ and $\mathcal{P}'$.

We make the following observation about $\mathcal{P}$ and $\mathcal{P}'$.

▶ **Observation 15.** *A subset of paths in $\mathcal{P}'$ is edge-disjoint in G' if and only if the corresponding subset of paths in $\mathcal{P}$ is edge-disjoint in G.*

As applying the reduction rule strictly decreases the number of redundant edges, an iterative application of this rule yields an irreducible routing on a minor of the original graph.

▶ **Theorem 16.** *Let $\mathcal{G}$ be a minor-closed class of multigraphs and let $p_{\mathcal{G}} > 0$. If for each graph $G \in \mathcal{G}$ and every non-empty irreducible routing $\mathcal{S}$ of G with congestion c there exists a path in $\mathcal{S}$ of length at most $p_{\mathcal{G}}$, then the average length of the paths in $\mathcal{S}$ is at most $c \cdot p_{\mathcal{G}}$.*

Proof. Take a path P_0 of length at most $p_{\mathcal{G}}$. Contract all edges of P_0 in G and obtain a minor $G' \in \mathcal{G}$ of G. For each path in $\mathcal{S}$ contract all edges shared with P_0 to obtain a set $\mathcal{S}'$ of paths. Remove P_0 along with all degenerated paths from $\mathcal{S}'$, thus $|\mathcal{S}'| < |\mathcal{S}|$. Note that $\mathcal{S}'$ is an irreducible routing of G' with congestion c. We repeat this reduction procedure recursively on G' and S' until S' is empty which happens after at most $|\mathcal{S}|$ steps. At each step we decrease the total path length by at most $c \cdot p_{\mathcal{G}}$. Hence, the total length of paths in $\mathcal{S}$ is at most $|\mathcal{S}| \cdot c \cdot p_{\mathcal{G}}$. ◀

As a consequence of Theorem 16, we get the following result for forests.

▶ **Lemma 17.** *Let F be a forest and let $\mathcal{S}$ be a non-empty irreducible routing of F with congestion c. Then the average path length in $\mathcal{S}$ is at most $2c$.*

Proof. We show that $\mathcal{S}$ contains a path of length as most 2. The lemma follows immediately by applying Theorem 16.

Take any tree in F, root it with any node and consider a leaf v of maximum depth. If v is adjacent to the root, then the tree is a star and every path in the tree has length at most 2. Otherwise, let e_1 and e_2 be the first two edges on the path from v to the root. By definition of irreducible routing, the set of all paths covering e_1 is not a subset of the paths covering e_2; hence, e_1 is covered by a path which does not cover e_2. Since all other edges incident to e_1 end in a leaf, this path has length at most 2. ◀

Note that the bound provided in Lemma 17 is actually tight up to a constant. Let $c \geq 1$ be an arbitrary integer. Consider a graph that is a path of length $c-1$ with a star of $c-1$ leafs attached to one of its end points. The $c-1$ paths of length c together with the $2c-2$ paths of length 1 form an irreducible routing with congestion c. The average path length is $((c-1)c + (2c-2))/(3c-3) = (c+2)/3$.

4.2 Approximation Algorithm

Consider an instance $(G, \mathcal{M})$ of MaxEDP, and let r be the size of a feedback vertex set R in G. Using our result of Sect. 3, we can efficiently compute a routing $\mathcal{P}$ with congestion $c := \mathcal{O}\left(\frac{\log kr}{\log\log kr}\right)$ containing $\Omega(\mathrm{OPT})$ paths.

Below we argue how to use the routing $\mathcal{P}$ to obtain a feasible routing of cardinality $\Omega\left(|\mathcal{P}|/(c^{1.5}\sqrt{r})\right)$, which yields an overall approximation ratio of $\mathcal{O}\left(\sqrt{r} \cdot \log^{1.5} rk\right)$; that will prove Theorem 3.

Let $r' = \sqrt{r/c}$. We distinguish the following cases.

Case 1: At least half of the paths in $\mathcal{P}$ visit at most r' nodes of the feedback vertex set R. Let $\overline{\mathcal{P}}$ be the subset of these paths. Initialize $\mathcal{P}'$ with $\overline{\mathcal{P}}$. As long as there is an edge e not adjacent to R that is redundant in $\mathcal{P}'$, we iteratively apply the reduction rule from Sect. 4.1 on e. Let G' be the obtained minor of G with forest $F' = G' - R$. The obtained set $\mathcal{P}'$ is a set of (not necessarily simple) paths in G' corresponding to $\overline{\mathcal{P}}$. By (iterated application of) Observation 15 to path sets $\overline{\mathcal{P}}$ and $\mathcal{P}'$, it suffices to show that there is a subset $\mathcal{P}'_0 \subseteq \mathcal{P}'$ of pairwise edge-disjoint paths of size $|\mathcal{P}'_0| = \Omega\left(|\mathcal{P}|/(cr')\right)$ in order to obtain a feasible routing for $(G, \mathcal{M})$ of size $\Omega\left(|\mathcal{P}|/(cr')\right)$.

To obtain $\mathcal{P}'_0$, we first bound the total path length in $\mathcal{P}'$. Removing R from G' “decomposes” the set P' into a set $\mathcal{S} := \{S \text{ is a connected component of } P \cap F \mid P \in \mathcal{P}'\}$ of subpaths lying in F'. Observe that $\mathcal{S}$ is an irreducible set of F' with congestion c, as the reduction rule is not applicable anymore. (Note that a single path in $\mathcal{P}'$ may lead to many paths in the cover $\mathcal{S}$ which are considered distinct.) Thus, by Lemma 17, the average path length in $\mathcal{S}$ is at most $2c$.

Let P be an arbitrary path in $\mathcal{P}'$. Each edge on P that is *not* in a subpath in $\mathcal{S}$ is incident on a node in R, and each node in R is incident on at most two edges in P. Together with the fact that P visits at most r' nodes in R and that the average length of the subpaths in $\mathcal{S}$ is at most $2c$, we can upper bound the total path length $\sum_{P \in \mathcal{P}'} |P|$ by $|\mathcal{P}'| r'(2c+2)$. Let $\mathcal{P}''$ be the set of the $|\mathcal{P}'|/2$ shortest paths in $\mathcal{P}'$. Hence, each path in $\mathcal{P}''$ has length at most $4r'(c+1)$.

We greedily construct a feasible solution $\mathcal{P}'_0$ by iteratively picking an arbitrary path P from $\mathcal{P}''$ adding it to $\mathcal{P}'_0$ and removing all paths from $\mathcal{P}''$ that share some edge with P (including P itself). We stop when $\mathcal{P}''$ is empty. As $\mathcal{P}''$ has congestion c, we remove at most $4r'c(c+1)$ paths from $\mathcal{P}''$ per iteration. Thus, $|\mathcal{P}'_0| \geq |\mathcal{P}''|/(4r'c(c+1)) = \Omega\left(|\mathcal{P}|/(c^{1.5}\sqrt{r}\right)$.

Case 2: At least half of the paths in $\mathcal{P}$ visit at least r' nodes of the feedback vertex set R. Let $\mathcal{P}'$ be the subset of these paths. Consider each path in $\mathcal{P}'$ as a flow of value $1/c$ and let f be the sum of all these flows. Note that f provides a feasible solution to the MaxEDP LP relaxation for (G, M) of value at least $|\mathcal{P}|/(2c)$. Note that each such flow path contributes $1/c$ unit of flow to each of the r' nodes in R it visits. Since every flow path in f has length at least r', the total inflow of the nodes in R is at least $|f|r'$. By averaging, there must be a node $v \in R$ of inflow at least $r'|f|/r = |f|/r'$. Let f' be the subflow of f consisting of all flow paths visiting v. This subflow corresponds to a feasible solution $(f', \mathbf{x}')$ of the LP relaxation of value at least $|f|/r' \geq |\mathcal{P}|/(2cr')$. Using Proposition 7, we can recover an integral feasible routing of size at least $\frac{1}{12}\sum_i x'_i \geq |\mathcal{P}|/(24cr') = \Omega\left(|\mathcal{P}|/(c^{1.5}\sqrt{r}\right)$.

This completes the proof of Theorem 3. ◀

5 Fixed-Parameter Algorithm for MaxNDP

We give a fixed-parameter algorithm for MaxNDP with run time $(k+r)^{\mathcal{O}(r)} \cdot n$, where r is the size of a minimum feedback vertex set in the given instance $(G, \mathcal{M})$. A feedback vertex set R of size r can be computed in time $2^{O(r)} \cdot \mathcal{O}(n)$ [36]. By the matching assumption, each terminal in $\mathcal{M}$ is a leaf. We can thus assume that none of the terminals is contained in R.

Consider an optimal routing $\mathcal{P}$ of the given MaxNDP instance. Let $\mathcal{M}_R \subseteq \mathcal{M}$ be the set of terminal pairs that are connected via $\mathcal{P}$ by a path that visits at least one node in R. Let $P \in \mathcal{P}$ be a path connecting a terminal pair $(s_i, t_i) \in \mathcal{M}_R$. This path has the form $(s_i, \dots, r_1, \dots, r_2, \dots, r_\ell, \dots, t_i)$, where $r_1, \dots, r_\ell$ are the nodes in R that are traversed by P in this order. The pairs $(s_i, r_1), (r_\ell, t_i)$ and (r_j, r_{j+1}) with $j = 1, \dots, \ell-1$ are called *essential* pairs for P. A node pair is called *essential* if it is essential for some path in $\mathcal{P}$. Let $\mathcal{M}_e$ be the set of essential pairs.

Let F be the forest that arises when deleting R from the input graph G. Let (u, v) be an essential pair. A u-v path P in G is said to *realize* (u, v) if all internal nodes of P lie in F. A set $\mathcal{P}'$ of paths is said to *realize* $\mathcal{M}_e$ if every pair in $\mathcal{M}_e$ is realized by some path in $\mathcal{P}'$ and if two paths in $\mathcal{P}'$ can only intersect at their end nodes. Note that the optimal routing $\mathcal{P}$ induces a natural realization of $\mathcal{M}_e$, by considering all maximal subpaths of paths in $\mathcal{P}$ whose internal nodes all lie in F. Conversely, for any realization $\mathcal{P}'$ of $\mathcal{M}_e$, we can concatenate paths in $\mathcal{P}'$ to obtain a feasible routing that connects all terminal pairs in $\mathcal{M}_R$. Therefore, we consider $\mathcal{P}'$ (slightly abusing notation) also as a feasible routing for $\mathcal{M}_R$.

In our algorithm, we first guess the set $\mathcal{M}_e$ (and thus $\mathcal{M}_R$). Then, by a dynamic program, we construct two sets of paths, $\mathcal{P}_e$ and $\mathcal{P}_F$ where $\mathcal{P}_e$ realizes $\mathcal{M}_e$ and $\mathcal{P}_F$ connects in F a subset of $\overline{\mathcal{M}}_R := \mathcal{M} \setminus \mathcal{M}_R$. In our algorithm, the set $\mathcal{P}_e \cup \mathcal{P}_F$ forms a feasible routing that maximizes $|\mathcal{P}_F|$ and routes all pairs in $\mathcal{M}_R$. (Recall that we consider the realization $\mathcal{P}_e$ of $\mathcal{M}_e$ as a feasible routing for $\mathcal{M}_R$.)

Now assume that we know set $\mathcal{M}_e$. We will describe below a dynamic program that computes an optimum routing in time $2^{\mathcal{O}(r)}(k+r)^{\mathcal{O}(1)}n$. For the sake of easier presentation, we only describe how to compute the cardinality of such a routing.

We make several technical assumptions that help to simplify the presentation. First, we modify the input instance as follows. We subdivide every edge incident on a node in R by introducing a single new node on this edge. Note that this yields an instance equivalent to the input instance. As a result, every neighbor of a node in R that lies in F, that is, every node in $N_G(R)$, is a leaf in F. Moreover, the set R is an independent set in G. Also recall that we assumed that every terminal is a leaf. Therefore, we may assume that R does not contain any terminal. We also assume that forest F is a rooted tree, by introducing a dummy node (which plays the role of the root) and arbitrarily connecting this node to every connected component of F by an edge. In our dynamic program, we will take care that no path visits this root node. We also assume that F is an ordered tree by introducing an arbitrary order among the children of each node.

For any node v, let F_v be the subtree of F rooted at v. Let $c_v := \deg_F(v) - 1$ be the number of children of v and let $v_1, \ldots v_{c_v}$ be the (ordered) children of v. Then, for $i = 1, \ldots, c_v$, let F_v^i denote the subtree of F_v induced by the union of v with the subtrees $F_{v_1}, \ldots, F_{v_i}$. For leaves v, we define F_v^0 as $F_v = v$.

We introduce a dynamic programming table T. It contains an entry for every F_v^i and every subset $\mathcal{M}'_e$ of $\mathcal{M}_e$. Roughly speaking, the value of such an entry is the solution to the subproblem, where we restrict the forest to F_v^i, and the set of essential pairs to $\mathcal{M}'_e$. More precisely, table T contains five parameters. Parameters v and i describing F_v^i, parameter $\mathcal{M}'_e$, and two more parameters u and b. Parameter u is either a terminal, or a node in R, and b is in one of the three states: *free*, *to-be-used*, or *blocked*. The value $T[v, i, \mathcal{M}'_e, u, b]$ is the maximum cardinality of a set $\mathcal{P}_F$ of paths with the following properties:

1. $\mathcal{P}_F$ is a feasible routing of some subset of $\overline{\mathcal{M}}_R$.
2. $\mathcal{P}_F$ is completely contained in F_v^i.
3. There is an additional set $\mathcal{P}_e$ of paths with the following properties:
   a. $\mathcal{P}_e$ is completely contained in $F_v^i \cup R$ and node-disjoint from the paths in $\mathcal{P}_F$.
   b. $\mathcal{P}_e$ is a realization of $\mathcal{M}'_e \cup \{(u, v)\}$ if $b =$ *to-be-used*. Else, it is a realization of $\mathcal{M}'_e$.
   c. There is no path in $\mathcal{P}_e \cup \mathcal{P}_F$ visiting v if $b =$ *free*.

If no such set $\mathcal{P}_F$ exists then $T[v, i, \mathcal{M}'_e, u, b]$ is $-\infty$.

Note that the parameter u is only relevant when $b =$ *to-be-used* (otherwise, it can just be ignored). Observe that $T[v, i, \mathcal{M}'_e, u, \textit{blocked}] \geq T[v, i, \mathcal{M}'_e, u, \textit{free}] \geq T[v, i, \mathcal{M}'_e, u, \textit{to-be-used}]$. Below, we describe how to compute the entries of T in a bottom-up manner.

In the base case v is a leaf. We set $T[v, 0, \emptyset, u, \textit{free}] = 0$. Then we set $T[v, 0, \mathcal{M}'_e, u, \textit{blocked}] = 0$ if $\mathcal{M}'_e$ is either empty, consists of a single pair of nodes in $R \cap N_G(v)$, or consists of a single pair where one node is v and the other one is in $R \cap N_G(v)$. Finally, we set $T[v, 0, \emptyset, u, \textit{to-be-used}] = 0$ if $u = v$ or u is in $R \cap N_G(v)$. For all other cases where v is a leaf, we set $T[v, i, \mathcal{M}'_e, u, b] = -\infty$.

For the inductive step, we consider the two cases $i = 1$ and $i > 1$. Let $i = 1$. It holds that $T[v, 1, \mathcal{M}'_e, u, \textit{to-be-used}] = T[v_1, c_v, \mathcal{M}'_e, u, \textit{to-be-used}]$ since the path in $\mathcal{P}_e$ realizing (u, v) has to start at a leaf node of F_{v_1}. It also holds that $T[v, 1, \mathcal{M}'_e, u, \textit{blocked}]$ and $T[v, 1, \mathcal{M}'_e, u, \textit{free}]$ are equal to $T[v_1, c_v, \mathcal{M}'_e, u, \textit{blocked}]$.

Now, let $i > 1$. In a high level view, we guess which part of $\mathcal{M}'_e$ is realized in $F_v^{i-1} \cup R$ and which part is realized in $F_{v_i} \cup R$. For this, we consider every tuple $(\mathcal{M}'_{e1}, \mathcal{M}'_{e2})$ such that $\mathcal{M}'_{e1} \uplus \mathcal{M}'_{e2}$ is a partition of $\mathcal{M}'_e$. By our dynamic programming table, we find a tuple that maximizes our objective. In the following, we assume that we guessed $(\mathcal{M}'_{e1}, \mathcal{M}'_{e2})$ correctly. Let us consider the different cases of b in more detail.

For $b =$ *free*, node v is not allowed to be visited by any path, especially by any path in $F_v^{i-1} \cup R$. Hence, $T[v, i, \mathcal{M}'_e, u, \textit{free}]$ is equal to

$$T[v, i-1, \mathcal{M}'_{e1}, u, \textit{free}] + T[v_i, c_{v_i}, \mathcal{M}'_{e2}, u, \textit{blocked}] \ .$$

In the case of $b = \textit{to-be-used}$, we have to realize (u, v) in $F_v^i \cup R$. For this, there are two possibilities: rither (u, v) is realized by a path in $F_v^{i-1} \cup R$, or there is a realizing path that first goes through $F_{v_i} \cup R$ and then reaches v via the edge (v_i, v). Hence, for the first case, we consider

$$T[v, i-1, \mathcal{M}'_{e1}, u, \textit{to-be-used}] + T[v_i, c_{v_i}, \mathcal{M}'_{e2}, u, \textit{blocked}],$$

for the second case, we consider

$$T[v, i-1, \mathcal{M}'_{e1}, u, \textit{free}] + T[v_i, c_{v_i}, \mathcal{M}'_{e2}, u, \textit{to-be-used}] \ .$$

Maximizing over both, we obtain $T[v, i, \mathcal{M}'_e, u, \textit{to-be-used}]$.

For the case of $b = \textit{blocked}$, we will consider two subcases. In the first subcase, there is no path in $\mathcal{P}_e \cup \mathcal{P}_F$ going through edge (v_i, v), hence, we get

$$T[v, i-1, \mathcal{M}'_{e1}, u, \textit{blocked}] + T[v_i, c_{v_i}, \mathcal{M}'_{e2}, u, \textit{blocked}] \ .$$

In the second subcase, there is a path P in $\mathcal{P}_e \cup \mathcal{P}_F$ going through edge (v_i, v). Since P is connecting two leafs in F_v^i, a part of P is in $F_v^{i-1} \cup R$ and the other part is in $F_{v_i} \cup R$. If $P \in \mathcal{P}_e$, then it is realizing a pair of $\mathcal{M}'_e$. Hence, for every pair $(u_1, u_2) \in \mathcal{M}'_e$, we have to consider the term

$$T[v, i-1, \mathcal{M}'_{e1} - (u_1, u_2), u_1, \textit{to-be-used}] + T[v_i, c_{v_i}, \mathcal{M}'_{e2} - (u_1, u_2), u_2, \textit{to-be-used}]$$

and the symmetric term where we swap u_1 and u_2. If $P \in \mathcal{P}_F$, then it is realizing a terminal pair of $\overline{\mathcal{M}}_R$. Hence, for every pair $(u_1, u_2) \in \overline{\mathcal{M}}_R$ we get the term

$$1 + T[v, i-1, \mathcal{M}'_{e1}, u_1, \textit{to-be-used}] + T[v_i, c_{v_i}, \mathcal{M}'_{e2}, u_2, \textit{to-be-used}]$$

and the symmetric term where we swap u_1 and u_2. Note that we count the path realizing (u_1, u_2) in our objective. Maximizing over all the terms of the two subcases, we obtain $T[v, i, \mathcal{M}'_e, u, \textit{to-be-used}]$.

Let us analyze the run time of algorithm described in Sect. 5. In order to guess $\mathcal{M}_e$, we enumerate all potential sets of essential pairs. There are at most $(2k + r + 1)^{2r}$ candidate sets to consider, since each pair contains a node in R, and each node in R is paired with at most two other nodes each of which is either a terminal or another node in R. For each particular guess $\mathcal{M}_e$, we run the above dynamic program. The number of entries in T—as specified by the five parameters v, i, $\mathcal{M}'_e, u$ and b—for each fixed $\mathcal{M}_e$ is at most $(\sum_{v \in V(F)} \deg_F(v)) \times 2^{2r} \times (2k + r) \times 3$. For the computation of each such entry, we consider all combinations of at most 2^{2r} partitions of $\mathcal{M}'_e$ with either at most r essential pairs in $\mathcal{M}'_e$, or with at most k terminal pairs in $\overline{\mathcal{M}}_R$. Altogether, this gives a run time of $(8k + 8r)^{2r+2} \cdot \mathcal{O}(n)$. This finishes the proof of Theorem 4.

6 Hardness of Edge-Disjoint Paths in Almost-Forests

In this section we show that EDP (and hence MaxEDP) is NP-hard already in graphs that are forests after deleting two nodes. That is, we prove Theorem 6.

Proof of Theorem 6. We first show NP-hardness of EDP for $r = 2$. We reduce from the problem Edge 3-Coloring in cubic graphs, which is NP-hard [26]. Given a cubic graph H, we construct a complete bipartite graph G, where one of the two partite classes of $V(G)$ consists of three nodes $\{v_1, v_2, v_3\}$, and the other partite class consists of $V(H)$. As terminal pairs, we create the set $\mathcal{M} = \{(s,t) \mid \{s,t\} \in E(H)\}$; in words, we want to connect a pair of nodes by a path in G if and only if they are connected by an edge in H. This completes the construction of the instance $(G,\mathcal{M})$ of MaxEDP. Notice that G has a feedback vertex set of size $r = 2$, since removing any size-2 subset of $\{v_1, v_2, v_3\}$ from G yields a forest.

Regarding correctness of the reduction, we show that H is 3-edge-colorable if and only if *all* pairs in $\mathcal{M}$ can be routed in G.

In the forward direction, suppose that H is 3-edge-colorable. Let $\varphi : E(H) \to \{1,2,3\}$ be a proper 3-edge-coloring of H. For $c = 1,2,3$, let $E_c \subseteq E(H)$ be the set of edges that receive color c under φ. Then there is a routing in G that routes all terminal pairs $\{(s,t) \in \mathcal{M} \mid \{s,t\} \in E_c\}$ exclusively via the node v_c (and thus via paths of length 2). Notice that this routing indeed yields edge-disjoint paths, for if there are distinct vertices $s, t_1, t_2 \in V(H)$ and edges $e_1 = \{s,t_1\}, e_2 = \{s,t_2\} \in E(H)$, then e_1, e_2 receive distinct colors under φ (as φ is proper), and so the two terminal pairs $\{s,t_1\}, \{s,t_2\}$ are routed via distinct nodes $c_1, c_2 \in \{v_1, v_2, v_3\}$, and thus also via edge-disjoint paths.

In the backward direction, suppose that all terminal pairs in $\mathcal{M}$ can be routed in G. Since H is cubic, any node $s \in V(H)$ is contained in three terminal pairs. Therefore, no path of the routing can have a node in $V(H)$ as an internal node and thus all paths in the routing have length 2. Then this routing naturally corresponds to a proper 3-edge-coloring φ of H, where any terminal pair $\{s,t\}$ routed via c means that we color the edge $\{s,t\} \in E(H)$ with color c under φ.

In order to show NP-hardness of MaxEDP for $r = 1$, we also reduce from Edge 3-Coloring in cubic graphs and perform a similar construction as described above: This time, we construct a bipartite graph G with one subset of the partition being $\{v_1, v_2\}$, the other being $V(H)$, and the set $\mathcal{M}$ of terminal pairs being again specified by the edges of H. This completes the reduction. The resulting graph G has a feedback vertex set of size $r = 1$.

We claim that H is 3-colorable if and only if we can route $n = |V(H)|$ pairs in G.

In the forward direction, suppose that H is 3-edge-colorable. Let $\varphi : E(H) \to \{1,2,3\}$ be a proper 3-edge-coloring of H. For $c = 1,2,3$, let $E_c \subseteq E(H)$ be the set of edges that receive color c under φ. Then there is a routing in G that routes all f $\{(s,t) \in \mathcal{M} \mid \{s,t\} \in E_c\}$ exclusively via the node v_c (and thus via paths of length 2) for the colors $c = 1,2$. (The terminals corresponding to edges receiving color 3 remain unrouted.)

The reasoning that the resulting routing is feasible is analogous to the case of $r = 2$. Since for each of the n terminals exactly two of the three terminal pairs are routed, this means that precisely n terminal pairs are routed overall.

In the backward direction, suppose that n terminal pairs in $\mathcal{M}$ can be routed in G. Since any terminal v in G is a node in $V(H)$ has therefore has degree two in G, this means that at most two paths can be routed for v. As n terminal pairs are realized, this also means that *exactly* two paths are routed for each terminal. Hence, none of the paths in the routing has length more than two. Otherwise, it would contain an internal node in $V(H)$, which then could not be part of two other paths in the routing. Then this routing naturally corresponds to a partial edge-coloring of H, where any terminal pair $\{s,t\}$ routed via c means that we color the edge $\{s,t\} \in E(H)$ with color c. Since each terminal v in $V(H)$ is involved in exactly two paths in the routing, exactly one terminal pair for v remains unrouted. Hence, exactly one edge incident on v in H remains uncolored in the partial coloring. We color all uncolored edges in H by color 3 to obtain a proper 3-coloring. ◀

Thus, we almost close the complexity gap for EDP with respect to the size of a minimum feedback vertex set, only leaving the complexity of the case $r = 1$ open.

Abstract

In the context of formal language recognition, we demonstrate the superiority of streaming property testers against streaming algorithms and property testers, when they are not combined. Initiated by Feigenbaum *et al.*, a streaming property tester is a streaming algorithm recognizing a language under the property testing approximation: it must distinguish inputs of the language from those that are ε-far from it, while using the smallest possible memory (rather than limiting its number of input queries). Our main result is a streaming ε-property tester for visibly pushdown languages (VPL) with memory space $\mathrm{poly}((\log n)/\varepsilon)$.

Our construction is done in three steps. First, we simulate a visibly pushdown automaton in one pass using a stack of small height but whose items can be of linear size. In a second step, those items are replaced by small sketches. Those sketches rely on a notion of suffix-sampling we introduce. This sampling is the key idea for taking benefit of both streaming algorithms and property testers in the third step. Indeed, the last step relies on a (non-streaming) property tester for weighted regular languages based on a previous tester by Alon *et al.* This tester can directly be used for streaming testing special cases of instances of VPL that are already hard for both streaming algorithms and property testers. We then use it to decide the correctness of completed items, given their sketches, before removing them from the stack.

1 Introduction

We focus on streams representing data with both a linear ordering and a hierarchically nested matching of items. Data with such dual linear-hierarchical structure arise in various context, *e.g.* in semi-structured data management when handling HTML/XML documents or in program analysis when considering executions of recursive programs. Regular languages, as recognized by finite state automata, revealed a natural and successful tool to express properties of streams but lack the ability to handle the hierarchical structure. Context-free languages easily capture the latter but turn out to be too expressive hence, quickly lead to intractable complexity. In contrast, visibly pushdown languages (VPL) [6] while encompassing regular languages, enjoy most of its good properties and permit to handle

data with both a linear and a hierarchical structure. In the context of semi-structured documents, they are closely related with regular languages of unranked trees as captured by hedge automata: indeed, a well-known result [3] states that, when the tree is given by its depth-first traversal, such automata correspond to visibly pushdown automata (Vpa) (see *e.g.* [18] for an overview on automata and logic for unranked trees). In databases, this word encoding of XML document is known as SAX representation: the document is a linear sequence of text characters, along with a hierarchically nested matching of open-tags with closing tags. Numerous popular subclasses of XML documents (*e.g.* those satisfying a given DTD specifications) are subclasses of Vpl. In program analysis, Vpa permit to capture natural properties of execution traces of recursive finite-state programs. For such programs, desirable specifications are expressed on the call-stack (*e.g.* "a module A should be invoked only if the module B belongs to the call-stack"): such properties can be expressed in the temporal logic of calls and returns (CaRet) [5, 4] that itself is captured by Vpa. Hence, the analysis of execution traces boils down to check membership in a Vpl.

Therefore, the study of Vpl is central to understand how massive semi-structured data (*e.g.* large semi-structured documents or execution traces) can be analyzed by sublinear algorithms, such as streaming algorithms and property testers.

Historically, Vpl got several names such as input-driven languages or, more recently, languages of nested words. Intuitively, a Vpa is a pushdown automaton whose actions on stack (push, pop or nothing) are solely decided by the currently read symbol. As a consequence, symbols can be partitioned into three groups: push, pop and neutral symbols. The complexity of Vpl recognition has been addressed in various computational models. The first results go back to the design of logarithmic space algorithms [11] as well as NC^1-circuits [13]. Later on, other models motivated by the context of massive data were considered, such as streaming algorithms and property testers (described below).

Streaming algorithms (see *e.g.* [22]) have only a sequential access to their input, on which they can perform a single pass, or sometimes a small number of additional passes. The size of their internal (random access) memory is the crucial complexity parameter, which should be sublinear in the input size, and even polylogarithmic if possible. The area of streaming algorithms has experienced tremendous growth in many applications since the late 1990s. The analysis of Internet traffic [2], in which traffic logs are queried, was one of their first applications. Nowadays, they have found applications with big data, notably to test graphs properties, and more recently in language recognition on very large inputs. The streaming complexity of language recognition has been firstly considered for languages that arise in the context of memory checking [8, 12], of databases [28, 27], and later on for formal languages [20, 7]. However, even for simple Vpl, any randomized streaming algorithm with p passes requires memory $\Omega(n/p)$, where n is the input size [17].

As opposed to streaming algorithms, (standard) property testers [9, 10, 16] have random access to their input but in the query model. They must query each piece of the input they need to access. They should sample only a sublinear fraction of their input, and ideally make a constant number of queries. In order to make the task of verification possible, decision problems need to be approximated as follows. Given a distance on words, an ε-tester for a language L distinguishes with high probability the words in L from those ε-far from L, using as few queries as possible. Property testing of regular languages was first considered for the Hamming distance [1]. When the distance allows sufficient modifications of the input, such as moves of arbitrarily large factors, it has been shown that any context-free language becomes testable with a constant number of queries [19, 15]. However, for more realistic distances, property testers for simple languages require a large number of queries, especially if they have one-sided error only. For example the complexity of an ε-tester for well-parenthesized expressions with two types of parentheses is between $\Omega(n^{1/11})$ and $O(n^{2/3})$ [25], and it becomes linear, even for one type of parentheses, if we require one-sided error [1]. The difficulty of testing regular tree languages was also addressed when the tester can directly query the tree structure [23, 24].

Faced by the intrinsic hardness of VPL in both streaming and property testing, we study the complexity of *streaming property testers* of formal languages, a model of algorithms combining both approaches. Such testers were historically introduced for testing specific problems (groupedness) [14] relevant for network data. They were later studied in the context of testing the insert/extract-sequence of a priority-queue structure [12]. We extend these studies to classes of problems. A streaming property tester is a streaming algorithm recognizing a language under the property testing approximation: it must distinguish inputs of the language from those that are ε-far from it, while using the smallest possible memory (rather than limiting its number of input queries). Such an algorithm can simulate any standard non-adaptive property tester. Moreover, we will see that, using its full scan of the input, it can construct better sketches than in the query model.

In this paper, we consider a natural notion of distance for VPL, the *balanced-edit distance*, which refines the edit distance on *balanced words* (where for each push symbol there is a matching pop symbol at the same height of the stack, and conversely). It can be interpreted as the edit distance on trees when trees are encoded as balanced words. Neutral symbols can be deleted/inserted, but any push symbol can only be deleted/inserted together with its matching pop symbol. Since our distance is larger than the standard edit distance, our testers are also valid for the edit distance.

In Section 3, we first design an exact algorithm that maintains a small stack but whose items can be of linear size as opposed to the standard simulation of a pushdown automaton which usually has a stack of possible linear size but with constant size items. In our algorithm, stack items are prefixes of some peaks (which we call unfinished peaks), where a *peak* is a balanced factor whose push symbols appear all before the first pop symbol. Our algorithm compresses an unfinished peak $u = u_+v_-$ when it is followed by a long enough sequence. More precisely, the compression applies to the peak v_+v_- obtained by disregarding part of the prefix of push sequence u_+. Those peaks are then inductively replaced, and therefore compressed, by the state-transition relation they define on the given automaton. The relation is then considered as a single symbol whose weight is the size of the peak it represents. In addition, to maintain a stack of logarithmic depth, one of the crucial properties of our algorithm (**Proposition 6**) is rewriting the input word as a peak formed by potentially a linear number of intermediate peaks, but with only a logarithmic number of nested peaks.

In Section 4, for the case of a single peak, we show how to sketch the current unfinished peak of our algorithm. The simplicity of those instances will let us highlight our first idea. Moreover, they are already expressive enough in order to demonstrate the superiority of streaming testers against streaming algorithms and property testers, when they are not combined. We first reduce the problem of streaming testing such instances to the problem of testing regular languages in the standard model of property testing (**Theorem 16**). Since our reduction induces weights on the letters of the new input word, we need a tester for weighted regular languages. Such a property tester has previously been devised in [24] extending constructions for unweighted regular languages [1, 23]. However, we consider a slightly simpler construction that could be of independent interest. As a consequence we get a streaming property tester with polylogarithmic memory for recognizing peak instances of any given VPL (**Theorem 17**), a task already hard for streaming algorithms and property testers (**Fact 8**).

In Section 5, we construct our main tester for a VPL L given by some VPA. For this we introduce a more involved notion of sketches made of a polylogarithmic number of samples. They are based on a new notion of suffix sampling (**Definition 18**). This sampling consists in a decomposition of the string into an increasing sequence of suffixes, whose weights increase geometrically. Such a decomposition can be computed online on a data stream, and one can maintain samples in each suffix of the decomposition using a standard reservoir sampling. This suffix decomposition will allow us to simulate an appropriate sampling on the peaks we compress, even if we do not yet know where they start. Our sampling can be used to perform an approximate computation of the compressed relation by our new property tester of weighted regular languages which we also used for single peaks. We first establish a result of stability which basically states that we can assume that our algorithm knows in advance where the peak it will compress starts (**Lemma 22**). Then we prove the robustness of our algorithm: words that are ε-far from L are rejected with high probability (**Lemma 23**). As a consequence, we get a one-pass streaming ε-tester for L with one-sided error η and memory space $\mathrm{O}(m^5 2^{3m^2}(\log n)^6(\log 1/\eta)/\varepsilon^4)$, where m is the number of states of a VPA recognizing L (**Theorem 20**).

2 Definitions and Preliminaries

Let $\mathbb{N}^*$ be the set of positive integers, and for any $n \in \mathbb{N}^*$, let $[n] = \{1, 2, \dots, n\}$. A t-subset of a set S is any subset of S of size t. For a finite alphabet Σ we denote the set of finite words over Σ by Σ^*. We denote by $u \cdot v$ (or simply uv) the word obtained by concatenating u and v. For a word $u = u(1)u(2)\cdots u(n)$, we call n the *length* of u, and $u(i)$ the ith letter in u. A *factor* of u is a word $u[i, j] = u(i)u(i+1)\cdots u(j)$ with $1 \le i \le j \le n$. When we mention letters and factors of u we implicitly also mention their positions in u. We say that v is a *sub-factor* of v', denoted $v \le v'$, if $v = u[i, j]$ and $v' = u[i', j']$ with $[i, j] \subseteq [i', j']$. Similarly we say that $v = v'$ if $[i, j] = [i', j']$. If $i \le i' \le j \le j'$ we say that the *overlap* of v and v' is $u[i', j]$. If v is a sub-factor of v' then the overlap of v and v' is v. Given two multisets of factors S and S', we say that $S \le S'$ if there is an injection $f : S \mapsto S'$ such that for each factor $v \in S$, $v \le f(v)$.

2.1 Weighted Words and Sampling

A *weight function* on a word u with n letters is a function $\lambda : [n] \to \mathbb{N}^*$ on the letters of u, whose value $\lambda(i)$ is called the *weight of* $u(i)$. A *weighted word* over Σ is a pair (u, λ) where $u \in \Sigma^*$ and λ is a weight function on u. We define $|u(i)| = \lambda(i)$ and $|u[i, j]| = \lambda(i) + \lambda(i+1) + \ldots + \lambda(j)$. The length of (u, λ) is the length of u. For simplicity, we will denote by u the weighted word (u, λ). Weighted letters will be used to substitute factors of same weights.

Our algorithms will be based on sampling of small factors according to their weights. We introduce a very specific notion adapted to our setting. For a weighted word u, we denote by *k-factor sampling on u* the sampling over factors $u[i, i + l]$ with probability $|u(i)|/|u|$, where $l \ge 0$ is the smallest integer such that $|u[i, i + l]| \ge k$ if it exists, otherwise l is such that $i + l$ is the last letter of u. More generally, we call *k-factor* such a factor. For the special case of $k = 1$, we call this sampling a *letter sampling on u*. In fact the general case $k > 1$ simply reduces to $k = 1$. Indeed, simply observe that k-factor sampling can be obtained from letter sampling by sampling on the first letters of the factors and online completing any sampled letter to produce its associated k-factor. Therefore, from now on, we only focus on how to perform letter samplings, that we implicitly extend to samplings on k-factors when

Algorithm 1 Reservoir Sampling

```
Input: Data stream $u$, Integer $t > 1$ standing for the number of samples
Data structure:
  $\sigma \leftarrow 0$ // Current weight of the processed stream
  $S \leftarrow$ empty multiset // Multiset of sampled letters
Code:
$a \leftarrow \mathrm{Next}(u)$, $\sigma \leftarrow |a|$
$S \leftarrow t$ copies of $a$
While $u$ not finished
    $a \leftarrow \mathrm{Next}(u)$, $\sigma \leftarrow \sigma + |a|$
    For each $b \in S$
        Replace $b$ by $a$ with probability $|a|/\sigma$
Output $S$
```

required. In particular, without further constraints, letter sampling can be implemented using a standard reservoir sampling (see Algorithm 1).

Even if our algorithm will require several samples from a k-factor sampling, we will often only be able to simulate this sampling by sampling either larger factors, more factors, or both. We introduce the notion of *over-sampling* to formalize this:

▶ **Definition 1.** Let $\mathcal{W}_1$ be a sampler producing a random multiset S_1 of factors of some given weighted word u. Then $\mathcal{W}_2$ *over-samples* $\mathcal{W}_1$ if it produces a random multiset S_2 of factors of u such that for each factor v of u, we have $\Pr(\exists v' \in S_2$ such that v is a factor of $v') \geq \Pr(\exists v' \in S_1$ such that v is a factor of $v')$.

2.2 Finite State Automata and Visibly Pushdown Automata

A *finite state automaton* is a tuple of the form $\mathcal{A} = (Q, \Sigma, Q_{in}, Q_f, \Delta)$ where Q is a finite set of control states, Σ is a finite input alphabet, $Q_{in} \subseteq Q$ is a subset of initial states, $Q_f \subseteq Q$ is a subset of final states and $\Delta \subseteq Q \times \Sigma \times Q$ is a transition relation. We write $p \xrightarrow{u} q$, to mean that there is a sequence of transitions in $\mathcal{A}$ from p to q while processing u, and we call (p, q) a u-*transition*. A word u is accepted if $q_{in} \xrightarrow{u} q_f$ for some $q_{in} \in Q_{in}$ and $q_f \in Q_f$. The language $L(\mathcal{A})$ of $\mathcal{A}$ is the set of words accepted by $\mathcal{A}$, and we refer to such a language as a *regular language*. For $\Sigma' \subseteq \Sigma$, the Σ'-*diameter* (or simply *diameter* when $\Sigma' = \Sigma$) of $\mathcal{A}$ is the maximum over all possible pairs $(p, q) \in Q^2$ of $\min\{|u| : p \xrightarrow{u} q$ and $u \in \Sigma'^*\}$, whenever this minimum is not over an empty set. We say that $\mathcal{A}$ is Σ'-*closed*, when $p \xrightarrow{u} q$ for some $u \in \Sigma^*$ if and only if $p \xrightarrow{u'} q$ for some $u' \in \Sigma'^*$.

A *pushdown alphabet* is a triple $\langle \Sigma_+, \Sigma_-, \Sigma_= \rangle$ that comprises three disjoint finite alphabets: Σ_+ is a finite set of *push symbols*, Σ_- is a finite set of *pop symbols*, and $\Sigma_=$ is a finite set of *neutral symbols*. For any such triple, let $\Sigma = \Sigma_+ \cup \Sigma_- \cup \Sigma_=$. Intuitively, a *visibly pushdown automaton* [26] over $\langle \Sigma_+, \Sigma_-, \Sigma_= \rangle$ is a pushdown automaton restricted so that it pushes onto the stack only on reading a push, it pops the stack only on reading a pop, and it does not modify the stack on reading a neutral symbol. Up to coding, this notion is similar to the one of input driven pushdown automata [21] and of nested word automata [6].

▶ **Definition 2.** A *visibly pushdown automaton* (VPA) over $\langle \Sigma_+, \Sigma_-, \Sigma_= \rangle$ is a tuple $\mathcal{A} = (Q, \Sigma, \Gamma, Q_{in}, Q_f, \Delta)$ where Q is a finite set of states, $Q_{in} \subseteq Q$ is a set of initial states, $Q_f \subseteq Q$ is a set of final states, Γ is a finite stack alphabet, and $\Delta \subseteq (Q \times \Sigma_+ \times Q \times \Gamma) \cup (Q \times \Sigma_- \times \Gamma \times Q) \cup (Q \times \Sigma_= \times Q)$ is the transition relation.

To represent stacks we use a special bottom-of-stack symbol $\perp$ that is not in Γ. A *configuration* of a VPA $\mathcal{A}$ is a pair (σ, q), where $q \in Q$ and $\sigma \in \perp \cdot \Gamma^*$. For $a \in \Sigma$, there is an *a-transition* from a configuration (σ, q) to (σ', q'), denoted $(\sigma, q)\xrightarrow{a}(\sigma', q')$, in the following cases:

- If a is a push symbol, then $\sigma' = \sigma\gamma$ for some $(q, a, q', \gamma) \in \Delta$, and we write $q\xrightarrow{a}(q', \mathsf{push}(\gamma))$.
- If a is a pop symbol, then $\sigma = \sigma'\gamma$ for some $(q, a, \gamma, q') \in \Delta$, and we write $(q, \mathsf{pop}(\gamma))\xrightarrow{a}q'$.
- If a is a neutral symbol, then $\sigma = \sigma'$ and $(q, a, q') \in \Delta$, and we write $q\xrightarrow{a}q'$.

For a finite word $u = a_1 \cdots a_n \in \Sigma^*$, if $(\sigma_{i-1}, q_{i-1})\xrightarrow{a_i}(\sigma_i, q_i)$ for every $1 \leq i \leq n$, we also write $(\sigma_0, q_0)\xrightarrow{u}(\sigma_n, q_n)$. The word u is *accepted* by a VPA if there is $(p, q) \in Q_{in} \times Q_f$ such that $(\perp, p)\xrightarrow{u}(\perp, q)$. The language $L(\mathcal{A})$ of $\mathcal{A}$ is the set of words accepted by $\mathcal{A}$, and we refer to such a language as a *visibly pushdown language* (VPL).

At each step, the height of the stack is pre-determined by the prefix of u read so far. The *height* $\text{height}(u)$ of $u \in \Sigma^*$ is the difference between the number of its push symbols and of its pop symbols. A word u is *balanced* if $\text{height}(u) = 0$ and $\text{height}(u[1, i]) \geq 0$ for all i. We also say that a push symbol $u(i)$ *matches* a pop symbol $u(j)$ if $\text{height}(u[i, j]) = 0$ and $\text{height}(u[i, k]) > 0$ for all $i < k < j$. By extension, the height of $u(i)$ is $\text{height}(u[1, i-1])$ when $u(i)$ is a push symbol, and $\text{height}(u[1, i])$ otherwise.

For all balanced words u, the property $(\sigma, p)\xrightarrow{u}(\sigma, q)$ does not depend on σ, therefore we simply write $p\xrightarrow{u}q$, and say that (p, q) is a *u-transition.* We also define similarly to the notions for finite automata above the Σ'*-diameter* of $\mathcal{A}$ (or simply diameter) and the notion of $\mathcal{A}$ being Σ'*-closed.* These definitions only consider balanced words.

Our model is inherently restricted to input words having no prefix of negative stack height, and we defined acceptance with an empty stack. This implies that only balanced words can be accepted. From now on, we assume that the input is balanced as verifying this in a streaming context is easy.

2.3 Streaming Property Testers

Assume we have, for any $\varepsilon > 0$, a criterion to declare that an input u is ε-far from a language L. An ε-tester for L accepts all inputs in L with probability 1 and rejects with high probability all inputs ε-far from L. Two-sided error testers have also been studied but in this paper we stay with the notion of one-sided testers, that we adapt in the context of streaming algorithm as in [14].

▶ **Definition 3.** Let $\varepsilon > 0$ and let L be a language. A *streaming ε-tester* for L with one-sided error η and memory $s(n)$ is a randomized algorithm A such that, for any input u of length n given as a data stream:

- If $u \in L$, then A accepts with probability 1;
- If u is ε-far from L, then A rejects with probability at least $1 - \eta$;
- A processes u within a single sequential pass while maintaining a memory

Even if we only focus on the space complexity of streaming testers, all our streaming testers have polylogarithmic (in n/ε) time per processing letter.

For a distance d between words, we say that a word u is ε-far from a language L if $d(u, v) > \varepsilon|u|$ for every $v \in L$, *i.e.* the ε-neighborhood of u does not intersect L. Hence, any distance on words leads to a notion of streaming property tester. Remark that any ε-tester for some distance d_1 turns out to be also a $(c\varepsilon)$-tester for any other distance d_2 such that $d_2 \leq cd_1$, where $c > 0$ is some constant.

2.4 Balanced/Standard Edit Distance

The usual distance between words in property testing is the Hamming distance. In this work, we consider an easier distance to manipulate in property testing but still relevant for most applications, which is the edit distance, that we adapt to weighted words.

Given a word u, we define two possible *edit operations*: the *deletion* of a letter in position i with corresponding cost $|u(i)|$, and its converse operation, the *insertion* where we also select a weight for the new $u(i)$. Note that, for simplicity, we drop the usual substitution operation, leading to a possible multiplicative factor of 2 in the resulting distance. This is not an issue when designing streaming property testers as observed above. The *(standard) edit distance* $\mathsf{dist}(u,v)$ between two weighted words u and v is defined as the minimum total cost of a sequence of edit operations changing u to v. All letters that have not been inserted nor deleted must keep the same weight. For a restricted set of letters Σ', define $\mathsf{dist}_{\Sigma'}(u,v)$ when insertions (but not deletions) are restricted to letters in Σ' (this makes $\mathsf{dist}_{\Sigma'}$ not symmetric).

We will also consider a restricted version of this distance for balanced words, motivated by our study of VPL. Similarly, *balanced-edit operations* can be deletions or insertions of letters, but each deletion of a push symbol (resp. pop symbol) requires the deletion of the matching pop symbol (resp. push symbol). Similarly for insertions: if a push (resp. pop) symbol is inserted, then a matching pop (resp. push) symbol must also be inserted simultaneously. The cost of these operations is the weight of the affected letters, as with the edit operations. We define the *balanced-edit distance* $\mathsf{bdist}(u,v)$ between two balanced words as the total cost of a sequence of balanced-edit operations changing u to v. Similarly to $\mathsf{dist}_{\Sigma'}(u,v)$ we define $\mathsf{bdist}_{\Sigma'}(u,v)$. We omit Σ' when $\Sigma' = \Sigma$.

When dealing with a visibly pushdown language, we will always use the balanced-edit distance, whereas we will use the standard-edit distance for regular languages. Note that since balanced-edit distance is larger than the standard edit distance, our testers will also be valid for that distance.

3 Exact Algorithm

Fix a VPA $\mathcal{A}$ recognizing some VPL L on $\Sigma = \Sigma_+ \cup \Sigma_- \cup \Sigma_=$. In this section, we design an exact streaming algorithm that decides whether an input belongs to L. Algorithm 2 maintains a stack of small height but whose items can be of linear size. In Section 5, we replace stack items by appropriate small sketches.

3.1 Notations and Algorithm Description

Call a *peak* a sequence of push symbols followed by an equal number of pop symbols, with possibly intermediate neutral symbols, *i.e.* an element of the language $\Lambda = \bigcup_{j\geq 0}((\Sigma_=)^* \cdot \Sigma_+)^j \cdot (\Sigma_=)^* \cdot (\Sigma_- \cdot (\Sigma_=)^*)^j$. One can compress any peak $v \in \Lambda$ by the set $R_v = \{(p,q) : p \xrightarrow{v} q\}$ of the v-transitions, and consider R_v as a new neutral symbol with weight $|v|$. In fact, for the purpose of the analysis of our algorithm, we augment neutral symbols by many more relations for which $\mathcal{A}$ remains Σ-closed. Indeed, we allow any relation R of any weight such that, when $(p,q) \in R$, there is a $v \in \Lambda$ such that $p \xrightarrow{v} q$, but that v could be different for every $(p,q) \in R$. For the rest of the paper, they will be the only symbols with weight potentially larger than 1.

▶ **Definition 4.** Let Σ_Q be $\Sigma_=$ augmented by all letters 'R' encoding a relation $R \subseteq Q \times Q$ such that for every $(p,q) \in R$ there is a balanced word $u \in \Sigma^*$ with $p \xrightarrow{u} q$. In addition we allow any weight $|R| \geq 1$ for those letters. Let Λ_Q be Λ where $\Sigma_=$ is replaced by Σ_Q.

Algorithm 2 Exact Tester for a VPL

```
Input: Balanced data stream $u$
Data structure:
$Stack \leftarrow$ empty stack // Stack of items $v$ with $v \in \mathrm{Prefix}(\Lambda_Q)$
$u_0 \leftarrow \emptyset$ // $u_0 \in \mathrm{Prefix}(\Lambda_Q)$ is a suffix of the processed part $u[1,i]$ of $u$
     // with possibly some factors $v \in \Lambda_Q$ replaced by $R_v$
$R_{\mathtt{temp}} \leftarrow \{(p,p)\}_{p\in Q}$ //Set of transitions for the max. prefix of $u[1,i]$ in $\Lambda_Q$
Code:
While $u$ not finished
  $a \leftarrow \mathrm{Next}(u)$ //Read and process a new symbol $a$
  If $a \in \Sigma_+$ and $u_0$ has a letter in $\Sigma_-$ // $u_0 \cdot a \notin \mathrm{Prefix}(\Lambda_Q)$
    Push $u_0$ on $Stack$, $u_0 \leftarrow a$
  Else $u_0 \leftarrow u_0 \cdot a$
  If $u_0$ is balanced // $u_0 \in \Lambda_Q$: compression
    Compute $R_{u_0}$ the set of $u_0$-transitions
    If $Stack = \emptyset$, then $R_{\mathtt{temp}} \leftarrow R_{\mathtt{temp}} \circ R_{u_0}$, $u_0 \leftarrow \emptyset$
      // where $\circ$ denotes the composition of relations
    Else Pop $v$ from $Stack$, $u_0 \leftarrow v \cdot R_{u_0}$
  Let $(v_1 \cdot v_2) \leftarrow \mathrm{top}(Stack)$ s.t. $v_2$ is maximal and balanced // $v_2 \in \Lambda_Q$
  If $|u_0| \geq |v_2|/2$  // $u_0$ is big enough and $v_2$ can be replaced by $R_{v_2}$
    Compute $R_{v_2}$ the $v_2$-transitions, Pop $v$ from Stack, $u_0 \leftarrow (v_1 \cdot R_{v_2}) \cdot u_0$
If $(Q_{in} \times Q_f) \cap R_{\mathtt{temp}} \neq \emptyset$, Accept; Else Reject // $R_{\mathtt{temp}} = R_u$
```

We then write $p\xrightarrow{R}q$ whenever $(p,q) \in R$, and extend $\mathcal{A}$ and L accordingly. Of course, our notion of distance will be solely based on the initial alphabet Σ. If $R_1, R_2 \subseteq Q \times Q$ are two relations on Q we define their composition $R_1 \circ R_2$ to be $\{(x,z) \mid \exists y \text{ s.t. } (x,y) \in R_1 \text{ and } (y,z) \in R_2\}$.

A general balanced input instance u will consist of many nested peaks. However, we will recursively replace each factor $v \in \Lambda_Q$ by R_v with weight $|v|$.

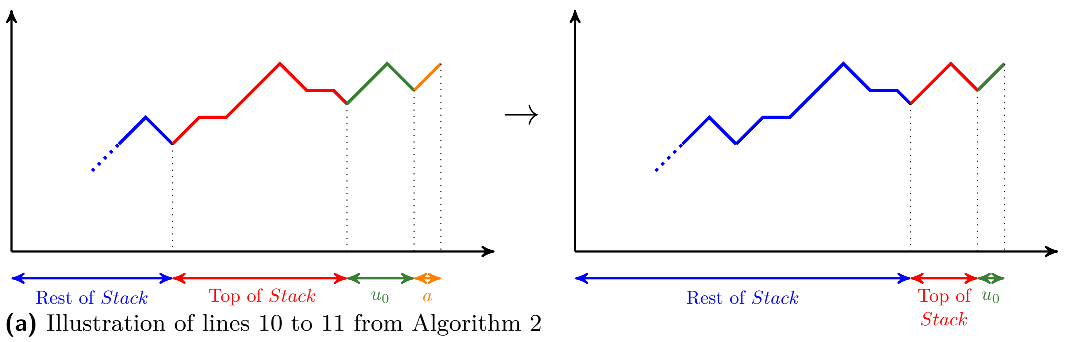
Denote by $\mathrm{Prefix}(\Lambda_Q)$ the language of prefixes of words in Λ_Q. While processing the prefix $u[1,i]$ of the data stream u, Algorithm 2 maintains a suffix $u_0 \in \mathrm{Prefix}(\Lambda_Q)$ of $u[1,i]$, that is an unfinished peak, with some simplifications of factors v in Λ_Q by their corresponding relation R_v. Therefore u_0 consists of a sequence of push symbols and neutral symbols possibly followed by a sequence of pop symbols and neutral symbols. The algorithm also maintains a subset $R_{\mathtt{temp}} \subseteq Q \times Q$ that is the set of transitions for the maximal prefix of $u[1,i]$ in Λ_Q. When the stream is over, the set $R_{\mathtt{temp}}$ is used to decide whether $u \in L$ or not.

When a push symbol a comes after a pop sequence, $u_0 \cdot a$ is no longer in $\mathrm{Prefix}(\Lambda_Q)$ hence, Algorithm 2 puts u_0 on the stack of unfinished peaks (see lines 10 to 11 and Figure 1a) and u_0 is reset to a. In other situations, it adds a to u_0. In case u_0 becomes a word in Λ_Q (see lines 13 to 17 and Figure 1b), Algorithm 2 computes the set of u_0-transitions $R_{u_0} \in \Sigma_Q$, and adds R_{u_0} to the previous unfinished peak that is retrieved on top of the stack and becomes the current unfinished peak; in the special case where the stack is empty it simply updates $R_{\mathtt{temp}}$ by taking its composition with R_{u_0}.

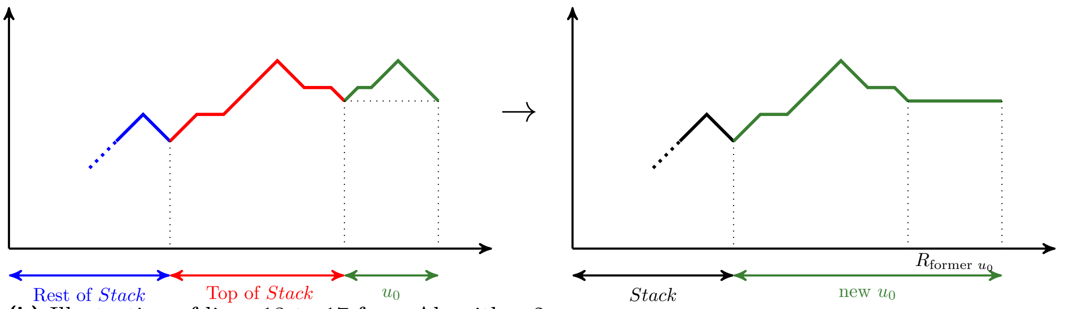
3.2 Algorithm Analysis

For each factor v constructed in Algorithm 2, we define $\mathrm{Depth}(v)$ as the number of processed nested peaks in v. This is formalized as follows.

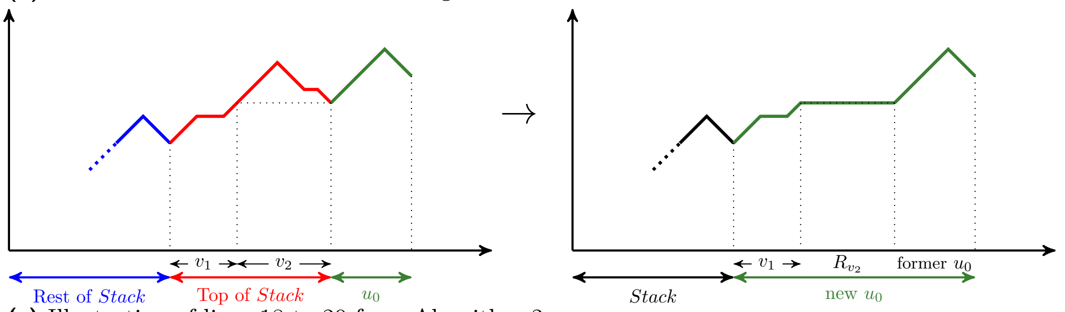
▶ **Definition 5.** For each factor constructed in Algorithm 2, Depth is defined dynamically by $\mathrm{Depth}(a) = 0$ when $a \in \Sigma$, $\mathrm{Depth}(v) = \max_i \mathrm{Depth}(v(i))$ and $\mathrm{Depth}(R_v) = \mathrm{Depth}(v) + 1$.



(a) Illustration of lines 10 to 11 from Algorithm 2



(b) Illustration of lines 13 to 17 from Algorithm 2



(c) Illustration of lines 18 to 20 from Algorithm 2

Figure 1 Illustration of Algorithm 2.

In order to bound the size of the stack, Algorithm 2 considers the maximal balanced suffix v_2 of the topmost element $v_1 \cdot v_2$ of the stack and, whenever $|u_0| \geq |v_2|/2$, it computes the relation R_{v_2} and continues with a bigger current peak starting with v_1 (see lines 18 to 20 and Figure 1c). A consequence of this compression is that the elements in the stack have geometrically decreasing weight and therefore the height of the stack used by Algorithm 2 is logarithmic in the length of the input stream. This can be proved by a direct inspection of Algorithm 2.

▶ **Proposition 6.** *Algorithm 2 accepts exactly when $u \in L$, while maintaining a stack of at most $\log |u|$ items.*

We state that Algorithm 2, when processing an input u of length n, considers at most $\mathrm{O}(\log n)$ nested peaks, that is $\mathrm{Depth}(v) = \mathrm{O}(\log n)$ for all factors constructed in Algorithm 2.

▶ **Lemma 7.** *Let v be the factor used to compute R_v at line either 14 or 20 of Algorithm 2. Then $|v(i)| \leq 2|v|/3$, for all i. Moreover, for any factor w constructed by Algorithm 2 it holds that $\mathrm{Depth}(w) = \mathrm{O}(\log |w|)$.*

4 The Special Case Of Peaks

We now consider restricted instances consisting of a *single peak*. For these instances, Algorithm 2 never uses its stack but u_0 can be of linear size. We show how to replace u_0 by a small random sketch in order to get a streaming property tester using polylogarithmic memory. In Section 5, this notion of sketch will be later extended to obtain our final streaming property tester for general instances.

4.1 Hard Peak Instances

Peaks are already hard for both streaming algorithms and property testers. Indeed, consider the language Disj $\subseteq \Lambda$ over alphabet $\Sigma = \{0,1,\overline{0},\overline{1},a\}$ and defined as the union of all languages $a^* \cdot x(1) \cdot a^* \cdot \ldots \cdot x(j) \cdot a^* \cdot \overline{y(j)} \cdot a^* \cdot \ldots \cdot \overline{y(1)} \cdot a^*$, where $j \geq 1$, $x, y \in \{0,1\}^j$, and $x(i)y(i) \neq 1$ for all i.

Then Disj can be recognized by a VPA with 3 states, $\Sigma_+ = \{0,1\}$, $\Sigma_- = \{\overline{0},\overline{1}\}$ and $\Sigma_= = \{a\}$. However, the following fact states its hardness for both models. The hardness for non-approximation streaming algorithms comes for a standard reduction to Set-Disjointness. The hardness for property testing algorithms is a corollary of a similar result due to [25] for parenthesis languages with two types of parentheses.

▶ **Fact 8.** *Any randomized p-pass streaming algorithm for* Disj *requires memory space $\Omega(n/p)$, where n is the input length. Moreover, any (non-streaming) (2^{-6})-tester for* Disj *requires to query $\Omega(n^{1/11}/\log n)$ letters of the input word.*

Surprisingly, for every $\varepsilon > 0$, we will show that languages of the form $L \cap \Lambda$, where L is a VPL, become easy to ε-test by streaming algorithms. This is mainly because, given their full access to the input, streaming algorithms can perform an input sampling which makes the property testing task easy, using only a single pass and little memory.

4.2 Slicing Automaton

Observe that Algorithm 2 will never use the stack in the case of a single peak. After Algorithm 2 has processed the i-th letter of the data stream, u_0 contains $u[1,i]$ where the eventual initial sequence of neutral symbols has been removed. We will show how to compute R_{u_0} at line 14 using a standard finite state automaton without any stack.

Indeed, for every VPL L, one can construct a regular language $\widehat{L}$ such that testing whether $u \in L \cap \Lambda$ is equivalent to test whether some other word $\widehat{u}$ belongs to $\widehat{L}$. For this, let I be a special symbol not in $\Sigma_=$ encoding the relation set $\{(p,p) : p \in Q\}$. For a word $v \in \Sigma_=^l$, write $[v,\mathrm{I}]$ for the word $(v(1),\mathrm{I}) \cdot (v(2),\mathrm{I}) \cdots (v(l),\mathrm{I})$, and similarly $[\mathrm{I},v]$. Consider a weighted word of the form $u = \left(\prod_{i=1}^{j} v_i \cdot a_i\right) \cdot v_{j+1} \cdot \left(\prod_{i=j}^{1} b_i \cdot w_i\right)$, where $a_i \in \Sigma_+$, $b_i \in \Sigma_-$, and $v_i, w_i \in \Sigma_=^*$. Then the *slicing* of u (see Figure 2) is the word $\widehat{u}$ over the alphabet $\widehat{\Sigma} = (\Sigma_+ \times \Sigma_-) \cup (\Sigma_= \times \{\mathrm{I}\}) \cup (\{\mathrm{I}\} \times \Sigma_=)$ defined by $\widehat{u} = \left(\prod_{i=1}^{j} [v_i,\mathrm{I}] \cdot [\mathrm{I},w_i] \cdot (a_i,b_i)\right) \cdot [v_{j+1},\mathrm{I}]$, and which has weight $\left(\sum_{i=1}^{j} \lambda(v_i) + \lambda(w_i) + 2\right) + \lambda(v_{j+1})$.

▶ **Definition 9.** Let $\mathcal{A} = (Q,\Sigma,\Gamma,Q_{in},Q_f,\Delta)$ be a VPA. Define $\widehat{Q} = Q \times Q$, $\widehat{Q_{in}} = Q_{in} \times Q_f$, $\widehat{Q_f} = \{(p,p) : p \in Q\}$. The *slicing* of $\mathcal{A}$ is the finite automaton $\widehat{\mathcal{A}} = (\widehat{Q},\widehat{\Sigma},\widehat{Q_{in}},\widehat{Q_f},\widehat{\Delta})$ where the transitions $\widehat{\Delta}$ are:

1. $(p,q)\xrightarrow{(a,b)}(p',q')$ when $p\xrightarrow{a}(p',\mathsf{push}(\gamma))$ and $(q',\mathsf{pop}(\gamma))\xrightarrow{b}q$ are both transitions of Δ.
2. $(p,q)\xrightarrow{(c,\mathrm{I})}(p',q)$, resp. $(p,q)\xrightarrow{(\mathrm{I},c)}(p,q')$, when $p\xrightarrow{c}p'$, resp. $q\xrightarrow{c}q'$, is a transition of Δ.

Run in the VPA $\mathcal{A}$ on u
Run in the slicing automaton $\widehat{\mathcal{A}}$ on $\widehat{u}$

Figure 2 Slicing of a word $u \in \Lambda$.

This construction will be later used in Section 5 for weighted languages. In that case, we define the weight of a letter in $\widehat{u}$ by $|(a,b)| = |a| + |b|$, with the convention that $|I| = 0$. Moreover, we write $\widehat{\Sigma_Q}$ for the alphabet obtained similarly to $\widehat{\Sigma}$ using Σ_Q instead of $\Sigma_{=}$. Note that the slicing automaton $\widehat{\mathcal{A}}$ defined on $\widehat{\Sigma_Q}$ is $\widehat{\Sigma}$-closed and has $\widehat{\Sigma}$-diameter at most $2m^2$ where $m = |Q|$. Indeed, the slicing automaton has m^2 states and every letter in $\widehat{\Sigma}$ has weight at most 2, hence the shortest path from two states (when exists) has weight at most $2m^2$. In particular, it directly implies the following.

▶ **Proposition 10.** *Let $v \in \Lambda$ be such that $(p,q) \xrightarrow{\widehat{v}} (p',q')$. There is $w \in \Lambda$ such that $|w| \leq 2m^2$ and $(p,q) \xrightarrow{\widehat{w}} (p',q')$.*

▶ **Lemma 11.** *If $\mathcal{A}$ is a* VPA *accepting L, then $\widehat{\mathcal{A}}$ is accepts $\widehat{L} = \{\widehat{u} : u \in L \cap \Lambda\}$.*

4.3 Random Sketches

We are now ready to build a tester for $L \cap \Lambda$. To test a word u we use a property tester for the regular language $\widehat{L}$. Regular languages are known to be ε-testable for the Hamming distance with $\mathrm{O}((\log 1/\varepsilon)/\varepsilon)$ non-adaptive queries on the input word [1], that is queries that can all be made simultaneously. Those queries define a small random sketch of u that can be sent to the tester for approximating R_u. Since the Hamming distance is larger than the edit distance, those testers are also valid for the latter distance. Observe also that, for $v_1, v_2 \in \Lambda_Q$, we have $\mathsf{bdist}(v_1, v_2) \leq 2\mathsf{dist}(\widehat{v_1}, \widehat{v_2})$. The only remaining difficulty is to provide to the tester an appropriate sampling on $\widehat{u}$ while processing u.

We will proceed similarly for the general case in Section 5, but then we will have to consider weighted words. Therefore we show how to sketch u in that general case already. Indeed, the tester of [1] was simplified for the edit distance in [23], and later on adapted for weighted words in [24]. We consider here an alternative approach that we believe to be simpler, but slightly less efficient than the tester of [24].

Our tester for weighted regular languages is based on k-factor sampling on $\widehat{u}$ that we will simulate by an over-sampling built from a letter sampling on u, that is according to the weights of the letters of u only. This new sampling can be easily performed given a stream of u using a standard reservoir sampling.

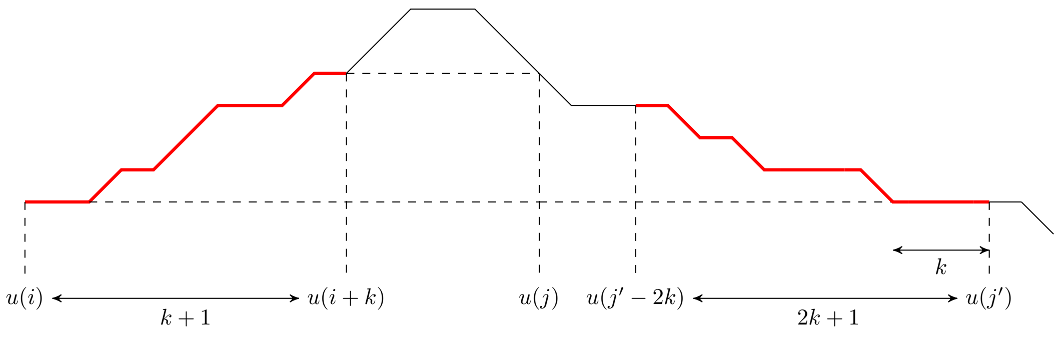

Figure 3 The sampling $\mathcal{W}_k(u)$ from Definition 12: sample is in red.

Let $u \in \Lambda$ and let $u[i, i+k]$ be a factor that contains at least one push symbol. Call i_1 (resp. i_2) the smallest (resp. largest) integer such that $i_1 \geq i$ (resp. $i_2 \leq i+k$) and $u(i_1)$ (resp. $u(i_2)$) is a push symbol. Then the *matching pop sequence* of $u[i, i+k]$ is defined as $u[j_1, j_2]$ where $u(j_1)$ (resp. $u(j_2)$) is the matching pop symbol of $u(i_1)$ (resp. $u(i_2)$).

▶ **Definition 12.** For a weighted word $u \in \Lambda_Q$, denote by $\mathcal{W}_k(u)$ the sampling over subwords of u constructed as follows (see Figure 3):
(1) Sample a factor $u[i, i+k]$ of u with probability $|u(i)|/|u|$.
(2) If $u[i, i+k]$ contains at least one push symbol, let $u[j, j']$ be the matching pop sequence of $u[i, i+k]$, extended by the first k neutral symbols after the last pop symbol, if any. Add $u[\max(j, j'-2k), j']$ to the sample (hence, some matching pops of $u[i, i+k]$ may not belong to $u[\max(j, j'-2k), j']$).

Let us stress that in the above definition the weight of letters only matter in (1), and not in (2) which cares about matching push and pop symbols, which are of weight 1. One consequence is that one can design a randomized streaming algorithm performing this sampling.

▶ **Fact 13.** *There is a randomized streaming algorithm with memory* $\mathrm{O}(k + \log n)$ *which, given* k *and* u *as input, samples* $\mathcal{W}_k(u)$.

▶ **Lemma 14.** *Let* u *be a weighted word, and let* k *be such that* $4k \leq |u|$. *Then* $4k$ *independent copies of* $\mathcal{W}_k(u)$ *over-sample the* k*-factor sampling on* $\widehat{u}$.

We can now give an analogue of the property tester for weighted regular languages in $L \cap \Lambda_Q$. For that, we use the following notion of approximation.

▶ **Definition 15.** Let $R \subseteq Q^2$ and $\varepsilon \geq 0$. Then R (ε, Σ)-*approximates* a balanced word $u \in (\Sigma_+ \cup \Sigma_- \cup \Sigma_Q)^*$ on $\mathcal{A}$, if for all $p, q \in Q$:
(1) If $p \xrightarrow{u} q$, then $(p, q) \in R$;
(2) If $(p, q) \in R$, there is a word v such that $\mathsf{dist}_\Sigma(u, v) \leq \varepsilon|u|$ and $p \xrightarrow{v} q$.

Our tester is going to be robust enough in order to consider samples that do not exactly match the peaks we want to compress.

▶ **Theorem 16.** *Let* $\mathcal{A}$ *be a* VPA *with* $m \geq 2$ *states and* Σ*-diameter* $d \geq 2$. *Let* $\varepsilon > 0$, $\eta > 0$, $t = 2\lceil 4dm^3(\log 1/\eta)/\varepsilon\rceil$, $k = \lceil 4dm/\varepsilon\rceil$ *and* $T = 4kt$. *There is an algorithm that, given* T *random subwords* $z_1, \ldots, z_T$ *of some weighted word* $v \in \Lambda_Q$, *such that each* z_i *comes from an independent sampling* $\mathcal{W}_k(v)$, *outputs a set* $R \subseteq Q \times Q$ *that* (ε, Σ)*-approximates* v *on* $\mathcal{A}$ *with bounded error* η.

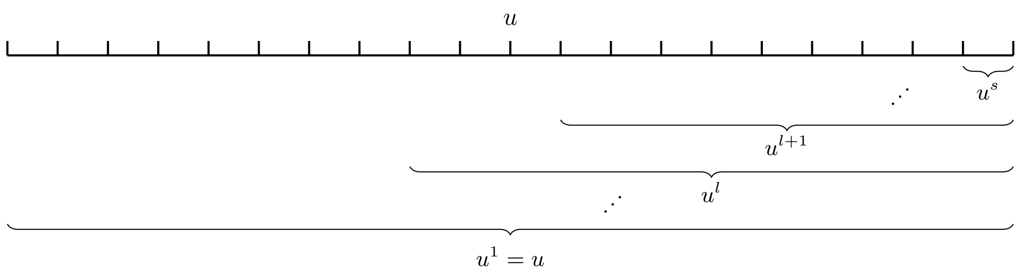

Figure 4 An α suffix decomposition of u of size s. For every l, either $|u^l| \leq \alpha|u^{l+1}|$, or $u^l = a \cdot u^{l+1}$ where a is a letter.

Let v' be obtained from v by at most $\varepsilon|v|$ balanced deletions. Then, the conclusion is still true if the algorithm is given an independent $\mathcal{W}_k(v')$ for each z_i instead, except that R now provides a $(3\varepsilon, \Sigma)$-approximation. Last, each sampling can be replaced by an over-sampling.

As a consequence we get our first streaming tester for $L \cap \Lambda$.

▶ **Theorem 17.** *Let $\mathcal{A}$ be a* VPA *for L with $m \geq 2$ states, and let $\varepsilon, \eta > 0$. Then there is a streaming ε-tester for $L \cap \Lambda$ with one-sided error η and memory space $O((m^8 \log(1/\eta)/\varepsilon^2)(m^3/\varepsilon + \log n))$, where n is the input length.*

Proof. We use Algorithm 2 where we replace the current factor u_0 by $T = 4kt$ independent samplings $\mathcal{W}_k(u_0)$. We know that such samplings can be computed using memory space $O(k + \log n)$ by Fact 13. By Proposition 10, the slicing automaton has $\widehat{\Sigma}$-diameter d at most $2m^2$. Therefore, from Theorem 16, taking $t = 4\lceil 4dm^3(\log 1/\eta)/\varepsilon\rceil$ and $k = \lceil 4dm/\varepsilon\rceil$ leads to the desired conclusion. ◀

5 Algorithm With Sketching

5.1 Sketching Using Suffix Samplings

We now describe the sketches used by our main algorithm. They are based on the generalization of the random sketches described in Section 4.3. Moreover, they rely on a notion of suffix sampling, that ensures a good letter sampling on each suffix of a data stream. Recall (see Section 2.1) that a letter sampling on a weighted word u samples a random letter $u(i)$ (with its position) with probability $|u(i)|/|u|$, and that a sampling on k-factors can be derived from a letter sampling. Therefore we will sample k-factors using an (α, t)-suffix sampling.

▶ **Definition 18.** Let u be a weighted word and let $\alpha > 1$. An *α-suffix decomposition of u of size s* (see Figure 4) is a sequence of suffixes $(u^l)_{1 \leq l \leq s}$ of u such that: $u^1 = u$, u^s is the last letter of u, and for all l, u^{l+1} is a strict suffix of u^l and if $|u^l| > \alpha|u^{l+1}|$ then $u^l = a \cdot u^{l+1}$ where a is a single letter.
An *(α, t)-suffix sampling on u of size s* is an α-suffix decomposition of u of size s with t letter samplings on each suffix of the decomposition.

We observe that (α, t)-suffix samplings can be either concatenated or compressed as stated below.

▶ **Proposition 19.** *Given an (α, t)-suffix sampling D_u on u of size s_u and another one D_v on v of size s_v, there is an algorithm **Concatenate**(D_u, D_v) computing an (α, t)-suffix sampling on the concatenated word $u \cdot v$ of size at most $s_u + s_v$ in time $O(s_u)$.*

Data Structure 3 Sketch for an unfinished peak

```
Parameters: real $\varepsilon' > 0$, integers $T \geq 1$ and $k \geq 1$.
Data structure for a weighted word $v \in \mathrm{Prefix}(\Lambda_Q)$
  Weights of $v$ and of its first letter $v(1)$
  Height of $v(1)$
  Boolean indicating whether $v$ contains a pop symbol
  $(1+\varepsilon')$-suffix decomposition $v^1, \ldots, v^s$ of $v$ encoded for $l = 1, \ldots, s$ by
     Estimates $|v^l|_{\mathtt{low}}$ and $|v^l|_{\mathtt{high}}$ of $|v^l|$
     $T$ independent samplings $S_{v^l}$ on $k$-factors of $v^l$ //See details
        below with corresponding weights and heights
```

Moreover, given an (α, t)-suffix sampling D_u on u of size s_u, there is an algorithm ***Simplify***(D_u) *computing an (α, t)-suffix sampling on u of size at most $2\lceil \log |u| / \log \alpha \rceil$ in time $\mathrm{O}(s_u)$.*

Proof. For **Concatenate**, it suffices to do the following. For each suffix u^l of D_u: (1) replace u^l by $u^l \cdot v$; and (2) replace the i-th sampling of u^l by the i-th sampling of v with probability $|v|/(|u| + |v|)$, for $i = 1, \ldots, t$.

For **Simplify**, do the following. For each suffix u^l of D_u, from $l = s_u$ (the smallest one) to $l = 1$ (the largest one): (1) replace all suffixes $u^{l-1}, u^{l-2}, \ldots, u^m$ by the largest suffix u^m such that $|u^m| \leq \alpha |u^l|$; and (2) suppress all samples from deleted suffixes. ◀

Using this proposition, one can easily design a streaming algorithm constructing online a suffix decomposition of polylogarithmic size. Starting with an empty suffix-sampling S, simply concatenate S with the next processed letter a of the stream, and then simplify it.

5.2 Final Algorithm

Our final algorithm is a modification of Algorithm 2: in particular it approximates relations R_v (in the spirit of Definition 15) by elements in Σ_Q, instead of exactly computing them. Let us stress that even if some R_v is approximated by an R that does not correspond to any R_u, one has $R \in \Sigma_Q$, which means that for any $(p, q) \in R$, there is a balanced word $u \in \Sigma^*$ depending on (p, q) with $p \xrightarrow{u} q$.

To mimic Algorithm 2 we need to encode (compactly) each unfinished peak v of the stack and u_0: for that we use the data structure described in Data Structure 3. Our final algorithm, Algorithm 4, is simply Algorithm 2 with this new data structure and corresponding adapted operations, where $\varepsilon' = \varepsilon/(6 \log n)$, $T = 4608 m^4 2^{2m^2} (\log^2 n)(\log 1/\eta)/\varepsilon^2$ and $k = 24 m 2^{m^2} (\log n)/\varepsilon$.

The methods are described in Algorithm 4, where we implicitly assume that each letter processed by the algorithm comes with its respective height and (exact or approximate) weight. They use functions **Concatenate** and **Simplify** described in Proposition 19, while adapting them.

In the next section, we show that the samplings S_{v^l} are close enough to an $(1+\varepsilon')$-suffix sampling on v^l. This lets us build an over-sampling of an $(1+\varepsilon')$-suffix sampling. We also show that it only requires a polylogarithmic number of samples. Then, we explain how to recursively apply the tester from Theorem 16 (with ε') in order to obtain the compressions at line 14 and 20 while keeping a cumulative error below ε. We now state our main result whose proof relies on Lemmas 22 and 23.

Algorithm 4 Adaptation of Algorithm 2 using sketches

```
Run Algorithm 2 using Data structure 3 with the following adaptations:
Adaption of functions from Proposition 19
 Concatenate($D_u, D_v$) with an exact estimate of $|v|$ is modified s.t.
   the replacement probability is now $|v|/(|u|_{\texttt{high}} + |v|)$
   and $|u^l \cdot v|_z \leftarrow |u^l|_z + |v|$, for $z = \texttt{low}, \texttt{high}$
 Simplify($D_u$) with $\alpha = 1 + \varepsilon'$ has now relaxed condition $|u^m|_{\texttt{high}} \leq (1+\varepsilon')|u^l|_{\texttt{low}}$
 Online-Suffix-Sampling is unchanged except for doing $k$-factor sampling.
Adaption of operations on factors used in Algorithm 2
 Compute relation: $R_v$
   Run the algorithm of Theorem 16 using samples in $D_v$
 Decomposition: $v_1 \cdot v_2 \leftarrow v$
  Find largest suffix $v^i$ in $D_v$ s.t. $v^i \in \mathrm{Prefix}(\Lambda_Q)$ //i.e. $v^i$ is in $v_2$
  $D_{v|v_1} \leftarrow$suffixes $(v^l)_{l<i}$ with their samples
  $D_{v_2} \leftarrow$suffix $v^i$ with its samples & weight estimates //to compute $R_{v_2}$
   -($|v^i|_{\texttt{high}}, |v^i|_{\texttt{low}}$) when $v^{i-1}$ and $v^i$ differ by only one letter (then $v^i = v_2$)
   -($|v^{i-1}|_{\texttt{high}}, |v^i|_{\texttt{low}}$) otherwise
 Test: $|u_0| \geq |v_2|/2$ using $|v_2|_{\texttt{low}}$ instead of $|v_2|$
 Concatenation: $u_0 \leftarrow (v_1 \cdot R_{v_2}) \cdot u_0$
   $D_{v'} \leftarrow (D_{v|v_1}, R_{v_2})$ replacing each sample of $D_{v|v_1}$ in $v_2$ by $R_{v_2}$
   // The height of a sample determines whether it is in $v_2$
   $D_{u_0} \leftarrow$ Simplify(Concatenate($D_{v'}, D_{u_0}$))
```

▶ **Theorem 20.** *Let $\mathcal{A}$ be a* VPA *for L with $m \geq 2$ states, and let $\varepsilon, \eta > 0$. Then there is an ε-streaming algorithm for L with one-sided error η and memory space* $\mathrm{O}(m^5 2^{3m^2} (\log^6 n)(\log 1/\eta)/\varepsilon^4)$, *where n is the input length.*

5.3 Final Analysis

As Algorithm 4 may fail at various steps, the relations it considers may not correspond to any word. However, each relation R that it produces is still in Σ_Q. Furthermore, the slicing automaton $\widehat{\mathcal{A}}$ over $\widehat{\Sigma_Q}$ is $\widehat{\Sigma}$-closed. Fact 21 below bounds the $\widehat{\Sigma}$-diameter of $\widehat{\mathcal{A}}$ (which is equal to the Σ-diameter of $\mathcal{A}$) by 2^{m^2}. For simpler languages, as those coming from a DTD, this bound can be lowered to m.

▶ **Fact 21.** *Let $\mathcal{A}$ be a* VPA *with m states. Then the Σ-diameter of $\mathcal{A}$ is at most 2^{m^2}.*

We first state that the decomposition, weights and sampling we maintain are close enough to an $(1+\varepsilon')$-suffix sampling with the correct weights. Recall that $\varepsilon' = \varepsilon/(6 \log n)$.

▶ **Lemma 22** (Stability lemma). *Let v be an unfinished peak with $\mathcal{W}_1, \mathcal{W}_2$ two of the T samplers maintained by Algorithm 4. Then the joint process $(\mathcal{W}_1, \mathcal{W}_2)$ over-samples an $(1+\varepsilon')$-suffix sampling on v, and the decomposition has size at most $144(\log|v|)(\log n)/\varepsilon + \mathrm{O}(\log n)$.*

Using the tester from Theorem 16 for computing each R, we get our robustness lemma.

▶ **Lemma 23** (Robustness lemma). *Let $\mathcal{A}$ be a* VPA *recognizing L and let $u \in \Sigma^n$. Let $R_{\texttt{final}}$ be the final value of $R_{\texttt{temp}}$ in Algorithm 4.*

If $u \in L$, then $R_{\texttt{final}} \in L$; and if $R_{\texttt{final}} \in L$, then $\mathsf{bdist}_\Sigma(u, L) \leq \varepsilon n$ *with probability at least $1 - \eta$.*

Abstract

In the pattern matching with d wildcards problem we are given a text T of length n and a pattern P of length m that contains d wildcard characters, each denoted by a special symbol $'?'$. A wildcard character matches any other character. The goal is to establish for each m-length substring of T whether it matches P. In the streaming model variant of the pattern matching with d wildcards problem the text T arrives one character at a time and the goal is to report, before the next character arrives, if the last m characters match P while using only $o(m)$ words of space.

In this paper we introduce two new algorithms for the d wildcard pattern matching problem in the streaming model. The first is a randomized Monte Carlo algorithm that is parameterized by a constant $0 \le \delta \le 1$. This algorithm uses $\tilde{O}(d^{1-\delta})$ amortized time per character and $\tilde{O}(d^{1+\delta})$ words of space. The second algorithm, which is used as a black box in the first algorithm, is a randomized Monte Carlo algorithm which uses $O(d + \log m)$ worst-case time per character and $O(d \log m)$ words of space.

1 Introduction

We investigate one of the basic problems in pattern matching, the *pattern matching with d wildcards problem* (PMDW), in the *streaming model*. Let Σ be an alphabet and let $'?' \notin \Sigma$ be a special character called the *wildcard* which matches any character in Σ. The PMDW problem is defined as follows. Given a *text* string $T = t_0t_1 \dots t_{n-1}$ over Σ and a *pattern* string $P = p_0p_1 \dots p_{m-1}$ over alphabet $\Sigma \cup \{?\}$ such that P contains exactly d wildcard characters, report all of the occurrences of P in T. This definition of a match is one of the most well studied problems in pattern matching [21, 35, 26, 28, 18, 9].

The streaming model. The advances in technology over the last decade and the massive amount of data passing through the internet has intrigued and challenged computer scientists, as the old models of computation used before this era are now less relevant or too slow. To this end, new computational models have been suggested to allow computer scientists to tackle these technological advances. One prime example of such a model is the *streaming*

* Supported in part by NSF grants CCF-1217338, CNS-1318294, and CCF-1514383.

model [1, 25, 34, 29]. Pattern matching problems in the streaming model are allowed to preprocess P into a data structure that uses space that is sublinear in m (notice that space usage during the preprocessing phase itself is not restricted). Then, the text T is given online, one character at a time, and the goal is to report any matching substrings right after the last relevant text character has arrived, but before the next text character arrives. Another closely related model is the *online* model, which is the same as the streaming model without the constraint of using sublinear space.

Following the breakthrough result of Porat and Porat [36], there has recently been a rising interest in solving pattern matching problems in the streaming model [6, 19, 33, 7, 27, 13, 14]. However, this is the first paper to directly consider the important wildcard variant. Notice that one way for solving PMDW (not necessarily in the streaming model), is to treat $'?'$ as a regular character, and then run an algorithm that finds all occurrences of P (that does not contain any wildcards) in T with up to $k = d$ mismatches. This is known as the k-mismatch problem [32, 37, 2, 12, 11, 16, 14]. The most recent result by Clifford et al. [14] for the k-mismatch problem in the streaming model implies a solution for PMDW in the streaming model that uses $O(d^2 \operatorname{polylog} m)$ words[1] of space and $O(\sqrt{d}\log d + \operatorname{polylog} m)$ time per character. Notice that Clifford et al. [14] focused on solving a more general problem.

1.1 New results and Related Work

We improve upon the work of Clifford et al. [14], for the special case that applies to PMDW, by presenting the following algorithms (the $\tilde{O}$ notation hides logarithmic factors). Notice that Theorem 1 improves upon the results of Clifford et al. [14] whenever $\delta > 1/2$.

▶ **Theorem 1.** *For any constant $0 \le \delta \le 1$ there exists a a randomized Monte Carlo algorithm for the PMDW problem in the streaming model that succeeds with probability $1 - 1/poly(n)$, uses $\tilde{O}(d^{1+\delta})$ words of space and spends $\tilde{O}(d^{1-\delta})$ amortized time per arriving text character.*

▶ **Theorem 2.** *There exists a a randomized Monte Carlo algorithm for the PMDW problem in the streaming model that succeeds with probability $1 - 1/poly(n)$, uses $O(d \log m)$ words of space and spends $O(d + \log m)$ time per arriving text character.*

1.2 Algorithmic Overview and Related Work

Our algorithms make use of the notion of a *candidate*, which is a location in the last m indices of the current text that is currently considered as a possible occurrence of P. As more characters arrive, it becomes clear if this candidate is an actual occurrence or not. In general, an index continues to be a candidate until the algorithm encounters proof that the candidate is not a valid occurrence (or until it is reported as a match). The algorithm of Theorem 2 works by obtaining such proofs efficiently. We discuss some of the ideas used in this algorithm after discussing the overview of Theorem 1.

Overview of algorithm for Theorem 1. The algorithm of Theorem 1 uses the algorithm of Theorem 2 (with a minor adaptation) combined with a new combinatorial perspective of *periodicity* that applies to strings with wildcards. The notion of periodicity in strings (without wildcards) and its usefulness are well studied [20, 31, 36, 6, 23, 22]. However, extending the usefulness of periodicity to strings with wildcards runs into difficulties, since the notions

[1] We assume the RAM model where each word has size of $O(\log n)$ bits.

are either too inclusive or too exclusive (see [4, 3, 5, 8, 38]). Thus, we introduce a new definition of periodicity, called the *wildcard-period length* that captures, for a given pattern with wildcards, the smallest possible average distance between occurrences of the pattern in any text. See Definition 5. For a string with wildcards S, we denote the wildcard-period length of S by π_S.

Let P^* be the longest prefix of P such that $\pi_{P^*} \leq d^\delta$. The algorithm of Theorem 1 has two main components, depending on whether $P^* = P$ or not. In the case where $P^* = P$, the algorithm takes advantage of the wildcard-period length of P being small, which together with techniques from number theory and new combinatorial properties of strings with wildcards allows to spend only $\tilde{O}(1)$ time per character and uses $\tilde{O}(d^{1+\delta})$ words of space. This is summarized in Theorem 18. Of particular interest is Lemma 17 which combines number theory with combinatorial string properties in a new way. We expect these ideas to be useful in other applications.

If $P^* \neq P$, then we use the algorithm of Theorem 18 to locate occurrences of P^*, and by maximality of P^*, occurrences of any prefix of P that is longer than P^* must appear far apart (on average). These occurrences are given as input to a minor adaptation of the algorithm of Theorem 2 in the form of candidates. Utilizing the large average distance between candidates and combining with a lazy approach, we obtain an $\tilde{O}(d^{1-\delta})$ amortized time cost per character.

Overview of algorithm for Theorem 2. For the streaming pattern matching problem without wildcards, the algorithms of Porat and Porat [36] and Breslauer and Galil [6] have three major components[2]. The first component is a partitioning of the pattern into *pattern intervals* of exponentially increasing lengths. The algorithm uses *text intervals* corresponding to the pattern intervals, which are the reversed pattern intervals and appear at the end of the text. When a new text character arrives, the text intervals are shifted by one location. The second component maintains all of the candidates in a given text interval. This implementation leverages periodicity properties of strings in order to guarantee that the candidates in a given text interval form an arithmetic progression, and thus can be maintained with constant space. The third component is a fingerprint mechanism for testing if a candidate is still valid. A candidate is tested each time it leaves a text interval.

The main challenge in applying the above framework for patterns with wildcards comes from the lack of a good notion of periodicity which can guarantee that the candidates in a text interval form an arithmetic progression. Notice that the notion of wildcard-period length, for example, has to do with the average of distances between occurrences, and so it does not apply to arithmetic progressions. To tackle this challenge, we design a new method for partitioning the pattern into intervals, which combined with new fundamental combinatorial properties leads to an efficient way for maintaining the candidates in small space. In particular, we prove that with our new partitioning there are at most $O(d \log m)$ candidates that are not part of the arithmetic progression of some text interval. Remarkably, the proof bounding the number of such candidates uses a more global perspective of the pattern, as opposed to the techniques used in non-wildcard results.

More related work. We mention that while our work is in the streaming model, in the closely related online model (see [17, 15]), Clifford et al. [10] presented an algorithm, known

[2] The algorithms of Porat and Porat [36] and Breslauer and Galil [6] are not presented in this way. However, we find that this new way of presenting our algorithm (and theirs) does a better job of explaining what is going on.

as the black box algorithm, that when applied to PMDW uses $O(m)$ words of space and $O(\log^2 m)$ time per arriving text character.

Full version. Due to space consideration some of the proofs and details have been omitted, for a full version of this paper see [24].

2 Preliminaries

2.1 Periods

We assume without loss of generality that the alphabet is $\Sigma = \{1, 2, \dots, n\}$. For a string $S = s_0 s_1 \dots s_{\ell-1}$ over Σ and integer $0 \le k \le \ell$, the substring $s_0 s_1 \dots s_{k-1}$ is called a *prefix* of S and $s_{\ell-k} \dots s_{\ell-1}$ is called a *suffix* of S.

A prefix of S of length $i \ge 1$ is a *period* of S if and only if $s_j = s_{j+i}$ for every $0 \le j \le \ell - i - 1$. The shortest period of S is called *the principal period* of S, and its length is denoted by ρ_S. If $\rho_S \le \frac{|S|}{2}$ we say that S is *periodic.*

Due to space reasons, we omit proofs here, proofs appear in the full version of the paper.

▶ **Lemma 3.** *Let v be a string of length ℓ and let u be a string of length at most 2ℓ. If u contains at least three occurrences of v then:*
1. *v is a periodic string.*
2. *the distance between any two occurrences of v in u is a multiple of ρ_v.*

▶ **Lemma 4.** *Let u be a periodic string over Σ with principal period length ρ_u. If v is a substring of u of length $> 2\rho_u$ then $\rho_u = \rho_v$.*

Periods and wildcards. For strings with no wildcards there is an inverse relation between the maximum number of occurrences of u in a text of a given length and ρ_u. Here we define the *wildcard-period length* of a string over $\Sigma \cup \{?\}$ which captures a similar type of relationship for strings with wildcards. The usefulness of this definition for our needs is discussed in more detail in Section 6. Let $occ(S', S)$ be the number of occurrences of a string S in a string S'.

▶ **Definition 5.** For a string S over $\Sigma \cup \{?\}$, its wildcard-period length is

$$\pi_S = \left\lceil \frac{|S|}{\max_{S' \in \Sigma^{2|S|-1}} occ(S', S)} \right\rceil .$$

Notice that for periodic string S without wildcards $\pi_S = \rho_S$.

2.2 Fingerprints

For the following let $u, v \in \bigcup_{i=0}^{n} \Sigma^i$ be two strings of size at most n. Porat and Porat [36] and Breslauer and Galil [6] proved the existence of a *sliding fingerprint function* $\phi : \bigcup_{i=0}^{n} \Sigma^i \to [n^c]$, for some constant $c > 0$, which is a function where:
1. If $|u| = |v|$ and $u \ne v$ then $\phi(u) \ne \phi(v)$ with high probability (at least $1 - \frac{1}{n^{c-1}}$).
2. *The sliding property:* Let w=uv be the concatenation of u and v. If $|w| \le n$ then given the length and the fingerprints of any two strings from u,v and w, one can compute the fingerprint of the third string in constant time.

3 A Generic Algorithm

We introduce a generic algorithm (pseudo-code is given in Figure 1) for solving online pattern matching problems. With proper implementations of its components, this generic algorithm solves the PMDW problem. The generic algorithm makes use of the notion of a *candidate*. Initially every text index c is considered as a candidate for a pattern occurrence from the moment t_c arrives. An index continues to be a candidate until the algorithm encounters proof that the candidate is not a valid occurrence (or until it is reported as a match). A candidate is *alive* until such proof is given.

The generic algorithm is composed of three conceptual parts that affect the complexities of the algorithm; a running example of the execution of the generic algorithm appears in Figures 2 and 3:

- **Pattern and text intervals.** The first part is an ordered partitioning $\mathcal{I} = (I_0, \dots, I_k)$ of the interval $[0, m-1]$. Each interval $I \in \mathcal{I}$ is called a **pattern interval**. When a character t_α arrives then a candidate c is alive if and only if there is a pattern interval $I = [i, j] \in \mathcal{I}$ such that $t_c \cdots t_{c+i-1}$ matches $p_0 \cdots p_{i-1}$ and $\alpha - c + 1 \in [i, j]$. Notice that for any pattern interval $I = [i, j]$, any candidate c that is alive in I must be in exactly one **text interval** $c \in [\alpha - j + 1, \alpha - i + 1]$. When a new text character arrives, all the text intervals move one position ahead, and some candidates move between intervals.
- **Candidate queues.** The second conceptual part of the generic algorithm is an implementation of a **candidate-queue** data structure. This data structure supports the following operations on candidates that are in the same text interval $[\alpha - j + 1, \alpha - i + 1]$, where α is the index of the last character to arrive from T.

▶ **Definition 6.** Let α be the index of the last text character that has arrived. Then a candidate-queue on an interval $I = [i, j]$ supports the following operations.

1. *Enqueue*(c): Given candidate $c = \alpha - i + 1$ add c to the candidate-queue.
2. *Dequeue*$()$: Remove and return a candidate $c = \alpha - j$, if it exists.

Since there is a bijection between pattern intervals and text intervals we say that a candidate-queue that is associated with a given text interval is also associated with the corresponding pattern interval.

- **Assassinating candidates.** The third conceptual part is a mechanism for testing if a candidate is alive after it leaves one text interval, in order to determine if the candidate should enter the candidate queue of the next text interval, or be reported as a match if there is no more text intervals.

The implementation of each of these components controls the complexities of the algorithm. Minimizing the number of intervals reduces the number of candidates leaving an interval at any given time. Efficient implementations of the queue operations and testing if a candidate is alive control both the space usage and the amount of time spent on each candidate that leaves an interval. Notice that the implementations of these components may depend on each other, which is also the case in our solution.

If there are no wildcards in P, one can use a sliding fingerprint based approach (related to the Karp and Rabin [30] algorithm) for testing if a candidate is alive. In order to use these fingerprints, we maintain the *text fingerprint* which is the fingerprint of the text from its beginning up to the last arriving character. This maintenance uses only constant time per character and constant space.

```
PROCESS-CHARACTER($t_\alpha$)
1  $Q_0.Enqueue(\alpha)$
2  for $h = 0$ to $k$
3      $c = Q_h.Dequeue()$
4      if $c$ exists and $c$ is still alive
5          if $h = k$
6              report $c$ as a match
7          else $Q_{h+1}.Enqueue(c)$
```

Figure 1 Generic Algorithm.

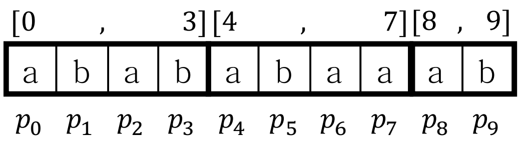

Figure 2 Example of a pattern and its arbitrary chosen pattern intervals. The pattern length is 10 and the pattern intervals are $[0, 3]$, $[4, 7]$ and $[8, 9]$.

3.1 Fingerprints with Wildcards

Using fingerprints together with wildcards seems to be a difficult task, since for any string with x wildcards there are $|\Sigma|^x$ different strings over Σ that match the string. Each one of these different strings may have a different fingerprint and therefore there are $O(|\Sigma|^x)$ fingerprints to store, which is not feasible. In order to still use fingerprints for solving PMDW we use a special partitioning of $[0, m-1]$.

Partitioning algorithm. We use a representation of P as $P = P_0?P_1?\ldots?P_d$ where each subpattern P_i contains only characters from Σ (and may also be the empty string). Let $W = (w_1, w_2, \ldots, w_d)$ be the indices such that $p_{w_i} = '?'$ and for all $1 \le i < d$ we have $w_i < w_{i+1}$. The interval $[0, m-1]$ is partitioned into pattern intervals as follows:

$$\mathcal{J} = ([0, w_1 - 1], [w_1, w_1], [w_1 + 1, w_2 - 1], \ldots, [w_d, w_d], [w_d + 1, m - 1]).$$

Since some of the pattern intervals in this partitioning could be empty, we discard such intervals. The pattern intervals of the form $[w_i, w_i]$ are called *wildcard intervals* and the other pattern intervals are called *regular intervals*. Notice that for a text index c, the substring $t_c \ldots t_{c+m-1}$ matches P if and only if for each regular interval $[i, j]$, $t_{c+i} \ldots t_{c+j} = p_i \ldots p_j$. During the initialization of the algorithm we precompute and store the fingerprints for all of the subpatterns corresponding to regular intervals.

Testing liveness. Given the partition $\mathcal{J}$, the algorithm for testing if a candidate c is alive is as follows. Each time a candidate c is added to a candidate-queue for interval $[i, j] \in \mathcal{J}$ via the $Enqueue(c)$ operation, the algorithm stores the current text fingerprint $\phi(t_0 \ldots t_{c+i-1})$ with the candidate c. When the character t_{c+j} arrives the text fingerprint is $\phi(t_0 \ldots t_{c+j})$. At this time, the algorithm uses the $Dequeue()$ operation to extract c together with $\phi(t_0 t_1 \ldots t_{c+i-1})$

Figure 3 Example of the generic algorithm execution with the pattern of Figure 2. In each row a new text character arrives. The bold borders are on the text intervals, each blue cell is a position of a candidate and the green cell corresponds a match.
When t_{52} arrives the candidate $c_1 = 45$ is tested, since it exists a text interval and found to be alive because *abababaa* is a prefix of the pattern. At this time we can see that the candidate $c_2 = 47$ cannot be a valid occurrence of the pattern, however the algorithm will not remove it until it reaches the end of the text interval.
When t_{54} arrives, the candidates $c_1 = 45$ and $c_2 = 47$ are tested since they reach the end of their text intervals. c_2 is removed because the text *ababaaab* is not a prefix of the pattern. The candidate c_1 is still alive, and since it reaches the end of the last text interval, it reported as a match.

from the candidate-queue of interval $[i, j]$. If $[i, j]$ is a regular interval, then the algorithm tests if c is alive. This is done by applying the sliding property of the fingerprint function to compute $\phi(t_{c+i} \dots t_{c+j})$ from the current text fingerprint $\phi(t_0 t_1 \dots t_{c+j})$ and the fingerprint $\phi(t_0 t_1 \dots t_{c+i-1})$, and then testing if $\phi(t_{c+i} \dots t_{c+j})$ is the same as $\phi(p_i \dots p_j)$. If $[i, j]$ is a wildcard interval then c stays alive without any test.

A naïve implementation of the candidate queues provides an algorithm that costs $O(d)$ time per character, but uses $\Theta(m)$ words of space. To overcome this space usage we employ a more complicated partitioning, which together with a modification of the requirements from the candidate-queues allows us to design a data structure that uses much less space. However, this space efficiency comes at the expense of a slight increase in time per character.

4 The Partitioning

The key idea of the new partitioning is to use the partitioning of Section 3.1 as a preliminary partitioning, and then perform a secondary partitioning of the regular pattern intervals, thereby creating even more regular intervals. As mentioned, the intervals are partitioned in a special way which allows us to implement candidate-queues in a compact manner (see Section 5).

The following definition is useful in the next lemma.

▶ **Definition 7.** For an ordered set of intervals $\mathcal{I} = (I_0, I_1, \dots I_k)$ and for any integer $0 \le i \le k$, let $\mu_{\mathcal{I}}(i) = \max_{j=0}^{i} |I_j|$ be the length of the longest interval in the sequence $I_0, \dots I_i$. When $\mathcal{I}$ is clear from context we simply write $\mu(i) = \mu_{\mathcal{I}}(i)$

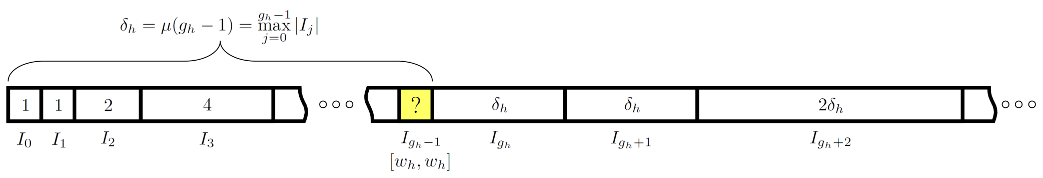

Figure 4 The general case: on each $J_h \in \mathcal{J}$ we first create two intervals of length δ_h and then we iteratively create pattern intervals where the length of each pattern interval is double the length of the previous pattern interval.

The following lemma shows a partitioning which is used to improve the preliminary partitioning algorithm. The properties of the partitioning that are described in the statement of the lemma are essential for our new algorithm. In the proof we introduce a specific partitioning which has all of these properties.

▶ **Lemma 8.** *Given a pattern P of length m with d wildcards There exists a partitioning of the interval $[0, m-1]$ into subintervals $\mathcal{I} = (I_0, I_1 \dots, I_k)$ which has the following properties:*

1. *If $I = [i, j]$ is a pattern interval then $p_i \dots p_j$ either corresponds to exactly one wildcard from P (and so $j = i$) or it is a substring that does not contain any wildcards.*
2. *$k = O(d + \log m)$.*
3. *For each regular pattern interval $I = [i, j]$ with $|I| > 1$, the length i prefix of P contains a consecutive sequence of $|I|$ non-wildcard characters.*
4. *$|\{\mu_{\mathcal{I}}(0), \mu_{\mathcal{I}}(1) \dots \mu_{\mathcal{I}}(k)\}| = O(\log m)$.*

Proof. We introduce a secondary partitioning of the preliminary partitioning described in Section 3.1, and prove that it has all the required properties; see Figures 4, 5 and 6. Let J_h be the preliminary pattern interval corresponding to P_h. The secondary partitioning is executed on the pattern intervals $\mathcal{J} = (J_0, J_1, \dots, J_d)$, where the partitioning of J_h is dependent on the partitioning of $J_0, \dots, J_{h-1}$. Thus, the secondary partitioning of J_h takes place only after the second partitioning of J_{h-1}.

When partitioning pattern interval $J_h = [i, j]$, let g_h be the number of pattern intervals in the secondary partitioning in $[0, i-1]$, and let $\delta_h = \mu_{\mathcal{I}}(g_h - 1)$ be the length of the longest pattern interval in the secondary partitioning of $[0, i-1]$. For the first pattern interval let $\delta_0 = 1$. If $j \le i + \delta_h - 1$ then the only pattern interval is all of J_h. If $j \le i + 2\delta_h - 1$ then we create the pattern intervals $[i, i + \delta_h - 1]$ and $[i + \delta_h, j]$. Otherwise, we first create the pattern intervals $[i, i + \delta_h - 1]$ and $[i + \delta_h, i + 2\delta_h - 1]$, and for as long as there is enough room in the remaining preliminary pattern interval J_h (between the position right after the end of the last secondary pattern interval that was just created and j) we iteratively create pattern intervals where the length of each pattern interval is double the length of the previous pattern interval. Once there is no more room left in J_h , let ℓ be the length of the last pattern interval we created. If the remaining part of the preliminary pattern interval is of length at most ℓ, then we create one pattern interval for all the remaining preliminary pattern interval. Otherwise we create two pattern intervals, the first pattern interval of length ℓ and the second pattern interval using the remaining part of J_h.

The secondary partitioning implies all of the desired properties, the proof appears in the full version of this paper. ◀

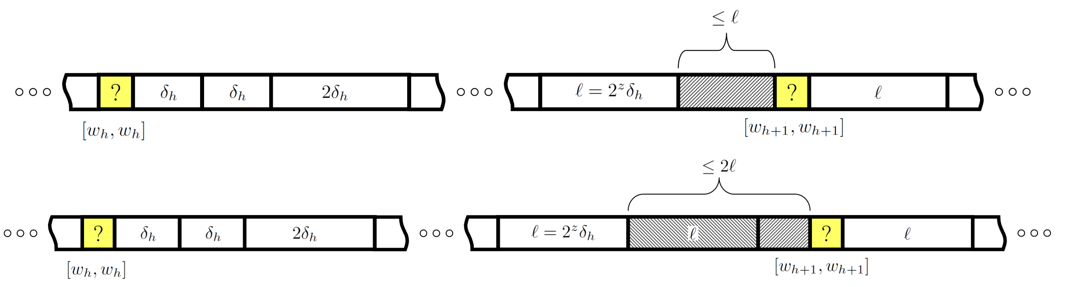

Figure 5 Once there is no more room left in J_h, if the remaining interval is of length at most ℓ (the top case), then we create one pattern interval for all the remaining interval. Otherwise (the bottom case) we create two pattern intervals, the first pattern interval of length ℓ and the second pattern interval using the remaining part of J_h.

Figure 6 Example of patterns and their intervals in the secondary partitioning. Each bold rectangle corresponds to an interval in the partition.

5 The Candidate-fingerprint-queue

The algorithm of Theorem 2 is obtained via an implementation of the candidate-queues that uses $O(d \log m)$ space, at the expense of having $O(d + \log m)$ intervals in the partitioning. Such space usage implies that we do not store all candidates explicitly. This is obtained by utilizing properties of periodicity in strings. Since candidates are not stored explicitly, we cannot store any explicit information per candidate, and in particular we cannot explicitly store fingerprints to quickly test if a candidate is still alive. On the other hand, we are still interested in using fingerprints in order to perform these tests.

To tackle this, we strengthen our requirements from the candidate-queue data structure to return not just the candidate but also the fingerprint information that is needed to perform the test of whether the candidate is still alive. Thus, we extend the definition of a candidate-queue to a *candidate-fingerprint-queue* as follows.

► **Definition 9.** Let α be the index of the last text character that has arrived. Then a candidate-fingerprint-queue on an interval $I = [i, j]$ supports the following operations.

1. *Enqueue*$(c, \phi(t_0 \dots t_{c-1}), \phi(t_0 \dots t_\alpha))$: given $c = \alpha - i + 1$ add c to the candidate-queue, together with $\phi(t_0 \dots t_{c-1})$ and $\phi(t_0 \dots t_\alpha)$.
2. *Dequeue*$()$: Remove and return a candidate $c = \alpha - j$, if it exists, together with $\phi(t_0 \dots t_{c-1})$ and $\phi(t_0 \dots t_{c+i-1})$.

In order to reduce clutter of presentation, in the rest of this section we refer to the candidate-fingerprint-queue simply as the *queue*.

5.1 Implementation

The implementation of the queue assumes that we use a partitioning that has the properties stated in Lemma 8. Let $I = [i, j]$ be a pattern interval in the partitioning and let c be a candidate which is maintained in the queue Q_I associated with I. For candidate c, the *entrance prefix* is the substring $t_c \dots t_{c+i-1}$, the *entrance interval* is $[c, c+i-1]$, and the *entrance fingerprint* is $\phi(t_c \dots t_{c+i-1})$. Since c was alive at the time it was inserted into Q_I, the entrance prefix of c matches $p_0 \dots p_{i-1}$ (which may contain wildcards). Recall that a candidate c is inserted into Q_I together with $\phi(t_0 \dots t_{c-1})$, which we call the *candidate fingerprint* of c.

Satellite information. The implementation associates each candidate c with *satellite information* (SI), which includes the candidate fingerprint and the entrance fingerprint of the candidate. The SI of a candidate combined with the the sliding property of fingerprints are crucial for the implementation of the queue. When c is added to Q_I, for some $I = [i, j]$, we compute the entrance fingerprint of c from the candidate fingerprint and from $\phi(t_0 \dots t_{c+i-1})$ which is the text fingerprint at this time. When c is removed from Q_I, we compute $\phi(t_0 \dots t_{c+i-1})$ in constant time from the SI of c.

Entrance prefixes and arithmetic progressions. A key component of the queue data structure is Lemma 10. This lemma defines for each interval $I = [i, j] \in \mathcal{I}$ at most one unique entrance prefix u_I that is the only string that can be the entrance prefix of more than two candidates in Q_I at the same time. That is, the existence of an entrance prefix u_I and determination u_I if it exists **depends only** on the prefix pattern $p_0 \dots p_{i-1}$, *regardless* of the characters in the text. If I has such a string u_I we say that I is an *arithmetic interval*, since, as we prove in Lemma 11 the candidates in Q_I that have entrance prefix u_I form an arithmetic progression.

▶ **Lemma 10.** *For a pattern interval $I = [i, j]$ with queue Q_I, there exists at most one string u_I such that if there are more than two candidates in Q_I with the same entrance prefix then this entrance prefix must be u_I.*

Proof Sketch. By Lemma 8 there is a string of length $|I|$ containing only non-wildcard characters that is a substring of $p_0 \dots p_{i-1}$. Let v be this string. Notice that v must appear in the entrance prefix of every candidate in Q_I. If there are three candidates in Q_I then they must all appear in the text within a range of size $j - i + 1$, which is close enough to guarantee that v must be periodic.

Now, consider three candidates $c_4 < c_5 < c_6$ in Q_I that have the same entrance prefix u. Since c_4, c_5, and c_6 are all occurrences of u then $c_6 - c_5$ and $c_5 - c_4$ are period lengths of u. Thus, $\rho_u \le \min\{c_5 - c_4, c_6 - c_5\} \le \frac{c_6 - c_4}{2} \le \frac{j-i}{2} < \frac{|I|}{2} = \frac{|v|}{2}$. Therefore, by Lemma 4 $\rho_u = \rho_v$. Combined with the fact that u contains v at a particular location (since u is an entrance prefix), and v is longer than ρ_u (since $\rho_u = \rho_v$), the string u must be uniquely defined. ◀

▶ **Lemma 11.** *Let $I = [i, j]$ be an arithmetic interval. If there are $h \ge 3$ candidates $c_1 < c_2 < \dots < c_h$ in Q_I that have u_I as their entrance prefix, then the sequence $c_1, c_2, \dots, c_h$ forms an arithmetic progression whose difference is ρ_{u_I}.*

Implementation details. For an interval I, we use a linked list $\mathcal{L}_{Q_I}$ to store all of the candidates in Q_I together with their SI, except for when I is an arithmetic interval in which case candidates whose entrance fingerprint is $\phi(u_I)$ are not stored in $\mathcal{L}_{Q_I}$. Adding and removing a candidate that belongs in $\mathcal{L}_{Q_I}$ together with its SI is straightforward. If I is an arithmetic interval, the candidates in Q_I whose entrance fingerprint is $\phi(u_I)$ are stored using a separate data structure that leverages Lemma 11. Thus, during a *Dequeue*() operation, the queue verifies if the candidate to be returned is in $\mathcal{L}_{Q_I}$ or in the separate data structure for the candidates with entrance fingerprint $\phi(u_I)$.

▶ **Lemma 12.** *There exists an implementation of candidate-fingerprint-queues so that for any arithmetic interval I, the queue Q_I maintains all the candidates with entrance fingerprint $\phi(u_I)$ and their SI using $O(1)$ words of space.*

Space usage. The space usage of all of the queues has two components. The first component is the lists $\mathcal{L}_{Q_I}$ for all the intervals I. The second component is the data structure for storing the candidates that create the arithmetic progression of an arithmetic interval, for each such arithmetic interval. By Lemma 10 there is at most one such progression per arithmetic interval, and so all of these arithmetic progressions use $O(d + \log m)$ space. In the following lemma we prove that the total space usage of all of the lists is $O(d \log m)$.

▶ **Lemma 13.** $\sum_{I\in\mathcal{I}} |\mathcal{L}_{Q_I}| = O(d\log m)$.

Proof. By Lemma 8, we know that $|\{\mu(0),\dots,\mu(k)\}| = O(\log m)$. For each $\ell \in \{\mu(0),\dots,\mu(k)\}$ let $\mathcal{I}_\ell$ be the sequence of all pattern intervals in $\mathcal{I}$ that are between the leftmost interval of length ℓ, inclusive, and the first of either the leftmost interval of length larger than ℓ, exclusive, or the last interval in $\mathcal{I}$, inclusive. Notice that $|I| \le \ell$ for each $I \in \mathcal{I}_\ell$. Let $\mathcal{D}_\ell$ be the set of queues for pattern intervals in $\mathcal{I}_\ell$. We show that $\sum_{I\in\mathcal{I}_\ell} |\mathcal{L}_{Q_I}| = O(|\mathcal{I}_\ell| + d)$. This implies that:

$$\sum_{I\in\mathcal{I}} |\mathcal{L}_{Q_I}| = \sum_{\ell\in\{\mu(0),\dots,\mu(k)\}} \sum_{I\in\mathcal{I}_\ell} |\mathcal{L}_{Q_I}| = \sum_{\ell\in\{\mu(0),\dots,\mu(k)\}} O(|\mathcal{I}_\ell| + d) = O(d\log m).$$

We focus on queues for which $|\mathcal{L}_{Q_I}| \ge 3$, since otherwise the bound is immediate. Notice that this includes all queues for wildcard intervals. Set $\ell \in \{\mu(0),\dots,\mu(k)\}$ and let α be the index of the last text character that has arrived.

We now establish that there exists a periodic string v of length ℓ that contains no wildcards, such that for any candidate c in any of the queues of $\mathcal{D}_\ell$ the entrance prefix of c contains v. Let $[i,j]$ be the leftmost interval in $\mathcal{I}_\ell$. Notice that $j = i + \ell - 1$ by the definition of $\mathcal{I}_\ell$. By Lemma 8, there is a string of length ℓ containing only non-wildcard characters that is a substring $p_0 \dots p_{i-1}$. Let r be the starting location of this string, and let $v = p_r \dots p_{r+\ell-1}$ be this string.

For each queue $Q_{I'} \in \mathcal{D}_\ell$ where $I' = [i',j']$ and for each candidate $c' \in Q_{I'}$, the entrance prefix of c' matches the prefix of P of length i'. Since $i' \ge i$ this means that $t_{c'+r} \dots t_{c'+r+\ell-1} = v$. The text substring $t_{\alpha-j'+r+1} \dots t_{\alpha-i'+r+\ell}$ contains at least three occurrences of v and its length is $|I'| + \ell \le 2\ell$. Therefore, by Lemma 3, v is a periodic string and the distance between any two candidates in the same queue is a multiple of ρ_v. Notice that for any $Q_{I'} \in \mathcal{D}_\ell$ that contains at least three candidates $c_1 < c_2 < c_3$, we bound $\rho_v \le \min\{c_3 - c_2, c_2 - c_1\} \le \frac{c_3-c_1}{2} \le \frac{j'-i'}{2}$.

Let $\hat{c}$ be the rightmost (largest index) candidate maintained in the queues of $\mathcal{D}_\ell$. In particular $t_{\hat{c}+r} \dots t_{\hat{c}+r+\ell-1} = v$. We extend this occurrence of v to the left and to the right in T for as long as the length of the period does not increase. Let the resulting substring be $t_{x+1} \dots t_{y-1}$. Unless, $x = -1$, the index x is called the *left violation* of v. Similarly, unless $y = \alpha+1$, the index y is called the *right violation* of v. Notice that $x < \hat{c}+r \le \hat{c}+r+\ell-1 < y$.

For the following, let the entrance interval of a candidate c be $[c, e_c]$.

▶ **Claim 14.** *If $Q_{[i',j']} \in \mathcal{D}_\ell$ contains at least three candidates, then for each candidate c in $\mathcal{L}_{Q_{[i',j']}}$ either $x \in [c, e_c]$ or $y \in [c, e_c]$.*

Proof Sketch. There exists a text index $\beta = \hat{c} + r$, such that β appears in the entrance interval of any candidate in the queues of $\mathcal{D}_\ell$, and $x < \beta < y$. Therefore, for each candidate $c \in \mathcal{L}_{Q_{[i',j']}}$, if $x \notin [c, e_c]$ and $y \notin [c, e_c]$ it must be the case that $[c, e_c] \subseteq [x+1, y-1]$. Recall that the principal period length of $t_{x+1} \dots t_{y-1}$ is ρ_v. Since $u = t_c \dots t_{e_c}$ is a substring of $t_{x+1} \dots t_{y-1}$, it must be that $\rho_u \le \rho_v$. Hence, one can prove that $[i', j']$ is an arithmetic interval with $u_{[i',j']} = u$, contradicting the fact that c is stored in $\mathcal{L}_{Q_{[i',j']}}$. ◀

Let $\mathcal{L}^x_{Q_I}$ ($\mathcal{L}^y_{Q_I}$) be the sets of candidates that are stored in $\mathcal{L}_{Q_I}$ such that their entrance interval contains x (y). $\mathcal{L}^x_{Q_I}$ and $\mathcal{L}^y_{Q_I}$ are not necessarily disjoint. Notice that by Claim 14, $\mathcal{L}^x_{Q_I} \cup \mathcal{L}^y_{Q_I}$ contains all the candidates stored in $\mathcal{L}_{Q_I}$.

▶ **Claim 15.** *$\sum_{I \in \mathcal{I}_\ell} |\mathcal{L}^x_{Q_I}| = O(|\mathcal{I}_\ell| + d)$ and $\sum_{I \in \mathcal{I}_\ell} |\mathcal{L}^y_{Q_I}| = O(|\mathcal{I}_\ell| + d)$.*

Proof. Let $I \in \mathcal{I}_\ell$ and let $\approx$ denote the match relation between symbols in $\Sigma \cup \{?\}$.

Notice that the contribution to $\sum_{I \in \mathcal{I}_\ell} |\mathcal{L}^x_{Q_I}|$ from all sets $\mathcal{L}^x_{Q_I}$ that have less than two candidates is at most $O(|\mathcal{I}_\ell|)$. Thus, for the following we assume that $\mathcal{L}^x_{Q_I}$ contains at least two candidates. Let $c_{I,x} = \max \mathcal{L}^x_{Q_I}$ be the most recent candidate in $\mathcal{L}^x_{Q_I}$. Let $c < c_{I,x}$ be a candidate in $\mathcal{L}^x_{Q_I}$. Since $c \in \mathcal{L}^x_{Q_I}$ we have that $p_{x-c} \approx t_{c+x-c} = t_x$ (recall that both x and c are indices in the text). Similarly, since $c_{I,x} \in \mathcal{L}^x_{Q_I}$ we have that $p_{x-c} \approx t_{c_{I,x}+x-c} = t_{x+(c_{I,x}-c)}$. Recall that the distance between any two candidates in Q_I is a multiple of ρ_v. In particular the distance $(c_{I,x} - c)$ is a multiple of ρ_v and $(c_{I,x} - c) \le |I| \le |v|$. Thus, $t_x \ne t_{x+(c_{I,x}-c)}$ since x violates the period of length ρ_v. Recall that $t_x \approx p_{x-c} \approx t_{x+(c_{I,x}-c)}$, and so p_{x-c} must be a wildcard. Therefore, each $c \in \mathcal{L}^x_{Q_I}$, except for possibly $c_{I,x}$, is in a position c such that p_{x-c} is a wildcard. Since x is the same for all of the candidates in all of the $\mathcal{L}^x_{Q_{I'}}$ for all $I' \in \mathcal{I}_\ell$, then the contribution to $\sum_{I \in \mathcal{I}_\ell} |\mathcal{L}^x_{Q_I}|$ of the candidates that are not the most recent in their set $\mathcal{L}^x_{Q_I}$ is at most $O(d)$. The contribution of the most recent candidates is at most $O(|\mathcal{I}_\ell|)$. Thus, $\sum_{I' \in \mathcal{I}_\ell} |\mathcal{L}^x_{Q_{I'}}| = O(|\mathcal{I}_\ell| + d)$. The proof that $\sum_{I' \in \mathcal{I}_\ell} |\mathcal{L}^y_{Q_{I'}}| = O(|\mathcal{I}_\ell| + d)$ is symmetric. ◀

Finally, $\sum_{I \in \mathcal{I}_\ell} |\mathcal{L}_{Q_I}| \le \sum_{I \in \mathcal{I}_\ell} |\mathcal{L}^x_{Q_I}| + \sum_{I \in \mathcal{I}_\ell} |\mathcal{L}^y_{Q_I}| = O(|\mathcal{I}_\ell| + d)$. Thus, we have completed the proof of Lemma 13. ◀

6 The Tradeoff Algorithm

The algorithm of Theorem 2 for PMDW uses $\tilde{O}(d)$ time per character and $\tilde{O}(d)$ words of space. In this section we introduce a randomized algorithm which expands this result for a parameter $0 \le \delta \le 1$ to an algorithm that uses $\tilde{O}(d^{1-\delta})$ time per character and $\tilde{O}(d^{1+\delta})$ words of space.

An overview of a slightly modified version (for the sake of intuition) of the tradeoff algorithm is described as follows. Let P^* be the longest prefix of P such that $\pi_{P^*} \le d^\delta$. The tradeoff algorithm first finds all the occurrences of P^* using a specialized algorithm for patterns with wildcard-period length at most d^δ. If $P^* = P$ then this completes the tradeoff algorithm. Otherwise, let $I^* = [i^*, j^*]$ be the interval in the secondary partitioning of Theorem 2 such that $i \le |P^*| \le j$. Each occurrence of P^* in the text is inserted as a candidate in the algorithm of Theorem 2 directly into Q_{I^*} Thus, the entrance prefixes of candidates in the queues match prefixes of P that are longer than P^* and, by maximality of P^*, these prefixes of P have large wildcard-period length. This means that the average distance between each two consecutive candidates is at least d^δ, and so combined with a lazy approach we are able to obtain an $\tilde{O}(d^{1-\delta})$ amortized time cost per character.

In the rest of this section we describe an overview of the specialized algorithm for dealing with patterns whose wildcard-period length is at most d^δ. The rest of the details for the tradeoff algorithm appear in the full version of this paper.

6.1 Patterns with Small Wildcard-period Length

Let P be a pattern of length m with $\pi_P < d^\delta$. Let q be an integer, which for simplicity is assumed to divide m. Consider the conceptual matrix $M^q = \{m^q_{x,y}\}$ of size $\left\lceil \frac{m}{q} \right\rceil \times q$ where $m^q_{x,y} = p_{(x-1)\cdot q+y-1}$. For any integer $0 \le r < q$ the rth column corresponds to an *offset pattern* $P_{q,r} = p_r p_{r+q} p_{r+2q} \dots p_{m-q+r}$. Notice that some offset patterns might be equal. Let $\Gamma_q = \{P_{q,r} | 0 \le r < q, '?' \notin P_{q,r}\}$ be the set of all the offset patterns that do not contain any wildcards. Each unique offset pattern is associated with a unique id. The set of unique ids is denoted by ID_q. We say that index i in P is *covered* by q if the column containing p_i is given a unique id. The columns of M^q define a *column pattern* P_q of length q, where the i'th character is the unique id of the i'th column, or '?' if no such id exists (the column has wildcards).

We partition T into q *offset texts*, where for every $0 \le r < q$ we define $T_{q,r} = t_r t_{r+q} t_{r+2q} \dots$. Using the dictionary matching streaming (DMS) algorithm of Clifford et al. [13] we find occurrences of offset patterns from Γ_q in each of the offset texts. Notice that we do *not* only find occurrences of $P_{q,r}$ in $T_{q,r}$ (since we cannot guarantee that the offset of T synchronizes with an occurrence of P). When the character t_α arrives, the algorithm passes t_α to the DMS algorithm for $T_{q,\alpha \bmod q}$. We also create a streaming *column text* T_q whose characters correspond to the ids of offset patterns as follows. If one of the offset patterns is found in $T_{q,\alpha \bmod q}$, then its unique id is the αth character in T_q. Otherwise, we use a dummy character for the αth character in T_q.

Notice that on occurrence of P in T necessarily creates an occurrence of P_q in T_q. Such occurrences are found via the black box algorithm of Clifford et al. [10]. However, an occurrence of P_q in T_q does not necessarily mean there was an occurrence of P in T, since some characters in P are not covered by q. In order to avoid such false positives we run the process in parallel with several choices of q, while guaranteeing that each non wildcard character in P is covered by at least one of those choices. Thus, if there is an occurrence of P_q at location i in T_q for all the choices of q, then it must be that P appears in T at location i. The choices of q are given by the following lemma.

▶ **Lemma 16.** *There exists a set Q of $O(\log d)$ prime numbers such that any index of a non-wildcard character in P is covered by at least one prime number $q \in Q$, and $\forall q \in Q : q = \tilde{O}(d)$.*

From a space usage perspective, we need the size of $|\Gamma_q|$ to be small, since this directly affects the space usage of the DMS algorithm which uses $\tilde{O}(k)$ space, where k is the number of patterns in the dictionary. In our case $k = |\Gamma_q|$. In order to bound the size of Γ_q we use the following lemma.

▶ **Lemma 17.** *If $q = \tilde{O}(d)$ and $\pi_P \le d^\delta$ then $|\Gamma_q| = O(d^\delta)$.*

Proof. Since $\pi_P \le d^\delta$, there exists a string $S = s_0 \dots s_{2m-2}$ that contains $\Omega(\frac{m}{d^\delta})$ occurrences of P. Using this string we show that $|\Gamma_q| = O(d^\delta)$.

For each id in ID_q we pick an index of a representative column in M_q that has this id, and denote this set by R_q. Let r_1 be the minimum index in R_q. For every index $0 \le i < m$

let $S_i = s_i \dots s_{i+m-1}$. For every $0 \le r < q$ let $S_{i,q,r} = s_{i+r}s_{i+r+q} \dots s_{i+m-q+r}$, and so for any integer $0 \le \Delta < q - r$ we have $S_{i,q,r+\Delta} = S_{i+\Delta,q,r}$. Notice that if S_i matches P then $P_{q,r} = S_{i,q,r}$ for each $r \in R_q$.

Let i be an index of an occurrence of P in S. For any distinct $r, r' \in R_q$, it must be that $S_{i,q,r} = P_{q,r} \neq P_{q,r'} = S_{i,q,r'}$. Thus, for any $r \in R_q$ such that $r > r_1$, we have $P_{q,r_1} = S_{i,q,r_1} \neq S_{i,q,r} = S_{i+r-r_1,q,r_1}$. This implies that $i + r - r_1$ is not occurrence of P. Therefore, every occurrence of P in S is associated with $|R_q| - 1$ indices that cannot be an occurrence of P. We further argue that each index i is associated with an occurrence of P (as just described) at most once. This is because if $S_{i,q,r_1} = P_{q,r}$ for some $r \in R_q$ then i can be associated only with an occurrence of P in index $i - (r - r_1)$. So the maximum number of instances of P in S is at most $\frac{|S|}{|R_q|} = \frac{2m-1}{|R_q|}$. However, S contains at least $\frac{m}{d^\delta}$ instances of P, so $\frac{m}{d^\delta} \le \frac{2m-1}{|R_q|}$ which implies that $|\Gamma_q| = |R_q| \le 2d^\delta = O(d^\delta)$. ◀

Complexities. For a single $q \in Q$, the algorithm creates $q = \tilde{O}(d)$ offset patterns and texts. For each such offset text the algorithm applies an instance of the DMS algorithm with a dictionary of $O(d^\delta)$ strings (by Lemma 17). Since each instance of the DMS algorithm uses $\tilde{O}(d^\delta)$ words of space [13], the total space usage for all instances of the DMS algorithm is $\tilde{O}(d^{1+\delta})$ words. Moreover, the time per character in each DMS algorithm is $\tilde{O}(1)$ time, and each time a character appears we inject it into only one of the DMS algorithms (for this specific q). In addition, the algorithm uses an instance of the black box algorithm for T_q, with a pattern of length q. This uses another $O(q) = \tilde{O}(d)$ space and another $\tilde{O}(1)$ time per character [10]. Thus the total space usage due to one element in Q is $\tilde{O}(d^{1+\delta})$ words. Since $|Q| = O(\log d)$ the total space usage for all elements in Q is $\tilde{O}(d^{1+\delta})$ words, and the total time per arriving character is $\tilde{O}(1)$. Thus we have proven the following.

▶ **Theorem 18.** *For any $0 \le \delta \le 1$ the online d wildcards pattern matching problem can be solved for patterns P with $\pi_P < d^\delta$ with a randomized Monte Carlo algorithm, in $\tilde{O}(1)$ time per arriving text character and using $\tilde{O}(d^{1+\delta})$ words of space.*

Abstract

In recent years much effort has been put into developing polynomial-time conditional lower bounds for algorithms and data structures in both static and dynamic settings. Along these lines we introduce a framework for proving conditional lower bounds based on the well-known 3SUM conjecture. Our framework creates a *compact representation* of an instance of the 3SUM problem using hashing and domain specific encoding. This compact representation admits false solutions to the original 3SUM problem instance which we reveal and eliminate until we find a true solution. In other words, from all *witnesses* (candidate solutions) we figure out if an *honest* one (a true solution) exists. This enumeration of witnesses is used to prove conditional lower bounds on *reporting* problems that generate all witnesses. In turn, these reporting problems are then reduced to various decision problems using special search data structures which are able to enumerate the witnesses while only using solutions to decision variants. Hence, 3SUM-hardness of the decision problems is deduced.

We utilize this framework to show conditional lower bounds for several variants of convolutions, matrix multiplication and string problems. Our framework uses a strong connection between all of these problems and the ability to find *witnesses*.

Specifically, we prove conditional lower bounds for computing partial outputs of convolutions and matrix multiplication for sparse inputs. These problems are inspired by the open question raised by Muthukrishnan 20 years ago [22]. The lower bounds we show rule out the possibility (unless the 3SUM conjecture is false) that almost linear time solutions to sparse input-output convolutions or matrix multiplications exist. This is in contrast to standard convolutions and matrix multiplications that have, or assumed to have, almost linear solutions.

Moreover, we improve upon the conditional lower bounds of Amir et al. [5] for histogram indexing, a problem that has been of much interest recently. The conditional lower bounds we show apply for both reporting and decision variants. For the well-studied decision variant, we show a full tradeoff between preprocessing and query time for every alphabet size > 2. At an extreme, this implies that no solution to this problem exists with subquadratic preprocessing time and $\tilde{O}(1)$ query time for every alphabet size > 2, unless the 3SUM conjecture is false. This is in contrast to a recent result by Chan and Lewenstein [9] for a binary alphabet.

While these specific applications are used to demonstrate the techniques of our framework, we believe that this novel framework is useful for many other problems as well.

1 Introduction

In recent years much effort has been invested towards developing polynomial time lower bounds for algorithms and data structures in both static and dynamic settings. This effort is directed towards obtaining a better understanding of the complexity class P for well-studied problems which seem hard in the polynomial sense. The seminal paper by Gajentaan and Overmars [13] set the stage for this approach by proving lower bounds for many problems in computational geometry conditioned on the 3SUM conjecture. In the 3SUM problem we are given a set A of n integers and we need to establish if there are $a, b, c \in A$ such that $a+b+c = 0$. This problem has a simple $O(n^2)$ algorithm (and some poly-logarithmic improvements in [6, 17]) but no truly subquadratic algorithm is known, where truly subquadratic means $O(n^{2-\epsilon})$ for some $\epsilon > 0$. The 3SUM conjecture states that no truly subquadratic algorithm exists for the 3SUM problem.

Based on this conjecture, there has been a recent extensive line of work establishing conditional lower bounds (CLBs) for many problems in a variety of fields other than computational geometry, including many interesting dynamic problems, see e.g. [1, 2, 3, 4, 19, 23].

1.1 Decision and Reporting Problems

Algorithmic problems come in many flavors. The classic one is the *decision* variant. In this variant, we are given an instance of a problem and we are required to decide if it has some property or not. Some examples include: (1) given a 3-CNF formula we may be interested in deciding if it satisfiable by some truth assignment; (2) given a bipartite graph we may be interested in deciding if the graph has a perfect matching; (3) given a text T and a pattern P we may be interested in deciding if P occurs in T. It is well-known that the first example is NP-complete while the two others are in P. An instance that has the property in question has at least one *witness* that proves the existence of the property. In the examples above a witness is: (1) a satisfying assignment; (2) a perfect matching in the graph; (3) a position of an occurrence of P in T. Sometimes, we are not only interested in understanding if a witness *exists*, but rather we wish to *enumerate* all of the witnesses. This is the *reporting* variant of the problem. In the examples mentioned above the goal of the reporting variant is to: (1) enumerate all satisfying assignments; (2) enumerate all perfect matchings; (3) enumerate all occurrences of P in T. For the first two examples it is known from complexity theory that it is most likely hard to count the number of witnesses (not to mention reporting them) (these are #P-complete problems), while the third example can be solved by classic linear time algorithms.

In this paper we investigate the interplay between the decision and reporting variants of algorithmic problems and present a systematic framework that is used for proving CLBs for these variants. We expect this framework to be useful for proving CLBs on other problems not considered here.

1.2 Our Framework

We introduce and follow a framework that shows 3SUM-hardness of decision problems via their reporting versions. The high-level idea is to reduce an instance of 3SUM to an instance of a reporting problem, and then reduce the instance of a reporting problem to several instances of its decision version using a sophisticated search structure. The outline of this framework is described next.

- **Compact Representation**. One of the difficulties in proving CLBs based on the 3SUM conjecture is that the input universe for 3SUM could be too large for accommodating a reduction to a certain problem. To tackle this, we *embed* the universe using special hashing techniques. This is sometimes coupled with a secondary problem-specific encoding scheme in order to match the problem at hand.
- **Reporting**. The embedding in the first step may introduce false-positives. To tackle this, we report *all* the candidate solutions (witnesses) for the embedded 3SUM instance, in order to verify if a true solution (an honest witness) to 3SUM really exists. This is where we are able to say something about the difficulty of solving reporting problems. This is done by reducing the embedded 3SUM instance to an instance of such a reporting problem, if it provides an efficient way to find all the false-positives. In some cases, such reductions reveal tradeoff relationships between the preprocessing time and reporting/query time.
- **Reporting via Decision**. In this step the goal is to establish 3SUM-hardness of a decision problem. To do so we reduce an instance of the reporting version of the problem to instances of the decision version by creating a data structure on top of the many instances of the decision version. This data structure allows us to efficiently report all of the elements in the output of the instance of the reporting version. By constructing the data structure in different ways we obtain varying CLBs for the decision variants depending on the specific structure that we use.

By following this route we introduce new CLBs for some important problems which are discussed in detail in Section 2. We point out that the embedding in the first step follows along the lines of [23] and [19]. However, in some cases we also add an additional encoding scheme to fit the needs of the specific problem at hand.

Implications. In Section 2 we discuss three applications from two different domains which utilize our framework for proving CLBs, thereby demonstrating the usefulness of our framework. Table 1 summarizes these results. Of particular interest are new results on Histogram Indexing (defined in Section 2) which, together with the algorithm of [9], demonstrate a sharp separation when allowing truly subquadratic preprocessing time between binary and trinary alphabet settings. Moreover, our framework is the first to obtain a CLB for the reporting version, which, as opposed to the decision variant, also holds for the binary alphabet case.

2 Applications

Convolution Problems

The *convolution* of two vectors $u, v \in \{\mathbb{R}^+ \cup \{0\}\}^n$ is a vector w, such that $w[k] = \sum_{i=0}^{k} u[i]v[k-i]$ for $0 \leq k \leq 2n-2$. Computing the convolution of u and v takes $O(n \log n)$ time using the celebrated FFT algorithm. Convolutions are used extensively in many areas including signal processing, communications, image compression, pattern matching, etc. A *convolution witness* for the kth entry in w is a pair (a, b) such that $a+b = k$ and $u[a] \cdot v[b] > 0$. In other words, the witnesses of entry k in w are all values i that contribute a non-zero value to the summation $w[k] = \sum_{i=0}^{k} u[i]v[k-i]$. The first convolution problem we consider is the *convolution witnesses problem* which is defined as follows.

▶ **Definition 1.** In the **convolution witnesses problem** we preprocess two vectors $u, v \in \{\mathbb{R}^+ \cup \{0\}\}^n$ and their convolution vector w, so that given a query integer $0 \leq k \leq 2n-2$, we list *all* convolution witnesses of index k in w.

We prove the following CLB for the convolution witnesses problem that holds even if u and v are binary vectors and all numbers in w are non-negative integers.

▶ **Theorem 2.** *Assume the 3SUM conjecture is true. Then for any constant $0 < \alpha < 1$, there is no algorithm solving the convolution witnesses problem with $O(n^{2-\alpha})$ expected preprocessing time and $O(n^{\alpha/2-\Omega(1)})$ expected amortized query time* ***per witness****.*

Theorem 2 implies that when using only truly subquadratic preprocessing time one is required to spend a significant polynomial amount of time on every single witness. In particular, this means that, assuming the 3SUM conjecture, one cannot expect to find witnesses much faster than following the naive algorithm for computing convolution naïvely according to the convolution definition. This is in contrast to the decision version of the problem, where we only ask if a witness exists. This variant is easily solved using constant query time after a near linear time preprocessing procedure (computing the convolution itself).

Another variation of the convolution problem which we consider is the *sparse convolution problem.* There are two different problems named sparse convolution, both appearing as open questions in a paper by Muthukrishnan [22]. In the first, which is now well understood, we are given Boolean vectors u and v of lengths N and M, where $M < N$. There are n ones in u, m ones in v and z ones in w, where w is the Boolean convolution vector of u and v. The goal is to report the non-zero elements in w in $\tilde{O}(z)$ time. This problem has been extensively studied, and the goal has been achieved; see for example [9, 11, 15]. The second variant which we call *partial convolutions* is as follows.

▶ **Definition 3.** The **partial convolution problem** on two vectors u and v of real numbers (of length N and M respectively, where $M < N$) and a set S of indices is to compute, for each $i \in S$, the value of the i-th element in the convolution of u and v.

Muthukrishnan in [22] asked if it is possible to compute a partial convolution significantly faster than the time needed to compute a (classic) convolution. We prove a CLB based on the 3SUM conjecture, that holds also for the special case of Boolean vectors, and, therefore, also for the special case in which we only want to know if the output values at indices in S are zero or more. Moreover, we focus on the important variant of this problem that deals with the case where the two input vectors have only $n = O(N^{1-\Omega(1)})$ ones and are both given implicitly (specifying only the indices of the ones). Our results also extend to the indexing version of the partial convolution problem, which we call the *partial convolution indexing problem*, and is defined as follows.

▶ **Definition 4.** The partial convolution indexing problem is to preprocess an N-length vector u of real numbers and a set of indices S to support the following queries: given an M-length vector v ($M < N$) of real numbers, for each $i \in S$ compute the value of the i-th element of the convolution of u and v.

Once again this variant already relevant when the input is Boolean and sparse, i.e. u and v have $n = O(N^{1-\Omega(1)})$ ones and are represented implicitly by specifying their indices.

We prove the following CLBs for these problems with the help of our framework.

▶ **Theorem 5.** *Assume the 3SUM conjecture is true. Then there is no algorithm for the partial convolution problem with $O(N^{1-\Omega(1)})$ time, even if $|S|$ and the number of ones in both input vectors are less than $N^{1-\Omega(1)}$.*

▶ **Theorem 6.** *Assume the 3SUM conjecture is true. Then there is no algorithm for the partial convolution indexing problem with $O(N^{2-\Omega(1)})$ preprocessing time and $O(N^{1-\Omega(1)})$ query time, even if both $|S|$ and the number of ones of the input vectors are $O(N^{1-\Omega(1)})$.*

As mentioned above, the convolution of vectors of length N can be computed in $\tilde{O}(N)$ time with the FFT algorithm. However, in the partial convolution problem and partial convolution indexing problem, despite the input vectors being sparse and represented sparsely (specifying only the $O(N^{1-\Omega(1)})$ indices of the ones in each vector), and despite the portion of the output we need to compute being sparse ($|S| = O(N^{1-\Omega(1)})$), no linear time algorithm (in $n = O(N^{1-\Omega(1)})$) exists, unless the 3SUM conjecture is false.

Notice that the partial convolution problem and its indexing variant are *decision* problems, since they require a *decision* for each location $i \in S$, whether $w[i] > 0$ or not. This is in contrast to the convolution witnesses problem, which is a reporting problem, as it requires the reporting of *all* of the witnesses for $w[i]$.

To prove CLBs for the convolution problems we follow our framework. That is, we first use a hash function to embed a 3SUM instance to a *smaller* universe. This mapping introduces false-positives, which we enumerate by utilizing the reporting problem of convolution witnesses. To solve the reporting version we reduce it to several instances of a decision problem, partial convolution or its indexing variant, by constructing a suitable data structure. Tying it all together leads to CLBs for both the reporting and decision problems.

Matrix Problems

We also present some similar CLBs for matrices.

▶ **Definition 7.** The **partial matrix multiplication problem** on two $N \times N$ matrices A and B of real numbers and a set of entries $S \subseteq N \times N$ is to compute, for each $(i, j) \in S$, the value $(A \times B)[i, j]$.

The indexing variant of this problem is defined as follows.

▶ **Definition 8.** The **partial matrix multiplication indexing problem** is to preprocess an $N \times N$ matrix A of real numbers and a collection $\mathcal{S} = \{S_1, S_2, ..., S_k\}$ of sets of entries, where $S_i \subseteq N \times N$, so that given a sequence $B_1, \ldots, B_k$ of $N \times N$ matrices of real numbers, we enumerate the entries of $A \times B_i$ that correspond to S_i.

For $\mathcal{S} = \{S_1, S_2, ..., S_k\}$ let $SIZE(\mathcal{S}) = \sum_{i=1}^{k} |S_i|$. We prove the following CLBs, which hold also for the special case of Boolean multiplication assuming that the input is given implicitly by specifying only the indices of the ones.

▶ **Theorem 9.** *Assume the 3SUM conjecture is true. Then there is no algorithm for the partial matrix multiplication problem running in $O(N^{2-\Omega(1)})$ expected time, even if $|S|$ and the number of ones in the input matrices is $O(N^{2-\Omega(1)})$.*

▶ **Theorem 10.** *Assume the 3SUM conjecture is true. Then there is no algorithm for the partial matrix multiplication indexing problem with $O(SIZE(\mathcal{S}))$ preprocessing time and $O(N^{2-\Omega(1)})$ query time.*

Matrix multiplication, and in particular Boolean matrix multiplication, can be solved in $\tilde{O}(n^\omega)$ time, where $\omega \approx 2.373$ [14, 25]. Many researchers believe that the true value of ω is 2. This belief implies that the running time for computing the product of two Boolean matrices is proportional to the size of the input matrices and the resulting output. However, our results demonstrate that such a result is unlikely to exist for sparse versions of the problem, where the number of ones in the matrices is $O(N^{2-\Omega(1)})$ and we are interested in only a partial output matrix (only $O(N^{2-\Omega(1)})$ entries of the matrix product).

To prove Theorem 9 and 10 we follow our framework. The process is very similar to the path for proving CLBs for convolution problems. In fact, instead of considering a reporting version of the partial matrix multiplication problem for proving these CLBs, we once again utilize the reporting problem of convolution witnesses. However, this time we transform the convolution witnesses to the matrix multiplication problems using a more elaborate data structure. The main difficulty in this transformation is to guarantee the sparsity of both the input and the required output. This transformation illustrates how a reporting version of a problem can be used to prove CLBs for decision versions of other problems, by changing the way we look for honest witnesses.

String Problems

Another application of our framework, which is seemingly unrelated to the previous two, is the problem of histogram indexing. A *histogram*, also called a *Parikh vector*, of a string T over alphabet Σ is a $|\Sigma|$-length vector containing the character count of T. For example, for $T = abbbacab$ the histogram is $\psi(T) = (3, 4, 1)$.

▶ **Definition 11.** In the **histogram indexing problem** we preprocess a string T to support the following queries: given a query Parikh vector ψ, return whether there is a substring T' of T such that $\psi(T') = \psi$.

▶ **Definition 12.** In the **histogram indexing reporting problem** we preprocess a string T to support the following queries: given a query Parikh vector ψ, report indices of T at which a substring T' of T begins such that $\psi(T') = \psi$.

The problem of histogram indexing (not the reporting version) is sometimes called *jumbled indexing.* It has received much attention in recent years. For example, for binary alphabets – that is histograms of length 2 – there is a straightforward algorithm with $O(n^2)$ preprocessing time and constant query time, see [10]. Burcsi et al. [8] and Moosa and Rahman [20] improved the preprocessing time to $O(n^2/\log n)$. Using the four-Russian trick a further improvement was achieved by Moosa and Rahman [21]. Then, using a connection to the recent improvement of all-pairs-shortest path by Williams [24], as observed by Bremner et al. [7] and by Hermelin et al. [16], the preprocessing time was further reduced to $O(\frac{n^2}{2^{\Omega(\log n)^{0.5}}})$. Finally, Chan and Lewenstein [9] presented an $O(n^{1.859})$ preprocessing time algorithm for the problem with constant query time. For non-binary alphabets some progress was achieved in the work by Kociumaka et al. [18] and even further achievement was shown in [9]. On the negative side, some CLBs were recently shown by Amir et al. [5].

We follow our framework and first obtain CLBs for the reporting version of histogram indexing. This is the first time CLBs are shown for the reporting version. Moreover, these CLBs apply to binary alphabets, as opposed to the decision version in which there currently is no CLB known for binary alphabets. The CLBs for the reporting version admit a full tradeoff between preprocessing and query time. For the decision variant, we improve upon the CLB by Amir et al. [5] by presenting full-tradeoffs between preprocessing and query

Table 1 Summary of CLBs proved in this paper. In this table N is the size of vectors, strings and the dimension of matrices. #1 refers to the number of ones in the input. The rows in this table are interpreted to mean that there is no data structure that beats these preprocessing, query, and reporting (if exists) complexities at the same time. For partial convolution and matrix multiplication the CLB on the preprocessing time should be interpreted as a CLB on the total running time as these are offline problems.

Problem *(Type)*	Preprocessing Time	Query Time	Reporting Time	Remarks
Conv. Witnesses *(Reporting)*	$\Omega(N^{2-\alpha})$	$\Omega(N^{1-\alpha/2})$	$\Omega(N^{\alpha/2-o(1)})$	[Theorem 2] $0 < \alpha < 1$
Partial Conv. *(Decision)*	$\Omega(N^{1-o(1)})$	—	—	[Theorem 5] Sparse input: $\#1 < N^{1-\Omega(1)}$; Sparse required output: $\|S\| < N^{1-\Omega(1)}$
Partial Conv. Indexing *(Decision)*	$\Omega(N^{2-o(1)})$	$\Omega(N^{1-o(1)})$	—	[Theorem 6] Sparse input: $\#1 < N^{1-\Omega(1)}$; Sparse required output: $\|S\| < N^{1-\Omega(1)}$
Partial Matrix Mult. *(Decision)*	$\Omega(N^{2-o(1)})$	—	—	[Theorem 9] Sparse input: $\#1 < N^{2-\Omega(1)}$; Sparse required output: $\|S\| < N^{2-\Omega(1)}$
Partial Matrix Mult. Indexing *(Decision)*	$\Omega(SIZE(S))$	$\Omega(N^{2-o(1)})$	—	[Theorem 10] Sparse input: $\#1 < N^{2-\Omega(1)}$; Sparse required output: $\|S_i\| < N^{2-\Omega(1)}$; $SIZE(S) = \sum_{i=1}^{k} \|S_i\|$
Histogram Reporting *(Reporting)*	$\Omega(N^{2-\frac{2\gamma}{\ell+\gamma}-o(1)})$	$\Omega(N^{1-\frac{\gamma}{\ell+\gamma}-o(1)})$	$\Omega(N^{\frac{\gamma\ell}{\ell+\gamma}-\frac{2\gamma}{\ell+\gamma}-o(1)})$	[Theorem 13] alphabet size: $\ell \geq 2$; $0 < \gamma < \ell$
Histogram Indexing *(Decision)*	$\Omega(N^{2-\frac{2(1-\alpha)}{\ell-1-\alpha}-o(1)})$	$\Omega(N^{1-\frac{1+\alpha(\ell-3)}{\ell-1-\alpha}-o(1)})$	—	[Theorem 14] alphabet size: $\ell > 2$; $0 \leq \alpha \leq 1$

time based on the standard 3SUM conjecture. Specifically, our new CLB implies that no solution to the histogram indexing problem exists with subquadratic preprocessing time and $\tilde{O}(1)$ query time for every alphabet size bigger than 2, unless the 3SUM conjecture is false. This demonstrates a sharp separation between binary and trinary alphabets, since Chan and Lewenstein [9] introduced an algorithm for histogram indexing on binary alphabets with $\tilde{O}(n^{1.859})$ preprocessing time and constant query time.

The CLBs are summarized by the following theorems.

▶ **Theorem 13.** *Assume the 3SUM conjecture is true. Then the histogram reporting problem for an N-length string and constant alphabet size $\ell \geq 2$ cannot be solved using $O(N^{2-\frac{2\gamma}{\ell+\gamma}-\Omega(1)})$ preprocessing time, $O(N^{1-\frac{\gamma}{\ell+\gamma}-\Omega(1)})$ query time and $O(N^{\frac{\gamma\ell}{\ell+\gamma}-\frac{2\gamma}{\ell+\gamma}-\Omega(1)})$ reporting time per item, for any $0 < \gamma < \ell$.*

▶ **Theorem 14.** *Assume the 3SUM conjecture holds. Then the histogram indexing problem for a string of length N and constant alphabet size $\ell \geq 3$ cannot be solved with $O(N^{2-\frac{2(1-\alpha)}{\ell-1-\alpha}-\Omega(1)})$ preprocessing time and $O(N^{1-\frac{1+\alpha(\ell-3)}{\ell-1-\alpha}-\Omega(1)})$ query time.*

The main structure of these proofs follows our framework. We first embed a 3SUM instance and encode it in a string with limited length. We then report the false-positives using the reporting variant of the histogram indexing problem, which implies CLBs for this variant. Finally, we reduce the reporting version to the decision version thereby obtaining CLBs for the decision version. The reduction utilizes a sophisticated data structure for reporting witnesses using many instances of the decision version.

3 Preliminaries

In the basic 3SUM problem we are given a set A of n integers and we need to answer whether there are $a, b, c \in A$ such that $a + b + c = 0$. In a common variant of the classic problem, which we also denote by 3SUM, three arrays A, B and C are given and we need to answer whether there are $a \in A, b \in B, c \in C$ such that $a + b + c = 0$. Both versions have the same computational cost (see [13]). There are some other variants of the 3SUM problem shown to be as hard as 3SUM up to poly-logarithmic factors. One such variant is Convolution3SUM, shown to be hard by Pătraşcu [23], see also [19]. In Convolution3SUM A is an ordered set and we need to answer whether there exist indices $0 \leq i, j \leq n-1$ such that $A[i] + A[j] = A[i+j]$. We also define DiffConv3SUM, in which we are given an ordered set A and we need to verify whether there exists $0 \leq i, k \leq n-1$ such that $A[k] - A[i] = A[k-i]$. It is easy to see that this is equivalent to Convolution3SUM.

Let $\mathcal{H}$ be a family of hash functions from $[u] \to [m]$.

$\mathcal{H}$ is called *linear* if for any $h \in \mathcal{H}$ and any $x, x' \in [u]$, we have $h(x) + h(x') \equiv h(x + x') \pmod{m}$. $\mathcal{H}$ is called *almost-linear* if for any $h \in \mathcal{H}$ and any $x, x' \in [u]$, we have either $h(x)+h(x') \equiv h(x+x')+c_h \pmod{m}$, or $h(x)+h(x') \equiv h(x+x')+c_h+1 \pmod{m}$, where c_h is an integer that depends only on the choice of h. For a function $h : [u] \to [m]$ and a set $S \subset [u]$ where $|S| = n$, we say that $i \in [m]$ is an overflowed value of h if $|\{x \in S : h(x) = i\}| > 3n/m$. $\mathcal{H}$ is called *almost-balanced* if for a random $h \in \mathcal{H}$ and any set $S \subset [u]$ where $|S| = n$, the expected number of elements from S that are mapped to overflowed values is $O(m)$. See [19] for constructions of families that are almost-linear and almost-balanced (see also [6, 12]).

For simplicity of presentation, and following the footsteps of previous papers that have used such families of functions [6, 23], we assume for the rest of the paper that almost linearity implies that for any $h \in \mathcal{H}$ and any $x, x' \in [u]$ we have $h(x) + h(x') \equiv h(x + x') \pmod{m}$.

There are actually two assumptions taking place here. The first is that there is only one option of so-called linearity. Overcoming this assumption imposes only a constant factor overhead. The second assumption is that $c_h = 0$. However, the constant c_h only affects offsets in our algorithm in a straightforward and not meaningful way, so we drop it in order to avoid clutter in our presentation.

4 Convolution Witnesses

We first prove a CLB for the convolution witnesses problem. We begin with a lemma which has elements from the proof of Pătraşcu's reduction [23] and from [6]. However, the lemma diverges from [23] by treating the hashed subsets differently. Specifically, many special 3SUM subproblems are created and then reduced to convolution witnesses.

We say that a binary vector of length n is *r-sparse* if it contains at most r 1's. An instance of convolution witnesses problem (u, v, w) is *(n, R)-sparse* if u and v are both of length n and n/R-sparse.

▶ **Lemma 15.** *Let sequence $A = \langle x_1, \cdots, x_n\rangle$ be an instance of Convolution3SUM. Let $R = O(n^\delta)$, where $0 < \delta < 0.5$ is a constant. There exists a truly subquadratic reduction from the instance A to $O(R^2)$ (n, R)-sparse instances of convolution witnesses problem for which we need to report $O(n^2/R)$ witnesses (over all instances).*

Proof. We use an almost-linear, almost-balanced, hash function $h : U \to [R]$ and create R buckets $B_0, \cdots, B_{R-1}$ where each B_a contains the indices of all elements $x_i \in A$ for which $h(x_i) = a$. Since h is almost-balanced the expected overall number of elements in buckets with more than $3n/R$ elements is $O(R)$. For each index i in an overflowed bucket, we verify whether $x_i + x_j = x_{i+j}$ for every other j in $O(n)$ time. Hence, we verify whether any index in an overflowed bucket is part of a Convolution3SUM solution in $O(nR)$ expected time. Since $R = O(n^{1-\Omega(1)})$ the expected time is truly subquadratic time.

We now assume that every bucket contains at most $3n/R$ elements. From the properties of almost-linear hashing, if $x_i + x_j = x_{i+j}$ then $h(x_i) + h(x_j) \bmod R = h(x_{i+j}) \bmod R$. Hence, if $x_i + x_j = x_{i+j}$ then $i \in B_a, j \in B_b$ implies that $i + j \in B_{a+b \bmod R}$.

Every three buckets form an instance of 3SUM and are uniquely defined by a and b. Hence, there are $R(R-1)/2 = O(R^2)$ 3SUM subproblems each on $O(n/R)$ elements from the small universe $[n]$. However, h may generate false positives. So, we must be able to verify that any 3SUM solution (a witness) for any instance is indeed a solution (an honest witness) for the problem on A. The number of false positives is expected to be $O(n^2/R)$ over all $O(R^2)$ instances, see [6]. So, we need an efficient tool to report each such witness in order to be able to solve Convolution3SUM.

To obtain such a tool, we reduce the problem to the convolution setting in the following way. We generate a characteristic vector v_a of length n for every set B_a ($v_a[i] = 1$ if $i \in B_a$ and $v_a[i] = 0$ otherwise, for $0 \le i < n$). This vector will be $3n/R$-sparse, since $|B_a| \le 3n/R$. Note that: $i \in B_a, j \in B_b$ and $\mathrm{i+j \in B_{a+b \bmod R} \iff v_a[i] = 1, v_b[j] = 1}$ and $\mathrm{v_{a+b \bmod R}[i+j] = 1}$.

Now, for each pair of vectors, v_a and v_b, we generate their convolution. Let $v = v_a * v_b$ be the convolution of v_a and v_b, and let $\ell = v[i + j]$. If $v_{a+b \bmod R}[i + j] = 1$, then we need to extract the ℓ witnesses of $v[i + j]$. For each witness (i, j) we check whether $x_i + x_j = x_{i+j}$. We note that if, while verifying, we discover that the overall number of the false-positives exceeds expectation (cn^2/R, for some constant c) by more than twice we rehash.

Thus, we see that Convolution3SUM can be solved by generating $O(R^2)$ (n, R)-sparse instances of convolution witnesses problem. These instances are computed in $O(nR^2)$ time, which is truly subquadratic as $R = O(n^\delta)$ for $\delta < 1/2$. ◀

It now follows that:

▶ **Theorem 2** (restated). *Assume the 3SUM conjecture is true. Then for any constant $0 < \alpha < 1$, there is no algorithm solving the convolution witnesses problem with $O(n^{2-\alpha})$ expected preprocessing time and $O(n^{\alpha/2-\Omega(1)})$ expected amortized query time **per witness**.*

Proof. We make use of Lemma 15 and its parameter R. In particular, the total cost of solving Convolution3SUM is at most $O(R^2 \cdot P(n,R) + n^2/R \cdot Q(n,R))$ expected time, where $P(n,R)$ is the time needed to preprocess an (n,R)-sparse instance of a convolution witness and $Q(n,R)$ is the time per witness query for an (n,R)-sparse instance of a convolution witness.

If we choose $R = n^{\alpha/2-\Omega(1)}$ we have that for $P(n) = O(n^{2-\alpha})$ and $Q(n) = O(n^{\alpha/2-\Omega(1)})$ we solve Convolution3SUM in $O(n^{2-\Omega(1)})$ time which is truly subquadratic. ◀

5 From Reporting to Decision I: Hardness of Partial Convolutions

We further consider the problem of reporting witnesses for convolutions. However, now we use the third step of our framework. We will construct a search data structure over decision problems which will allow us to efficiently search for witnesses. This will be our method for proving CLBs for the decision problems of partial convolutions [22]. Specifically, we intend to generate a data structure that uses convolutions on small sub-vectors of the input vectors in order to solve the problem. However, the data structure cannot be fully constructed as it will be too large. Hence, the construction is partial and we defer some of the work to the query phase.

We start with Lemma 15, and focus on an (n,R)-sparse instance of the convolution witnesses problem(u,v,w). We generate a specialized search tree for efficiently finding witnesses, which is created in an innovative way exploiting the sparsity of the input.

5.1 Search Tree Construction

Assume, without loss of generality, that n is a power of 2. We construct a binary tree in the following way. First, we generate the root of the tree with the convolution of v and u. Then we split u into 2 sub-vectors, say u_1 and u_2, each containing exactly $n/(2R)$ 1s. For each sub-vector we generate nodes that are children of the root, where the first node contains the convolution of v and u_1 and the second node contains the convolution of v and u_2. We continue this construction recursively so that at the ith recursive level we partition u into 2^i sub-vectors each containing $n/(2^iR)$ 1s. A vertex at level i represents the convolution of v and a sub-vector u_A containing $n/2^iR$ 1s. The vertex has two children, one represents the convolution of v and the sub-vector of u_A with the first $n/2^{i+1}R$ 1s of u_A (denoted by $u_{A,1}$). The other represents the convolution of v and the rest of u_A with the other $n/2^{i+1}R$ 1s (denoted by $u_{A,2}$). We stop the construction at the leaf level in which u is split to sub-vectors that each one of them contains X/R 1s from u, for some $X < n$ to be determined later. Calculating the convolution in each vertex is done bottom-up. First, we calculate the convolution for each vertex in the leaf level. Then, we use these results to calculate the convolution of the next level upwards. Specifically, if we have vertex that represent the convolution v and some sub-vector u_A and it has two children one which represents the convolution of v and $u_{A,1}$ and the other which represents the convolution of v and $u_{A,2}$, then $(v * u_A)[k] = (v * u_{A,1})[k] + (v * u_{A,2})[k - l_1]$ for every $k \in [0, n + l_1 + l_2 - 1]$, where l_1 and l_2 are the lengths of $u_{A,1}$ and $u_{A,2}$ respectively, and we consider the value of out of range entries as zero. This way we continue to calculate all the convolutions in the tree until reaching its root.

Construction Time. It is straightforward to verify that the total cost of the construction procedure is dominated by the time of constructing the lowest level of the binary tree. In this level, we have n/X sub-vectors of u as each of them has X/R 1's and the total number of 1s in u is n/R. We calculate the convolution of v with each of these sub-vectors, which can be done in $\tilde{O}(n)$ time. Thus, the total time needed to build the tree is $\tilde{O}(n^2/X)$. herefore, the total time for calculating the binary trees for all $O(R^2)$ (n, R)-sparse instances of the convolution witnesses problem is $\tilde{O}(R^2n^2/X)$.

Witness Search. To search for a witness we begin from the root of the binary tree and traverse down to a leaf containing a non-zero value in the result of the convolution at the query index (adjusting the index as needed while moving down the structure). The search for a leaf costs logarithmic time per query (as the tree has logarithmic height and in each level we just need to find a child with a non-zero value in the convolution it represents in the specific index of interest). Within the leaf, representing the convolution of v and some sub-vector u_A of u we can simply find a witness in $\tilde{O}(X/R)$ time as u_A contains just X/R 1s. Thus, as we have $O(n^2/R)$ false-positives over all $O(R^2)$ instances, the total time for finding all them is $\tilde{O}(n^2X/R^2)$.

Consequently, using the binary tree for solving Convolution3SUM will cost $\tilde{O}(R^2n^2/X + n^2X/R^2)$ time, which for $X = R^2$ is $\tilde{\Theta}(n^2)$ time. Since the tradeoff between the preprocessing time and query time meets at n^2, any improvement to the running time of either of them will imply a subquadratic solution for the Convolution3SUM problem.

5.2 Conditional Lower Bounds for Partial Convolution

As a consequence of our discussion above we obtain the following results regarding partial convolution and its indexing variant:

▶ **Theorem 5** (restated). *Assume the 3SUM conjecture is true. Then there is no algorithm for the partial convolution problem with $O(N^{1-\Omega(1)})$ time, even if $|S|$ and the number of ones in both input vectors are less than $N^{1-\Omega(1)}$.*

Proof. We make use of Lemma 15. In order to construct the binary tree as described in Section 5.1, we need to be able compute the convolution of v with some sub-vector of u for each leaf in the tree (all other convolution can be calculated efficiently from the convolutions in the leaves as described in the previous section). Recall that both input vectors have length $N = n$, n/R 1s (which is $O(N^{1-\Omega(1)})$ for $R = n^a$, where a is a positive constant), and we are interested in finding their convolution result only at the $O(n/R)$ indices (that is, $|S| = O(N^{1-\Omega(1)})$). If we preprocess the input for partial convolution in truly sublinear time (for example, proportional to n/R) then the total time for constructing all the search trees will be $O(R^2n^{2-\Omega(1)}/X)$ while the total query time will remain $O(n^2X/R^2)$. Choosing $X = n^c$ for small enough constant c and setting $R = X$, we obtain a subquadratic solution to Convolution3SUM. ◀

▶ **Theorem 6** (restated). *Assume the 3SUM conjecture is true. Then there is no algorithm for the partial convolution indexing problem with $O(N^{2-\Omega(1)})$ preprocessing time and $O(N^{1-\Omega(1)})$ query time, even if both $|S|$ and the number of ones of the input vectors are $O(N^{1-\Omega(1)})$.*

Proof. Use Lemma 15 and the previous discussion. If the preprocessing time for the partial convolution indexing problem is truly subquadratic and queries are answered in truly sublinear time then the total time for constructing all the structures for all $O(R^2)$ instances is $O(R^2[n^{2-\Omega(1)} + n^{1-\Omega(1)} \cdot n/X])$ while the total time for all of the queries remains $O(n^2X/R^2)$ (note that $N = n$). Choosing $X = n^c$ for small enough constant c and setting $R = X$, we obtain a subquadratic algorithm for Convolution3SUM. ◀

6 From Reporting to Decision II: Hardness of Partial Matrix Multiplication

We present another transformation from the reporting problem of convolution witnesses to decision problems. This time we prove CLBs for the partial matrix multiplication and its indexing variant. The main difficulty in this transformation is to ensure the sparsity of both input and required output. The CLBs that we prove are stated as follows (full details and proofs will appear in the full version of this paper).

▶ **Theorem 9** (restated). *Assume the 3SUM conjecture is true. Then there is no algorithm for the partial matrix multiplication problem running in $O(N^{2-\Omega(1)})$ expected time, even if $|S|$ and the number of ones in the input matrices is $O(N^{2-\Omega(1)})$.*

▶ **Theorem 10** (restated). *Assume the 3SUM conjecture is true. Then there is no algorithm for the partial matrix multiplication indexing problem with $O(SIZE(S))$ preprocessing time and $O(N^{2-\Omega(1)})$ query time.*

7 Hardness of Data Structures for Histogram Indexing

In order to prove a CLB for both the histogram indexing problem and the histogram (indexing) reporting problem, we will first focus on reducing 3SUM to the histogram reporting problem, and then turn our focus to reducing the the histogram reporting problem to the histogram indexing problem.

7.1 Reducing Convolution3SUM to Histogram Reporting

We are given an ordered set A of integers $x_1, x_2, ..., x_n$ for which we want to solve DiffConv3SUM. Our methodology here is to encode the input integers into a compact string S so that histogram indexing with carefully chosen query patterns implies a solution to DiffConv3SUM. Since the size of the universe of the input integers can be as large as n^3, we hash down the universe size while (almost) maintaining the linearity property of the input. To do this, we make use of an almost-linear almost-balanced hash function $h : U \to [R]$ as defined in Section 3, and apply h to all of the input integers.

After utilizing h to compress the input range, we are ready to encode the input and create the string S. To do this, we encode each $h(x_k)$ separately, and then concatenate the encodings in the same order as their corresponding original integers in A. We use the following encoding scheme, using an alphabet $\Sigma = \{\sigma_0, \sigma_1, , ..., \sigma_{\ell-1}\}$. Some other encoding schemes, which surprisingly provide the same bounds, will be presented in the full version of this paper.

Encoding 1. The encoding will consist of two separate partial encodings concatenated together. The first partial encoding is partitioned into ℓ parts which together will represent $h(x_k)$ in base $R^{1/\ell}$. For $0 \le j \le \ell - 1$ the jth part of this first partial encoding is a unary representation of $p_{j,h(x_k)} = \lfloor h(x_k)/R^{j/\ell} \rfloor \bmod R^{1/\ell}$ using σ_j, and is denoted by $enc(j, h(x_k)) = \sigma_j^{p(j,h(x_k))}$. The first partial encoding of $h(x_k)$, which we also call a *regular encoding* of $h(x_k)$, is $enc_\ell(h(x_k)) = enc(0, h(x_k))enc(1, h(x_k)) \cdots enc(\ell - 1, h(x_k))$ $= \sigma_0^{p_{0,h(x_k)}} \sigma_1^{p_{1,h(x_k)}} \cdots \sigma_{\ell-1}^{p_{\ell-1,h(x_k)}}$.

For the second partial encoding we encode the *complement* of each $enc(j, h(x_k))$ which is the unary representation of $\bar{p}_{j,h(x_k)} = R^{1/\ell} - (\lfloor h(x_k)/R^{j/\ell} \rfloor \bmod R^{1/\ell})$ using σ_j, and is denoted by $\overline{enc}(j, h(x_k))$. The second partial encoding of $h(x_k)$, which we also call a *complement encoding* of $h(x_k)$, is $\overline{enc_\ell}(h(x_k)) = \overline{enc}(0, h(x_k))\overline{enc}(1, h(x_k)) \cdots \overline{enc}(\ell - 1, h(x_k)) = \sigma_0^{\bar{p}_{0,h(x_k)}} \sigma_1^{\bar{p}_{1,h(x_k)}} \cdots \sigma_{\ell-1}^{\bar{p}_{\ell-1,h(x_k)}}$.

The full encoding of $h(x_k)$ is the concatenation of $\overline{enc_\ell}(h(x_k))$ and $enc_\ell(h(x_k))$ which we denote by $ENC_\ell(h(x_k))$. Finally, the string S is set to be $ENC_\ell(h(x_1))ENC_\ell(h(x_2)) \cdots ENC_\ell(h(x_n))$. The size of S is clearly $N = O(\ell \cdot R^{\frac{1}{\ell}} n)$. We denote the substring of S starting at the location of the beginning of $enc_\ell(h(x_i))$ and ending at the location of the end of $\overline{enc_\ell}(h(x_j))$ by $S_{i,j}$.

Consider a Parikh vector v_k obtained from x_k and h where the rth element has a count of $\bar{p}_{r,h(x_k)} + R^{1/\ell} \cdot (k - 1)$. We say that v_k *represents* x_k. For a vector $w = (w_0, w_1, ..., w_m)$ we define $w^{>>1} = (0, w_0, w_1, ..., w_{m-1})$. We also define the *carry set* of v_k to be $V_k = \{v_k + R^{1/\ell}u - u^{>>1} \mid u = (u_0, u_1, ..., u_{\ell-2}, 0),\ u_i \in \{0, 1\}\ 0 \le i < \ell - 1\}$. It is easy to see that $|V_k| = 2^{\ell-1}$ and that V_k can be obtained from v_k in $O(\ell \cdot 2^{\ell-1})$ time. We call v_k the *base* of V_k. We have the following lemma regarding V_k:

▶ **Lemma 16.** *If there exists a pair x_i, x_j such that $x_k = x_j - x_i$ and $k = j - i$, then the Parikh vector of $S_{i,j}$ must be in V_k.*

Proof. Since h is linear we know that $h(x_k) = h(x_j) - h(x_i)$. This is equivalent to saying that $R + R^{\frac{\ell-1}{\ell}} - h(x_k) = R + R^{\frac{\ell-1}{\ell}} - [h(x_j) - h(x_i)] = (R + R^{\frac{\ell-1}{\ell}} - h(x_j)) + h(x_i)$. In $S_{i,j}$ we have the full encoding of all integers $x_{i+1}, ..., x_{j-1}$. There are exactly $k - 1$ integers between x_i and x_j. Therefore, each of them adds $R^{1/\ell}$ occurrences of each σ_r $(0 \le r \le l - 1)$ to $S_{i,j}$. In addition to the full encodings of these integers we have two more partial encodings: $enc_\ell(h(x_i))$ and $\overline{enc_\ell}(h(x_j))$. Notice that $enc_\ell(h(x_i))$ and $\overline{enc_\ell}(h(x_j))$ represent $h(x_i)$ and $R + R^{\frac{\ell-1}{\ell}} - h(x_j)$, respectively, in base $R^{1/\ell}$. If we look at the vector v_k (the base of V_k) after subtracting $(k - 1)R^{1/\ell}$ from the count of each character, we obtain the representation of $R + R^{\frac{\ell-1}{\ell}} - h(x_k)$ in base $R^{1/\ell}$, which intuitively implies that v_k is the Parikh vector that we are looking for. However, it is possible to generate a carry at each of the ℓ digits of the base $R^{1/\ell}$ during the addition of $(R + R^{\frac{\ell-1}{\ell}} - h(x_j)) + h(x_i)$. To handle these carries we consider all possible 2^ℓ carry scenarios and generate a vector for each of the $2^{\ell-1}$ scenarios. These carry scenarios are exactly represented by the vectors in V_k, as each vector u in the definition of V_k specifies the indices in which we have a carry. Hence, the Parikh vector of $S_{i,j}$ must be one of the vectors in V_k. ◀

Thus, we preprocess S with an algorithm for histogram reporting, and then query the resulting data structure with all the vectors in V_k, whose base v_k represents some x_k, in an attempt to decide if x_k is part of a solution to DiffConv3SUM. The reported locations are classified into two types:

Candidates: Locations where the histogram match begins and ends exactly between the complement and regular encodings of two input integers. All these locations correspond to x_i and x_j such that for the particular $h(x_k)$ for which the query was constructed, we have $h(x_k) = h(x_j) - h(x_i)$ and also $k = j - i$.

Encoding Errors: All matches that are not candidates.

While encoding errors clearly do not provide a solution for DiffConv3SUM on A, candidates may also not be suitable for a solution since the function h introduces false-positives. The following lemma bounds the total expected number of false-positives (both from false-positive candidates and encoding errors) that can be reported by a single query vector (and the vectors in the carry set that it serves as it base).

▶ **Lemma 17.** *The expected number of false positives that are reported when considering all vectors in V_k (whose base represents x_k) as queries is $O(2^{\ell-1}N/R^{1-\frac{1}{\ell}})$.*

Proof. We focus on $v \in V_k$ that is queried when considering x_k. This vector v implies the value of m which is the length of substrings of S that can have v as their Parikh vector. Clearly, there are at most N such substrings. We focus on the substring from location α to location $\alpha + m - 1$ in S. Due to our encoding scheme, this substring contains a (possibly empty) suffix of $ENC_\ell(h(x_i))$, for some x_i, followed by $k-1$ full encodings of some integers from A, and then a (possibly empty) prefix of $ENC_\ell(h(x_j))$, for some integers x_i and x_j. The only way in which we may falsely report location α as a match is if for each $\sigma \in \Sigma$ the number of σ characters in the substring of S, denoted by $f(\sigma, \alpha, m)$, is equal to the count of σ in v, denoted by v_σ. For a given σ, since the substring contains $k-1$ complete encodings, we can consider $v_\sigma - (k-1)R^{1/\ell}$ which is a function of $\bar{p}_{r,h(x_k)}$, compared to $f(\sigma, \alpha, m) - (k-1)R^{1/\ell}$. Now, since $\bar{p}_{r,h(x_k)}$ is uniformly random (due to h) in the range $[R^{1/\ell}]$, the probability that they are equal is $R^{-1/\ell}$. This is true for every character σ on its own, but when considering all of the ℓ characters, once we set the count for the first $\ell - 1$ characters the count for the last character completely depends on the other counts. Therefore, the probability that the comparison passes for all of the characters only depends on the first $\ell - 1$ characters, and is $1/R^{1-1/\ell}$. By linearity of expectation over all possible locations in S and all $2^{\ell-1}$ vectors in V_k, the expected number of false positives is $O(2^{\ell-1}N/R^{1-\frac{1}{\ell}})$. ◀

7.2 Hardness of Histogram Reporting

Utilizing the reduction we have described in the previous section, that transforms an ordered set A to a string S, we can prove the following CLB.

▶ **Theorem 13** (restated). *Assume the 3SUM conjecture holds. The histogram reporting problem for an N-length string and constant alphabet size $\ell \geq 2$ cannot be solved using $O(N^{2-\frac{2\gamma}{\ell+\gamma}-\Omega(1)})$ preprocessing time, $O(N^{1-\frac{\gamma}{\ell+\gamma}-\Omega(1)})$ query time and $O(N^{\frac{\gamma\ell}{\ell+\gamma}-\frac{2\gamma}{\ell+\gamma}-\Omega(1)})$ reporting time per item, for any $0 < \gamma < \ell$.*

Proof. We follow the reduction in Section 7.1. For an instance of the histogram reporting problem on a string of length N denote the preprocessing time by $O(N^\alpha)$, the query time by $O(N^\beta)$ and the reporting time per item by $O(N^\delta)$. The total expected running time used by our reduction to solve DiffConv3SUM is $O(N^\alpha) + n \cdot O(N^\beta) + E_{fp} \cdot O(N^\delta)$, where E_{fp} is the expected total number of false positives. This running time must be $\Omega(n^{2-\Omega(1)})$, unless 3SUM conjecture is false.

Since $N = O(\ell \cdot R^{\frac{1}{\ell}}n)$ and $E_{fp} = O(n2^\ell N/R^{1-\frac{1}{\ell}})$, then either $(\ell \cdot R^{\frac{1}{\ell}}n)^\alpha = \Omega(n^{2-o(1)})$, $(\ell \cdot R^{\frac{1}{\ell}}n)^\beta = \Omega(n^{1-o(1)})$, or $n2^\ell(\ell \cdot R^{\frac{1}{\ell}}n)/R^{1-\frac{1}{\ell}} \cdot (\ell \cdot R^{\frac{1}{\ell}}n)^\delta = \Omega(n^{2-o(1)})$. Set R to be n^γ. By straightforward calculations following our choice of R we get that $\alpha = 2 - \frac{2\gamma}{\ell+\gamma} - \Omega(1)$, $\beta = 1 - \frac{\gamma}{\ell+\gamma} - \Omega(1)$, and $\delta = \frac{\gamma\ell}{\ell+\gamma} - \frac{2\gamma}{\ell+\gamma} - \Omega(1)$. ◀

7.3 From Reporting to Decision: Hardness of Histogram Indexing

We make use of Theorem 13 to obtain a CLB on the decision variant of the problem. Amir et al. [5] proved similar lower bounds based on a stronger 3SUM conjecture. Our proof here shows that this stronger assumption is not needed and that the common 3SUM conjecture suffices. The idea of the proof is to make the expected number of false-positives small by a suitable choice of R.

▶ **Lemma 18.** *Assume the 3SUM conjecture holds. The histogram indexing problem for a string of length N and constant alphabet size $\ell \geq 3$ cannot be solved with $O(N^{2-\frac{2}{\ell-1}-\Omega(1)})$ preprocessing time and $O(N^{1-\frac{1}{\ell-1}-\Omega(1)})$ query time.*

Proof. We follow the reduction in Section 7.1. In order to use histogram indexing we will reduce the probability of a false positive for any query to be less than 1/2. From Lemma 17 we know that the expected number of false positives due to query is at most $O(\frac{2^{\ell-1}(\ell R^{\frac{1}{\ell}} n)}{R^{1-\frac{1}{\ell}}})$. By setting R to be $c_1 n^{\frac{\ell}{\ell-2}}$ for sufficiently large constant c_1 the number of false positives is strictly smaller than 1/2, which implies immediately that the probability of a false positive is strictly smaller than 1/2. Therefore, if we were to solve histogram indexing instead of histogram reporting on the same input as in Theorem 13, the probability of a false positive is less than 1/2. We can make this probability smaller by repeating the process $O(\log n)$ times, each time using a different hash function h. This way, the probability that all of the queries that are due to a specific x_k return false positives is less than $1/poly(n)$. If a given x_k passes all of the query processes (that is, a positive answer is received by each one of them), then we can verify that there is indeed a match with this x_k in $O(n)$ time, which will add a negligible cost to the expected running time in the case it is indeed a false positive. Thus, the total expected running time of this procedure is $O(\log n(P(N,\ell)+nQ(N,\ell)))$, where $P(N,\ell)$ is the preprocessing time (for input string of length N and alphabet size ℓ) and $Q(N,\ell)$ is the query time (for the same parameters). Therefore, unless the 3SUM conjecture is false, there is no solution for histogram indexing such that $P(N,\ell) = O(n^{2-\Omega(1)})$ and $Q(N,\ell) = O(n^{1-\Omega(1)})$. If we plug-in the value of R we have chosen and follow the calculations in the proof of Theorem 13 (with $\gamma = \frac{\ell}{\ell-2}$), then we obtain that there is no solution for the histogram indexing problem with $P(N,\ell) = O(N^{2-\frac{2}{\ell-1}-\Omega(1)})$ and $Q(N,\ell) = O(N^{1-\frac{1}{\ell-1}-\Omega(1)})$. ◀

We generalize this CLB by presenting a full-tradeoff between preprocessing and query time. The proof will appear in the full version of this paper. The idea of the proof is to artificially split the encoded string S to smaller parts, so we can have many false positives in S, but the probability for a false positive in each part will be small.

▶ **Theorem 14** (restated). *Assume the 3SUM conjecture holds. The histogram indexing problem for a string of length N and constant alphabet size $\ell \geq 3$ cannot be solved with $O(N^{2-\frac{2(1-\alpha)}{\ell-1-\alpha}-\Omega(1)})$ preprocessing time and $O(N^{1-\frac{1+\alpha(\ell-3)}{\ell-1-\alpha}-\Omega(1)})$ query time, for any $0 \leq \alpha \leq 1$.*

Abstract

We present a deterministic incremental algorithm for *exactly* maintaining the size of a minimum cut with $\widetilde{O}(1)$ amortized time per edge insertion and $O(1)$ query time. This result partially answers an open question posed by Thorup [Combinatorica 2007]. It also stays in sharp contrast to a polynomial conditional lower-bound for the fully-dynamic weighted minimum cut problem. Our algorithm is obtained by combining a recent sparsification technique of Kawarabayashi and Thorup [STOC 2015] and an exact incremental algorithm of Henzinger [J. of Algorithm 1997].

We also study space-efficient incremental algorithms for the minimum cut problem. Concretely, we show that there exists an $O(n \log n/\varepsilon^2)$ space Monte-Carlo algorithm that can process a stream of edge insertions starting from an empty graph, and with high probability, the algorithm maintains a $(1+\varepsilon)$-approximation to the minimum cut. The algorithm has $\widetilde{O}(1)$ amortized update-time and constant query-time.

1 Introduction

Computing a minimum cut of a graph is a fundamental algorithmic graph problem. While most of the focus has been on designing static efficient algorithms for finding a minimum cut, the dynamic maintenance of a minimum cut has also attracted increasing attention over the last two decades. The motivation for studying the dynamic setting is apparent, as important networks such as social or road network undergo constant and rapid changes.

Given an initial graph G, the goal of a dynamic graph algorithm is to build a data-structure that maintains G and supports update and query operations. Depending on the types of update operations we allow, dynamic algorithms are classified into three main

categories: (i) *fully dynamic*, if update operations consist of both edge insertions and deletions, (ii) *incremental*, if update operations consist of edge insertions only and (iii) *decremental*, if update operations consist of edge deletions only. In this paper, we study incremental algorithms for maintaining the size of a minimum cut of an unweighted, undirected graph (denoted by $\lambda(G) = \lambda$) supporting the following operations:

- Insert(u, v): insert the edge (u, v) in G.
- QuerySize: return the size of a minimum cut of the current G.

For any $\alpha \geq 1$, we say that an algorithm is an α-approximation of λ if QuerySize returns a positive number k such that $\lambda \leq k \leq \alpha \cdot \lambda$. Our problem is characterized by two time measures; *query time*, which denotes the time needed to answer each query and *total update time*, which denotes the time needed to process *all* edge insertions. We say that an algorithm has an $O(t(n))$ amortized update time if it takes $O(m(t(n)))$ total update time for m edge insertions starting from an empty graph. We use $\widetilde{O}(\cdot)$ to hide poly-logarithmic factors.

Related Work

For over a decade, the best known static and deterministic algorithm for computing a minimum cut was due to Gabow [10] which runs in $O(m + \lambda^2 \log n)$ time. Recently, Kawarabayashi and Thorup [19] devised a $\widetilde{O}(m)$ time algorithm which applies only to simple, unweighted and undirected graphs. Randomized Monte Carlo algorithms in the context of static minimum cut were initiated by Karger [17]. The best known randomized algorithm is due to Karger [18] and runs in $O(m \log^3 n)$ time.

Karger [16] was the first to study the dynamic maintenance of a minimum cut in its full generality. He devised a fully dynamic, albeit randomized, algorithm for maintaining a $\sqrt{1 + 2/\varepsilon}$-approximation of the minimum cut in $\widetilde{O}(n^{1/2+\varepsilon})$ expected amortized time per edge operation. In the incremental setting, he showed that the update time for the same approximation ratio can be further improved to $\widetilde{O}(n^{\varepsilon})$. Thorup and Karger [28] improved upon the above guarantees by achieving an approximation factor of $\sqrt{2 + o(1)}$ and an $\widetilde{O}(1)$ expected amortized time per edge operation.

Henzinger [14] obtained the following guarantees for the incremental minimum cut; for any $\varepsilon \in (0, 1]$, (i) an $O(1/\varepsilon^2)$ amortized update-time for a $(2 + \varepsilon)$-approximation, (ii) an $O(\log^3 n/\varepsilon^2)$ expected amortized update-time for a $(1 + \varepsilon)$-approximation and (iii) an $O(\lambda \log n)$ amortized update-time for the exact minimum cut.

For minimum cut up to some poly-logarithmic size, Thorup [27] gave a fully dynamic Monte-Carlo algorithm for maintaining exact minimum cut in $\widetilde{O}(\sqrt{n})$ time per edge operation. He also showed how to obtain an $1 + o(1)$-approximation of an arbitrary sized minimum cut with the same time bounds. In comparison to previous results, it is worth pointing out that his work achieves *worst-case* update times.

Łącki and Sankwoski [21] studied the dynamic maintenance of the exact size of the minimum cut in planar graphs with arbitrary edge weights. They obtained a fully dynamic algorithm with $\widetilde{O}(n^{5/6})$ query and update time.

There has been a growing interest in proving conditional lower bounds for dynamic problems in the last few years [1, 13]. A recent result of Nanongkai and Saranurak [24] shows the following conditional lower-bound for the *exact weighted* minimum cut assuming the Online Matrix-Vector Multiplication conjecture: for any $\varepsilon > 0$, there are no fully-dynamic algorithms with polynomial-time preprocessing that can simultaneously achieve $O(n^{1-\varepsilon})$ update-time and $O(n^{2-\varepsilon})$ query-time.

Results and Technical Overview

We present two new incremental algorithms concerning the maintenance of the size of a minimum cut. Both algorithms apply to undirected, unweighted simple graphs.

Our first and main result, presented in Section 4, shows that there is a deterministic incremental algorithm for *exactly* maintaining the size of a minimum cut with $\widetilde{O}(1)$ amortized time per operation and $O(1)$ query time. This result allows us to partially answer in the affirmative a question regarding efficient dynamic algorithms for exact minimum cut posed by Thorup [27]. Meanwhile, it also stays in sharp contrast to the recent polynomial conditional lower-bound for the fully-dynamic weighted minimum cut problem [24].

We obtain our result by heavily relying on a recent sparsification technique developed in the context of static minimum cut. Specifically, for some given simple graph G, Kawarabayashi and Thorup [19] designed an $\widetilde{O}(m)$ procedure that contracts vertex sets of G and produces a multigraph H with considerably less vertices and edges while preserving some family of cuts of size up to $3/2\lambda(G)$. Motivated by the properties of H, we crucially observe that it is "safe" to escape from G and work entirely with graph H as long as the sequence of newly inserted edges have not increased the size of a minimum cut in H by more than $3/2\lambda(G)$. If the latter occurs, we then recompute a new multigraph H for the current graph G. Since $\lambda(G) \leq n$, we note the number of such re-computations can be at most $O(\log n)$. For maintaining the minimum-cut of H, we appeal to the exact incremental algorithm due to Henzinger [14]. Though the combination of this two algorithms might seem immediate at first sight, we remark that it is not alone sufficient for achieving the claimed bounds. Our main contribution is to overcome some technical obstacles and formally argue that such combination indeed leads to our desirable guarantees.

Motivated by the recent work on *space-efficient* dynamic algorithms [5, 12], we next study the efficient maintenance of the size of a minimum cut using only $\widetilde{O}(n)$ space. Concretely, we present a $O(n \log n/\varepsilon^2)$ space Monte-Carlo algorithms that can process a stream of edge insertions starting from an empty graph, and with high probability, the algorithm maintains an $(1+\varepsilon)$-approximation to the minimum cut in $O(\alpha(n)\log^3 n/\varepsilon^2)$ amortized update-time and constant query-time. Note that none of the existing streaming algorithms for $(1+\epsilon)$-approximate minimum cut [2, 20, 3] achieve these update and query times.

2 Preliminary

Let $G = (V, E)$ be an undirected, unweighted multigraph with no self-loops. Two vertices x and y are *k-edge connected* if there exist k edge-disjoint paths connecting x and y. A graph G is *k-connected* if every pair of vertices is k-edge connected. The *local edge connectivity* $\lambda(G, x, y)$ of vertices x and y is the largest k such that x and y are k-edge connected in G. The *edge connectivity* $\lambda(G)$ of G is the largest k such that G is k-edge connected.

For a subset $S \subseteq V$, the *edge cut* $E(S, V \setminus S)$ is a set of edges that have one endpoint in S and the other in $V \setminus S$. If S is a singleton, we refer to such cut as *trivial* cut. Two vertices x and y are *separated* from $E(S, V \setminus S)$ if they do not belong to the same connected component induced by the edge cut. A *minimum edge cut* of x and y is a cut of minimum size among all cuts separating x and y. A *global minimum cut* $\lambda(G)$ for G is the minimum edge cut over all pairs of vertices. By Menger's Theorem [22], (a) the size of the minimum edge cut separating x and y is $\lambda(G, x, y)$, and (b) the size of the global minimum cut is equal to $\lambda(G)$.

Let n, m_0 and m_1 be the number of vertices, initial edges and inserted edges, respectively. The total number of edges m is the sum of the initial and inserted edges. Moreover, let

λ and δ denote the size of the global minimum cut and the minimum degree in the final graph, respectively. Note that the minimum degree is always an upper bound on the edge connectivity, i.e., $\lambda \leq \delta$ and $m = m_0 + m_1 = \Omega(\delta n)$.

A subset $U \subseteq V$ is *contracted* if all vertices in U are identified with some element from U and all edges between them are discarded. Note that this may not correspond to edge contractions, since we do not know whether U is connected. For $G = (V, E)$ and a collection of vertex sets, let $H = (V_H, E_H)$ denote the graph obtained by contracting such vertex sets. Such contractions are associated with a mapping $h : V \to V_H$. For an edge subset $N \subseteq E$, let $N_h = \{(h(a), h(b)) : (a, b) \in N\} \subseteq E_H$ be its corresponding edge subset induced by h.

3 Sparse certificates

In this section we review a useful sparsification tool, introduced by Nagamochi and Ibaraki [23].

▶ **Definition 1** ([4]). A *sparse k-connectivity certificate*, or simply a *k-certificate*, for an unweighted graph G with n vertices is a subgraph G' of G such that

1. G' consists of at most $k(n-1)$ edges, and
2. G' contains all edges crossing cuts of size at most k.

Given an undirected graph $G = (V, E)$, a *maximal spanning forest decomposition (msfd)* of order k is a decomposition of G into k edge-disjoint spanning forests F_i, $1 \leq i \leq k$, such that F_i is a maximal spanning forest of $G \setminus (F_1 \cup F_2 \ldots \cup F_{i-1})$. If we let $G' = (V, \bigcup_{i \leq k} F_i)$, then G' is a k-certificate. An msfd that fulfills the following additional properties is called a DA-msfd of order k: For a multigraph G, (1) for all $1 \leq i \leq k$, if x and y are connected in F_i, then they are i-edge connected in G; (2) G is k-edge connected iff G' is k-edge connected; (3) for any $1 \leq i \leq k$ and $x, y \in V$, $\lambda(\bigcup_{j \leq i} F_j, x, y) \geq \min(\lambda(G, x, y), i)$. As G' is a subgraph of G, $\lambda(G') \leq \lambda(G)$. This implies that $\lambda(G') = \min(k, \lambda(G))$. Nagamochi and Ibaraki [23] presented a $O(m + n)$ time algorithm to construct a DA-msfd, of order k.

4 Incremental Exact Minimum Cut

In this section we present a deterministic incremental algorithm that exactly maintains $\lambda(G)$. The algorithm has an $\widetilde{O}(1)$ update-time, an $O(1)$ query time and it applies to any undirected, unweighted, simple graph $G = (V, E)$. The result is obtained by carefully combining a recent result of Kawarabayashi and Thorup [19] on static min-cut and the incremental exact min-cut algorithm of Henzinger [14]. We start by describing the maintenance of non-trivial cuts, that is, cuts with at least two vertices on both sides.

Maintaining non-trivial cuts

Kawarabayashi and Thorup [19] devised a near-linear time algorithm that contracts vertex sets of a simple input graph G and produces a sparse multi-graph preserving all non-trivial minimum cuts of G. In the following theorem, we state a slightly generalized version of this algorithm.

▶ **Theorem 2** (KT-Sparsifier [19]). *Given an undirected, unweighted graph G with n vertices, m edges, and min-cut λ, in $\widetilde{O}(m)$ time, we can contract vertex sets and produce a multigraph H which consists of only $m_H = \widetilde{O}(m/\lambda)$ edges and $n_H = \widetilde{O}(n/\lambda)$ vertices, and which preserves all non-trivial minimum cuts along with the non-trivial cuts of size up to $3/2\lambda$ in G.*

As far as non-trivial cuts are concerned, the above theorem implies that it is safe to abandon G and work on H as long as the sequence of newly inserted edges satisfies $\lambda_H \leq 3/2\lambda$. To incrementally maintain the correct λ_H, we apply Henzinger's algorithm [14] on top of H. The basic idea to verify the correctness of the solution is to compute and store all min-cuts. Clearly, a solution is correct as long as an edge insertion does not increase the size of all min-cuts. If all min-cuts have increased, a new solution is computed using information about the previous solution. We next show how to do this efficiently.

To store all minimum edge cuts we use the *cactus tree* representation by Dinitz, Karzanov and Lomonosov [7]. A cactus tree of a graph $G = (V, E)$ is a weighted graph $G_c = (V_c, E_c)$ defined as follows: There is a mapping $\phi : V \to V_c$ such that:

1. Every node in V maps to exactly one node in V_c and every node in V_c corresponds to a (possibly empty) subset of V.
2. $\phi(x) = \phi(y)$ iff x and y are $(\lambda(G) + 1)$-edge connected.
3. Every minimum cut in G_c corresponds to a min-cut in G, and every min-cut in G corresponds to at least one min-cut in G_c.
4. If λ is odd, every edge of E_c has weight λ and G_c is a tree. If λ is even, G_c consists of paths and simple cycles sharing at most one vertex, where edges that belong to a cycle have weight $\lambda/2$ while those not belonging to a cycle have weight λ.

Dinitz and Westbrook [8] showed that given a cactus tree, we can use the data structures from [11, 25] to maintain the cactus tree for minimum cut size λ under u insertions, reporting when the minimum cut size increases to $\lambda + 1$ in $O(u + n)$ total time.

To quickly compute and update the cactus tree representation of a given multigraph G, we use an algorithm due to Gabow [9]. The algorithm computes first a subgraph of G, called a *complete λ-intersection* or $I(G, \lambda)$, with at most λn edges, and uses $I(G, \lambda)$ to compute the cactus tree. Given some initial graph with m_0 edges, the algorithm computes $I(G, \lambda)$ and the cactus tree in $\widetilde{O}(m_0 + \lambda^2 n)$ time. Moreover, given $I(G, \lambda)$ and a sequence of edge insertions that increase the minimum cut by 1, the new $I(G, \lambda)$ and the new cactus tree can be computed in $\widetilde{O}(m')$, where m' is the number of edges in the current graph (this corresponds to one execution of Round Robin subroutine [10]).

Maintaining trivial cuts

We remark that the multigraph H from Theorem 2 preserves only non-trivial cuts of G. If $\lambda = \delta$, then we also need a way to keep track of a trivial minimum cut. We achieve this by maintaining a minimum heap $\mathcal{H}_G$ on the vertices, where each vertex is stored with its degree. If an edge insertion is performed, the values of the edge endpoints are updated accordingly in the heap. It is well known that constructing $\mathcal{H}_G$ takes $O(n)$ time. The supported operations $\textsc{Min}(\mathcal{H}_G)$ and $\textsc{UpdateEndpoints}(\mathcal{H}_G, e)$ can be implemented in $O(1)$ and $O(\log n)$ time, respectively (see [6]).

This leads to the following Algorithm 1.

Correctness

Let G be some current graph throughout the execution of the algorithm and let H be the corresponding multigraph maintained by the algorithm. Recall that H preserves some family of cuts from G. We say that H is *correct* if and only if there exists a minimum cut from G that is contained in the union of (a) all trivial cuts of G and (b) all cuts in H. Note that we consider H to be correct even in the `Special Step` (i.e., when $\lambda_H > 3/2\lambda^*$), where H is not

Algorithm 1 INCREMENTAL EXACT MINIMUM CUT

```
1: Compute the size $\lambda_0$ of the min-cut of $G$ and set $\lambda^* = \lambda_0$.
   Build a heap $\mathcal{H}_G$ on the vertices, where each vertex stores its degree as a key.
   Compute a multigraph $H$ by running KT-SPARSIFIER on $G$ and a mapping $h : V \to V_H$.
   Compute the size $\lambda_H$ of the min-cut of $H$, a DA-msfd $F_1, \ldots, F_m$ of order $m$ of $H$,
   $I(H, \lambda_H)$, and a cactus-tree of $\bigcup_{i \le \lambda_H + 1} F_i$.
2: Set $N_h = \emptyset$.
   while there is at least one minimum cut of size $\lambda_H$ do
      Receive the next operation.
      if it is a query then return $\min\{\lambda_H, \text{MIN}(\mathcal{H}_G)\}$
      else it is the insertion of an edge $(u, v)$, then
      update the cactus tree according to the insertion of the new edge $(h(u), h(v))$,
      add the edge $(h(u), h(v))$ to $N_h$ and update the degrees of $u$ and $v$ in $\mathcal{H}_G$.
      endif
   endwhile
   Set $\lambda_H = \lambda_H + 1$.
3: if $\min\{\lambda_H, \text{MIN}(\mathcal{H}_G)\} > 3/2\lambda^*$ then
      // Full Rebuild Step
      Compute $\lambda(G)$ and set $\lambda^* = \lambda(G)$.
      Compute a multigraph $H$ by running KT-SPARSIFIER on the current graph $G$.
      Update $\lambda_H$ to be the min-cut of $H$, compute a DA-msfd $F_1, \ldots, F_m$ of order $m$ of $H$,
      and then $I(H, \lambda_H)$ and a cactus tree of $\bigcup_{i \le \lambda_H + 1} F_i$.
   else if $\lambda_H \le 3/2\lambda^*$ then
         // Partial Rebuild Step
         Compute a DA-msfd $F_1, \ldots, F_m$ of order $m$ of $\bigcup_{i \le \lambda_H + 1} F_i \cup N_h$ and
         call the resulting forests $F_1, \ldots, F_m$.
         Let $H' = (V_H, E')$ be a graph with $E' = I(H, \lambda_H - 1) \cup \bigcup_{i \le \lambda_H + 1} F_i$.
         Compute $I(H', \lambda_H)$ and a cactus tree of $H'$.
      else // Special Step
         while $\text{MIN}(\mathcal{H}_G) \le 3/2\lambda^*$ do
            if the next operation is a query then return $\text{MIN}(\mathcal{H}_G)$
            else update the degrees of the edge endpoints in $\mathcal{H}_G$.
            endif
         endwhile
         Goto 3.
      endif
   endif
   Goto 2.
```

updated anymore since we are certain that the smallest trivial cut is smaller than any cut in H.

To prove the correctness of the algorithm we will show that (1) it correctly maintains a trivial min-cut at any time, (2) H is correct as long as $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} \leq 3/2\lambda^*$ (and when this condition fails we rebuild H), and (3) as long as $\lambda_H \leq 3/2\lambda^*$, the algorithm correctly maintains all cuts of size up to $\lambda_H + 1$ of H.

Let N be the set of recently inserted edges in G that the algorithm maintains during the execution of the **while** loop in Step 2. Similarly, let N_h be the corresponding edge set in H.

▶ **Lemma 3.** *Let $H = (V_H, E_H)$ be a multigraph with minimum cut λ_H and let N_h be a set with $N_h \subseteq E_H$. Further, let $F_1, \ldots, F_m$ be a DA-msfd of order $m \geq \lambda_H + 1$ of $H \setminus N_h$, and let $H' = (V_H, E')$ be a graph with $E' = N_h \cup \bigcup_{i \leq \lambda_H + 1} F_i$. Then, a cut is a min-cut in H' iff it is a min-cut in H.*

Proof. We first show that every non-min cut in H is a non-min cut in H'. By contrapositive, we get that a min-cut in H' is a min-cut in H.

To this end, let $(S, V_H \setminus S)$ be a cut with $|E_H(S, V_H \setminus S)| \geq \lambda_H + 1$ in H. Define $E_H(S, V_H \setminus S) \cap N_h = S_{N_h}$ and $E_H(S, V_H \setminus S) \cap (E_H \setminus N_h) = S_{H \setminus N_h}$ such that $E_H(S, V_H \setminus S) = S_{N_h} \uplus S_{H \setminus N_h}$ and $|E_H(S, V_H \setminus S)| = |S_{N_h}| + |S_{H \setminus N_h}|$. Letting $F' = \bigcup_{i \leq \lambda_H + 1} F_i$, we similarly define edge sets S'_{N_h} and $S'_{F'}$ partitioning the edges $E'(S, V_H \setminus S)$ that cross the cut $(S, V_H \setminus S)$ in H'. First, observe that $|S_{N_h}| = |S'_{N_h}|$ since edges of N_h are always included in H'. In addition, by second property of Definition 1, we know that F' preserves all cuts of $H \setminus N_h$ up to size $\lambda_H + 1$. Thus, if $|S_{H \setminus N_h}| \leq \lambda_H + 1$, we get that $|E'(S, V_H \setminus S)| = |E_H(S, V_H \setminus S)| \geq \lambda_H + 1$. If $|S_{H \setminus N_h}| > \lambda_H + 1$, then F' must contain at least $\lambda_H + 1$ edges crossing such cut and thus $|S'_{F'}| \geq \lambda_H + 1$. The latter implies that $|E'(S, V_H \setminus S)| \geq \lambda_H + 1$. But H' being a subgraph of H implies that $\lambda(H') \leq \lambda_H$, thus $(S, V_H \setminus S)$ cannot be a min-cut in H'.

For other direction, let $(S, V_H \setminus S)$ be a min-cut in H. Since H' is a subgraph of H, we know that $|E'(S, V_H \setminus S)| \leq \lambda_H$. Therefore, showing that $|E'(S, V_H \setminus S)| \geq \lambda_H$ implies that $(S, V_H \setminus S)$ is also a min cut in H'. Fix x, y and consider a min-cut $(D, V_H \setminus D)$ of size $\lambda(H', x, y)$ separating x and y. Using the above notation and considering the cut $(D, V_H \setminus D)$ in H, we know that $|E_H(D, V_H \setminus D)| = |D_{N_h}| + |D_{H \setminus N_h}| \geq \lambda_H$. We first note that $|D_{N_h}| = |D'_{N_h}|$ since edges of N_h are always included in H'. Then, similarly as above, by second property of Definition 1 we know that if $|D_{H \setminus N_h}| \leq \lambda_H + 1$, then $|E'(D, V_H \setminus D)| = |E_H(D, V_H \setminus D)| \geq \lambda_H$. If $|D_{H \setminus N_H}| > \lambda_H + 1$, then F' must contain at least $\lambda_H + 1$ edges crossing such cut and thus $|E'(D, V_H \setminus D)| \geq \lambda_H + 1$. Combining both bounds we obtain that $\lambda(H', x, y) = |E'(D, V_H \setminus D)| \geq \lambda_H$. Since the later is valid for any x and y, we get that $\lambda(H') \geq \lambda_H$ must hold and in particular, $|E'(S, V_H \setminus S)| \geq \lambda_H$. ◀

▶ **Lemma 4.** *The algorithm correctly maintains a trivial min-cut in G.*

Proof. This follows directly from the min-heap property of $\mathcal{H}_G$. ◀

To simplify our notation, in the following we will refer to Step 1 as a `Full Rebuild Step` (namely the initial `Full Rebuild Step`).

▶ **Lemma 5.** *For some current graph G, let H be the multigraph obtained from G and assume that $\lambda_H \leq 3/2\lambda^*$, where λ^* denotes the value of min-cut at the last* `Full Rebuild Step`. *Then the algorithm correctly maintains $\lambda_H = \lambda(H)$.*

Proof. At the time of the last `Full Rebuild Step`, the algorithm applies KT-sparsifier on G, which yields a multigraph H that preserves all non-trivial min-cuts of G. The value of

λ_H is updated to $\lambda(H)$ and a DA-msfd and a cactus tree are constructed for H. The latter preserve all cuts of H of size up to $\lambda_H + 1$. Thus, the value of λ_H is correct at this step.

Now, suppose that the graph after the last `Full Rebuild Step` has undergone a sequence of edge insertions, which resulted in the current graph G. During these insertions, as long as $\lambda_H \leq 3/2\lambda^*$, a sequence of k `Partial Rebuild Steps` is executed, for some $k \geq 1$. Let $\lambda_H^{(i)}$ be the value of λ_H after the i-th execution of `Partial Rebuild Step`, where $1 \leq i \leq k$. Since, $\lambda_H^{(k)} = \lambda(H)$, it suffices to show that $\lambda_H^{(k)}$ is correct. We proceed by induction.

For the base case, we show that $\lambda_H^{(1)}$ is correct. First, using the fact that λ_H and the cactus tree are correct at the last `Full Rebuild Step` and that the incremental cactus tree algorithm correctly tell us when to increment λ_H, we conclude that incrementing the value of λ_H in Step 2 is valid. Thus, $\lambda_H^{(1)}$ is correct. Next, in a `Partial Rebuild Step`, the algorithm sparsifies the graph while preserving all cuts of size up to $\lambda_H^{(1)} + 1$ and producing a new cactus tree for the next insertions. The correctness of the sparsification follows from Lemma 3.

For the induction step, let us assume that $\lambda_H^{(k-1)}$ is correct. Then, similarly to the base case, the correctness of $\lambda_H^{(k-1)}$, the cactus tree from the $(k-1)$-th `Partial Rebuild Step` and the correctness of the incremental cactus tree algorithm give that incrementing the value of $\lambda_H^{(k-1)}$ in Step 2 is valid and yields a correct $\lambda_H^{(k)}$. ◀

Note that when $\lambda_H > 3/2\lambda^*$, the above lemma is not guaranteed to hold. However, we will show below that this is not necessary for the correctness of the algorithm. The fact that we do not need to update the cactus tree in this setting is crucial for achieving our time bound.

▶ **Lemma 6.** *If* $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} \leq 3/2\lambda^*$*, then H is correct.*

Proof. Let C' be any non-trivial cut in G that is not in H. Such a cut must have cardinality strictly greater than $3/2\lambda^*$ since otherwise it would be contained in H. We show that C' cannot be a minimum cut as long as $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} \leq 3/2\lambda^*$ holds. We distinguish two cases.

1. If $\lambda_H \leq 3/2\lambda^*$, then by Lemma 5 the algorithm maintains λ_H correctly. Since H is obtained from G by contracting vertex sets, there is a cut C in H, and thus in G, of value λ_H. It follows that C' cannot be a minimum cut of G since $|C'| > 3/2\lambda^* \geq \lambda_H = \lambda(H) \geq \lambda(G)$, where the last inequality follows from the fact that H is a contraction of G.
2. If $\textsc{Min}(\mathcal{H}_G) \leq 3/2\lambda^*$, then by Lemma 4 there is a cut of size $\textsc{Min}(\mathcal{H}_G) = \delta$ in G. Similarly, C' cannot be a minimum cut of G since $|C'| > 3/2\lambda^* \geq \delta \geq \lambda(G)$.

Appealing to the above cases, we conclude H is correct since a min-cut of G is either contained in H or it is a trivial cut of G. ◀

▶ **Lemma 7.** *The algorithm correctly maintains $\lambda(G)$, i.e., $\lambda(G) = \min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\}$.*

Proof. Let G be some current graph. If $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} \leq 3/2\lambda^*$, then by Lemma 6, H is correct. Thus, if $\lambda_H \leq 3/2\lambda^*$, then Lemma 5 ensures that λ_H is also maintained correctly and, hence, $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} = \lambda(G)$. If, however, $\lambda_H > 3/2\lambda^*$ but $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} \leq 3/2\lambda^*$, then $\lambda_H > \min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\}$ which implies that $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} = \textsc{Min}(\mathcal{H}_G)$. As the algorithm correctly maintains $\textsc{Min}(\mathcal{H}_G)$ at any time by Lemma 4, it follows that the algorithm maintains λ correctly in this case as well.

The only case that remains to consider is $\textsc{Min}(\mathcal{H}_G) > 3/2\lambda^*$ and $\lambda_H > 3/2\lambda^*$. But this implies that $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} > 3/2\lambda^*$, and the algorithm computes a H and $\lambda(G)$ from scratch and sets λ_H correctly. After this full rebuild $\lambda(G) = \min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\}$ trivially holds. ◀

Running Time Analysis

▶ **Theorem 8.** *Let G be a simple graph with n nodes and m_0 edges. Then the total time for inserting m_1 edges and maintaining a minimum edge cut of G is $\widetilde{O}(m_0 + m_1)$. If we start with an empty graph, the amortized time per edge insertion is $\widetilde{O}(1)$. The size of the minimum cut can be answered in constant time.*

Proof. We first analyse Step 1. Building the heap $\mathcal{H}_G$ and computing λ_0 take $O(n)$ and $\widetilde{O}(m_0)$ time, respectively. The total running time for constructing H, $I(H, \lambda_H)$ and the cactus tree is dominated by $\widetilde{O}(m_0 + \lambda_0^2 \cdot (n/\lambda_0)) = \widetilde{O}(m_0)$. Thus, the total time for Step 1 is $\widetilde{O}(m_0)$.

Let $\lambda_H^0, \ldots, \lambda_H^f$ be the values that λ_H assumes in Step 2 during the execution of the algorithm in increasing order. We define Phase i to be all steps executed after Step 1 while $\lambda_H = \lambda_H^i$, excluding Full Rebuild Steps and Special Steps. Additionally, let $\lambda_0^*, \ldots, \lambda_{O(\log n)}^*$ be the values that λ^* assumes during the algorithm. We define *Superphase* j to consist of the j-th `Full Rebuild Step` along with all steps executed while $\min\{\textsc{Min}(\mathcal{H}_G), \lambda_H\} \leq 3/2\lambda_j^*$, where λ_j^* is the value of $\lambda(G)$ at the `Full Rebuild Step`. Note that a superphase consists of a sequence of phases and potentially a final `Special Step`. Moreover, the algorithm runs a phase if $\lambda_H \leq 3/2\lambda^*$.

We say that λ_H^i *belongs* to superphase j, if the i-th phase is executed during superphase j and $\lambda_H^i \leq 3/2\lambda_j^*$. We remark that the number of vertices in H changes only at the beginning of a superphase, and remains unchanged during its lifespan.

Let n_j denote the number of vertices in some superphase j. We bound this quantity as follows:

▶ **Fact 9.** *Let j be a superphase during the execution of the algorithm. Then, we have*

$$n_j = \widetilde{O}(n/\lambda_H^i), \text{ for all } \lambda_H^i \text{ belonging to superphase } j.$$

Proof. From Step 3 we know that $n_j = \widetilde{O}(n/\lambda_j^*)$. Moreover, observe that $\lambda_j^* \leq \lambda_H^i$ and a phase is executed whenever $\lambda_H^i \leq 3/2\lambda_j^*$. Thus, for all λ_H^i's belonging to superphase j, we get the following relation

$$\lambda_j^* \leq \lambda_H^i \leq 3/2\lambda_j^*, \tag{1}$$

which in turn implies that $n_j = \widetilde{O}(n/\lambda_j^*) = \widetilde{O}(n/\lambda_H^i)$. ◀

For the remaining steps, we divide the running time analysis into two parts (one part corresponding to phases, and the other to superphases).

Part 1

For some superphase j, the i-th phase consists of the i-th execution of a `Partial Rebuild Step` followed by the execution of Step 2. Let u_i be the number of edge insertions in Phase i. The total time for Step 2 is $O(n_j + u_i \log n) = \widetilde{O}(n + u_i)$. Using Fact 9, we observe that $\bigcup_{i \leq \lambda_H + 1} F_i \cup N_h$ has size $O(u_{i-1} + \lambda_H^i n_j) = \widetilde{O}(u_{i-1} + n)$. Thus, the total time for computing DA-msfd in a `Partial Rebuild Step` is $\widetilde{O}(u_{i-1} + n)$. Similarly, since H' has $O(\lambda_H^i n_j) = \widetilde{O}(n)$ edges, it takes $\widetilde{O}(n)$ time to compute $I(H', \lambda_H^i)$ and the new cactus tree.

The total time spent in Phase i is $\widetilde{O}(u_{i-1} + u_i + n)$. Let λ and λ_H denote the size of the minimum cut in the final graph and its corresponding multigraph, respectively. Note that

$\sum_{i=1}^{\lambda} u_i \leq m_1$, $\lambda n \leq m_0 + m_1$ and recall Eqn. (1). This gives that the total work over all phases is

$$\sum_{i=1}^{\lambda_H} \widetilde{O}\left(u_{i-1} + u_i + n\right) = \sum_{i=1}^{\lambda} \widetilde{O}\left(u_{i-1} + u_i + n\right) = \widetilde{O}(m_0 + m_1).$$

Part 2

The j-th superphase consists of the j-th execution of a `Full Rebuild Step` along with a possible execution of a `Special Step`, depending on whether the condition is met. In a `Full Rebuild Step`, the total running time for constructing H, $I(H, \lambda_j^*)$ and the cactus tree is dominated by $\widetilde{O}(m_0 + m_1 + (\lambda_j^*)^2 \cdot (n/\lambda_j^*)) = \widetilde{O}(m_0 + m_1)$. The running time of a Special Step is $\widetilde{O}(m_1)$.

Throughout its execution, the algorithm begins a new superphase whenever $\lambda(G) = \min \{\textsc{Min}(\mathcal{H}_G), \lambda_H\} > 3/2\lambda^*$. This implies that $\lambda(G)$ must be at least $3/2\lambda^*$, where λ^* is the value of $\lambda(G)$ at the last `Full Rebuild Step`. Thus, a new superphase begins whenever $\lambda(G)$ has increased by a factor of $3/2$, i.e., only $O(\log n)$ times over all insertions. This gives that the total time over all superphases is $\widetilde{O}(m_0 + m_1)$. ◀

5 Incremental $(1 + \varepsilon)$ Minimum Cut with $\widetilde{O}(n)$ space

In this section we present two $\widetilde{O}(n)$ space incremental Monte-Carlo algorithms that w.h.p maintain the size of a min-cut up to a $(1+\varepsilon)$-factor. Both algorithms have $\widetilde{O}(1)$ update-time and $\widetilde{O}(1)$, resp. $O(1)$ query-time.

5.1 An $O(n \log^2 n/\varepsilon^2)$ space algorithm

Our first algorithm follows an approach that was used in several previous works [14, 28, 27], where the space requirement is not considered. The basic idea is to maintain the min-cut up to some size k using small space. We achieve this by maintaining a sparse k-certificate and incorporating it into the incremental exact min-cut algorithm due to Henzinger [14], as described in Section 4. Finally we apply the well-known randomized sparsification result due to Karger [17] to obtain our result.

Maintaining min-cut up to size k using $O(kn)$ space

We incrementally maintain a DA-msfd for an unweighted multigraph G using k union-find data structures $\mathcal{F}_1, \ldots, \mathcal{F}_k$ (see [6]). Each $\mathcal{F}_i$ maintains a spanning forest F_i of G. Recall that $F_1, \ldots, F_k$ are edge-disjoint. When a new edge $e = (u, v)$ is inserted into G, we define i to be the first index such that $\mathcal{F}_i.\textsc{Find}(u) \neq \mathcal{F}_i.\textsc{Find}(v)$. If we found such an i, we append the edge e to the forest F_i by setting $\mathcal{F}_i.\textsc{Union}(u, v)$ and return i. If such an i cannot be found after k steps, we simply discard edge e and return NULL. We refer to such procedure as k-$\textsc{Connectivity}(e)$.

It is easy to see that the forests maintained by k-$\textsc{Connectivity}(e)$ for every newly inserted edge e are indeed edge-disjoint. Combining this procedure with techniques from Henzinger [14] leads to the following Algorithm 2.

The space requirement of the above algorithm is only $O(kn)$, since we always maintain at most k spanning forests during its execution. The total running time for testing the k-connectivity of the endpoints of the newly inserted edges in Step 2 is $O(km\alpha(n))$, where

Algorithm 2 Incremental Exact Min-Cut up to size k

```
1: Set $\lambda = 0$, initialize $k$ union-find data structures $\mathcal{F}_1, \ldots, \mathcal{F}_k$,
   $k$ empty forests $F_1, \ldots, F_k$, $I(\lambda)$, and an empty cactus tree.
2: while there is at least one minimum cut of size $\lambda$ do
       Receive the next operation.
       if it is a query then return $\lambda$
       else it is the insertion of an edge $e$, then
       Set $i = k$-Connectivity$(e)$.
           if $i \neq$ NULL then
             Set $F_i = F_i \cup \{e\}$.
             Update the cactus tree according to the insertion of the edge $e$.
           endif
       endif
   endwhile
3: Set $\lambda = \lambda + 1$.
   Let $G' = (V, E')$ be a graph with $E' = I(\lambda - 1) \cup \bigcup_{i \leq \lambda+1} F_i$.
   Compute $I(\lambda)$ and a cactus tree of $G'$.
   Goto 2.
```

$\alpha(n)$ stands for the inverse of Ackermann function. These guarantees combined with the arguments from Theorem 8 of Henzinger [14] give the following corollary.

▶ **Corollary 10.** *For $k > 0$, there is an $O(kn)$ space algorithm that processes a stream of edge insertions starting from any empty graph G and maintains an exact value of* $\min\{\lambda(G), k\}$. *The total time for inserting m edges is $O(km\alpha(n)\log n)$ and queries can be answered in constant time.*

Dealing with min-cuts of arbitrary size

We observe that Corollary 10 gives polylogarithmic amortized update time only for min-cuts up to some polylogarithmic size. For dealing with min-cuts of arbitrary size, we use the well-known sampling technique due to Karger [17]. This allows us to get an $(1+\varepsilon)$-approximation to the value of min-cut with high probability.

▶ **Lemma 11** ([17]). *Let G be any graph with minimum cut λ and let $p \geq 10(\log n)/(\varepsilon^2\lambda)$. Let $S(p)$ be a subgraph of G obtained by including each of edge of G to $S(p)$ with probability p independently. Then the probability that the value of any cut of $S(p)$ has value more than $(1+\varepsilon)$ or less than $(1-\varepsilon)$ times its expected value is $O(1/n^3)$.*

For some integer $i \geq 1$, let G_i denote a subgraph of G obtained by including each edge of G to G_i with probability $1/2^i$ independently. We now have all necessary tools to present our incremental algorithm:

1. For $i = 0, \ldots, \lfloor \log n \rfloor$, let G_i be the initially empty sampled subgraphs.
2. If an edge e is inserted into G, include e to each G_i with probability $1/2^i$ and maintain the exact minimum cut of G_i up to size $k = 40\log n/\varepsilon^2$ using Algorithm 2.
3. If the operation is a query, find the minimum j such that the min-cut of G_j is at most k. Return $2^j\lambda(G_j)$.

▶ **Theorem 12.** *There is an $O(n \log^2 n/\varepsilon^2)$ space randomized algorithm that processes a stream of edge insertions starting from an empty graph G and maintains a $(1+\varepsilon)$-approximation to the min-cut of G with high probability. The amortized update time per operation is $O(\alpha(n)\log^3 n/\varepsilon^2)$ and queries can be answered in $O(\log n)$ time.*

Proof. We first prove the correctness of the algorithm. For an integer $t \geq 0$, let $G^{(t)} = (V, E^{(t)})$ be the graph after the first t edge insertions. Further, let $\lambda(G^{(t)})$ denote the min-cut of $G^{(t)}$ and $p^{(t)} = 10(\log n)/(\varepsilon^2\lambda^{(t)})$. For any integer $i \leq \lfloor \log_2 1/p^{(t)} \rfloor$, Lemma 11 implies that $2^i\lambda(G_i^{(t)})$ is an $(1 \pm \varepsilon)$-approximation to $\lambda(G^{(t)})$. Setting $i = \lfloor \log_2 1/p^{(t)} \rfloor$, we get that:

$$\mathbb{E}[\lambda(G_i^{(t)})] \leq \lambda(G^{(t)})/2^i \leq 2p^{(t)}\lambda(G^{(t)}) \leq 20\log n/\varepsilon^2.$$

The later along with Lemma 11 imply that for any $\varepsilon \in (0,1)$, the size of the minimum cut in $G_i^{(t)}$ is at most $(1+\varepsilon)20\log n/\varepsilon^2 \leq 40\log n/\varepsilon^2$ with probability $1 - O(1/n^3)$. Thus, $j \leq \lfloor \log_2 1/p^{(t)} \rfloor$ and the algorithm returns a $(1 \pm \varepsilon)$-approximation to the minimum cut of $G^{(t)}$ with probability $1 - O(1/n^3)$. Note that for any t, $\lfloor \log_2 1/p^{(t)} \rfloor \leq \lfloor \log n \rfloor$, and thus it is sufficient to maintain only $O(\log n)$ sampled subgraphs.

Since our algorithm applies to unweighted simple graphs, we know that $t \leq O(n^2)$. Now applying union bound over all $t \in \{1, \ldots O(n^2)\}$ gives that the probability that the algorithm does not maintain a $(1 \pm \varepsilon) \leq 1 + O(\varepsilon)$-approximation is at most $O(1/n)$.

The total expected time for maintaining a sampled subgraph is $O(m\alpha(n)\log^2 n/\varepsilon^2)$ and the required space is $O(n \log n/\varepsilon^2)$ (Corollary 10). Maintaining $O(\log n)$ such subgraphs gives an $O(\alpha(n)\log^3 n/\varepsilon^2)$ amortized time per edge insertion and an $O(n\log^2 n/\varepsilon^2)$ space requirement. The $O(\log n)$ query time follows as in the worst case we scan at most $O(\log n)$ subgraphs, each answering a min-cut query in constant time. ◀

5.2 Improving the space to $O(n \log n/\varepsilon^2)$

We next show how to bring down the space requirement of the previous algorithm to $O(n\log n/\varepsilon^2)$ without degrading its running time. The main idea is to keep a single sampled subgraph instead of $O(\log n)$ of them.

Let $G = (V, E)$ be an unweighted undirected graph and assume each edge is given some random weight p_e chosen uniformly from $[0,1]$. We call the resulting weighted graph G^w. For any $p > 0$, we denote by $G(p)$ the unweighted subgraph of G that consists of all edges that have weight at most p. We state the following lemma due to Karger [15]:

▶ **Lemma 13.** *Let $k = 40\log n/\varepsilon^2$. Given a connected graph G, let p be a value such that $p \geq k/(4\lambda(G))$. Then with high probability, $\lambda(G(p)) \leq k$ and $\lambda(G(p))/p$ is an $(1+\varepsilon)$-approximation to the min-cut of G.*

Proof. Since the weight of every edge is uniformly distributed, the probability that an edge has weight at most p is exactly p. Thus, $G(p)$ can be viewed as taking G and including each edge with probability p. The claim follows from Lemma 11. ◀

For any graph G and some appropriate weight p, the above lemma tells us that the min-cut of $G(p)$ is bounded by k with high probability. Thus, instead of considering the graph G along with its random edge weights, we build a collection of k minimum edge-disjoint spanning forests (using those edge weights). We note that such a collection is a DA-msfd of order k for G with $O(kn)$ edges and by Lemma 3, it preserves all minimum cuts of G up to size k.

Our algorithm uses the following two data structures:

(1) NI-Sparsifier(k) data-structure: Given a graph G, where each edge e is assigned some weight p_e and some parameter k, we maintain an insertion-only data-structure that maintains a collection of k minimum edge-disjoint spanning forests $S_1, \dots, S_k$ with respect to the edge weights. Let $S = \bigcup_{i=1}^{k} S_i$. Since we are in the incremental setting, it is known that the problem of maintaining a single minimum spanning forest can be solved in time $O(\log n)$ per insertion using the dynamic tree structure of Sleator and Tarjan [26]. Specifically, we use this data-structure to determine for each pair of nodes (u, v) the maximum weight of an edge in the cycle that the edge (u, v) induces in the minimum spanning forest S_i. Let max-weight$(S_i(u, v))$ denote such a maximum weight. The update operation works as follows: when a new edge $e = (u, v)$ is inserted into G, we first use the dynamic tree data structure to test whether u and v belong to the same tree. If no, we link their two trees with the edge (u, v) and return the pair (TRUE, NULL) to indicate that e was added to S_i and no edge was evicted from S_i. Otherwise, we check whether $p_e >$ max-weight$(S_i(e))$. If the latter holds, we make no changes in the forest and return (FALSE, e). Otherwise, we replace one of the maximum edges, say e', on the path between u and v in the tree by e and return (TRUE, e'). The boolean value that is returned indicates whether e belongs to S_i or not, the second value that is returned gives an edge that does not (or no longer) belong to S_i. Note that each edge insertion requires $O(\log n)$ time. We refer to this insert operation as INSERT-MSF(S_i, e, p_e).

Now, the algorithm that maintains the weighted minimum spanning forests implements the following operations:

- INITIALIZE-NI(k): initializes the data structure for k empty minimum spanning forests.
- INSERT-NI(e, p_e): Set $i = 1$, $e' = e$, taken = FALSE.

```
while (($i \le k$) and $e' \neq$ NULL) do
    Set ($t'$, $e''$) = INSERT-MSF($S_i, e', p_{e'}$).
    if ($e' = e$) then set taken = $t'$ endif
    Set $e' = e''$ and $i = i + 1$.
endwhile
if ($e' \neq e$) then return (taken, $e'$) else return (taken, NULL).
```

Recall that $S = \bigcup_{i \le k} S_i$. We use the abbreviation NI-SPARSIFIER(k) to refer to this data-structure. By slight abuse of notation we will associate a weight with each edge in S and use S^w to refer to this weighted version of S.

▶ **Lemma 14.** *For $k > 0$ and any graph G,* NI-SPARSIFIER(k) *maintains a weighted* DA-msfd of order k of G under edge insertions. The algorithm uses $O(kn)$ space and the total time for inserting m edges is $O(km \log n)$.

(2) Limited Exact Min-Cut(k) data-structure: We use Algorithm 2 to implement the following operations for any unweighted graph G and parameter k,

- INSERT-LIMITED(e): executes the insertion of edge e into Algorithm 2.
- QUERY-LIMITED(): returns λ
- INITIALIZE-LIMITED(G, k): builds a data structure for G with parameter k by calling INSERT-LIMITED(e) for each edge e in G.

We use the abbreviation LIM(k) to refer to such data-structure.

Combining the above data-structures leads to the following algorithm:

Correctness and Running Time Analysis

Let S denote the unweighted version of S^w. Throughout the execution of Algorithm 3, S corresponds exactly to the DA-msfd of order k of G maintained by NI-SPARSIFIER(k). In

Algorithm 3 $(1+\varepsilon)$-Min-Cut with $O(n \log n/\varepsilon^2)$ Space

```
1: Set $k = 40 \log n/\varepsilon^2$.
   Set $p = 10 \log n/\varepsilon^2$.
   Let $H$ and $S^w$ be empty graphs.
2: Initialize-Limited$(H, k)$.
   while Query-Limited() $< k$ do
       Receive the next operation.
       if it is a query then return Query-Limited()$/\min\{1, p\}$.
       else it is the insertion of an edge $e$, then
       Sample a random weight from $[0, 1]$ for the edge $e$ and denote it by $p_e$.
       if $p_e \leq p$ then Insert-Limited$(e)$ endif
       Set (taken, $e'$) = Insert-NI$(e, p_e)$.
           if taken then
             Insert $e$ into $S^w$ with weight $p_e$.
             if ($e' \neq$ NULL) then remove $e'$ from $S^w$.
           endif
       endif
   endwhile
3: // Rebuild Step
   Set $p = p/2$.
   Let $H$ be the unweighted subgraph of $S^w$ consisting of all edges of weight at most $p$.
   Goto 2.
```

the following, let H be the graph that is given as input to Lim(k). Thus, by Corollary 10, Query-Limited() returns $\min\{k, \lambda(H)\}$, i.e., it returns $\lambda(H)$ as long as $\lambda(H) \leq k$. We now formally prove the correctness.

▶ **Lemma 15.** *Let $\epsilon \leq 1$. If $\lambda(G) < k$, then $H = G$, $p = k/4$, and* Query-Limited() *returns $\lambda(G)$. The first rebuild step is triggered after the first insertion that increases $\lambda(G)$ to k and let $\lambda(G) = \lambda(H) = k$ at that time.*

Proof. The algorithm starts with an empty graph G, i.e., initially $\lambda(G) = 0$. Throughout the sequence of edge insertions $\lambda(G)$ never decreases. We show by induction on the number m of edge insertions that $H = G$ and $p = k/4$ as long as $\lambda(G) < k$.

Note that $k/4 \geq 1$ by our choice of ϵ. For $m = 0$, the graphs G and H are both empty graphs and p is set to $k/4$. For $m > 0$, consider the m-th edge insertion, which inserts an edge e. Let G and H denote the corresponding graphs after the insertion of e. By the inductive assumption, $p = k/4$ and $G \setminus \{e\} = H \setminus \{e\}$. As $p \geq 1$, e is added to H and, thus, it follows that $G = H$. Hence, $\lambda(H) = \lambda(G)$. If $\lambda(G) < k$, no rebuild is performed and p is not changed. If $\lambda(G) = k$, then the last insertion was exactly the insertion that increased $\lambda(G)$ from $k - 1$ to k. As $H = G$ before the rebuild, Query-Limited() returns k, triggering the first execution of the rebuild step. ◀

We next analyze the case that $\lambda(G) \geq k$. In this case, both H and p are random variables, as they depend on the randomly chosen weights for the edges. Let $S(p)$ be the unweighted subgraph of S^w that contains all edge of weight at most p.

▶ **Lemma 16.** *Let $N_h(p)$ be the graph consisting of all edges that were inserted after the last rebuild and have weight at most p and let $S^{old}(p)$ be $S(p)$ right after the last rebuild. Then the graph $H = S^{old}(p) \cup N_h(p)$.*

▶ **Lemma 17.** *At the time of a rebuild $S(p)$ is a DA-msfd of order k of $G(p)$.*

By Lemma 13, in order to show that $\lambda(H)/\min\{1,p\}$ is an $(1+\varepsilon)$-approximation of $\lambda(G)$ with high probability, we need to show that if $\lambda(G) \geq k$ then (a) the random variable p is at least $k/(4\lambda(G))$ w.h.p., which implies that $\lambda(G(p))$ is a $(1+\varepsilon)$-approximation of $\lambda(G)$ w.h.p. , and (b) that $\lambda(H) = \lambda(G(p))$.

▶ **Lemma 18.** *Let $\varepsilon \leq 1$. If $\lambda(G) \geq k$, then (1) $p \geq k/(4\lambda(G))$ w.h.p. and (2) $\lambda(H) = \lambda(G(p))$.*

Proof. For any $i \geq 0$, after the i-th rebuild we have $p = p^{(i)} := 10 \log n/(2^i\varepsilon^2)$. We will show by induction on i that (1) $p^{(i)} = 10 \log n/(2^i\varepsilon^2) \geq 10 \log n/(\varepsilon^2\lambda(G))$ with high probability, which is equivalent to showing that $\lambda(G) \geq 2^i$ and that (2) at any point between the $i-1$-st and the i-th rebuild, $\lambda(H) = \lambda(G(p^{(i-1)}))$.

We first analyse $i = 1$. Assume that the insertion of edge e caused the first rebuild. Lemma 15 showed that (1) at the first rebuild $\lambda(G) = k \geq 2^1 = 2$ and (2) that up to the first rebuild $G(p) = G = H$.

For the induction step ($i > 1$), we inductively assume that (1) at the $(i-1)$-st rebuild, $p^{(i-1)} \geq 10 \log n/\varepsilon^2\lambda(G^{\text{old}})$ with high probability, where G^{old} is the graph G right before the insertion that triggered the i-th rebuild (i.e., at the last point in time when Query-Limited() returned a value less than k), and (2) that $\lambda(H) = \lambda(G(p^{(i-2)}))$ at any time between the $(i-2)$-nd and the $(i-1)$-st rebuild. Let e be the edge whose insertion caused the i-th rebuild. Define $G^{\text{new}} = G^{\text{old}} \cup \{e\}$. Note that w.h.p. $p^{(i-1)} \geq 10 \log n/(\varepsilon^2\lambda(G^{\text{old}})) \geq 10 \log n/(\varepsilon^2\lambda(G^{\text{new}}))$ as $\lambda(G^{\text{old}}) \leq \lambda(G^{\text{new}})$. Thus, by Lemma 13, we get that $\lambda(G^{\text{new}}(p^{(i-1)}))/p^{(i-1)} \leq (1+\varepsilon)\lambda(G^{\text{new}})$ with high probability.

We show below that $\lambda(G^{\text{new}}(p^{(i-1)})) = \lambda(H^{\text{new}})$, where H^{new} is the graph stored in Lim(k) right before the i-th rebuild. Thus, $\lambda(H^{\text{new}}) = k$, which implies that

$$\begin{aligned}\lambda(G^{\text{new}}(p^{(i-1)})) = k = 40 \log n/\varepsilon^2 &\leq (1+\varepsilon)\lambda(G^{\text{new}}) \cdot p^{(i-1)} \\ &= (1+\varepsilon)\lambda(G^{\text{new}}) \cdot 10 \log n/(2^{i-1}\varepsilon^2),\end{aligned}$$

w.h.p.. This in turn implies that $\lambda(G^{\text{new}}) \geq 2^{i+1}/(1+\varepsilon) \geq 2^i$ w.h.p. by our choice of ε.

It remains to show that $\lambda(G^{\text{new}}(p^{(i-1)})) = \lambda(H^{\text{new}})$. Note that this is a special case of (2), which claims that at any point between that $(i-1)$-st and the i-th rebuild $\lambda(H) = \lambda(G(p^{(i-1)}))$, where H and G are the current graphs. Thus, to complete the proof of the lemma it suffices to show (2).

As H is a subgraph of $G(p^{(i-1)})$, we know that $\lambda(G(p^{(i-1)})) \geq \lambda(H)$. Thus, we only need to show that $\lambda(G(p^{(i-1)})) \leq \lambda(H)$. Let G^{i-1}, resp. S^{i-1}, resp. H^{i-1}, be the graph G, resp. S, resp. H, right after rebuild $i-1$ and let N_h be the set of edges inserted since, i.e., $G = G^{(i-1)} \cup N_h$. As we showed in Lemma 16, $H = S^{i-1}(p^{(i-1)}) \cup N_h(p^{(i-1)})$. Thus, $H^{i-1} = S^{i-1}(p^{(i-1)})$. Additionally, by Lemma 17, $S^{i-1}(p^{(i-1)})$ is a DA-msfd of order k of $G^{i-1}(p^{(i-1)})$. Thus by Property (3) of a DA-msfd of order k, for every cut $(A, V \setminus A)$ of value at most k in H^{i-1}, $\lambda(H^{i-1}, A) = \lambda(S^{i-1}(p^{(i-1)}), A) = \lambda(G^{i-1}(p^{(i-1)}), A)$, where $\lambda(G, A)$ denotes the number of edges crossing from A to $V \setminus A$ in G. Now assume by contradiction that $\lambda(G(p^{(i-1)})) > \lambda(H)$ and consider a minimum cut $(A, V \setminus A)$ in H, i.e., $\lambda(H) = \lambda(H, A)$. We know that at any time $k \geq \lambda(H)$. Thus $k \geq \lambda(H) = \lambda(H, A)$, which implies $k \geq \lambda(H^{i-1}, A)$. By Property (3) of DA-msfd it follows that $\lambda(H^{i-1}, A) = \lambda(G^{i-1}(p^{(i-1)}), A)$. Note that $H = H^{i-1} \cup N_h(p^{(i-1)})$ and $G(p^{(i-1)}) = G^{i-1}(p^{(i-1)}) \cup E_H(p^{(i-1)})$. Let x be the number of edges of $N_h(p^{(i-1)})$ that cross the cut $(A, V \setminus A)$. Then $\lambda(H) = \lambda(H, A) = \lambda(H^{i-1}, A) + x = \lambda(G^{i-1}(p^{(i-1)}), A) + x = \lambda(G(p^{(i-1)}), A)$, which contradicts the assumption that $\lambda(G(p^{(i-1)})) > \lambda(H)$. ◀

Since our algorithm is incremental and applies only to unweighted graphs, we know that there can be at most $O(n^2)$ edge insertions. Thus, by the above lemma and an union bound over these $O(n^2)$ different graphs, we get that throughout its execution, our algorithm maintains a $(1+\varepsilon)$-approximation to the min cut with high probability.

▶ **Theorem 19.** *There is an $O(n \log n/\varepsilon^2)$ space randomized algorithm that processes a stream of edge insertions starting from an empty graph G and maintains a $(1+\varepsilon)$-approximation to the min-cut of G with high probability. The total time for insertiong m edges is $O(m\alpha(n) \log^3 n/\varepsilon^2)$ and queries can be answered in constant time.*

Proof. The space requirement is $O(n \log n/\varepsilon^2)$ since at any point of time, the algorithm keeps H, S^w, Lim(k), and NI-Sparsifier (k), each of size at most $O(n \log n/\varepsilon^2)$ (Corollary 10 and Lemma 14).

When Algorithm 3 executes a `Rebuild Step`, only the Lim(k) data-structure is rebuilt, but not NI-Sparsifier(k). During the whole algorithm m Insert-NI operations are performed. Thus, by Lemma 14, the total time for all operations involving NI-Sparsifier(k) is $O(m \log^2 n/\varepsilon^2)$.

It remains to analyze Steps 2 and 3. In Step 2, Initialize-Limited(H, k) takes at most $O(m\alpha(n) \log^2 n/\varepsilon^2)$ total time (Corollary 10). The running time of Step 3 is $O(m)$ as well. Since the number of `Rebuild Steps` is at most $O(\log n)$, it follows that the total time for all Initialize-Limited(H, k) calls in Steps 2 and the total time of Step 3 throughout the execution of the algorithm is $O(m\alpha(n) \log^3 n/\varepsilon^2)$.

We are left with analyzing the remaining part of Step 2. Each query operation executes one Query-Limited() operation, which takes constant time. Each insertion executes one Insert-NI(e, p_e) operation, which takes amortized time $O(\log^2 n/\varepsilon)$. We maintain the edges of S^w in a binary tree so that each insertion and deletion takes $O(\log n)$ time. As there are m edge insertions the remaining part of Step 2 takes total time $O(m \log^2 n/\varepsilon^2)$. Combining the above bounds gives the theorem. ◀

Abstract

In this paper, we design the first polynomial time approximation schemes for the Set Cover and Dominating Set problems when the underlying sets are non-piercing regions (which include pseudodisks). We show that the local search algorithm that yields PTASs when the regions are disks [5, 19, 28] can be extended to work for non-piercing regions. While such an extension is intuitive and natural, attempts to settle this question have failed even for pseudodisks. The techniques used for analysis when the regions are disks rely heavily on the underlying geometry, and do not extend to topologically defined settings such as pseudodisks. In order to prove our results, we introduce novel techniques that we believe will find applications in other problems.

We then consider the Capacitated Region Packing problem. Here, the input consists of a set of points with capacities, and a set of regions. The objective is to pick a maximum cardinality subset of regions so that no point is covered by more regions than its capacity. We show that this problem admits a PTAS when the regions are k-admissible regions (pseudodisks are 2-admissible), and the capacities are bounded. Our result settles a conjecture of Har-Peled (see Conclusion of [20]) in the affirmative. The conjecture was for a weaker version of the problem, namely when the regions are pseudodisks, the capacities are uniform, and the point set consists of all points in the plane.

Finally, we consider the Capacitated Point Packing problem. In this setting, the regions have capacities, and our objective is to find a maximum cardinality subset of points such that no region has more points than its capacity. We show that this problem admits a PTAS when the capacity is unity, extending one of the results of Ene et al. [16].

1 Introduction

Geometric packing and covering problems have received wide attention in the last decade, especially in the context of approximation algorithms. Besides the inherent aesthetic appeal, the interest in the geometric setting arises from the fact that in many applications, the packing and covering problems involve geometric objects. For example, see [3, 4, 14, 24, 30]. Several tools and techniques have been developed for this purpose, but for many fundamental problems there are still large gaps between the known approximation factors, and the existing hardness results.

Classic techniques for solving packing and covering problems rely on grid-shifting techniques introduced by Hochbaum and Maass [22], and extensions by Erlebach et al. [17] and Chan [10]. All these algorithms are restricted to the setting where the regions are *fat*. Recent progress has been based mainly on two paradigms. The first is algorithms that use LP rounding [7, 9, 12, 18], and the other is *local search* (albeit only in the unweighted setting). Local Search has been used to obtain PTASs[1] for several problems besides packing and covering. For example, see [5, 12, 19, 23, 28] and [8, 13] for more recent work.

Har-Peled and Chan [12], and Mustafa and Ray [28] obtained PTASs for the Independent Set and Hitting Set problems respectively, via local search when the underlying regions are non-piercing[2]. Non-piercing regions constitute a general setting studied widely, examples of which include disks, homothets of convex objects, unit height rectangles, arbitrary sized squares, etc. In contrast, for the Set Cover and Dominating Set problems, PTASs exist only when the underlying regions are disks [5, 19, 28]. Since these are natural and important problems, there have been attempts to extend these results to more general settings. The main difficulty is that the analysis for the case of disks relies heavily on the geometry. Durocher and Fraser [15] showed the existence of a PTAS for the Set Cover problem when the regions are pseudodisks satisfying a *cover-free* condition by *dualizing* and converting the problem to a Hitting Set problem. Further, they show that the approach of dualizing the problem can not be extended to work for a general family of pseudodisks.

In this paper, we develop new techniques to analyze the local search algorithm for problems when the underlying regions are non-piercing. These techniques lead to the first PTAS for the unweighted Set Cover and Dominating Set problems when the underlying regions are non-piercing. In the weighted setting, Chan et al. [11] building on the work of Varadarajan [31] obtained $O(1)$-approximation algorithms for the Set Cover and Dominating Set problems for non-piercing regions with low union complexity. For the Set Cover problem, the current best result is a QPTAS [27] that extends the technique of Adamaszek and Wiese [1, 2] which obtains QPTAS for the Independent Set problem for polygons.

We also develop new techniques for obtaining a PTAS for the Capacitated Region packing problem when the capacities are bounded by a constant and the regions are k-admissible[3]. This result proves a conjecture of Har-Peled [20]. We also consider the dual problem, namely Capacitated Point Packing for non-piercing regions. We show that it admits a PTAS using local search for the special case when the capacity is unity, extending a result of Ene et al. [16], who obtained a PTAS for Capacitated Point Packing for disks with unit capacity in the plane.

2 Preliminaries

Two compact, simply connected regions A, B are said to be *non-piercing* if both $A \setminus B$ and $B \setminus A$ are connected. A set $\mathcal{X}$ of compact, simply connected regions is non-piercing if the regions in $\mathcal{X}$ are pairwise non-piercing. For a region A, let $\partial(A)$ denote the boundary of A. We assume $\partial(A)$ is oriented counter-clockwise. The boundary divides the plane into two

[1] A polynomial time $(1+\epsilon)$-approximation algorithm for any $\epsilon > 0$.
[2] A set of simply connected regions is said to be non-piercing if for any pair A, B of regions, the sets $A \setminus B$ and $B \setminus A$ are connected.
[3] k-admissible regions are non-piercing regions whose boundaries intersect at most k times.

regions the interior of A, denoted $int(A)$, and the exterior of A, denoted $ext(A)$. By the orientation of $\partial(A)$, $int(A)$ lies to the left of $\partial(A)$. We further assume that any pair of regions in $\mathcal{X}$ intersect *properly* by which we mean that for any two regions A, B, $\partial(A) \cap \partial(B)$, i.e., the points of intersection of their boundaries is a finite set, and at each point of intersection, their boundaries cross. In this paper, when we use the term *region*, we implicitly mean that the region is compact and simply connected, and a set of regions is assumed to be properly intersecting.

In some applications considered in this paper, we are given a set $\mathcal{R}$ of regions as well as a set P of points in $\mathbb{R}^2$. In this case, we assume that the regions in $\mathcal{R}$ intersect properly, and each point $p \in P$ is at least at a distance $\epsilon > 0$ away from the boundary of any region in $\mathcal{R}$.

We will use Lemma 6 from [29], which we state here for completeness.

▶ **Lemma 1** ([29]). *Given a set of non-piercing regions $\mathcal{X}$ and a set P of points in the plane, we can construct a plane graph*[4] *$H = (P, E)$ in polynomial time such that for any region $X \in \mathcal{X}$, the induced sub-graph on the set of points in $P \cap X$ is connected. Furthermore, the sub-graph formed by edges of H lying within X also form a connected sub-graph on $P \cap X$.*

The Lemma as stated is slightly more general than the statement in [29]. However, this follows from their proof.

3 Local Search Framework

The local search algorithm we use in this paper is the following:

Local Search Algorithm: For a parameter k, start with a feasible solution. At each iteration, attempt to find a better feasible solution by swaps of a bounded size k of objects in the current solution with objects not in the solution. Stop and return the current solution when no such swap is possible.

In the rest of the paper, when we say the "local search algorithm", we implicitly refer to the algorithm above. The running time of this algorithm is $n^{O(k)}$. We choose the local search parameter k to be an appropriate polynomial in $1/\epsilon$ to achieve the approximation factor of $(1 + \epsilon)$ [5, 12, 28].

Let $\mathcal{R}$ and $\mathcal{B}$ denote an optimal solution and the solution returned by the local search algorithm, respectively. To analyze the approximation factor of the algorithm, we need to construct a suitable bipartite graph on the elements in $\mathcal{R}$ and $\mathcal{B}$. We refer to the exposition by Aschner et al. [5] as well as [12, 28] for a more complete description of this framework and its analysis. The following Theorem then follows.

▶ **Theorem 2** ([5, 12, 28]). *Consider a problem Π.*

1. *Suppose Π is a minimization problem. If there exists a bipartite graph $H = (\mathcal{R} \cup \mathcal{B}, E)$, that belongs to a family of graphs having a balanced vertex separator of sub-linear size, and it satisfies the* local-exchange property*: For any subset $\mathcal{B}' \subseteq \mathcal{B}$, $(\mathcal{B} \setminus \mathcal{B}') \cup N(\mathcal{B}')$ is a feasible solution. Then, the Local Search algorithm is a PTAS for Π. Here, $N(\mathcal{B}')$ denotes the set of neighbors of $\mathcal{B}'$ in H.*
2. *Suppose Π is a maximization problem. If there exists a bipartite graph $H = (\mathcal{R} \cup \mathcal{B}, E)$ that belongs to a family of graphs having a balanced vertex separator of sub-linear size,*

[4] An embedding of a planar graph in the plane such that the vertices are points and edges are continuous curves between the end-points.

and such that it satisfies the local-exchange property*: For any $\mathcal{R}' \subseteq \mathcal{R}$, $(\mathcal{B} \cup \mathcal{R}') \setminus N(\mathcal{R}')$ is a feasible solution. Then, the Local Search algorithm is a PTAS for* Π. *Here, as above $N(\mathcal{R}')$ denotes the set of neighbors of $\mathcal{R}'$ in H.*

Note that it can be assumed that $\mathcal{R} \cap \mathcal{B} = \emptyset$. This is because, otherwise, the common elements can be removed from both the sets and then the analysis can be restricted to the modified sets.

In Sections 6, 7, and 8, we construct graphs satisfying the conditions of Theorem 2 above, and thereby obtain a PTAS for the Dominating Set, Set Cover, Capacitated Region Packing, and Capacitated Point Packing problems. *Note that we only need to show the existence of these graphs and we do not require their construction to be algorithmic as they are only used in the analysis and not in the algorithm.*

4 Our Results

In this paper, we study the following problems.

Set Cover: Given a finite set of non-piercing regions $\mathcal{X}$, and a set of points P covered by the union of the regions in $\mathcal{X}$, compute $\mathcal{Y} \subseteq \mathcal{X}$ of smallest cardinality such that for each $p \in P$, there exists $Y \in \mathcal{Y}$ s.t., $p \in Y$.

Note that when the regions are disks, a PTAS for this problem follows from a PTAS for the Hitting-Set problem of halfspaces in $\mathbb{R}^3$ [28] via lifting. However, this technique does not generalize even for pseudodisks. An appealing approach is to try to *dualize* the problem, and use results for the Hitting Set problem. However, as Durocher and Frazer [15] observed, such a dual does not exist. Currently, the best approximation algorithm is a QPTAS given by Mustafa et al., [27] that works even in the weighed setting. In the unweighted setting, the work of Har-Peled and Quanrud [21] implies a PTAS for the above problem under the assumption that the regions are fat, and that no point is contained in more than a constant number of regions. We obtain a PTAS without these assumptions. The only requirement is that the regions are non-piercing, and in this sense, our work complements the work of Har-Peled and Quanrud [21].

▶ **Theorem 3.** *The Local Search algorithm yields a PTAS for the geometric Set Cover problem when the regions are non-piercing.*

Dominating Set: Given a finite set of non-piercing regions $\mathcal{X}$, find a subset $\mathcal{Y} \subseteq \mathcal{X}$ of smallest cardinality such that for each $X \in \mathcal{X}$, there exists $Y \in \mathcal{Y}$ so that $Y \cap X \neq \emptyset$.

Gibson and Pirwani [19] gave a PTAS for this problem, via local search when restricted to disks. However, their construction of the planar graph uses power diagrams [6] which strongly relies on the fact that the regions are circular disks. It is not clear how one could generalize their result to the setting of non-piercing regions, or even pseudodisks. Har-Peled and Quanrud [21] prove that local search yields a PTAS for *low-density graphs.* However, it is not clear how we could apply these techniques even in the setting where the regions are fat. We obtain a PTAS for this problem when the regions are non-piercing. In Section 6, we prove the following:

▶ **Theorem 4.** *The Local Search algorithm yields a PTAS for the Dominating Set problem in the intersection graph of non-piercing regions.*

Capacitated Region Packing: Given a finite set of non-piercing regions $\mathcal{X}$, a set of points P each having a constant capacity ℓ, compute the largest cardinality set $\mathcal{Y} \subseteq \mathcal{X}$ such that each point of P is contained in at most ℓ regions of $\mathcal{Y}$.

Currently, the best algorithm for this problem is by Ene et al., [16] that is an $O(1)$-approximation. This algorithm works even in the weighted setting as long as the regions have linear union complexity. Aschner et al. [5] gave PTAS for fat objects, Har-Peled [20] gave a QPTAS for family of pseudodisks. The results in [5, 20] is for the special case where $P = \mathbb{R}^2$. Har-Peled [20] conjectured that a PTAS must exist for this problem. Indeed, we obtain a PTAS for the more general problem. In Section 7 we prove the following theorem.

▶ **Theorem 5.** *The Local search algorithm yields a PTAS for the Capacitated Region Packing problem when the regions are k-admissible for $k = O(1)$, and the capacities are bounded above by a constant.*

Capacitated Point Packing: Given a finite set of non-piercing regions $\mathcal{X}$, with a constant capacity ℓ and a set of points P, compute the largest cardinality set $Q \subseteq P$ such that each region in $\mathcal{X}$ contains at most ℓ points of Q.

Ene et al., [16] gave $O(1)$-approximation algorithms for disks in plane with arbitrary capacities. For unit capacities, they show a PTAS for halfspaces in $\mathbb{R}^3$ and disks in the plane. To the best of our knowledge, there is no known $O(1)$-approximation algorithm for pseudodisks, even for unit capacity (standard pack points). We show that the problem admits a PTAS when the regions have unit capacity. In Section 8 we prove the following theorem.

▶ **Theorem 6.** *The Local search algorithm yields a PTAS for the Capacitated Point Packing problem for non-piercing regions when the regions have unit capacity.*

We define the notion of *lens bypassing*, and use this to build graphs with a small separator for the Set Cover and the Dominating Set problems thus obtaining a PTAS for these problems. Lens-bypassing is a finer tool than *lens-cutting* used in [27], and allows us to simplify one intersection at a time, instead of all intersections with one region at a time. This technique may find applications elsewhere. For the Capacitated Region Packing problem, we argue that the natural intersection graph relevant to the problem has a small separator by comparing it to a planar graph on the points.

5 Lens Bypassing

For two regions A and B, each connected component of $A \cap B$ bounded by two arcs, one from the boundary of A and the other from that of B is called a *lens*. Since the boundary of any region is oriented counter-clockwise, observe that the arcs from A and B forming the boundary of a lens are oriented in opposite directions.

Let L_{AB} denote the set of lenses formed by the intersection of regions A and B. We define a *lens bypassing* for a lens $\ell_{AB} \in L_{AB}$ formed by A and B as follows: Leaving B as is, we modify the boundary of A to follow the boundary of B along the arc of B bounding ℓ_{AB}, at an arbitrarily small distance $\beta > 0$ away from this arc. In this case, we say that we do lens bypassing in favor of B. If we did the reverse, we would call this lens bypassing in favor of A. More formally, let D_β be a ball of radius β. Then, bypassing lens ℓ_{AB} in favor of B is the operation of replacing A by $A' = A \setminus (\ell_{AB} \oplus D_\beta)$, where $\oplus$ denotes a Minkowski-sum. Figures 1 and 2 shows the operation of lens-bypassing for non-piercing regions.

▶ Remark. Our goal in lens-bypassing is to preserve the union of the regions while simplifying the arrangement. For this, we need $\beta = 0$ in the definition of lens-bypassing. But, this would

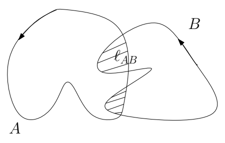

Figure 1 The figure shows lenses in the arrangement of non-piercing regions.

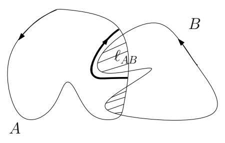

Figure 2 The figure shows the operation of bypassing lens ℓ_{AB} in favor of B

imply that A' and B share a portion of their boundaries and they are no longer properly intersecting. To avoid this technical complication, we take β to be an arbitrarily small positive quantity. However, for the rest of the paper, we do not make this distinction and state our results as if $\beta = 0$ for better readability. For instance, we say that lens-bypassing does not change the union of the regions. This is to be understood as: $A' \cup B$ contains all points in $A \cup B$ that are at least a distance $\delta > 0$ away from $\partial(A)$ and $\partial(B)$. Here, we assume that $\beta < \delta$ for an arbitrarily small positive quantity δ.

▶ **Proposition 6.1.** *Let A and B be two regions in $\mathbb{R}^2$. Let ℓ_{AB} be a lens formed by A and B. Let A', B be the regions obtained by bypassing the lens ℓ_{AB} in favor of B. Then, A' and B are non-piercing regions if and only if A, B are non-piercing.*

For two regions A and B, let $X(A, B)$ denote the intersection points of $\partial(A)$ and $\partial(B)$. Let σ_{AB} denote the cyclic sequence of $X(A, B)$ along $\partial(A)$, i.e., walking in counter-clockwise order along $\partial(A)$. Similarly, let σ_{BA} denote the cyclic sequence of the intersection points $X(A, B)$ along $\partial(B)$. For two points x, y on ∂A, we let $\gamma_{xy}(A)$ denote the arc on $\partial(A)$ from x to y in counter-clockwise direction along ∂A. We use γ_{xy}, when the region A is clear from context. Two cyclic sequences σ and σ' on the same set of elements are said to be reverse-cyclic if σ can be obtained from σ' by reversing the order. For example x_1, x_2, x_3, x_4, x_1 and x_4, x_3, x_2, x_1, x_4 are reverse-cyclic. For a cyclic sequence σ, we say x precedes y in σ, or $x \prec_\sigma y$ if x immediately precedes y in the cyclic sequence σ.

For a pair of reverse-cyclic sequences σ, σ' on the same set of elements, we define a *lens* in the sequences as pair of elements x, y that appear consecutively in σ and appear consecutively in σ', but in reverse-cyclic order; i.e., $x \prec_\sigma y$ and $y \prec_{\sigma'} x$. Bypassing a lens xy in a pair σ, σ' of reverse-cyclic sequences is the operation of removing x and y from σ and σ', i.e., $\pi = \sigma \setminus \{x, y\}$ and $\pi' = \sigma' \setminus \{x, y\}$.

For regions A, B consider the cyclic sequences σ_{AB} and σ_{BA}. If x, y form a lens in the sequences σ_{AB} and σ_{BA}, it is easy to see that the arcs of $\partial(A)$ and $\partial(B)$ between points x and y in $X(A, B)$ form a lens of the regions A and B. If $x \prec_{\sigma_{AB}} y$ and $x \prec_{\sigma_{BA}} y$, then the region bounded by the arcs of $\partial(A)$ and $\partial(B)$ between points x and y forms a region that is contained in either $A \setminus B$ or $B \setminus A$.

We will see that the pair of cyclic sequences σ_{AB} and σ_{BA} of the intersection points of regions A and B are reverse-cyclic if and only if the regions A, B are non-piercing. Further, a lens in the sequences σ_{AB} and σ_{BA} corresponds to a lens in the intersection of A and B, and bypassing a lens in σ_{AB} and σ_{BA} is the operation of lens bypassing in A and B. The following proposition is intuitively clear, and we skip the easy proof.

▶ **Proposition 6.2.** *If σ, σ' are two reverse-cyclic sequences on the same set X of elements, then*

1. *For a lens in the sequences σ, σ' formed by elements x, y, bypassing the lens leaves the sequences reverse-cyclic, i.e., the sequences $\pi = \sigma \setminus \{x, y\}$ and $\pi' = \sigma' \setminus \{x, y\}$, are reverse-cyclic.*

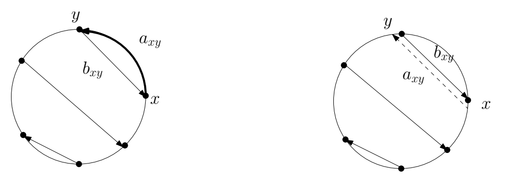

Figure 3 The figure on the left shows the segments of the boundary of B in A. The figure on the right shows the lens bypassed to obtain the modified region for A. This is shown as a dotted line.

2. *π and π' are reverse-cyclic sequences, where π and π' are obtained from σ and σ' respectively, by adding elements $x, y \notin X$ between the same pair of consecutive elements in σ and σ' such that $x \prec_{\pi} y$ and $y \prec_{\pi'} x$.*

We now give a combinatorial characterization of non-piercing regions that will be useful for the rest of the paper.

▶ **Theorem 7.** *Two regions A, B in $\mathbb{R}^2$ are non-piercing if and only if σ_{AB} and σ_{BA} are reverse-cyclic.*

Proof. We prove both directions by induction on $|X(A, B)|$. If A and B are non-piercing, then we show that σ_{AB} and σ_{BA} are reverse-cyclic. The base case is when $|X(A, B)| = 0$; sequences σ_{AB} and σ_{BA} are empty and and are therefore reverse-cyclic. Suppose the theorem holds for $|X(A, B)| < k$. Given two regions A, B with $|X(A, B)| = k$. Consider $S = \partial(B) \cap A$. Since $\partial(B)$ is not self-intersecting, S is a set of non-intersecting chords connecting disjoint pairs of points in $X(A, B)$.

Let $\gamma_{yx}(B)$ be a chord from y to x in S of smallest length, where the length of a chord in S joining x to y is the number of points of $X(A, B)$ encountered when going from y to x in σ_{AB}. We claim that x and y are adjacent in σ_{AB} since points between y and x along σ_{AB} can not be connected by a chord of S to a point outside without intersecting $\gamma_{yx}(B)$, and all such chords have smaller length than $\gamma_{yx}(B)$, contradicting the fact that $\gamma_{yx}(B)$ is the chord of smallest length.

Suppose $x \prec_{\sigma_{AB}} y$. Let $\gamma_{xy}(A)$ be the arc on $\partial(A)$ joining x to y. Since $\gamma_{yx}(B)$ is a chord joining y to x, it follows that $y \prec_{\sigma_{BA}} x$. Then, the region bounded by $\gamma_{yx}(B)$ and $\gamma_{xy}(A)$ forms a lens ℓ_{AB}. Suppose we bypass ℓ_{AB} in favor of B then, by Proposition 6.1 regions A and B remain non-piercing and $|X(A, B)|$ decreases by 2. Figure 3 shows this operation. By the inductive hypothesis, the two sequences are reverse-cyclic. Adding this pair x, y of adjacent points in both sequences σ_{AB} and σ_{BA} (in opposite order), the sequences remain reverse-cyclic by Proposition 6.2.

If $y \prec_{\sigma_{AB}} x$. Let a_{yx} be the arc joining y to x on $\partial(A)$. Since $\gamma_{yx}(B)$ lies in A, the region R bounded by a_{yx} and $\gamma_{yx}(B)$ lies in $A \setminus B$. In this case, we show $|X(A, B)| = 2$. Suppose not. Then, there are points u, v different from x, y in $X(A, B)$. If b_{uv} is a chord of S joining u to v. Then, around this region, we again obtain a region of $A \setminus B$ disconnected from R, contradicting the fact that $A \setminus B$ is connected. If $|X(A, B)| = 2$, then the sequences are reverse-cyclic.

We show the reverse direction again by induction on $|X(A, B)|$. If $|X(A, B)| = 0$, the regions are disjoint and are therefore non-piercing. Suppose that the theorem is true for $|X(A, B)| < k$. Let A, B be two regions with $|X(A, B)| = k$ and such that σ_{AB} and σ_{BA} are reverse-cyclic. By applying the lens-bypassing as before between two points x, y such that $x \prec_{\sigma_{AB}} y$ (in σ_{BA}, $y \prec_{\sigma_{BA}} x$, by virtue of the sequences being reverse-cyclic) the sequences remain reverse-cyclic by Proposition 6.2 and $|X(A, B)|$ has reduced by 2. By the inductive hypothesis, A and B are non-piercing. Adding the two intersection points x, y results in adding the lens between x and y, and this does not change $A \setminus B$ or $B \setminus A$, and the regions are non-piercing. ◀

▶ **Corollary 8.** *For two non-piercing regions A, B if there exist $x \prec_{\sigma_{AB}} y$ and $x \prec_{\sigma_{BA}} y$, then $|X(A, B)| = 2$.*

▶ **Corollary 9.** *For two non-piercing regions A, B, such that one is not contained in the other, $A \cap B$ is a collection of disjoint lenses.*

The lenses formed in an arrangement of a set $\mathcal{X}$ of regions can be ordered as a partial order by inclusion. That is, lenses $\ell_{AB} \prec \ell_{CD}$ if $\ell_{AB} \subseteq \ell_{CD}$. Note that either C or D could be equal to A or B. Now we prove the key lemma about lenses.

▶ **Lemma 10.** *Let $\mathcal{X}$ be a set of non-piercing regions. Let ℓ_{AB} be a minimal lens, defined by regions $A, B \in \mathcal{X}$. Let A' be the region obtained from A by bypassing the lens ℓ_{AB} in favor of B. Then, the regions $\mathcal{X}' = (\mathcal{X} \setminus \{A\}) \cup \{A'\}$ is a set of non-piercing regions.*

Proof. Let x, y be the two vertices of the lens ℓ_{AB} so that the arcs bounding ℓ_{AB} are $\gamma_{xy}(A)$, and $\gamma_{yx}(B)$. Let C be any region intersecting A. We will show that after bypassing the lens ℓ_{AB} in favor of B, the modified region A' remains non-piercing with respect to C. In particular, we will show that $\sigma_{A'C}$ and $\sigma_{CA'}$ remain reverse-cyclic. Let S be the set of chords in ℓ_{AB} formed by $\partial(C)$.

Suppose there is a chord $\gamma_{pq}(C)$ in S, such that p and q both lie on the boundary of the lens ℓ_{AB} defined by B, i.e., on $\gamma_{yx}(B)$. If q precedes p along $\partial(B)$, i.e., on σ_{BC} then $\gamma_{pq}(C)$ and $\gamma_{qp}(B)$ form a lens contained in ℓ_{AB}, contradicting the minimality of ℓ_{AB}. Therefore, it follows that p must precede q along $\partial(B)$, i.e., on σ_{BC}. But, this implies that p precedes q in both reverse-cyclic sequences σ_{BC} and σ_{CB}. By Corollary 8 therefore, $\partial(B)$ and $\partial(C)$ do not have any other points of intersection. In particular, this implies that $\partial(C)$ does not intersect the boundary of the lens ℓ_{AB} at any point other than p or q and so there are no other chords in S. After lens-bypassing therefore, $\sigma_{A'C}$ and $\sigma_{CA'}$ are obtained by inserting consecutive points p, q (in fact by points p', q' arbitrarily close to p and q respectively, but we do not make this distinction) between the same two consecutive points in opposite order into σ_{AC} and σ_{CA}. By Proposition 6.2 the sequences remain reverse-cyclic. This case is shown in Figure 4.

Now, suppose there is a chord $\gamma_{pq}(C)$ in S that joins two points on the boundary of the ℓ_{AB} defined by $\partial(A)$, namely $\gamma_{xy}(A)$. If q precedes p on $\gamma_{xy}(A)$, then this forms a lens contained in ℓ_{AB} contradicting the minimality of ℓ_{AB}. Otherwise, p precedes q in σ_{AC}. But this implies that p precedes q in both reverse-cyclic sequences σ_{AC} and σ_{CA}. Hence, by Corollary 8 $\partial(A)$ and $\partial(C)$ have no more points of intersection. In this case, after lens-bypassing, $\partial(A')$ and $\partial(C)$ do not intersect. Hence, $\sigma_{A'C}$ and $\sigma_{CA'}$ are empty and therefore the regions remain non-piercing. In fact, in this case we will have $A' \subseteq C$. This case is shown in Figure 5.

If none of the above hold, then all chords in S have one end-point on $\gamma_{xy}(A)$ and the other end-point on $\gamma_{yx}(B)$. In this case, after lens-bypassing $\sigma_{A'C}$ and $\sigma_{CA'}$ are obtained by replacing for each chord of C, the end-point of the chord on $\gamma_{xy}(A)$ by its other end-point on $\gamma_{yx}(B)$. The sequences σ_{AC} and $\sigma_{A'C}$ are identical except for renaming of the points in $\gamma_{xy}(A)$ by corresponding points in $\gamma_{yx}(B)$. The same holds for the sequence σ_{CA} and $\sigma_{CA'}$. Therefore the sequences $\sigma_{A'C}$ and $\sigma_{CA'}$ remain reverse-cyclic. This case is shown in Figure 6. ◀

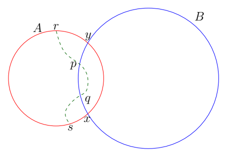

Figure 4 There is a chord of C between two points on $\gamma_{yx}(B)$.

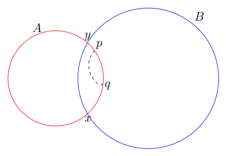

Figure 5 There is a chord of C between two points on $\gamma_{xy}(A)$.

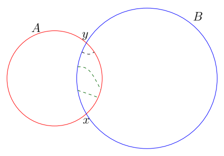

Figure 6 All chords of C connect a point on $\gamma_{xy}(A)$ and a point $\gamma_{yx}(B)$.

▶ **Corollary 11.** *Let ℓ_{AB} be a minimal lens. Let A' be the region obtained after bypassing ℓ_{AB} in favor of B. Then, for any region $C \neq B$, $A \cap C \neq \emptyset$ implies $A' \cap C \neq \emptyset$.*

6 Dominating Set and Set Cover

In this section, we first describe the construction of a graph over a set of non-piercing regions. The graph we construct satisfies the conditions required for Theorem 2, and thereby obtaining a PTAS for the Dominating Set and Set Cover problems.

For the Set Cover problem, in order to satisfy the local-exchange property, we require a bipartite graph $H = (\mathcal{R} \cup \mathcal{B}, E)$ with a small separator so that for any set $\mathcal{S} \subseteq \mathcal{B}$, the set $\mathcal{B}' = (\mathcal{B} \setminus \mathcal{S}) \cup N(\mathcal{S})$ is a Set Cover, where $N(\mathcal{S})$ is the set of neighbors of the vertices in H corresponding to regions in $\mathcal{S}$. In other words, the required graph $H = (\mathcal{R} \cup \mathcal{B}, E)$ must satisfy the following property: For each point $p \in P$, there is an $R \in \textsc{Red}(p)$ and $B \in \textsc{Blue}(p)$ that are adjacent in H, where $\textsc{Red}(p)$ is the set of regions in $\mathcal{R}$ containing p, and $\textsc{Blue}(p)$ is the set of regions in $\mathcal{B}$ containing p.

For the Dominating Set problem, the property that the bipartite graph H is required to satisfy is that for any region $X \in \mathcal{X}$, there is a region $R \in \textsc{Red}(X)$ and a region $B \in \textsc{Blue}(X)$ such that R and B are adjacent in H, where $\textsc{Red}(X)$ is the set of regions in $\mathcal{R}$ intersecting X, and $\textsc{Blue}(X)$ is the set of regions in $\mathcal{B}$ intersecting X. We let $\mathcal{G}$ denote the regions of $\mathcal{X}$ that are not in $\mathcal{R}$ or $\mathcal{B}$. Since we assumed that $\mathcal{R} \cap \mathcal{B} = \emptyset$, the three sets form a partition of the input $\mathcal{X}$.

We give a graph construction of a planar graph for any set $\mathcal{X} = \mathcal{R} \sqcup \mathcal{B} \sqcup \mathcal{G}$ of non-piercing regions from which the construction of the graphs for the Dominating Set and Set Cover problems follow.

Henceforth we refer to the regions in $\mathcal{R}, \mathcal{B}$ and $\mathcal{G}$ as Red, Blue, and Green regions respectively. We call a region $X \in \mathcal{X}$ *bi-chromatic* if and only if X intersects a Red as well as a Blue region. We assume that a region intersects itself. Therefore a Red region is bi-chromatic if it intersects a Blue region. Similarly, a point in the plane is called bi-chromatic if and only if it is contained in both a Red as well as a Blue region. As before, we let $\textsc{Red}(X)$ and $\textsc{Blue}(X)$ denote the Red and Blue regions intersecting X, respectively. Similarly, for any point p, we let $\textsc{Red}(p)$ and $\textsc{Blue}(p)$ denote the Red and Blue regions containing p respectively. We now define the properties that our constructed graph satisfies.

▶ **Definition 12.** Let $\mathcal{X} = \mathcal{R} \sqcup \mathcal{G} \sqcup \mathcal{B}$ be a set of non-piercing regions. A bipartite planar graph $H = (\mathcal{R} \cup \mathcal{B}, E)$ is called a *locality-preserving* graph for $\mathcal{X}$ if it satisfies the following properties.

P1. For each bi-chromatic region $X \in \mathcal{X}$, there exists an $R \in \textsc{Red}(X)$ and a $B \in \textsc{Blue}(X)$ such that R and B are adjacent in H.

P2. For each bi-chromatic point p in the plane, there exists an $R \in \textsc{Red}(p)$ and a $B \in \textsc{Blue}(p)$ such that R and B are adjacent in H.

We can assume that in any instance, all Green regions are bi-chromatic since Green regions that are not bi-chromatic can be removed without changing the problem. We say that a graph H on $\mathcal{R} \cup \mathcal{B}$ *satisfies* a region $X \in \mathcal{X}$ if Property P1 holds for X. We also state this as "region X is *satisfied* by H". We use a similar terminology for the points. If in a given instance $\mathcal{X}$, there are regions $R \in \mathcal{R}, B \in \mathcal{B}$ and $G \in \mathcal{G}$ such that $R \cap B \cap G \neq \emptyset$, we say that $\mathcal{X}$ has a Red-Blue-Green intersection. The main theorem we prove in this section is the following:

▶ **Theorem 13.** *For any set $\mathcal{X} = \mathcal{R} \sqcup \mathcal{G} \sqcup \mathcal{B}$ of non-piercing regions, there is a locality-preserving graph H.*

The broad approach to construct a locality-preserving graph H for $\mathcal{X}$ is as follows. If the instance $\mathcal{X}$ satisfies certain additional conditions, then we can directly describe the construction of such a graph. If the instance $\mathcal{X}$ does not satisfy these additional conditions, we show that can *reduce* the instance to one that does.

In order to do this, we describe a sequence of reduction steps that either remove a region, or bypasses a minimal lens in the arrangement of the regions, thus getting us closer to an arrangement enjoying the additional conditions alluded to above. These reduction steps have the crucial property that if we are given a locality-preserving graph for the reduced instance, we can obtain a locality-preserving graph for the original instance. We start with a construction of a locality-preserving graph for an instance $\mathcal{X}$ satisfying the additional conditions. Then, in a sequence of lemmas, namely Lemma 15, 16 and 17 we describe the reduction steps for an instance not enjoying the additional properties. Finally, we can prove Theorem 13.

▶ **Lemma 14.** *Suppose $\mathcal{X} = \mathcal{R} \sqcup \mathcal{G} \sqcup \mathcal{B}$ is a set of non-piercing regions satisfying the following properties:*

1. *$R \cap R' = \emptyset$, for all $R, R' \in \mathcal{R}$ and $B \cap B' = \emptyset$, for all $B, B' \in \mathcal{B}$, i.e., the* Red *regions are pairwise disjoint, and the* Blue *regions are pairwise disjoint.*
2. *For each $R \in \mathcal{R}, B \in \mathcal{B}$ and $G \in \mathcal{G}$, $R \cap B \cap G = \emptyset$, i.e., there is no* Red-Blue-Green *intersection.*

Then, there is a locality-preserving graph for $\mathcal{X}$.

Proof. In order to construct the graph, we temporarily add Red and Blue points to the arrangement of the regions in the following way: For each intersection $R \cap G$ of a Red region R and a Green region G, we place a Red point in $R \cap G$. Similarly, we place a Blue point for each Blue-Green intersection. Since there are no Red-Blue-Green intersections, observe that in the interior of any Green region the Red and Blue regions are disjoint. Therefore, for any Green region, the point we place corresponding to a Red region does not lie in a Blue region, and vice-versa.

Now, by Lemma 1, applied to the Green regions and the Red and Blue points we place, there is a plane graph K such that for each Green region $G \in \mathcal{G}$, there is an edge in K between a Red point contained in G and a Blue point contained in G lying entirely in G.

For each $G \in \mathcal{G}$, we pick one such edge e_G arbitrarily. Let r and b be the Red and Blue end-points of e_G, respectively. As observed earlier, r lies in a Red region, and b lies in a Blue region. So, walking from b to r along e_G we encounter a Red region R and a Blue region B that are consecutive along e_G. We now extend B along e_G so that R and B now intersect. Note that this can be done in a way that they remain non-piercing. An example is shown in Figures 7 and 8.

We remove any Green region with a Red-Blue-Green intersection, and repeat the operation above on the remaining Green regions. Since the graph K is planar, the extended

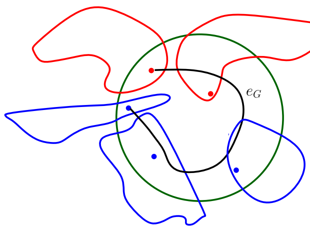

Figure 7 The edge e_G.

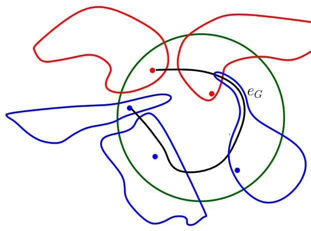

Figure 8 Extending the BLUE region to intersect the adjacent RED region along e_G.

BLUE regions remain disjoint. Extending a BLUE region along an edge of K chosen for a GREEN region may intersect other GREEN regions in an arbitrary fashion. However, this does not matter as the GREEN regions will not play any role henceforth. It is possible that the same BLUE region is extended multiple times to intersect the same RED region. However, the regions remain non-piercing as each extension of the BLUE ensures this property.

By extending the BLUE regions, we have the property that for each $G \in \mathcal{G}$, there is now an $R \in \text{RED}(G)$ and $B \in \text{BLUE}(G)$ such that $R \cap B \neq \emptyset$. Therefore, the intersection graph of the RED and BLUE regions gives us the desired locality-preserving graph.

Since we ensure that the RED regions are pairwise disjoint, the BLUE regions are pairwise disjoint, and $\mathcal{R} \cup \mathcal{B}$ is non-piercing, the intersection graph of $\mathcal{R} \cup \mathcal{B}$ is planar as observed by Chan and Har-Peled [12]. ◀

We now describe the reductions for an instance $\mathcal{X}$ that does not satisfy the conditions of Lemma 14. The reduction steps are the following: We first show that we can remove RED-BLUE-GREEN intersections if any in our instance. Then, we show that if our instance has two regions such that one is contained in another, then we can remove one of them (this statement is not entirely accurate; we do not get rid of containments where a RED or BLUE region is contained in a GREEN region, but such containments do not affect our construction). Then, we show that we can decrease the number vertices in the arrangement by bypassing minimal lenses. The latter two reductions are applied repeatedly until none apply. At that point, we can show that the instance satisfies the conditions of Lemma 14 and a locality-preserving graph can thus be constructed.

▶ **Lemma 15.** *Let $\mathcal{X} = \mathcal{R} \sqcup \mathcal{B} \sqcup \mathcal{G}$ be a set of non-piercing regions. Suppose there exists $R \in \mathcal{R}, B \in \mathcal{B}$ and $G \in \mathcal{G}$ such that $R \cap B \cap G \neq \emptyset$, i.e., the instance contains a* RED-BLUE-GREEN *intersection. Then, a locality-preserving graph for the reduced instance $\mathcal{X}' = \mathcal{X} \setminus G$ is a locality-preserving graph for $\mathcal{X}$.*

Proof. Let H' be a locality-preserving graph for $\mathcal{X}'$. By Property P2, there is an edge between a region $R \in \text{RED}(p)$ and $B \in \text{BLUE}(p)$ for $p \in R \cap B \cap G$. This implies that H' is locality-preserving for $\mathcal{X}$ since $\text{RED}(p) \subseteq \text{RED}(G)$ and $\text{BLUE}(p) \subseteq \text{BLUE}(G)$. ◀

▶ **Lemma 16.** *Let $\mathcal{X} = \mathcal{R} \sqcup \mathcal{B} \sqcup \mathcal{G}$ be a set of non-piercing regions with no* RED-BLUE-GREEN *intersections. If there are two regions P and Q such that $P \subseteq Q$, and either both P and Q are* GREEN*, or both are not* GREEN*, a locality-preserving graph for a suitable reduced instance $\mathcal{X}'$ with one less region than $\mathcal{X}$ implies a locality-preserving graph for $\mathcal{X}$.*

Proof. Note that, as mentioned in the conditions of the lemma, we do not deal with the case where Q is GREEN and P is either RED or BLUE. Thus, we have the following cases.

Case 1: Q is either Red or Blue, and P is Green. This case does not arise, since we assume that there are no Red-Blue-Green intersections and all Green regions are bi-chromatic.

Case 2: Q is either Red or Blue, and P is either Red or Blue. The reduced instance in this case is obtained by removing P, i.e., $\mathcal{X}' = \mathcal{X} \setminus P$. If H' is a locality-preserving graph for $\mathcal{X}'$, then we obtain the locality-preserving graph H for $\mathcal{X}$ by adding an edge between P and Q if they have distinct colors. Otherwise, we add P to any Red or Blue region intersecting P and having a color different from P, if such a region exists. If such a region does not exist, then we set $H = H'$.

Now we argue that the graph H so constructed is locality-preserving for $\mathcal{X}$. In obtaining the graph H, we added at most one vertex of degree 1 to H', and hence H is planar. Since the only regions affected by the removal of P are those that intersect P, we only argue about such regions. Similarly the only points affected are those lying in P and we argue only about these points.

Case 2a: P and Q have the same color. To show that H is locality-preserving for $\mathcal{X}$, note that if P is bi-chromatic, then the edge we added satisfies P. Any other region intersecting P also intersects a region of the same color as P, namely Q. Therefore, such a region is satisfied by H'. Similarly, all bi-chromatic points in P remain bi-chromatic in $\mathcal{X}'$ since they are contained in Q. Therefore, it follows that the edges in H' satisfy all bi-chromatic points with respect to $\mathcal{X}$.

Case 2b: P and Q have different colors. In this case, we connect P to Q. This satisfies the region P. Since $P \subset Q$, all other regions intersecting P also intersect Q and are therefore satisfied by the edge we added. By the same argument, all bi-chromatic points in P are also satisfied by H.

Case 3: P and Q are both Green. In this case, $\mathcal{X}' = \mathcal{X} \setminus Q$ is the desired reduced instance. If H' is a locality-preserving graph, then H' is also locality-preserving with respect to $\mathcal{X}$, since any region intersecting P also intersects Q. ◀

▶ **Lemma 17.** *Let $\mathcal{X} = \mathcal{R} \sqcup \mathcal{B} \sqcup \mathcal{G}$ be a set of non-piercing regions such that there are no* Red-Blue-Green *intersections. Then, a locality-preserving graph H' for a reduced instance $\mathcal{X}'$ is a locality-preserving graph for $\mathcal{X}$. Here, $\mathcal{X}'$ is obtained by bypassing a minimal lens ℓ_{PQ} using the following rules:*

1. *If P and Q have the same color. Bypass ℓ_{PQ} in favor of either P or Q chosen arbitrarily.*
2. *If ℓ_{PQ} is contained in a region $R \in \mathcal{R}$, where R is distinct from P and Q, then bypass the lens in favor of the region that is not* Red.
3. *If ℓ_{PQ} is contained in a region $B \in \mathcal{B}$, where B is distinct from P and Q, then bypass the lens in favor of the region that is not* Blue.

Proof. We assume without loss of generality that we bypass the lens ℓ_{PQ} in favor of Q, and let P' be the resulting region corresponding to P. Then, $\mathcal{X}' = (\mathcal{X} \setminus P) \cup P'$. By Lemma 10, the regions in $\mathcal{X}'$ are non-piercing since we bypass a minimal lens ℓ_{PQ}.

Suppose P and Q have the same color. By Corollary 11, any region $X \neq Q$ intersecting P also intersects P'. This ensures that the set of Red or Blue regions intersecting a region $X \neq Q$ remains unchanged in $\mathcal{X}'$. Thus, H' satisfies all regions except possibly Q. Since P and Q have the same color, Q remains bi-chromatic in $\mathcal{X}'$ if it was bi-chromatic in $\mathcal{X}$. Since

$P \cup Q$ remains unchanged due to lens-bypassing and the fact that they have the same color, all bi-chromatic points in $\mathcal{X}$ remain bi-chromatic in $\mathcal{X}'$. Since no region gains a new intersection and no point is contained in a new region when going from $\mathcal{X}$ to $\mathcal{X}'$, a locality-preserving graph H' for $\mathcal{X}'$ is also locality-preserving for $\mathcal{X}$.

Now suppose that P and Q have distinct colors, then we bypass ℓ_{PQ} only if it lies in a RED or a BLUE region. Let us assume that ℓ_{PQ} is contained in a RED region R. The other case is symmetric. By our assumption that there is no RED-BLUE-GREEN intersection, one of P or Q must be RED. Since we assume that we bypass ℓ_{PQ} in favor of Q, P is RED. We claim that H' is locality-preserving with respect to $\mathcal{X}$.

By Corollary 11, it follows that for every region $X \neq P, Q$, the set of regions intersecting X does not change. These regions are therefore satisfied by H'. For the region Q, while it possibly loses its intersection with P, it continues to intersect a RED region, namely R. Therefore, Q is also satisfied by H'. The region P' may not be bi-chromatic even if P was bi-chromatic. This can happen only when Q is the unique BLUE region intersecting P, which is RED by assumption. However, in that case, consider any point $p \in \ell_{PQ}$. Such a point p is bi-chromatic in $\mathcal{X}'$ since it lies in Q and R. Therefore the point p is satisfied in H'. Now, the fact that P is satisfied in H' follows from the fact that any region containing p also intersects P. ◀

Proof of Theorem 13. Given an instance $\mathcal{X} = \mathcal{R} \sqcup \mathcal{B} \sqcup \mathcal{G}$ of non-piercing regions, we first remove all RED-BLUE-GREEN intersections by applying Lemma 15. Then, we repeatedly apply Lemma 16 followed by Lemma 17 until neither applies. At this point, we claim that the RED regions are pairwise disjoint, and the BLUE regions are pairwise disjoint.

First, note that no RED or BLUE region is contained in another RED or BLUE region by Lemma 16. In particular, this implies that any intersection of a pair P, Q of RED regions is a union of lenses formed by them. However, any such lens ℓ_{PQ} is removed by Lemma 17 so long as it is minimal. We argue that ℓ_{PQ} must be minimal. Suppose not. Then, there is a minimal lens ℓ_{WZ} contained in ℓ_{PQ}. We can check that for all possible colors of W and Z, Lemma 17 applies to ℓ_{WZ} and is thus bypassed. A symmetric argument applies for the BLUE regions.

Thus, when the conditions of Lemma 16 or Lemma 17 do not apply, the RED regions are pairwise disjoint, the BLUE regions are pairwise disjoint, and there are no RED-BLUE-GREEN intersections. Hence, the conditions of Lemma 14 apply and we can obtain a locality-preserving graph H'. This implies a locality-preserving graph H for the instance $\mathcal{X}$. ◀

Now, we can prove that the Dominating Set and Set Cover problem for non-piercing regions admits a PTAS.

Proof of Theorem 4. Let $\mathcal{R}$ denote an optimal solution to the Dominating Set problem. Let $\mathcal{B}$ denote a solution returned by local search. Let $\mathcal{G}$ be the remaining regions. Recall that we assume $\mathcal{R} \cap \mathcal{B} = \emptyset$. Let $\mathcal{X} = \mathcal{R} \sqcup \mathcal{B} \sqcup \mathcal{G}$. Note that since every region in $\mathcal{X}$ is bi-chromatic, Property P1 is precisely the locality condition required for the graph of the Dominating Set problem. Now, Theorem 13 gives us a planar graph satisfying Property P1, and is therefore the desired graph. Since planar graphs have separators of size $O(\sqrt{n})$ [25], where n is the number of regions in the input $\mathcal{X}$, by Theorem 2 a $(1+\epsilon)$-approximation algorithm follows. ◀

Proof of Theorem 3. Let $\mathcal{R}$ denote an optimal solution to the Set Cover problem. Let $\mathcal{B}$ denote a solution returned by local search. Recall that we assume $\mathcal{R} \cap \mathcal{B} = \emptyset$. Let $\mathcal{X} = \mathcal{R} \cup \mathcal{B}$, and let $\mathcal{G} = \emptyset$. Since every point P is in $R \cap B$, for some $R \in \mathcal{R}$ and $B \in \mathcal{B}$, Property P2 is precisely the locality condition required for the Set Cover problem. Now, Theorem 13 gives us a planar graph satisfying the required locality conditions. The graph returned by Theorem 13 is planar. Since planar graphs have separators of size $O(\sqrt{n})$ [25], where n is the number of regions in the input $\mathcal{X}$, by Theorem 2 a $(1+\epsilon)$-approximation follows. ◀

7 Capacitated Region Packing

Recall that in the Capacitated Region Packing problem, we are given a family of r-admissible regions $\mathcal{X}$, a set of points P, and a positive integer constant ℓ. We want to find a maximum sized subset $\mathcal{X}' \subseteq \mathcal{X}$ such that every point $p \in P$ is contained in at most ℓ regions in $\mathcal{X}'$. Unlike the earlier results in this paper, here we require that the regions be r-admissible for a constant r, i.e., they are non-piercing and their boundaries intersect at most a constant number of times.

Let $\mathcal{X} = \mathcal{R} \cup \mathcal{B}$ and $k = 2\ell$. Note that the depth of a point in P with respect to $\mathcal{X}$, that is the number of regions in $\mathcal{X}$ containing it, is at most k. For this problem, the graph we construct is as follows: For each point $p \in P$, add an edge between all regions in $\mathcal{R}$ containing p and all regions in $\mathcal{B}$ containing p. It is easy to check that this graph satisfies the local-exchange property as stated in Theorem 2. We now show that this graph has a small balanced separator. In fact, we show the following super-graph $H(\mathcal{X}, k)$ has a small, balanced separator. For each point $p \in \mathbb{R}^2$ whose depth is at most k, add an edge between all pairs of regions in $\mathcal{R} \cup \mathcal{B}$ containing p.

▶ **Theorem 18.** *Given a set $\mathcal{X}$ of r-admissible regions for a constant r, the graph $H(\mathcal{X}, k)$ on $\mathcal{X}$ has a balanced separator of size $O(k^{3/2}\sqrt{|\mathcal{X}|})$.*

Proof. In order to prove the statement for $H(\mathcal{X}, k)$, we prove it for an isomorphic graph that is the intersection graph of a family of trees $\mathcal{T}$ that we obtain in the following way: We put one point in every cell whose depth is at most k in the arrangement of the regions in $\mathcal{X}$, and call this point set P. By Lemma 1 there exists a plane graph G_P on the point set P such that the subgraph induced by $X \cap P$ is connected, for every $X \in \mathcal{X}$. For each $X \in \mathcal{X}$, consider an arbitrary spanning tree T_X of the subgraph induced by $X \cap P$. Observe that the intersection graph of the family of these spanning trees $\mathcal{T} = \{T_X \mid X \in \mathcal{X}\}$ is isomorphic to $H(\mathcal{X}, k)$. We now claim that such an intersection graph has a small and balanced separator.

▶ **Lemma 19.** *Given a family of trees $\mathcal{T}$ as above, its intersection graph has a balanced separator of size $O(k^{3/2}\sqrt{|\mathcal{T}|})$.*

Proof. We prove this statement as follows. We assign appropriate weights on the points in P, and use the fact that the graph G_P on the points, constructed by applying Lemma 1 is planar, and therefore has a balanced weighted separator.

We assign weights to the points in P as follows: We start by assigning a weight of 0 to each point in P. For each region $X \in \mathcal{X}$, we add $1/|X \cap P|$ to the weight of each point in X. Thus, the weight of a point in P is given by $wt(p) = \sum_{X \mid p \in X} 1/|X \cap P|$.

By the Lipton-Tarjan separator theorem [25], G_P has a separator S of size $O(\sqrt{|P|})$ such that removing S separates the graph into two disjoint sets A and B, each of which has at most 2/3 of the total weight of the points. The separator S for G_P gives a separator for the graph $\mathcal{T}$ by taking $\mathcal{S} = \{T \mid S \cap T \neq \emptyset\}$. We claim that $\mathcal{S}$ is a small, balanced separator. The fact that removing $\mathcal{S}$ separates $\mathcal{T}$ into two parts $\mathcal{A}, \mathcal{B}$ follows since a tree containing a vertex from A and a vertex from B must contain a vertex from S.

To show that $|\mathcal{S}| \leq O(k^{3/2}\sqrt{|\mathcal{T}|})$, we proceed as follows. By our construction, every point in P has depth at most k. This implies that $|\mathcal{S}| \leq k|S|$. However, $|S| \leq O(\sqrt{|P|})$, as S is a separator in G_P. Since r-admissible regions have linear union complexity [32], the Clarkson-Shor technique [26, p. 141] implies that the number of cells in the arrangement is at most $O(k|\mathcal{T}|)$. Thus, $|P| = O(k|\mathcal{T}|)$ and hence, $|\mathcal{S}| \leq O(k\sqrt{k|\mathcal{T}|})$.

Now, we need to show that $\mathcal{S}$ is balanced. To see this, let $\mathcal{T}_A$ be the set of trees whose vertex set is a subset of A. $\mathcal{T}_B$ is defined similarly. Since, the weight of all trees in $\mathcal{T}_A$ were distributed among the points in A, $wt(A) \geq |\mathcal{T}_A|$. Also, from the planar separator theorem we know that $wt(A) \leq \frac{2}{3}|\mathcal{T}|$. Therefore, $|\mathcal{T}_A| \leq \frac{2}{3}|\mathcal{T}|$. The same holds for $\mathcal{T}_B$. Therefore, $\mathcal{S}$ is a balanced separator of size $O(k^{3/2}\sqrt{|\mathcal{T}|})$ of the intersection graph of $\mathcal{T}$. ◀

From Lemma 19, it follows that $H(\mathcal{X}, k)$ has a balanced separator of size $O(k^{3/2}\sqrt{|\mathcal{X}|})$. ◀

Proof of Theorem 5. The graph constructed satisfies the conditions of Theorem 2. Therefore a PTAS follows. ◀

8 Capacitated Point Packing

Recall that in the Capacitated Point Packing problem, we are given a set P of n points, a set $\mathcal{X}$ of non-piercing regions, and a positive integer constant ℓ. The goal is to obtain the maximum sized subset of points $Q \subseteq P$ such that for every region $X \in \mathcal{X}$, $|X \cap Q| \leq \ell$. We consider the Capacitated Point Packing problem when $\ell = 1$. We show that the Local search algorithm yields a PTAS for this special case.

Proof of Theorem 6. We construct a bipartite graph on the union of red and blue points in the following way. We put an edge between a red point and a blue point if they are contained in some region $X \in \mathcal{X}$. It is easy to check that this graph satisfies the local-exchange property as stated in Theorem 2. As both the local search and the optimum solutions are feasible, every region contains at most one red point and at most one blue point. Observe that the graph constructed in Lemma 1 is such a graph, because it ensures that the graph induced by the points contained in an input region is connected. This in turn means that there is always an edge between a red point and a blue point contained in the same region. Lemma 1 states that this graph is planar. Thus, the graph constructed satisfies the condition of Theorem 2. Therefore, a PTAS follows. ◀

Abstract

During the last 10 years it has become popular to study dynamic graph problems in a *emergency planning* or *sensitivity* setting: Instead of considering the general fully dynamic problem, we only have to process a *single* batch update of size d; after the update we have to answer queries.

In this paper, we consider the dynamic subgraph connectivity problem with sensitivity d: We are given a graph of which some vertices are activated and some are deactivated. After that we get a single update in which the states of up to d vertices are changed. Then we get a sequence of connectivity queries in the subgraph of activated vertices.

We present the first fully dynamic algorithm for this problem which has an update and query time only slightly worse than the best decremental algorithm. In addition, we present the first incremental algorithm which is tight with respect to the best known conditional lower bound; moreover, the algorithm is simple and we believe it is implementable and efficient in practice.

1 Introduction

Dynamic graph algorithms maintain a data structure to answer queries about certain properties of the graph while the underlying graph is changed, e.g., by vertex or edge deletions and additions; such properties could be, for example, the connectivity or the shortest paths between two vertices. The main goal is that after an update the algorithm does not have to recompute the data structure from scratch, but only has to make a small number of changes to it. Due to strong conditional lower bounds for various dynamic graph problems (see [1, 16, 22]), it is necessary to restrict the dynamic model in some way to improve the efficiency of the operations. One model that has become increasingly popular is to study dynamic graph problems in a *sensitivity* or *emergency planning* setting (see, e.g., [10, 23, 7, 8, 4, 3, 21]): Instead of considering the general fully dynamic problem in which we get a sequence of updates and queries, we only allow for a single batch update of size d after which we want to answer queries. Since we allow only a single update, the update and query times for such sensitivity problems are much faster than for the general fully dynamic problem.

* The research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Programme (FP/2007-2013) / ERC Grant Agreement no. 340506.

In this paper, we consider the subgraph connectivity problem with sensitivity d: We get a graph $G = (V, E)$ of which some vertices are *activated* and some are *deactivated* and we can preprocess it. There is a single update changing the states of up to d vertices. In the subsequent queries we need to answer if two given vertices are connected by a path which traverses only activated vertices. If the update can only active previously deactivated vertices, then an algorithm for this problem is called *incremental*; if it can only deactivate activated vertices, then it is *decremental*; if it can turn vertices on and off arbitrarily, then it is called *fully dynamic*.

The problem is of high practical interest as it models a scenario which is very relevant to infrastructure problems. For example, assume you are an internet service provider and you maintain many hubs which are connected to each other. In case of a defect, some of the hubs fail but there is a small number of *backup* hubs which can be used until the defect hubs are repaired in order to provide your services to your customers. Notice that in such a scenario it is likely that the number of backup hubs is much smaller than the number of regular hubs.

1.1 Our Contributions

We present the first incremental and fully dynamic algorithms for the subgraph connectivitiy problem with sensitivity d. The update and query times of our fully dynamic algorithm are only slightly slower than those of the best decremental algorithm for this problem. In addition, the incremental algorithm is essentially tight with respect to the best known conditional lower bound for this problem. Additionally, we contribute a characterization of the paths which are added to a graph when activating some nodes.

Our result for the fully dynamic problem with sensitivity d is given in the following theorem. We state the running time with respect to a blackbox algorithm for the decremental version of the problem as subprocedure. The number of initially deactivated vertices is denoted by n_{off}.

▶ **Theorem 1.** *Assume there exists an algorithm for the decremental subgraph connectivity problem with sensitivity d that has preprocessing time t_p, update time t_u, query time t_q and uses space S. Then there exists an algorithm for the fully dynamic subgraph connectivity problem with sensitivity d that uses space $O(n_{\mathit{off}}^2 \cdot S)$ and has preprocessing time $O(n_{\mathit{off}}^2 \cdot t_p)$. It can process an update of d vertices in time $O(d^2 \cdot \max\{t_u, t_q\})$ and queries in time $O(d \cdot t_q)$.*

For the decremental version of the subgraph connectivity problem with sensitivity d (which is also referred to as *d-failure connectivity*), the best known algorithm is by Duan and Pettie [11]. Their result is given in the following lemma.

▶ **Lemma 2** ([11]). *Let $G = (V, E)$ be a graph and let $n = |V|$, $m = |E|$, let $c \in \mathbb{N}$. Then there exists a data structure for the decremental subgraph connectivity problem with sensitivity d that has size $S = O(d^{1-2/c} m n^{1/c-1/(c \log(2d))} \log^2 n)$ and preprocessing time $\tilde{O}(S)$. An update deactivating d vertices takes time $O(d^{2c+4} \log^2 n \log\log n)$ and subsequent connectivity queries in the graph after the vertex deactivations take $O(d)$ time.*

As pointed out in [11], for moderate values of d the space S used by the data structure from Lemma 2 is $o(mn^{1/c})$; further, if $m < n^2$, then we always have $S = o(mn^{2/c})$. Using the algorithm of Lemma 2 as a subprocedure for our result from Theorem 1, we obtain the following corollary. The number of initially activated vertices is given by n_{on} and the number of initially activated edges in the graph is denoted by m_{on}.

▶ **Corollary 3.** *There exists an algorithm for the fully dynamic subgraph connectivity problem with sensitivity d with the following properties. For any $c \in \mathbb{N}$, it uses space $S' = O(n_{\mathit{off}}^2 \cdot S)$ and preprocessing time $\tilde{O}(S')$, where $S = O(d^{1-2/c} m_{on} n_{on}^{1/c-1/(c\log(2d))} \log^2 n_{on})$. It can process an update of d vertices in time $O(d^{2c+6} \log^2 n_{on} \log\log n_{on})$ and answer queries in the updated graph in time $O(d^2)$.*

In the case that we get an update of size $d' < d$, we can make the update and query times of the data structure depend only on d': We build the data structure for all values $d' = 2^1, \dots, 2^\ell$, where ℓ is the smallest integer such that $d \leq 2^\ell$. Asymptotically this will not use more space than building the data structure once for d; for an update of size d' we use the instance of the data structure for the smallest $2^i \geq d'$.

In the incremental algorithm we only allow for initially deactivated vertices to be activated. Our result for the incremental problem is given in the following theorem.

▶ **Theorem 4.** *There exists an algorithm for the incremental subgraph connectivity problem with sensitivity d which has preprocessing time $O(n_{\mathit{off}}^2 \cdot n_{on} + m)$, update time $O(d^2)$ and query time $O(d)$. It uses space $O(n_{\mathit{off}} \cdot n)$.*

The algorithm is simple and we believe it is implementable and efficient in practice.

For our incremental data structure the sensitivity parameter d does not have to be fixed beforehand, i.e., once initialized, the data structure can process updates of arbitrary sizes and the update and query times will only depend on the size of the given update.

We observe that the conditional lower bound given in Henzinger et al. [16] for the decremental version of the problem can easily be altered to work for the incremental problem as well. The conditional lower bound states that under the Online Matrix vector (OMv) conjecture any algorithm solving the incremental subgraph connectivity problem with sensitivity d which uses preprocessing time polynomial in n and and update time polynomial in d must have a query time of $\Omega(d^{1-\varepsilon})$ for all $\varepsilon > 0$. Examining the proof of the lower bound, we observed that the maximum of the query and update time even has to be in $\Omega(d^{2-\varepsilon})$ for all $\varepsilon > 0$. Hence, the update and query times of our incremental algorithm are essentially optimal under the OMv conjecture.

1.2 Related Work

In recent years there have been several results studying data structures for problems in an emergency planning or sensitivity setting when only a single update of small size is allowed. The field was introduced by Patrascu and Thorup [23] who considered connectivity queries after d edge failures. Demetrescu et al. [8] studied distance oracles avoiding a single failed node or edge. This setting was also considered by Bernstein and Karger [3, 4]. Later, Duan and Pettie [10] studied distance and connectivity oracles in case of two vertex failures. Khanna and Baswana [21] studied approximate shortest paths for a single vertex failure. As mentioned in Section 1.1, Duan and Pettie [11] studied the decremental subgraph connectivity problem with sensitivity d. Chechik et al. [7] considered distance oracles and routing schemes in case of d edge failures.

For the decremental subgraph connectivity problem with sensitivity d there also exist conditional lower bounds by Henzinger et al. [16] from the OMv conjecture and most recently by Kopelowitz, Pettie and Porat [22] from the 3SUM conjecture. The highest conditional lower bounds is the one in [16], which states that under the OMv conjecture any algorithm using preprocessing time polynomial in n and and update time polynomial in d must have a query time of $\Omega(d^{1-\varepsilon})$ for all $\varepsilon > 0$. Hence, the query time of the decremental algorithm by Duan and Pettie [11] is essentially optimal with respect to the lower bound.

The general subgraph connectivity problem, which allows for an arbitrary number of updates, has gained an increasing interest during the last years. The problem was introduced by Frigoni and Italiano [14], who studied it for planar graphs; they achieved amortized polylogarithmic update and query times. In general graphs, Duan [9] constructed a data structure which uses almost linear space, preprocessing time $\tilde{O}(m^{6/5})$, worst-case update time $\tilde{O}(m^{4/5})$ and worst-case query time $\tilde{O}(m^{1/5})$. In an amortized setting, the data structure given by Chan, Patrascu and Roditty [6] has an update time $\tilde{O}(m^{2/3})$ and query time $\tilde{O}(m^{1/3})$; its space usage and preprocessing time is $\tilde{O}(m^{4/3})$. This improved an earlier result by Chan [5] significantly. The data structure of [6] was later improved by Duan [9] to use only $\tilde{O}(m)$ space. Baswana et al. [2] gave a deterministic worst-case algorithm with update time $\tilde{O}(\sqrt{mn})$ and query time $O(1)$. Further, conditional lower bounds were derived for the subgraph connectivity problem from multiple conjectures [1, 16]. The highest such lower bound was given in [16]; it states that under the OMv conjecture, the subgraph connectivity problem cannot be solved faster than with update time $\Omega(m^{1-\delta})$ and query time $\Omega(m^{\delta})$ for any $\delta \in (0, 1)$ when we only allow polynomial preprocessing time of the input graph. Hence, the update and query times of the aforementioned algorithms are optimal up to polylogarithmic factors and tradeoffs between update and query times.

Compared to the subgraph connectivity problem, it has a much longer tradition to study the (edge) connectivity problem in which updates delete or add edges to the graph. Henzinger and King [17] were the first to give an algorithm with expected polylogarithmic update and query times; the best algorithm using Las Vegas randomization is by Thorup [24] with an amortized update time of $O(\log n(\log\log n)^3)$. Holm, de Lichtenberg and Thorup [18] gave the first deterministic algorithm with amortized polylogarithmic update times; currently the best such algorithm is given by Wulff-Nilsen [25] which has an update time of $O(\log^2 n/\log\log n)$. Recently, Kapron, King and Mountjoy [19] were able to provide the first data structure which has expected *worst case* polylogarithmic time per update and query. The result of [19] was lately improved by Gibb et al. [15] to have update time $O(\log^4 n)$. However, the best deterministic worst case data structures still have running times polynomial in the number of nodes of the graph. For a long time the results by Frederickson [13] and Eppstein et al. [12] running in time $O(\sqrt{n})$ were the best known. Only recently this was slightly improved by Kejlberg-Rasmussen et al. [20], who were able to obtain a worst case update time of $O\left(\sqrt{\frac{n(\log\log n)^2}{\log n}}\right)$.

The rest of the paper is outlined as follows: We start with notation and preliminaries in Section 2. In Section 3 we prove the results for the incremental algorithm which will already contain the main ideas for the more complicated fully dynamic algorithm. Section 4 provides the main result of this paper.

2 Preliminaries

In this section, we formally introduce the subgraph connectivity problem with sensitivity d. At the end of the section, we show a lemma that characterizes when disconnected vertices become connected after activating additional vertices; the lemma will be essential to prove the correctness of our algorithms.

The *subgraph connectivity problem* with sensitivity d is as follows: Let $G = (V, E)$ be a graph with n vertices and m edges and a partition of the vertices into sets V_{on} and V_{off}. The vertices in V_{on} are said to be *turned on* or *activated* and those in V_{off} are said to be *turned* *off* or *deactivated*. We get a single batch update in which the states of up to d vertices are be changed. In a query for two vertices u and v, the algorithm has to return if there exists a path from u to v only traversing activated vertices.

As we consider the subgraph connectivity problem in a sensitivity setting, after processing a single update and a sequence of queries, we roll back to the initial input graph. Hence, the data structure does not allow to alter the graph by an arbitrary amount. This allows us to offer much faster update and query times than the best algorithms which solve the general fully dynamic problem.

We introduce more notation. By G_{on} we denote the projection of G on the vertices which are initially on, i.e., $G_{\text{on}} = G[V_{\text{on}}] = (V_{\text{on}}, E_{\text{on}})$, where $E_{\text{on}} = \{(u,v) \in E : u, v \in V_{\text{on}}\}$. We set $E_{\text{off}} = E \setminus E_{\text{on}}$ to the set of edges which have at least one endpoint in V_{off}. To distinguish between the sizes of the activated and deactivated vertices and edges, we set $n_{\text{on}} = |V_{\text{on}}|$ to the number of activated vertices and $n_{\text{off}} = |V_{\text{off}}|$ to the number of deactivated vertices. Further, we set $m_{\text{on}} = |E_{\text{on}}|$ to the number of edges in G_{on} and $m_{\text{off}} = |E_{\text{off}}|$.

With this notation we can quickly describe the main difficulties of the subgraph connectivity problem: If G_{on} is connected, then already deactivating a single vertex of V_{on} can make it fall apart into $\Theta(n_{\text{on}})$ connected components; on the other hand, in G_{on} we can have $\Theta(n_{\text{on}})$ connected components initially and activating a single vertex of V_{off} with $\Theta(n_{\text{on}})$ edges can make the resulting graph connected. Hence, when deactivating or activating vertices, the number of connected components can change arbitrarily much. However, the update and query times of our algorithms are not supposed to polynomially depend on n, but only on the size of the udpate d which will usually be much smaller.

2.1 Characterisation of Paths After Activating Vertices

In this subsection, we introduce the terminology to characterize when vertices in a graph G become connected after we activated the vertices of a set I.

We say that a deactivated vertex $v \in V_{\text{off}}$ and a connected component C of G are *adjacent*, if there exists a vertex $u \in C$ such that $(u, v) \in E$. Two vertices $u, v \in V_{\text{off}}$ are *connected via a connected component*, if (1) there exists a connected component C to which both u and v are adjacent or (2) if $(u, v) \in E$. In other words, u and v are connected via a connected component if they can reach each other by a path that only traverses vertices from a single connected component of G or if u and v are connected by an edge. Two connected components $C_1 \neq C_2$ are *connected by the set* I if there exists a sequence of vertices $v_1, \dots, v_k \in I$ such that (1) v_1 is adjacent to C_u, (2) v_k is adjacent to C_v and (3) v_i and v_{i+1} are connected via a connected component for all $i = 1, \dots, k-1$.

We can characterize when two disconnected vertices become connected in G after the vertices of the set I are activated. This is done in the following lemma.

▶ **Lemma 5.** *Let $G = (V, E)$ be a graph with V_{on} and V_{off} as before. Further, let $I \subseteq V_{off}$ be a set of vertices which is activated. Let u, v be two disconnected vertices in G_{on} and let $C_u \neq C_v$ be their connected components. Then u and v are connected in G after activating the vertices in I if and only if C_u and C_v are connected by the set I.*

Proof. Assume u and v are connected in G after activating the vertices in I. Then there exists a path $u = w_0 \to w_1 \to \cdots \to w_\ell \to w_{\ell+1} = v$ in G; let $w_{j_1}, \dots, w_{j_r}$ be the vertices of the path which are from the set I with $j_i < j_{i+1}$ for all $i = 1, \dots, r$. Now observe that for all i, the vertices $w_{j_i+1}, \dots, w_{j_{i+1}-1}$ must be in the same connected component C_{j_i}. Clearly, w_{j_i} and $w_{j_{i+1}}$ are adjacent to C_{j_i} and they are connected by the connected component C_{j_i}.

The same arguments can be used to show that C_u and w_{j_1} are adjacent and to show that C_v and w_{j_r} are adjacent. This implies that C_u and C_v are connected by the set I.

The other direction of the proof is symmetric. ◀

We will use Lemma 5 to argue about the correctness of our algorithms. In particular, when we prove the correctness of our algorithms we show that the connected components of the query vertices become connected by the set I of newly activated vertices. This is useful as we can preprocess which vertices of V_{off} are connected via connected components and which deactivated vertices are reachable from the connected components of G. With these properties, we are able to avoid having to keep track of all connected components of G after an update.

3 Incremental Algorithm

In this section, we describe an algorithm for the incremental subgraph connectivity problem that has preprocessing time $O(n_{\text{off}}^2 \cdot n_{\text{on}} + m)$, update time $O(d^2)$, query time $O(d)$ and uses space $O(n_{\text{off}} \cdot n)$. This will prove Theorem 4 stated in the introduction.

The main idea of the algorithm is to exploit Lemma 5 by preprocessing which deactivated vertices are connected by connected components of G_{on} and preprocessing the adjacency of deactivated vertices and connected components of G_{on}.

3.1 Preprocessing

We first compute the connected components $C_1, \dots, C_k$ of G_{on} and label each vertex in V_{on} with its connected component. For each connected component C_i, we use a binary array A_{C_i} of size n_{off} to store which vertices in V_{off} are adjacent to C_i. We further equip each vertex $u \in V_{\text{off}}$ with a binary array A_u of size $k + n_{\text{off}} = O(n)$: In the first k entries of A_u, we store to which connected components u is connected; in the final n_{off} components of A_u, we store to which $v \in V_{\text{off}}$ the vertex u is connected by a connected component.

When the algorithm performs updates, it uses the arrays A_u to determine in constant time if u is connected to other deactivated vertices from V_{off} via connected components. This avoids having to check all connected components C_i of the vertex u which could take time $\Theta(n_{\text{on}})$.

The preprocessing takes time $O(m_{\text{on}})$ to compute the connected components C_i and labeling the vertices in V_{on}. Using one pass over all edges we can compute the arrays containing the connectivity information between the C_i and V_{off}, i.e., we can fill the arrays A_{C_i} and the first k components of the A_u. This takes $O(m)$ time.

Notice that if u is adjacent to C_i, then A_u must have a 1 wherever A_{C_i} has a 1. Then to finish building the arrays A_u, we can compute the last n_{off} entries of A_u as the bitwise OR of the arrays A_{C_i} for all C_i which u is adjacent to. This can be done in time $O(k \cdot n_{\text{off}}) = O(n_{\text{on}} \cdot n_{\text{off}})$ for a single vertex u. Since we have n_{off} vertices in V_{off}, computing all A_u takes time $O(n_{\text{off}}^2 \cdot n_{\text{on}})$. The computation of the A_u therefore dominates the running time of the preprocessing.

The space we require during the preprocessing is $O(n_{\text{off}})$ for each connected component of G_{on} and $O(n)$ for each vertex in V_{off}. Hence, in total we require $O(n_{\text{off}} \cdot n)$ space and preprocessing time $O(n_{\text{off}}^2 \cdot n_{\text{on}} + m)$.

3.2 Updates

During an update which activates d vertices from a set I, we build the *increment graph S* with the vertices of I as its nodes. We add an edge between a pair of vertices $u, v \in I$ if they are connected by a connected component C of G_{on}. Notice that the increment graph encodes the connectivity of the vertices in I via the connected components of G_{on}.

Computationally, this can be done in time $O(d^2)$: For each pair of vertices $u, v \in I$, we check in A_u if u is connected to v via a connected component in time $O(1)$. As we have to consider $O(d^2)$ pairs of vertices, the total time to construct the increment graph is $O(d^2)$.

Finally, we compute the connected components $S_1, \dots, S_\ell$ of S and label each vertex in S with its connected component. This can be done in time $O(|S|) = O(d^2)$. Hence, the total update time is $O(d^2)$.

3.3 Queries

Consider a query if two activated vertices u and v are connected.

We find the connected components C_u and C_v of u and v, respectively. If $C_u = C_v$, then we return that u and v are connected and we are done.

Otherwise, let S_i be a connected component of S. We consider each vertex w of S_i and check if it is connected to C_u or C_v using A_{C_u} and A_{C_v}. After considering all vertices of S_i, we check if both C_u and C_v are connected to S_i. If this is the case, we return that u and v are connected, otherwise, we proceed to the next connected component of S.

During the query we considered each vertex in S exactly once and spent time $O(1)$ processing it. Hence, the total query time is $O(d)$.

It is left to prove the correctness of the result of the queries. This is done in the following lemma.

▶ **Lemma 6.** *Consider an update which activates the vertices from a set $I \subseteq V_{\text{off}}$. Then a query if two vertices u and v are connected in G after the update delivers the correct result.*

Proof. If in the query procedure we encountered that $C_u = C_v$, then the result of the algorithm is clearly correct.

If $C_u \neq C_v$, then observe that the algorithm returns true if and only if C_u and C_v are connected by the set I: Let S_i be the connected component of S for which the query returns true. Then there must exist vertices $w_1, \dots, w_t$ in the increment graph such that (1) w_1 is adjacent to C_u, (2) w_t is adjacent to C_v and (3) (w_i, w_{i+1}) is an edge in S for all $i = 1, \dots, t-1$. The first two claims are true because the query procedure checks this in the arrays A_{C_u} and A_{C_v}. By construction of the increment graph, the increment graph has an edge (w_i, w_{i+1}) if and only if those vertices are connected by a connected component (this follows from what we preprocessed in the arrays A_{w_i}). This implies that a query returns true iff C_u and C_v are connected by the set I.

By Lemma 5 the algorithm returns the correct answer. ◀

4 Fully Dynamic Algorithm

In this section, we present the main result of the paper. We provide a data structure for the fully dynamic subgraph connectivity problem with sensitivity d, i.e., we process a batch update which changes the states of at most d vertices. Our algorithm uses a data structure for the decremental problem as a subprocedure. Assume the decremental algorithm uses space S, preprocessing time t_p, update time t_u and query time t_q. Then the fully dynamic algorithm uses space $O(n_{\text{off}}^2 \cdot S)$, preprocessing time $O(n_{\text{off}}^2 \cdot t_p)$, update time $O(d^2 \cdot \max\{t_u, t_q\})$ and query time $O(d \cdot t_q)$.

We reuse the increment graphs which we used in the incremental algorithm. For the construction of the increment graphs we replace the vectors A_u and A_{C_i} of the previous section by slightly augmented versions of G_{on} which are equipped with a decremental subgraph connectivity data structure, e.g., the one of Lemma 2 by Duan and Pettie [11]. The purpose of the augmented graphs is to check if a pair of initially deactivated vertices is connected via a connected component after deactivating some vertices of V_{on}.

We sketch the main steps of our algorithm. In the preprocessing we build an augmented graph for each pair of vertices of V_{off}; each augmented graph is equipped with a decremental subgraph connectivity data structure. In an update, we first process the vertex deactivations in the augmented graphs. Then we build the increment graph of vertices that were activated. Queries are handled similarly to the incremental algorithm by using the increment graph, but we have to check if the vertices of the increment graph can still reach the query vertices (this connectivity may have been destroyed by the vertex deactivations).

4.1 Preprocessing

For each pair of nodes $u, v \in V_{\text{off}}$, we build the augmented graph $G_{u,v} = G[V_{\text{on}} \cup \{u, v\}]$, i.e., $G_{u,v}$ consists of G_{on} after adding u and v. Observe that u and v cannot introduce more than $O(n_{\text{on}})$ edges and hence $G_{u,v}$ still has $O(n_{\text{on}})$ vertices and $O(m_{\text{on}})$ edges. We equip $G_{u,v}$ with a decremental subgraph connectivity data structure with sensitivity d. Later, we use the graph $G_{u,v}$ to check if u and v are connected via a connected component after deleting vertices from G_{on}; intuitively, the graphs $G_{u,v}$ replace the vectors A_u and A_v of the incremental algorithm. We need space $O(n_{\text{off}}^2 \cdot S)$ to store the $G_{u,v}$ where S is the space to store G_{on} with the decremental data structure.

For each $u \in V_{\text{off}}$, we build the graph $G_u = G[V_{\text{on}} \cup \{u\}]$ and equip it with the decremental data structure; we further equip G_{on} with the decremental data structure. We use the graphs G_u to replace the arrays A_{C_i} of the incremental algorithm; we cannot use the arrays anymore because the connected components of G_{on} can fall apart due to vertex deactivations. The space we need to store the graphs G_u and G is $O(n_{\text{off}} \cdot S)$.

In total, the preprocessing takes space $O(n_{\text{off}}^2 \cdot S)$ and time $O(n_{\text{off}}^2 \cdot t_p)$.

4.2 Updates

Assume that we get an update U which deactivates the vertices of a set $D \subseteq V_{\text{on}}$ and activates the vertices of a set $I \subseteq V_{\text{off}}$ with $|D| + |I| \leq d$. Our update procedure has two steps: We first remove the vertices in D from $G_{u,v}$ for all newly activated vertices $u, v \in I$. After that we build the increment graph consisting of the vertices of I as we did in the incremental algorithm.

We describe the sketched steps of the update procedure in more detail. Firstly, we process the deletions of the set D. For each pair $u, v \in I$, we delete the vertices of D in $G_{u,v}$ in time t_u. Since we have $O(d^2)$ pairs of vertices of I to consider, this takes time $O(d^2 \cdot t_u)$.

We update G_{on} and all G_u by deleting the vertices the vertices from D. This does not take longer than updating the graphs $G_{u,v}$.

Secondly, we build the increment graph consisting of the vertices in I. For each pair of vertices $u, v \in I$, we add an edge $e = (u, v)$ to the increment graph if a query in $G_{u,v}$ returns that u and v are connected. Such a query takes time t_q. The time we spend to build the increment graph is $O(d^2 \cdot t_u)$. Finally, we compute the connected components of the increment graph in time $O(d^2)$.

Altogether, the total update time of the update procedure is $O(d^2 \cdot \max\{t_u, t_q\})$.

4.3 Queries

We handle the query if two vertices u and v of G are connected similarly as in the incremental algorithm by using the increment graph.

Before we use the increment graph, we query if u and v are connected in the instance of G_{on} in which we deactivated the vertices of the set D. If the query returns true, then u and v are connected, otherwise, we proceed by using the increment graph.

For each connected component B of the increment graph, we consider each vertex $w \in B$ and we query in G_w if w is connected to u or v. If B had vertices w, w' which are connected to u and v, respectively, then we return that u and v are connected. Otherwise, we proceed to the next connected component of the increment graph.

The total query time of our algorithm is $O(d \cdot t_q)$ as in the worst case we have to perform a query in G_w for each of the $O(d)$ vertices $w \in I$.

Notice that due to the vertex deactivations we cannot precompute the connected components C_i of G_{on} and their connectivity with vertices in V_{off} as we did in the incremental algorithm: Each C_i may consist of $\Theta(n_{\text{on}})$ vertices and might as well fall apart into $\Theta(n)$ connected components after the vertex deactivations. Hence, in the update procedure we cannot keep the information about the connectivity of the vertices C_i and the added vertices up to date, as this may take time $\Theta(n)$. For our construction this also rules out obtaining a better query time.

We conclude the section by proving that the query returns the correct results in the following lemma.

▶ **Lemma 7.** *Consider an update U deactivating the vertices from a set D and activating the ones from a set I. Then a query if two vertices u and v are connected in G after the update delivers the correct result.*

Proof. In the query procedure, we first check if u and v are connected in G_{on} after deleting the vertices from D. Clearly, if the algorithm returns true, then u and v are connected.

We move on to argue about the correctness in the case that u and v are not connected in the graph $H = G_{\text{on}} \setminus D$. Let $C_1, \dots, C_k$ be the connected components of H (not those of G_{on}) and let C_u and C_v be the connected components of u and v. We show that a query returns that u and v are connected if and only if C_u and C_v are connected by the set I. Then Lemma 5 implies the correctness of the algorithm.

Observe that a query returns that u and v are connected if and only if there exists a connected component B in the increment graph which contains vertices $w_1, \dots, w_\ell \in B \subseteq I$, such that (1) w_1 is connected to u, (2) w_ℓ is connected to v and (3) there is an edge between w_i and w_{i+1} in the increment graph for all $i = 1, \dots, \ell - 1$: We obtain the first two properties from the queries in G_{w_1} and G_{w_ℓ}; the third property is true due to the queries in the augmented graphs $G_{w_i, w_{i+1}}$ and implies that the w_i are connected via connected components.

Hence, we conclude that a query returns that u and v are connected if and only if C_u and C_v are connected by the set I. Lemma 5 implies that the algorithm is correct. ◀

Abstract

Makespan minimization in restricted assignment $(R|p_{ij} \in \{p_j, \infty\}|C_{\max})$ is a classical problem in the field of machine scheduling. In a landmark paper in 1990 [9], Lenstra, Shmoys, and Tardos gave a 2-approximation algorithm and proved that the problem cannot be approximated within 1.5 unless P=NP. The upper and lower bounds of the problem have been essentially unimproved in the intervening 25 years, despite several remarkable successful attempts in some special cases of the problem [2, 3, 13] recently.

In this paper, we consider a special case called *graph-balancing with light hyper edges*, where heavy jobs can be assigned to at most two machines while light jobs can be assigned to any number of machines. For this case, we present algorithms with approximation ratios strictly better than 2. Specifically,

- **Two job sizes**: Suppose that light jobs have weight w and heavy jobs have weight W, and $w < W$. We give a 1.5-approximation algorithm (note that the current 1.5 lower bound is established in an even more restrictive setting [1, 4]). Indeed, depending on the specific values of w and W, sometimes our algorithm guarantees sub-1.5 approximation ratios.
- **Arbitrary job sizes**: Suppose that W is the largest given weight, heavy jobs have weights in the range of $(\beta W, W]$, where $4/7 \leq \beta < 1$, and light jobs have weights in the range of $(0, \beta W]$. We present a $(5/3 + \beta/3)$-approximation algorithm.

Our algorithms are purely combinatorial, without the need of solving a linear program as required in most other known approaches.

1 Introduction

Let $\mathcal{J}$ be a set of n jobs and $\mathcal{M}$ a set of m machines. Each job $j \in \mathcal{J}$ has a *weight* w_j and can be assigned to a specific subset of the machines. An assignment $\sigma : \mathcal{J} \to \mathcal{M}$ is a mapping where each job is mapped to a machine to which it can be assigned. The objective is to minimize the *makespan*, defined as $\max_{i \in \mathcal{M}} \sum_{j:\sigma(j)=i} w_j$. This is the classical MAKESPAN MINIMIZATION IN RESTRICTED ASSIGNMENT $(R|p_{ij} \in \{p_j, \infty\}|C_{\max})$, itself a special case of the MAKESPAN MINIMIZATION IN UNRELATED MACHINES $(R||C_{\max})$, where a job j has possibly different weight w_{ij} on different machines $i \in \mathcal{M}$. In the following, we just call them RESTRICTED ASSIGNMENT and UNRELATED MACHINE PROBLEM for short.

The first constant approximation algorithm for both problems is given by Lenstra, Shmoys, and Tardos [9] in 1990, where the ratio is 2. They also show that RESTRICTED ASSIGNMENT (hence also the UNRELATED MACHINE PROBLEM) cannot be approximated within 1.5 unless P=NP, even if there are only two job weights. The upper bound of 2 and the lower bound of 1.5 have been essentially unimproved in the intervening 25 years. How to close the gap continues to be one of the central topics in approximation algorithms. The recent book of Williamson and Shmoys [15] lists this as one of the ten open problems.

Our Result

We consider a special case of RESTRICTED ASSIGNMENT, called GRAPH BALANCING WITH LIGHT HYPER EDGES, which is a generalization of the GRAPH BALANCING problem introduced by Ebenlendr, Krčál and Sgall [4]. There the restriction is that every job can be assigned to only two machines, and hence the problem can be interpreted in a graph-theoretic way: each machine is represented by a node, and each job is represented by an edge. The goal is to find an orientation of the edges so that the maximum weight sum of the edges oriented towards a node is minimized. In our problem, jobs are partitioned into *heavy* and *light*, and we assume that heavy jobs can go to only two machines while light jobs can go to any number of machines[1]. In the graph-theoretic interpretation, light jobs are represented by hyper edges, while heavy jobs are represented by regular edges.

We present approximation algorithms with performance guarantee *strictly better than* 2 in the following settings. For simplicity of presentation, we assume that all job weights w_j are integral (this assumption is just for ease of exposition and can be easily removed).

Two job sizes: Suppose that heavy jobs are of weight W and light jobs are of weight w, and $w < W$. We give a 1.5-approximation algorithm, matching the general lower bound of RESTRICTED ASSIGNMENT (it should be noted that this lower bound is established in an even more restrictive setting [1, 4], where all jobs can only go to two machines and job weights are 1 and 2). This is the first time the lower bound is matched in a nontrivial case of RESTRICTED ASSIGNMENT (without specific restrictions on the job weight values). In fact, sometimes our algorithm achieves an approximation ratio strictly better than 1.5. Supposing that $w \leq \frac{W}{2}$, the ratio we get is $1 + \frac{\lfloor W/2 \rfloor}{W}$.

Arbitrary job sizes: Suppose that $\beta \in [4/7, 1)$ and W is the largest given weight. A heavy job has weight in $(\beta W, W]$ while a light job has weight in $(0, \beta W]$. We give a $(5/3 + \beta/3)$-approximation algorithm.

Both algorithms have the running time of $\mathcal{O}\big(n^2 m^3 \log\big(\sum_{j\in\mathcal{J}} w_j\big)\big)$.[2]

The general message of our result is clear: as long as the heaviest jobs have only two choices, it is relatively easy to break the barrier of 2 in the upper bound of RESTRICTED ASSIGNMENT. This should coincide with our intuition. The heavy jobs are in a sense the "trouble-makers". A mistake on them causes bigger damage than a mistake on lighter jobs. Restricting the choices of the heavy jobs thus simplifies the task.

[1] If some jobs can be assigned to just one machine, then it is the same as saying a machine has some *dedicated load*. All our algorithms can handle arbitrary dedicated loads on the machines.

[2] For simplicity, here we upper bound $\sum_{j\in\mathcal{J}} a_j$, where a_j is the number of the machines j can be assigned to, by nm.

The original GRAPH BALANCING problem assumes that all jobs can be assigned to only two machines and the algorithm of Ebenlendr et al. [4] gives a 1.75-approximation. According to [11], their algorithm can be extended to our setting: given any $\beta \in [0.5, 1)$, they can obtain a $(3/2 + \beta/2)$-approximation. Although this ratio is superior to ours, let us emphasize two interesting aspects of our approach.

(1) The algorithm of Ebenlendr et al. requires solving a linear program (in fact, almost all known algorithms for the problem are LP-based), while our algorithms are purely combinatorial. In addition to the advantage of faster running time, our approach introduces new proof techniques (which do not involve linear programming duality).

(2) In GRAPH BALANCING, Ebenlendr et al. showed that with only two job weights and dedicated loads on the machines, their strongest LP has the integrality gap of 1.75, while we can break the gap. Our approach thus offers a possible angle to circumvent the barrier posed by the integrality gap, and has the potential of seeing further improvement.

Before explaining our technique in more detail, we should point out another interesting connection with a result of Svensson [13] for general RESTRICTED ASSIGNMENT. He gave two local search algorithms, which terminate (but it is unknown whether in polynomial time) and (1) with two job weights $\{\epsilon, 1\}$, $0 < \epsilon < 1$, the returned solution has an approximation ratio of $5/3 + \epsilon$, and (2) with arbitrary job weights, the returned solution has an approximation ratio of ≈ 1.94. It is worth noting that his analysis is done via the primal-duality of the configuration-LP (thus integrality gaps smaller than two for the configuration-LP are implied). With two job weights, our algorithm has some striking similarity to his algorithm – but it should be emphasized that the two algorithms behave differently. We are able to prove our algorithm terminates in polynomial time – but our setting is more restrictive. A very interesting direction for future work is to investigate how the ideas in the two algorithms can be related and combined.

Our Technique

Our approach is inspired by that of Gairing et al. [5] for general RESTRICTED ASSIGNMENT. So let us first review their ideas. Suppose that a certain optimal makespan t is guessed. Their core algorithm either (1) correctly reports that t is an underestimate of OPT, or (2) returns an assignment with makespan at most $t + W - 1$. By a binary search on the smallest t for which an assignment with makespan $t + W - 1$ is returned, and the simple fact that $\text{OPT} \geq W$, they guarantee the approximation ratio of $\frac{t+W-1}{\text{OPT}} \leq 1 + \frac{W-1}{\text{OPT}} \leq 2 - \frac{1}{W}$ (the first inequality holds because t is the smallest number an assignment is returned by the core algorithm). Their core algorithm is a preflow-push algorithm. Initially all jobs are arbitrarily assigned. Their algorithm tries to redistribute the jobs from overloaded machines, i.e., those with load more than $t + W - 1$, to those that are not. The redistribution is done by pushing the jobs around while updating the height labels (as commonly done in preflow-push algorithms). The critical thing is that after a polynomial number of steps, if there are still some overloaded machines, they use the height labels to argue that t is a wrong guess, i.e., $\text{OPT} \geq t + 1$. Our contribution is a refined core algorithm in the same framework. With a guess t of the optimal makespan, our core algorithm either (1) correctly reports that $\text{OPT} \geq t + 1$, or (2) returns an assignment with makespan at most $(5/3 + \beta/3)t$.

We divide all jobs into two categories, the *rock jobs* $\mathbb{R}$, and the *pebble jobs* $\mathbb{P}$ (not to be confused with heavy and light jobs). The former consists of those with weights in $(\beta t, t]$ while the latter includes all the rest. We use the rock jobs to form a graph $G_{\mathbb{R}} = (V, \mathbb{R})$, and assign the pebbles arbitrarily to the nodes. Our core algorithm will push around the pebbles so as to redistribute them. Observe that as $t \geq W$, all rocks are heavy jobs. So the formed graph $G_{\mathbb{R}}$ has only simple edges (no hyper edges). As $\beta \geq 4/7$, if OPT $\leq t$, then every node can receive at most one rock job in the optimal solution. In fact, it is easy to see that we can simply assume that the formed graph $G_{\mathbb{R}}$ is a disjoint set of trees and cycles. Our entire task boils down to the following:

> Redistribute the pebbles so that there exists an orientation of the edges in $G_{\mathbb{R}}$ in which each node has total load (from both rocks and pebbles) at most $(5/3 + \beta/3)t$; and if not possible, gather evidence that t is an underestimate.

Intuitively speaking, our algorithm maintains a certain *activated set* $\mathbb{A}$ of nodes. Initially, this set includes those nodes whose total loads of pebbles cause conflicts in the orientation of the edges in $G_{\mathbb{R}}$. A node "reachable" from a node in the activated set is also included into the set. (Node u is reachable from node v if a pebble in v can be assigned to u.) Our goal is to push the pebbles among nodes in $\mathbb{A}$, so as to remove all conflicts in the edge orientation. Either we are successful in doing so, or we argue that the total load of all pebbles currently owned by the activated set, together with the total load of the rock jobs assigned to $\mathbb{A}$ in any *feasible orientation* of the edges in $G_{\mathbb{R}}$ (an orientation in $G_{\mathbb{R}}$ is *feasible* if every node receives at most one rock), is strictly larger than $t \cdot |\mathbb{A}|$. The progress of our algorithm (hence its running time) is monitored by a potential function, which we show to be monotonically decreasing.

The most sophisticated part of our algorithm is the "activation strategy". We initially add nodes into $\mathbb{A}$ if they cause conflicts in the orientation or can be (transitively) reached from such. However, sometimes we also include nodes that do not fall into the two categories. This is purposely done for two reasons: pushing pebbles from these nodes may help alleviate the conflict in edge orientation indirectly; and their presence in $\mathbb{A}$ strengthens the contradiction proof.

Due to the intricacy of our main algorithm, we first present the algorithm for the two job weights case in Section 3 and then present the main algorithm for the arbitrary weights in Section 4. The former algorithm is significantly simpler (with a straightforward activation strategy) and contains many ingredients of the ideas behind the main algorithm.

Due to the space limit, some of the proofs are omitted. Please refer to the full version [7] for details.

Related Work

For RESTRICTED ASSIGNMENT, besides the several recent advances mentioned earlier, see the survey of Leung and Li for other special cases [10]. For two job weights, Chakrabarti, Khanna and Li [2] showed that using the configuration-LP, they can obtain a $(2 - \delta)$-approximation for a fixed $\delta > 0$ (and note that there is no restriction on the number of machines a job can go to). Kolliopoulos and Moysoglou [8] also considered the two job weights case. In the GRAPH BALANCING setting (with two job weights), they gave a 1.652-approximation algorithm using a flow technique (thus they also break the integrality gap in [3]). They also show that the optimal makespan for RESTRICTED ASSIGNMENT with two job weights can be estimated in polynomial time within a factor of at most 1.883 (and this is further improved to 1.833 in [2]).

For UNRELATED MACHINES, Shchepin and Vakhania [12] improved the approximation ratio to $2 - 1/m$. A combinatorial 2-approximation algorithm was given by Gairing, Monien, and Woclaw [6]. Verschae and Wiese [14] showed that the configuration-LP has integrality gap of 2, even if every job can be assigned to only two machines. They also showed that it is possible to achieve approximation ratios strictly better than 2 if the job weights w_{ij} respect some constraints.

2 Preliminary

Let t be a guess of OPT. Given t, our two core algorithms either report that OPT $\geq t+1$, or return an assignment with makespan at most $1.5t$ or $(5/3+\beta/3)t$, respectively. We conduct a binary search on the smallest $t \in [W, \sum_{j\in\mathcal{J}} w_j]$ for which an assignment is returned by the core algorithms. This particular assignment is then the desired solution.

We now explain the initial setup of the core algorithms. In our discussion, we will not distinguish a machine and a node. Let $dl(v)$ be the dedicated load of v, i.e., the sum of the weights of jobs that can only be assigned to v. We can assume that $dl(v) \leq t$ for all nodes v. Let $\mathcal{J}' \subseteq \mathcal{J}$ be the jobs that can be assigned to at least two machines. We divide $\mathcal{J}'$ into rocks $\mathbb{R}$ and pebbles $\mathbb{P}$. A job $j \in \mathcal{J}'$ is a rock,

- in the 2 job weights case (Section 3), if $w_j > t/2$ and $w_j = W$;
- in the general job weights case (Section 4), if $w_j > \beta t$.

A job $j \in \mathcal{J}'$ that is not a rock is a pebble. Define the graph $G_{\mathbb{R}} = (V, \mathbb{R})$ as a graph with machines $\mathcal{M}$ as node set and rocks $\mathbb{R}$ as edge set. By our definition, a rock can be assigned to exactly two machines. So $G_{\mathbb{R}}$ has only simple edges (no hyper edges). For the sake of convenience, we call the rocks just "edges", avoiding ambiguity by exclusively using the term "pebble" for the pebbles.

Suppose that OPT $\leq t$. Then a machine can receive at most one rock in the optimal solution. If any connected component in $G_{\mathbb{R}}$ has more than one cycle, we can immediately declare that OPT $\geq t+1$. If a connected component in $G_{\mathbb{R}}$ has exactly one cycle, we can direct all edges away from the cycle and remove these edges, i.e., assign the rock to the node v to which it is directed. W.L.O.G, we can assume that this rock is part of v's dedicated load. (Also observe that then node v must become an isolated node). Finally, we can eliminate cycles of length 2 in $G_{\mathbb{R}}$ with the following simple reduction. If a pair of nodes u and v is connected by two distinct rocks $r1$ and $r2$, remove the two rocks, add $\min(w_{r1}, w_{r2})$ to both u's and v's dedicated load, and introduce a new pebble of weight $|w_{r1} - w_{r2}|$ between u and v. Let Ψ denote the set of orientations in $G_{\mathbb{R}}$ where each node has at most one incoming edge. We use a proposition to summarize the above discussion.

▶ **Proposition 1.** *We can assume that*

- *the rocks in $\mathbb{R}$ correspond to the edge set of the graph $G_{\mathbb{R}}$, and all pebbles can be assigned to at least two machines;*
- *the graph $G_{\mathbb{R}}$ consists of disjoint trees, cycles (of length more than 2), and isolated nodes;*
- *for each node $v \in V$, $dl(v) \leq t$;*
- *if OPT $\leq t$, then the orientation of the edges in $G_{\mathbb{R}}$ in the optimal assignment must be one of those in Ψ.*

3 The 2-Valued Case

In this section, we describe the core algorithm for the two job weights case, with the guessed makespan $t \geq W$. Observe that when $t \in [W, 2w)$, if OPT $\leq t$, then every node can receive at most one job (pebble or rock) in the optimal assignment. Hence, we can solve the problem exactly using the standard max-flow technique. So in the following, assume that $t \geq 2w$.

```
EXPLORE1
Initialize $\mathbb{A} := \{v | v$ is hypercritical, or $v$ is critical in a bad system$\}$.
    Set LEVEL$(v) := 0$ for all nodes in $\mathbb{A}$; $i := 0$.
While $\exists v \notin \mathbb{A}$ reachable from $\mathbb{A}$ do:
    $i := i + 1$.
    $\mathbb{A}_i := \{v \notin \mathbb{A} | v$ reachable from $\mathbb{A}\}$.
    $\mathbb{A}'_i := \{v \notin \mathbb{A} |\ v$ is critical in a good system and $\exists u \in \mathbb{A}_i$ in the same system$\}$.
    Set LEVEL$(v) := i$ for all nodes in $\mathbb{A}_i$ and $\mathbb{A}'_i$.
    $\mathbb{A} := \mathbb{A} \cup \mathbb{A}_i \cup \mathbb{A}'_i$.
For each node $v \notin \mathbb{A}$, set LEVEL$(v) = \infty$.
```

Figure 1 The procedure EXPLORE1.

Furthermore, let us first assume that $t < 2W$ (the case of $t \geq 2W$ will be discussed at the end of the section). Then the rocks have weight W and the pebbles have weight w. Initially, the pebbles are arbitrarily assigned to the nodes. Let $pl(v)$ be the total weight of the pebbles assigned to node v.

▶ **Definition 2.** A node v is

- *uncritical*, if $dl(v) + pl(v) \leq 1.5t - W - w$;
- *critical*, if $dl(v) + pl(v) > 1.5t - W$;
- *hypercritical*, if $dl(v) + pl(v) > 1.5t$.

(Notice that it is possible that a node is neither uncritical nor critical.)

▶ **Definition 3.** Each tree, cycle, or isolated node in $G_{\mathbb{R}}$ is a *system*. A system is *bad* if any of the following conditions holds.

- It is a tree and has at least two critical nodes, or
- It is a cycle and has at least one critical node, or
- It contains a hypercritical node.

A system that is not bad is *good*.

If all systems are good, then orienting the edges in each system such that every node has at most one incoming edge gives us a solution with makespan at most $1.5t$. So let assume that there is at least one bad system.

We next define the *activated set* $\mathbb{A}$ of nodes constructively. Roughly speaking, we will move pebbles around the nodes in $\mathbb{A}$ so that either there is no more bad system left, or we argue that, in every feasible assignment, *some* nodes in $\mathbb{A}$ cannot handle their total loads, thereby arriving at a contradiction.

In the following, if a pebble in u can be assigned to node v, we say v is reachable from u. Node v is reachable from $\mathbb{A}$ if v is reachable from any node $u \in \mathbb{A}$. A node added into $\mathbb{A}$ is *activated*.

Informally, all nodes that cause a system to be bad are activated. A node reachable from $\mathbb{A}$ is also activated. Furthermore, suppose that a system is good and it has a critical node v (thus the system cannot be a cycle). If any other node u in the same system is activated, then so is v. We now give the formal procedure EXPLORE1 in Figure 1. Notice that in the process of activating the nodes, we also define their *levels*, which will be used later for the algorithm and the potential function.

The next proposition follows straightforwardly from EXPLORE1.

▶ **Proposition 4.** *The following holds.*

1. *All nodes reachable from $\mathbb{A}$ are in $\mathbb{A}$.*
2. *Suppose that v is reachable from $u \in \mathbb{A}$. Then $\textsc{Level}(v) \leq \textsc{Level}(u) + 1$.*
3. *If a node v is critical and there exists another node $v' \in \mathbb{A}$ in the same system, then $\textsc{Level}(v) \leq \textsc{Level}(v')$.*
4. *Suppose that node $v \in \mathbb{A}$ has $\textsc{Level}(v) = i > 0$. Then there exists another node $u \in \mathbb{A}$ with $\textsc{Level}(u) = i - 1$ so that either v is reachable from u, or there exists another node $v' \in \mathbb{A}$ reachable from u with $\textsc{Level}(v') = i$ in the same system as v and v is critical.*

After Explore1, we apply the Push operation (if possible), defined as follows.

▶ **Definition 5.** Push operation: push a pebble from u^* to v^* if the following conditions hold.

1. The pebble is at u^* and it can be assigned to v^*.
2. $\textsc{Level}(v^*) = \textsc{Level}(u^*) + 1$.
3. v^* is uncritical, or v^* is in a good system that remains good with an additional weight of w at v^*.
4. Subject to the above three conditions, choose a node u^* so that $\textsc{Level}(u^*)$ is minimized (if there are multiple candidates, pick any).

Our algorithm can be simply described as follows.

Algorithm 1: As long as there is a bad system, apply Explore1 and Push operation repeatedly. When there is no bad system left, return a solution with makespan at most $1.5t$. If at some point, push is no longer possible, declare that OPT $\geq t + 1$.

▶ **Lemma 6.** *When there is at least one bad system and the* Push *operation is no longer possible,* OPT $\geq t + 1$.

Proof. Let $\mathbb{A}(S)$ denote the set of activated nodes in system S. Recall that Ψ denotes the set of all orientations in $G_{\mathbb{R}}$ in which each node has at most one incoming edge. We prove the lemma via the following claim.

▶ **Claim 7.** *Let S be a system.*

- *Suppose that S is bad. Then*

$$W \cdot (\min_{\psi \in \Psi} \textit{number of rocks to } \mathbb{A}(S) \textit{ according to } \psi) + \sum_{v \in \mathbb{A}(S)} pl(v) + dl(v) > |\mathbb{A}(S)|t. \quad (1)$$

- *Suppose that S is good. Then*

$$W \cdot (\min_{\psi \in \Psi} \textit{number of rocks to } \mathbb{A}(S) \textit{ according to } \psi) + \sum_{v \in \mathbb{A}(S)} pl(v) + dl(v) > |\mathbb{A}(S)|t - w. \quad (2)$$

Observe that the term $|\mathbb{A}(S)|t$ is the maximum total weight that all nodes in $\mathbb{A}(S)$ can handle if OPT $\leq t$. As pebbles owned by nodes in $\mathbb{A}$ can only be assigned to the nodes in $\mathbb{A}$, by the pigeonhole principle, in all orientations $\psi \in \Psi$, and all possible assignments of the pebbles, at least one bad system S has at least the same number of pebbles in $\mathbb{A}(S)$ as the current assignment, or a good system S has at least one more pebble than it currently has in $\mathbb{A}(S)$. In both cases, we reach a contradiction.

Proof of Claim 7. First observe that in all orientations in Ψ, the nodes in $\mathbb{A}(S)$ have to receive at least $|\mathbb{A}(S)| - 1$ rocks. If S is a cycle, then the nodes in $\mathbb{A}(S)$ have to receive exactly $|\mathbb{A}(S)|$ rocks.

Next observe that none of the nodes in $\mathbb{A}(S)$ is uncritical, since otherwise, by Proposition 4(4) and Definition 5(3), the Push operation would still be possible. By the same reasoning, if S is a tree and $\mathbb{A}(S) \neq \emptyset$, at least one node $v \in \mathbb{A}(S)$ is critical; furthermore, if $|\mathbb{A}(S)| = 1$, this node v satisfies $dl(v) + pl(v) > 1.5t - w$, as an additional weight of w would make v hypercritical. Similarly, if S is an isolated node $v \in \mathbb{A}$, then $dl(v) + pl(v) > 1.5t - w$.

We now prove the claim by the following case analysis.

1. Suppose that S is a good system and $\mathbb{A}(S) \neq \emptyset$. Then either S is a tree and $\mathbb{A}(S)$ contains exactly one critical (but not hypercritical) node, or S is an isolated node, or S is a cycle and has no critical node. In the first case, if $|\mathbb{A}(S)| \geq 2$, the LHS of (2) is at least
$$(1.5t - W + 1) + (|\mathbb{A}(S)| - 1)(1.5t - W - w + 1) + (|\mathbb{A}(S)| - 1)W =$$
$$|\mathbb{A}(S)|t + (|\mathbb{A}(S)| - 2)(0.5t - w + 1) + t - W - w + 2 > |\mathbb{A}(S)|t - w,$$
using the fact that $0.5t \geq w$, $t \geq W$, and $|\mathbb{A}(S)| \geq 2$. If, on the other hand, $|\mathbb{A}(S)| = 1$, then the LHS of (2) is strictly more than
$$1.5t - w \geq t = |\mathbb{A}(S)|t,$$
and the same also holds for the case when S is an isolated node. Finally, in the third case, the LHS of (2) is at least
$$|\mathbb{A}(S)|(1.5t - W - w + 1) + |\mathbb{A}(S)|W > |\mathbb{A}(S)|t.$$
2. Suppose that $\mathbb{A}(S)$ contains at least two critical nodes, or that S is a cycle and $\mathbb{A}(S)$ has at least one critical node. In both cases, S is a bad system. Furthermore, the LHS of (1) can be lower-bounded by the same calculation as in the previous case with an extra term of w.
3. Suppose that $\mathbb{A}(S)$ contains a hypercritical node. Then the system S is bad, and the LHS of (1) is at least
$$(1.5t + 1) + (|\mathbb{A}(S)| - 1)(1.5t - W - w + 1) + (|\mathbb{A}(S)| - 1)W =$$
$$|\mathbb{A}(S)|t + (|\mathbb{A}(S)| - 1)(0.5t - w + 1) + 0.5t + 1 > |\mathbb{A}(S)|t,$$
where the inequality holds because $0.5t \geq w$. ◀

◀

We argue that Algorithm 1 terminates in polynomial time by the aid of a potential function, defined as
$$\Phi = \sum_{v \in \mathbb{A}} (|V| - \textsc{Level}(v)) \cdot (\text{number of pebbles at } v).$$

Trivially, $0 \leq \Phi \leq |V| \cdot |\mathbb{P}|$. The next lemma implies that Φ is monotonically decreasing after each Push operation. The proof can be found in the full version.

▶ **Lemma 8.** *For each node $v \in V$, let $\textsc{Level}(v)$ and $\textsc{Level}'(v)$ denote the levels before and after a* Push *operation, respectively. Then $\textsc{Level}'(v) \geq \textsc{Level}(v)$.*

Proof. We prove by contradiction. Suppose that there exist nodes x with $\textsc{Level}'(x) < \textsc{Level}(x)$. Choose v to be one among them with minimum $\textsc{Level}'(v)$. By the choice of v, and Definition 5(3), $\textsc{Level}'(v) > 0$ and $v \in \mathbb{A}$ after the Push operation. Thus, by Proposition 4(4), there exists a node u with $\textsc{Level}'(u) = \textsc{Level}'(v) - 1$, so that after Push,

- Case 1: v is reachable from $u \in \mathbb{A}$, or
- Case 2: there exists another node $v' \in \mathbb{A}$ reachable from $u \in \mathbb{A}$ with $\textsc{Level}'(v') = \textsc{Level}'(v)$ in the same system as v, and v is critical.

Notice that by the choice of v, in both cases, $\textsc{Level}'(u) \geq \textsc{Level}(u)$, and $u \in \mathbb{A}$ also before the Push operation. Let p be the pebble by which u reaches v (Case 1), or v' (Case 2), after Push. Before the Push operation, p was at some node $u' \in \mathbb{A}$ (u' may be u, or p is the pebble pushed: from u' to u).

By Proposition 4(2), in Case 1, $\textsc{Level}(v) \leq \textsc{Level}(u') + 1$ (as v is reachable from u' via p before Push), and $\textsc{Level}(v') \leq \textsc{Level}(u') + 1$ in Case 2. Furthermore, if in Case 2 v was already critical before push, then $\textsc{Level}(v) \leq \textsc{Level}(v')$ by Proposition 4(3) (note that $v' \in \mathbb{A}$ as it is reachable from $u' \in \mathbb{A}$). Hence, in both cases we would have

$$\textsc{Level}(v) \leq \textsc{Level}(u') + 1 \leq \textsc{Level}(u) + 1 \leq \textsc{Level}'(u) + 1 = \textsc{Level}'(v),$$

a contradiction. Note that the second inequality holds no matter $u = u'$ or not.

Finally consider Case 2 where v was not critical before the Push operation. Then a pebble $p' \neq p$ is pushed into v in the operation. Note that in this situation, v's system is a tree and contains no critical nodes before Push (by Definition 5(3)); in particular v' is not critical. Furthermore, the presence of p in u implies that $\textsc{Level}(v') \leq \textsc{Level}(u) + 1$ by Proposition 4(2), and that $v' \in \mathbb{A}$ by Proposition 4(1). As v' is not critical, $\textsc{Level}(v') > 0$, and by Proposition 4(4) there exists a node u'' with $\textsc{Level}(u'') = \textsc{Level}(v') - 1$ so that u'' can reach v' by a pebble p'' (u'' may be u and p'' may be p). As

$$\textsc{Level}(v') \leq \textsc{Level}(u) + 1 \leq \textsc{Level}'(u) + 1 = \textsc{Level}'(v) < \textsc{Level}(v),$$

the Push operation should have pushed p'' into v' instead of p' into v (see Definition 5(4)), since u'' and v' satisfy all the first three conditions of Definition 5. ◀

By Lemma 8 and the fact that a pebble is pushed to a node with higher level, the potential Φ strictly decreases after each Push operation, implying that Algorithm 1 finishes in polynomial time.

Approximation Ratio: When $t < 2W$, we apply Algorithm 1. In the case of $t \geq 2W$, we apply the algorithm of Gairing et al. [5], which either correctly reports that $\text{OPT} \geq t + 1$, or returns an assignment with makespan at most $t + W - 1 < 1.5t$.

Suppose that t is the smallest number for which an assignment is returned. Then $\text{OPT} \geq t$, and our approximation ratio is bounded by $\frac{1.5t}{\text{OPT}} \leq 1.5$. We use a theorem to conclude this section.

▶ **Theorem 9.** *With arbitrary dedicated loads on the machines, jobs of weight W that can be assigned to two machines, and jobs of weight w that can be assigned to any number of machines, we can find a 1.5 approximate solution in polynomial time.*

In the full version, we show that a slight modification of our algorithm yields an improved approximation ratio of $1 + \frac{\lfloor \frac{W}{2} \rfloor}{W}$ if $W \geq 2w$.

4 The General Case

In this section, we describe the core algorithm for the case of arbitrary job weights. This algorithm inherits some basic ideas from the previous section, but has several significantly new ingredients – mainly due to the fact that the rocks now have different weights. Before formally presenting the algorithm, let us build up intuition by looking at some examples.

For simplicity, we rescale the numbers and assume that $t = W = 1$ and $\beta = 0.7$. We aim for an assignment with makespan of at most $5/3 + 0.7/3 = 1.9$ or decide that $\text{OPT} > 1$.

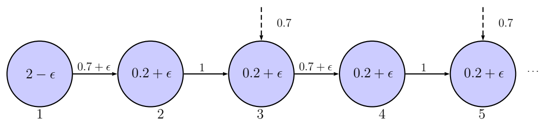

Figure 2 There are $2k+1$ nodes (the rest is repeating the same pattern). Numbers inside the shaded circles (nodes) are their pebble load.

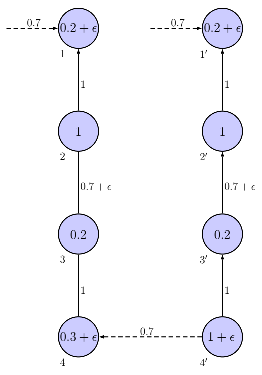

Figure 3 A naive PUSH will oscillate the pebble between nodes 4 and $4'$.

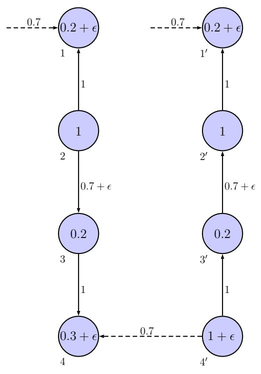

Figure 4 A fake orientation from node 2 to 3 causes node 4 to have an incoming edge, thus informing node $4'$ not to push the pebble.

Consider the example in Figure 2. Note that there are $2k+1$ (for some large k) nodes (the pattern of the last two nodes repeats). Due to node 1 (which can be regarded as the analog of a critical node in the previous section), all edges are to be directed toward the right if we shoot for the makespan of 1.9. Suppose that there is an isolated node with the pebble load of $2+\epsilon$ (this node can be regarded as a bad system by itself) and it has a pebble of weight 0.7 that can be assigned to node 3, 5, 7 and so on up to $2k+1$. Clearly, we do not want to push the pebble into any of them, as it would cause the makespan to be larger than 1.9 by whatever orientation. Rather, we should activate node 1 and send its pebbles away with the aim of relieving the "congestion" in the current system (later we will see that this is activation rule 1). In this example, all odd-numbered nodes are activated, and the entire set of nodes (including even-numbered nodes) form a *conflict set* (which will be defined formally later). Roughly speaking, the conflict sets contain activated nodes and the nodes that can be reached by "backtracking" the directed edges from them. These conflict sets embody the "congestion" in the systems.

Recall that in the previous section, if the PUSH operation was no longer possible, we argued that the total load is too much for the activated nodes *system by system*. Analogously, in this example, we need to argue that in all feasible orientations, the activated set of nodes (totally $k+1$ of them) in this conflict set cannot handle the total load. However, if all edges are directed toward the left, their total load is only $(0.2+\epsilon)k+(2-\epsilon)+(0.7+\epsilon)k = 2+0.9k+\epsilon(2k-1)$, which is less than what they can handle (which is $k+1$) when k is large. As a result, we are unable to arrive at a contradiction.

To overcome this issue, we introduce another activation rule to strengthen our contradiction argument. If all edges are directed to the left, *on the average*, each activated node has a total load of about $0.2+0.7$. However, each inactivated node has, *on the average*, a total load of about $0.2+1$. This motivates our activation rule 2 : if an activated node is connected by a "relatively light" edge to some other node in the conflict set, the latter should be activated as well. The intuition behind is that the two nodes *together* will receive a relatively heavy load. We remark that it is easy to modify this example to show that if we do not apply activation rule 2, then we cannot hope for a $2 - \delta$ approximation for any small $\delta > 0$. [3]

Next consider the example in Figure 3. Here nodes 2, $2'$, and $4'$ can be regarded as the critical nodes, and $\{1, 2\}$, $\{1', 2', 3', 4'\}$ are the two conflict sets. Both nodes 1 and $1'$ can be reached by an isolated node with heavy load (the bad system) with a pebble of weight 0.7. Suppose further that node $4'$ can reach node 4 by another pebble of weight 0.7. It is easy to see that a naive PUSH definition will simply "oscillate" the pebble between nodes 4 and $4'$, causing the algorithm to cycle.

Intuitively, it is not right to push the pebble from $4'$ into 4, as it causes the conflict set in the left system to become bigger. Our principle of pushing a pebble should be to relieve the congestion in one system, while not worsening the congestion in another. To cope with this problematic case, we use *fake orientations*, i.e., we direct edges away from a conflict set, as shown in Figure 4. Node 2 directs the edge toward node 3, which in turn causes the next edge to be directed toward node 4. With the new incoming edge, node 4 now has a total load of $1 + 0.3 + \epsilon$ to handle, and the pebble thus will not be pushed from node $4'$ to node 4.

4.1 Formal description of the algorithm

We inherit some terminology from the previous section. We say that v is *reachable* from u if a pebble in u can be assigned to v, and that v is reachable from $\mathbb{A}$ if v is reachable from any node $u \in \mathbb{A}$. Each tree, cycle, isolated node in $G_{\mathbb{R}}$ is a system. Note that there is exactly one edge between two adjacent nodes in $G_{\mathbb{R}}$ (see Proposition 1). For ease of presentation, we use the short hand vu to refer to the edge $\{v, u\}$ in $G_{\mathbb{R}}$ and w_{vu} is its weight.

The orientation of the edges in $G_{\mathbb{R}}$ will be decided dynamically. If uv is directed toward v, we call v a *father* of u, and u a *child* of v (notice that a node can have several fathers and children). We write $rl(v)$ to denote total weight of the rocks that are (currently) oriented towards v, and $pl(v)$ still denotes the total weight of the pebbles at v. An edge that is currently un-oriented is *neutral*. In the beginning, all edges in $G_{\mathbb{R}}$ are neutral.

A set $\mathbb{C}$ of nodes, called the *conflict set*, will be collected in the course of the algorithm. Let $\mathcal{D}(v) := \{u \in \mathbb{C} : u \text{ is child of } v\}$ and $\mathcal{F}(v) := \{u \in \mathbb{C} : u \text{ is father of } v\}$ for any $v \in \mathbb{C}$. A node $v \in \mathbb{C}$ is a *leaf* if $\mathcal{D}(v) = \emptyset$, and a *root* if $\mathcal{F}(v) = \emptyset$. Furthermore, a node v is *overloaded* if $dl(v) + pl(v) + rl(v) > (5/3 + \beta/3)t$, and a node $v \in \mathbb{C}$ is *critical* if there exists $u \in \mathcal{F}(v)$ such that $dl(v) + pl(v) + w_{vu} > (5/3 + \beta/3)t$. In other words, a node in the conflict set is critical if it has enough load by itself (without considering incoming rocks) to "force" an incident edge to be directed toward a father in the conflict set.

Initially, the pebbles are arbitrarily assigned to the nodes. The orientation of a subset of the edges in $G_{\mathbb{R}}$ is determined by the procedure FORCED ORIENTATIONS in Figure 5.

Intuitively, the procedure first finds a "source node" v, whose dedicated, pebble, and rock load is so high that it "forces" an incident edge vu to be oriented away from v. The orientation of this edge then propagates through the graph, i.e. edge-orientations induced by

[3] Looking at this particular example, one is tempted to use the idea of activating all nodes in the conflict set. However, such an activation rule will not work. Consider the following example: There are $k + 2$ nodes forming a path, and the $k + 1$ edges connecting them all have weight $0.95 + \epsilon$. The first node has a pebble load of 1 and thus "forces" an orientation of the entire path (for a makespan of at most 1.9). The next k nodes have a pebble load of 0, and the last node has a pebble load of 0.25 and is reachable from a bad system via a pebble of weight 0.7. The conflict set is the entire path, and activating all nodes leads to a total load of $(k + 1) \cdot (0.95 + \epsilon) + 1 + 0.25$, which is less than $k + 2$ for large k.

```
FORCED ORIENTATIONS
While ∃ neutral edge $vu$ in $G_{\mathbb{R}}$, s.t. $dl(v) + pl(v) + rl(v) + w_{vu} > (5/3 + \beta/3)t$:
    Direct $vu$ towards $u$; MARKED := $\{u\}$.
    While ∃ neutral edge $v'u'$ in $G_{\mathbb{R}}$, s.t. $dl(v') + pl(v') + rl(v') + w_{v'u'} > (5/3 + \beta/3)t$ and $v' \in$ MARKED:
        Direct $v'u'$ towards $u'$; MARKED := MARKED $\cup \{u'\}$.
```

Figure 5 The procedure FORCED ORIENTATIONS.

the direction of vu are established. Then the next "source" is found, and so on. To simplify our proofs, we assume that ties are broken according to a fixed total order if several pairs (v, u) satisfy the conditions of the while-loops.

The following lemma describes a basic property of the procedure FORCED ORIENTATIONS, that will be used in the subsequent discussion. Its proof can be found in the full version.

▶ **Lemma 10.** *Suppose that a node v becomes overloaded during* FORCED ORIENTATIONS. *Then there exists a path $u_0u_1 \dots u_kv$ of neutral edges, such that $dl(u_0) + pl(u_0) + rl(u_0) + w_{u_0u_1} > (5/3 + \beta/3)t$ before the procedure, that becomes directed from u_0 towards v during the procedure (note that u_0 could be v). Furthermore, other than u_kv, no edge becomes directed toward v in the procedure.*

Proof. We start with a simple observation. Let ab be the first edge directed in some iteration of the procedure's outer while-loop; suppose from a to b. It is easy to see that up to this moment, no edge has been directed toward a in course of the procedure. Furthermore, if another edge $a'b'$ is directed in the same iteration of the outer while-loop, then there exists a path of neutral edges, starting with ab and ending with $a'b'$, that becomes directed during this iteration. This proves the first part of the lemma.

Now suppose that some node v becomes overloaded and has more than one edge directed towards it during the procedure. Let vx and vy be the last two edges directed toward v, and note that both, vx and vy, become directed in the same iteration of the outer while-loop (because as soon as one of the two is directed toward v, the other edge satisfies the conditions of the inner while-loop). Hence, there are two different paths directed towards v (with final edges vx and vy, respectively), both of which start with the first edge that becomes directed in this iteration of the outer while-loop. This is not possible, since every system is a tree or a cycle, a contradiction. ◀

Clearly, if after the procedure FORCED ORIENTATIONS a node v still has a neutral incident edge vu, then $dl(v)+pl(v)+rl(v)+w_{vu} \le (5/3+\beta/3)t$. Now suppose that after the procedure, none of the nodes is overloaded. Then orienting the neutral edges in each system in such a way that every node has at most one more incoming edge gives us a solution with makespan at most $(5/3 + \beta/3)t$. So assume the procedure ends with a non-empty set of overloaded nodes. We then apply the procedure EXPLORE2 in Figure 6.

Let us elaborate the procedure. In each round, we perform the following three tasks.

1. Add those nodes reachable from the nodes in $\mathbb{A}_{i-1}$ into $\mathbb{A}_i$ in case of $i > 1$; or the overloaded nodes into $\mathbb{A}_i$ in case of $i = 0$. These nodes will be referred to as Type A nodes.
2. In the sub-procedure *Conflict set construction*, nodes not in the conflict set and having a directed path to those Type A nodes in $\mathbb{A}_i$ are continuously added into the conflict set

```
EXPLORE2

Initialize $\mathbb{A} := \emptyset$; $\mathbb{C} := \emptyset$; $i := 0$. Call FORCED ORIENTATIONS.
Repeat:
    If $i = 0$: $\mathbb{A}_i := \{v | v$ is overloaded$\}$.
    Else $\mathbb{A}_i := \{v | v \notin \mathbb{A}, v$ is reachable from $\mathbb{A}_{i-1}\}$.
    If $\mathbb{A}_i = \emptyset$: stop.
    $\mathbb{C}_i := \mathbb{A}_i$; $\mathbb{A} := \mathbb{A} \cup \mathbb{A}_i$; $\mathbb{C} := \mathbb{C} \cup \mathbb{C}_i$.

    (Conflict set construction)
    While $\exists v \notin \mathbb{C}$ with a father $u \in \mathbb{C}$ or $\exists$ neutral $vu$ with $v \in \mathbb{C}$ do:
        While $\exists v \notin \mathbb{C}$ with a father $u \in \mathbb{C}$:
            $\mathbb{C}_i := \mathbb{C}_i \cup \{v\}$; $\mathbb{C} := \mathbb{C} \cup \mathbb{C}_i$.
        If $\exists$ neutral $vu$ with $v \in \mathbb{C}$:
            Direct $vu$ towards $u$; Call FORCED ORIENTATIONS.

    (Activation of nodes)
    While $\exists v \in \mathbb{C} \setminus \mathbb{A}$ satisfying one of the following conditions:
        Rule 1: $\exists u \in \mathcal{F}(v)$, such that $dl(v) + pl(v) + w_{vu} > (5/3 + \beta/3)t$
        Rule 2: $\exists u \in \mathbb{A} \cap (\mathcal{D}(v) \cup \mathcal{F}(v))$, such that $w_{vu} < (2/3 + \beta/3)t$
    Do: $\mathbb{A}_i := \mathbb{A}_i \cup \{v\}$; $\mathbb{A} := \mathbb{A} \cup \mathbb{A}_i$.

    $i := i + 1$.
```

Figure 6 The procedure EXPLORE2.

$\mathbb{C}_i$. Furthermore, the earlier mentioned *fake orientations* are applied: each node $v \in \mathbb{C}_i$, if having an incident neutral edge vu, direct it toward u and call the procedure FORCED ORIENTATIONS. It may happen that in this process, two disjoint nodes in $\mathbb{C}_i$ are now connected by a directed path P, then all nodes in P along with all nodes having a path leading to P are added into $\mathbb{C}_i$ (observe that all these nodes have a directed path to some Type A node in $\mathbb{A}_i$). We note that the order of fake orientations does not materially affect the outcome of the algorithm.

3. In the next sub-procedure *Activation of nodes*, we use two rules to activate extra nodes in $\mathbb{C} \setminus \mathbb{A}$. Rule 1 activates the critical nodes; Rule 2 activates those nodes whose father or child are already activated and they are connected by an edge of weight less than $(2/3 + \beta/3)t$. We will refer to the former as Type B nodes and the latter as Type C nodes.

Observe that except in the initial call of FORCED ORIENTATIONS, no node ever becomes overloaded in EXPLORE2 (by Lemma 10 and the fact that every system is a tree or a cycle). Let us define LEVEL$(v) = i$ if $v \in \mathbb{A}_i$. In case $v \notin \mathbb{A}$, let LEVEL$(v) = \infty$. The next proposition summarizes some important properties of the procedure EXPLORE2.

▶ **Proposition 11.** *After the procedure* EXPLORE2, *the following holds.*

1. *All nodes reachable from $\mathbb{A}$ are in $\mathbb{A}$.*
2. *Suppose that $v \in \mathbb{A}$ is reachable from $u \in \mathbb{A}$. Then* LEVEL$(v) \leq$ LEVEL$(u) + 1$.

Furthermore, at the end of each round i, the following holds.

3. *Every node v that can follow a directed path to a node in $\mathbb{C} := \cup_{\tau=0}^{i} \mathbb{C}_\tau$ is in $\mathbb{C}$. Furthermore, if a node $v \in \mathbb{C}$ has an incident edge vu with $u \notin \mathbb{C}$, then vu is directed toward u.*
4. *Each node $v \in \mathbb{A}_i$ is one of the following three types.*

(a) **Type A**: *there exists another node $u \in \mathbb{A}_{i-1}$ so that v is reachable from u, or v is overloaded and is part of $\mathbb{A}_0$.*
(b) **Type B**: *v is activated via Rule 1 (hence v is critical)*[4]*, and there exists a directed path from v to $u \in A_i$ of Type A.*
(c) **Type C**: *v is activated via Rule 2, and there exists an adjacent node $u \in \cup_{\tau=0}^{i} \mathbb{A}_\tau$ so that $w_{vu} < (2/3 + \beta/3)t$ and $u \in \mathcal{D}(v) \cup \mathcal{F}(v)$.*

After the procedure EXPLORE2, we apply the PUSH operation (if possible), defined as follows.

▶ **Definition 12.** PUSH operation: push a pebble from u^* to v^* if the following conditions hold (if there are multiple candidates, pick any).
1. The pebble is at u^* and it can be assigned to v^*.
2. $\text{LEVEL}(v^*) = \text{LEVEL}(u^*) + 1$.
3. $dl(v^*) + pl(v^*) + rl(v^*) \leq (5/3 - 2/3 \cdot \beta)t.$
4. $\mathcal{D}(v^*) = \emptyset$, or $dl(v^*) + pl(v^*) + w_{v^*u} \leq (5/3 - 2/3 \cdot \beta)t$ for all $u \in \mathcal{F}(v)$.

Definition 12(3) is meant to make sure that v^* does not become overloaded after receiving a new pebble (whose weight can be as heavy as βt). Definition 12(4) says either v^* is a leaf, or adding a pebble with weight as heavy as βt does not cause v^* to become critical.

Algorithm 2: Apply EXPLORE2. If it ends with $\mathbb{A}_0 = \emptyset$, return a solution with makespan at most $(5/3 + \beta/3)t$. Otherwise, apply PUSH. If PUSH is impossible, declare that OPT $\geq t + 1$. Un-orient all edges in $G_{\mathbb{R}}$ and repeat this process.

▶ **Lemma 13.** *When there is at least one overloaded node and the* PUSH *operation is no longer possible,* OPT $\geq t + 1$.

▶ **Lemma 14.** *For each node $v \in V$, let* $\text{LEVEL}(v)$ *and* $\text{LEVEL}'(v)$ *denote the levels before and after a* PUSH *operation, respectively. Then* $\text{LEVEL}'(v) \geq \text{LEVEL}(v)$.

The proofs of the preceding two lemmas can be found in the full version. We again use the potential function

$$\Phi = \sum_{v \in \mathbb{A}} (|V| - \text{LEVEL}(v)) \cdot (\text{number of pebbles at } v)$$

to argue the polynomial running time of Algorithm 2. Trivially, $0 \leq \Phi \leq |V| \cdot |\mathbb{P}|$. Furthermore, by Lemma 14 and the fact that a pebble is pushed to a node with higher level, the potential Φ strictly decreases after each PUSH operation. This implies that Algorithm 2 finishes in polynomial time.

We can therefore conclude:

▶ **Theorem 15.** *Let $\beta \in [4/7, 1)$. With arbitrary dedicated loads on the machines, if jobs of weight greater than βW can be assigned to only two machines, and jobs of weight at most βW can be assigned to any number of machines, we can find a $5/3 + \beta/3$ approximate solution in polynomial time.*

[4] For simplicity, if a node can be activated by both Rule 1 and Rule 2, we assume it is activated by Rule 1.

Abstract

With the dramatic growth in the number of application domains that generate probabilistic, noisy and uncertain data, there has been an increasing interest in designing algorithms for geometric or combinatorial optimization problems over such data. In this paper, we initiate the study of constructing ε-kernel coresets for uncertain points. We consider uncertainty in the existential model where each point's location is fixed but only occurs with a certain probability, and the locational model where each point has a probability distribution describing its location. An ε-kernel coreset approximates the width of a point set in any direction. We consider approximating the expected width (an ε-EXP-KERNEL), as well as the probability distribution on the width (an (ε, τ)-QUANT-KERNEL) for any direction. We show that there exists a set of $O(\varepsilon^{-(d-1)/2})$ deterministic points which approximate the expected width under the existential and locational models, and we provide efficient algorithms for constructing such coresets. We show, however, it is not always possible to find a subset of the original uncertain points which provides such an approximation. However, if the existential probability of each point is lower bounded by a constant, an ε-EXP-KERNEL is still possible. We also provide efficient algorithms for construct an (ε, τ)-QUANT-KERNEL coreset in nearly linear time. Our techniques utilize or connect to several important notions in probability and geometry, such as Kolmogorov distances, VC uniform convergence and Tukey depth, and may be useful in other geometric optimization problem in stochastic settings. Finally, combining with known techniques, we show a few applications to approximating the extent of uncertain functions, maintaining extent measures for stochastic moving points and some shape fitting problems under uncertainty.

resulted in an abundance of uncertain, noisy and probabilistic data in many scientific and application domains. Managing, analyzing, and solving optimization problems over such data have become an increasingly important issue and have attracted significant attentions from several research communities including theoretical computer science, databases, machine learning and wireless networks.

In this paper, we focus on two stochastic models, the existential model and locational model. Both models have been studied extensively for a variety of geometric or combinatorial problems, such as closest pairs [34], nearest neighbors [5, 34], minimum spanning trees [32, 35], convex hulls [6, 24, 49, 52], maxima [3], perfect matchings [32], clustering [16, 26] , minimum enclosing balls [43] and range queries [1, 4, 38].

1. Existential uncertainty model: In this model, there is a set $\mathcal{P}$ of n points in $\mathbb{R}^d$. Throughout this paper, we assume that the dimension d is a constant. Each point $v \in \mathcal{P}$ is associated with a real number (called *existential probability*) $p_v \in [0, 1]$ which indicates that v is present independently with probability p_v.
2. Locational uncertainty model: There are a set $\mathcal{P}$ of n points and the existence of each point is certain. However, the location of each point $v \in \mathcal{P}$ is a random location in $\mathbb{R}^d$. We assume the probability distribution is discrete and independent of other points. For a point $v \in \mathcal{P}$ and a location $s \in \mathbb{R}^d$, we use $p_{v,s}$ to denote the probability that the location of point v is s. Let S be the set of all possible locations, and let $|S| = m$ be the number of all such locations.

In the locational uncertainty model, we distinguish the use of the terms "points" and "locations"; a point refers to the object with uncertain locations and a location refers to a point (in the usual sense) in $\mathbb{R}^d$. We will use capital letters (e.g., $P, S, \ldots$) to denote sets of deterministic points and calligraphy letters ($\mathcal{P}, \mathcal{S}, \ldots$) to denote sets of stochastic points.

Coresets: Given a large dataset P and a class C of queries, a coreset S is a dataset of much smaller size such that for every query $r \in C$, the answer $r(S)$ for the small dataset S is close to the answer $r(P)$ for the original large dataset P. Coresets [46] have become more relevant in the era of big data as they can drastically reduce the size of a dataset while guaranteeing that answers for certain queries are provably close. An early notion of a coreset concerns the directional width problem (in which a coreset is called an ε-kernel) and several other geometric shape-fitting problems in the seminal paper [7].

We introduce some notations and review the definition of ε-kernel. We assume the dimension d is a constant. For a set P of deterministic points, the *support function* $f(P, u)$ is defined to be $f(P, u) = \max_{p \in P}\langle u, p\rangle$ for $u \in \mathbb{R}^d$, where $\langle ., .\rangle$ is the inner product. The *directional width* of P in direction $u \in \mathbb{R}^d$, denoted by $\omega(P, u)$, is defined by $\omega(P, u) = f(P, u) + f(P, -u)$. It is not hard to see that the support function and the directional width only depend on the convex hull of P. A subset $Q \subseteq P$ is called an *ε-kernel of P* if for each direction $u \in \mathbb{R}^d$, $(1 - \varepsilon)\omega(P, u) \leq \omega(Q, u) \leq \omega(P, u)$. For any set of n points, there is an ε-kernel of size $O(\varepsilon^{-(d-1)/2})$ [7, 8], which can be constructed in $O(n+\varepsilon^{-(d-3/2)})$ time [13, 53].

1.1 Problem Formulations

We focus on constructing ε-kernel coresets when the input data is uncertain. These results not only provide an understanding of how to compactly represent an approximate convex hull under uncertainty, but can lead to solutions to a variety of other shape-fitting problems.

ε-Kernels for expectations. Suppose $\mathcal{P}$ is a set of stochastic points (in either the existential or locational uncertainty model). Define the *expected* directional width of $\mathcal{P}$ in direction u to be $\omega(\mathcal{P}, u) = \mathbb{E}_{P\sim\mathcal{P}}[\omega(P, u)]$, where $P \sim \mathcal{P}$ means that P is a (random) realization of $\mathcal{P}$.

▶ **Definition 1.** For a constant $\varepsilon > 0$, a set S of (deterministic or stochastic) points in $\mathbb{R}^d$ is called an ε-EXP-KERNEL of $\mathcal{P}$, if for all directions $u \in \mathbb{R}^d$,

$$(1-\varepsilon)\omega(\mathcal{P}, u) \le \omega(S, u) \le \omega(\mathcal{P}, u).$$

Recall in the deterministic setting, we require that the ε-kernel S be a subset of the original point set (we call this *the subset constraint*). It is important to consider the subset constraint since it can reveal how concisely arbitrary uncertain point sets can be represented with just a few uncertain points (size depending only on ε). For ε-kernels on deterministic points, $\Omega(\varepsilon^{-(d-1)/2})$ points may be required and can always be found under the subset constraint [7, 8]. However, in the stochastic setting, we will show this is no longer true. Yet, coresets without the subset constraint, in fact made of deterministic points, can sometimes be obtained when no coreset with the subset constraint is possible.

ε-Kernels for probability distributions. Sometimes it is useful to obtain more than just the expected value (say of the width) on a query; rather one may want (an approximation of) a representation of the full probability distribution that the query can take.

▶ **Definition 2.** For a constant $\varepsilon, \tau > 0$, a set $\mathcal{S}$ of stochastic points in $\mathbb{R}^d$ is called an (ε, τ)-QUANT-KERNEL of $\mathcal{P}$, if for all directions u and all $x \ge 0$,

$$\begin{aligned}\Pr_{P\sim\mathcal{P}}\Big[\omega(P,u) \le (1-\varepsilon)x\Big] - \tau \le \Pr_{S\sim\mathcal{S}}\Big[\omega(S,u) \le x\Big] \\ \le \Pr_{P\sim\mathcal{P}}\Big[\omega(P,u) \le (1+\varepsilon)x\Big] + \tau. \qquad (1)\end{aligned}$$

In the above definition, we do not require the points in $\mathcal{S}$ are independent. So when they are correlated, we will specify the distribution of $\mathcal{S}$. If all points in $\mathcal{P}$ are deterministic and $\tau < 0.5$, the above definition essentially boils down to requiring $(1-\varepsilon)\omega(\mathcal{P}, u) \le \omega(\mathcal{S}, u) \le (1+\varepsilon)\omega(\mathcal{P}, u)$. Assuming the coordinates of the input points are bounded, an (ε, τ)-QUANT-KERNEL ensures that for any choice of u, the cumulative distribution function of $\omega(\mathcal{S}, u)$ is within a distance ε under the Lévy metric, to that of $\omega(\mathcal{P}, u)$.

ε-Kernels for expected fractional powers. Sometimes, the notion ε-EXP-KERNEL is not powerful enough for certain shape fitting problems (e.g., the minimum enclosing cylinder problem and the minimum spherical shell problem) in the stochastic setting. The main reason is the appearance of the l_2-norm in the objective function. So we need to be able to handle the fractional powers in the objective function. For a set P of points in $\mathbb{R}^d$, the polar set of P is defined to be $P^\star = \{u \in \mathbb{R}^d \mid \langle u, v\rangle \ge 0, \forall v \in P\}$. Let r be a positive integer. Given a set P of points in $\mathbb{R}^d$ and $u \in P^\star$, we define a function

$$T_r(P, u) = \max_{v\in P}\langle u, v\rangle^{1/r} - \min_{v\in P}\langle u, v\rangle^{1/r}.$$

We only care about the directions in $\mathcal{P}^\star$ (i.e., the polar of the points in $\mathcal{P}$) for which $T_r(P, u), \forall P \sim \mathcal{P}$ is well defined.

▶ **Definition 3.** For a constant $\varepsilon > 0$, a positive integer r, a set $\mathcal{S}$ of stochastic points in $\mathbb{R}^d$ is called an (ε, r)-FPOW-KERNEL of $\mathcal{P}$, if for all directions $u \in \mathcal{P}^\star$,

$$(1-\varepsilon)\mathbb{E}_{P\sim\mathcal{P}}[T_r(P,u)] \le \mathbb{E}_{P\sim\mathcal{S}}[T_r(P,u)] \le (1+\varepsilon)\mathbb{E}_{P\sim\mathcal{P}}[T_r(P,u)].$$

1.2 Our Results

Now, we discuss the main technical results of the paper.

ε-Kernels for expectations. First, we consider ε-EXP-KERNELs under various constraints. Our first main result is that an ε-EXP-KERNEL of size $O(\varepsilon^{-(d-1)/2})$ exists for both existential and locational uncertainty models and can be constructed in nearly linear time.

▶ **Theorem 4.** *$\mathcal{P}$ is a set of n uncertain points in $\mathbb{R}^d$ (in either locational uncertainty model or existential uncertainty model). There exists an ε-EXP-KERNEL of size $O(\varepsilon^{-(d-1)/2})$ for $\mathcal{P}$. For existential uncertainty model (locational uncertainty model resp.), such an ε-EXP-KERNEL can be constructed in $O(\varepsilon^{-(d-1)}n\log n)$ time, ($O(\varepsilon^{-(d-1)}m\log m)$ time resp.), where n is the number of points and m is the total number of possible locations.*

The existential result is a simple Minkowski sum argument. We first show that there exists a convex polytope M such that for any direction, the directional width of M is exactly the same as the expected directional width of $\mathcal{P}$ (Lemma 10). This immediately implies the existence of a ε-EXP-KERNEL consisting $O(\varepsilon^{-(d-1)/2})$ deterministic points (using the result in [7]), but without the subset constraint. The Minkowski sum argument seems to suggest that the complexity of M is exponential. However, we show that the complexity of M is in fact polynomial $O(n^{2d-2})$ and we can construct it explicitly in $O(n^{2d-1}\log n)$ time (Theorem 14).

Although the complexity of M is polynomial, we cannot afford to construct it explicitly if we are to construct an ε-EXP-KERNEL in nearly linear time. Thus we construct the ε-EXP-KERNEL without explicitly constructing M. In particular, we show that it is possible to find the extreme vertex of M in a given direction in nearly linear time, by computing the gradient of the support function of M. We also provide quadratic-size data structures that can calculate the exact width $\omega(\mathcal{P},\cdot)$ in logarithmic time under both models in $\mathbb{R}^2$.

We also show that under subset constraint (i.e., the ε-EXP-KERNEL is required to be a subset of the original point set, with the same probability distribution for each chosen point), there is no ε-EXP-KERNEL of sublinear size (Lemma 15). However, if there is a constant lower bound $\beta > 0$ on the existential probabilities (called β-assumption), we can construct an ε-EXP-KERNEL of constant size (Theorem 16).

ε-Kernels for probability distributions. Now, we describe our main results for (ε,τ)-QUANT-KERNELs. We first propose a quite simple but general algorithm for constructing (ε,τ)-QUANT-KERNELs, which achieves the following guarantee.

▶ **Theorem 5.** *An (ε,τ)-QUANT-KERNEL of size $\widetilde{O}\left(\tau^{-2}\varepsilon^{-3(d-1)/2}\right)$ can be constructed in $\widetilde{O}\left(n\tau^{-2}\varepsilon^{-(d-1)}\right)$ time, under both existential and locational uncertainty models.*

The algorithm is surprisingly simple. Take a certain number N of i.i.d. realizations, compute an ε-kernel for each realization, and then associate each ε-kernel with probability $1/N$ (so the points are not independent). The analysis requires the VC uniform convergence bound for unions of halfspaces. The details can be found in Section 3.1.

For existential uncertainty model, we can improve the size bound as follows.

▶ **Theorem 6.** *$\mathcal{P}$ is a set of uncertain points in $\mathbb{R}^d$ with existential uncertainty. Let $\lambda = \sum_{v\in\mathcal{P}}(-\ln(1-p_v))$. There exists an (ε,τ)-QUANT-KERNEL for $\mathcal{P}$, which consists of a set of independent uncertain points of cardinality $\min\{\widetilde{O}(\tau^{-2}\max\{\lambda^2,\lambda^4\}),\widetilde{O}(\varepsilon^{-(d-1)}\tau^{-2})\}$. The algorithm for constructing such a coreset runs in $\widetilde{O}(n\log^{O(d)} n)$ time.*

We note that another advantage of the improved construction is that the (ε, τ)-QUANT-KERNEL is a set of independent stochastic points (rather than correlated points as in Theorem 5). We achieve the improvement by two algorithms. The first algorithm transforms the Bernoulli distributed variables into Poisson distributed random variables and creates a probability distribution using the parameters of the Poissons, from which we take a number of i.i.d. samples as the coreset. Our analysis leverages the additivity of Poisson distributions and the VC uniform convergence bound (for halfspaces). However, the number of samples required depends on $\lambda(\mathcal{P})$, so the first algorithm only works when $\lambda(\mathcal{P})$ is small. The second algorithm complements the first one by identifying a convex set K that lies in the convex hull of $\mathcal{P}$ with high probability (K exists when $\lambda(\mathcal{P})$ is large) and uses a small size deterministic ε-kernel to approximate K. The points in $\overline{K} = \mathcal{P} \setminus K$ can be approximated using the same sampling algorithm as in the first algorithm and we can show that $\lambda(\overline{K})$ is small, thus requiring only a small number of samples. In the appendix (Section 3.2.3), we show such an (ε, τ)-QUANT-KERNEL can be computed in $O(n \cdot \text{polylog} n)$ time using an iterative sampling algorithm. Our technique has some interesting connections to other important geometric problems (such as the Tukey depth problem) [42], may be interesting in its own right.

ε-Kernels for expected fractional powers. For (ε, r)-FPOW-KERNELs, we provide a linear time algorithm for constructing an (ε, r)-FPOW-KERNEL of size $\widetilde{O}(\varepsilon^{-(rd-r+2)})$ in the existential uncertainty model under the β-assumption. The algorithm is almost the same as the construction in Section 3.1 except that some parameters are different.

▶ **Theorem 7** (Section 4). *An (ε, r)-FPOW-KERNEL of size $\widetilde{O}(\varepsilon^{-(rd-r+2)})$ can be constructed in $\widetilde{O}\left(n\varepsilon^{-(rd-r+4)/2}\right)$ time in the existential uncertainty model under the β-assumption.*

Applications to Uncertain Function Approximation and Shape Fitting. Finally, we show that the above results, combined with the duality and linearization arguments [7], can be used to obtain constant size coresets for the function extent problem in the stochastic setting, and to maintain extent measures for stochastic moving points.

Using the above results, we also obtain efficient approximation schemes for various shape-fitting problems in the stochastic setting, such as minimum enclosing ball, minimum spherical shell, minimum enclosing cylinder and minimum cylindrical shell in different stochastic settings. We summarize our application results in the following theorems. The details can be found in Section 5.

▶ **Theorem 8.** *Suppose $\mathcal{P}$ is a set of n independent stochastic points in $\mathbb{R}^d$ under either existential or locational uncertainty model. There are linear time approximation schemes for the following problems: (1) finding a center point c to minimize $\mathbb{E}[\max_{v\in\mathcal{P}} \|v-c\|^2]$; (2) finding a center point c to minimize $\mathbb{E}[\mathsf{obj}(c)] = \mathbb{E}[\max_{v\in P} \|v-c\|^2 - \min_{v\in P} \|v-c\|^2]$. Note that when $d = 2$ the above two problems correspond to minimizing the expected areas of the enclosing ball and the enclosing annulus, respectively.*

Under β-assumption, we can obtain efficient approximation schemes for the following shape fitting problems.

▶ **Theorem 9.** *Suppose $\mathcal{P}$ is a set of n independent stochastic points in $\mathbb{R}^d$, each appearing with probability at least β, for some fixed constant $\beta > 0$. There are linear time approximation schemes for minimizing the expected radius (or width) for the minimum spherical shell, minimum enclosing cylinder, minimum cylindrical shell problems over $\mathcal{P}$.*

1.3 Other Related Work

Besides the stochastic models mentioned above, geometric uncertain data has also been studied in the *imprecise* model [11, 31, 36, 40, 44, 45, 50]. In this model, each point is provided with a region where it might be. This originated with the study of imprecision in data representation [27, 47], and can be used to provide upper and lower bounds on several geometric constructs such as the diameter, convex hull, and flow on terrains [19, 50].

Convex hulls have been studied for uncertain points: upper and lower bounds are provided under the imprecise model [20, 41, 44, 50], distributions of circumference and volume are calculated in the locational model [33, 39], the most likely convex hull is found in the existential model in $\mathbb{R}^2$ and shown NP-hard for $\mathbb{R}^d$ for $d > 2$ and in the locational model [49], and the probability a query point is inside the convex hull [6, 24, 52]. As far as we know, the expected complexity of the convex hull under uncertain points has not been studied, although it has been studied [28] under other random data models.

There is a large body of literature [46] on constructing coresets for various problems, such as shape fitting [7, 8], shape fitting with outliers [30], clustering [14, 22, 23, 29, 37], integrals [37], matrix approximation and regression [17, 22] and in different settings, such as geometric data streaming [8, 13] and privacy setting [21]. Coresets were constructed for imprecise points [41] to help derive results for approximating convex hulls and a variety of other shape-fitting problems, but because of the difference in models, these approaches do not translate to existential or locational models. In the locational model, coresets are created for range counting queries [1] under the subset constraint, but again these techniques do not translate because ε-kernel coresets in general cannot be constructed from a density-preserving subset of the data, as is preserved for the range counting coresets. Also in the locational model (and directly translating to the existential model) Löffler and Phillips [39] show how a large set of uncertain points can be approximated with a set of deterministic point sets, where each certain point set can be an ε-kernel. This can provide approximations similar to the (ε, τ)-QUANT-KERNEL with space $O(\varepsilon^{-(d+3)/2} \log(1/\delta))$ with probability at least $1 - \delta$. However it is not a coreset of the data, and answering width queries requires querying $O(\varepsilon^{-2} \log(1/\delta))$ deterministic point sets.

Recently, Munteanu et al. [43] studied the minimum enclosing ball problem over stochastic points, and obtained an efficient approximation scheme. Their algorithm and analysis utilize the results from the deterministic coreset literature [2]. However, they do not directly address the problem of constructing coresets for stochastic points and it is also unclear how to extend their technique to other shape fitting problems, such as minimum spherical shells.

Technically, our (ε, τ)-QUANT-KERNEL construction bears some similarity to the coreset by Har-Peled and Wang [30] for handling outliers. From the dual (function extent) perspective, they want to approximate the distance between two level sets in an arrangement of hyperplanes, and (the dual of) $\mathcal{H}$ in Section 3.2.2 also needs to be (approximately) sandwiched by two fractional level sets (our hyperplanes have weights). However, we have an important requirement that the total weight outside $(1+\varepsilon)\mathcal{H}$ must be small, which cannot be addressed by their technique.

2 ε-Kernels for Expectations of Width

We first state our results in this section for the existential uncertainty model. All results can be extended to the locational uncertainty model, with slightly different bounds (essentially replacing the number of points n with the number of locations m) or assumptions. We describe the difference for locational model in the full version.

For simplicity of exposition, we assume in this section that all points in $\mathcal{P}$ are in general positions and all p_vs are strictly between 0 and 1. For any $u, v \in \mathbb{R}^d$, we use $\langle u, v\rangle$ to denote the usual inner product $\sum_{i=1}^d u_i v_i$. For ease of notation, we write $v \succ_u w$ as a shorthand notation for $\langle u, v\rangle > \langle u, w\rangle$. For any $u \in \mathbb{R}^d$, the binary relation $\succ_u$ defines a total order of all vertices in $\mathcal{P}$. (Ties should be broken in an arbitrary but consistent manner.) We call this order the *canonical order of $\mathcal{P}$ with respect to u*. For any two points u and v, we use $\mathrm{d}(u, v)$ or $\|v - u\|$ to denote their Euclidean distance. For any two sets of points, A and B, the Minkowski sum of A and B is defined as $A \oplus B := \{a + b \mid a \in A, b \in B\}$. Recall the definitions for a set P of deterministic points and a direction $u \in \mathbb{R}^d$, the support function is $f(P, u) = \max_{p\in P}\langle u, p\rangle$ and the *directional width* is $\omega(P, u) = f(P, u) - f(P, -u)$. The support function and the directional width only depend on the convex hull of P.

▶ **Lemma 10.** *Consider a set $\mathcal{P}$ of uncertain points in $\mathbb{R}^d$ (in either locational uncertainty model or existential uncertainty model). There exists a set S of deterministic points in $\mathbb{R}^d$ (which may not be a subset of $\mathcal{P}$) such that $\omega(u, \mathcal{P}) = \omega(u, S)$ for all $u \in \mathbb{R}^d$.*

Proof. By the definition of the expected directional width of $\mathcal{P}$, we have that $\omega(\mathcal{P}, u) = \mathbb{E}_{P\sim\mathcal{P}}[\omega(P, u)] = \sum_{P\sim\mathcal{P}} \Pr[P]\Big(f(P, u) + f(P, -u)\Big)$. Consider the Minkowski sum $M = M(\mathcal{P}) := \sum_{P\sim\mathcal{P}} \Pr[P]\mathsf{ConvH}(P)$, where $\mathsf{ConvH}(P)$ is the convex hull of P (including the interior). It is well known that the Minkowski sum of a set of convex sets is also convex. Moreover, it also holds that for all $u \in \mathbb{R}^d$ (see e.g., [48]) $f(M, u) = \sum_{P\sim\mathcal{P}} \Pr[P]f(P, u)$. Hence, $\omega(\mathcal{P}, u) = \omega(M, u)$ for all $u \in \mathbb{R}^d$. ◀

By the result in [7], for any convex body in $\mathbb{R}^d$, there exists an ε-kernel of size $O(\varepsilon^{-(d-1)/2})$. Combining with Lemma 10, we can immediately obtain the following corollary.

▶ **Corollary 11.** *For any $\varepsilon > 0$, there exists an ε-*EXP-KERNEL *of size $O(\varepsilon^{-(d-1)/2})$.*

Recall that in Lemma 10, the Minkowski sum $M = \sum_{P\sim\mathcal{P}} \Pr[P]\mathsf{ConvH}(P)$. Since M is the Minkowski sum of exponential many convex polytopes, so M is also a convex polytope. At first sight, the complexity of M (i.e., number of vertices) could be exponential. However, as we will show shortly, the complexity of M is in fact polynomial.

We need some notations first. For each pair (r, w) of points in $\mathcal{P}$ consider the hyperplane $H_{r,w}$ that passes through the origin and is orthogonal to the line connecting r and w. We call these $\binom{n}{2}$ hyperplanes *the separating hyperplanes induced by $\mathcal{P}$* and use Γ to denote the set. Each such hyperplane divides $\mathbb{R}^d$ into 2 halfspaces. For all vectors $u \in \mathbb{R}^d$ in each halfspace, the order of $\langle r, u\rangle$ and $\langle w, u\rangle$ is the same (i.e., we have $r \succ_u w$ in one halfspace and $w \succ_u r$ in the other). Those hyperplanes in Γ pass through the origin and thus partition $\mathbb{R}^d$ into d-dimensional polyhedral cones. We denote this *arrangement* as $\mathbb{A}(\Gamma)$.

Consider an arbitrary cone $C \in \mathbb{A}(\Gamma)$. Let $\operatorname{int} C$ denote the interior of C. We can see that for all vectors $u \in \operatorname{int} C$, the canonical order of $\mathcal{P}$ with respect to u is the same (since all vector $u \in \operatorname{int} C$ lie in the same set of halfspaces). We use $|M|$ to denote the complexity of M, i.e., the number of vertices in $\mathsf{ConvH}(M)$.

▶ **Lemma 12.** *Assuming the existential model and $p_v \in (0, 1)$ for all $v \in \mathcal{P}$, the complexity of M is the same as the cardinality of $\mathbb{A}(\Gamma)$, i.e., $|M| = |\mathbb{A}(\Gamma)|$. Moreover, each cone $C \in \mathbb{A}(\Gamma)$ corresponds to exactly one vertex v of $\mathsf{ConvH}(M)$ in the following sense: the gradient $\nabla f(M, u) = v$ for all $u \in \operatorname{int} C$ (note that here v should be understood as a vector).*

Proof. (sketch) We have shown that M is a convex polytope. We first note that the support function uniquely defines a convex body (see e.g., [48]). We need the following well known

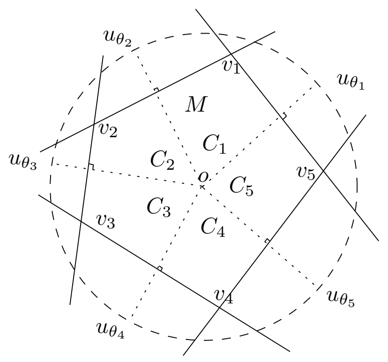

Figure 1 The figure depicts a pentagon M in $\mathbb{R}^2$ to illustrate some intuitive facts in convex geometry. (1) The plane can be divided into 5 cones $C_1, \ldots, C_5$, by 5 angles $\theta_1, \ldots, \theta_5$. u_{θ_i} is the unit vector corresponding to angle θ_i. Each cone C_i corresponds to a vertex v_i and for any direction $u \in C_i$, $f(M,u) = \langle u, v_i \rangle$ and the vector $\nabla f(M,u)$ is v_i. (2) Each direction θ_i is perpendicular to an edge of M. $M = \cap_{i=1}^5 H_i$ where H_i is the supporting halfplane with normal vector u_{θ_i}.

fact in convex geometry (see e.g., [25]): For any convex polytope M, $\mathbb{R}^d$ can be divided into exactly $|M|$ polyhedral cones (of dimension d, ignoring the boundaries), such that each such cone C_v corresponds to a vertex v of M, and for each vector $u \in C_v$, it holds $f(M,u) = \langle u, v \rangle$ (i.e., the maximum of $f(M,u) = \max_{v' \in M} \langle u, v' \rangle$ is achieved by v for all $u \in C_v$)[1]. See Figure 1 for an example in $\mathbb{R}^2$. Hence, for each $u \in \operatorname{int} C_v$ the gradient of of the support function (as a function of u) is exactly v:

$$\nabla f(M,u) = \left\{ \frac{\partial f(M,u)}{\partial u_j} \right\}_{j \in [d]} = \left\{ \frac{\partial \langle u, v \rangle}{\partial u_j} \right\}_{j \in [d]} = \left\{ \frac{\partial \sum_{j \in [d]} v_j u_j}{\partial u_j} \right\}_{j \in [d]} = v, \tag{2}$$

where u_j is the jth coordinate of u. With a bit abuse of notation, we denote the set of cones defined above by $\mathbb{A}(M)$.

Now, consider a cone $C \in \mathbb{A}(\Gamma)$. We show that for all $u \in \operatorname{int} C$, $\nabla f(M,u)$ is a distinct constant vector independent of u. In fact, we know that $f(M,u) = f(\mathcal{P},u) = \sum_{v \in \mathcal{P}} \Pr^R(v,u) \langle v, u \rangle$, where $\Pr^R(v,u) = \prod_{v' \succ_u v}(1 - p_{v'}) p_v$. For all $u \in \operatorname{int} C$, the $\Pr^R(v,u)$ value is the same since the value only depends on the canonical order with respect to u, which is the same for all $u \in C$. Hence, we can get that for all $u \in \operatorname{int} C$, $\nabla f(M,u) = \sum_{v \in \mathcal{P}} \Pr^R(v,u) v$, which is a constant independent of u. We can also show that the gradient $\nabla f(M,u)$ must be different for two adjacent cones C_1, C_2 (separated by some hyperplane in Γ) in $\mathbb{A}(\Gamma)$. So $\nabla f(M,u)$ is piecewise constant, with a distinct constant in each cone in $\mathbb{A}(M)$. The same also holds for $\mathbb{A}(\Gamma)$. This is only possible if $\mathbb{A}(\Gamma)$ (thinking as a partition of $\mathbb{R}^d$) partitions $\mathbb{R}^d$ exactly the same way as $\mathbb{A}(M)$ does. Hence, we have $\mathbb{A}(\Gamma) = \mathbb{A}(M)$ and the lemma follows immediately. ◀

Since $O(n^2)$ hyperplanes passing through the origin can divide $\mathbb{R}^d$ into at most $O(\binom{n^2}{d-1})$ d-dimensional polyhedral cones (see e.g., [9]), we immediately obtain the following corollary.

▶ **Corollary 13.** *It holds that* $|M| \le O(\binom{n^2}{d-1}) = O(n^{2d-2})$.

[1] The support function for a polytope is just the upper envelope of a finite set of linear functions, thus a piecewise linear function, and the domain of each piece is a polyhedral cone.

▶ **Theorem 14.** *In $\mathbb{R}^d$ for constant d, the polytope M which defines $f(\mathcal{P}, u)$ for any direction u can be described with $O(n^{2d-2})$ vertices in $\mathbb{R}^d$, and can be computed in $O(n^{2d-1}\log n)$ time. In $\mathbb{R}^2$, the runtime can be improved to $O(n^2 \log n)$.*

In fact, we can reduce the construction time to nearly linear time, which leads to Theorem 4. The details can be found in the full version.

2.1 ε-exp-kernel Under the Subset Constraint

First, we show that under the subset constraint (i.e., the ε-EXP-KERNEL is required to be a subset of the original point set, with the same probability distribution for each chosen point), there exists no ε-EXP-KERNEL with small size in general.

▶ **Lemma 15.** *For some constant $\varepsilon > 0$, there exist a set $\mathcal{P}$ of stochastic points such that no $o(n)$ size ε-EXP-KERNEL exists for $\mathcal{P}$ under the subset constraint (for both locational model and existential model).*

In light of the above negative result, we make the following β-*assumption*: we assume each possible location realizes a point with probability at least β, for a constant $\beta > 0$.

▶ **Theorem 16.** *Under the β-assumption, in the existential uncertainty model, there is an ε-EXP-KERNEL in $\mathbb{R}^d$ of size $O(\beta^{-(d-1)}\varepsilon^{-(d-1)/2}\log(1/\varepsilon))$ that satisfies the subset constraint.*

3 ε-Kernels for Probability Distributions of Width

Recall $\mathcal{S}$ is an (ε, τ)-QUANT-KERNEL if for all $x \geq 0$, $\Pr_{P\sim\mathcal{P}}\Big[\omega(P, u) \leq (1-\varepsilon)x\Big] - \tau \leq \Pr_{P\sim\mathcal{S}}\Big[\omega(S, u) \leq x\Big] \leq \Pr_{P\sim\mathcal{P}}\Big[\omega(P, u) \leq (1+\varepsilon)x\Big] + \tau$. For ease of notation, we sometimes write $\Pr\big[\omega(\mathcal{P}, u) \leq t\big]$ to denote $\Pr_{P\sim\mathcal{P}}\big[\omega(P, u) \leq t\big]$, and abbreviate the above as $\Pr\Big[\omega(S, u) \leq x\Big] \in \Pr\Big[\omega(\mathcal{P}, u) \leq (1 \pm \varepsilon)x\Big] \pm \tau$. We first provide a simple linear time algorithm for constructing an (ε, τ)-QUANT-KERNEL for both existential and locational models, in Section 3.1. The points in the constructed kernel are not independent. Then, for existential models, we provide a nearly linear time (ε, τ)-QUANT-KERNEL construction where all stochastic points in the kernel are independent in Section 3.2.

3.1 A Simple (ε, τ)-quant-kernel Construction

In this section, we show a linear time algorithm for constructing an (ε, τ)-QUANT-KERNEL for any stochastic model if we can sample a realization from the model in linear time (which is true for both locational and existential uncertainty models).

Algorithm: Let $N = O\big(\tau^{-2}\varepsilon^{-(d-1)}\log(1/\varepsilon)\big)$. We sample N independent realizations from the stochastic model. Let $\mathcal{H}_i$ be the convex hull of the present points in the ith realization. For $\mathcal{H}_i$, we use the algorithm in [7] to find a deterministic ε-kernel $\mathcal{E}_i$ of size $O(\varepsilon^{-(d-1)/2})$. Our (ε, τ)-QUANT-KERNEL $\mathcal{S}$ is the following simple stochastic model: with probability $1/N$, all points in $\mathcal{E}_i$ are present. Hence, $\mathcal{S}$ consists of $O\big(\tau^{-2}\varepsilon^{-3(d-1)/2}\log(1/\varepsilon)\big)$ points (two such points either co-exist or are mutually exclusive). Hence, for any direction u, $\Pr[\omega(\mathcal{S}, u) \leq t] = \frac{1}{N}\sum_{i=1}^{N}\mathbb{I}(\omega(\mathcal{E}_i, u) \leq t)$, where $\mathbb{I}(\cdot)$ is the indicator function.

For a realization $P \sim \mathcal{P}$, we use $\mathcal{E}(P)$ to denote the deterministic ε-kernel for P. So, $\mathcal{E}(P)$ is a random set of points, and we can think of $\mathcal{E}_1, \ldots, \mathcal{E}_N$ as samples from the random set. We first show that $\mathcal{S}$ is an (ε, τ)-QUANT-KERNEL for $\mathcal{E}(P)$.

▶ **Lemma 17.** *Let $N = O(\tau^{-2}\varepsilon^{-(d-1)}\log(1/\varepsilon))$. For any $t \geq 0$ and any direction u,*

$$\Pr[\omega(\mathcal{S}, u) \leq t] \in \Pr_{P\sim\mathcal{P}}[\omega(\mathcal{E}(P), u) \leq t] \pm \tau.$$

Proof (Sketch). Let $L = O(\varepsilon^{-(d-1)/2})$. We first build a mapping g that maps each realization $\mathcal{E}(P)$ to a point in $\mathbb{R}^{dL}$, as follows: Consider a realization P of $\mathcal{P}$. Suppose $\mathcal{E}(P) = \{(x_1^1, \dots, x_d^1), \dots, (x_1^L, \dots, x_d^L)\}$ (if $|\mathcal{E}(P)| < L$, we pad it with $(0, \dots, 0)$). We let $g(\mathcal{E}(P)) = (x_1^1, \dots, x_d^1, \dots, x_1^L, \dots, x_d^L) \in \mathbb{R}^{dL}$. For any $t \geq 0$ and any direction $u \in \mathbb{R}^d$, note that $\omega(\mathcal{E}(P), u) \geq t$ holds if and only if there exists some $1 \leq i, j \leq |\mathcal{E}(P)|, i \neq j$ satisfies that $\sum_{k=1}^{d}(x_k^i - x_k^j)u_k \geq t$, which is equivalent to saying that point $g(\mathcal{E}(P))$ is in the union of the those $O(|\mathcal{E}(P)|^2)$ halfspaces. We can show that the VC dimension of the union of $O(|\mathcal{E}(P)|^2)$ such halfspaces is bounded by $O(\varepsilon^{-(d-1)}\log(1/\varepsilon))$. Then, the lemma follows from the VC uniform convergence theorem [51, 10]. ◀

From the above lemma, it is not difficult to obtain Theorem 5.

3.2 Improved (ε, τ)-quant-kernel for Existential Models

In this section, we show an (ε, τ)-QUANT-KERNEL $\mathcal{S}$ can be constructed in nearly linear time for the existential model, and all points in $\mathcal{S}$ are independent of each other. The size bound $\widetilde{O}(\tau^{-2}\varepsilon^{-(d-1)})$ (see Theorem 6) is better than that in Theorem 5 for the general case, and the independence property may be useful in certain applications. Moreover, some of the insights developed in this section may be of independent interest (e.g., the connection to Tukey depth). Due to the independence requirement, the construction is somewhat more involved. For ease of the description, we assume the Euclidean plane first. All results can be easily extended to $\mathbb{R}^d$. We also assume that all probability values are strictly between 0 and 1 and $0 < \varepsilon, \tau \leq 1/2$ is a fixed constant.

Let $\lambda(\mathcal{P}) = \sum_{v\in\mathcal{P}}(-\ln(1-p_v))$. In the following, we present two algorithms. The first algorithm works for any $\lambda(\mathcal{P})$ and produces an (ε, τ)-QUANT-KERNEL $\mathcal{S}$ whose size depends on $\lambda(\mathcal{P})$. In Section 3.2.2, we present the second algorithm that only works for $\lambda(\mathcal{P}) \geq 3\ln(2/\tau)$ but produces an (ε, τ)-QUANT-KERNEL $\mathcal{S}$ with a constant size (the constant only depends on ε, τ and δ). Thus, we can get a constant size (ε, τ)-QUANT-KERNEL by running the first algorithm when $\lambda(\mathcal{P}) \leq 3\ln(2/\tau)$ and running the second algorithm otherwise.

3.2.1 Algorithm 1: For Any $\lambda(\mathcal{P})$

In this section, we present the first algorithm which works for any $\lambda(\mathcal{P})$. We can think of each point v associated with a Bernoulli random variable X_v that takes value 1 with probability p_v and 0 otherwise. Now, we replace the Bernoulli random variable X_v by a Poisson distributed random variable $\widetilde{X}_v$ with parameter $\lambda_v = -\ln(1-p_v)$ (denoted by Pois(λ_v)), i.e., $\Pr[\widetilde{X}_v = k] = \frac{1}{k!}\lambda_v^k e^{-\lambda_v}$, for $k = 0, 1, 2, \dots$. Here, $\widetilde{X}_v = k$ means that there are k realized points located at the position of v. We call the new instance *the Poissonized instance corresponding to* $\mathcal{P}$. We can check that $\Pr[\widetilde{X}_v = 0] = e^{-\lambda_v} = 1 - p_v = \Pr[X_v = 0]$. Also note that co-locating points does not affect any directional width, so the Poissonized instance is essentially equivalent to the original instance for our problem.

The construction of the (ε, τ)-QUANT-KERNEL $\mathcal{S}$ is as follows: Let $\mathfrak{A}$ be the probability measure over all points in $\mathcal{P}$ defined by $\mathfrak{A}(\{v\}) = \lambda_v/\lambda$ for every $v \in \mathcal{P}$, where $\lambda := \lambda(\mathcal{P}) = \sum_{v\in\mathcal{P}}\lambda_v$. Let τ_1 be a small positive constant to be fixed later. We take $N = \widetilde{O}(\tau_1^{-2})$ independent samples from $\mathfrak{A}$ (we allow more than one point to be co-located at the same position), and let $\mathfrak{B}$ be the empirical measure, i.e., each sample point having probability

$1/N$. The coreset $\mathcal{S}$ consists of the N sample points in $\mathfrak{B}$, each with the same existential probability $1 - \exp(-\lambda/N)$.

▶ **Theorem 18.** *Let $\tau_1 = O(\frac{\tau}{\max\{\lambda,\lambda^2\}})$ and $N = O(\frac{1}{\tau_1^2}\log\frac{1}{\delta}) = O(\frac{\max\{\lambda^2,\lambda^4\}}{\tau^2}\log\frac{1}{\delta})$. With probability at least $1-\delta$, for any $t \geq 0$ and any direction u, we have that $\Pr\Big[\omega(\mathcal{S},u) \leq t\Big] \in \Pr\Big[\omega(\mathcal{P},u) \leq t\Big] \pm \tau$.*

3.2.2 Algorithm 2: For $\lambda(\mathcal{P}) > 3\ln(2/\tau)$

In the second algorithm, we assume that $\lambda(\mathcal{P}) = \sum_{v\in\mathcal{P}} \lambda_v > 3\ln(2/\tau)$. When $\lambda(\mathcal{P})$ is large, we cannot directly use the sampling technique in the previous section since it requires a large number of samples. However, the condition $\lambda(\mathcal{P}) \geq 3\ln(2/\tau)$ implies there is a nonempty convex region $\mathcal{K}$ inside the convex hull of $\mathcal{P}$ with high probability. Moreover, we can show the sum of λ_v values in $\overline{\mathcal{K}} = \mathbb{R}^2 \setminus \mathcal{K}$ is small. Hence, we can use the sampling technique just for $\overline{\mathcal{K}}$ and use the deterministic ε-kernel construction for $\mathcal{K}$.

Again consider the Poissonized instance of $\mathcal{P}$. Imagine the following process. Fix a direction u. We move a sweep line ℓ_u orthogonal to u, along the direction u, to sweep through the points in $\mathcal{P}$. We use H_u to denote the halfplane defined by ℓ_u (with normal vector u) and $\overline{H}_u$ denote its complement. So $\mathcal{P}(\overline{H}_u) = \mathcal{P} \cap \overline{H}_u$ is the set of points that have been swept so far. We stop the movement of ℓ_u at the first point such that $\sum_{v\in\overline{H}_u} \lambda_v \geq \ln(2/\tau)$ (ties should be broken in an arbitrary but consistent manner). One important property about $\overline{H}_u$ is that $\Pr[\overline{H}_u \models 0] \leq \tau/2$. We repeat the above process for all directions u and let $\mathcal{H} = \cap_u H_u$. Since $\lambda(\mathcal{P}) > 3\ln(2/\tau)$, by Helly's theorem, $\mathcal{H}$ is nonempty. A careful examination of the above process reveals that $\mathcal{H}$ is in fact a convex polytope and each edge of the polytope is defined by two points in $\mathcal{P}$.

The construction of the (ε,τ)-QUANT-KERNEL $\mathcal{S}$ is as follows. First, we use the algorithm in [7] to find a deterministic ε-kernel $\mathcal{E}_{\mathcal{H}}$ of size $O(\varepsilon^{-1/2})$ for $\mathcal{H}$. One useful property of the algorithm in [7] is that $\mathcal{E}_{\mathcal{H}}$ is a subset of the vertices of $\mathcal{H}$. Hence the convex polytope $\mathsf{ConvH}(\mathcal{E}_{\mathcal{H}})$ is contained in $\mathcal{H}$. Since $\mathcal{E}_{\mathcal{H}}$ is an ε-kernel, $(1+\varepsilon)\mathsf{ConvH}(\mathcal{E}_{\mathcal{H}}))$ (properly shifted) contains $\mathcal{H}$. Let $\mathcal{K} = (1+\varepsilon)\mathsf{ConvH}(\mathcal{E}_{\mathcal{H}})$ and $\overline{\mathcal{K}} = \mathcal{P} \setminus \mathcal{K}$. See Figure 2.

Now, we apply the random sampling construction over $\overline{\mathcal{K}}$. More specifically, let $\lambda := \lambda(\overline{\mathcal{K}}) = \sum_{v\in\overline{\mathcal{K}}\cap\mathcal{P}} \lambda_v$. Let $\mathfrak{A}$ be the probability measure over $\mathcal{P}\cap\overline{\mathcal{K}}$ defined by $\mathfrak{A}(\{v\}) = \lambda_v/\lambda$ for every $v \in \mathcal{P}\cap\overline{\mathcal{K}}$. Let $\tau_1 = O(\tau/\lambda)$. We take $N = O(\tau_1^{-2}\log(1/\delta))$ independent samples from $\mathfrak{A}$ and let $\mathfrak{B}$ be the empirical distribution with each sample point having probability $1/N$. The (ε,τ)-QUANT-KERNEL $\mathcal{S}$ consists of the N points in $\mathfrak{B}$, each with the same existential probability $1-\exp(-\lambda/N)$, as well as all vertices of $\mathcal{K}$, each with probability 1.

▶ **Theorem 19.** *Let $\lambda = \lambda(\overline{\mathcal{K}})$ and $\tau_1 = O(\tau/\lambda)$, and $N = O\Big(\frac{1}{\tau_1^2}\log\frac{1}{\delta}\Big) = O\Big(\frac{\ln^2 1/\tau}{\varepsilon\tau^2}\log\frac{1}{\delta}\Big)$. With probability at least $1-\delta$, for any $t \geq 0$ and any direction u, we have that*

$$\Pr\Big[\omega(\mathcal{S},u) \leq t\Big] \in \Pr\Big[\omega(\mathcal{P},u) \leq (1\pm\varepsilon)t\Big] \pm \tau. \tag{3}$$

In summary, we obtain Theorem 6 combining Theorem 18 and Theorem 19.

4 (ε, r)-fpow-kernel Under the β-Assumption

We now show an (ε,r)-FPOW-KERNEL exists in the existential uncertainty model under the β-assumption. Recall that the function $T_r(P,u) = \max_{v\in P}\langle u,v\rangle^{1/r} - \min_{v\in P}\langle u,v\rangle^{1/r}$. For

Figure 2 Construction of (ε,τ)-QUANT-KERNEL $\mathcal{S}$. The dashed polygon is $\mathcal{H}$. The inner solid polygon is $\mathsf{ConvH}(\mathcal{E}_{\mathcal{H}})$ and the outer one is $K = (1+\varepsilon)\mathsf{ConvH}(\mathcal{E}_{\mathcal{H}})$. $\overline{\mathcal{K}}$ is the set of points outside $\mathcal{K}$.

ease of notation, we write $\mathbb{E}[T_r(\mathcal{P},u)]$ to denote $\mathbb{E}_{P\sim\mathcal{P}}[T_r(P,u)]$. Our goal is to find a set $\mathcal{S}$ of stochastic points so for all directions $u \in \mathcal{P}^\star$, that $\mathbb{E}[T_r(\mathcal{S},u)] \in (1\pm\varepsilon)\mathbb{E}[T_r(\mathcal{P},u)]$.

Our construction of $\mathcal{S}$ is almost the same as that in Section 3.1. Suppose we sample N (fixed later) independent realizations and take the ε_0-kernel for each of them. Suppose they are $\{\mathcal{E}_1,\ldots,\mathcal{E}_N\}$ and we associate each a probability $1/N$. We denote the resulting (ε,r)-FPOW-KERNEL by $\mathcal{S}$. Hence, for any direction $u \in \mathcal{P}^\star$, $\mathbb{E}[T_r(\mathcal{S},u)] = \frac{1}{N}\sum_{i=1}^{N} T_r(\mathcal{E}_i,u)$ and we use this value as the estimation of $\mathbb{E}[T_r(\mathcal{P},u)]$. Our result is summarized by Theorem 7.

5 Applications

In this section, we show that our coreset results for the directional width problem readily imply several coreset results for other stochastic problems, just as in the deterministic setting. We introduce these stochastic problems and briefly summarize our results below.

5.1 Approximating the Extent of Uncertain Functions

We first consider the problem of approximating the extent of a set $\mathcal{H}$ of uncertain functions. As before, we consider both the existential model and the locational model of uncertain functions.

1. In the existential model, each uncertain function h is a function in $\mathbb{R}^d$ associated with a existential probability p_f, which indicates the probability that h presents in a random realization.
2. In the locational model, each uncertain function h is associated with a finite set $\{h_1,h_2,\ldots\}$ of deterministic functions in $\mathbb{R}^d$. Each h_i is associated with a probability value $p(h_i)$, such that $\sum_i p(h_i) = 1$. In a random realization, h is independently realized to some h_i, with probability $p(h_i)$.

We use $\mathcal{H}$ to denote the random instance, that is a random set of functions. We use $h \in \mathcal{H}$ to denote the event that the deterministic function h is present in the instance. For each point $x \in \mathbb{R}^d$, we let the random variable $\mathfrak{E}_{\mathcal{H}}(x) = \max_{h\in\mathcal{H}} h(x) - \min_{h\in\mathcal{H}} h(x)$ be the extent of $\mathcal{H}$ at point x. Suppose $\mathcal{S}$ is another set of uncertain functions. We say $\mathcal{S}$ is the ε-EXP-KERNEL for $\mathcal{H}$ if $(1-\varepsilon)\mathfrak{E}_{\mathcal{H}}(x) \le \mathfrak{E}_{\mathcal{S}}(x) \le \mathfrak{E}_{\mathcal{H}}(x)$ for any $x \in \mathbb{R}^d$. We say $\mathcal{S}$ is the (ε,τ)-QUANT-KERNEL for $\mathcal{H}$ if $\Pr_{S\sim\mathcal{S}}\Big[\mathfrak{E}_S(x) \le t\Big] \in \Pr_{H\sim\mathcal{H}}\Big[\mathfrak{E}_H(x) \le (1\pm\varepsilon)t\Big] \pm \phi$. for any $t \ge 0$ and any $x \in \mathbb{R}^d$.

Let us first focus on linear functions in $\mathbb{R}^d$. Using the *duality transformation* that maps linear function $y = a_1x_1 + \ldots + a_dx_d + a_{d+1}$ to the point $(a_1, \ldots, a_{d+1}) \in \mathbb{R}^{d+1}$, we can reduce the extent problem to the directional width problem in $\mathbb{R}^{d+1}$. Let $\mathcal{H}$ be a set of uncertain linear functions (under either existential or locational model) in $\mathbb{R}^d$ for constant d. From Theorem 14 and Corollary 11, we can construct a set S of $O(n^{2d})$ deterministic linear functions in $\mathbb{R}^d$, such that $\mathfrak{E}_S(x) = \mathbb{E}[\mathfrak{E}_{\mathcal{H}}(x)]$ for any $x \in \mathbb{R}^d$. Moreover, for any $\varepsilon > 0$, there exists an ε-EXP-KERNEL of size $O(\varepsilon^{-d/2})$ and an (ε, τ)-QUANT-KERNEL of size $\widetilde{O}(\tau^{-2}\varepsilon^{-d})$. Using the standard linearization technique [7], we can obtain the following generalization for uncertain polynomials.

▶ **Theorem 20.** *Let $\mathcal{H}$ be a family of uncertain polynomials in $\mathbb{R}^d$ (under either existential or locational model) that admits linearization of dimension k. We can construct a set M of $O(n^{2k})$ deterministic polynomials, such that $\mathfrak{E}_M(x) = \mathbb{E}[\mathfrak{E}_{\mathcal{H}}(x)]$ for any $x \in \mathbb{R}^d$. Moreover, for any $\varepsilon > 0$, there exists an ε-EXP-KERNEL of size $O(\varepsilon^{-k/2})$ and an (ε, τ)-QUANT-KERNEL of size $\min\{\widetilde{O}(\tau^{-2}\max\{\lambda^2, \lambda^4\}), \widetilde{O}(\varepsilon^{-k}\tau^{-2})\}$. Here $\lambda = \sum_{h\in\mathcal{H}}(-\ln(1-p_h))$.*

Now, we consider functions of the form $u(x) = p(x)^{1/r}$ where $p(x)$ is a polynomial and r is a positive integer. We call such a function a *fractional polynomial*. We still use $\mathcal{H}$ to denote the random set of fractional polynomials. Let $\mathcal{H}^\star \subseteq \mathbb{R}^d$ be the set of points such that for any points $x \in \mathcal{H}^\star$ and any function $u \in \mathcal{H}$, we have $u(x) \geq 0$. For each point $x \in \mathcal{H}^\star$, we let the random variable $\mathfrak{E}_{r,\mathcal{H}}(x) = \max_{h\in\mathcal{H}} h(x)^{1/r} - \min_{h\in\mathcal{H}} h(x)^{1/r}$. We say another random set $\mathcal{S}$ of functions is the (ε, r)-FPOW-KERNEL for $\mathcal{H}$ if $(1-\varepsilon)\mathfrak{E}_{r,\mathcal{H}}(x) \leq \mathfrak{E}_{r,\mathcal{S}}(x) \leq \mathfrak{E}_{r,\mathcal{H}}(x)$ for any $x \in \mathcal{H}^\star$. By the duality transformation and Theorem 7, we can obtain the following result.

▶ **Theorem 21.** *Let $\mathcal{H}$ be a family of uncertain fractional polynomials in $\mathbb{R}^d$ in the existential uncertainty model under the β-assumption. Further assume that each polynomial admits a linearization of dimension k. For any $\varepsilon > 0$, there exists an (ε, r)-FPOW-KERNEL of size $\widetilde{O}(\varepsilon^{-(rk-r+2)})$. Furthermore, the (ε, r)-FPOW-KERNEL consists of $N = O\big(\varepsilon^{-(rk-r+4)/2}\big)$ sets, each occurring with probability $1/N$ and containing $O\big(\varepsilon^{-r(k-1)/2}\big)$ deterministic fractional polynomials.*

5.2 Stochastic Moving Points

We can extend our stochastic models to moving points. In the existential model, each point v is present with probability p_v and follows a trajectory $v(t)$ in $\mathbb{R}^d$ when present ($v(t)$ is the position of v at time t). In the locational model, each point v is associated with a distribution of trajectories (the support size is finite) and the actual trajectory of v is a random sample for the distribution. Such uncertain trajectory models have been used in several applications in spatial databases [54]. For ease of exposition, we assume the existential model in the following. Suppose each trajectory is a polynomial of t with degree at most r. For each point v, any direction u and time t, define the polynomial $f_v(u,t) = \langle v(t), u\rangle$ and let $\mathcal{H}$ include f_v with probability p_v. For a set $\mathcal{P}$ of points, the directional width at time t is $\mathfrak{E}_{\mathcal{H}}(u,t) = \max_{v\in\mathcal{P}} f_v(u,t) - \min_{v\in\mathcal{P}} f_v(u,t)$. Each polynomial f_v admits a linearization of dimension $k = (r+1)d - 1$. Using Theorem 20, we can see that there is a set M of $O(n^{2k})$ deterministic moving points, such that the directional width of M in any direction u is the same as the expected directional width of $\mathcal{P}$ in direction u. Moreover, for any $\varepsilon > 0$, there exists an ε-EXP-KERNEL (which consists of only deterministic moving points) of size $O(\varepsilon^{-(k-1)/2})$ and an (ε, τ)-QUANT-KERNEL (which consists of both deterministic and stochastic moving points) of size $\widetilde{O}(\varepsilon^{-k}\tau^{-2})$.

5.3 Shape Fitting Problems

Theorem 20 can be also applied to some stochastic variants of certain shape fitting problems. We first consider the following variant of the minimum enclosing ball problem over stochastic points. We are given a set $\mathcal{P}$ of stochastic points (under either existential or locational model), find the center point c such that $\mathbb{E}[\max_{v\in\mathcal{P}} \|v-c\|^2]$ is minimized. It is not hard to see that the problem is equivalent to minimizing the expected area of the enclosing ball in $\mathbb{R}^2$. For ease of exposition, we assume the existential model where v is present with probability p_v. For each point $v \in P$, define the polynomial $h_v(x) = \|x\|^2 - 2\langle x, v\rangle + \|v\|^2$, which admits a linearization of dimension $d+1$ [7]. Let $\mathcal{H}$ be the family of uncertain polynomials $\{h_v\}_{v\in\mathcal{P}}$ (h_v exists with probability p_v). We can see that for any $x \in \mathbb{R}^d$, $\max_{v\in\mathcal{P}} \|x-v\|^2 = \max_{h_v\in\mathcal{H}} h_v(x)$. Using Theorem 20, we can see that there is a set M of $O(n^{2d+2})$ deterministic polynomials such that $\max_{h\in M} h(x) = \mathbb{E}[\max_{v\in\mathcal{P}} \|x-v\|^2]$ for any $x \in \mathbb{R}^d$ and a set S of $O(\varepsilon^{-(d+1)/2})$ deterministic polynomials such that $(1-\varepsilon)\mathbb{E}[\max_{v\in\mathcal{P}} \|x-v\|^2] \leq \max_{h\in S} h(x) \leq \mathbb{E}[\max_{v\in\mathcal{P}} \|x-v\|^2]$ for any $x \in \mathbb{R}^d$. We can store the set S instead of the original point set in order to answer the following queries: given a point v, return the expected length of the furthest point from v. The problem of finding the optimal center c can be also carried out over S, which can be done in $O(\varepsilon^{-O(d^2)})$ time: We can decompose the arrangement of n semialgebraic surfaces in $\mathbb{R}^d$ into $O(n^{O(d+k)})$ cells of constant description complexity, where k is the linearization dimension (see e.g., [9]). By enumerating all those cells in the arrangement of S, we know which polynomials lie in the upper envelopes, and we can compute the minimum value in each such cell in constant time when d is constant.

The above argument can also be applied to the following variant of the spherical shell for stochastic points. We are given a set $\mathcal{P}$ of stochastic points (under either existential or locational model). Our objective is to find the center point c such that $\mathbb{E}[\mathsf{obj}(c)] = \mathbb{E}[\max_{v\in P} \|v-c\|^2 - \min_{v\in P} \|v-c\|^2]$ is minimized. The problem is equivalent to minimizing the expected area of the enclosing annulus in $\mathbb{R}^2$. The objective can be represented as a polynomial of linearization dimension $k = d+1$. Proceeding as for the enclosing balls, we can show there is a set S of $O(\varepsilon^{-(k-1)/2})$ deterministic polynomials such that $(1-\varepsilon)\mathbb{E}[\mathsf{obj}(c)] \leq \mathfrak{E}_S(x) \leq \mathbb{E}[\mathsf{obj}(c)]$ for any $x \in \mathbb{R}^d$. We summarize our results by Theorem 8. We would like to make a few remarks here.

1. We take the minimum enclosing ball for example. If we examine the construction of set S, each polynomial $h \in S$ may *not* be of the form $h(x) = \|x\|^2 - 2\langle x, v\rangle + \|v\|^2$, therefore does not translate back to a minimum enclosing ball problem over deterministic points.
2. Another natural objective function for the minimum enclosing ball and the spherical shell problem would be the expected radius $\mathbb{E}[\max_{v\in P} \mathrm{d}(v,c)]$ and the expected shell width $\mathbb{E}[\max_{v\in P} \mathrm{d}(v,c) - \min_{v\in P} \mathrm{d}(v,c)]$. However, due to the fractional powers (square roots) in the objectives, simply using an ε-EXP-KERNEL does not work. This is unlike the deterministic setting. [2] We leave the problem of finding small coresets for the spherical shell problem as an interesting open problem. However, under the β-assumption, we can use (ε, r)-FPOW-KERNELs to handle such fractional powers, as in the next subsection.

5.4 Shape Fitting Problems (Under the β-assumption)

In this subsection, we consider several shape fitting problems in the existential model *under the β-assumption.* We show how to use Theorem 21 to obtain linear time approximation schemes for those problems.

[2] In particular, there is no stochastic analogue of Lemma 4.6 in [7].

1. (Minimum spherical shell) We first consider the minimum spherical shell problem. Given a set $\mathcal{P}$ of stochastic points (under the β-assumption), our goal is to find the center point c such that $\mathbb{E}[\max_{v\in P}\|v-c\|-\min_{v\in P}\|v-c\|]$ is minimized. For each point $v\in P$, let $h_v(x)=\|x\|^2-2\langle x,v\rangle+\|v\|^2$, which admits a linearization of dimension $d+1$. It is not hard to see that $\mathbb{E}[\max_{v\in P}\|v-c\|]=\mathbb{E}[\max_{v\in P}\sqrt{h_v(c)}]$ and $\mathbb{E}[\min_{v\in P}\|v-c\|]=\mathbb{E}[\min_{v\in P}\sqrt{h_v(c)}]$. Using Theorem 21, we can see that there are $N=\widetilde{O}\big(\varepsilon^{-(d+3)}\big)$ sets S_i, each containing $O\big(\varepsilon^{-(d+1)}\big)$ fractional polynomial $\sqrt{h_v}$s such that for all $x\in\mathbb{R}^d$,

$$\frac{1}{N}\sum_{i\in[N]}(\max_{S_i}\sqrt{h_v(x)}-\min_{S_i}\sqrt{h_v(x)})\in(1\pm\varepsilon)(\mathbb{E}[\max_{v\in P}\|v-x\|]-\mathbb{E}[\min_{v\in P}\|v-x\|]). \tag{4}$$

Note that our (ε,r)-FPOW-KERNEL satisfies the subset constraint. Hence, each function $\sqrt{h_v}$ corresponds to an original point in $\mathcal{P}$. So, we can store N point sets $P_i\subseteq\mathcal{P}$, with $|P_i|=O\big(\varepsilon^{-d}\big)$ as the coreset for the original point set. By (4), an optimal solution for the coreset is an $(1+\varepsilon)$-approximation for the original problem.
Now, we briefly sketch how to compute the optimal solution for the coreset. Consider all points in $\cup_i P_i$. Consider the arrangement of $O\big(\varepsilon^{-O(d)}\big)$ hyperplanes, each bisecting a pair of points in $\cup_i P_i$. For each cell C of the arrangement, for any point $v\in C$, the ordering of all points in $\cup_i P_i$ is fixed. We then enumerate all those cells in the arrangement and try to find the optimal center in each cell. Fix a cell C. For any point set P_i, we know which point is the furthest one and which point is the closest one from points in C_0. Say they are $v_i=\arg\max_{v\in P_i}\|v-x\|$ and $v_i'=\arg\min_{v\in P_i}\|v-x\|$. Hence, our problem can be formulated as the following optimization problem:

$$\min_x\frac{1}{N}\sum_i(d_i-d_i'),\quad \text{s.t.}\quad d_i^2=\|v_i-x\|^2, d_i'^2=\|v_i'-x\|^2, d_i,d_i'\ge 0,\forall i\in[N]; x\in C_0.$$

The polynomial system has a constant number of variables and constraints, hence can be solved in constant time. More specifically, we can introduce a new variable t and let $t=\frac{1}{N}\sum_i(d_i-d_i')$. All polynomial constraints define a semi-algebraic set. By using constructive version of Tarski-Seidenberg theorem, we can project out all variables except t and the resulting set is still a semi-algebraic set (which would be a finite collection of points and intervals in $\mathbb{R}^1$) (See e.g.,[12]).
2. (Minimum enclosing cylinder, Minimum cylindrical shell) Let $\mathcal{P}$ be a set of stochastic points in the existential uncertainty model under the β-assumption. Let $\mathrm{d}(\ell,v)$ denote the distance between a point $v\in\mathbb{R}^d$ and a line $\ell\subset\mathbb{R}^d$. The goal for the minimum enclosing cylinder problem is to find a line ℓ such that $\mathbb{E}[\max_{v\in\mathcal{P}}\mathrm{d}(\ell,v)]$ is minimized, while that for the minimum cylindrical shell problem is to minimize $\mathbb{E}[\max_{v\in\mathcal{P}}\mathrm{d}(\ell,v)-\min_{v\in\mathcal{P}}\mathrm{d}(\ell,v)]$. The algorithms for both problems are almost the same and we only sketch the one for the minimum enclosing cylinder problem.
We follow the approach in [7]. We represent a line $\ell\in\mathbb{R}^d$ by a $(2d-1)$-tuple $(x_1,\ldots,x_{2d-1})\in\mathbb{R}^{2d-1}$: $\ell=\{p+tq\mid t\in\mathbb{R}\}$, where $p=(x_1,\cdots,x_{d-1},0)$ is the intersection point of ℓ with the hyperplane $x_d=0$ and $q=(x_d,\ldots,x_{2d-1})$, $\|q\|^2=1$ is the orientation of ℓ. Then for any point $v\in\mathbb{R}^d$, we have that

$$\mathrm{d}(\ell,v)=\|(p-v)-\langle p-v,q\rangle q\|,$$

where the polynomial $\mathrm{d}^2(\ell,v)$ admits a linearization of dimension $O(d^2)$. Now, proceeding as for the minimum enclosing ball problem and using Theorem 21, we can obtain a coreset $\mathcal{S}$ consisting $N=O\big(\varepsilon^{-O(d^2)}\big)$ deterministic point sets $P_i\subseteq\mathcal{P}$.

We briefly sketch how to obtain the optimal solution for the coreset. We can also decompose $\mathbb{R}^{2d-1}$ (a point x in the space with $\|(x_d, \ldots, x_{2d-1})\| = 1$ represents a line in $\mathbb{R}^d$) into $O\big(\varepsilon^{-O(d^2)}\big)$ semi-algebraic cells such that for each cell, the ordering of the points in $\mathcal{S}$ (by their distances to a line in the cell) is fixed. Note that such a cell is a semi-algebraic cell. For a cell C, assume that $v_i = \arg\max_{v\in P_i} \mathrm{d}(\ell, v_i)$ for all $i \in [N]$, where ℓ is an arbitrary line in C. We can formulate the problem as the following polynomial system:

$$\min_{l} \frac{1}{N}\sum_i d_i, \quad \text{s.t.} \quad d_i^2 = \mathrm{d}^2(\ell, v_i), d_i \geq 0, \forall i \in [N]; \ell = (p,q) \in C_0, \|q\|^2 = 1.$$

Again the polynomial system has a constant number of variables and constraints. Thus, we can compute the optimum in constant time. We summarize our results by Theorem 9.

Every Property Is Testable on a Natural Class of Scale-Free Multigraphs*

Abstract

In this paper, we introduce a natural class of multigraphs called hierarchical-scale-free (HSF) multigraphs, and consider constant-time testability on the class. We show that a very wide subclass of HSF is hyperfinite. Based on this result, an algorithm for a deterministic partitioning oracle can be constructed. We conclude by showing that every property is constant-time testable on the above subclass of HSF. This algorithm utilizes findings by Newman and Sohler of STOC'11. However, their algorithm is based on a bounded-degree model, while it is known that actual scale-free networks usually include hubs, which have a very large degree. HSF is based on scale-free properties and includes such hubs. This is the first universal result of constant-time testability on a class of graphs made by a model of scale-free networks, and it has the potential to be applicable on a very wide range of scale-free networks.

1 Introduction

How to handle big data is a very important issue in computer science. In the theoretical area, developing efficient algorithms for handling big data is an urgent task. For this purpose, constant-time algorithms look like they could be powerful tools, as they are able to read very small parts (constant size) of inputs.

Property testing is the most well-studied area in constant-time algorithms. A testing algorithm (or a tester) for a property accepts an input if it has the stipulated property and rejects it if it is far away from having the stipulated property with a high probability (e.g., at least 2/3) by reading a constant part of the input. A property is said to be testable if there is a tester [10].

Property testing of graph properties has been well studied and many fruitful results have been obtained [2, 3, 7, 10, 11, 12, 13, 18, 20, 22, 23]. Testers on the graphs are separated into three groups according to model: the dense-graph model (the adjacent-matrix model), the bounded-degree model, and the general model. The dense-graph model is the best clarified: In this model, the characteristics of testable properties have been obtained [2]. However,

* This work was partially supported by the Algorithms on Big Data project (ABD14) of CREST, JST, the ELC project (MEXT KAKENHI Grant Number 24106003), and JSPS KAKENHI Grant Numbers 24650006 and 15K11985.

graphs based on actual networks are usually sparse and thus unfortunately the dense-graph model does not fit. Studies on the bounded-degree model have been proceeding recently. One of the most important findings for this model is that every minor-closed property is testable [3]. This result can be extended to the surprising result that every property of a hyperfinite graph is testable [23]. However, graphs based on actual models have no degree bounds, i.e., it is known that web-graphs have hubs [1, 17], which have a large degree, and, unfortunately once again, these algorithms do not work for them.

Typical big-data graph models are scale-free networks, which are characterized by the power-law degree distribution. Many models have been proposed for scale-free networks [1, 4, 5, 6, 9, 17, 21, 24, 25, 26, 27]. Recently, a promising model based on another property of a hierarchical isomorphic structure has been presented: If we look at a graph in a broad perspective, we find a similar structure to local structures. Shigezumi, Uno, and Watanabe [25] presented a model that is based on the idea of the hierarchical isomorphic structure of power-law distribution of isolated cliques. An idea of isolated cliques was given by Ito and Iwama [15, 16], and the definition is as follows. For a nonnegative integer $c \geq 0$, a *c-isolated clique* is a clique such that the number of outgoing edges (edges between the clique and the other vertices) is less than ck, where k is the number of vertices of the clique. A 1-isolated clique is sometimes simply called an *isolated clique*.

Based on the model of [25], we introduce a class of multigraphs, hierarchical scale-free multigraphs (HSF, Definitions 1.8)[1], which represents natural scale-free networks. We show the following result (Theorem 1.10):

Every property is testable on HSF if the power-law exponent[2] *is greater than two.*

Given this result, many problems on actual scale-free big networks will prove to be solvable in constant time. Although this result is an application of the algorithms of [23], which is a result on bounded-degree graphs, HSF is not a class of bounded-degree graphs. This is the first universal result of constant-time testability on a class of graphs made by a model of scale-free networks.

1.1 Definitions

In this paper, we consider undirected multigraphs without self-loops. We simply call this type of multigraph a "graph" in this paper and use $G = (V, E)$ to denote it, where V is the vertex set and E is the edge (multi)set. Sometimes V and E are denoted by $V[G]$ and $E[G]$, respectively. Henceforth, we use "set" to refer to a multiset for notational simplicity. Throughout this paper, n is used to denote the number of vertices of a graph, i.e., $|V| = n$.

For a graph $G = (V, E)$ and vertex subsets $X, Y \subseteq V$, $E_G(X, Y)$ denotes the edge set between X and Y, i.e., $E_G(X, Y) = \{(x, y) \in E \mid x \in X, y \in Y\}$. $E_G(X, V \backslash X)$ is also simply written as $E_G(X)$. $|E_G(X)|$ is denoted by $d_G(X)$. For a vertex $v \in V$, the number of edges incident to v is called the *degree* of v. A singleton set $\{x\}$ is often written as x for notational simplicity. E.g., the degree of v is represented by $d_G(v)$. The subscript G in the above $E_G(*)$, $d_G(*)$, etc., may be omitted if it is clear.

For a vertex $v \in V$, $\Gamma_G(v)$ denotes the set of vertices adjacent to v, i.e., $\Gamma_G(v) := \{u \in V \mid (v, u) \in E\}$. Note that $|\Gamma_G(v)|$ may not be equal to $d_G(v)$ as parallel edges may exist.

[1] In a preliminary version of this paper, [14], the definition of HSF is different. The definition in this paper is far more general (wider) than in the preliminary version.

[2] This is a parameter of HSF. For the definition, see the sentence just after Definitions 1.7.

For a graph $G = (V, E)$ and a vertex subset $X \subseteq V$, the *subgraph induced by* X is defined as $G(X) = (X, \{(u, v) \in E \mid u, v \in X\})$.

For a vertex subset $X \subseteq V$, a *contraction* of X is defined as an operation to (i) replace X with a new vertex v_X, (ii) replace each edge (v, u) in $E(X)$ $(v \in X, u \in V \backslash X)$ with a new edge (v_X, u), and (iii) remove all edges between vertices in X. That is, by contracting $X \subseteq V$, a graph $G = (V, E)$ is changed to $G' = (V', E')$ such that

$$V' = V \backslash X \cup \{v_X\}, \text{ and}$$
$$E' = E \backslash \{(v, u) \mid v \in X, u \in V\} \cup \{(v_X, u) \mid (v, u) \in E, v \in X, u \in V - X\}.$$

We identify the above $(v_X, u) \in E'$ with $(v, u) \in E$. In other words, we say that (v, u) remains in G' (as (v_X, u)). Note that the graphs are multigraphs, and thus if there are two edges $(v, u), (v', u) \in E$ for $v, v' \in X$, $v \neq v'$ and $u \in V \backslash X$, then two parallel edges, both represented by (v_X, u), one of which corresponds to (v, u) and the other of which corresponds to (v', u), are added to E'. Also note that none of the graphs considered in this paper contain self-loops, and hence an edge $(v, v') \in E$ with $v, v' \in X$ is removed by contracting X.

Two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ are *isomorphic* if there is a one-to-one correspondence $\Phi : V_1 \to V_2$ such that $E_{G_1}(u, v) = E_{G_2}(\Phi(u), \Phi(v))$ for all $u, v \in V_1$. A graph property (or property, for short) is a (possibly infinite) family of graphs, which is closed under isomorphism.

▶ **Definition 1.1** (ϵ-far and ϵ-close)**.** Let $G = (V, E)$ and $G' = (V', E')$ be two graphs with $|V| = |V'| = n$ vertices. Let $m(G, G')$ be the number of edges that need to be deleted and/or inserted from G in order to make it isomorphic to G'. The distance between G and G' is defined as[3] $\text{dist}(G, G') = m(G, G')/n$. We say that G and G' are *ϵ-far* if $\text{dist}(G, G) > \epsilon$; otherwise *$\epsilon$-close*. Let P be a non-empty property. The distance between G and P is $\text{dist}(G, P) = \min_{G'' \in P} \text{dist}(G, G'')$. We say that G is *ϵ-far* from P if $\text{dist}(G, P) > \epsilon$; otherwise *$\epsilon$-close*.

▶ **Definition 1.2** (testers)**.** A *testing algorithm* for a property P is an algorithm that, given query access to a graph G, accepts every graph from P with a probability of at least 2/3, and rejects every graph that is ϵ-far from P with probability at least 2/3. Oracles in the general graph model are: for any vertex v, the algorithm may ask for the degree $d(v)$, and may ask for the ith neighbor of the vertex (for $1 \le i \le d(v)$).[4] The number of queries made by an algorithm to the given oracle is called the *query complexity* of the algorithm. If the query complexity of a testing algorithm is a constant, independent of n (but it may depend on ϵ), then the algorithm is called a *tester*[5]. A (graph) property is *testable* if there is a tester for the property.

▶ **Definition 1.3** (isolated cliques [15])**.** For a graph $G = (V, E)$ and a real number $c \ge 0$, a vertex subset $Q \subseteq V$ is called a *c-isolated clique* if Q is a clique (i.e., $(u, v) \in E$, for all $u, v \in Q$ and $u \neq v$) and $d_G(Q) < c|Q|$. A 1-isolated clique is sometimes called an *isolated clique*. In this paper, we don't use $c > 1$ except section **4** (summary and future work).

[3] The distance defined here may be larger than 1 as $m(G, G') > n$ may occur. (In the bounded-degree model it is defined as $\text{dist}(G, G') = m(G, G')/dn$.) However, here we consider sparse graphs and they have an implicit upper bound of the average (not possibly maximum) degree, say d, and thus $\text{dist}(G, G')$ is bounded by d.

[4] Although asking whether there is an edge between any two vertices is also allowed in the general graph model, the algorithms we use in this paper do not need to use this query.

[5] In this paper, a tester may be nonuniform, i.e., it may depend on n and ϵ.

▶ **Definition 1.4.** Let $\mathcal{E}(G)$ be the graph obtained from G by contracting all isolated cliques. Two distinct isolated cliques never overlap, except in the special case of *double-isolated-cliques*, which consists of two isolated cliques with size k sharing $k-1$ vertices. A double-isolated-clique Q has no edge between Q and the other part of the graph (i.e., $d_G(Q) = 0$), and thus we specially define that a double-isolated-clique in G is contracted into a vertex in $\mathcal{E}(G)$. Under this assumption, $\mathcal{E}(G)$ is uniquely defined.

▶ **Definition 1.5** (hyperfinite [8]). For real numbers $t > 0$ and $\epsilon > 0$, a graph $G = (V, E)$ consisting of n vertices is (t, ϵ)*-hyperfinite* if one can remove at most ϵn edges from G and obtain a graph whose connected components have size at most t. For a function $\rho : \boldsymbol{R}^+ \to \boldsymbol{R}^+$, G is ρ*-hyperfinite* if it is $(\rho(\epsilon), \epsilon)$-hyperfinite for all $\epsilon > 0$. A family $\mathcal{G}$ of graphs is ρ*-hyperfinite* if all $G \in \mathcal{G}$ are ρ-hyperfinite. A family $\mathcal{G}$ of graphs is *hyperfinite* if there exists a function ρ such that $\mathcal{G}$ is ρ-hyperfinite.

Hyperfinite is a large class, as it is known that any minor-closed property is hyperfinite in a bounded-degree model. From the viewpoint of testing, the importance of hyperfiniteness stems from the following result.

▶ **Theorem 1.6** ([23]). *For the bounded-degree model, any property is testable for any class of hyperfinite graphs.*

This result is very strong, but there is a problem in that the result works on bounded-degree graphs and it is natural to consider that actual scale-free networks do not have a degree bound.

1.2 Our contribution and related work

In this paper, we apply the universal algorithm of [23] to scale-free networks. We formalize two natural classes, $\mathcal{SF}$ and $\mathcal{HSF}$ that represent scale-free networks[6]. The latter is a subclass of the former.

▶ **Definition 1.7.** For positive real numbers $c > 1$ and $\gamma > 1$, a class of *scale-free graphs (SF)* $\mathcal{SF}(c, \gamma)$ consists of (multi)graphs $G = (V, E)$ for which the following condition holds: Let ν_i be the number of vertices v with $d(v) = i$. Then:

$$\nu_i \le cni^{-\gamma}, \quad \forall i \in \{2, 3, \dots, \}. \tag{1}$$

The above property (1) is generally called a power-law and we call γ a *power-law exponent.* In many actual scale-free networks, it is said that $2 < \gamma < 3$ [1]. That is, $\mathcal{SF}$ is a class of multigraphs that obey the power-law degree distribution.

We show that this class is ϵ-close to a bounded-degree class if $\gamma > 2$ (Lemma 2.1).

After showing this property, we show the hyperfiniteness of the class. Hyperfiniteness seems to be closely related to a high clustering coefficient, where the cluster coefficient $\mathrm{cl}(G)$ of a graph $G = (V, E)$ is defined as[7]:

$$\mathrm{cl}(G) := \frac{1}{n}\sum_{v \in V} \mathrm{cl}_G(v), \qquad \mathrm{cl}_G(v) := \frac{|\{(u, w) \in E \mid u, w \in \Gamma_G(v), u \ne w\}|}{\binom{|\Gamma_G(v)|}{2}}.$$

[6] $\mathcal{HSF}$ was introduced in the preliminary version of this paper [14]. However, the definition in this paper is more general (wider) than in the preliminary version.

[7] There is another way to define the cluster coefficient: $3 \times$ (# of cycles of length three)/(# of paths of length two). Although these two values are different generally, they are close under the assumption of the power-law degree distribution.

Sometimes $\mathrm{cl}_G(v)$ is called the *local cluster coefficient* of v. It is said that $\mathrm{cl}(G)$ is $\Theta(1)$ for many classes that model actual social networks, while $\lim_{n\to\infty} \mathrm{cl}(G) = 0$ for random graphs.

These three characterizations, "high clustering coefficient," "existence of isolated cliques," and "hyperfiniteness" appear to be closely related to each other. In fact, it is readily observed that if $\mathrm{cl}_G(v) = 1$ for a bounded-degree graph G (the degree bound is d), then G consists of only (completely) isolated cliques with size at most $d + 1$, and G is $(d + 1, 0)$-hyperfinite!

Unfortunately, however, it is also observed that for any $0 < c < 1$, there is a class of bounded-degree graphs G such that $\lim_{n\to\infty} \mathrm{cl}(G) = c$ and it is not (t, ϵ)-hyperfinite for any pair of constants t and $\epsilon < 1/2$, e.g., $G = (V, E)$ consists of n/d cliques of size d, and random $n/2$ edges between vertices in different cliques (each vertex has $d - 1$ adjacent vertices in its clique and one adjacent vertex outside the clique). To separate this graph into constant-sized connected components, almost all of the edges between cliques (their number is $n/2$) must be removed.

However, we do not need to give up here, as the above model is very special, e.g., by contracting each isolated clique, it becomes a mere random graph with n/d vertices[8]. From this fact, the hierarchical structure of a high cluster coefficient looks important. The model presented by [25] has such a structure. Based on this model, we present the following class of multigraphs:

▶ **Definition 1.8** (Hierarchical Scale-Free Graphs)**.** For positive real numbers $c, \gamma > 1$ and a positive integer $n_0 \geq 1$, a class of *hierarchical scale-free graphs (HSF)* $\mathcal{HSF} = \mathcal{HSF}(c, \gamma, n_0)$ consists of (multi)graphs $G = (V, E)$ for which the following conditions hold:

(i) $G \in \mathcal{SF}(c, \gamma)$

(ii) Consider the infinite sequence of graphs $G_0 = G$, $G_1 = \mathcal{E}(G_0)$, $G_2 = \mathcal{E}(G_1)$, $\ldots$. If $|V[G_i]| \geq n_0$, then G_i includes at least one isolated clique $Q \subseteq V$ with $|Q| \geq 2$. (Note that if G_k has no such isolated clique, then $G_k = G_{k+1} = G_{k+2} = \cdots$.)

We show the following results.

▶ **Theorem 1.9.** *For any $\mathcal{HSF} = \mathcal{HSF}(c, \gamma, n_0)$ with $\gamma > 2$ and any real number $\epsilon > 0$, there is a real number $t_{1.9} = t_{1.9}(\mathcal{HSF}, \epsilon)$ such that $\mathcal{HSF}$ is $(t_{1.9}, \epsilon)$-hyperfinite.*

We give a global algorithm for obtaining the partition realizing the hyperfiniteness of Theorem 1.9. The algorithm is deterministic, i.e., if a graph and the parameter ϵ are fixed, then the partition is also fixed. The algorithm can be easily revised to a local algorithm and we obtain a deterministic partitioning oracle to get the partition (Lamma 3.2). Note that almost all algorithms for partitioning oracles presented to date have been randomized algorithms[9]. By using this partitioning oracle and an argument similar to one used in [23], we get the following main theorem.

▶ **Theorem 1.10.** *Any property is testable for $\mathcal{HSF}(c, \gamma, n_0)$ with $\gamma > 2$.*

As stated earlier, for the bounded-degree model, Newman and Sohler [23] presented a universal tester (which can test any property) for hyperfinite graphs. In the general graph model, although some works have tried to found universal tester [7, 18, 22], these results are weaker than for the bounded-degree graph model and the dense graph model.

[8] However, note that this model is not useless, since it is investigated in some works [19].

[9] The algorithm for testing forests presented by Kusumi and Yoshida [18] may be only deterministic one so far. That is, our partitioning oracle looks the first deterministic one for a graph class that includes cyclic graphs.

This paper gives a universal tester that can test every property on a natural class of scale-free multigraphs in constant time. This is the first result for universal constant-time algorithms which cover a class of graphs made by a model of scale-free networks.

2 Hyperfiniteness and a Global Partitioning Algorithm

2.1 Degree bounding

For a graph G and a nonnegative integer $d \geq 0$, $G|d$ is a graph made by deleting all edges incident to each vertex v with $d(v) > d$ from G. Note that $G|d$ is a bounded-degree graph with degree bound d.

▶ **Lemma 2.1.** *For any $\mathcal{SF} = \mathcal{SF}(c, \gamma)$ with $\gamma > 2$, and any positive real number $\epsilon > 0$, there is a constant $\delta_{2.1} = \delta_{2.1}(\epsilon, c, \gamma)$ such that for any graph $G \in \mathcal{SF}$, $G|\delta_{2.1}$ is ϵ-close to G.*

Before showing a proof of this lemma, we introduce some definitions. Riemann zeta function is defined by $\zeta(\gamma) = \sum_{i=1}^{\infty} i^{-\gamma}$. This function is known to converge to a constant ($\zeta(\gamma) < 1 + (\gamma - 1)^{-1}$) for any $\gamma > 1$. We introduce a generalization of this function by using a positive integer $k \geq 1$ as $\zeta(k, \gamma) = \sum_{i=k}^{\infty} i^{-\gamma}$. Note that $\zeta(\gamma) = \zeta(1, \gamma)$.

▶ **Lemma 2.2.** *For any $\epsilon > 0$ and $\gamma > 1$, there is an integer $k_{2.2} = k_{2.2}(\epsilon, \gamma) \geq 1$ such that $\zeta(k_{2.2}, \gamma) < \epsilon$.*

Proof. It is clear from the above fact that $\zeta(\gamma)$ converges for every $\gamma > 1$. ◀

Proof of Lemma 2.1. Let d be an arbitrary positive integer. Let m_d be the number of removed edges to make $G|d$ from G. From (1),

$$m_d = \sum_{i=d+1}^{\infty} i\nu_i \leq \sum_{i=d+1}^{\infty} cni^{-(\gamma-1)} = cn\zeta(d+1, \gamma - 1).$$

From the assumption of $\gamma > 2$ and Lemma 2.2, $\zeta(d+1, \gamma-1) < \epsilon/c$ if $d+1 \geq k_{2.2}(\epsilon/c, \gamma - 1)$. Thus by letting $\delta_{2.1}(\epsilon, c, \gamma) = k_{2.2}(\epsilon/c, \gamma - 1) - 1$, we have $m_{\delta_{2.1}} < \epsilon n$. ◀

From here, we denote the above $\delta_{2.1}(\epsilon, c, \gamma)$ by δ for notational simplicity.

2.2 Hierarchical contraction, structure tree, and coloring

Let $W_1, \dots, W_k$ ($W_i \subseteq V$, $\forall i \in \{1, \dots, k\}$) be a family of subsets of vertices satisfying that $W_i \cap W_j = \emptyset$ for every $i, j \in \{1, \dots, k\}$ and $i \neq j$, and $W_1 \cup \cdots \cup W_k = V$. Then $\{W_1, \dots, W_k\}$ is called a *partition* of V. Below, we explain a global algorithm for obtaining a partition of V realizing the hyperfiniteness of a graph in $\mathcal{HSF}$ with $\gamma > 2$, i.e., $|W_i|$ is bounded by a constant and the number of edges between different W_i and W_j is, at most, ϵn. First, we give a base algorithm.

```
procedure HierarchicalContraction($G$)
begin
1    $i := 0$, $G_0 := G$
2    while there exists an isolated clique in $G_i = (V_i, E_i)$ do
3       $i := i + 1$, $G_i := \mathcal{E}(G_{i-1})$
4    enddo
end.
```

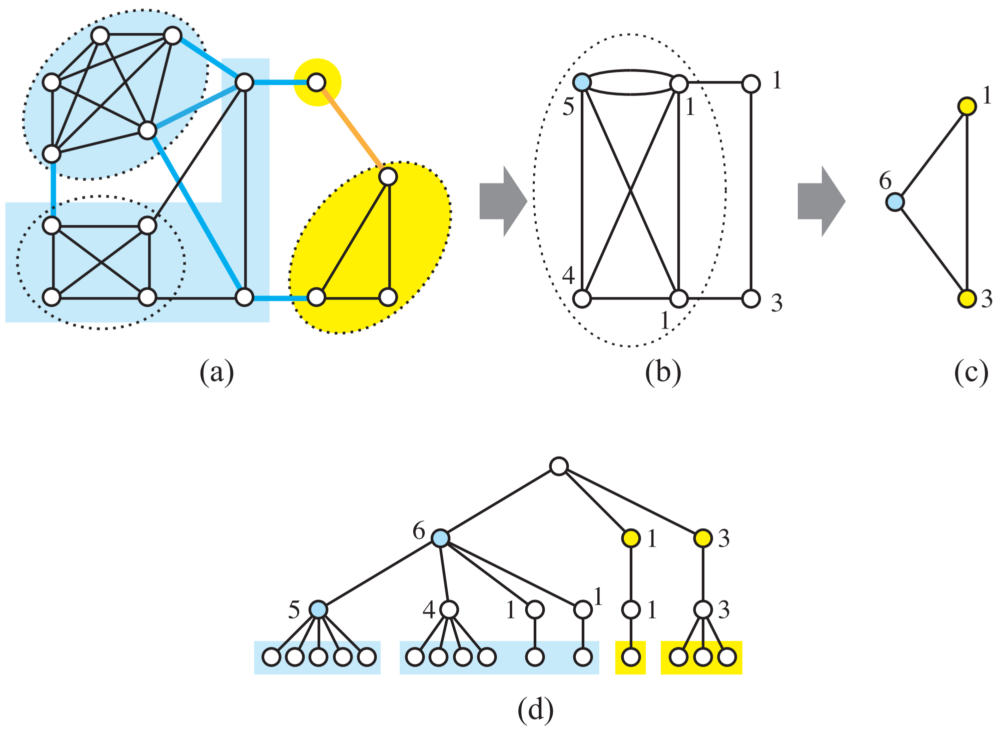

Figure 1 An example of HierarchicalContraction, the structure tree T, and the coloring: Here, we assume $\delta/\epsilon = 4.5$; the number beside a vertex is $w(*)$; the dotted circles are isolated cliques; colored areas are blue or yellow components.

We denote $G_i = (V_i, E_i)$ for $i \in \{0, 1, \ldots\}$. Let $G_k = (V_k, E_k)$ be the final graph of HierarchicalContraction(G). From the definitions of HSF, $|V_k| < n_0$. See Fig. 1 (a)–(c) for an example of applying this procedure.

The trail of the contraction can be represented by a rooted tree $T = (V[T], E[T])$, which is called the *structure tree* of G, defined as follows. (Fig. 1 (d) shows an example of the structure tree[10].)

$V[T] := V_0 \cup V_1 \cup \cdots \cup V_k \cup \{r\}$, where r is the (artificial) root of T. Each $v \in V_0$ is a leaf of T, and a vertex $v \in V_i$ $(i \in \{0, \ldots, k\})$ is on the level i of T, i.e., $v \in V_i$ $(i \geq 1)$ is the parent of $u \in V_{i-1}$ if "v is made by contracting a subset (an isolated-clique or a double-isolated-clique) $Q \subseteq V_{i-1}$ such that $u \in Q$" or "$v = u$ (i.e., u is not included in an isolated clique in G_{i-1})." The root r is the parent of every vertex in V_k. (The reason r is added is only to make T a tree.)

We introduce a function $W : V[T]\backslash\{r\} \rightarrow 2^V$ and coloring on the vertices in $V[T]$ as follows:

- For $v \in V_0$:
  - $W(v) = \{v\}$, and
  - if $d(v) > \delta$, then v is colored *red*, otherwise uncolored.
- For $v \in V_i$ $(i = 1, \ldots, k)$:
  - let $S(v)$ be the set of uncolored children of v,

[10] In this example, we ignore to color vertices red. Since $\delta < 4.5$ follows $\delta/\epsilon = 4.5$, some vertices in this figure might have to be red.

- $W(v) = \bigcup_{u \in S(v)} W(u)$, and
- if $|W(v)| > \delta/\epsilon$, then v is colored *blue*,
- else if $v \in V_k$ and $W(v) \neq \emptyset$, then v is colored *yellow*,
- otherwise, v is uncolored.

Note that for any two distinct colored vertices $u, v \in V[T]$, $W(u) \cap W(v) = \emptyset$. For every $v \in V[T]$, we also define a weight function as $w(v) = |W(v)|$. For a blue (resp. yellow) colored vertex $v \in V[T]$, $W(v) \subseteq V$ is called a *blue (resp. yellow) component*.

By using these colors, we also color the edges in E $(= E_0)$ in the following manner:

- For every red vertex $v \in V_0$ $(= V)$, all edges in $E_G(v)$ are colored *red*.
- For every blue component $W \subseteq V$, for every edge $e \in E_G(W)$, if e is not colored red, then e is colored *blue*.
- For every yellow component $W \subseteq V$, for every edge $e \in E_G(W)$, if e is not colored either red or blue, then e is colored *yellow*.

The other edges in E are uncolored. The set of red, blue, and yellow edges in E are represented by R, B, and Y, respectively. These colors are preserved in $G_1 = \mathcal{E}(G_0)$, $G_2 = \mathcal{E}(G_1)$, …, $G_k = \mathcal{E}(G_{k-1})$, e.g., if an edge $e \in E_i$ is red, then the corresponding edge in E_{i+1} is also red.

2.3 Proof of Theorem 1.9

Before showing the proof of Theorem 1.9, we prepare some lemmas.

▶ **Lemma 2.3.** *For any G_i $(i \in \{0, \dots, k\})$, all edges incident to a vertex with a degree higher than δ are red.*

Proof. For $G_0 = G$, the statement clearly holds from the coloring rule. Assume that the statement holds in G_{i-1}, and does not hold in some G_i. Let v be a vertex in V_i such that $d_{G_i}(v) \geq \delta + 1$ and a non-red edge is incident to v. Then v must be made by contracting an isolated clique in G_{i-1}, say $Q \subseteq V_{i-1}$, such that $d_{G_{i-1}}(Q) \geq \delta + 1$. From the definition of isolated cliques, $|Q| \geq d_{G_{i-1}}(Q) + 1 \geq \delta + 2$. Since Q is a clique, every vertex Q has degree at least $|Q| - 1 \geq \delta + 1$ in G_{i-1}. It follows that all edges incident to a vertex in Q must be red. This contradicts the assumption that a non-red edge is incident to v. ◀

▶ **Lemma 2.4.** $|R|, |B| < \epsilon n$*,* $|Y| < \delta n_0/2$*.*

Proof. $|R| < \epsilon n$ is directly obtained from Lemma 2.1. Let $v \in V_i$ be a blue vertex such that a non-red edge exists in $E(W(v))$. From Lemma 2.3, $d(W(v)) \leq \delta$. Thus $d(W(v))/w(v) < \delta/(\delta/\epsilon) = \epsilon$. This means that the average number of blue edges per a vertex is less than ϵ. Therefore $|B| < \epsilon n$. From Lemma 2.3, all edges incident to a vertex with degree higher than δ are red. From this it follows that the number of non-red edges in E_k is at most $\delta|V_k|/2$. Thus the number of yellow edges in E is also at most $\delta|V_k|/2$. By considering $|V_k| < n_0$, we have $|Y| < \delta n_0/2$. ◀

Let v_1^R, …, $v_{k_r}^R$ be the red vertices (k_r is the number of red vertices). Let W_1^B, …, $W_{k_b}^B$ be the blue components (k_b is the number of blue components). Let W_1^Y, …, $W_{k_y}^Y$ be the yellow components (k_y is the number of yellow components). We consider a family of vertex subsets as

$$\mathcal{P} := \{\{v_i^R\} \mid i = 1, \dots, k_r\} \cup \{W_i^B \mid i = 1, \dots, k_b\} \cup \{W_i^Y \mid i = 1, \dots, k_y\}.$$

From the definition of the function W and the coloring, $\mathcal{P}$ is clearly a partition of V.

Now we can prove Theorem 1.9.

Proof of Theorem 1.9. If $n \leq \delta n_0/(2\epsilon)$, then the statement is clear by setting $t \geq \delta n_0/(2\epsilon)$. Thus, we assume that $n > \delta n_0/(2\epsilon)$. Let G' be a graph obtained by deleting all red, blue, and yellow edges from G. From Lemma 2.4, the number of deleted edges is less than

$$2\epsilon n + \delta n_0/2 < 3\epsilon n. \tag{2}$$

Next, we will show that the maximum size of connected components in G' is at most $\delta(\delta+1)/\epsilon$. Assume that there exists a connected component $G'(X) = (X, E_X)$ consisting of more than $\delta(\delta+1)/\epsilon$ vertices in G'. X includes no vertex v with $d_G(v) > \delta$, since from Lemma 2.3 all edges in $E_G(v)$ are colored red. Moreover, there is no blue component $W \subseteq V$ such that $X \cap W \neq \emptyset$ and $X \backslash W \neq \emptyset$, as otherwise X would be disconnected in G' (by deleting blue edges).

From this it follows that there is a blue or yellow component $W = W(x)$ such that $X \subseteq W(x)$. If x is a yellow vertex, then $w(x) \leq \delta/\epsilon$ (as otherwise x would be colored blue), and $|X| \leq w(v) \leq \delta/\epsilon < \delta(\delta+1)/\epsilon$, which is a contradiction. Thus x must be a blue vertex. Assume that $x \in V_h$. Let $Z \subseteq V_{h-1}$ be the set of children of x (in T). Z consists of an isolated clique or a double-isolated-clique in G_{h-1}. Let $S(x)(\subseteq Z)$ be the set of uncolored vertices in Z. For every vertex $v \in S(x)$, $d_{G_{h-1}}(v) \leq \delta$ (from Lemma 2.3). From this and the fact that Z consists of an isolated clique or a double-isolated-clique, it follows that $|Z| \leq \delta + 1$.

For $v \in S(x)$, $w(v) \leq \delta/\epsilon$. Hence,

$$w(x) = \sum_{v \in S(x)} w(v) \leq |S(x)| \cdot \delta/\epsilon \leq |Z| \cdot \delta/\epsilon \leq (\delta+1)\delta/\epsilon,$$

which is a contradiction. Therefore, the maximum size of connected components in G' is $\delta(\delta+1)/\epsilon$.

Thus, we have proved that G is $(\max\{\delta n_0/(2\epsilon), \delta(\delta+1)/\epsilon\}, 3\epsilon)$-hyperfinite. Here, ϵ is an arbitrary real number in $(0,1]$, then by defining $t_{1.9} = \max\{3\delta n_0/(2\epsilon), 3\delta(\delta+1)/\epsilon\}$, G is $(t_{1.9}, \epsilon)$-hyperfinite for any $\epsilon > 0$. ◀

3 Testing Algorithm

3.1 Deterministic partitioning oracle

The global partitioning algorithm of Theorem 1.9 can be easily revised to run locally, i.e., a "partitioning oracle" based on this algorithm can be obtained. A partitioning oracle, which calculates a partition realizing hyperfiniteness locally, was introduced by Benjamini, et al. [3] implicitly and by Hassidim, et al. [13] explicitly. It is a powerful tool for constructing constant-time algorithms for sparse graphs. It has been revised by some researchers and Levi and Ron's algorithm [20] is the fastest to date. As mentioned before almost all algorithms for partitioning oracles presented to date have been randomized algorithms. Our algorithm, however, does not use any random valuable and it runs deterministically. That is, we call it a *deterministic partitioning oracle*, which is rigorously defined as follows[11]:

▶ **Definition 3.1.** $\mathcal{O}$ is a deterministic (t, ϵ)-partitioning oracle for a class of graphs $\mathcal{C}$, if, given query access to a graph $G = (V, E)$, it provides query access to a partition $\mathcal{P}$ of G. For a query about $v \in V$, $\mathcal{O}$ returns $\mathcal{P}(v)$. The partition has the following properties: (i) $\mathcal{P}$ is a function of G, t, and ϵ. (It does not depend on the order of queries to $\mathcal{O}$.) (ii) For

[11] However, since Levi and Ron's algorithm [20] looks fast, using it may be better in practice.

every $v \in V$, $|\mathcal{P}(v)| \leq t$ and $\mathcal{P}(v)$ induces a connected subgraph of G. (iii) If $G \in \mathcal{C}$, then $|\{(u,v) \in E \mid \mathcal{P}(u) \neq \mathcal{P}(v)\}| \leq \epsilon|V|$.

▶ **Lemma 3.2.** *There is a deterministic $(t_{1.9}, \epsilon)$-partitioning oracle $\mathcal{O}_{HSF}$ for HSF with $\gamma > 2$ with query complexity $\delta^{O(\delta^2/\epsilon + n_0)}$ for one query.*

Before giving a proof of this lemma, we introduce some notation as follows. A connected graph $G = (V, E)$ with a specified marked vertex v is called a *rooted graph*, and we sometimes say that G is rooted at v. A rooted graph $G = (V, E)$ has a radius t, if every vertex in V has a distance at most t from the root v. Two rooted graphs are isomorphic if there is a graph isomorphism between these graphs that identifies the roots with each other. We denote by $N(d, t)$ the number of all non-isomorphic rooted graphs with a maximum degree of d and a maximum radius of t. For a graph $G = (V, E)$, integers d and t, and a vertex $v \in V$, let $B_G(v, d, t)$ be the subgraph rooted at v that is induced by all vertices of $G|d$ that are at distance t or less from v. $B_G(v, d, t)$ is called a (d, t)-*disk* around v. From these definitions, the number of possible non-isomorphic (d, t)-disks is at most $N(d, t)$.

Proof of Lemma 3.2. The global algorithm of Theorem 1.9 can be easily simulated locally. To find $\mathcal{P}(v)$, if $d(v) > \delta$, then the algorithm outputs $\mathcal{P}(v) := \{v\}$. Otherwise, if the algorithm finds a vertex u with $d(u) > \delta$ in the process of the local search, u is ignored (the algorithm does not check the neighbors of u). Thus, the algorithm behaves as on the bounded-degree model. For any vertex v, $|\mathcal{P}(v)| \leq t_{1.9} = O(\delta^2/\epsilon)$. Each $u \in B_G(v, \delta, t_{1.9})$ may be included in $\mathcal{P}(w)$ of $w \in B_G(u, \delta, t_{1.9})$. Then, the algorithm checks most vertices in $B_G(v, \delta, 2t_{1.9}) = B_G(v, \delta, O(\delta^2/\epsilon + n_0))$, and thus the query complexity for one call of $\mathcal{P}(v)$ is at most $\delta^{O(\delta^2/\epsilon + n_0)}$. ◀

3.2 Abstract of the algorithm

The method of constructing a testing algorithm based on the partitioning oracle of Lemma 3.2 is almost the same as the method used in [23]. We use a distribution vector, which will be defined in Definition 3.3, of rooted subgraphs consisting of at most a constant number of vertices.

▶ **Definition 3.3.** For a graph $G = (V, E)$ and integers d and t, let $\text{disk}_G(d, t)$ be the distribution vector of all (d, t)-disks of G, i.e., $\text{disk}_G(d, t)$ is a vector of dimension $N(d, t)$. Each entry of $\text{disk}_G(d, t)$ corresponds to some fixed rooted graph H, and counts the number of (d, t)-disks of $G|d$ that are isomorphic to H. Note that $G|d$ has $n = |V|$ different disks, thus the sum of entries in $\text{disk}_G(d, t)$ is n. Let $\text{freq}_G(d, t)$ be the normalized distribution, namely $\text{freq}_G(d, t) = \text{disk}_G(d, t)/n$. For a vector $v = (v_1, \ldots, v_r)$, its l_1-norm is $||v||_1 = \sum_{i=1}^{r} |v_i|$. The l_1-norm is also the length of the vector. We say that the two unit-length vectors v and u are ϵ-close for $\epsilon > 0$ if $||v - u||_1 \leq \epsilon$.

By using the same discussion as in Theorem 3.1 in [23], the following lemma is proven.

▶ **Lemma 3.4.** *There exist functions $\lambda_{3.4} = \lambda_{3.4}(\mathcal{HFS}, \epsilon)$, $d_{3.4} = d_{3.4}(\mathcal{HFS}, \epsilon)$, $t_{3.4} = t_{3.4}(\mathcal{HFS}, \epsilon)$, $N_{3.4} = N_{3.4}(\mathcal{HFS}, \epsilon)$ such that for every $\epsilon > 0$ the following holds: For every $G_1, G_2 \in \mathcal{HFS}$ on $n \geq N_{3.4}$ vertices, if $|freq_{G_1}(d_{3.4}, t_{3.4}) - freq_{G_2}(d_{3.4}, t_{3.4})| \leq \lambda_{3.4}$, then G_1 and G_2 are ϵ-close.* ◀

A sketch of the algorithm is as follows. Let $G = (V, E)$ be a given graph and P be a property to test. First, we select some (constant) number $\ell = \ell(\epsilon)$ of vertices $v_i \in V$

$(i = 1, \dots, \ell)$ and find $\mathcal{P}(v_i)$ given by Theorem 1.9. This is done locally (shown by Lemma 3.2). Consider a graph $G' := \mathcal{P}(v_1) \cup \cdots \cup \mathcal{P}(v_\ell)$. Here, $\mathrm{freq}_G(d,t)$ and $\mathrm{freq}_{G'}(d,t)$ are very close with high probability. Next, we calculate $\min_{G \in P} |\mathrm{freq}_{G'}(d,t) - \mathrm{freq}_G(d,t)|$ approximately. There is a problem in that the number of graphs in P is generally infinite. However, to approximate it with a small error is adequate for our objective, and thus it is sufficient to compare G' with a constant number of vectors of $\mathrm{freq}(d,t)$. (Note that calculating such a set of frequency vectors requires much time. However, we can say that there exists such a set. This means that the existence of the algorithm is assured.) The algorithm accepts G if the approximate distance of $\min_{G \in P} |\mathrm{freq}_{G'}(d,t) - \mathrm{freq}_G(d,t)|$ is small enough, and otherwise it is rejected.

The above algorithm is the same as the algorithm presented in [23] except for two points – in our model: (1) G is not a bounded-degree graph, and (2) G is a multigraph. However, these differences are trivial. For the first difference, it is enough to add an ignoring-large-degree-vertex process, i.e., if the algorithm find a vertex v having a degree larger than $d_{3.4}$, all edges incident to v are ignored. By adding this process, G is regarded as $G|d_{3.4}$. This modification does not effect the result by Lemma 2.1. For the second difference, the algorithm treats bounded-degree graphs as mentioned above, and the number of non-isomorphic multigraphs with n vertices and degree upper bound $d_{3.4}$ is finite (bounded by $O({d_{3.4}}^{n^2})$).

Proof of Theorem 1.10. Obtained from the above discussion. ◀

4 Summary and future work

We presented a natural class of multigraphs $\mathcal{HSF}$ representing scale-free networks, and we showed that a very wide subclass of it is hyperfinite (Theorem 1.9). By using this result, the useful result that every property is testable on the class (Theorem 1.10) is obtained.

$\mathcal{HSF}$ is a class of multigraphs based on the hierarchical structure of isolated cliques. We may relax “isolated cliques” to “c-isolated cliques” or “isolated dense subgraphs [15]” and we may introduce a wider class. We consider such classes also to be hyperfinite. Finding such classes and proving their hyperfiniteness is important future work.

Abstract

We derandomize G. Valiant's [*J. ACM* 62 (2015) Art. 13] subquadratic-time algorithm for finding outlier correlations in binary data. Our derandomized algorithm gives deterministic subquadratic scaling essentially for the same parameter range as Valiant's randomized algorithm, but the precise constants we save over quadratic scaling are more modest. Our main technical tool for derandomization is an explicit family of *correlation amplifiers* built via a family of zigzag-product expanders in Reingold, Vadhan, and Wigderson [*Ann. of Math.* 155 (2002) 157–187]. We say that a function $f : \{-1,1\}^d \to \{-1,1\}^D$ is a *correlation amplifier* with threshold $0 \le \tau \le 1$, error $\gamma \ge 1$, and strength p an even positive integer if for all pairs of vectors $x, y \in \{-1,1\}^d$ it holds that (i) $|\langle x,y\rangle| < \tau d$ implies $|\langle f(x), f(y)\rangle| \le (\tau\gamma)^p D$; and (ii) $|\langle x,y\rangle| \ge \tau d$ implies $\bigl(\frac{\langle x,y\rangle}{\gamma d}\bigr)^p D \le \langle f(x), f(y)\rangle \le \bigl(\frac{\gamma\langle x,y\rangle}{d}\bigr)^p D$.

1 Introduction

Identifying weak correlations in data. We consider the task of finding outlier-correlated pairs from large collections of weakly correlated binary vectors in $\{-1,1\}^d$. In more precise terms, we are interested in the following computational problem.

▶ **Problem 1** (Outlier correlations). *Suppose we are given as input two sets $X, Y \subseteq \{-1,1\}^d$ with $|X| = |Y| = n$ and two thresholds, the* outlier *threshold $\rho > 0$ and the* background *threshold $\tau < \rho$. Our task is to output all* outlier *pairs $(x,y) \in X \times Y$ with $|\langle x,y\rangle| \ge \rho d$ subject to the assumption that at most q of the pairs $(x,y) \in X \times Y$ satisfy $|\langle x,y\rangle| > \tau d$.*

[*] We use the dagger-symbol ("†") to indicate a result whose proof for reasons of space has been relegated to the full version available at `http://arxiv.org/abs/1606.05608`.

[†] The research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Programme (FP/2007-2013) / ERC Grant Agreement 338077 "Theory and Practice of Advanced Search and Enumeration" (M.K., P.K., J.K.) and from the Academy of Finland, Grants 276031, 282938, 283262, and 283437 (P.Ó C.).

[‡] Work done in part while the second author was visiting the Simons Institute for the Theory of Computing.

▶ Remark. This setting of binary vectors and (Pearson) correlation is directly motivated, among others, by the connection to Hamming distance. Indeed, for two vectors $x, y \in \{-1, 1\}^d$ we have $d - 2D_H(x, y) = \langle x, y\rangle$, where $D_H(x, y) = |\{u = 1, 2, \ldots, d : x(u) \neq y(u)\}|$ is the *Hamming distance* between x and y.

A naïve way to solve Problem 1 is to compute all the n^2 inner products $\langle x, y\rangle$ for $(x, y) \in X \times Y$ and filter out everything but the outliers. Our interest is in algorithms that scale *subquadratically* in n when both d and q are bounded from above by slowly growing functions of n. That is, we seek running times of the form $O(n^{2-\epsilon})$ for a constant $\epsilon > 0$. Furthermore, we seek to do this without *a priori* knowledge of q.

Running times of the form $O(n^{2-c\rho})$ for a constant $c > 0$ are immediately obtainable using techniques such as the seminal *locality-sensitive hashing* of Indyk and Motwani [17] and its variants[1]; however, such algorithms converge to quadratic running time in n unless ρ is bounded from below by a positive constant. Our interest is in algorithms that avoid such a "curse of weak outliers" and run in subquadratic time essentially *independently of the magnitude of ρ, provided that ρ is sufficiently separated from τ*. Such ability to identify weak outliers from large amounts of data is useful, among others, in machine learning from noisy data.

One strategy to circumvent the curse of weak outliers is to pursue the following intuition: (i) partition the input vectors into *buckets* of at most s vectors each, (ii) aggregate each bucket into a single vector by taking the vector sum, and (iii) compute the inner products between the $\lceil n/s\rceil \times \lceil n/s\rceil$ pairs of aggregate vectors. With sufficient separation between τ and ρ, at most q of these inner products between aggregates will be large, and every outlier pair is discoverable among the at most $s \times s$ input pairs that correspond to each large inner product of aggregates. Furthermore, a strategy of this form is oblivious to q until we actually start searching inside the buckets, which enables adjusting ρ and τ based on the number of large aggregate inner products.

Randomized amplification. Such bucketing strategies have been studied before with the help of randomization. In 2012, G. Valiant [33] presented a breakthrough algorithm that, before bucketing, replaces each input vector with a randomly subsampled[2] version of its p^{th} Kronecker power. Because of the tensor-power identity

$$\langle x^{\otimes p}, y^{\otimes p}\rangle = \langle x, y\rangle^p\,, \tag{1}$$

the ratio between outlier and background correlations gets *amplified* to essentially its p^{th} power, assuming that the sample is large enough so that sufficient concentration bounds hold with high probability. This amplification makes the outliers stand out from the background even after bucketing, which enables detection in subquadratic time using fast matrix multiplication.

A subset of the present authors [20] further improved on Valiant's algorithm by a modified sampling scheme that *simultaneously* amplifies and aggregates the input by further use of fast matrix multiplication. With this improvement, Problem 1 can be solved in subquadratic time if the logarithmic ratio $\log_\tau \rho = (\log \rho)/(\log \tau)$ is bounded from above by a constant less than 1. Also this improved algorithm relies on randomization.

[1] We postpone a more detailed discussion of related work and applications to the end of this section.
[2] Random sampling is used to reduce the dimension because the full d^p-dimensional Kronecker power is too large to be manipulated explicitly to yield subquadratic running times.

Explicit amplification. In this paper we seek *deterministic* subquadratic algorithms. As with the earlier randomized algorithms, we seek to map the d-dimensional input vectors to a higher dimension D so that inner products are sufficiently amplified in the process. Towards this end, we are interested in explicit functions $f : \{-1,1\}^d \to \{-1,1\}^D$ that approximate the tensor-power identity (1).

▶ **Definition 2** (Correlation amplifier). Let d, D and p be positive integers, with p even, and let $0 \le \tau \le 1$ and $\gamma \ge 1$. A function $f : \{-1,1\}^d \to \{-1,1\}^D$ is a *correlation amplifier* with parameters (d, D, p, τ, γ) if for all pairs of vectors $x, y \in \{-1,1\}^d$ we have

$$\text{if } \big|\langle x,y\rangle\big| < \tau d, \text{ then } \big|\langle f(x), f(y)\rangle\big| \le (\tau\gamma)^p D\,; \text{ and} \tag{2}$$

$$\text{if } \big|\langle x,y\rangle\big| \ge \tau d, \text{ then } \left(\tfrac{\langle x,y\rangle}{\gamma d}\right)^p D \le \langle f(x), f(y)\rangle \le \left(\tfrac{\gamma\langle x,y\rangle}{d}\right)^p D\,. \tag{3}$$

▶ Remark. A correlation amplifier f guarantees by (2) that correlations below τ in absolute value stay bounded; and by (3) that correlations at least τ in absolute value *become positive* and are governed by the two-sided approximation with multiplicative error $\gamma \ge 1$. In particular, (3) implies that correlations at least τ cannot mask outliers under bucketing because all such correlations get positive sign under amplification.

It is immediate that correlation amplifiers exist. For example, take $f(x) = x^{\otimes p}$, with p even, to obtain a correlation amplifier with $D = d^p$, $\tau = 0$, and $\gamma = 1$ by (1). For our present purposes, however, we seek correlation amplifiers with D substantially smaller than d^p. Furthermore, we seek constructions that are *explicit* in the strong[3] form that there exists a deterministic algorithm that computes any individual coordinate of $f(x)$ in time $\mathrm{poly}(\log D, p)$ by accessing $\mathrm{poly}(p)$ coordinates of a given $x \in \{-1,1\}^d$. In what follows explicitness always refers to this strong form.

Our results. The main result of this paper is that sufficiently powerful explicit amplifiers exist to find outlier correlations in deterministic subquadratic time.

▶ **Theorem 3** (Explicit amplifier family). *There exists an explicit correlation amplifier $f : \{-1,1\}^d \to \{-1,1\}^{2^K}$ with parameters $(d, 2^K, 2^\ell, \tau, \gamma)$ whenever $0 < \tau < 1$, $\gamma > 1$, and d, K, ℓ are positive integers with*

$$2^K \ge d\left(2^{10}\left(1-\gamma^{-1/2}\right)^{-1}\right)^{20\ell+1}\left(\frac{\gamma}{\tau}\right)^{60\cdot 2^\ell}. \tag{4}$$

As a corollary we obtain a deterministic algorithm for finding outlier correlations in subquadratic time using bucketing and fast matrix multiplication. Let us write α for the limiting exponent of rectangular integer matrix multiplication. That is, for all constants $\eta > 0$ there exists an algorithm that multiplies an $m \times \lfloor m^\alpha \rfloor$ integer matrix with an $\lfloor m^\alpha \rfloor \times m$ integer matrix in $O(m^{2+\eta})$ arithmetic operations. In particular, it is known that $0.3 < \alpha \le 1$ [22].

▶ **Theorem 4** (Deterministic subquadratic algorithm for outlier correlations). *For any constants $0 < \epsilon < 1$, $0 < \tau_{\max} < 1$, $0 < \delta < \alpha$, and $C > 60$, there exists a deterministic algorithm that solves a given instance of Problem 1 in time*

$$O\left(n^{2-\frac{0.99\epsilon(\alpha-\delta)}{4C+1}} + qn^{\delta+\frac{1.99\epsilon(\alpha-\delta)}{4C+1}}\right) \tag{5}$$

[3] In comparison, a weaker form of explicitness could require, for example, that there exists a deterministic algorithm that computes the entire vector $f(x)$ from a given x in time $D \cdot \mathrm{poly}(\log D, p)$.

assuming that the parameters n, d, ρ, τ satisfy the following three constraints
1. $d \le n^{\delta}$,
2. $n^{-\Theta(1)} \le \tau \le \tau_{\max}$, *and*
3. $\log_\tau \rho \le 1 - \epsilon$.

▶ Remark. Observe in particular that (5) is subquadratic regardless of the magnitude of ρ provided that the separation between ρ and τ via $\log_\tau \rho \le 1 - \epsilon$ holds.[4] The constants in (4) and (5) have not been optimized beyond our desired goal of obtaining deterministic subquadratic running time when d and q are bounded by slowly growing functions of n. In particular, (5) gives substantially worse subquadratic running times compared with the existing randomized strategies [20, 33]. The algorithm in Theorem 4 needs no *a priori* knowledge of q and is oblivious to q until it starts searching inside the buckets.

Overview and discussion of techniques. A straightforward application of the probabilistic method establishes that low-dimensional correlation amplifiers can be obtained by subsampling uniformly at random the dimensions of the tensor power $x^{\otimes p}$ as long as the sample size D is large enough.

▶ **Lemma 5** (Existence †). *There exists a correlation amplifier $f : \{-1,1\}^d \to \{-1,1\}^D$ with parameters (d, D, p, τ, γ) whenever $0 < \tau < 1$, $\gamma > 1$, and d, p, D are positive integers satisfying*

$$D \ge 3d\left(\gamma^p - 1\right)^{-2}\left(\frac{\gamma}{\tau}\right)^{2p} . \tag{6}$$

Thus, in essence our Theorem 3 amounts to *derandomizing* such a subsampling strategy by presenting an explicit sample that is, up to the error bounds (2) and (3), indistinguishable from the "perfect" amplifier $x \mapsto x^{\otimes p}$ under taking of inner products.

The construction underlying Theorem 3 amounts to an ℓ-fold composition of explicit *squaring* amplifiers ($p = 2$) with increasingly strong control on the error (γ) and the interval of amplification ($[\tau, 1]$) at each successive composition. Towards this end, we require a flexible explicit construction of squaring amplifiers with strong control on the error and the interval. We obtain such a construction from an explicit family of expander graphs (Lemma 9) obtainable from the explicit zigzag-product constructions of Reingold, Vadhan, and Wigderson [31]. In particular, the key to controlling the error and the interval is that the expander family gives *Ramanujan-like*[5] concentration $\lambda/\Delta \le 16\Delta^{-1/4}$ of the normalized second eigenvalue λ/Δ by increasing the degree Δ. In essence, since we are working with $\{-1,1\}$-valued vectors, by increasing the degree we can use the Expander Mixing Lemma (Lemma 8) and the Ramanujan-like concentration to control (Lemma 11) how well the restriction x^G to the edges of an expander graph G approximates the full tensor square $x^{\otimes 2}$ under taking of inner products.

Our construction has been motivated by the paradigm of *gradually increasing independence* [6, 11, 12, 18] in the design of pseudorandom generators. Indeed, we obtain the final amplifier gradually by successive squarings, taking care that the degree Δ_i of the expander

[4] The technical constraint $n^{-\Theta(1)} \le \tau$ only affects inputs where the dimension d grows essentially as a root function of n since $\tau \ge 1/d$. The constant subsumed by $\Theta(1)$ depends on the chosen constants $\epsilon, \tau_{\max}, \delta, C$ but not on the other parameters.

[5] Actual *Ramanujan graphs* (see [15, 23]) would give somewhat stronger concentration $\lambda/\Delta = O(\Delta^{-1/2})$ and hence improved constants in (4). However, we are not aware of a sufficiently fine-grained family of explicit Ramanujan graphs to comfortably support successive squaring.

that we apply in each squaring $i = 0, 1, \ldots, \ell - 1$ increases with a similar squaring schedule given by (10) and (12) to simultaneously control the error and the interval, and to bound the output dimension roughly by the square of the degree of the last expander in the sequence.[6] The analogy with pseudorandom generators can in fact be pushed somewhat further. Namely, a correlation amplifier can be roughly seen as a pseudorandom generator that by (3) seeks to fool a "truncated family of uniform combinatorial rectangles" with further control requested by (2) below the truncation threshold τ.[7] Our goal to obtain a small output dimension D roughly corresponds to optimizing the seed length of a pseudorandom generator.

While our explicit construction (4) does not reach the exact output dimension obtainable by Lemma 5, it should be observed that in our parameter range of interest (with $\gamma > 1$ a constant and $0 < \tau \leq \tau_{\max}$ for a constant $0 < \tau_{\max} < 1$), both (4) and (6) are of the form $D \geq d\tau^{-\Theta(p)}$; only the constants hidden by the asymptotic notation differ between the explicit and nonconstructive bounds. Moreover, using results of Alon [3] we show a *lower bound* on the output dimension D of any correlation amplifier: namely, that $D \geq d\tau^{-\Theta(p)}$ if $6p\tau^{-2}d^{-1}\log\frac{1}{\gamma\tau}$ is bounded from above by a constant strictly less than 1 (†). Thus, viewed as a pseudorandom generator with "seed length" $\log D$, Theorem 3 essentially does not admit improvement except possibly at the multiplicative constants.

Related work and applications. Problem 1 is a basic problem in data analysis and machine learning admitting many extensions, restrictions, and variants. A large body of work exists studying *approximate near neighbour search* via techniques such as locality-sensitive hashing (e.g. [4, 5, 17, 10, 26, 27]), with recent work aimed at derandomization (see Pagh [28] and Pham and Pagh [30]) and resource tradeoffs (see Kapralov [19]) in particular. However, these techniques enable subquadratic scaling in n only when ρ is bounded from below by a positive constant, whereas the algorithm in Theorem 4 remains subquadratic even in the case of weak outliers when ρ tends to zero with increasing n, as long as ρ and τ are separated. Ahle, Pagh, Razenshteyn, and Silvestri [1] show that subquadratic scaling in n is not possible for $\log_\tau \rho = 1 - o(1/\sqrt{\log n})$ unless both the Orthogonal Vectors Conjecture and the Strong Exponential Time Hypothesis [16] fail.

In small dimensions, Alman and Williams [2] present a randomized algorithm that finds *exact* Hamming-near neighbours in a batch-query setting analogous to Problem 1 in subquadratic time in n when the dimension is constrained to $d = O(\log n)$. Recently, Chan and Williams [7] show how to derandomize related algorithm designs, but the probabilistic polynomials for symmetric Boolean functions used in [2] to our knowledge have not yet been derandomized.

[6] The term "gradual" is of course not particularly descriptive since growth under successive squaring amounts to *doubly* exponential growth in the number of squarings. Yet such growth *can* be seen as gradual and controlled since we obtain strong amplification compared with the final output dimension precisely because the first $\ell - 1$ squarings "come for free" since $\Delta_0\Delta_1\cdots\Delta_{\ell-2}$ is (up to low-order multiplicative terms) no more than $\Delta_{\ell-1}^2$, essentially because we are taking the sum of powers of 2 in the exponent.

[7] To see the rough analogy, let $z \in \{-1, 1\}^d$ be the Hadamard product of the vectors $x, y \in \{-1, 1\}^d$ and observe that (3) seeks to approximate (with multiplicative error) the expectation of a uniform random entry in the d^p-length Kronecker power $z^{\otimes p}$ by instead taking the expectation over an explicit D-dimensional sample given by f. The Kronecker power $z^{\otimes p}$ is a uniform special case (with $z = z_1 = z_2 = \cdots = z_p$) of a "combinatorial rectangle" formed by a Kronecker product $z_1 \otimes z_2 \otimes \cdots \otimes z_p$, and truncation means that we only seek approximation in cases where $|\sum_{u=1}^d z(u)| \geq \tau d$, and accordingly want constructions that take this truncation into account—that is, we do not seek to fool all combinatorial rectangles and accordingly want stronger control on the dimension D (that is, the "seed length" $\log D$). For a review of the state of the art in pseudorandom generators we refer to Gopalan, Kane, and Meka [11] and Kothari and Meka [21].

One special case of Problem 1 is the problem of learning a weight 2 parity function in the presence of noise, or *the light bulb problem.*

▶ **Problem 6** (Light bulb problem, L. Valiant [34]). *Suppose we are given as input a parameter $0 < \rho < 1$ and a set of n vectors in $\{-1, 1\}^d$ such that one planted pair of vectors has inner product at least ρd in absolute value, and all other $n - 2$ vectors are chosen independently and uniformly at random. Our task is to find the planted pair among the n vectors.*

▶ Remark. From e.g. the Hoeffding bound (20) it follows that there exists a constant c such that when $d \geq c\rho^{-2} \log n$ the planted pair is with high probability (as n increases) the unique pair in the input with the maximum absolute correlation.

For a problem whose instances are drawn from a random ensemble, we say that an algorithm solves *almost all* instances of the problem if the probability of drawing an instance where the algorithm fails tends to zero as n increases.

Paturi, Rajasekaran, and Reif [29], Dubiner [8], and May and Ozerov [24] present randomized algorithms that can be used to solve almost all instances of the light bulb problem in subquadratic time if we assume that ρ is bounded from below by a positive constant; if ρ tends to zero these algorithms converge to quadratic running time in n.

G. Valiant [33] showed that a randomized algorithm can identify the planted correlation in subquadratic time on almost all inputs even when ρ tends to zero as n increases. As a corollary of Theorem 4, we can derandomize Valiant's design and still retain subquadratic running time (but with a worse constant) for almost all inputs, except for extremely weak planted correlations with $\rho \leq n^{-\Omega(1)}$ that our amplifier is not in general able to amplify with sufficiently low output dimension to enable an overall subquadratic running time.

▶ **Corollary 7** (Deterministic subquadratic algorithm for the light bulb problem). *For any constants $0 < \delta < \alpha$, $C > 60$, $0 < \rho_{\max} < 1$, and $\kappa > 1$, there exists a deterministic algorithm that solves almost all instances of Problem 6 in time*

$$O\left(n^{2-\frac{0.99(1-1/\kappa)(\alpha-\delta)}{4C+1}}\right)$$

assuming the parameters n, d, ρ satisfy the two constraints

1. $5\rho^{-2\kappa} \log n \leq d \leq n^{\delta}$ *and*
2. $n^{-\Theta(1)} \leq \rho \leq \rho_{\max}$.[8]

Corollary 7 extends to parity functions of larger (constant) weight (cf. [13, 20, 33]), however, we omit the details from this conference abstract. Algorithms for learning parity functions enable extensions to further classes of Boolean functions such as sparse juntas and DNFs (cf. [9, 25, 33]).

Conventions and notation. All vectors in this paper are integer-valued. For a vector $x \in \mathbb{Z}^d$ we denote the entry $u = 1, 2, \ldots, d$ of x by $x(u)$. For two vectors $x, y \in \mathbb{Z}^d$ we write $\langle x, y\rangle = \sum_{u=1}^{d} x(u)y(u)$ for the inner product of x and y. We write log for the logarithm with base 2 and ln for the logarithm with base exp(1).

[8] The constant hidden by the $\Theta(1)$ notation depends on the constants $\delta, \alpha, C, \rho_{\max}$ but not on the other parameters. For details consult the proof.

2 Explicit amplifiers by approximate squaring

This section proves Theorem 3. We start with preliminaries on expanders, show an approximate squaring identity using expander mixing, and then rely on repeated approximate squaring for our main construction. The proof is completed by some routine preprocessing.

Preliminaries on expansion and mixing. We work with undirected graphs, possibly with self-loops and multiple edges. A graph G is Δ-*regular* if every vertex is incident to exactly Δ edges, with each self-loop (if present) counting as one edge. Suppose that G is Δ-regular with vertex set V, and let L be a set of Δ labels such that the Δ edge-ends incident to each vertex have been labeled with unique labels from L. The *rotation map* $\mathrm{Rot}_G : V \times L \to V \times L$ is the bijection such that for all $u \in V$ and $i \in L$ we have $\mathrm{Rot}_G(u,i) = (v,j)$ if the edge incident to vertex u and labeled with i at u leads to the vertex v and has the label j at v.

For $S, T \subseteq V(G)$, let us write $E(S,T)$ for the set of edges of G with one end in S and the other end in T. Suppose that G has D vertices and let $\lambda_1, \lambda_2, \ldots, \lambda_D$ be the eigenvalues of the adjacency matrix of G with $|\lambda_1| \geq |\lambda_2| \geq \cdots \geq |\lambda_D|$. Let us say that a graph G is a (D,Δ,λ)-*graph* if G has D vertices, G is Δ-regular, and $|\lambda_2| \leq \lambda$. For an excellent survey on expansion and expander graphs, we refer to Hoory, Linial, and Wigderson [15].

▶ **Lemma 8** (Expander mixing lemma, [15, Lemma 2.5]). *For all $S, T \subseteq V(G)$ we have*

$$\left| |E(S,T)| - \frac{\Delta |S||T|}{D} \right| \leq \lambda \sqrt{|S||T|}\,.$$

We work with the following family of graphs obtained from the zig-zag product of Reingold, Vadhan, and Wigderson [31]. In particular Lemma 9 gives us $\lambda/\Delta \leq 16\Delta^{-1/4}$, which will enable us to control relative inner products by increasing Δ.

▶ **Lemma 9.** *For all integers $t \geq 1$ and $b \geq 10$ there exists a $(2^{16bt}, 2^{4b}, 16 \cdot 2^{3b})$-graph whose rotation map can be evaluated in time* $\mathrm{poly}(b,t)$.[9]

Proof. See Appendix A. ◀

Main construction. The main objective of this section is to prove the following lemma, which we will then augment to Theorem 3 by routine preprocessing of the input dimension.

▶ **Lemma 10** (Repeated approximate squaring). *There exists an explicit correlation amplifier $\hat{f} : \{-1,1\}^{2^k} \to \{-1,1\}^{2^K}$ with parameters $(2^k, 2^K, 2^\ell, \tau_0, \gamma_0)$ whenever $0 < \tau_0 < 1$, $\gamma_0 > 1$, and k, K, ℓ are positive integers with*

$$2^K \geq 2^k \left(2^{10} \left(1 - \gamma_0^{-1}\right)^{-1} \right)^{20\ell} \left(\frac{\gamma_0}{\tau_0} \right)^{40 \cdot 2^\ell - 20}. \tag{7}$$

Approximate squaring via expanders. For a vector $x \in \{-1,1\}^D$, let us write $x^{\otimes 2} \in \{-1,1\}^{D^2}$ for the Kronecker product of x with itself. Our construction for correlation amplifiers will rely on approximating the *squaring identity*

$$\langle x^{\otimes 2}, y^{\otimes 2} \rangle = \langle x, y \rangle^2\,,$$

[9] *Caveat.* Reingold, Vadhan, and Wigderson [31] work with eigenvalues of the *normalized* adjacency matrix (with $|\lambda_1| = 1$) whereas we follow Hoory, Linial, and Wigderson [15] and work with unnormalized adjacency matrices (with $|\lambda_1| = \Delta$) in the manuscript proper. Appendix A works with normalized adjacency matrices for compatibility with Reingold, Vadhan, and Wigderson [31].

for vectors in $\{-1,1\}^D$. In more precise terms, let G be a (D,Δ,λ)-graph and let $x^G \in \{-1,1\}^{\Delta D}$ be a vector that contains each coordinate $x(u)x(v)$ of $x^{\otimes 2}$ with $(u,v) \in V(G) \times V(G)$ exactly once for each edge of G that joins the vertex u to the vertex v. Equivalently, let $\mathrm{Rot}_G : V \times L \to V \times L$ be a rotation map for G, and define x^G for all $u \in V$ and all $i \in L$ by $x^G(u,i) = x(u)x(v)$ where $v \in V$ is given by $\mathrm{Rot}_G(u,i) = (v,j)$. In particular, x^G has exactly ΔD coordinates.

▶ **Lemma 11** (Approximate squaring). *For all $x, y \in \{-1,1\}^D$ we have*

$$\left| \langle x^G, y^G \rangle - \frac{\Delta}{D} \langle x^{\otimes 2}, y^{\otimes 2} \rangle \right| \le 2\lambda D\,.$$

Proof. Let $S = \{u \in V(G) : x(u) = y(u)\}$ and let us write $\bar{S} = V(G) \setminus S$. Since x, y are $\{-1,1\}$-valued, we have

$$\langle x^G, y^G \rangle = |E(S,S)| + |E(\bar{S},\bar{S})| - |E(S,\bar{S})| - |E(\bar{S},S)|\,.$$

Observing that

$$|S|^2 + |\bar{S}|^2 - |S||\bar{S}| - |\bar{S}||S| = \big(2|S| - D\big)^2 = \langle x, y \rangle^2 = \langle x^{\otimes 2}, y^{\otimes 2} \rangle$$

and applying Lemma 8 four times, we have

$$\left| \langle x^G, y^G \rangle - \frac{\Delta}{D} \langle x^{\otimes 2}, y^{\otimes 2} \rangle \right| \le \lambda\big(D + 2\sqrt{|S|(D - |S|)}\big) \le 2\lambda D\,.$$ ◀

The amplifier function. We now construct an amplifier function $\hat{f}$ that uses ℓ approximate squarings, $\ell \ge 1$, with the graphs drawn from the graph family in Lemma 9. Accordingly, we assume that all vectors have lengths that are positive integer powers of 2.

The input $x = \tilde{x}_0 \in \{-1,1\}^{d_0}$ to the amplifier has dimension $d_0 = 2^k$ for a positive integer k. For $i = 0, 1, \ldots, \ell - 1$, suppose we have the vector $\tilde{x}_i \in \{-1,1\}^{d_i}$. Let b_i be a positive integer whose value will be fixed later. Let t_i be the unique positive integer with

$$d_i \le D_i = 2^{16 b_i t_i} < 2^{16 b_i} d_i\,.$$

Note in particular that d_i divides D_i since d_i is a power of 2. Let G_i be a $(2^{16 b_i t_i}, 2^{4 b_i}, 16 \cdot 2^{3 b_i})$-graph from Lemma 9. Take D_i / d_i copies of $\tilde{x}_i$ to obtain the vector $x_i \in \{-1,1\}^{D_i}$. Let $\tilde{x}_{i+1} = x_i^{G_i} \in \{-1,1\}^{d_{i+1}}$ with $d_{i+1} = \Delta_i D_i$ and $\Delta_i = 2^{4 b_i}$. The amplifier outputs $\hat{f}(x) = \tilde{x}_\ell$ with $\tilde{x}_\ell \in \{-1,1\}^{d_\ell}$.

Since the graph family in Lemma 9 admits rotation maps that can be computed in time $\mathrm{poly}(b,t)$, we observe that $\hat{f}$ is explicit. Indeed, from the construction it is immediate that to compute any single coordinate of $\hat{f}(x)$ it suffices to (i) perform in total $2^{\ell-1-i}$ evaluations of the rotation map of the graph G_i for each $i = 0, 1, \ldots, \ell - 1$, and (ii) access at most 2^ℓ coordinates of x. Since $b_i t_i = O(\log d_\ell)$ for all $i = 0, 1, \ldots, \ell - 1$, we have that we can compute any coordinate of $\hat{f}(x)$ in time $\mathrm{poly}(\log d_\ell, 2^\ell)$ and accessing at most 2^ℓ coordinates of x.

Parameterization and analysis. Fix $\tau_0 > 0$ and $\gamma_0 > 1$. To parameterize the amplifier (that is, it remains to fix the values b_i), let us track a pair of vectors as it proceeds through the ℓ approximate squarings for $i = 0, 1, \ldots, \ell - 1$.

We start by observing that copying preserves *relative* inner products. That is, for any pair of vectors $\tilde{x}_i, \tilde{y}_i \in \{-1,1\}^{d_i}$ we have $\langle \tilde{x}_i, \tilde{y}_i \rangle = \nu_i d_i$ if and only if $\langle x_i, y_i \rangle = \nu_i D_i$ for $0 \le \nu_i \le 1$.

An easy manipulation of Lemma 11 using the parameters in Lemma 9 gives us additive control over an approximate squaring via

$$\nu_i^2 - 32\Delta_i^{-1/4} \le \nu_{i+1} \le \nu_i^2 + 32\Delta_i^{-1/4} . \tag{8}$$

For all inner products that are in absolute value above a threshold, we want to turn this additive control into multiplicative control via

$$\nu_i^2\gamma_0^{-1} \le \nu_{i+1} \le \nu_i^2\gamma_0 . \tag{9}$$

Let us insist this multiplicative control holds whenever $|\nu_i| \ge \tau_i$ for the threshold parameter τ_i defined for all $i = 0, 1, \ldots, \ell - 1$ by

$$\tau_{i+1} = \gamma_0^{-1}\tau_i^2 . \tag{10}$$

Enforcing (9) via (8) at the threshold, let us assume that

$$\tau_i^2\gamma_0^{-1} \le \tau_i^2 - 32\Delta_i^{-1/4} . \tag{11}$$

The next lemma confirms that assuming (11) gives two-sided control of inner products which is retained to the next approximate squaring. The following lemma shows that small inner products remain small.

▶ **Lemma 12** (†). *If $\tau_i \le |\nu_i|$, then $\nu_i^2\gamma_0^{-1} \le \nu_{i+1} \le \nu_i^2\gamma_0$ and $\tau_{i+1} \le \nu_{i+1}$.*

▶ **Lemma 13** (†). *If $|\nu_i| < \tau_i$, then $|\nu_{i+1}| \le \tau_i^2\gamma_0$.*

Let us now make sure that (11) holds. Solving for Δ_i in (11), we have

$$\Delta_i \ge \left(32(1-\gamma_0^{-1})^{-1}\tau_i^{-2}\right)^4 . \tag{12}$$

In particular, we can make sure that (12) and hence (11) holds by simply choosing a large enough Δ_i (that is, a large enough b_i).

Before proceeding with the precise choice of b_i for $i = 0, 1, \ldots, \ell-1$, let us analyze the input–output relationship of the amplifier $\hat{f}$ using Lemma 12 and Lemma 13. Let $x, y \in \{-1, 1\}^{d_0}$ be two vectors given as input with $\langle x, y\rangle = \nu_0 d_0$. The outputs $\hat{f}(x), \hat{f}(y) \in \{-1, 1\}^{d_\ell}$ then satisfy $\langle \hat{f}(x), \hat{f}(y)\rangle = \nu_\ell d_\ell$, where the following two lemmas control ν_ℓ via ν_0.

▶ **Lemma 14** (†). *If $|\nu_0| \ge \tau_0$, then $\nu_0^{2^\ell}\gamma_0^{-2^\ell+1} \le \nu_\ell \le \nu_0^{2^\ell}\gamma_0^{2^\ell-1}$.*

▶ **Lemma 15** (†). *If $|\nu_0| < \tau_0$, then $|\nu_\ell| \le \tau_0^{2^\ell}\gamma_0^{2^\ell-1}$.*

Since $\gamma_0 > 1$, from Lemma 14 and Lemma 15 it now follows that $\hat{f}$ meets the required amplification constraints (2) and (3) with $p = 2^\ell$, $\tau = \tau_0$, and $\gamma = \gamma_0$.

Let us now complete the parameterization and derive an upper bound for d_ℓ. For each $i = 0, 1, \ldots, \ell-1$, take b_i to be the smallest nonnegative integer so that $b_i \ge 10$ and $\Delta_i = 2^{4b_i}$ satisfies (12). Since $D_i \le 2^{16b_i}d_i = \Delta_i^4 d_i$, we have $d_{i+1} = \Delta_i D_i \le \Delta_i^5 d_i$, and hence

$$d_\ell \le (\Delta_{\ell-1}\Delta_{\ell-2}\cdots\Delta_0)^5 d_0 .$$

Recall that $d_0 = 2^k$. From (12) we have that

$$\Delta_i = 2^{4b_i} \le \max\left(2^{40}, 2^4\left(32(1-\gamma_0^{-1})^{-1}\tau_i^{-2}\right)^4\right) \le \left(2^{10}(1-\gamma_0^{-1})^{-1}\tau_i^{-2}\right)^4 .$$

Since $\tau_i = \tau_0^{2^i}\gamma_0^{-2^i+1}$ by (10), it follows that

$$d_\ell \le 2^k\left(2^{10}\left(1-\gamma_0^{-1}\right)^{-1}\right)^{20\ell}\left(\frac{\gamma_0}{\tau_0}\right)^{20(2^{\ell+1}-1)} .$$

Repeatedly taking two copies of the output as necessary, for all 2^K with $2^K \ge d_\ell$ we obtain a correlation amplifier with parameters $(2^k, 2^K, 2^\ell, \tau_0, \gamma_0)$. This completes the proof of Lemma 10. ◀

Copy-and-truncate preprocessing of the input dimension. We still want to remove the assumption from Lemma 10 that the input dimension is a positive integer power of 2. The following copy-and-truncate preprocessing will be sufficient towards this end.

Let $x \in \{-1,1\}^d$ and let k be a positive integer. Define the vector $\hat{x} \in \{-1,1\}^{2^k}$ by concatenating $\lceil 2^k/d \rceil$ copies of x one after another, and truncating the result to the 2^k first coordinates to obtain $\hat{x}$.

Let us study how the map $x \mapsto \hat{x}$ operates on a pair of vectors $x, y \in \{-1,1\}^d$. For notational compactness, let us work with relative inner products $\nu, \hat{\nu}$ with $\langle x, y\rangle = \nu d$ and $\langle \hat{x}, \hat{y}\rangle = \hat{\nu} 2^k$.

▶ **Lemma 16** (†). *For any $0 < \tau_0 < 1$, $\gamma_0 > 1$, and $2^k \geq 2d\tau_0^{-1}(1-\gamma_0^{-1})^{-1}$ we have that*
1. *$|\nu| < \tau_0$ implies $|\hat{\nu}| \leq \gamma_0\tau_0$,*
2. *$|\nu| \geq \tau_0$ implies $\gamma_0^{-1}\nu \leq |\hat{\nu}| \leq \gamma_0\nu$.*

Completing the proof of Theorem 3. Let d, K, ℓ, τ, γ be parameters meeting the constraints in Theorem 3, in particular the constraint (4). To construct a required amplifier f, we preprocess each input vector x with copy-and-truncate, obtaining a vector $\hat{x}$ of length 2^k. We then then apply an amplifier $\hat{f} : \{-1,1\}^{2^k} \to \{-1,1\}^{2^K}$ given by Lemma 10. In symbols, we define $f : \{-1,1\}^d \to \{-1,1\}^{2^K}$ for all $x \in \{-1,1\}^d$ by $f(x) = \hat{f}(\hat{x})$. It is immediate from Lemma 10 and Lemma 16 that the resulting composition is explicit.

We begin by relating the given parameters of Theorem 3 to those of Lemma 10. Take $\gamma_0 = \gamma^{1/2}$, $\tau_0 = \tau\gamma^{-1}$, and select the minimal value of k so that the constraint in Lemma 16 is satisfied; that is 2^k is constrained as follows,

$$2d(1-\gamma^{-1/2})^{-1}\gamma\tau^{-1} \leq 2^k < 4d(1-\gamma^{-1/2})^{-1}\gamma\tau^{-1} .$$

Substituting this upper bound into the bound of Lemma 10, we get a lower bound for 2^K,

$$2^K \geq 2^{-8} d \left(2^{-10}(1-\gamma^{-1/2})^{-1}\right)^{20\ell+1} \frac{\gamma}{\tau} \left(\frac{\gamma^{60}}{\tau^{40}}\right)^{2^\ell} \frac{\tau^{20}}{\gamma^{30}} . \tag{13}$$

Observe that an integer 2^K satisfying (4) also satisfies (13). We have not attempted to optimise our construction, and prefer the the statement of Theorem 3 as it is reasonably clean and is sufficient to prove Theorem 4.

Let us study how the map $x \mapsto f(x)$ operates on a pair of vectors $x, y \in \{-1,1\}^d$. For notational compactness, again we work with relative inner products $\nu, \hat{\nu}, \phi$ with $\langle x, y\rangle = \nu d$, $\langle \hat{x}, \hat{y}\rangle = \hat{\nu}2^k$, and $\langle f(x), f(y)\rangle = \phi 2^K$. Observe that in the notation of the proof of Lemma 10, we have $\hat{\nu} = \nu_0$ and $\phi = \nu_\ell$.

▶ **Lemma 17** (†). *If $|\nu| < \tau$ then $|\phi| \leq (\gamma\tau)^{2^\ell}$.*

▶ **Lemma 18** (†). *If $|\nu| \geq \tau$ then $(\nu\gamma^{-1})^{2^\ell} \leq \phi \leq (\nu\gamma)^{2^\ell}$.*

Now, f satisfies (2) and (3) with $p = 2^\ell$ by Lemmas 17 and 18 respectively.
This completes the proof of Theorem 3. ◀

3 A deterministic algorithm for outlier correlations

This section proves Theorem 4. We start by describing the algorithm, then parameterize it and establish its correctness, and finally proceed to analyze the running time.

The algorithm. Fix the constants $\epsilon, \tau_{\max}, \delta, C$ as in Theorem 4. Based on these constants, fix the constants $0 < \sigma < 1$ and $\gamma > 1$. (We fix the precise values of σ and γ later during the analysis of the algorithm, and stress that σ, γ do not depend on the given input.)

Suppose we are given as input the parameters $0 < \tau < \rho < 1$ and $X, Y \subseteq \{-1,1\}^d$ with $|X| = |Y| = n$ so that the requirements in Theorem 4 hold. We work with a correlation amplifier $f : \{-1,1\}^d \to \{-1,1\}^D$ with parameters (d, D, p, τ, γ). (We fix the precise values of the parameters p and D later during the analysis of the algorithm so that f originates from Theorem 3.)

The algorithm proceeds as follows. First, apply f to each vector in X and Y to obtain the sets X_f and Y_f. Let $s = \lfloor n^\sigma \rfloor$. Second, partition the n vectors in both X_f and Y_f into $\lceil n/s \rceil$ buckets of size at most s each, and take the vector sum of the vectors in each bucket to obtain the sets $\tilde{X}_f, \tilde{Y}_f \subseteq \{-s, -s+1, \ldots, s-1, s\}^D$ with $|\tilde{X}_f|, |\tilde{Y}_f| \leq \lceil n/s \rceil$. Third, using fast rectangular matrix multiplication on $\tilde{X}_f$ and $\tilde{Y}_f$, compute the matrix Z whose entries are the inner products $\langle \tilde{x}, \tilde{y} \rangle$ for all $\tilde{x} \in \tilde{X}_f$ and all $\tilde{y} \in \tilde{Y}_f$. Fourth, iterate over the entries of Z, and whenever the *detection inequality*

$$\langle \tilde{x}, \tilde{y} \rangle > n^{2\sigma}(\tau\gamma)^p \tag{14}$$

holds, brute-force search for outliers among the at most $s \times s$ inner products in the corresponding pair of buckets. Output any outliers found.

Parameterization and correctness. Let us now parameterize the algorithm and establish its correctness. Since $\gamma > 1$ is a constant and assuming that p is large enough, by Theorem 3 we can select D to be the integer power of 2 with

$$\frac{1}{2} d \left(\frac{\gamma}{\tau}\right)^{Cp} < D \leq d \left(\frac{\gamma}{\tau}\right)^{Cp} .$$

Recall that we write α for the exponent of rectangular matrix multiplication. To apply fast rectangular matrix multiplication in the third step of the algorithm, we want

$$D \leq 2 \left(\frac{n}{s}\right)^{\alpha} , \tag{15}$$

so recalling that $d \leq n^\delta$ and $n^\sigma - 1 < s$, it suffices to require that

$$\left(\frac{\gamma}{\tau}\right)^{Cp} \leq n^{(1-\sigma)\alpha - \delta} .$$

Let us assume for the time being that $(1-\sigma)\alpha - \delta > 0$. (We will justify this assumption later when we choose a value for σ.) Let p be the unique positive-integer power of 2 such that

$$\frac{((1-\sigma)\alpha - \delta)\log n}{2C \log \frac{\gamma}{\tau}} < p \leq \frac{((1-\sigma)\alpha - \delta)\log n}{C \log \frac{\gamma}{\tau}} . \tag{16}$$

Observe that p exists and is positive for all large enough n since $\gamma > 1$ is a constant and $n^{-\Theta(1)} \leq \tau$ by our assumption.[10] By the detection inequality (14), we require each entry of Z to have value strictly greater than $n^{2\sigma}(\tau\gamma)^p$ if among the correspoding at most $s \times s$

[10] In particular, since $\sigma, \delta, \alpha, C, \gamma$ are constants, we can choose the constant hidden by the $\Theta(1)$ so that $1 \leq (((1-\sigma)\alpha - \delta)\log n)/(2C \log \frac{\gamma}{\tau})$.

inner products between the two buckets there is at least one inner product with absolute value at least ρd. Furthermore, we want (14) to hold only if among the at most $s \times s$ inner products between the two buckets there is at least one inner product with absolute value strictly greater than τd. Since f satisfies (2) and (3), and recalling that $s \le n^\sigma$, it suffices to require that

$$s^2\big(\tau\gamma\big)^p \le n^{2\sigma}\big(\tau\gamma\big)^p < \big(\rho\gamma^{-1}\big)^p - n^{2\sigma}\big(\tau\gamma\big)^p\,. \tag{17}$$

Rearranging the right-hand side of (17) and solving for p, we require that

$$p > \frac{1+2\sigma\log n}{\log\frac{\rho}{\tau\gamma^2}}\,. \tag{18}$$

From (16) and (18) we thus see that it suffices to have

$$p > \frac{((1-\sigma)\alpha-\delta)\log n}{2C\log\frac{\gamma}{\tau}} \ge \frac{1+2\sigma\log n}{\log\frac{\rho}{\tau\gamma^2}}\,,$$

or equivalently,

$$\frac{\log\frac{\rho}{\tau\gamma^2}}{\log\frac{\gamma}{\tau}} \ge \frac{\frac{2C}{\log n}+4C\sigma}{(1-\sigma)\alpha-\delta}\,. \tag{19}$$

Let us derive a lower bound for the left-hand side of (19). Fix the constant $\gamma > 1$ so that $\log\gamma = -\frac{\epsilon\log\tau_{\max}}{100000}$. By our assumptions we have $\tau \le \tau_{\max}$ and $1-\log_\tau\rho \ge \epsilon$, so we have the lower bound

$$\frac{\log\frac{\rho}{\tau\gamma^2}}{\log\frac{\gamma}{\tau}} = \frac{\log\rho-\log\tau-2\log\gamma}{\log\gamma-\log\tau} = \frac{1-\log_\tau\rho+\frac{2\log\gamma}{\log\tau}}{1-\frac{\log\gamma}{\log\tau}} \ge \frac{\epsilon+\frac{2\log\gamma}{\log\tau_{\max}}}{1-\frac{\log\gamma}{\log\tau_{\max}}} > 0.99\epsilon\,.$$

Thus, (19) holds for all large enough n when we require

$$0.99\epsilon \ge \frac{4C\sigma}{(1-\sigma)\alpha-\delta}\,.$$

Since $\alpha\epsilon < 1$, we have that (19) holds when we set

$$\sigma = \frac{0.99\epsilon(\alpha-\delta)}{4C+1} \le \frac{0.99\epsilon(\alpha-\delta)}{4C+0.99\alpha\epsilon}\,.$$

We also observe that $(1-\sigma)\alpha-\delta > 0$, or equivalently, $\sigma < (\alpha-\delta)/\alpha$ holds for our choice of σ. This completes the parameterization of the algorithm.

Running time. Let us now analyze the running time of the algorithm. The first and second steps run in time $\tilde{O}(nD)$ since $p = O(\log n)$ by (16) and f originates from Theorem 3 and hence is explicit. From (15) and $n^\sigma - 1 < s$, we have $nD \le 4n^{1+(1-\sigma)\alpha} \le 4n^{2-\sigma}$. Since (15) holds, the third step of the algorithm runs in time $O\big((n/s)^{2+\eta}\big)$ for any constant $\eta > 0$ that we are free to choose. Since $n/s \le 2n^{1-\sigma}$ for all large enough n, we can choose $\eta > 0$ so that $(2+\eta)(1-\sigma) \le 2-\sigma$. Thus, the first, second, and third steps together run in time $O(n^{2-\sigma})$. The fourth step runs in time $O(n^{2-\sigma} + qs^2d)$. Indeed, observe from (17) that the inequality (14) holds for at most q entries in Z. We have $qs^2d \le qn^{2\sigma+\delta}$, which completes the running time analysis and the proof of Theorem 4. ◀

4 Proof of Corollary 7

A useful variant of the Problem 1 asks for all outlier pairs of distinct vectors drawn from a *single* set $S \subseteq \{-1,1\}^d$ rather than two sets X, Y. We observe that the single-set variant reduces to $\lceil \log |S| \rceil$ instances of the two-set variant by numbering the vectors in S with binary numbers from 0 to $|S|-1$ and splitting S into two sets X_i, Y_i based on the value of the i^{th} bit for each $i = 0, 1, \ldots, \lceil \log |S| \rceil - 1$.

We will need the following bound due to Hoeffding which provides an exponentially small upper bound on the deviation of a sum of bounded independent random variables from its expectation.

▶ **Theorem 19** (Hoeffding [14, Theorem 2]). *Let $Z_1, Z_2, \ldots, Z_D$ be independent random variables satisfying $\ell_i \le Z_i \le u_i$ for all $1 \le i \le D$, and let $Z = \sum_{i=1}^{D} Z_i$. Then, for all $c > 0$, the following holds:*

$$\Pr\left(Z - \mathrm{E}[Z] \ge c\right) \le \exp\left(-\frac{2c^2}{\sum_{i=1}^{D}(u_i - \ell_i)^2}\right). \tag{20}$$

▶ **Corollary 7.** *For any constants $0 < \delta < \alpha$, $C > 60$, $0 < \rho_{\max} < 1$, and $\kappa > 1$, there exists a deterministic algorithm that solves almost all instances of Problem 6 in time*

$$O\left(n^{2-\frac{0.99(1-1/\kappa)(\alpha-\delta)}{4C+1}}\right)$$

assuming the parameters n, d, ρ satisfy the two constraints

1. $5\rho^{-2\kappa}\log n \le d \le n^{\delta}$ *and*
2. $n^{-\Theta(1)} \le \rho \le \rho_{\max}$. [11]

Proof. We reduce to (the single-set version of) Problem 1 and apply Theorem 4. Towards this end, in Theorem 4 set $\epsilon = 1 - 1/\kappa$ and $\tau_{\max} = \rho_{\max}^{\kappa}$. Suppose we are given an instance of Problem 6 whose parameters n, d, ρ satisfy the constraints. Set $\tau = \rho^{\kappa}$. We observe that the constraints in Theorem 4 are satisfied since (i) $d \le n^{\delta}$ holds by assumption, (ii) $\tau \le \tau_{\max}$ holds since $\tau = \rho^{\kappa} \le \rho_{\max}^{\kappa}$, (iii) since $\kappa > 1$ is a constant and $\tau = \rho^{\kappa}$ we can satisfy the requirement that $\tau \ge n^{-\Theta(1)}$ for any desired constant hidden by the $\Theta(1)$ notation [12] by our assumption that $\rho \ge n^{-\Theta(1)}$, and (iv) $\log_{\tau}\rho = \frac{\log \rho}{\log \tau} = \frac{\log \rho}{\log \rho^{\kappa}} = 1/\kappa \le 1 - \epsilon$.

We claim that $q = 1$ for almost all instances of Problem 6 whose parameters satisfy the constraints in Corollary 7. Indeed, by the Hoeffding bound (20) and the union bound, the probability that some other pair than the planted pair in an instance has inner product that exceeds τd in absolute value is at most

$$2n^2 \exp\left(-\tau^2 d/2\right) \le 2n^2 \exp\left(-\rho^{2\kappa} \cdot 5\rho^{-2\kappa}\log n\right) = 2n^{-1/2},$$

so $q = 1$ with high probability as n increases. The claimed running time follows by substituting the chosen constants and $q = 1$ to (5). ◀

A An expander family

This section proves Lemma 9 following Reingold, Vadhan and Wigderson [31]; we present the proof for completeness of exposition only with no claim of originality. Following Reingold, Vadhan and Wigderson [31] we will work with *normalized* eigenvalues. To avoid confusion with the unnormalized treatment in the manuscript proper, we say that a graph is a $[D,\Delta,\lambda]$-*graph* if the graph has D vertices, is Δ-regular, and $|\lambda_2|/\Delta \leq \lambda$. (Here $|\lambda_2|$ is the unnormalized second eigenvalue as defined in the manuscript proper.)

We refer to Sections 2.3 and 3.1 of Reingold, Vadhan, and Wigderson [31] for the definition of the square G^2 of a graph G, the tensor product $G_1 \otimes G_2$ of graphs G_1, G_2, and the zigzag product $G \circledz H$ of graphs G, H. The following omnibus result collects elements of Propositions 2.3, Proposition 2.4, Theorem 3.2 and Theorem 4.3 of [31] which will be sufficient to control the second normalized eigenvalue for our present purposes. (We choose to omit the details of the rotation maps with the understanding that they can be found in [31].)

▶ **Lemma 20** (Reingold, Vadhan, and Wigderson [31]). *The following bounds hold.*

1. *If G is a $[D,\Delta,\lambda]$-graph, then G^2 is a $[D,\Delta^2,\lambda^2]$-graph.*
2. *If G_1 is a $[D_1,\Delta_1,\lambda_1]$-graph and G_2 is a $[D_2,\Delta_2,\lambda_2]$-graph, then $G_1 \otimes G_2$ is a $[D_1D_2,\Delta_1\Delta_2,\max(\lambda_1,\lambda_2)]$-graph.*
3. *If G is a $[D_1,\Delta_1,\lambda_1]$-graph and H a $[\Delta_1,\Delta_2,\lambda_2]$-graph, then $G \circledz H$ is a $[D_1\Delta_1,\Delta_2^2,f(\lambda_1,\lambda_2)]$-graph with*

$$f(\lambda_1,\lambda_2) = \frac{1}{2}\left(1-\lambda_2^2\right)\lambda_1 + \frac{1}{2}\sqrt{\left(1-\lambda_2^2\right)^2\lambda_1^2 + 4\lambda_2^2} \leq \lambda_1 + \lambda_2\,.$$

Let us study the following sequence of graphs. Let H be a $[D,\Delta,\lambda]$-graph. Let $G_1 = H^2$, $G_2 = H \otimes H$, and for $t = 3,4,\ldots$ let

$$G_t = \left(G_{\lceil\frac{t-1}{2}\rceil} \otimes G_{\lfloor\frac{t-1}{2}\rfloor}\right)^2 \circledz H\,. \tag{21}$$

From Lemma 20 it is easily seen that G_t is a $[D^t,\Delta^2,\lambda_t]$-graph with λ_t defined by

$$\begin{aligned}
\lambda_1 &= \lambda^2\,, \\
\lambda_2 &= \lambda\,, \\
\lambda_{2t-1} &= \lambda + \lambda_{t-1}^2\,, && \text{for } t = 2,3\ldots\,, \text{ and} \\
\lambda_{2t} &= \max(\lambda+\lambda_t^2, \lambda+\lambda_{t-1}^2)\,, && \text{for } t = 2,3,\ldots\,.
\end{aligned}$$

▶ **Lemma 21** (Reingold, Vadhan, and Wigderson [31, Theorem 3.3]). *The rotation map* Rot_{G_t} *can be computed in time* $\mathrm{poly}(t,\log D)$ *and by making* $\mathrm{poly}(t)$ *evaluations of* Rot_H.

▶ **Lemma 22.** *If $0 \leq \lambda \leq 1/4$ then $\lambda_t \leq \lambda + 4\lambda^2$ for all $t \geq 1$.*

Proof. The conclusion is immediate for $t \leq 2$. So suppose that the conclusion holds up to $2t-2$. We need to show that the conclusion holds for λ_{2t-1} and λ_{2t}. By induction, it suffices to show that

$$\lambda_{2t-1} \leq \lambda + (\lambda+4\lambda^2)^2 \leq \lambda + 4\lambda^2\,.$$

Observing that $\lambda^2 + 8\lambda^3 + 16\lambda^4 \leq 4\lambda^2$ holds for $0 \leq \lambda \leq 1/4$ yields the desired conclusion. The proof for λ_{2t} is identical. ◀

Finally, we construct the expanders that we require in the manuscript proper.

▶ **Lemma 23** (Lemma 9 stated with normalized eigenvalue notation)**.** *For all integers* $t \geq 1$ *and* $b \geq 10$ *there exists a* $[2^{16bt}, 2^{4b}, 16 \cdot 2^{-b}]$*-graph whose rotation map can be evaluated in time* $\mathrm{poly}(b, t)$*.*

Proof. Take $q = 2^b$ and $d = 15$ in Proposition 5.3 of Reingold, Vadhan, and Wigderson [31] to obtain a $[2^{16b}, 2^{2b}, 15 \cdot 2^{-b}]$-graph H whose rotation map can be computed in time $\mathrm{poly}(b)$. (Indeed, observe that an irreducible polynomial to perform the required arithmetic in the finite field of order 2^b can be constructed in deterministic time $\mathrm{poly}(b)$ by an algorithm of Shoup [32].) Let us study the sequence G_t given by (21). The time complexity of the rotation map follows immediately from Lemma 21. Since $b \geq 10$, Lemma 22 gives that $\lambda_t \leq \lambda + 4\lambda^2$ for all $t \geq 1$. Take $\lambda = 15 \cdot 2^{-b}$ and observe that since $b \geq 10$ we have $2^{-b} < 1/900$. Thus, $\lambda_t \leq 15 \cdot 2^{-b} + 4(15 \cdot 2^{-b})^2 = 15 \cdot 2^{-b} + 900 \cdot 2^{-2b} \leq 16 \cdot 2^{-b}$. ◀

Faster Worst Case Deterministic Dynamic Connectivity*

Abstract

We present a deterministic dynamic connectivity data structure for undirected graphs with worst case update time $O\left(\sqrt{\frac{n(\log\log n)^2}{\log n}}\right)$ and constant query time. This improves on the previous best deterministic worst case algorithm of Frederickson (*SIAM J. Comput.*, 1985) and Eppstein Galil, Italiano, and Nissenzweig (*J. ACM*, 1997), which had update time $O(\sqrt{n})$. All other algorithms for dynamic connectivity are either randomized (Monte Carlo) or have only amortized performance guarantees.

1 Introduction

Dynamic Connectivity is perhaps the single most fundamental unsolved problem in the area of dynamic graph algorithms. The problem is simply to maintain a dynamic undirected graph $G = (V, E)$ subject to edge updates and connectivity queries:
INSERT(u, v) : Set $E \leftarrow E \cup \{(u, v)\}$.
DELETE(u, v) : Set $E \leftarrow E \setminus \{(u, v)\}$.
CONN?(u, v) : Determine whether u and v are in the same connected component in G.

Over thirty years ago Frederickson [10] introduced *topology trees* and *2-dimensional* topology trees, which gave the first non-trivial solution to the problem. Each edge insertion/deletion is handled in $O(\sqrt{m})$ time and each query is handled in $O(1)$ time. Here m is the current number of edges and n the number of vertices. On sparse graphs (where

* This work is supported in part by the Danish National Research Foundation grant DNRF84 through the Center for Massive Data Algorithmics (MADALGO), and by NSF grants CCF-1217338, CNS-1318294, and CCF-1514383.

† M. Thorup's research is partly supported by Advanced Grant DFF-0602-02499B from the Danish Council for Independent Research under the Sapere Aude research career programme.

$m = O(n)$) Frederickson's data structure has not been improved by any deterministic worst case algorithm. However, when the graph is dense Frederickson's data structure can be improved using the general sparsification method of Eppstein, Galil, Italiano, and Nissenzweig [7]. Using simple sparsification [6] the update time becomes $O(\sqrt{n}\log(m/n))$ and using more sophisticated sparsification [7] the running time becomes $O(\sqrt{n})$. This last bound has not been improved in twenty years.

1.1 New Results

In this paper we return to the classical model of deterministic worst case complexity. We give a new dynamic connectivity structure with worst case update time on the order of

$$\min\left\{\sqrt{\frac{m(\log\log n)^2}{\log n}},\quad \sqrt{\frac{m\log^5 w}{w}}\right\},$$

where $w = \Omega(\log n)$ is the word size.[1] These are the first improvements to Frederickson's 2D-topology trees [10] in over 30 years. Using the sparsification reduction of Eppstein et al. [7] the running time expressions can be made to depend on 'n' rather than 'm', so we obtain $O(\sqrt{\frac{n(\log\log n)^2}{\log n}})$ bounds (or faster) for all graph densities.

1.2 Related Work

Most research on the dynamic connectivity problem has settled for *amortized* update time guarantees. Following [15, 16], Holm et al. [17] gave a very simple deterministic algorithm with amortized update time $O(\log^2 n)$ and query time $O(\log n/\log\log n)$.[2] However, in the worst case Holm et al.'s [17] update takes $\Omega(m)$ time, the same as computing a spanning tree from scratch! Recently Wulff-Nilsen [25] improved the update time of [17] to $O(\log^2 n/\log\log n)$. Using Las Vegas randomization, Thorup [24] gave a dynamic connectivity data structure with an $O(\log n(\log\log n)^3)$ amortized update time. In other words, the algorithm answers all connectivity queries correctly but the amortized update time holds with high probability.

In a major breakthrough Kapron, King, and Mountjoy [18] used Monte Carlo randomization to achieve a worst case update time of $O(\log^5 n)$. However, this algorithm has three notable drawbacks. The first is that it is susceptible to undetected false negatives: $\textsc{Conn?}(u, v)$ may report that u, v are disconnected when they are, in fact, connected. The second is that even when $\textsc{Conn?}(u, v)$ (correctly) reports that u, v are connected, it is forbidden from exhibiting a connectivity witness, i.e., a spanning forest in which u, v are joined by a path. The Kapron et al. [18] algorithm <u>does</u> maintain such a spanning forest internally, but if this witness were made public, a very simple attack could force the algorithm to answer connectivity queries incorrectly. Lastly, the algorithm uses $\Omega(n\log^2 n)$ space, which for sparse graphs is superlinear in m. Very recently Gibb et al. [13] reduced the update time of [18] to $O(\log^4 n)$.

On special graph classes, dynamic connectivity can often be handled more efficiently. For example, Sleator and Tarjan [22] maintain a dynamic set of trees in $O(\log n)$ worst-case update time subject to $O(\log n)$ time connectivity queries. (See also [1, 3, 15, 23].)

[1] Our algorithms use the standard repertoire of AC^0 operations: left and right shifts, bitwise operations on words, additions and comparisons. They do not assume unit-time multiplication.

[2] Any connectivity structure that maintains (internally) a spanning forest can have query time $O(\log_{t_u/\log n} n)$ if the update time is $t_u = \Omega(\log n)$.

Table 1 A survey of dynamic connectivity results. The lower bounds hold in the cell probe model with word size $w = \Theta(\log n)$.

Worst Case Data Structures

Amort./Worst Case Lower Bounds

Ref.	Update Time t_u	Query Time t_q	Notes
[11, 14, 19]		$t_q = \Omega\left(\frac{\log n}{\log(t_u \log n)}\right)$	
[20]	$t_u = \Omega\left(\frac{\log n}{\log(t_q/t_u)}\right)$	$t_q = \Omega\left(\frac{\log n}{\log(t_u/t_q)}\right)$	Implies $\max\{t_u, t_q\} = \Omega(\log n)$.
[21]	$o(\log n)$ implies	$\Omega(n^{1-o(1)})$	

Connectivity in dynamic planar graphs can be reduced to the dynamic tree problem [8, 9], and therefore solved in $O(\log n)$ time per operation. The cell probe lower bounds of Pătraşcu and Demaine [20] show that Sleator and Tarjan's algorithm is optimal in the sense that *some* operation must take $\Omega(\log n)$ time. Superlogarithmic updates can be used to get modestly sublogarithmic queries, but Pătraşcu and Thorup [21] prove the reverse is not possible. In particular, any dynamic connectivity algorithm with $o(\log n)$ update time has $n^{1-o(1)}$ query time. Refer to Table 1 for a history of upper and lower bounds for dynamic connectivity.

Compared to the amortized algorithms [17, 24, 25], ours is better suited to *online* applications that demand a bound on the latency of *every* operation.[3] Compared to the Monte Carlo algorithms [13, 18], ours is attractive in applications that demand linear space, zero probability of error, and a public witness of connectivity.

2 The High Level Algorithm

The algorithm maintains a spanning tree of each connected component of the graph as a *witness* of connectivity. Each such witness tree T is represented as an Euler tour $\text{Euler}(T)$.[4] $\text{Euler}(T)$ is the sequence of vertices encountered in some Euler tour around T, as if each undirected edge were replaced by two oriented edges. It has length precisely $2(|V(T)|-1)$ if $|V(T)| \geq 2$ (the last vertex is excluded from the list, which is necessarily the same as the first) or length 1 if $|V(T)| = 1$. Vertices may appear in $\text{Euler}(T)$ several times. We designate one copy of each vertex the *principal copy*, which is responsible for all edges incident to the vertex. Each vertex in the graph maintains a pointer to its principal copy. Each T-edge (u, v) maintains two pointers to the (possibly non-principal) copies of u and v that precede the oriented occurrences of (u, v) and (v, u) in $\text{Euler}(T)$, respectively. Note that cyclic rotations of $\text{Euler}(T)$ are also valid Euler tours; if $\text{Euler}(T) = (u, \ldots, v)$ the last element of the list is associated with the tree edge (v, u).

When an edge (u, v) that connects distinct witness trees T_0 and T_1 is inserted, (u, v) becomes a tree edge and we need to construct $\text{Euler}(T_0 \cup \{(u, v)\} \cup T_1)$ from $\text{Euler}(T_0)$ and $\text{Euler}(T_1)$. In the reverse situation, if a tree edge (u, v) is deleted from $T = T_0 \cup \{(u, v)\} \cup T_1$ we first construct $\text{Euler}(T_0)$ and $\text{Euler}(T_1)$ from $\text{Euler}(T)$, then look for a *replacement edge*, $(\hat{u}, \hat{v})$ with $\hat{u} \in V(T_0)$ and $\hat{v} \in V(T_1)$. If a replacement is found we construct $\text{Euler}(T_0 \cup \{(\hat{u}, \hat{v})\} \cup T_1)$ from $\text{Euler}(T_0)$ and $\text{Euler}(T_1)$. Lemma 1 establishes the nearly obvious fact that the new Euler tours can be obtained from the old Euler tours using $O(1)$ of the following *surgical operations*: splitting and concatenating lists of vertices, and creating and destroying singleton lists containing non-principal copies of vertices.

▶ **Lemma 1.** *If $T = T_0 \cup \{(u, v)\} \cup T_1$ and (u, v) is deleted,* $\text{Euler}(T_0)$ *and* $\text{Euler}(T_1)$ *can be constructed from* $\text{Euler}(T)$ *with $O(1)$ surgical operations. In the opposite direction, from* $\text{Euler}(T_0)$ *and* $\text{Euler}(T_1)$ *we can construct* $\text{Euler}(T_0 \cup \{(u, v)\} \cup T_1)$ *with $O(1)$ surgical operations. It takes $O(1)$ time to determine which surgical operations to perform.*

Proof. Recall that cyclic shifts of Euler tours are valid Euler tours. Suppose without loss of generality that $\text{Euler}(T) = (P_0, u, v, P_1, v, u, P_2)$ where P_0, P_1, and P_2 are sequences of

[3] Amortized data structures are most useful when employed by offline algorithms that do not care about individual operation times. The canonical example is the use of amortized Fibonacci heaps [12] to implement Dijkstra's algorithm [5].

[4] Henzinger and King [15] were the first to use Euler tours to represent dynamic trees. G. Italiano (personal communication) observed that Euler tours could be used in lieu of Frederickson's topology trees to obtain an $O(\sqrt{m})$-time dynamic connectivity structure.

vertices. (Note that Euler tours never contain immediate repetitions. If P_1 is empty then Euler(T) would be just (P_0, u, v, u, P_2); if both P_0 and P_2 are empty then Euler$(T) = (u, v, P_1, v)$.) Then we obtain Euler$(T_0) = (P_0, u, P_2)$ and Euler$(T_1) = (v, P_1)$ with $O(1)$ surgical operations, which includes the destruction of non-principal copies of u and v; at least one of the two copies must be non-principal. We could also set Euler$(T_1) = (P_1, v)$, which would be more economical if the v following P_1 in Euler(T) were the principal copy.

In the reverse direction, write Euler$(T_0) = (P_0, u, P_1)$ and Euler$(T_1) = (P_2, v, P_3)$, where the labeled occurrences are the principal copies of u and v. Then Euler$(T_0 \cup \{(u, v)\} \cup T_1) = (P_0, u, v, P_3, P_2, v, u, P_1)$, where the new copies of u and v are clearly non-principal copies. If P_2 and P_3 were empty (or P_0 and P_1 were empty) then we would not need to add a non-principal copy of v (or a non-principal copy of u.) ◀

Thus, we have *reduced* dynamic connectivity in graphs to implementing several simple operations on dynamic lists. Our algorithm maintains a pair $(\mathcal{L}, E)$, where $\mathcal{L}$ is a set of lists (containing principal and non-principal copies of vertices) and E is the dynamic set of edges joining principal copies of vertices. In addition to the creation and destruction of single element lists we must support the following primitive operations.

List(x) : Return the list in $\mathcal{L}$ containing element x.

Join(L_0, L_1) : Set $\mathcal{L} \leftarrow \mathcal{L} \setminus \{L_0, L_1\} \cup \{L_0L_1\}$, that is, replace L_0 and L_1 with their concatenation L_0L_1.

Split(x) : Let $L = L_0L_1 \in \mathcal{L}$, where x is the last element of L_0. Set $\mathcal{L} \leftarrow \mathcal{L}\setminus\{L\}\cup\{L_0, L_1\}$.

ReplacementEdge(L_0, L_1) : Return any edge joining elements in L_0 and L_1.

Our implementations of these operations will only be efficient if, after each Insert or Delete operation, there are no edges connecting distinct lists. That is, the ReplacementEdge operation is only employed by Delete when deleting a tree edge in order to restore Invariant 2.

▶ **Invariant 2.** *Each list $\mathcal{L}$ corresponds to the Euler tour of a spanning tree of some connected component.*

The dynamic connectivity operations are implemented as follows. To answer a Conn?(u, v) query we simply check whether List(u) = List(v). To insert an edge (u, v) we do Insert(u, v), and if List$(u) \neq$ List(v) then make (u, v) a tree edge and perform suitable Splits and Joins to merge the Euler tours List(u) and List(v). To delete an edge (u, v) we do Delete(u, v), and if (u, v) is a tree edge in $T = T_0 \cup \{(u, v)\} \cup T_1$, perform suitable Splits and Joins to create Euler(T_0) and Euler(T_1) from Euler(T). At this point Invariant 2 may be violated as there could be an edge joining T_0 and T_1. We call ReplacementEdge(Euler(T_0), Euler(T_1)) and if it finds an edge, say $(\hat{u}, \hat{v})$, we perform more Splits and Joins to form Euler$(T_0 \cup \{(\hat{u}, \hat{v})\} \cup T_1)$.

Henzinger and King [15] observed that most off-the-shelf balanced binary search trees can support Split, Join, and other operations in logarithmic time. However, they provide no direct support for the ReplacementEdge operation, which is critical for the dynamic connectivity application.

Section 3 gives a relatively simple instantiation of the high-level approach with update time $O(\sqrt{n}/w^{1/4})$, $w = \Omega(\log n)$ being the word size. This is slightly slower than our claimed result. In Section 4 we describe the modifications needed to achieve the claimed bounds.

3 A New Data Structure for Dynamic Lists

3.1 Chunks and Superchunks

In order to simplify the maintenance of Invariant 3, stated below, we shall make two simplifying assumptions. We assume that we have a fixed upper bound $\hat{m}$ on the number of edges and that the maximum degree never exceeds K, where $K \approx \sqrt{\hat{m}/\operatorname{poly}(w)}$. The first assumption is justified by the fact that the sparsification method of [7] creates instances in which $\hat{m}$ is known to be linear in the number of vertices. (It can also be removed by the standard technique of periodic rebuilding.) Refer to Section 5.1 for clean ways to remove the degree-bound assumption.

If L' is a sublist of a list $L \in \mathcal{L}$, define $\operatorname{mass}(L')$ to be the number of edges incident to elements of L', counting an edge twice if both endpoints are in L'.[5] The sum of list masses, $\sum_{L\in\mathcal{L}} \operatorname{mass}(L)$, is clearly at most $2\hat{m}$, where $\hat{m}$ is the fixed upper bound on the number of edges. We maintain a partition of each list $L \in \mathcal{L}$ into *chunks* satisfying Invariant 3.

▶ **Invariant 3.** *Let $L \in \mathcal{L}$ be an Euler tour. If $\operatorname{mass}(L) < K$ then L consists of a single chunk. Otherwise $L = C_0C_1 \cdots C_{p-1}$ is partitioned into $\Theta(\operatorname{mass}(L)/K)$ chunks such that $\operatorname{mass}(C_l) \in [K, 3K]$ for all $l \in [p] \overset{\text{def}}{=} \{0, \ldots, p-1\}$.*

The chunks are partitioned into contiguous sequences of $\Theta(h)$ superchunks according to Invariant 4. For the time being define $h = 2\lfloor\sqrt{w}/2\rfloor$, where w is the word size.

▶ **Invariant 4.** *A list in $\mathcal{L}$ having fewer than $h/2$ chunks forms a single superchunk with ID $\perp$. A list in $\mathcal{L}$ with at least $h/2$ chunks is partitioned into superchunks, each consisting of between $h/2$ and $h-1$ consecutive chunks. Each such superchunk has a unique ID in $[J] \overset{\text{def}}{=} \{0, \ldots, J-1\}$, where $J = 4\hat{m}/(Kh)$. (IDs are completely arbitrary. They do not encode any information about the order of superchunks within a list.)*

Call an Euler tour list *short* if it consists of fewer than $h/2$ chunks. We shall assume that no lists are ever short, as this simplifies the description of the data structure and its analysis. In particular, all superchunks have proper IDs in $[J]$. Refer to Section 5.2 for a description of how to handle $\perp$ IDs and short lists.

3.2 Word Operations

When $h \le \lfloor\sqrt{w}\rfloor$, Invariant 4 implies that we can store a matrix $A \in \{0,1\}^{h\times h}$ in one word that represents the adjacency between the chunks within two superchunks i and j. This matrix will always be represented in row-major order; rows and columns are indexed by $[h] = \{0, \ldots, h-1\}$. In this format it is straightforward to insert a new all-zero row above a specified row k (and destroy row $h-1$) by shifting the old rows $k, \ldots, h-2$ down by one. It is also easy to copy an interval of rows from one matrix to another. Lemma 5 shows that the corresponding operations on *columns* can also be effected in $O(1)$ time with a fixed mask μ precomputable in $O(\log w)$ time.

▶ **Lemma 5.** *Let $h = 2\lfloor\sqrt{w}/2\rfloor$ and let μ be the word $(1^h0^h)^{h/2}$. Given μ we can in $O(1)$ time copy/paste any interval of columns from/to a matrix $A \in \{0,1\}^{h\times h}$, represented in row-major order.*

[5] Remember that edges are only incident to principal copies of vertices, so non-principal copies never contribute any mass.

Proof. Recall that the rows and columns are indexed by integers in $[h] = \{0, \ldots, h-1\}$. We first describe how to build a mask ν_k for columns $k, \ldots, h-1$ then illustrate how it is used to copy/paste intervals of columns. In C notation,[6] the word $\nu'_k = (\mu \gg k) \,\&\, \mu$ is a mask for the intersection of the even rows and columns $k, \ldots, h-1$, so $\nu_k = \nu'_k \mid (\nu'_k \gg h)$ is a mask for columns k through $h-1$.

To insert an all-zero column before column k of A (and delete column $h-1$) we first copy columns $k, \ldots, h-2$ to $A' = A \,\&\, (\nu_{k+1} \ll 1)$ then set $A = (A \,\&\, (\sim\nu_k)) \mid (A' \gg 1)$. Other operations can be effected in $O(1)$ time with copying/pasting intervals of columns, e.g., splitting an array into two about a designated column, or merging two arrays having at most h columns together. ◀

3.3 Adjacency Data Structures

In order to facilitate the efficient implementation of ReplacementEdge we maintain an $O(\hat{m}/K) \times O(\hat{m}/K)$ adjacency matrix between chunks, and a $J \times J$ adjacency matrix between superchunks. However, in order to allow for efficient dynamic updates it is important that these matrices be represented in a non-standard format described below. The data structure maintains the following information.

- Each list element maintains a pointer to the chunk containing it. Each chunk maintains a pointer to the superchunk containing it, as well as an index in $[h]$ indicating its position within the superchunk. Each superchunk maintains its ID in $[J] \cup \{\perp\}$ and a pointer to the list containing it.
- ChAdj is a $J \times J$ array of h^2-bit words ($h^2 \leq w$) indexed by superchunk IDs. The entry $\text{ChAdj}(i,j)$ is interpreted as an $h \times h$ 0-1 matrix that keeps the adjacency information between all pairs of chunks in superchunk i and superchunk j. (It may be that $i = j$.) In particular, $\text{ChAdj}(i,j)(k,l) = 1$ iff there is an edge with endpoints in the kth chunk of superchunk i and the lth chunk of superchunk j, so $\text{ChAdj}(i,j) = 0$ (i.e., the all-zero matrix) if no edge joins superchunks i and j. The matrix $\text{ChAdj}(i,j)$ is stored in row-major order.
- Let S be a superchunk with $ID(S) = \perp$. By Invariants 2 and 4, S is not incident to any other superchunks and has fewer than $h/2$ chunks. We maintain a single word ChAdj_S which stores the adjacency matrix of the chunks within S.
- For each superchunk with ID $i \in [J]$ we keep length-J bit-vectors SupAdj_i and Memb_i, where

  $$\begin{aligned} \text{SupAdj}_i(j) &= 1 \text{ if } \text{ChAdj}(i,j) \neq 0 \text{ and } 0 \text{ otherwise, whereas} \\ \text{Memb}_i(j) &= 1 \text{ if } j = i \text{ and } 0 \text{ otherwise.} \end{aligned}$$

  These vectors are packed into $\lceil J/w \rceil$ machine words, so scanning one takes $O(\lceil J/w \rceil)$ time.
- We maintain a *list-sum* data structure that allows us to take the bit-wise OR of the SupAdj_i vectors or Memb_i vectors, over all superchunks in an Euler tour. It is responsible for maintaining the $\{\text{SupAdj}_i, \text{Memb}_i\}$ vectors described above and supports the following operations. At all times the superchunks are partitioned into a set $\mathcal{S}$ of disjoint lists of superchunks. Each $S \in \mathcal{S}$ (a list of superchunks) is associated with an $L \in \mathcal{L}$ (an Euler tour), though short lists in $\mathcal{L}$ have no need for a corresponding list in $\mathcal{S}$.

[6] The operations &, |, and $\sim$ are bit-wise AND, OR, and NOT; $\ll$ and $\gg$ are left and right shift.

SCInsert(i) : Retrieve an unused ID, say i', and allocate a new superchunk with ID i' and all-zero vector $\mathrm{SupAdj}_{i'}$. Insert superchunk i' immediately after superchunk i in i's list in $\mathcal{S}$. If no i is given, create a new list in $\mathcal{S}$ consisting of superchunk i'.

SCDelete(i) : Delete superchunk i from its list and make ID i unused.

SCJoin(S_0, S_1) : Replace superchunk lists $S_0, S_1 \in \mathcal{S}$ with their concatenation S_0S_1.

SCSplit(i) : Let $S = S_0S_1 \in \mathcal{S}$ and i be the last superchunk in S_0. Replace S_0S_1 with two lists S_0, S_1.

UpdateAdj($i, x \in \{0,1\}^J$) : Set $\mathrm{SupAdj}_i \leftarrow x$ and update $\mathrm{SupAdj}_j(i) \leftarrow x(j)$ for all $j \neq i$.

AdjQuery(S) : Return the vector $\alpha \in \{0,1\}^J$ where

$$\alpha(j) = \bigvee_{i \in S} \mathrm{SupAdj}_i(j)$$

The index i ranges over the IDs of all superchunks in S.

MembQuery(S) : Return the vector $\beta \in \{0,1\}^J$, where

$$\beta(j) = \bigvee_{i \in S} \mathrm{Memb}_i(j)$$

We use the following implementation of the *list-sum* data structure. Each list of superchunks is maintained as any $O(1)$-degree search tree that supports logarithmic time inserts, deletes, splits, and joins. Each leaf is a superchunk that stores its two bit-vectors. Each internal node z keeps two bit-vectors, SupAdj^z and Memb^z, which are the bit-wise OR of their leaf descendants' respective bit-vectors. Because length-J bit-vectors can be updated in $O(\lceil J/w \rceil)$ time, all "logarithmic time" operations on the tree actually take $O(\log J \cdot J/w)$ time. The UpdateAdj(i, x) operation takes $O(\log J \cdot J/w)$ time to update superchunk i and its $O(\log J)$ ancestors. We then need to update the ith bit of potentially every other node in the tree, in $O(J)$ time. Since $w = \Omega(\log n) = \Omega(\log J)$ the cost per UpdateAdj is $O(J)$. The answer to an AdjQuery(S) or MembQuery(S) is stored at the root of the tree on S.

3.4 Creating and Destroying (Super)Chunks

There are essentially two causes for the creation and destruction of (super)chunks. The first is in response to a Split operation that forces a (super)chunk to be broken up. (The Split may itself be instigated by the insertion or deletion of an edge.) The second is to restore Invariants 3 and 4 after a Join or Insert or Delete operation. In this section we consider the problem of updating the adjacency data structures after four types of operations: (i) splitting a chunk in two, keeping both chunks in the same superchunk, (ii) merging two adjacent chunks in the same superchunk, (iii) splitting a superchunk along a chunk boundary, and (iv) merging adjacent superchunks. Once we have bounds on (i)–(iv), implementing the higher-level operations in the stated bounds is relatively straightforward. Note that (i)–(iv) may temporarily violate Invariants 3 and 4.

3.4.1 Splitting Chunks

Suppose we want to split the kth chunk of superchunk i into two pieces, both of which will (at least temporarily) stay within superchunk i.[7] We first zero-out all bits of $\mathrm{ChAdj}(i, \star)(k, \star)$

[7] Remember that 'k' refers to the actual position of the chunk within its superchunk whereas 'i' is an arbitrary ID that does not relate to its position within the list.

and $\mathrm{ChAdj}(\star, i)(\star, k)$ in $O(J)$ time. For each j we need to insert an all-zero row below row k in $\mathrm{ChAdj}(i, j)$ and an all-zero column after column k of $\mathrm{ChAdj}(j, i)$. This can be done in $O(1)$ time for each j, or $O(J)$ in total; see Lemma 5.

In $O(K)$ time we scan the edges incident to the new chunks k and $k+1$ and update the corresponding bits in $\mathrm{ChAdj}(i, \star)(k', \star)$ and $\mathrm{ChAdj}(\star, i)(\star, k')$, for $k' \in \{k, k+1\}$.

3.4.2 Merging Adjacent Chunks

In order to merge chunks k and $k+1$ of superchunk i we need to replace row k of $\mathrm{ChAdj}(i, j)$, for all j, with the bit-wise OR of rows k and $k+1$ of $\mathrm{ChAdj}(i, j)$, zero out row $k+1$, then scoot rows $k+2, \cdots$ back one row. A similar transformation is performed on columns k and $k+1$ of $\mathrm{ChAdj}(j, i)$, which takes $O(1)$ time per j, by Lemma 5. In total the time is $O(J)$, independent of K.

3.4.3 Splitting Superchunks

Suppose we want to split superchunk i after its kth chunk. We first call SCInsert(i), which allocates an empty superchunk with ID i' and inserts i' after i in its superchunk list in $\mathcal{S}$. In $O(J)$ time we transfer rows $k+1, \ldots, h-1$ from $\mathrm{ChAdj}(i, j)$ to $\mathrm{ChAdj}(i', j)$ and transfer columns $k+1, \ldots, h-1$ from $\mathrm{ChAdj}(j, i)$ to $\mathrm{ChAdj}(j, i')$. By Lemma 5 this takes $O(1)$ time per j.

At this point ChAdj is up-to-date but the list-sum data structure and $\{\mathrm{SupAdj}_j\}$ bit-vectors are not. We update $\mathrm{SupAdj}_i, \mathrm{SupAdj}_{i'}$ with calls to UpdateAdj(i, x) and UpdateAdj(i', x'). Using ChAdj, each bit of x and x' can be generated in constant time. This takes $O(J)$ time.

3.4.4 Merging Superchunks

Let the two adjacent superchunks have IDs i and i'. It is guaranteed that they will be merged only if they contain at most h chunks together. In $O(J)$ time we transfer the non-zero rows of $\mathrm{ChAdj}(i', j)$ to $\mathrm{ChAdj}(i, j)$ and transfer the non-zero columns of $\mathrm{ChAdj}(j, i')$ to $\mathrm{ChAdj}(j, i)$. A call to SCDelete(i') deletes superchunk i' from its list in $\mathcal{S}$ and retires ID i'. We then call UpdateAdj(i, x) with the new incidence vector x. In this case we can generate x in $O(J/w)$ time since it is merely the bit-wise OR of the old vectors SupAdj_i and $\mathrm{SupAdj}_{i'}$, with bit i' set to zero. Updating the list-sum data structure takes $O(J)$ time.

3.5 Joining and Splitting Lists

Once we have routines for splitting and merging adjacent (super)chunks, implementing Join and Split on lists in $\mathcal{L}$ is much easier. The goal is to restore Invariant 3 governing chunk masses and Invariant 4 on the number of chunks per superchunk.

3.5.1 Performing Join(L_0, L_1)

Write $L_0 = C_0, \ldots, C_{p-1}$ and $L_1 = D_0, \ldots, D_{q-1}$ as a list of chunks. If both L_0 and L_1 are not short then they have corresponding superchunk lists $S_0, S_1 \in \mathcal{S}$. Call SCJoin(S_0, S_1) to join S_0, S_1 in $\mathcal{S}$, in $O(J)$ time.

3.5.2 Performing $\textsc{Split}(x)$

Suppose x is contained in chunk C_l of $L = C_0 \cdots C_{l-1}C_lC_{l+1} \cdots C_{p-1}$. We split C_l into two chunks $C_l'C_l''$, and split the superchunk containing C_l along this line. Let S be the superchunk list corresponding to L and i be the ID of the superchunk ending at C_l'. We split S using a call to $\text{SC}\textsc{Split}(i)$, which corresponds to splitting L into $L_0 = C_0 \cdots C_{l-1}C_l'$ and $L_1 = C_l''C_{l+1} \cdots C_{p-1}$. At this point C_l' or C_l'' may violate Invariant 3 if $\text{mass}(C_l') < K$ or $\text{mass}(C_l'') < K$. Furthermore, Invariant 4 may be violated if the number of chunks in the superchunks containing C_l' and C_l'' is too small. We first correct Invariant 3 by possibly merging and resplitting $C_{l-1}C_l'$ and $C_l''C_{l+1}$ along new boundaries. If the superchunk containing C_l' has fewer than $h/2$ chunks, it and the superchunk to its left have strictly between $h/2$ and $3h/2$ chunks together, and so can be merged (and possibly resplit) into one or two superchunks satisfying Invariant 4. The same method can correct a violation of C_l'''s superchunk. This takes $O(K + J)$ time.

3.5.3 Performing $\textsc{ReplacementEdge}(L_0, L_1)$

The list-sum data structure makes implementing the $\textsc{ReplacementEdge}(L_0, L_1)$ operation easy. Let S_0 and S_1 be the superchunk lists corresponding to Euler tours L_0 and L_1. We compute the vectors $\alpha \leftarrow \textsc{AdjQuery}(S_0)$ and $\beta \leftarrow \textsc{MembQuery}(S_1)$ and their bit-wise AND $\alpha \wedge \beta$ with a linear scan of both vectors. If $\alpha \wedge \beta$ is the all-zero vector then there is no edge between L_0 and L_1. On the other hand, if $(\alpha \wedge \beta)(j) = 1$, then j must be the ID of a superchunk in S_1 that is incident to *some* superchunk in S_0. To determine *which* superchunk in S_0 we walk down from the root of S_0's list-sum tree to a leaf, say with ID i, in each step moving to a child z of the current node for which $\text{SupAdj}^z(j) = 1$. Once i and j are known we retrieve any 1-bit in the matrix $\text{ChAdj}(i, j)$, say at position (k, l), indicating that the kth chunk of superchunk i and the lth chunk of superchunk j are adjacent. We scan all its adjacent edges in $O(K)$ time and retrieve an edge joining L_0 and L_1. The total time is $O(J/w + \log J + K) = O(J/w + K)$.

3.5.4 Performing $\textsc{Insert}(u, v)$

If $\textsc{List}(u) \neq \textsc{List}(v)$, first perform $O(1)$ $\textsc{Split}$s and $\textsc{Join}$s to restore the Euler tour Invariant 2. Now u and v are in the same list in $\mathcal{L}$. Let i, j be the IDs of the superchunks containing the principal copies of u and v and let k, l be the positions of u and v's chunks within their respective superchunks. We set $\text{ChAdj}(i, j)(k, l) \leftarrow 1$. If $\text{ChAdj}(i, j)$ was formerly the all-zero matrix, we call $\textsc{UpdateAdj}(i, x)$ to update superchunk i's adjacency information with the correct vector x.[8] Inserting one edge changes the mass of the chunks containing u and v, which could violate Invariant 3. Invariants 3 and 4 are restored by splitting/merging $O(1)$ chunks and superchunks.

3.5.5 Performing $\textsc{Delete}(u, v)$

Compute i, j, k, l as defined above, in $O(1)$ time. After we delete (u, v) the correct value of the bit $\text{ChAdj}(i, j)(k, l)$ is uncertain. We scan chunk k of superchunk i in $O(K)$ time, looking for an edge connected to chunk l of superchunk j. If we do *not* find such an edge we set $\text{ChAdj}(i, j)(k, l) \leftarrow 0$, and if that makes $\text{ChAdj}(i, j) = 0$ (the all-zero matrix), we call

[8] Since x only differs from the former SupAdj_i at position $\text{SupAdj}_i(j)$, this update to the list-sum tree takes just $O(\log J)$ time since it only affects ancestors of leaves i and j.

UpdateAdj(i, x), where x is the new adjacency vector of superchunk i; it only differs from the former SupAdj_i at position j.

If (u, v) is a tree edge in $T = T_0 \cup \{(u, v)\} \cup T_1$ we perform Splits and Joins to replace $\mathrm{Euler}(T)$ with $\mathrm{Euler}(T_0), \mathrm{Euler}(T_1)$, which may violate Invariant 2 if there is a replacement edge between T_0 and T_1. We call ReplacementEdge$(\mathrm{Euler}(T_0), \mathrm{Euler}(T_1))$ to find a replacement edge. If one is found, say $(\hat{u}, \hat{v})$, we form $\mathrm{Euler}(T_0 \cup \{(\hat{u}, \hat{v})\} \cup T_1)$ with a constant number of Splits and Joins.

3.6 Running Time Analysis

Each operation ultimately involves splitting/merging $O(1)$ chunks, superchunks, and lists, which takes time $O(K + J + \log J \cdot J/w) = O(K + J) = O(K + \hat{m}/(K\sqrt{w}))$. We balance the terms by setting $K = \sqrt{\frac{\hat{m}}{\sqrt{w}}}$ so the running time is $O(K)$.

By the sparsification transformation of Eppstein, Galil, Italiano, and Nissenzweig [7] this implies an update time of $O\left(\frac{\sqrt{n}}{w^{1/4}}\right)$. Each instance of dynamic connectivity created by [7] has a fixed set of vertices, say of size $\hat{n}$, and a fixed upper bound $\hat{m} = O(\hat{n})$ on the number of edges.

4 Speeding Up the Algorithm

Observe that there are $\Theta((\hat{m}/(Kh))^2)$ matrices $(\mathrm{ChAdj}(i, j))$ but only $\hat{m}$ edges, so for $K = \sqrt{\hat{m}/h}$, the average $h \times h$ matrix has $O(h)$ 1s. Thus, storing each such matrix verbatim, using h^2 bits, is information theoretically inefficient on average. By storing only the locations of the 1s in each matrix we can represent each matrix in $O(h \log h)$ bits on average and thereby hope to solve dynamic connectivity faster with a larger 'h' parameter.

4.1 The Encoding

In this encoding we index rows and columns by indices in $\{1, \ldots, h\}$ rather than $[h]$. Let $m_{i,j} = m_{j,i}$ be the number of 1s in $\mathrm{ChAdj}(i, j)$. We encode $\mathrm{ChAdj}(i, j)$ by listing its 1 positions in $O(m_{i,j} \log h/w)$ lightly packed words. Each word is partitioned into *fields* of $1 + 2\lceil\log(h + 1)\rceil$ bits: each field consists of a control bit (normally 0), a row index, and a column index. Each word is between half-full and full, the fields in use being packed contiguously in the word. This invariant allows us to insert a new field after a given field in $O(1)$ time. We list the 1s of *either* $\mathrm{ChAdj}(i, j)$ *or* $\mathrm{ChAdj}(j, i) = \mathrm{ChAdj}(i, j)^\top$ in row-major order, with a bit indicating which of the two representations is used.

4.2 Fast Operations

Given $\mathrm{ChAdj}(i, j)$ in row-major order, we can determine if $\mathrm{ChAdj}(i, j)(k, l) = 1$ in $O(\log h)$ time by doing a binary search to find the correct word in the list, then a binary search within the word to find an entry $\langle k, l\rangle$, if any.[9]

[9] The time for a search can actually be improved to $O(\log((m_{i,j} \log h)/w))$, which is faster when $\mathrm{ChAdj}(i, j)$ has average density ($m_{i,j}$ is close to h) but is still $O(\log h)$ in the worst case. We still do a binary search over the first field in each word to determine which word (if any) has a field containing $\langle k, l\rangle$: the binary encoding of (k, l). This takes $O(\log((m_{i,j} \log h)/w))$ time since there are $\Theta((m_{i,j} \log h)/w)$ lightly packed words. If we add $2^{2\lceil\log(h+1)\rceil} - \langle k, l\rangle$ to each field in the word, the control bits for all fields that are equal to or greater than $\langle k, l\rangle$ will be flipped to 1. Similarly, if we set all control bits to 1

In the same time bound we can also identify the positions of the first and last 1s in row k. Thus, we can perform the following operations on $\mathrm{ChAdj}(i,j)$ in $O((m_{i,j}\log h)/w)$ time: setting a row to zero, incrementing/decrementing the row-index of some interval of rows, or copying an interval of rows.

The operations sketched above are only efficient if $\mathrm{ChAdj}(i,j)$ is in row-major order. If we have $\mathrm{ChAdj}(i,j)^\top$ in row-major order we can effect a transpose by (1) swapping the row and column indices in each field using masks and shifts, and (2) sorting the fields. In general, sorting x words of $O(w/\log h)$ fields takes $O(x(\log^2(w/\log h) + \log x \log(w/\log h)))$ time using Albers and Hagerup's implementation [2] of Batcher's bitonic mergesort [4].[10] We sort each word in $O(\log^2(w/\log h))$ time, resulting in x sorted lists, then iteratively merge the two shortest lists until one list remains. Merging two lists containing y words takes $O(y\log(w/\log h))$ time: we can merge the next $w/\log h$ fields of each list in $O(\log(w/\log h))$ time [2] and output at least $w/\log h$ items to the merged list.

Alternatively, if $w = \log n$ we can sort and merge lists of $\epsilon\log n/\log h$ fields in unit time using table lookup to precomputed tables of size $O(n^\epsilon)$. In this case sorting x packed words takes $O(x\log x)$ time.

4.3 Splitting and Joining

The cost of splitting and joining (super)chunks is now slightly more expensive. When handling superchunk i (or any chunk within it) we first put each $\mathrm{ChAdj}(i,j)$ in row-major order, in $\sum_{j=1}^{J} O(\lceil \frac{m_{i,j}\log h}{w}\rceil \log^2 h) = O(J\log^2 h + (Kh/w)\log^3 h)$ since, by Invariants 3 and 4, $\sum_j m_{i,j} = O(Kh)$. Once the relevant superchunks are in the correct format, splitting or joining $O(1)$ (super)chunks takes $O(K\log h + J + (Kh/w)\log h)$ time. Since $J = O(\hat{m}/(Kh))$, the overall update time is

$$O\left(K\log h + \frac{\hat{m}\log^2 h}{Kh} + \frac{Kh\log^3 h}{w}\right).$$

Setting $h = w$ and $K = \sqrt{\frac{\hat{m}}{w\log w}}$, the overall time is $O(\sqrt{\frac{\hat{m}\log^5 w}{w}})$. When $w = O(\log n)$ the cost of taking the transpose is cheaper since sorting and merging a packed word takes unit time via table lookup. Setting $h = \log n$, the total time is

$$O\left(K\log\log n + \frac{\hat{m}}{K\log n} + K(\log\log n)^2\right),$$

which is $O(\sqrt{\frac{\hat{m}(\log\log n)^2}{\log n}})$ when $K = \sqrt{\frac{\hat{m}}{\log n(\log\log n)^2}}$.

and subtract $\langle k,l\rangle + 1$ from each field, the control bits of fields that are equal to or less than $\langle k,l\rangle$ will be flipped to 0. Thus, we can single out the control bit for an occurrence of $\langle k,l\rangle$ (if any) with $O(1)$ bit-wise operations. If $\langle k,l\rangle$ is not present, the control bits reveal the field in the word after which it could be inserted, if we need to set $\mathrm{ChAdj}(i,j)(k,l) \leftarrow 1$.

[10] Albers and Hagerup also require that the fields to be sorted begin with control bits.

5 Loose Ends

5.1 Removing the Bounded Degree Assumption

Invariants 3 and 4 imply that there are $J = \Theta(\hat{m}/(Kh))$ superchunks with non-$\perp$ IDs. However, Invariant 3 cannot be satisfied (as stated) unless the maximum degree is bounded by $O(K)$. One way to guarantee this is to physically split up high degree vertices, replacing each v with a cycle on new vertices $v_1, \ldots, v_{\lceil \deg(v)/\Theta(K) \rceil}$, each of which is responsible for $\Theta(K)$ of v's edges. This is the method used by Frederickson [10], who actually demanded that the maximum degree be 3 at all times!

This vertex-splitting can be effectively simulated in our algorithm as follows. If $\deg(v) \geq K/2$, replace the principal copy of v in its Euler tour with an interval of artificial principal vertices $v_1, \ldots, v_{\lceil \deg(v)/(K/2) \rceil}$, each of which is responsible for between $K/2$ and K of v's edges. Invariant 3 is therefore maintained w.r.t. this modified tour. To keep the mass of artificial vertices between $K/2$ and K, each edge insertion/deletion may require splitting an artificial vertex or merging two consecutive artificial vertices. When the Euler tour changes we always preserve the invariant that v's artificial vertices form a contiguous interval in the tour.

5.2 Dealing with Short Lists

Until now we have assumed for simplicity that all superchunks have proper IDs in $[J]$. It is important that we *not* give out IDs to short lists (consisting of less than $h/2$ chunks) because the running time of the algorithm is linear in the maximum ID J. The modifications needed to deal with short lists are tedious but minor.

Consider an Insert(u, v) operation where u and v are in lists L_0, L_1 and L_1 is a short list consisting of one superchunk S with $\mathrm{ID}(S) = \perp$. If L_0 is not short (or if it is short but the combined list L_0L_1 will not be short) then we retrieve an unused ID, say i, set $\mathrm{ID}(S) \leftarrow i$, set $\mathrm{ChAdj}(i, i) \leftarrow \mathrm{ChAdj}_S$, and destroy ChAdj_S. By Invariant 2, S was not incident to any other superchunk, so $\mathrm{ChAdj}(i, j) = 0$ (the all-zero matrix) for all $j \neq i$. At this point S violates Invariant 4 (it is too small), so we need to merge it with the last superchunk in L_0 and resplit it along a different chunk boundary, in $O(J)$ time.

The modifications to Delete(u, v) are analogous. If we delete a tree edge (u, v), splitting its component into T_0 and T_1 having associated Euler tours L_0 and L_1, and ReplacementEdge(u, v) fails to find an edge joining L_0 and L_1, we need to check whether L_0 (and L_1) are short. If so let S be the superchunk in L_0. We allocate and set $\mathrm{ChAdj}_S \leftarrow \mathrm{ChAdj}(\mathrm{ID}(S), \mathrm{ID}(S))$, then set $\mathrm{ChAdj}(\mathrm{ID}(S), \mathrm{ID}(S)) \leftarrow 0$ and finally retire $\mathrm{ID}(S)$.

The implementation of ReplacementEdge(L_0, L_1) is different if L_0 and L_1 were originally in a short list $L = \mathrm{Euler}(T)$ before a tree edge in T was deleted. Suppose L originally had one superchunk S, whose chunk adjacency was stored in ChAdj_S. After $O(1)$ splits and joins, both L_0's chunks and L_1's chunks occupy $O(1)$ intervals of the rows and columns of ChAdj_S. Of course ChAdj_S is represented as a list of its 1 positions in row-major order, so we can isolate the correct intervals of rows and columns in $O(h^2 \log^3 h/w)$ time. If there is any 1 there, say at location $\mathrm{ChAdj}_S(k, l)$, then we know that there is an edge between L_0 and L_1, and can find it in $O(K)$ time by examining chunks k and l. The permutation of rows/columns in ChAdj_S must be updated to reflect any splits and joins that take place, and if no replacement edge is discovered, ChAdj_S must be split into two lists representing matrices ChAdj_{S_0} and ChAdj_{S_1}, to be identified with the single superchunks S_0 and S_1 in L_0 and L_1, respectively.

Abstract

The *Temp Secretary Problem* was recently introduced by Fiat et al. [11]. It is a generalization of the Secretary Problem, in which commitments are temporary for a fixed duration. We present a simple online algorithm with improved performance guarantees for cases already considered by Fiat et al. and give competitive ratios for new generalizations of the problem. In the classical setting, where candidates have identical contract durations $\gamma \ll 1$ and we are allowed to hire up to B candidates simultaneously, our algorithm is $(1/2 - O(\sqrt{\gamma}))$-competitive. For large B, the bound improves to $1 - O\left(1/\sqrt{B}\right) - O(\sqrt{\gamma})$.

Furthermore we generalize the problem from cardinality constraints towards general packing constraints. We achieve a competitive ratio of $1 - O\left(\sqrt{(1+\log d + \log B)/B}\right) - O(\sqrt{\gamma})$, where d is the sparsity of the constraint matrix and B is generalized to the capacity ratio of linear constraints. Additionally we extend the problem towards arbitrary hiring durations.

Our algorithmic approach is a relaxation that aggregates all temporal constraints into a non-temporal constraint. Then we apply a linear scaling algorithm that, on every arrival, computes a tentative solution on the input that is known up to this point. This tentative solution uses the non-temporal, relaxed constraints scaled down linearly by the amount of time that has already passed.

1 Introduction

Online resource allocation problems have a notion of time: Choices have to be made at some point in time without knowing the future input. Each decision may make a future one infeasible. The standard example of such a setting is the secretary problem where candidates of different value arrive over time. After each arrival, the algorithm has to decide whether to permanently accept or reject this candidate. Every decision is final. That is, once rejected a candidate will never come back again. Once a candidate is accepted, no other candidate can be accepted anymore.

In many practical applications, however, commitments are not eternal but affect only a finite time horizon. They may limit options for the upcoming days but not for the rest of the year or even longer. Nevertheless, even with such an assumption, traditional worst-case competitive analysis is typically too strong a benchmark. It is trivial to see that for the respective version of the secretary problem no algorithm achieves a bounded competitive ratio.

Therefore, we consider a partly stochastic model introduced by Fiat et al. [11]. First an adversary chooses which items will arrive. However, it does not determine the arrival times, which are instead drawn from a probability distribution, typically the uniform distribution on $[0, 1]$. In more detail, in the *temp secretary problem*, an adversary defines values of items $v_1, \dots, v_n$. Afterwards, arrival times τ_j are drawn independently uniformly from $[0, 1]$. As time proceeds, the values and arrival times are revealed to the algorithm. Upon each arrival, the algorithm has to decide whether to accept or to reject the respective item. Each item is accepted for a duration of γ, which is assumed to be much smaller than 1. At any point in time t at most B items may overlap, that is, during time $t - \gamma$ and t at most B items may be accepted.

The objective is to maximize $\sum_{j \in \mathrm{ALG}} v_j$, where ALG $\subseteq [n]$ denotes the selection by the algorithm. By OPT we denote the optimal selection OPT $\subseteq [n]$, which maximizes $\sum_{j \in \mathrm{OPT}} v_j$. As the arrival times $\tau_1, \dots, \tau_n$ are random, both ALG and OPT are random variables. We evaluate the performance of an algorithm by its competitive ratio, defined as $\mathbf{E}\left[\sum_{j \in \mathrm{ALG}} v_j\right] / \mathbf{E}\left[\sum_{j \in \mathrm{OPT}} v_j\right]$.

1.1 Our Contribution

We introduce a new algorithmic approach to online packing problems with temporal constraints. As key idea we consider a relaxation to OPT by removing the temporal constraints and exchanging them with global ones. In the special case of the temp secretary problem, we exploit that for every realization of the arrival dates $\tau_1, \dots, \tau_n$ the optimal offline solution OPT never contains more that $B\lceil 1/\gamma \rceil$ elements. Therefore, we exchange the constraints by only requiring $B\lceil 1/\gamma \rceil$ items to be picked throughout the process. An online solution to this relaxation can be found using algorithms for online linear packing problems. It then remains to derive a solution to the original constraints.

For the temp secretary problem, this approach allows us to derive a light-weight, easy to state algorithm. We show it to be $\frac{1}{2}\left(1 - O(\sqrt{\gamma})\right)$-competitive for all values of B. Furthermore, for large values of B, a different analysis shows a better competitive ratio of $1 - O\left(1/\sqrt{B}\right) - O(\sqrt{\gamma})$. The previous best results for this setting were $\frac{1}{2}\left(1 - O\left(\sqrt{\gamma \ln(1/\gamma)}\right)\right)$ for $B = 1$ and $1 - O\left(\sqrt{(\ln B)/B}\right) - O\left(\sqrt{\gamma \ln(1/\gamma)}\right)$ for large values of B, both by Fiat et al. [11]. Note that $1/2$ is known to be an asymptotic upper bound to the competitive ratio for $B = 1$ [11].

We also generalize the cardinality constraint in the temp secretary problem to arbitrary linear constraints. This enables us to capture more general combinatorial problems, like multiple knapsack constraints that have to be fulfilled simultaneously. For example, we could model scenarios in which the algorithm has to select production orders online in such a way that none of the involved machines is overloaded. Our algorithm is $1 - O\left(\sqrt{(1 + \log d + \log B)/B}\right) - O(\sqrt{\gamma})$-competitive, where d denotes the maximum number of constraints a single item is contained in. By B we denote the *capacity ratio*, which is defined to be the minimum ratio of a constraint's capacity and the usage of a single item. For non-timed constraints, there are lower bounds in the order of $1 - O\left(\sqrt{\log m/B}\right)$, where m is the number of constraints and $d = m$ [2, 6].

Our algorithm also has a natural generalization to settings with items of different lengths. For the temp secretary problem, we show a competitive ratio of $\frac{1}{4} - \Theta\left(\sqrt{\gamma}\right)$.

The main technical contribution are bounds on the probability that tentative selections made by the algorithm are actually feasible. In related work, it is usually enough to pretend all previous tentative choices were actually feasible. As these can be considered independent, a concentration bound can be applied. These techniques are apparently not strong enough here and we have to bound the actual commitments. We do so by analyzing coupled random variables that provide an upper bound on the random process. For the case of large B, this analysis is based on a symmetric random walk, representing arrivals and departures of items.

1.2 Related Work

Secretary problems have gained a lot of attention over the last decade, even though the most famous variant was already introduced and solved in the 1960s [12, 21, 7].

The most famous combinatorial generalization is the matroid secretary problem, introduced by Babaioff et al [4]. As of now, the big question of whether there is a constant competitive algorithm for the matroid secretary problem is still open. The best known algorithms for the problem are $O(\log\log\rho)$-competitive [10, 20]. Constant competitive algorithms are known for most special cases, e.g. there is a $1/2e$-competitive algorithm for graphical matroids [19], a $1/9.6$-competitive algorithm for laminar matroids [23] and there is an optimal $1/e$-competitive algorithm for transversal matroids [16]. For k-uniform matroids, the problem is also known as multiple-choice secretary problem and was solved by Kleinberg, who gave a $(1 - O(1/\sqrt{k}))$-competitive algorithm and showed that this is optimal [18].

Furthermore, online models with random arrival order have been used for online packing problems. The knapsack secretary problem was introduced by Babaioff et al. [3] and the currently best known competitive ratio is $1/8.1$ [17]. This problem was generalized towards general packing linear programs with special attention on the case with large capacities. There are several known algorithms [1, 13, 17] that feature a competitive ratio of $1 - O\left(\sqrt{\log m/B}\right)$, where m is the total number of constraints and B is a lower bound on the capacities of the constraints. These results match the lower bound by Agrawal et al.[2] and Devanur et al. [6] for the random order and i.i.d. model respectively. Note that the result in [17] is stronger in case of sparse matrices: If the maximal number of non-zero entries in any column is bounded by d, the guarantee only depends on d rather than m.

Another important way of generalizing the secretary problem is the submodular secretary problem introduced by Bateni et al. [5]. The problem generalizes the multiple-choice secretary problem towards submodular objective functions. The currently best known competitive ratio is $\frac{e-1}{e^2+e}$ by Feldmann et al. [9]. For submodular, transversal matroids the best known algorithm is $1/95$-competitive [23] and for linear packing constraints the best algorithm is known to be $\Omega(1/m)$-competitive [5].

The temp secretary problem that we consider and generalize in this paper was introduced in 2015 by Fiat et al. [11]. It introduces temporal constraints to the field of online algorithms with random order in a way that had only been considered before in the worst-case model for online interval scheduling [22, 25]. Fiat et al. give an algorithm that is inspired by Kleinbergs algorithm for the multiple-choice secretary problem. Their algorithm iteratively refines the sample $\log n$ times, while our algorithm updates the sample in every round. Both algorithm are closely related, but the one presented here can be described much more compact and allows for a more simple analysis.

Fiat et al. achieve a competitive ratio of $1/(1+k\gamma)\left(1 - 5/\sqrt{k} - 7.4\sqrt{\gamma\ln(1/\gamma)}\right)$ for the case where at most one candidate can be hired simultaneously and the sum of hires cannot

Algorithm 1: Scaling Algorithm for length γ and capacity B

```
for every arriving item $j$ do
    Set $t := \tau_j$;                                          // arrival time of $j$
    Let $S^{(t)}$ be the $\lfloor tB/\gamma \rfloor$ highest-valued items $j'$ with $\tau_{j'} \le t$;
    if $j \in S^{(t)}$ then                                     // if among best items
        if $S \cup \{j\}$ is a feasible schedule then           // and if feasible
            Set $S := S \cup \{j\}$;                            // then select $j$
```

exceed the budget k. To compare this result to ours, consider the unconstrained budget case $k = 1/\gamma$. In this case, they achieve a competitive ratio of $\frac{1}{2}\left(1 - O\left(\sqrt{\gamma \ln(1/\gamma)}\right)\right)$. Additionally, they show a lower bound $\frac{1+\gamma}{2}$ for this case, thus both algorithms, ours and theirs, are asymptotically tight for $\gamma \to 0$. For up to B concurrent hires, their algorithm is $1 - \Theta\left(\sqrt{(\ln B)/B}\right) - \Theta\left(\sqrt{\gamma \ln(1/\gamma)}\right)$-competitive. Additionally, they describe a black-box procedure that transforms any algorithm for a combinatorial secretary problem into an algorithm for the respective combinatorial temp secretary problem. This transformation loses a factor of $1/2$ in the competitive ratio, but also works for general arrival distributions as long as all items have an identical duration.

2 The Temp Secretary Problem

As our first result, we present a simplified and improved algorithm for the temp secretary problem. Here, an adversary chooses a value v_j for each of the n items and after values have been determined arrival times $\tau_1, \ldots, \tau_n$ are drawn independently uniformly at random from $[0, 1]$. Each item when selected stays active for γ time. At any point in time, at most B elements may be active simultaneously.

The optimal selection $\mathrm{OPT} \subseteq [n]$ is a random variable that depends on the arrival times. However, pointwise we have $|\mathrm{OPT}| \le B\lceil 1/\gamma \rceil$ for any realization of the arrival times $\tau_1, \ldots, \tau_n$. Therefore, the expected value of OPT can be upper-bounded by the value of the $B\lceil 1/\gamma \rceil$ highest-valued elements, which we denote by $\mathrm{OPT}^* \subseteq [n]$.

Algorithm 1 is inspired by online approximation algorithms for OPT^*, particularly [17]. If item j arrives at time t, then we determine whether it is among the $\lfloor tB/\gamma \rfloor$ highest-valued items seen so far, called $S^{(t)}$. In this case, we call it tentatively selected. If it is also feasible to accept j, we do so. Otherwise, we reject j.

Note that in expectation at time t we have seen a t fraction of OPT^*, so approximately tB/γ items from OPT^*. The set $S^{(t)}$ approximates this set by including the best $\lfloor tB/\gamma \rfloor$ up to this point.

We give two performance bounds for this algorithm. First, in Section 2.2, we show that it is $\frac{1}{2}\left(1 - O(\sqrt{\gamma})\right)$-competitive for all values of B. Afterwards, in Section 2.3, we perform a different analysis for large values of B giving a competitive ratio of $1 - O\left(1/\sqrt{B}\right) - O(\sqrt{\gamma})$.

2.1 Analysis Preliminaries

The analyses for both cases follow a similar pattern. First, we analyze the expected value of the set $S^{(t)}$ and thereby the expected value of the tentative selection. Then, we bound the probability that such a tentative selection is feasible.

For analysis purposes, we discretize time into N uniform intervals of length $1/N$, which we call rounds. If $N \gg n$, then the probability that two items fall into the same interval is negligible. Also, if N is large enough, we can effectively assume that all items arrive at times which are multiples of $1/N$ because the value of $\lfloor tB/\gamma \rfloor$ stays constant in almost all intervals. From time to time, it will be helpful to fill up rounds in which no actual item arrives with dummy items that do not have value but also do not use space. The order of these items and dummy items is then a uniformly drawn permutation. Furthermore, to avoid cumbersome notation, we assume that γN and $\sqrt{\gamma} N$ are integer. We overload notation and write $S^{(\ell)}$ instead of $S^{(\ell/N)}$.

To discuss the probability of feasibility, we introduce 0/1 random variables $(C_\ell)_{\ell \in [N]}$ and $(F_\ell)_{\ell \in [N]}$. We set $C_\ell = 1$ if and only if a tentative selection is made in round ℓ. Furthermore, let $F_\ell = 1$ for every round ℓ in which it would be feasible to actually select an item. Finally, let V_ℓ denote the value of the item tentatively selected in round ℓ if any, otherwise set $V_\ell = 0$. So formally $V_\ell = v_j C_\ell$ if item i arrives in round ℓ. The value achieved by the algorithm is given as $\sum_{j \in \mathrm{ALG}} v_j = \sum_{\ell=1}^N V_\ell F_\ell = \sum_{\ell=1}^N V_\ell C_\ell F_\ell$.

Observe that the value of a single random variable C_ℓ is already fully determined by the set $S^{(\ell)}$ and which of these items arrives in round ℓ. Neither the mutual order in rounds $1, \ldots, \ell - 1$ nor in $\ell + 1, \ldots, N$ matters. Furthermore, conditioned on any set $S^{(\ell)}$ and any order in rounds $\ell + 1, \ldots, N$, the probability of $C_\ell = 1$ is at most $\frac{|S^{(\ell)}|}{\ell} \leq \frac{B}{\gamma N}$. As a consequence, for every sequence of values $a_{\ell'} \in \{0, 1\}$ for $\ell < \ell' \leq N$, we have

$$\mathbf{Pr}\left[C_\ell = 1 \mid C_{\ell'} = a_{\ell'} \forall \ell < \ell' \leq N\right] \leq \frac{B}{\gamma N} \quad .$$

Note that there are still complicated dependencies among these random variables. For example, at most n of them can be 1. Therefore, based on the above observation, we define coupled random variables that dominate the actual ones but are easier to deal with. We introduce random variables $(\tilde{C}_\ell)_{\ell \in [N]}$ such that pointwise $\tilde{C}_\ell \geq C_\ell$ for which the above relation holds with equality. To define these formally, we iterate over the rounds from large to small index. Conditioned on any value of the variables $\tilde{C}_{\ell+1} = a_{\ell+1}, \ldots, \tilde{C}_N = a_N$, the probability $p = \mathbf{Pr}\left[C_\ell = 1 \;\middle|\; \tilde{C}_{\ell'} = a_{\ell'} \forall \ell < \ell' \leq N\right]$ is always at most $\frac{B}{\gamma N}$. Now let $\tilde{C}_\ell = 1$ whenever $C_\ell = 1$ and additionally $\tilde{C}_\ell = 1$ with probability $\frac{\frac{B}{\gamma N} - p}{1 - p}$ if $C_\ell = 0$. This guarantees

$$\mathbf{Pr}\left[\tilde{C}_\ell = 1 \;\middle|\; \tilde{C}_{\ell'} = a_{\ell'} \forall \ell < \ell' \leq N\right] = \frac{B}{\gamma N} \quad ,$$

and therefore, by induction on all subsets of $[N]$, the random variables $\tilde{C}_1, \ldots, \tilde{C}_N$ are independent and identically distributed. Note that $\tilde{C}_\ell = 1$ whenever $C_\ell = 1$. So therefore also $\sum_{j \in \mathrm{ALG}} v_j = \sum_{\ell=1}^n V_\ell \tilde{C}_\ell F_\ell$.

Next, we can bound the expected value of the items contained in the set $S^{(\ell)}$.

▶ **Lemma 1.** *For* $\ell \geq 2\sqrt{\frac{\gamma}{B}} N$

$$\mathbf{E}\left[\sum_{j \in S^{(\ell)}} v_j\right] \geq \left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N} \cdot \frac{B}{\gamma}}}\right) \frac{1 - \frac{1}{2}\sqrt{\frac{\gamma}{B}}}{1 + \gamma} \frac{\ell}{N} \sum_{j \in \mathrm{OPT}^*} v_j \quad .$$

The general idea is as follows. In round ℓ, we have seen an $\frac{\ell}{N}$-fraction of OPT^* in expectation, so ignoring rounding these are $\frac{\ell}{N} \frac{B}{\gamma}$ items in expectation. This approximately matches the size of $S^{(\ell)}$. The set $S^{(\ell)}$ has a slightly smaller value due to variance and rounding. The first two factors compensate these effects.

For the proof, we show that the non-temporal relaxation described here corresponds to a packing linear program and then we apply a result in [17]. For the detailed proof, please refer to the full version.

2.2 General Analysis

We are now ready to analyze the algorithm.

▶ **Theorem 2.** *Algorithm 1 is at least* $\frac{1}{2}\left(1 - \frac{7}{2}\sqrt{\gamma} - \frac{37}{2}\sqrt{\frac{\gamma}{B}} - \gamma\right)$*-competitive for the temp secretary problem with duration* γ *for all items.*

The key ingredient to the analysis is a bound on the probability that a tentative selection is feasible.

▶ **Lemma 3.** *For all* L*, we have*

$$\mathbf{E}\left[\sum_{\ell=L}^{L+\sqrt{\gamma}N-1} \tilde{C}_\ell F_\ell\right] \geq \left(\frac{1}{2} - \sqrt{\gamma} - \frac{1}{4\sqrt{\gamma}N}\right)\mathbf{E}\left[\sum_{\ell=L}^{L+\sqrt{\gamma}N-1} \tilde{C}_\ell\right] \ .$$

Proof. The crux when proving this lemma is that that F_ℓ depends on $\tilde{C}_\ell$ in a non-trivial way. Therefore, we instead introduce variables $\tilde{F}_\ell$ defined as follows. We set $\tilde{F}_\ell = 1$ for $\ell < L$ and $\tilde{F}_\ell = \max\{0, 1 - \frac{1}{B}\sum_{i=1}^{\gamma N} \tilde{C}_{\ell-i}\tilde{F}_{\ell-i}\}$ for $\ell \geq L$. The motivation behind this definition is that $F_\ell = 1$ if and only if it is feasible to select an item in round ℓ. So therefore, $F_\ell = 1$ if and only if $\sum_{i=1}^{\gamma N} C_{\ell-i}F_{\ell-i} < B$, implying $F_\ell \geq \max\{0, 1 - \frac{1}{B}\sum_{i=1}^{\gamma N} C_{\ell-i}F_{\ell-i}\}$. The definition of $\tilde{F}_\ell$ captures this last bound in a pessimistic way. Note that due to the independence of $(\tilde{C}_\ell)_{\ell\in[N]}$, $\tilde{C}_\ell$ and $\tilde{F}_\ell$ are now independent.

We first show that pointwise $\sum_{\ell=L}^{L+k} \tilde{C}_\ell F_\ell \geq \sum_{\ell=L}^{L+k} \tilde{C}_\ell \tilde{F}_\ell$ for all $k \in \mathbb{Z}$ by induction on k. Observe that the statement is trivial for $k < 0$ because then both sums are empty. So, let us consider $k \geq 0$ for the induction step. If $\tilde{C}_{L+k} = 0$ or $\tilde{F}_{L+k} = 0$, then also the statement follows trivially from the induction hypothesis. The only interesting case is $\tilde{C}_{L+k} = 1$ and $\tilde{F}_{L+k} > 0$. In this case, we get

$$\begin{aligned}\sum_{\ell=L}^{L+k} \tilde{C}_\ell\tilde{F}_\ell &= \tilde{F}_{L+k} + \sum_{\ell=L}^{L+k-1} \tilde{C}_\ell\tilde{F}_\ell = 1 - \frac{1}{B}\sum_{i=1}^{\gamma N} \tilde{C}_{L+k-i}\tilde{F}_{L+k-i} + \sum_{\ell=L}^{L+k-1} \tilde{C}_\ell\tilde{F}_\ell \\ &= 1 - \frac{1}{B}\sum_{\ell=L+k-\gamma N}^{L-1} \tilde{C}_\ell\tilde{F}_\ell + \left(1 - \frac{1}{B}\right)\sum_{\ell=L}^{L+k-1} \tilde{C}_\ell\tilde{F}_\ell + \frac{1}{B}\sum_{\ell=L}^{L+k-\gamma N-1} \tilde{C}_\ell\tilde{F}_\ell \ .\end{aligned}$$

At this point, we can apply the induction hypothesis, which states that in the second and third sum we can replace all occurrences of $\tilde{F}_\ell$ by F_ℓ to get a lower bound. Furthermore, $1 = \tilde{F}_\ell \geq F_\ell$ for $\ell \leq L - 1$. So, we can do the same in the first sum. Therefore

$$\begin{aligned}\sum_{\ell=L}^{L+k} \tilde{C}_\ell\tilde{F}_\ell &\leq 1 - \frac{1}{B}\sum_{\ell=L+k-\gamma N}^{L-1} \tilde{C}_\ell F_\ell + \left(1 - \frac{1}{B}\right)\sum_{\ell=L}^{L+k-1} \tilde{C}_\ell F_\ell + \frac{1}{B}\sum_{\ell=L}^{L+k-\gamma N-1} \tilde{C}_\ell F_\ell \\ &= 1 - \frac{1}{B}\sum_{i=1}^{\gamma N} \tilde{C}_{L+k-i}F_{L+k-i} + \sum_{\ell=L}^{L+k-1} \tilde{C}_\ell F_\ell \ .\end{aligned}$$

Now, we use that $F_{L+k} = 1$ if and only if less than B items have been selected in rounds $L + k - \gamma N$ to $L + k - 1$. This gives us $F_{L+k} \geq 1 - \frac{1}{B}\sum_{i=1}^{\gamma N} C_{L+k-i}F_{L+k-i} \geq$

$1 - \frac{1}{B} \sum_{i=1}^{\gamma N} \tilde{C}_{L+k-i} F_{L+k-i}$. We immediately get

$$\sum_{\ell=L}^{L+k} \tilde{C}_\ell \tilde{F}_\ell \leq \tilde{C}_{L+k} F_{L+k} + \sum_{\ell=L}^{L+k-1} \tilde{C}_\ell F_\ell \enspace .$$

Now, it only remains to bound $\mathbf{E}\left[\sum_{\ell=L}^{L+\sqrt{\gamma}N-1} \tilde{C}_\ell \tilde{F}_\ell\right] = \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} \mathbf{E}\left[\tilde{C}_\ell\right] \mathbf{E}\left[\tilde{F}_\ell\right]$. By definition $\mathbf{E}\left[\tilde{C}_\ell\right] = \frac{B}{\gamma N}$ for every ℓ, it is enough to show that $\frac{1}{\sqrt{\gamma}N} \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} \mathbf{E}\left[\tilde{F}_\ell\right] \geq \left(\frac{1}{2} - \sqrt{\gamma} - \frac{1}{4\sqrt{\gamma}N}\right)$.

Define $a_\ell = \mathbf{E}\left[\tilde{F}_\ell\right]$. We have $a_\ell \geq 1 - \frac{1}{B} \sum_{i=1}^{\gamma N} \mathbf{E}\left[\tilde{C}_{\ell-i}\right] a_{\ell-i} = 1 - \frac{1}{\gamma N} \sum_{i=1}^{\gamma N} a_{\ell-i}$ for $\ell \geq L$ and $a_\ell = 1$ for $\ell < L$. Averaging over the rounds $L, \ldots, L + \sqrt{\gamma}N - 1$ we get

$$\frac{1}{\sqrt{\gamma}N} \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} a_\ell \geq \frac{1}{\sqrt{\gamma}N} \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} \left(1 - \frac{1}{\gamma N} \sum_{i=1}^{\gamma N} a_{\ell-i}\right)$$
$$= \frac{1}{\sqrt{\gamma}N} \left(\sqrt{\gamma}N - \frac{1}{\gamma N} \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} \sum_{i=1}^{\gamma N} a_{\ell-i}\right) \enspace .$$

Here, we change the order of summation and split the inner sum into two parts which we bound separately

$$\frac{1}{\sqrt{\gamma}N} \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} a_\ell \geq \frac{1}{\sqrt{\gamma}N} \left(\sqrt{\gamma}N - \frac{1}{\gamma N} \sum_{i=1}^{\gamma N} \left(\sum_{\ell=L}^{L-1+i} a_{\ell-i} + \sum_{\ell=L+i}^{L+\sqrt{\gamma}N-1} a_{\ell-i}\right)\right) \enspace .$$

Since $a_{\ell-i} \leq 1$, we bound the first sum with $\sum_{\ell=L}^{L-1+i} a_{\ell-i} \leq i$. Furthermore, as $a_\ell \geq 0$ for all ℓ, we can pad the second sum so that $\sum_{\ell=L+i}^{L+\sqrt{\gamma}N-1} a_{\ell-i} \leq \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} a_\ell$, thus we have $\frac{1}{\gamma N} \sum_{i=1}^{\gamma N} \sum_{\ell=L+i}^{L+\sqrt{\gamma}N-1} a_{\ell-i} \leq \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} a_\ell$.

We use both bounds and get

$$\frac{1}{\sqrt{\gamma}N} \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} a_\ell \geq \frac{1}{\sqrt{\gamma}N} \left(\sqrt{\gamma}N - \frac{1}{\gamma N} \sum_{i=1}^{\gamma N} i - \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} a_\ell\right) \enspace .$$

This implies

$$\frac{1}{\sqrt{\gamma}N} \sum_{\ell=L}^{L+\sqrt{\gamma}N-1} a_\ell = \frac{1}{2} - \frac{\gamma N + 1}{4\sqrt{\gamma}N} = \frac{1}{2} - \frac{\sqrt{\gamma}}{4} - \frac{1}{4\sqrt{\gamma}N} \enspace .$$ ◀

Now we have all parts required to prove the theorem.

Proof of Theorem 2. If in round ℓ an item is tentatively selected, let V_ℓ denote its value. Otherwise set $V_\ell = 0$. Our task is to bound the sum of $\mathbf{E}\left[V_\ell F_\ell\right] = \mathbf{E}\left[V_\ell \tilde{C}_\ell F_\ell\right]$.

Fixing which items come in rounds $1, \ldots, \ell$ fixes the set $S^{(\ell)}$. As any order among these items and the respective dummy items is still equally likely, the item coming in round ℓ can be considered being drawn uniformly at random. This way, by Lemma 1, we have for all $\ell \geq 2\sqrt{\frac{\gamma}{B}}N$

$$\mathbf{E}\left[V_\ell\right] \geq \frac{1}{\ell} \mathbf{E}\left[\sum_{j \in S^{(\ell)}} v_i\right] \geq \left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N} \cdot \frac{B}{\gamma}}}\right) \frac{1}{N} \frac{1 - \frac{1}{2}\sqrt{\frac{\gamma}{B}}}{1+\gamma} \sum_{j \in \mathrm{OPT}^*} v_j \enspace .$$

Next, observe that V_ℓ given that $\tilde{C}_\ell = 1$ is independent of F_ℓ. This is due to the fact that the algorithm is comparison based. For this reason, the course of events in rounds $1, \ldots, \ell - 1$ is independent of the identity of the item from $S^{(\ell)}$ that actually arrives in round ℓ. Therefore the events leading up to round ℓ are identical, although they might involve different items. Also exploiting that $V_\ell = 0$ if $\tilde{C}_\ell = 0$, we get

$$\begin{aligned}\mathbf{E}\left[V_\ell \tilde{C}_\ell F_\ell\right] &= \mathbf{Pr}\left[\tilde{C}_\ell = 1, F_\ell = 1\right] \mathbf{E}\left[V_\ell \mid \tilde{C}_\ell = 1, F_\ell = 1\right] \\ &= \mathbf{Pr}\left[\tilde{C}_\ell = 1, F_\ell = 1\right] \mathbf{E}\left[V_\ell \mid \tilde{C}_\ell = 1\right] = \frac{\mathbf{Pr}\left[\tilde{C}_\ell = 1, F_\ell = 1\right]}{\mathbf{Pr}\left[\tilde{C}_\ell = 1\right]} \mathbf{E}\left[V_\ell\right] \ .\end{aligned}$$

To get the bound, we split the input sequence into blocks of length $\sqrt{\gamma}N$ and apply Lemma 3 on each of these blocks.

$$\begin{aligned}&\mathbf{E}\left[\sum_{j \in \mathrm{ALG}} v_j\right] \geq \sum_{k=2}^{\lfloor \frac{1}{\sqrt{\gamma}} \rfloor - 1} \sum_{\ell = k\sqrt{\gamma}N + 1}^{(k+1)\sqrt{\gamma}N} \mathbf{E}\left[V_\ell \tilde{C}_\ell F_\ell\right] \\ &\geq \sum_{k=2}^{\lfloor \frac{1}{\sqrt{\gamma}} \rfloor - 1} \sum_{\ell = k\sqrt{\gamma}N + 1}^{(k+1)\sqrt{\gamma}N} \frac{\mathbf{Pr}\left[\tilde{C}_\ell = 1, F_\ell = 1\right]}{\mathbf{Pr}\left[\tilde{C}_\ell = 1\right]} \left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N} \cdot \frac{B}{\gamma}}}\right) \frac{1}{N} \frac{1 - \frac{1}{2}\sqrt{\frac{\gamma}{B}}}{1 + \gamma} \sum_{j \in \mathrm{OPT}^*} v_j \\ &\geq \left(\frac{1}{2} - \frac{7}{4}\sqrt{\gamma} - \frac{37}{4}\sqrt{\frac{\gamma}{B}} - \frac{\gamma}{2} - \frac{1}{4\sqrt{\gamma}N}\right) \sum_{j \in \mathrm{OPT}^*} v_j \ .\end{aligned}$$

Details on the calculations can be found in the full version. ◀

2.3 Improved Analysis for Large Capacities

For the same algorithm, we can show a better competitive ratio if B is large, converging to 1 asymptotically.

▶ **Theorem 4.** *Algorithm 1 is at least $\left(1 - \frac{4}{\sqrt{B}} - \frac{41}{2}\sqrt{\frac{\gamma}{B}} - 3\gamma - O\left(\frac{1}{B}\right)\right)$-competitive for the temp secretary problem with duration γ for all items.*

The proof of this theorem is very similar to the proof of Theorem 2. Again, we will bound the number of rounds in which $\tilde{C}_\ell = 1$ but $F_\ell = 0$. The main difference is that we consider blocks of γN rounds each. In this case, the duration of an item corresponds to the length of the block. Therefore, no more than B items can be feasibly selected in any block.

If B items are selected at the beginning of such a block, then it is feasible to select one item for every item that times out. We use this concept and construct a symmetric random walk. The maximum of this random walk upper bounds the number of failure events, in which the algorithm performs a tentative selection before sufficiently many previous items have timed out.

In contrast to Lemma 3, the expected ratio of failure events to successful selections of item is decreasing in B and therefore our competitive ratio in Theorem 4 tends to 1 as B increases.

▶ **Lemma 5.** *The expected number of rounds $\ell \in \{L, \ldots, L + \gamma N - 1\}$ in which $\tilde{C}_\ell = 1$ but $F_\ell = 0$ is $\left|\left\{\ell \mid \tilde{C}_\ell = 1 \wedge F_\ell = 0\right\}\right| \leq \sqrt{B} + \frac{\pi^2}{6}\sqrt{B} + 2\sqrt{\frac{4B}{3\pi}} + O(1) \leq 4\sqrt{B} + O(1)$.*

Proof. We claim that the number of rounds $\ell \in \{L, \ldots, L + \gamma N - 1\}$ for which $\tilde{C}_\ell = 1$ but $F_\ell = 0$ is bounded by

$$Q := \max_{L \leq \ell < L + \gamma N} \left(\sum_{r=L}^{\ell} \tilde{C}_r - \sum_{r=L-\gamma N}^{\ell - \gamma N} \tilde{C}_r\right) + \left|\sum_{r=L-\gamma N}^{L-1} \tilde{C}_r - B\right| \ .$$

To show this, we define an alternative sequence $(\tilde{C}'_r)_{r\in[N]}$ by setting $\tilde{C}_r = \tilde{C}'_r$ for every r except for the first Q occurrences of $\tilde{C}_r = 1$ after L, where we set $\tilde{C}'_r = 0$. Consider an $\ell \geq L$ such that $\tilde{C}'_\ell = 1$. Now observe that

$$\sum_{r=\ell-\gamma N}^{\ell} \tilde{C}'_r = \sum_{r=\ell-\gamma N}^{\ell} \tilde{C}_r - Q \leq \sum_{r=L-\gamma N}^{L-1} \tilde{C}_r - \left| \sum_{r=L-\gamma N}^{L-1} \tilde{C}_r - B \right| \leq B \enspace .$$

This implies that $\sum_{r=L}^{L+\gamma N-1} \tilde{C}_r F_r \geq \sum_{r=L}^{L+\gamma N-1} \tilde{C}'_r$ because every case of $\tilde{C}_r = 1$ but $F_r = 0$ can be matched to a case where $\tilde{C}_r = 1$ but $\tilde{C}'_r = 0$. So, to show the lemma, it only remains to show that $\mathbf{E}[Q] = O(\sqrt{B})$.

First, observe that $\sum_{r=L-\gamma N}^{L-1} \tilde{C}_r$ is drawn from a binomial distribution with γN trials and probability $\frac{B}{\gamma N}$. Therefore, its expectation is $\mu = B$ and its standard deviation is $\sigma = \sqrt{B - \frac{B}{\gamma N}} \leq \sqrt{B}$. Thus by Chebyshev inequality, we get

$$\mathbf{E}\left[\left| \sum_{r=L-\gamma N}^{L-1} \tilde{C}_r - B \right| \right] \leq \sigma + \sum_{k=1}^{\infty} \mathbf{E}\left[\left| \sum_{r=L-\gamma N}^{L-1} \tilde{C}_r - B \right| \geq k\sigma \right] \sigma \leq \sigma + \sum_{k=1}^{\infty} \frac{\sigma}{k^2} = \sqrt{B} + \frac{\pi^2}{6}\sqrt{B}.$$

So, it only remains to show that

$$\mathbf{E}\left[\max_{L \leq \ell < L+\gamma N} \left(\sum_{r=L}^{\ell} \tilde{C}_r - \sum_{r=L-\gamma N}^{\ell-\gamma N} \tilde{C}_r \right) \right] \leq 2\sqrt{\frac{4B}{3\pi}} + O(1) \enspace .$$

Let $\tilde{C}''_\ell \in \{-1, 0, 1\}$ be a random variable with $\tilde{C}''_\ell = \tilde{C}_\ell - \tilde{C}_{\ell-\gamma N}$. Each $\tilde{C}''_\ell$ takes the values 1 and -1 with probability $p = \frac{B}{\gamma N}(1 - \frac{B}{\gamma N})$ each and 0 with the remaining probability $1 - 2p = \left(1 - \frac{2B}{\gamma N} + 2(\frac{B}{\gamma N})^2\right)$. Furthermore, because the $\tilde{C}_\ell$ random variables are independent, $\tilde{C}''_L, \ldots, \tilde{C}''_{L+\gamma N-1}$ also are.

We interpret this random process on the $\tilde{C}''_\ell$ as a random walk of length γN that moves up or down with probability p and stays the same with probability $1 - 2p$. In the next part of the proof, we are going to show that the maximal deviation of this random walk is in $\Theta(\sqrt{B})$. To this end, we condition our random walk on the number of zeros that occur. The remaining random walk is symmetric, thus results from the literature apply.

It has been shown that, for a symmetric random walk that starts in position 0 and does k steps, the expected final position is $\mathbf{E}[S_k] = \sqrt{\frac{2k}{3\pi}} + O(k^{-\frac{1}{2}})$ [14]. Furthermore, it is well known that the expected maximal deviation during such a random walk is $\mathbf{E}[M_k] \leq 2\mathbf{E}[S_k]$. Now, let K be the number of times $\tilde{C}''_r \neq 0$ for $r \in \{L, \ldots, L + \gamma N - 1\}$. Then we have

$$\mathbf{E}\left[\max_{L \leq \ell < L+\gamma N} \left(\sum_{r=L}^{\ell} \tilde{C}_r - \sum_{r=L-\gamma N}^{\ell-\gamma N} \tilde{C}_r \right) \right] \leq \sum_{k=0}^{\gamma N} \mathbf{E}[M_k] \cdot \mathbf{Pr}[K = k]$$

$$\leq \sum_{k=0}^{\gamma N} 2\mathbf{E}[S_k] \cdot \mathbf{Pr}[K = k] \leq \mathbf{E}\left[2\sqrt{\frac{2K}{3\pi}} + O(K^{-\frac{1}{2}}) \right] \leq 2\sqrt{\frac{2\mathbf{E}[K]}{3\pi}} + O(1)$$

$$= 2\sqrt{\frac{4B}{3\pi}} + O(1) \enspace . \qquad \blacktriangleleft$$

We use the same proof structure as in the previous proof of Theorem 2, but now we replace Lemma 3 with Lemma 5.

Proof of Theorem 4. Again, if in round ℓ an item is tentatively selected, let V_ℓ denote its value. Otherwise set $V_\ell = 0$. By the same arguments as in the proof of Theorem 2, we have

$$\mathbf{E}\left[V_\ell \tilde{C}_\ell F_\ell\right] = \frac{\mathbf{Pr}\left[\tilde{C}_\ell = 1, F_\ell = 1\right]}{\mathbf{Pr}\left[\tilde{C}_\ell = 1\right]} \mathbf{E}\left[V_\ell\right] \enspace .$$

To get the bound, we split the input sequence into blocks of length γN and ignore the blocks in which there is a round for which Lemma 1 does not hold.

$$\mathbf{E}\left[\sum_{j \in \mathrm{ALG}} v_j\right] \geq \sum_{k=\left\lceil 2\sqrt{\frac{1}{\gamma B}}\right\rceil}^{\lfloor \frac{1}{\gamma} \rfloor - 1} \sum_{\ell = k\gamma N + 1}^{(k+1)\gamma N} \mathbf{E}\left[V_\ell \tilde{C}_\ell F_\ell\right]$$

$$\geq \sum_{k=\left\lceil 2\sqrt{\frac{1}{\gamma B}}\right\rceil}^{\lfloor \frac{1}{\gamma} \rfloor - 1} \sum_{\ell = k\gamma N + 1}^{(k+1)\gamma N} \frac{\mathbf{Pr}\left[\tilde{C}_\ell = 1, F_\ell = 1\right]}{\mathbf{Pr}\left[\tilde{C}_\ell = 1\right]} \left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N} \cdot \frac{B}{\gamma}}}\right) \cdot \frac{1}{N} \frac{1 - \frac{1}{2}\sqrt{\frac{\gamma}{B}}}{1 + \gamma} \sum_{j \in \mathrm{OPT}^*} v_j$$

$$\geq \left(1 - \frac{4}{\sqrt{B}} - \frac{41}{2}\sqrt{\frac{\gamma}{B}} - 3\gamma - O\left(\frac{1}{B}\right)\right) \sum_{j \in \mathrm{OPT}^*} v_j \enspace .$$

The missing details on the calculations are included in the full version. ◀

3 The Temp Secretary Problem with Packing Constraints

Next, we turn to the temp secretary with general linear packing constraints. This generalizes the timed cardinality constraint of the temp secretary problem towards multiple knapsack constraints. Therefore we can model, e.g., production capacities of different types. Now, the problem is not about selecting a set of best candidates, but a set of contracts with different resource demands such that the value of the selected contracts is maximized and all demands are fulfilled at any point in time.

We assume that the items, or possible contracts, that arrive over time are variables of a packing LP that have to be set immediately and irrevocably at time of arrival. In more detail, we assume that an adversary defines an $n \times m$ constraint matrix A, a capacity vector b, and an objective function vector v. Again, for each variable x_j an arrival time is drawn independently uniformly at random from $[0, 1]$. We now have to find an assignment $\hat{x}_j \in \{0, 1\}$ for all $j \in [n]$, with the property that for every $t \in [0, 1]$, the set of variables that arrive between t and $t + \gamma$ solve the packing LP. That is, for every t, we need $Ax' \leq b$, where $x'_j = \hat{x}_j$ if $t_j \in [t, t + \gamma]$ and 0 otherwise. The objective is to maximize $v^T \hat{x}$. So, $\hat{x}$ represents the aggregate vector of which items are selected whenever they are present in the system. Therefore, the temp secretary problem can be captured by having only one constraint with all coefficients being 1 and the capacity being the cardinality bound. As the output of our algorithm will be integral, this algorithm also solved the temp secretary problem.

We assume that the matrix A is sparse. That is, each column of A contains at most d non-zero entries. Furthermore, we assume that the capacities in each constraint are large compared to the respective coefficients in A. Our bound will depend on the capacity ratio B, defined as $B = \min_{i \in [m]} \frac{b_i}{\max j \in [n] a_{i,j}}$. When modeling the temp secretary problem as above, this capacity ratio coincides with the capacity bound.

Again, we use a relaxation without temporal constraints like the one in Section 2. In this case, it reads $\max v^T x$ s.t. $Ax \leq \lceil \frac{1}{\gamma} \rceil b$, $0 \leq x_j \leq 1$ for all $j \in [n]$. While our algorithm chooses online which items to select and which to reject subject to the temporal constraints,

Algorithm 2: Scaling Algorithm for packing constraints

```
for every arriving item $j \in [n]$ do
    Set $t := \tau_j$;                                              // arrival time of $j$
    Let $x^{(t)}$ be an optimal solution to the LP $\max v^T x$ s.t. $Ax \leq t(1-\epsilon)\frac{b}{\gamma}$, $0 \leq x_{j'} \leq 1$
     for $j' \in U_{\leq t}$;                                       // optimal offline solution
    $\hat{x}^{(t)}_{j'} = \begin{cases} 1, & \text{with prob. } x^{(t)}_{j'} \text{ if } j' = j; \\ 0, & \text{otherwise;} \end{cases}$   // randomized rounding
    if $\hat{x} + \hat{x}^{(t)}$ is feasible with respect to temporal constraints then
        Set $\hat{x} := \hat{x} + \hat{x}^{(t)}$;                   // make allocation to $j$ permanent
```

our point of comparison is the best fractional solution to this LP relaxation. We use an algorithm similar to the one presented in [17] to solve the relaxed problem. We scale down the aggregated constraints slightly and solve the resulting linear packing problem. Next, we use randomized rounding to transform the fractional solution into our integral, tentative solution. At this point, the algorithm behaves exactly like the one in Section 2. If the item that just arrived is part of the tentative solution and it is feasible to select it, then the algorithm adds it to the online solution. In contrast to the analysis in [17], we have to show that temporal constraints are likely fulfilled although the algorithm only operates on the relaxed ones.

To define the algorithm, let $U_{\leq t}$ be the set of variables $U_{\leq t} \subseteq [n]$ that arrive before time t. Let $\epsilon = \sqrt{6\frac{(1+\log d+\log B)}{B}}$.

This algorithm can also be extended to the case in which there are not only timed constraints but also global ones. Additionally, it can be applied when multiple variables arrive at a time like in [17]. We omit these generalizations because the techniques are identical to the ones presented here, but correct notation gets a lot more involved.

▶ **Theorem 6.** *Algorithm 2 is* $\frac{1}{1+\gamma} - O\left(\sqrt{\frac{1+\log d+\log B}{B}}\right)$*-competitive for the temp secretary problem with linear packing constraints.*

Please note that this algorithm is invariant to scaling constraints and therefore we can assume without loss of generality that $\max_{j\in[n]} a_{i,j} \leq 1$ and $b_i \geq B$ for every constraint $i \in [m]$.

For the proof, we will first bound the expected consumption of the tentative solution of the algorithm. Then we will use a Chernoff bound to bound the probability that last *if*-clause of the algorithm is violated for a single constraint. Finally, we will aggregate the probabilities for all constraints in the relaxation.

We discretize time, like in Section 2, with arbitrary precision such that every discrete time interval only contains a single item of the input. We have $N \gg n$ rounds, spanning time $\frac{1}{N}$ each. For each of the $N - n$ rounds in which no variable arrives, we introduce a dummy variable with all coefficients zero. These N variables can now be considered being assigned to the rounds by a uniformly drawn permutation. In the proofs, we overload notation and write $x^{(\ell)} = x^{(t)}$ and $U_{\leq \ell} = U_{\leq t}$ if t lies within round ℓ.

▶ **Lemma 7.** *Let $U_{<\ell} \subseteq [n]$ be the set of items that arrive before round ℓ. Then, conditioned on this set, the sum of previous tentative allocations violates any constraint $i \in [m]$ with* *probability at most*

$$\mathbf{Pr}\left[\left(\sum_{\ell'=\ell-\gamma N}^{\ell-1} A\hat{x}^{(\ell')}\right)_i > b_i - 1 \;\middle|\; U_{<\ell}\right] \leq \frac{1}{dB}$$

if $\epsilon = \sqrt{6\frac{1+\log d+\log B}{B}} \leq \frac{1}{2}$.

We describe the capacity used by the tentative selection through random variables $X_{\ell'} = \left(A\hat{x}^{(\ell')}\right)_i$. These random variables are not independent but 1-correlated as defined by Panconesi and Srinivasan [24] and this allows us to apply a Chernoff bound to proof the lemma. Details can be found in the full version.

Proof of Theorem 6. We can assume without loss of generality that $\sqrt{6\frac{1+\log d+\log B}{B}} \leq \frac{1}{2}$ because otherwise the theorem statement follows trivially.

First, we bound the value of the tentative allocation performed in round $\ell \geq 2\sqrt{\frac{1+\ln d}{B}}N$ using a result in [17]. Compared to [17] our non-temporal relaxation is scaled down by an additional factor of $1-\epsilon$ this gives us

$$\mathbf{E}\left[v^T x^{(\ell)}\right] \geq \left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N}\cdot(1-\epsilon)\frac{B}{\gamma}}}\right)\frac{\ell}{N}(1-\epsilon)\cdot \max_{x: Ax \leq b/\gamma, 0 \leq x_j \leq 1 \text{ for all } j \in [m]} v^T x$$

Letting x^* denote the optimal solution to the relaxation, we also have

$$\max_{x: Ax \leq b/\gamma, 0 \leq x_j \leq 1 \text{ for all } j \in [m]} v^T x \geq \frac{\frac{1}{\gamma}}{\lceil \frac{1}{\gamma} \rceil} v^T x^* \geq \frac{1}{1+\gamma} v^T x^* \enspace .$$

So, this implies

$$\mathbf{E}\left[v^T x^{(\ell)}\right] \geq \left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N}\cdot(1-\epsilon)\frac{B}{\gamma}}}\right)\frac{\ell}{N}\frac{1-\epsilon}{1+\gamma} v^T x^* \enspace .$$

Observe that this outcome only depends on the set $U_{\leq \ell}$ but not the order in this set. Therefore, the variable that arrives in round ℓ can be considered being drawn uniformly from $U_{\leq \ell}$. This way, we get

$$\mathbf{E}\left[v^T \hat{x}^{(\ell)} \;\middle|\; U_{\leq \ell}\right] = \frac{1}{\ell}\mathbf{E}\left[v^T x^{(\ell)} \;\middle|\; U_{\leq \ell}\right]$$

Note that these outcomes only depend on the sets $U_{<\ell}$ and $U_{\leq \ell}$ but not the order within $U_{<\ell}$.

To bound the probability of feasibility, we will use Lemma 7, conditioning on the set $U_{<\ell}$ and $U_{\leq \ell}$. Let j be the index of the variable arriving in round ℓ. Taking a union bound over all $\leq d$ constraints in which variable j has non-zero coefficients, we get

$$\begin{aligned}&\mathbf{Pr}\left[\text{it is feasible to set } \hat{x}_j = 1 \mid U_{<\ell}, U_{\leq \ell}\right] \\ &\qquad \geq 1 - d \cdot \sum_{i: a_{i,j} > 0} \mathbf{Pr}\left[\left(\sum_{\ell'=\ell-\gamma N}^{\ell-1} A\hat{x}^{(\ell')}\right)_i > b_i - 1 \;\middle|\; U_{<\ell}\right] \geq \left(1 - \frac{1}{B}\right) \enspace .\end{aligned}$$

Overall, the expected value of the allocation performed in round ℓ is at least

$$\mathbf{E}\left[v^T \hat{x}^{(\ell)}\right] \geq \left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N}\cdot(1-\epsilon)\frac{B}{\gamma}}}\right)\frac{1}{N}\frac{1-\epsilon}{1+\gamma}\left(1 - \frac{1}{B}\right) v^T x^* \enspace .$$

Algorithm 3: Scaling Algorithm for different lengths and capacity B

```
for every arriving item $j$ do
    Set $t := \tau_j$, $U_{\leq t}$ := items arrived so far;
    Let $S^{(t)} := \textsc{GreedyRoundUp}(U_{\leq t}, \alpha t B)$;
    if $j \in S^{(t)}$ then                          // if among best items
        if $S \cup \{j\}$ is a feasible schedule then    // and if feasible
            Set $S := S \cup \{j\}$;                     // then select j
```

Taking the sum of all these bounds, we get

$$\mathbf{E}\left[v^T \hat{x}\right] \geq \sum_{\ell=2\sqrt{\frac{1+\ln d}{B}}N}^{N} \left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N}\cdot(1-\epsilon)\frac{B}{\gamma}}}\right)\frac{1}{N}\cdot\frac{1-\epsilon}{1+\gamma}\left(1-\frac{1}{B}\right)v^T x^*$$
$$\geq \frac{1-O(\epsilon)}{1+\gamma} v^T x^* \ . \qquad ◀$$

4 The Temp Secretary Problem with Different Lengths

We generalize the Temp Secretary Problem towards different item durations $\lambda_j \leq \gamma$ for all items $j \in [n]$. To define the relaxation, we use the fact that pointwise $\sum_{j \in \mathrm{OPT}} \lambda_j \leq B(1+\gamma)$. This is due to the fact that an item j selected at time $\tau_j = 1$ will be active until time $1 + \lambda_j$. Therefore, let OPT* denote the optimal solution to this knapsack problem with profits v_j. Due to the knapsack nature of the problem, the algorithm cannot be purely comparison-based anymore. Instead, whenever an item arrives, we compute an approximate knapsack solution and tentatively select the item if it is included in this solution. It will be crucial that these solutions only slowly change when adding or removing items. This is why, there is no obvious generalization of our algorithm and analysis to general packing LPs. In more detail, for $U' \subseteq [n]$ and $\Lambda > 0$ we define $\textsc{GreedyRoundUp}(U', \Lambda)$ as the set $U'' \subseteq U'$ which we get by ordering the items in U' in non-increasing order $\frac{v_j}{\lambda_j}$ and taking the minimal prefix such that $\sum_{j \in U''} \lambda_j \geq \Lambda$.

▶ **Theorem 8.** *With $\alpha = 1/2$, Algorithm 3 is at least $\frac{1}{4} - \Theta\left(\sqrt{\gamma}\right)$-competitive for the temp secretary problem with arbitrary durations $\lambda_j \leq \gamma$.*

We use the same proof structure like in Theorem 2. Here Lemma 9 gives a bound on the expected value of the tentative solution. The proof of this lemma is very similar to the proof of Lemma 1 and can be found in the full version.

▶ **Lemma 9.** *For $\ell \geq 2\sqrt{\frac{\gamma}{B}}N$*

$$\mathbf{E}\left[\sum_{j \in S^{(\ell)}} v_j\right] \geq \alpha\left(1 - 9\sqrt{\frac{1}{\frac{\ell}{N}\frac{B}{\gamma}}}\right)\frac{\ell}{N}\frac{1}{1+\gamma}\sum_{j \in \mathrm{OPT}^*} v_j \ .$$

The main difference to previous proofs in this paper is the fact that we cannot bound the probability of a selection for a fixed round because it depends on the lengths of the items that arrive up to this round. Fortunately, we can bound the probability that a selection would be feasible by the following lemma.

▶ **Lemma 10.** *Conditioning on any set of arrivals in rounds* $1, \dots, \ell - 1$, *the probability that an item can be feasibly selected in round* ℓ *is at least* $1 - \alpha - \frac{3\gamma N}{\ell - \gamma N}$.

As a key idea, we show that the probability of a selection does not significantly change between rounds.

▶ **Lemma 11.** *Let* $H_{i,\ell}$ *be the 0/1 indicator if an item with duration at least* i *rounds is tentatively selected in rounds* ℓ. *It holds that* $\mathbf{Pr}\left[H_{i,\ell-i} = 1\right] \leq \mathbf{Pr}\left[H_{i,\ell} = 1\right] + \frac{\alpha B + 1}{\ell - i}$.

Proof. First, we observe that an item j is tentatively selected in round ℓ' if it is contained in $S^{(\ell')}$ and arrives in round ℓ'. As the set $S^{(\ell')}$ only depends on the items arriving in rounds $1, \dots, \ell'$ but not on their order, the probability of j being tentatively selected is exactly $\frac{1}{\ell'}\mathbf{Pr}\left[j \in S^{(\ell')}\right]$. Therefore, to prove this lemma, we will compare the sets $S^{(\ell-i)}$ and $S^{(\ell)}$.

Instead of making statements about the set $S^{(\ell-i)}$ directly, we instead use a set $\tilde{S}$ defined as $\tilde{S}$:=GreedyRoundUp$(U_{\leq \ell - i}, \alpha\frac{\ell}{N}B)$. Note that by definition of GreedyRoundUp, this set $\tilde{S}$ is a superset of $S^{(\ell-i)}$ =GreedyRoundUp$(U_{\leq \ell-i}, \alpha\frac{\ell-i}{N}B)$.

Let now $\mathcal{E}^*_{i,\ell-i}$ be the event that an item of length at least i rounds arrives in round $\ell - i$ that is contained in $\tilde{S} \cap S^{(\ell)}$, and let $\mathcal{E}^-_{i,\ell-i}$ be the event that an item of length at least i rounds arrives in round $\ell - i$ that is contained in $\tilde{S} \setminus S^{(\ell)}$. As $S^{(\ell-i)}$ is contained in $\tilde{S}$, we have $\mathbf{Pr}\left[H_{i,\ell-i} = 1\right] \leq \mathbf{Pr}\left[\mathcal{E}^*_{i,\ell-i}\right] + \mathbf{Pr}\left[\mathcal{E}^-_{i,\ell-i}\right]$.

To bound the first probability, we use that every item in $S^{(\ell)}$ has already arrived in round $\ell - i$ with probability $\frac{\ell-i}{\ell}$. Every such item arrives exactly in round $\ell - i$ with probability $\frac{1}{\ell-i}$. Therefore we have $\mathbf{Pr}\left[\mathcal{E}^*_{i,\ell-i}\right] = \mathbf{Pr}\left[H_{i,\ell} = 1\right]$.

For the second probability, observe that $\tilde{S}$ contains all elements of $S^{(\ell)}$ that have arrived by round $\ell - i$, i.e., $\tilde{S} \supseteq S^{(\ell)} \cap U_{\leq \ell-i}$. Also if $\sum_{j \in S^{(\ell)}} \lambda_j < \alpha\frac{\ell}{N}B - \gamma$, it has to be $S^{(\ell)} = U_{\leq \ell}$. Therefore, $\tilde{S} = S^{(\ell)}$ and nothing has to be shown. This implies that $\mathbf{E}\left[\sum_{j \in \tilde{S} \cap S^{(\ell)}} \lambda_j\right] \geq \frac{\ell-i}{\ell}\alpha\frac{\ell}{N}B = \alpha\frac{\ell-i}{N}B$ because the probability for each item in $S^{(\ell)}$ to arrive until round $\ell - i$ is $\frac{\ell-i}{\ell}$. Therefore, the λ_j values for all but one item in $\tilde{S} \setminus S^{(\ell)}$ add up to at most $\alpha B\frac{i}{N}$.

Let K denote the number of items in $\tilde{S} \setminus S^{(\ell)}$ of length at least i blocks. On the one hand, K is bounded by $\mathbf{E}\left[K\right] \leq \alpha B + 1$ due to the above considerations. On the other hand, conditioning on K, we can bound the probability of $\mathbf{Pr}\left[\mathcal{E}^-_{i,\ell-i}\right]$ by $\mathbf{Pr}\left[\mathcal{E}^-_{i,\ell-i} \;\middle|\; K = k\right] \leq \frac{k}{\ell-i}$.

Taking the expectation over K, we get $\mathbf{Pr}\left[\mathcal{E}^-_{i,\ell-i}\right] \leq \frac{\alpha B+1}{\ell-i}$. ◀

Proof of Lemma 10. Using Lemma 11, we now have

$$\begin{aligned}\mathbf{Pr}\left[\text{round } \ell \text{ would be feasible} \mid U_{\leq \ell-1}\right] &\geq 1 - \frac{1}{B}\sum_{i=1}^{\gamma N}\mathbf{E}\left[H_{i,\ell-i} \mid U_{\leq \ell-1}\right] \\ &\geq 1 - \frac{1}{B}\sum_{i=1}^{\gamma N}\mathbf{E}\left[H_{i,\ell-1} \mid U_{\leq \ell-1}\right] - \frac{\alpha\gamma N + 1}{\ell - \gamma N} \quad .\end{aligned}$$

Observe that $\sum_{i=1}^{\gamma N}\mathbf{E}\left[H_{i,\ell-1} \mid U_{\leq \ell-1}\right]$ is exactly the length in rounds of the tentative selection in round $\ell - 1$, counting no tentative selection as 0. This length is bounded by $\frac{1}{\ell-1}\mathbf{E}\left[\sum_{j \in S^{(\ell-1)}} \lambda_j N \;\middle|\; U_{\leq \ell-1}\right]$. This sum can be bounded pointwise by $\sum_{j \in S^{(\ell-1)}} \lambda_j \leq \alpha\frac{\ell-1}{N}B + \gamma$. So we have $\sum_{i=1}^{\gamma N}\mathbf{E}\left[H_{i,\ell-1} \mid U_{\leq \ell-1}\right] \leq \alpha + \frac{\gamma N}{\ell-1}$.

This means $\mathbf{Pr}\left[\text{round } \ell \text{ would be feasible} \mid U_{\leq \ell-1}\right] \geq 1 - \alpha - \frac{(1+\alpha)\gamma N+1}{\ell-\gamma N} \geq 1 - \alpha - \frac{3\gamma N}{\ell-\gamma N}$. ◀

The remaining proof follows essentially the pattern of the previous sections.

Proof of Theorem 8. We have already shown that

$$\mathbf{Pr}\left[\text{round } \ell \text{ would be feasible} \mid U_{\leq \ell-1}\right] \geq 1 - \alpha - \frac{3\gamma N}{\ell - \gamma N} \enspace .$$

By combining this bound with Lemma 9, we get that the expected value gained from round $\ell \geq 2\sqrt{\gamma}N$ is at least

$$\frac{1}{2\ell} \cdot \left(1 - 9\sqrt{\frac{\gamma}{\frac{\ell}{N}B}}\right) \frac{\ell}{N} \frac{\sum_{j \in \mathrm{OPT}^*} v_j}{1+\gamma} \cdot \left(\frac{1}{2} - \frac{3\gamma N}{\ell - \gamma N}\right) \enspace .$$

Similar calculations like in the proof of Theorem 2 and $\alpha = \frac{1}{2}$ give a competitive ratio of

$$\begin{aligned} \mathbf{E}\left[\sum_{j \in \mathrm{ALG}} v_j\right] &\geq \sum_{k=2}^{\frac{1}{\sqrt{\gamma}}-1} \sum_{\ell = k\sqrt{\gamma}N}^{(k+1)\sqrt{\gamma}N-1} \frac{1}{2}\left(1 - 9\sqrt{\frac{\gamma}{\frac{\ell}{N}B}}\right) \frac{1}{N} \frac{\sum_{j \in \mathrm{OPT}^*} v_j}{1+\gamma} \cdot \left(\frac{1}{2} - \frac{3\gamma N}{\ell - \gamma N}\right) \\ &\geq \left(\frac{1}{4} - 5\sqrt{\gamma} - \frac{3}{2}\gamma \ln\left(\frac{1}{\sqrt{\gamma}}\right)\right) \cdot \frac{1}{1+\gamma} \sum_{j \in \mathrm{OPT}^*} v_j \enspace . \end{aligned}$$

The missing details are included in the full version. ◀

5 Future Work

The area of online problems with stochastic arrivals and temporal constraints leaves many open research directions. First of all, only very few impossibility results are known in this model. It seems natural that bounds in the related random order model should generalize in some way. For example in the temp secretary problem with large capacities, it seems plausible that the competitive ratio cannot be better than $1 - \Omega\left(\sqrt{\frac{1}{B}}\right)$ like in [18], independent of γ. A small γ increases the overall capacity, but in every step the algorithm is still tightly restricted by the timed capacity B.

Furthermore, the results in this paper apply if the arrival times are each drawn independently uniformly from $[0, 1]$. This condition can be relaxed in several ways. Firstly, other distributions than the uniform one are of important interest. Although the algorithms in this paper do admit a reasonable generalization using quantiles, our analyses as they are do not extend. Secondly, it is also very interesting to weaken the assumption that arrival times are independent and identically distributed. There is only little work in related models [15, 8] and none for this particular setting.

Other fruitful directions could be the extension to other feasibility structures, such as (special classes of) matroid, and to other objective functions, such as submodular ones. Finally, it might also be interesting to let the algorithm decide the contract starting/finishing dates or its duration.

Abstract

We study the natural problem of estimating the expansion of subsets of vertices on one side of a bipartite graph. More precisely, given a bipartite graph $G(U, V, E)$ and a parameter β, the goal is to find a subset $V' \subseteq V$ containing β fraction of the vertices of V which minimizes the size of $N(V')$, the neighborhood of V'. This problem, which we call *Bipartite Expansion*, is a special case of submodular minimization subject to a cardinality constraint, and is also related to other problems in graph partitioning and expansion. Previous to this work, there was no hardness of approximation known for Bipartite Expansion.

In this paper we show the following strong inapproximability for Bipartite Expansion: for any constants $\tau, \gamma > 0$ there is no algorithm which, given a constant $\beta > 0$ and a bipartite graph $G(U, V, E)$, runs in polynomial time and decides whether

- (YES case) There is a subset $S^* \subseteq V$ s.t. $|S^*| \geq \beta|V|$ satisfying $|N(S^*)| \leq \gamma|U|$, or
- (NO case) Any subset $S \subseteq V$ s.t. $|S| \geq \tau\beta|V|$ satisfies $|N(S)| \geq (1-\gamma)|U|$,

unless NP $\subseteq \cap_{\varepsilon>0}$DTIME $\left(2^{n^{\varepsilon}}\right)$ i.e. NP has subexponential time algorithms.

We note that our hardness result stated above is a vertex expansion analogue of the Small Set (Edge) Expansion Conjecture of Raghavendra and Steurer [23].

1 Introduction

Graph partitioning and graph expansion are very well studied topics in graph theory, combinatorics and theoretical computer science. A central goal in this line of research is to decide how well a given graph can be partitioned into smaller parts. Generally speaking, a partitioning is considered good if the graph is decomposed into reasonably sized components while removing only a small number of vertices or edges. Specific variants of the graph partitioning question are addressed by a number of well known problems – such as Vertex Separator, Sparsest Cut and Balanced Separator – which have been studied extensively in several previous works [18, 16, 17, 5, 15].

Related to the above is the *Bipartite Expansion* problem which measures the vertex expansion of subsets on one of the sides of a bipartite graph. Specifically, given a bipartite graph $G(U, V, E)$, the goal is to find a subset $V' \subseteq V$ of size at least $\beta|V|$ to minimize $|N(V')|$ for some parameter $\beta \in (0, 1)$, where $N(V')$ is the neighborhood of V' in U. The absence of V' with a small neighborhood implies that there is an edge between any two large enough subsets – one each of U and V, presenting a bottleneck to a good partitioning of the graph. Such graphs are known as *bipartite expanders*. They have been studied in several applications such as parallel sorting [22, 2], constructing good codes [26], randomness extractors [12, 25] and more recently for constructing secure public key cryptographic systems [4]. Since vertex expansion is a submodular function, Bipartite Expansion is a special case of minimizing a submodular function subject to a cardinality constraint, for which Svitkina and Fleischer [27] gave an $O\left(\sqrt{n/\ln n}\right)$ pseudo-approximation. In spite of this being a natural problem, we are not aware of any hardness of approximation results for Bipartite Expansion.

In this work we establish the following strong hardness of approximation result for Bipartite Expansion under the assumption that NP does not have subexponential time algorithms.

▶ **Theorem 1.1** (Main). *For any constants $\gamma, \tau > 0$, there is no algorithm which, given a constant $\beta > 0$ and an n-vertex bipartite graph $G(U, V, E \subseteq U \times V)$, runs in $O(n^c)$ time where $c = c(\tau, \gamma, \beta)$ and decides between the following cases,*

- (YES case) *There is a subset $S^* \subseteq V$ s.t. $|S^*| \geq \beta|V|$ satisfying $|N(S^*)| \leq \gamma|U|$, or*
- (NO case) *Any subset $S \subseteq V$ s.t. $|S| \geq \tau\beta|V|$ satisfies $|N(S)| \geq (1-\gamma)|U|$,*

unless $\mathrm{NP} \subseteq \cap_{\varepsilon>0}\mathrm{DTIME}\left(2^{n^{\varepsilon}}\right)$.

More concretely, the above shows (for example) that even if there exists a good subset V^* of at least β fraction of the vertices of V such that its neighborhood is 1% of U, it is hard to find V' of $\beta/100$ fraction of the vertices of V, such that the neighborhood of V' is at most 99% of U.

We note that Bipartite Expansion problem seems to bear resemblance to the Small Set Expansion problem which has recently received attention due to its connection to Khot's [13] Unique Games Conjecture. This connection was established by Raghavendra and Steurer [23] who proved that the Small Set Expansion Conjecture (see [23] for the statement) implies the Unique Games Conjecture. Theorem 1.1 is, in some sense, a vertex expansion analogue of the statement of the Small Set Expansion Conjecture which deals with edge expansion. Louis, Raghavendra, and Vempala [19] have shown that the Small Set Expansion Conjecture implies hardness of approximation for a variant of vertex expansion on general graphs. While a similar reverse reduction from vertex expansion to edge expansion of small sets is not known, this raises the intriguing possibility that techniques similar to those of this work could throw some light on the Small Set Expansion and Unique Games conjectures.

Our result also serves as a complexity theoretic lower bound for the $O\left(\sqrt{n/\ln n}\right)$ pseudo-approximation of [27] for minimizing submodular functions subject to a cardinality constraint, even when the function is monotone like bipartite vertex expansion.

1.1 Related Work

Bipartite Expansion is related to graph partitioning problems including Vertex Separator and Balanced Separator, and is known to be NP-hard via a reduction from the Balanced Vertex Separator problem [21].

Leighton and Rao [16] gave an $O(\log n)$ (pseudo-)approximation for Balanced Separator and Vertex Separator problems. For Balanced Separator, the factor was improved to the currently best known $O(\sqrt{\log n})$ in a seminal work of Arora, Rao, and Vazirani [5]. Subsequent work by Feige *et al.* [11] and Agarwal *et al.* [1] also proved $O(\sqrt{\log n})$ approximation for Vertex Separator. For both these problems PTAS was ruled out under standard complexity assumptions by Ambuhl, Mastrolilli, and Svensson [3] using the quasi-random Probabilistically Checkable Proof (PCP) of Khot [14]. Subsequently work of Raghavendra, Steurer, and Tulsiani [24] has ruled out a constant factor approximation for Balanced Separator based on the Small Set Expansion Conjecture [23] which implies the Unique Games Conjecture of Khot [13]. The latter conjecture was used in previous works [15, 7] to prove similar inapproximability for a non-uniform version of Balanced Separator. As mentioned above, the work of Svitkina and Fleischer [27] shows that Bipartite Expansion admits a $O\left(\sqrt{n/\ln n}\right)$ pseudo-approximation: given the existence of a subset V^* of size $\beta|V|$ and $|N(V^*)| \le \gamma|U|$, the algorithm outputs a subset V' of size at least $\sigma\beta|V|$ and $|N(V')| \le \rho\gamma|U|$, with $\rho/\sigma \le O\left(\sqrt{n/\ln n}\right)$.

While not much is known about the inapproximability of Bipartite Expansion, the problem of explicitly constructing bipartite expanders has been fairly well studied [20, 22, 2]. These constructions and their variants have applications in sorting networks [22, 2], error-correcting codes [26] and randomness extractors [12, 25]. We end with a brief mention of a result by Applebaum, Barak, and Wigderson [4] who construct public-key encryption schemes based on the (assumed) average case hardness of detecting a random unbalanced bipartite graph from one which has a randomly planted "shrinking" set S of $O(\log n)$ vertices on the larger side such that $|N(S)| \le |S|/3$. While the parameters they consider are different from our setting, their work has, in part, motivated this study of bipartite expansion.

1.2 Our Techniques

The starting point of our reduction is the quasi-random PCP constructed by Khot [14]. Unlike previously constructed PCPs, Khot's construction essentially showed that the YES and NO cases differ in how randomly the queries of the verifier's tests are distributed over the locations of the proof. This crucial quasi-randomness property – which we describe below – was used by Khot [14] to rule out PTAS for Min-Bisection, Dense k-Subgraph and Bipartite Clique, results which were only known earlier assuming the average case hardness of Random-3SAT [10].

The construction in [14] proceeded by (i) proving the inapproximability of an Homogeneous Algebraic CSP over a large field, (ii) transforming the latter into an *Outer Verifier* based on an algebraic test, and (iii) composing the Outer Verifier with a d-query *Inner Verifier* based on the Hadamard Encoding over $\mathbb{F}[2]$. The quasi-randomness finally obtained by this series of reductions can be roughly summarized as follows: in the YES case there is a subset of half the locations of the proof which contains all the d queries of $\approx 1/2^{d-1}$ fraction of tests of the Inner Verifier, while in the NO case any such subset of the proof locations completely contains $\approx 1/2^d$ fraction of the tests. Taking the locations of the proof on the LHS, the tests of the verifier on the RHS, and connecting a location with a test if it queries the former, this already gives us an instance of Bipartite Expansion with a small hardness factor.

However, the inapproximability obtained above is far too weak for us to amplify the hardness gap using (say) graph powering. For this we modify the construction of [14] to encode the proof of the Inner Verifier using a Hadamard Code over a larger field $\mathbb{F}[q]$ where $q \gg 2$. A similar abstraction of the Inner Verifier as a bipartite graph $G(U, V, E)$ yields a $\eta\delta$ versus η gap in the expansion of similar sized subsets of V, for arbitrarily small $\eta, \delta > 0$. Taking the bipartite kth graph power using OR-product of the edges, where $k \approx C/\eta$, amplifies the above to a $C\delta$ versus $(1 - \exp(-C))$ gap in the expansion. The modified quasi-random PCP also yields a gap in the sizes of the relevant subsets of V which is preserved by the powering operation. This, along with the expansion gap, is sufficient to prove Theorem 1.1.

The construction and the analysis of the modified quasi-random PCP proceed along the same lines as in [14]. The parameters of the construction are set appropriately so that the subsequent OR-product graph powering amplifies the gap as desired.

Organization of the paper. The next section formally defines Bipartite Expansion as a decision problem, and restates our hardness result as Theorem 2.2. Section 3 provides the description of the Homogeneous Algebraic CSP and the quasi-random PCP of Khot [14], along with the statement (Theorem 3.4) of the aforementioned modified quasi-random PCP. Section 4 is devoted to proving Theorem 2.2 starting from Theorem 3.4 and the construction of the modified quasi-random PCP, i.e. the proof of Theorem 3.4, is given in Section 5.

2 Our Results

Bipartite Expansion is defined as the following decision problem.

▶ **Definition 2.1.** For parameters $\tau, \gamma, \beta > 0$, the BipartiteExpansion (τ, γ, β) problem is: given a bipartite graph $G(U, V, E \subseteq U \times V)$ distinguish between the following cases.
- (YES Case) There is a subset $S^* \subseteq V$, $|S^*| \geq \beta|V|$ s.t. $|N(S^*)| \leq \gamma|U|$.
- (NO Case) For any subset $S \subseteq V$ s.t. $|S| \geq \tau\beta|V|$, $|N(S)| \geq (1-\gamma)|U|$.

We prove the following hardness of BipartiteExpansion which implies Theorem 1.1.

▶ **Theorem 2.2.** *For any choice of constants $\varepsilon, \tau, \gamma > 0$, there exists $\beta > 0$, such that there is a* DTIME $(2^{n^{\varepsilon}})$ *reduction from* SAT *to* BipartiteExpansion (τ, γ, β).

3 Preliminaries

3.1 The HomAlgCSP Problem

▶ **Definition 3.1.** Let an HomAlgCSP instance $\mathcal{A}(k, d, m, \mathbb{F}, \mathcal{C})$ be the following problem:
1. $\mathcal{C}$ is a system of constraints on functions $f : \mathbb{F}^m \mapsto \mathbb{F}$ where every constraint is on values of f on k different points and is given by a conjunction of homogeneous linear constraints on those k values. A constraint $C \in \mathcal{C}$ on $f(\overline{p}_1), \dots, f(\overline{p}_k)$ is is given as

$$\sum_{i=1}^{k} \gamma_{ij} f(\overline{p}_i) = 0 \quad \text{for } j = 1, 2, \dots \qquad \text{where} \overline{p}_i \in \mathbb{F}^m \text{ and } \gamma_{ij} \in \mathbb{F}.$$

   We denote a constraint C by the set of points $\{\overline{p}_i\}_{i=1}^{k}$, while the γ_{ij}'s will be implicit.
2. $\mathcal{C}$ has $|\mathbb{F}|^{O(m)}$ constraints.

The goal is to find a m-variate polynomial f of total degree at most d, not identically zero, so as to maximize the fraction of constraints satisfied.

The following inapproximability of HomAlgCSP was shown in [14] following from Theorems 1.5 and 3.4 proved therein.

▶ **Theorem 3.2.** *There is a universal constant $\Delta > 0$, such that for any constant $K > 0$ and any constant $\tilde{d} > 0$ possibly depending on K, there is a reduction from a* SAT *formula of size n to an instance $\mathcal{A}(k, d^* = 10\tilde{d}, m = O(\tilde{m}^3\tilde{d}), \mathbb{F}, \mathcal{C})$ of* HomAlgCSP *with $k = 21$, $N \leq |\mathbb{F}| \leq N^2$ where $N = n^{\Delta K}$, and any choice of $\tilde{m}$ satisfying $\binom{\tilde{m}}{\tilde{d}} \geq N$. The size of the instance $\mathcal{A}$ is $|\mathbb{F}|^{O(m)}$, where the field $\mathbb{F}$ is any suitably sized extension of $\mathbb{F}[2]$. The reduction is a* DTIME $(|\mathbb{F}|^{O(m)})$ *procedure*[1] *such that,*

[1] The work of Khot [14] was based on a randomized hardness reduction for *Minimum Distance of Codeword* [9], which can be made deterministic using subsequent results of Cheng and Wan [8] and Austrin and Khot [6].

1. (YES Case) *If the* SAT *formula is satisfiable then there is a degree d^* multivariate polynomial f, not identically zero, which satisfies $1 - 1/2^K$ fraction of constraints of $\mathcal{A}$.*
2. (NO Case) *If the* SAT *formula is unsatisfiable then no degree $1000d^*$ multivariate polynomial, which is not identically zero, satisfies more than $1/2^{2^K}$ fraction of constraints of $\mathcal{A}$.*

3.2 Quasi-Random PCP of Khot [14]

The following is the statement of Khot's quasi-random PCP.

▶ **Theorem 3.3** (Theorem 1.9 of [14]). *For every $\varepsilon > 0$, there exists an integer $d = O(1/\varepsilon \log(1/\varepsilon))$ such that the following holds : there is a PCP verifier for a* SAT *instance of size n satisfying:*
1. *The proof for the verifier is of size $2^{O(n^\varepsilon)}$.*
2. *The verifier uses $O(n^\varepsilon)$ random bits, runs in time $2^{O(n^\varepsilon)}$, and reads d locations from the proof. Let Q be the d locations queried by the verifier in a random test.*
3. *Every query location is uniformly distributed over the proof, though different query locations within Q are correlated.*
4. (YES Case) *Suppose that the* SAT *instance is satisfiable. Then there exists a subset Π^* of half the locations of the proof such that,*

$$\Pr_Q [Q \subseteq \Pi^*] \geq \frac{1}{2^{d-1}} \left(1 - O\left(\frac{1}{d}\right)\right),$$

where the probability is taken over a random test of the verifier.

5. (NO Case) *Suppose that the* SAT *instance is unsatisfiable, and let Π' be any set of half the locations in the proof. Then,*

$$\left| \Pr_Q [Q \subseteq \Pi'] - \frac{1}{2^d} \right| \leq \frac{1}{2^{20d}}.$$

3.3 Modified Quasi-Random PCP

As discussed in Section 1.2, for our hardness result we construct the quasi-random PCP with an Inner Verifier encoding over a large field $\mathbb{F}[q]$. While the details of the construction and its analysis are given in Section 5, here we abstract out the bounds on the distribution of the PCP queries required for our purposes.

▶ **Theorem 3.4.** *For every positive integer (power of two) $R > 2$, and arbitrarily small $\varepsilon > 0$, there exists an integer $d = \Theta((1/\varepsilon)\log((\log R)/\varepsilon))$ along with the setting $q := R^{4d}$, such that the following holds : there is a PCP verifier for a* SAT *instance of size n satisfying properties (1)-(3) of Theorem 3.3 along with,*

4. (YES Case) *Suppose that the* SAT *instance is satisfiable. Then there exists a subset Π^* of $1/q$ fraction of the locations of the proof, such that*

$$\Pr_Q [Q \subseteq \Pi^*] \geq \frac{1}{q^{d-1}} \left(1 - O\left(\frac{1}{d^2}\right)\right), \tag{1}$$

where the probability is taken over a random test of the verifier.

5. (NO Case) *Suppose that the* SAT *instance is unsatisfiable, and let Π' be any set of $\zeta \in [0, 1]$ fraction of the locations of the proof. Then,*

$$\left| \Pr_Q [Q \subseteq \Pi'] - \zeta^d \right| \leq \frac{1}{q^{2d^2}}. \tag{2}$$

4 Reducing the Modified Quasi-Random PCP to BipartiteExpansion

For convenience we first abstract out the Modified Quasi-Random PCP as a bipartite graph and translate its YES and NO cases into a gap in expansion of small subsets on one side of the bipartition. This gap in expansion is then strengthened using an appropriate powering of the initial bipartite graph to yield the desired hardness for BipartiteExpansion. We assume for the rest of this section that that the parameters R, d and q in Theorem 3.4 are large enough constants.

4.1 Modified Quasi-Random PCP as a Bipartite Graph

Starting from an instance of the Modified Quasi-Random PCP in Theorem 3.4 define the bipartite graph $G(U, V, E \subseteq U \times V)$ where U is the set of proof locations, V is the set of d-query tests of the verifier and $(u, v) \in E$ iff the test v contains the query location u. Restating the YES and NO cases in terms of expansion of subsets of V we have the following lemmas.

▶ **Lemma 4.1.** *If G is a* YES *instance then there is a subset $S^* \subseteq V$ of size at least $0.99|V|/q^{d-1}$ such that $|N(S^*)| \leq |U|/q$.*

Proof. Take S^* to be the set of tests completely contained in the $1/q$ fraction of the proof locations given by the YES case. The lemma follows from (1) and large enough d. ◀

▶ **Lemma 4.2.** *If G is a* NO *instance then for any subset $S \subseteq V$ s.t. $|S| = a|V|$ where $a \in [1/q^{2d^2}, 1]$,*

$$\frac{|N(S)|}{|U|} \geq a^{1/d} - \frac{1}{aq^{2d^2}}.$$

Proof. In the NO case we let $\zeta = \frac{|N(S)|}{|U|}$, and thus from (2) we have

$$a \leq \zeta^d + \frac{1}{q^{2d^2}} \quad \Rightarrow \quad \zeta^d \geq a - \frac{1}{q^{2d^2}} \geq 0,$$

since $a \geq 1/q^{2d^2}$. This implies that,

$$\zeta \geq \left(a - \frac{1}{q^{2d^2}}\right)^{\frac{1}{d}} \geq a^{1/d}\left(1 - \frac{1}{aq^{2d^2}}\right)^{\frac{1}{d}} \geq a^{1/d}\left(1 - \frac{1}{aq^{2d^2}}\right) \geq a^{1/d} - \frac{1}{aq^{2d^2}},$$

since $a^{1/d} \leq 1$. ◀

4.2 Graph powering using OR-product

Fix a parameter $k := R^{4d-1}$. From $G(U, V, E)$ obtained above we construct the bipartite graph $\overline{G}(\overline{U}, \overline{V}, \overline{E} \subseteq \overline{U} \times \overline{V})$ as follows.

- $\overline{U} = U^k$ and $\overline{V} = V^k$. For any $\overline{u} \in \overline{U}$, $j \in [k]$, $\overline{u}_j \in U$ denotes the jth coordinate of $\overline{u}$. Similarly for $\overline{v} \in \overline{V}$.
- $(\overline{u}, \overline{v}) \in \overline{E}$ iff $\exists j \in [k]$ s.t. $(\overline{u}_j, \overline{v}_j) \in E$.

The rest of this section is devoted to proving the desired YES and NO cases completing the proof of Theorem 2.2.

4.2.1 YES Case

We prove the following lemma.

▶ **Lemma 4.3.** *If G is a* YES *instance then there exists a subset $T^* \subseteq \overline{V}$ such that,*

$$|T^*| \geq \left(\frac{0.99}{q^{d-1}}\right)^k |\overline{V}|,$$

and,

$$|N(T^*)| \leq |\overline{U}|/R.$$

Proof. Let $T^* = (S^*)^k$ where S^* is as given in Lemma 4.1. The first condition above is directly satisfied by the bound on the size of S^* in Lemma 4.1. Further, by union bound over all the k coordinates,

$$\frac{|N(T^*)|}{|\overline{U}|} \leq k \cdot \frac{|N(S^*)|}{|U|} \leq \frac{k}{q} = \frac{R^{4d-1}}{R^{4d}} = R^{-1},$$

where $|N(S^*)|/|U| \leq 1/q$ as given in Lemma 4.1. ◀

4.2.2 NO Case

For convenience let $h := 1/q^{d-1/2}$. The NO case is given by the following lemma.

▶ **Lemma 4.4.** *If G is a* NO *instance then for any subset $T \subseteq \overline{V}$ s.t. $|T| \geq h^k|\overline{V}|$,*

$$|N(T)| \geq \left(1 - e^{-R/2}\right)|\overline{U}|.$$

Proof. Let us first define the projections $T_1, \ldots, T_k \subseteq V$ of T as: $T_j = \{v \in V \mid \exists \overline{v} \in T \text{ s.t. } \overline{v}_j = v\}$. By construction, $|T| \leq \prod_{j=1}^k |T_j|$. Let $a_j := |T_j|/|V|$. Thus, we have,

$$\prod_{j=1}^k (a_j|V|) \geq h^k|\overline{V}| = h^k|V|^k,$$

which implies

$$\prod_{j=1}^k a_j \geq h^k. \tag{3}$$

By the AM-GM inequality we have,

$$\mathbb{E}_{j\in[k]}\left[a_j^{1/d}\right] \geq \left(\prod_{j=1}^k a_j^{1/d}\right)^{1/k} = \left(\prod_{j=1}^k a_j\right)^{1/kd} \geq h^{1/d}. \tag{4}$$

We also have the following simple lemma.

▶ **Lemma 4.5.** *For at most k/d values $j \in \{1, \ldots, k\}$, $a_j < h^d$.*

Proof. Assuming that for $t > k/d$ values $j \in \{1, \ldots, k\}$ $a_j < h^d$, we obtain that $\prod_{j=1}^k a_j \leq h^{td} < h^k$ (since $h < 1$), which contradicts (3). ◀

Let us define $b_j := |N(T_j)|/|U|$ for $j \in [k]$. Since, by our setting, $h^d \geq q^{-d^2} \geq q^{-2d^2}$, Lemma 4.2 yields

$$\{a_j \geq h^d\} \Rightarrow \left\{b_j \geq a_j^{1/d} - \frac{1}{a_j q^{2d^2}}\right\} \Rightarrow \left\{b_j \geq a_j^{1/d} - \frac{1}{q^{d^2}}\right\}. \tag{5}$$

Therefore,

$$\begin{aligned}\sum_{j=1}^{k} b_j \geq \sum_{\substack{j\in[k]\\ a_j \geq h^d}} \left(a_j^{1/d} - \frac{1}{q^{d^2}}\right) &= \sum_{j=1}^{k}\left(a_j^{1/d} - \frac{1}{q^{d^2}}\right) - \sum_{\substack{j\in[k]\\ a_j < h^d}} \left(a_j^{1/d} - \frac{1}{q^{d^2}}\right) \\ &\geq \sum_{j=1}^{k}\left(a_j^{1/d} - \frac{1}{q^{d^2}}\right) - \sum_{\substack{j\in[k]\\ a_j < h^d}} a_j^{1/d} \\ &\geq \sum_{j=1}^{k}\left(a_j^{1/d} - \frac{1}{q^{d^2}}\right) - \sum_{\substack{j\in[k]\\ a_j < h^d}} h \\ &\geq \sum_{j=1}^{k}\left(a_j^{1/d} - \frac{1}{q^{d^2}}\right) - \left(\frac{k}{d}\right) h,\end{aligned}$$

where the last inequality uses Lemma 4.5. Taking an expectation we obtain,

$$\mathbb{E}_{j\in[k]}\left[b_j\right] \;\geq\; \mathbb{E}_{j\in[k]}\left[a_j^{1/d}\right] - \frac{1}{q^{d^2}} - \frac{h}{d} \;\geq\; h^{1/d} - \frac{1}{q^{d^2}} - \frac{h}{d} \;\geq\; h^{1/d}/2, \tag{6}$$

where second last inequality follows from (4) and the last inequality is due to the large enough setting of the parameters. Observe that,

$$h^{1/d} = \left(q^{-(d-1/2)}\right)^{1/d} = \left(R^{-4d(d-1/2)}\right)^{1/d} = R^{-4d+2}.$$

Using the above along with the construction of $\overline{G}$ we have,

$$\begin{aligned}1 - \frac{|N(T)|}{|\overline{U}|} &= \prod_{j=1}^{k}(1-b_j) \\ &\leq \left(\mathbb{E}_{j\in[k]}[1-b_j]\right)^k && \text{(By the AM-GM inequality)} \\ &\leq \left(1 - h^{1/d}/2\right)^k && \text{(Using (6))} \\ &\leq \left(1 - \frac{1}{2R^{4d-2}}\right)^{R^{4d-1}} \quad \leq\; e^{-R/2},\end{aligned}$$

which completes the proof of Lemma 4.4. ◀

4.2.3 Gap in the domain subset sizes

In the YES case there is a subset of $\overline{V}$ of fractional size at least

$$\beta := \left(\frac{0.99}{q^{d-1}}\right)^k \tag{7}$$

with neighborhood size at most $R^{-1}|\overline{U}|$, while in the NO case every subset of $\overline{V}$ of fractional size at least

$$h^k = \left(\frac{1}{q^{d-1/2}}\right)^k \tag{8}$$

has neighborhood of size at least $(1 - e^{-R/2})|\overline{U}|$. The subset size threshold in the NO case is much smaller than in the YES case with the gap being,

$$\left(\frac{\beta}{h^k}\right) = \left(\frac{0.99q^{d-1/2}}{q^{d-1}}\right)^k \geq q^{k/3} \geq e^R,$$

for large enough R, q, d which we may assume.

4.2.4 Setting the parameters and proof of Theorem 2.2

Given ε, τ and $\gamma > 0$, choose R large enough so that $\gamma \geq \max\{R^{-1}, e^{-R/2}\}$, and $\tau \geq e^{-R}$. Setting $d = \Theta((1/\varepsilon)\log((\log R)/\varepsilon))$ as per Theorem 3.4 along with Lemmas 4.3, Lemma 4.4, and Section 4.2.3 yields the proof of Theorem 2.2 with β given by (7).

5 Construction of the Quasi-Random PCP

The PCP given in Theorem 3.4 is a composition of an Outer Verifier which is an algebraic test on an instance of HomAlgCSP, with a Hadamard code based encoding (Inner Verifier). This is almost the same as the construction of [14], except that the Inner Verifier's encoding is over a larger field rather than $\mathbb{F}[2]$. We refer the reader to [14] for motivation behind this construction and its nuances, and instead give a concise description of the PCP and its analysis.

Let the HomAlgCSP instance be $\mathcal{A}(k = 21, d^*, m, \mathbb{F}, \mathcal{C})$. The Outer Verifier is given the polynomial f as a table of values at each point in $\mathbb{F}^m$, and it samples a constraint from $\mathcal{C}$ uniformly at random and attempts to verify whether it is satisfied by f, and whether the table of f is a polynomial of degree $\approx d^*$. We need the following definition of a *curve*.

▶ **Definition 5.1.** A *curve* L in $\mathbb{F}^m$ is a function $L : \mathbb{F} \mapsto \mathbb{F}^m$, where $L(t) = (a_1(t), \ldots, a_m(t))$. It is of degree d if each of the coordinate functions a_i is degree d (univariate) polynomial. A *line* is a curve of degree 1.

Let $t_1, t_2, \ldots, t_{k+3}$ be distinct field elements in $\mathbb{F}$ which we fix for the rest of the construction. Suppose the verifier chooses the constraint $C(\{\overline{p}_i\}_{i=1}^k) \in \mathcal{C}$ uniformly at random. For $\overline{a}, \overline{b}, \overline{c} \in \mathbb{F}^m$, define $L = L_{\overline{a},\overline{b},\overline{c}}$ be the unique degree $(k+2)$ curve that satisfies

$$L(t_i) = \overline{p}_i, \quad 1 \leq i \leq k, \quad L(t_{k+1}) = \overline{a}, \quad L(t_{k+2}) = \overline{b}, \quad L(t_{k+3}) = \overline{c}.$$

If f is a degree d^* multivariate polynomial over the vector space $\mathbb{F}^m$ then its restriction to the curve $L(t) = L_{\overline{a},\overline{b},\overline{c}}(t)$, denoted by $f|_L$, is a degree $d - 1 := (k+2)d^*$ univariate polynomial in t. This polynomial can be interpolated from any d values of f on the curve, which is then used to test its consistency at an additional random point. Similarly, given a line ℓ, the restriction of f, denoted by $f|_\ell$ is a degree d^* univariate polynomial. Allowing it degree up to $(d-2)$ it is interpolated using the values of f at $(d-1)$ random points on ℓ, which is used to run the Low Degree test. The following is the description of the Outer Verifier.

5.1 Outer Verifier

Steps of the Outer Verifier

1. Pick a constraint $C = \{\overline{p}_i\}_{i=1}^{k} \in \mathcal{C}$ at random.
2. Pick a random line ℓ in $\mathbb{F}^m$ and pick random points $\overline{v}_1, \ldots, \overline{v}_{d-1}, \overline{v}_d$ on the line.
3. Pick $t \in \mathbb{F} \setminus \{t_1, \ldots, t_{k+3}\}$ at random, points $\overline{a}, \overline{b}$ at random from $\mathbb{F}^m$ and let L be the unique degree $k+2$ curve $L = L_{\overline{a},\overline{b},\overline{c}}$ such that,
$$L(t_i) = \overline{p}_i, \quad 1 \le i \le k, \quad L(t_{k+1}) = \overline{a}, \quad L(t_{k+2}) = \overline{b}, \quad L(t) = \overline{v}_d,$$
and $\overline{c}$ is implicitly defined as $L(t_{k+3})$.
4. Pick random points $\overline{v}_{d+1}, \ldots, \overline{v}_{2d}$ on L.
5. Let $f|_\ell$ be the unique degree $d-2$ polynomial interpolated using the values $\{f(\overline{v}_i)\}_{i=1}^{d-1}$.
6. Let $f|_L$ be the unique degree $d-1$ polynomial interpolated using the values $\{f(\overline{v}_i)\}_{i=d+1}^{2d}$.
7. Check if,
$$f|_L(\overline{v}_d) = f(\overline{v}_d) = f|_\ell(\overline{v}_d).$$
8. Check if the values of $f|_L$ at points $\{\overline{p}_i\}_{i=1}^{k}$ satisfy the constraint C.
9. Check that the values $f(\overline{v}_i)$, $1 \le i \le 2d$ are not all zero.

As in [14], the Outer Verifier can be replaced by the following *Modified Outer Verifier* which reads more values from the proof and makes additional tests, and additionally abstracts out: (i) interpolation into multiplication by an invertible matrix, and (ii) checking the homogeneous constraints of the Outer Verifier into checking orthogonality with a certain subspace. Our construction is the same, except that instead of $\mathbb{F}[2]$ we shall use an extension field $\mathbb{F}[q]$ as the underlying field of representation, where q is as given in Theorem 3.4 and $\mathbb{F}$ in Theorem 3.2 is chosen to be an extension of $\mathbb{F}[q]$.

5.2 Modified Outer Verifier

Since $\mathbb{F}$ is an extension of $\mathbb{F}[q]$ the elements of $\mathbb{F}$ are represented as $\mathbb{F}[q]$-vectors of a length $l = (\log|\mathbb{F}|)/(\log q)$. Moreover, the representation can be chosen such that addition over $\mathbb{F}$ and multiplication by a constant in $\mathbb{F}$ are homogeneous linear operations on these vectors. The Modified Outer Verifier is given a table of values $f(\overline{v})$ (in the form of l length $\mathbb{F}[q]$-vectors) for every point $\overline{v} \in \mathbb{F}^m$ and it executes the following steps:

Steps of the Modified Outer Verifier

1. Pick a constraint $C = \{\overline{p}_i\}_{i=1}^{k} \in \mathcal{C}$ at random.
2. Pick a random line ℓ in $\mathbb{F}^m$ and pick random points $\overline{v}_1, \ldots, \overline{v}_{d-1}, \overline{v}_d$ on the line.
3. Pick $t \in \mathbb{F} \setminus \{t_1, \ldots, t_{k+3}\}$ at random, points $\overline{a}, \overline{b}$ at random from $\mathbb{F}^m$ and let L be the unique degree $k+2$ curve $L = L_{\overline{a},\overline{b},\overline{c}}$ such that,
$$L(t_i) = \overline{p}_i, \quad 1 \le i \le k, \quad L(t_{k+1}) = \overline{a}, \quad L(t_{k+2}) = \overline{b}, \quad L(t) = \overline{v}_d.$$
and $\overline{c}$ is implicitly defined to be $L(t_{k+3})$.
4. Pick random points $\overline{v}_{d+1}, \ldots, \overline{v}_{2d}$ on the curve L.
5. Pick additional random points $\overline{u}_1 \ldots \overline{u}_d$ on the line ℓ and $\overline{u}_{d+1}, \ldots, \overline{u}_{2d}$ from the curve L.
6. Let $T_{2ld \times 2ld}$ be an appropriate invertible matrix over $\mathbb{F}[q]$ and H be an appropriate subspace of $\mathbb{F}[q]^{2ld}$. Both depend only on the choice of the points $\{\overline{v}_i\}_{i=1}^{2d}$ and $\{\overline{u}_j\}_{j=1}^{2d}$. Remark 5.2 explains how T and H are chosen.

7. Read the values of the function f from the table at the points $\overline{v}_1, \dots, \overline{v}_{2d}$ and $\overline{u}_1, \dots, \overline{u}_{2d}$. Since the values are represented by length l $\mathbb{F}[q]$-vectors, let
$$x = f(\overline{v}_1) \circ f(\overline{v}_2) \circ \cdots \circ f(\overline{v}_{2d}) \tag{9}$$
$$y = f(\overline{u}_1) \circ f(\overline{u}_2) \circ \cdots \circ f(\overline{u}_{2d}) \tag{10}$$
where $\circ$ represents concatenation of vectors.
8. Accept iff,
$$x \neq 0, \; x = Ty \qquad \text{and} \qquad h \cdot x = 0 \quad \forall\, h \in H \quad (\text{i.e. } x \perp H). \tag{11}$$

▶ Remark 5.2. The choice of H is such that $h \cdot x = 0 \;\forall\; h \in H$ abstracts out the conditions: (i) the values at the field elements $\{t_i\}_{i=1}^k$ of the degree $d-1$ univariate polynomial interpolated from $f(\overline{v}_{d+1}) \dots f(\overline{v}_{2d})$ satisfy the homogeneous linear constraints of C, and (ii) the polynomial interpolated from the values $f(\overline{v}_1) \dots f(\overline{v}_{d-1})$ agrees with the degree $d-1$ polynomial interpolated from $f(\overline{v}_{d+1}) \dots f(\overline{v}_{2d})$ at the point $\overline{v}_d$, where both evaluate to $f(\overline{v}_d)$.

The invertible matrix T is chosen such that the constraint $x = Ty$ abstracts out the conditions: (i) the degree $d-1$ polynomial interpolated from the values $f(\overline{v}_1) \dots f(\overline{v}_d)$ is the same as the polynomial interpolated from the values $f(\overline{u}_1) \dots f(\overline{u}_d)$, and (ii) the degree $d-1$ polynomial interpolated from $f(\overline{v}_{d+1}) \dots f(\overline{v}_{2d})$ is the same as the polynomial interpolated from the values $f(\overline{u}_{d+1}) \dots f(\overline{u}_{2d})$.

The condition $x \neq 0$ essentially ensures that f is not a zero polynomial.

The following theorem, regarding the acceptance probability of the Outer Verifier, was proved in [14].

▶ **Theorem 5.3.** *There are constants c_1, c_2 such that the following holds. If, after picking a constraint $C(\{\overline{p}_i\}_{i=1}^k) \in \mathcal{C}$, the Outer Verifier (or the Modified Outer Verifier) accepts with probability δ, then for $1 \leq t \leq 2c_2/(\delta/2)^{c_1}$, $P_1, P_2, \dots, P_t$ are all the degree d polynomials that have agreement at least $(\delta/2)^{c_1}/c_2$ with f and for some $1 \leq j \leq t$, P_j is a non-zero polynomial whose values at the points $\{\overline{p}_i\}_{i=1}^k$ satisfies the constraint C.*

5.3 Inner Verifier

The Inner Verifier expects, for every point $\overline{v} \in \mathbb{F}^m$, the Hadamard Code of $f(\overline{v}) \in \mathbb{F}[q]^l$. (See Section 7 for a description of the Hadamard Code).

Steps of the Inner Verifier

1. Pick a constraint $C \in \mathcal{C}$ and the points $\overline{v}_1, \dots, \overline{v}_{2d}$ and $\overline{u}_1, \dots, \overline{u}_{2d}$ as in steps $1-5$ of the Modified Outer Verifier.
2. Let $T_{2ld \times 2ld}$ and H be the matrix and subspace respectively chosen as in step 7 of the Modified Outer Verifier.
3. Pick a random string $z \in (\mathbb{F}[q]^l)^{2d}$ and a random $h \in H$. Write,
$$z = z_1 \circ z_2 \circ \cdots \circ z_{2d}$$
$$h = h_1 \circ h_2 \circ \cdots \circ h_{2d}$$
$$zT = w_1 \circ w_2 \circ \cdots \circ w_{2d}.$$
4. Let $A_1, \dots, A_{2d}$ and $B_1, \dots, B_{2d}$ be the tables giving the supposed Hadamard Codes of $f(\overline{v}_1), \dots, f(\overline{v}_{2d})$ and $f(\overline{u}_1), \dots, f(\overline{u}_{2d})$ respectively.
5. Accept iff $\sum_{i=1}^{2d} A_i(z_i + h_i) + \sum_{j=1}^{2d} B_j(w_j) = 0$.

5.4 Analysis

Let Π_* be a subset of locations of the proof Π given to the Inner Verifier. Setting the locations of Π_* to be 1 and the rest of the locations to zero, we obtain the tables A_i and B_i ($1 \leq j \leq 2d$) which are queried in the description of the Inner Verifier. We wish to analyze the probability over a random test Q of the Inner Verifier that the locations queried by it are contained inside $\Pi*$, i.e.

$$\Pr_Q \left[Q \subseteq \Pi_* \right].$$

This is first arithmetized to,

$$\mathbb{E}_Q \left[\prod_{i=1}^{2d} A_i(z_i + h_i) \prod_{j=1}^{2d} B_j(w_j) \right]. \tag{12}$$

Here Q depends on the choice of the constraint C, the line ℓ and curve L, the points $\overline{v}_1, \ldots, \overline{v}_{2d}, \overline{u}_1, \ldots, \overline{u}_{2d}$, and the choice of z and h. Plugging in the Fourier expansion (see Section 6) of the A_i and B_i we obtain,

$$\begin{aligned} & \mathbb{E}_Q \left[\sum_{\alpha_1,\ldots,\alpha_{2d},\beta_1,\ldots,\beta_{2d}} \left[\prod_{i=1}^{2d} \widehat{A}_{i,\alpha_i} \prod_{j=1}^{2d} \widehat{B}_{j,\beta_j} \prod_{i=1}^{2d} \chi_{\alpha_i}(z_i + h_i) \prod_{j=1}^{2d} \chi_{\beta_j}(w_j) \right] \right] \\ = \quad & \mathbb{E}_Q \left[\sum_{\substack{\alpha=\alpha_1\circ\cdots\circ\alpha_{2d}, \\ \beta=\beta_1\circ\cdots\circ\beta_{2d}}} \left[\prod_{i=1}^{2d} \widehat{A}_{i,\alpha_i} \prod_{j=1}^{2d} \widehat{B}_{j,\beta_j} \cdot \phi(\alpha \cdot z + \beta \cdot w) \cdot \phi(\alpha \cdot h) \right] \right], \end{aligned} \tag{13}$$

where $\phi : \mathbb{F}[q] \to \{-1, 1\}$ is defined in Section 6. Now, since h is randomly chosen from H, the above expectation is zero unless $\alpha \perp H$. Also,

$$\begin{aligned} z \cdot \alpha + w \cdot \beta &= z \cdot \alpha + zT \cdot \beta \\ &= z \cdot (\alpha + T\beta) \end{aligned}$$

which implies that the expectation in (13) is zero unless $\alpha = T\beta$, since z is chosen randomly from $\mathbb{F}[q]^{2ld}$. Therefore we obtain the following expression,

$$\mathbb{E}_{\substack{C,\ell,L,\overline{v}_1,\ldots,\overline{v}_{2d} \\ \overline{u}_1,\ldots,\overline{u}_{2d}}} \left[\sum_{\substack{\alpha=\alpha_1\circ\cdots\circ\alpha_{2d}, \\ \beta=\alpha_1\circ\cdots\circ\beta_{2d}, \\ \alpha\perp H,\ \beta=T^{-1}\alpha}} \left[\prod_{i=1}^{2d} \widehat{A}_{i,\alpha_i} \prod_{j=1}^{2d} \widehat{B}_{j,\beta_j} \right] \right]. \tag{14}$$

5.4.1 YES Case

We prove the following lemma.

▶ **Lemma 5.4.** *If the instance $\mathcal{A}$ of* HomAlgCSP *is a* YES *instance then there exists a subset Π_* of $1/q$ fraction of the proof locations such that*

$$\Pr_Q \left[Q \subseteq \Pi_* \right] \geq \frac{1}{q^{4d-1}} \left(1 - \frac{1}{2^K} \right).$$

Proof. Let f be the polynomial given by the YES case. Since f is of degree at most d^*, it is nonzero at all points except for a negligible fraction ($O(d^*/|\mathbb{F}|)$) which we ignore. Construct the proof Π as follows: For each point $\overline{v} \in \mathbb{F}^m$ let the corresponding table $A_{\overline{v}}$ be defined as:

$$A_{\overline{v}}(x) = \begin{cases} 1 & \text{if the Hadamard Code of } f(\overline{v}) \text{ at location } x \text{ is } 0 \in \mathbb{F}[q], \\ 0 & \text{otherwise.} \end{cases} \tag{15}$$

Now, let Π_* be the subset of locations where Π is 1. Since we are dealing with Hadamard Codes of nonzero values, Π_* is exactly $(1/q)$ fraction of the locations. Also, from Lemma 7.1,

$$A_{\overline{v}} = (1/q) \sum_{t \in \mathbb{F}[q]} \chi_{tf(\overline{v})},$$

where $f(\overline{v})$ in the is represented as an element of $\mathbb{F}[q]^l$. Using this, we see that when the constraint C is satisfied by f, for each $t \in \mathbb{F}[q]$ setting $\alpha_i = tf(\overline{v}_i)$ and $\beta_i = tf(\overline{u}_i)$ $(1 \leq i \leq 2d$ where the f values are represented as elements of $\mathbb{F}[q]^l$) contributes $1/q^{4d}$ in (14). Since $1 - 1/2^K$ fraction of the constraints are satisfied by f in the YES case of Theorem 3.2 the lemma follows. ◀

5.4.2 NO Case

The NO case soundness is given by the following lemma.

▶ **Lemma 5.5.** *Let Π_* be any subset of $\zeta \in [0, 1]$ fraction of locations of the proof Π. Then, if $\mathcal{A}$ is a* NO *instance then,*

$$\left| \Pr_Q [Q \subseteq \Pi_*] - \zeta^{4d} \right| \leq \frac{C_0}{2^{2^K/C_1}}, \tag{16}$$

for some universal constants $C_0, C_1 > 0$.

Proof. Suppose that,

$$\left| \Pr_Q [Q \subseteq \Pi_*] - \zeta^{4d} \right| = \delta. \tag{17}$$

Let the proof Π evaluate to 1 at the locations in Π^* and zero otherwise. Thus,

$$\mathbb{E}_{\overline{v}} \left[\widehat{A}_{\overline{v}} \right] = \zeta.$$

Using the mixing property of curves and lines (refer to Appendix A.4 of [14]) we obtain that for the random line ℓ and curve L chosen by the Outer Verifier, except with probability $O(1/|\mathbb{F}|^{1/3})$ (which we shall ignore),

$$\forall\ i = 1, \ldots, 2d \quad \mathbb{E}_{\overline{v}_i \in \ell}[\widehat{A}_{i,0}] \approx \zeta \quad , \quad \mathbb{E}_{\overline{u}_j \in \ell}[\widehat{B}_{j,0}] \approx \zeta$$

where again the error in the above approximations is bounded by $O(1/|\mathbb{F}|^{1/3})$ which we shall ignore. Thus, the contribution of $\alpha = 0$ in (14) is (up to negligible error) ζ^{4d}. From (17), an analysis identical to that in Section 10.5 of [14] yields a table of values f such that the Outer Verifier accepts with probability δ^2 over a randomly chosen constraint $C \in \mathcal{C}$ of the HomAlgCSP instance $\mathcal{A}$. Thus, for at least $\delta^2/2$ of the constraints C, the Outer Verifier accepts with probability $\delta^2/2$. Using Theorem 5.3, this implies that there is a degree $d \leq (21+3)d^* \leq 100d^*$ polynomial which satisfies at least $(\delta/C_0)^{C_1}$ fraction of the constraints of $\mathcal{A}$ for some universal constants $C_0, C_1 > 0$. This contradicts the NO case of Theorem 3.2 unless δ is at most the RHS of (16), thus completing the proof of the lemma. We omit further details and refer the reader to [14]. ◀

5.4.3 Setting the parameters

The various parameters of the PCP reduction from HomAlgCSP are set so that Lemmas 5.4 and5.5 along with Theorem 3.2 yield Theorem 3.4. First we change $4d$ to d in Lemmas 5.4 and 5.5. As in Theorem 3.4, $q := R^{4d}$. We set $d := \Theta(2^{K/3}/(\log R))$ so that,

$$\frac{1}{2^K} = O\left(\frac{1}{d^3}\right) \quad \text{and} \quad \frac{C_0}{2^{2^K/C_1}} \leq \frac{1}{q^{2d^2}},$$

appropriately bounding the errors in Lemmas 5.4 and 5.5. Note that $d \leq (21+3)\cdot 10\cdot 4\cdot \tilde{d} \leq 1000\tilde{d}$ (where $\tilde{d}$ is as in Theorem 3.2). Thus, choosing $m = n^{1000\Delta K/d}$ yields $\binom{m}{\tilde{d}} \geq N$ as required, and that the entire reduction runs in time 2^{n^ε} where $\varepsilon = \Theta(K/d)$ can be made arbitrarily small by choosing K large enough. Rearranging, $d = \Theta((1/\varepsilon)\log((\log R)/\varepsilon))$.

6 Fourier Analysis

We will be working over the field $\mathbb{F}[q] := \mathbb{F}[2^r]$ for $r > 0$, which is a field extension of $\mathbb{F}[2]$. Let φ be the isomorphism from the additive group $(\mathbb{F}[2^r], +)$ to $(\mathbb{F}[2]^r, +)$. Define the following homomorphism ϕ from $(\mathbb{F}[2^r], +)$ to the multiplicative group $(\{-1, 1\}, .)$.

$$\phi(a) = \begin{cases} 1 & \text{if } \varphi(a) \text{ contains even number of 1s} \\ -1 & \text{otherwise} \end{cases}$$

for any $a \in \mathbb{F}[2^r]$. Note that $\phi(a+b) = \phi(a)\phi(b)$, $\forall a, b \in \mathbb{F}[2^r]$. We now define the 'characters' $\psi_a : \mathbb{F}[2^r] \mapsto \{-1, 1\}$ for $a \in \mathbb{F}[2^r]$ as follows.

$$\psi_a(b) := \phi(ab)$$

The characters ψ_a satisfy the following properties.

$$\begin{aligned} \psi_0(b) &= 1 & \forall b \in \mathbb{F}[2^r] \\ \psi_a(0) &= 1 & \forall a \in \mathbb{F}[2^r] \\ \psi_{a+b}(c) &= \psi_a(c)\psi_b(c) \end{aligned}$$

and,

$$\sum_{a \in \mathbb{F}[2^r]} \psi_a(b) = \begin{cases} |\mathbb{F}[2^r]| & \text{if } b = 0 \\ 0 & \text{otherwise} \end{cases}$$

We note that the 'character' functions form an orthonormal basis for the space $L^2(\mathbb{F}[2^r])$. We have that,

$$\langle \psi_a, \psi_b \rangle = \begin{cases} 1 & \text{if } a = b \\ 0 & \text{otherwise} \end{cases}$$

where,

$$\langle \psi_a, \psi_b \rangle := \mathbb{E}_{c \in \mathbb{F}[2^r]}\left[\psi_a(c)\psi_b(c)\right].$$

We now consider the vector space $\mathbb{F}[2^r]^m$ for some positive integer m. We define the 'characters' $\chi_\alpha : \mathbb{F}[2^r]^m \mapsto \{-1, 1\}$ for every $\alpha \in \mathbb{F}[2^r]^m$ as,

$$\chi_\alpha(f) := \phi(\alpha \cdot f), \qquad f \in \mathbb{F}[2^r]^m$$

where '$\cdot$' is the inner product in the vector space $\mathbb{F}[2^r]^m$. From the way we defined the characters ψ_a, we have,

$$\chi_\alpha(f) = \prod_{i=1}^{m} \psi_{\alpha_i}(f_i),$$

where α_i and f_i are the i^{th} coordinates of α and f respectively. The characters χ_α satisfy the following properties,

$$\begin{aligned} \chi_0(f) &= 1 && \forall f \in \mathbb{F}[2^r]^m \\ \chi_\alpha(0) &= 1 && \forall \alpha \in \mathbb{F}[2^r]^m \\ \chi_{\alpha+\beta}(f) &= \chi_\alpha(f)\chi_\beta(f) \\ \chi_\alpha(f+g) &= \chi_\alpha(f)\chi_\alpha(g) \end{aligned}$$

and,

$$\mathbb{E}_{f\in\mathbb{F}[2^r]^m}\left[\chi_\alpha(f)\right] = \begin{cases} 1 & \text{if } \alpha = 0 \\ 0 & \text{otherwise} \end{cases}$$

The characters χ_α form an orthonormal basis for $L^2(\mathbb{F}[2^r]^m)$. We have,

$$\langle \chi_\alpha, \chi_\beta \rangle = \begin{cases} 1 & \text{if } \alpha = \beta \\ 0 & \text{otherwise} \end{cases}$$

where,

$$\langle \chi_\alpha, \chi_\beta \rangle := \mathbb{E}_{f\in\mathbb{F}[2^r]^m}\left[\chi_\alpha(f)\chi_\beta(f)\right].$$

Let $A : \mathbb{F}[2^r]^m \mapsto \mathbb{R}$ be any real valued function. Then the Fourier expansion of A is given by,

$$A(x) = \sum_{\alpha\in\mathbb{F}[2^r]^m} \widehat{A}_\alpha \chi_\alpha(x),$$

where,

$$\widehat{A}_\alpha = \mathbb{E}_{x\in\mathbb{F}[2^r]^m}[A(x)\chi_\alpha(x)].$$

A useful equality is:

$$\widehat{A}_0 = \mathbb{E}_{x\in\mathbb{F}[2^r]^m}[A(x)].$$

7 Hadamard Codes

Let l be a positive integer and $\mathbb{F}[q]$ be an extension of $\mathbb{F}[2]$. Then, for any $a \in \mathbb{F}[q]^l$, its Hadamard Code $H_a : \mathbb{F}[q]^l \to \mathbb{F}[q]$ is given by $H_a(x) = a \cdot x = \sum_{i=1}^{l} a_i x_i$. We have the following simple lemma.

▶ **Lemma 7.1.** *For any $a \in \mathbb{F}[q]^l$, let $A : \mathbb{F}[q]^l \to \{0,1\}$ be defined as $A(x) := \mathbb{1}\{H_a(x) = 0\}$. Then,*

$$A = (1/q) \sum_{t\in\mathbb{F}[q]} \chi_{ta}.$$

Proof. If $a = 0$, then A is identically 1, and thus $A = \chi_0 = (1/q)\sum_{t\in\mathbb{F}[q]} \chi_{ta}$. If $a \neq 0$, then $\mathbb{E}_x[A(x)] = \Pr_x[a \cdot x = 0] = 1/q$. Further,

$$\{A(x) = 1\} \Leftrightarrow \{a \cdot x = 0\} \Leftrightarrow \{ta \cdot x = 0,\ \forall t \in \mathbb{F}[q]\} \Rightarrow \{\chi_{ta}(x) = 1,\ \forall t \in \mathbb{F}[q]\}.$$

Thus, $\widehat{A}_{ta} = \mathbb{E}_x[A(x)\chi_{ta}(x)] = \mathbb{E}_x[A(x)] = 1/q$, for all $t \in \mathbb{F}[q]$. By Parseval's identity these are the only non-zero Fourier coefficients. ◀

Abstract

We present the first streaming algorithm for the longest path problem in undirected graphs. The input graph is given as a stream of edges and RAM is limited to only a linear number of edges at a time (linear in the number of vertices n). We prove a per-edge processing time of $\mathcal{O}(n)$, where a naive solution would have required $\Omega(n^2)$. Moreover, we give a concrete linear upper bound on the number of bits of RAM that are required.

On a set of graphs with various structure, we experimentally compare our algorithm with three leading RAM algorithms: Warnsdorf (1823), Pohl-Warnsdorf (1967), and Pongrácz (2012). Although conducting only a small constant number of passes over the input, our algorithm delivers competitive results: with the exception of preferential attachment graphs, we deliver at least 71% of the solution of the best RAM algorithm. The same minimum relative performance of 71% is observed over *all* graph classes after removing the 10% worst cases. This comparison has strong meaning, since for each instance class there is one algorithm that on average delivers at least 84% of a Hamilton path. In some cases we deliver even better results than any of the RAM algorithms.

1 Introduction

Let $G = (V, E)$ be an undirected, simple, and finite graph (all our graphs are of this type). A *path* of length k in G is a sequence of k distinct vertices $(v_1, \ldots, v_k)$ such that $v_i v_{i+1} \in E$ for each $1 \leq i < k$. (We write uv or vu for the undirected edge $\{u, v\}$ between vertices u and v.) In the *longest path problem* (LPP), we ask for a path in G that has maximum length among all the paths in G. This problem is NP-hard as seen easily by a reduction from the Hamilton cycle problem. A long line of research has investigated its approximability,

* Supported by German Research Foundation (DFG), Grant SR7/15-1 *Algorithmic Foundations for Genome Assembly.*

and several polynomial-time heuristics and algorithms with proven worst-case guarantee are known. With increasing size of the input graph, not only the time complexity of an algorithm becomes important but also its space complexity. For large graphs G, e. g., graphs that occur in genome assembly, it is not realistic anymore to assume that G can be fully stored in (fast) random-access memory (RAM). Instead we should assume that it can only be accessed efficiently in a *sequential* manner. The *graph streaming model* formalizes this. Here, the graph is given as a sequence $e_1, \dots, e_m$ of its edges, and access is only provided in the form of *passes*: a *pass* means each edge in the sequence is presented to the algorithm once. RAM is restricted to $\mathcal{O}(n \cdot \operatorname{poly}\log(n))$ bits, so essentially we can store a number of edges linear in the number n of vertices. Besides the solution quality, the most important property of a streaming algorithm is the number of passes that it has to conduct in order to obtain a good solution. To be practical, this number should be a small constant. This model does not only make sense when the input is stored on a disk or remote server, but also in the context of memory hierarchies, where cache RAM is several magnitudes faster than main RAM.

The standard graph search techniques breadth-first search (BFS) and depth-first search (DFS) cannot be done in the streaming model within a constant number of passes [13]. However, all relevant existing algorithms for the LPP use some form of graph search and/or require super-linear data structures (as in the dynamic programming part for color coding [1]). We therefore take a different approach that will never have to do a graph search on a graph with more than a linear number of edges and moreover does not require more than a linear amount of RAM for additional data structures.

1.1 Our Contribution

We give a streaming algorithm for the longest path problem in undirected graphs with a proven per-edge processing time of $\mathcal{O}(n)$. Our algorithm works in two phases, which we outline here briefly and explain in detail in Section 3. In the first phase, global information on the graph is gathered in form of a constant number of spanning trees[1] $T_1, \dots, T_\tau$. This is possible in the streaming model since roughly speaking, for a spanning tree we can 'take edges as they come'. A spanning tree can be constructed in just one pass – we however use multiple passes and limit the maximum degree during the first passes in order to favor path-like structures and avoid clusters of edges. Experiments clearly indicate that this degree-limiting is essential for solution quality. The spanning trees fit into RAM, since we consider τ as constant (we will in fact have $\tau = 1$ or $\tau = 2$ in the experiments). After construction of the τ trees, they are merged into one graph U by taking the union of their edges. Then we use standard algorithms to determine a long path P in U, isolate P, and finally add enough edges around P to obtain a tree T.

Then, in the second phase, we conduct further passes during which we test if the exchange of single edges of T can improve the longest path in it. (A longest path in a tree can be found by conducting DFS two times [10]; the length of a longest path in a tree is its diameter.) The main challenge in the second phase is to quickly determine which edges should be exchanged. We show that this decision can be made in linear time, hence yielding a per-edge processing time of $\mathcal{O}(n)$.

An experimental study is conducted on randomly generated instances with different structure, including ones created with the recently published generator for hyperbolic geometric

[1] For simplicity, we always assume that our input graphs are connected, but it would be easy to adapt our algorithm to the general case.

random graphs [30]. Different variants of our streaming algorithm are compared with four RAM algorithms: Warnsdorf and Pohl-Warnsdorf (two related classical heuristics [24, 25]), Pongrácz (a recently published heuristic [26]), and a simple randomized DFS. Experiments show that although we never do more than 11 passes, results delivered by our algorithm are competitive. We deliver at least 71% of the best result delivered by any of the tested RAM algorithms, with the exception of preferential attachment graphs. By considering low percentiles, we observe a similar quality without any restriction on the graph class. This is a good result also in absolute terms, since we observe that for each graph class and set of parameters, there is one algorithm that on average gives a path of length $0.84 \cdot n$, i. e., 84% of a Hamilton path. On some graph classes, we outperform any of the tested RAM algorithms, which makes our algorithm interesting even outside of the streaming setting. A detailed discussion of results is given in Section 7.

1.2 Previous and Related Work

Algorithms for the LPP have been studied extensively in the RAM model. We start listing algorithms with proven guarantees. Bodlaender [9] and Monien [22] gave algorithms that find a path of length k (if it exists) in $\mathcal{O}(2^k k!\, n)$ and $\mathcal{O}(k!\, nm)$ time, respectively. Alon et al. [1] introduced the method of *color coding* and based on that gave an algorithm running in expected time $2^{\mathcal{O}(k)} n$. There is a recent randomized algorithm by Björklund et al. [7] that given k, finds a path of length k (if it exists) in $\mathcal{O}(1.66^k \cdot \operatorname{poly} n)$ time (see also [19, 32, 5]). Those works show that the problem is fixed-parameter tractable: a path of length k can be found (if it exists) in polynomial time, for fixed k. The particular dependence of the running time on k (factorial or exponential) determines up to which k we stay polynomial and thus determines the length guarantee for a polynomial-time approximation algorithm.

In Hamiltonian graphs, a path of length $\Omega\Big(\big(\frac{\log(n)}{\log\log(n)}\big)^2\Big)$ can be found with the algorithm by Vishwanathan [29]; and Feder et al. gave further results for sparse Hamiltonian graphs [11]. Björklund and Husfeldt [6] gave an algorithm that finds a path of length $\Omega\big(\frac{(\log(\mathrm{opt}))^2}{\log\log(\mathrm{opt})}\big)$, where opt is the length of a longest path. It works by a decomposition of the graph into paths and cycles. Their technique subsequently was extended by Gabow [14] and Gabow and Nie [15] yielding guarantees for the length of the path of $\exp\big(\Omega\big(\sqrt{\frac{\log(\mathrm{opt})}{\log\log(\mathrm{opt})}}\big)\big)$ and $\exp(\Omega(\sqrt{\log(\mathrm{opt})}))$, respectively. Apart from that, the field is dominated by heuristics, such as (Pohl-)Warnsdorf [24, 25] and Pongrácz [26].

The Björklund-Husfeldt algorithm uses color coding as an important subroutine. We implemented and tested a simple algorithm based on color coding, which gave inferior results and more importantly took very long time to complete, substantially longer than (Pohl-)Warnsdorf, Pongrácz, or our algorithm. Details will be given in the full version. Thus we refrained from further implementing the Björklund-Husfeldt algorithm. (The original description in [6] uses Bodlaender's algorithm [9], which has an even higher running time than color coding.) The Gabow-Nie algorithm [15] does not use color coding, but at the time of writing was only available as a short conference version, making it difficult to implement.

Several non-approximability results have been shown by Karger et al. [17]: a constant-factor approximation is NP-hard; and for any $\varepsilon > 0$, the LPP cannot be approximated with a ratio of $2^{\mathcal{O}(\log^{1-\varepsilon}(n))}$, unless NP $\subseteq$ DTIME$(2^{\mathcal{O}(\log^{1/\varepsilon}(n))})$, that is, such an approximation is quasi-NP-hard. Bazgan et al. showed that the same holds even when restricting to cubic Hamiltonian graphs [4].

The LPP is also interesting in directed graphs. For any $\varepsilon > 0$, it is NP-hard to approximate in directed graphs within $n^{1-\varepsilon}$ [8]. The best approximation guarantee in the directed case (unless restricting to special classes of graphs) is still the color coding algorithm that also works in the undirected case [1]. For special graph classes, there exist exact polynomial-time algorithms, e. g., for (undirected) trees (given by Dijkstra around 1960, see [10] for a proof), for directed acyclic graphs [27, pp. 661-666], for grid graphs [18], and for cactus graphs [28, 21].

The study of graph problems in streaming models started around the beginning of the 21st century, see [2, 12] for early works. The idea of using a linear amount of memory is due to Muthukrishnan [23]. Up to then, the ‘streaming’ term was associated with sub-linear memory, which is not enough for many graph problems [12]. To emphasize the difference, the streaming model with linear RAM (that we use) is also referred to as the *semi-streaming model* in the literature.

Since then, many kinds of graph problems have been addressed, such as shortest paths, spanning trees, connectivity, cuts, matching, and vertex cover. Several lower bounds are known. Most importantly for us, Feigenbaum et al. [13] proved that any BFS algorithm computing the first k layers with probability at least $2/3$, requires more than $k/2$ passes if staying within $\mathcal{O}(n \cdot \operatorname{poly}\log(n))$ memory (see Guruswami and Onak [16] for improved lower bounds). This constitutes a substantial hurdle when transferring existing algorithms into the streaming model. To the best of our knowledge, longest paths have not been addressed before in a streaming model.

It must be emphasized that streaming techniques also make sense when the graph is of size $c \cdot n \cdot \log(n)$ if a streaming algorithm can guarantee to stay within $c' \cdot n \cdot \log(n)$ for $c' < c$. Therefore, we give a memory guarantee for our algorithm using concrete constants.

1.3 Ongoing and Future Work

A major practical motivation for this work is the genome assembly problem. There, a graph is built based on the output of a sequencing machine, and long paths in this graph correspond to large sub-sequences of the genome. However, there the graphs are usually directed. Therefore, our next step will be the extension of our algorithm to directed graphs and the integration of it into existing genome assembly software.

In a separate line of research, we will try to give a streaming algorithm for the LPP (undirected or directed) with a proven worst-case guarantee on the length of the path and number of passes. At this time, it is unclear if any of the established theoretical techniques, such as color coding and Björklund-Husfeldt-type decompositions, are feasible in the streaming model.

Outline. We briefly describe three known RAM algorithms in Section 2. In Section 3, all the details of our algorithm are explained. In Section 4 we analyze its theoretical properties. The experimental studies takes place in Section 5 to Section 8.

2 Previous Algorithms

Trees. An algorithm for longest paths in trees was presented by Dijkstra around 1960; a proof of correctness can be found in [10]. It consists of two invocations of DFS, the first starting at an arbitrarily chosen vertex (e. g., chosen uniformly at random), and the second starting at a vertex that is in the final layer constructed by the first DFS.

Warnsdorf and Pohl-Warnsdorf. Warnsdorf’s rule was originally presented in 1823 and is a DFS that always picks a neighbor with a minimum number of unvisited neighbors. In case there are multiple such neighbors to choose from, Pohl gave a refinement [24, 25]: we restrict to those neighbors which themselves have a minimum-degree neighbor. Each vertex is used once as the starting point of the DFS, and the best path found is returned. This gives a total runtime of $\mathcal{O}(nm)$.

Pongrácz. This algorithm was announced in 2012 [26] and to the best of our knowledge has not been thoroughly studied since. We give a technically slightly modified description here. Given a start vertex r, using BFS we compute for each vertex v its distance to r. Then, starting at a randomly chosen v, we conduct a DFS that always picks an unvisited neighbor with maximum distance to r. Each vertex is used once as the start r, and the longest path found is returned. In the original version, for each r, also *each* v is tried (and not just one chosen randomly). In order to stay within $\mathcal{O}(nm)$, we decided to enumerate only one of the two possibilities: either r or v. In preliminary experiments, we found the choice given here (enumerate all r, pick one v randomly) to be superior. We leave a thorough study of the different variants of Pongrácz's algorithm for future work.

3 Description of Our Streaming Algorithm

Our algorithm works in two phases: (1) spanning tree construction, (2) spanning tree diameter improvement. Phase (1) is characterized by a parameter $\tau \in \mathbb{N}$ and a sequence $D = (D_1, \ldots, D_{q_1})$ of degree limits, where $q_1 \geq 2$ and $D_{q_1} = \infty$. For each $i \in [\tau] = \{1, \ldots, \tau\}$, a tree T_i is constructed. We start with the empty graph $T_i = (V, \emptyset)$ and then add edges to T_i over a number of q_1 passes. In each pass $p \in [q_1]$, we add an edge to T_i iff that does not create any cycle and it does not increase the maximum degree in T_i beyond D_p. Since $D_{q_1} = \infty$, we arrive at a spanning tree eventually (recall that we assume all our input graphs to be connected). The motivation for the degree limit is to favor path-like structures over clusters of edges. As an extreme example, consider a complete graph. Without degree restriction, it is possible that a spanning tree is constructed that is a star; whereas with a degree restriction of 2, we find a Hamilton path during the first pass.

In order to not just create the same tree τ times, in the first pass, we pick a number $r \in [m]$ uniformly at random (where $e_1, \ldots, e_m$ is the stream of edges) and ignore any edges with an index smaller than r. Due to this offset for the first pass, it makes sense (but is not necessary) to use the same degree limit for the second pass. We will test $D = (2, \infty)$ and $D = (2, 2, 3, \infty)$ in experiments. By standard techniques (keeping track of the connected components), this algorithm can be implemented with a per-edge processing time of $\mathcal{O}(n)$: we can decide in $\mathcal{O}(1)$ if the current edge is to be inserted and if so, it takes $\mathcal{O}(n)$ to update connectivity information.

When all trees $T_1, \ldots, T_\tau$ have been constructed, we unite them into a graph $U := (V, \bigcup_{i=1}^{\tau} E(T_i))$. This graph will in general contain cycles, but it has no more than τn edges. Since we construct U from trees, it is guaranteed to be connected and to span all the vertices of the input graph. In U, a long path P is constructed with a RAM algorithm; we use the Warnsdorf algorithm for this task. The final step of the first phase is to isolate P and then to build a spanning tree T around it using the same technique as for the trees $T_1, \ldots, T_\tau$. Since we may assume that the constructions of $T_1, \ldots, T_\tau$ are fed from the same passes, we thus have $2q_1$ passes for the first phase. We summarize phase (1) in Algorithm 1, which uses procedure `SpanningTree`, also given below. For a set X, we write $x :=_{\mathrm{unif}} X$ to express that x is drawn uniformly at random from X.

When phase (1) is concluded, we determine a longest path P in the spanning tree T using the Dijkstra algorithm (Section 2). In phase (2), we try to modify this tree in order

```
Algorithm 1: Streaming Phase (1): Spanning Tree Construction
  Input: connected graph $G = (V, E)$ as a stream of edges, parameter $\tau$,
         degree limit sequence $D = (D_1, \dots, D_{q_1})$
  Output: spanning tree of $G$
1 foreach $i = 1, \dots, \tau$ do
2     $T_i \coloneqq (V, \emptyset)$;
3     SpanningTree ($T_i$);
4 $U \coloneqq (V, \bigcup_{i=1}^{\tau} E(T_i))$;
5 find a long path $P$ in $U$ using Warnsdorf's algorithm;
6 $T \coloneqq (V, E(P))$;
7 SpanningTree ($T$);
8 return $T$;
```

```
Procedure SpanningTree(T)
  Input: forest $T$ on $V$, possibly empty
  Output: spanning tree on $V$
1 $r \coloneqq_{\text{unif}} [m]$;
2 fast-forward the stream to position $r$;
3 for $p = 1, \dots, q_1$ do
4     while not at the end of the stream do
5         get next edge $vw$ from the stream;
6         if $T + vw$ is cycle-free and $\max\{\deg_T(v), \deg_T(w)\} < D_p$ then $T \coloneqq T + vw$;
7         if $|T| = n - 1$ then break;
8     rewind the stream to its beginning;
```

that it admits longer paths than P. A number of additional passes is conducted. In order to save time, we developed a criterion based on which we only consider a fraction of the edges during those passes. We explored the two options: (i) consider each edge independently with probability $\frac{n}{m+1}$ (resulting in only $\mathcal{O}(n)$ edges being considered); or (ii) skip an edge if both endpoints are on the so-far longest path P. After preliminary experiments, we decided for option (ii) due to better solution quality at a moderate runtime expense. A detailed comparison of (i) and (ii) is planned for the full version of this work; in our tables in Section 8, however we already give results for one variant of our algorithm using option (i).

For each edge e that is considered and that is not in T, we temporarily add e to T, creating a fundamental cycle C in $T' \coloneqq T + e$. We want to go back to a tree. To this end, we have to remove an edge from C. This edge is chosen so that among all possibilities, the resulting tree has maximum diameter.

It should not be assumed that an edge with both endpoints on P could not yield an improvement. Intuitively, relative to P it acts like a shortcut, but examples can be found where adding such an edge (and subsequently removing one edge from the fundamental cycle) improves the diameter of the tree. Still, criterion (ii) has shown to be effective in practice.

Phase (2) terminates after a preset number of passes q_2. We summarize phase (2) in Algorithm 2, where for any graph H, we denote $\ell(H)$ the length of a longest path in H.

Algorithm 2: Streaming Phase (2): Improvement

```
   Input: connected graph $G$ as a stream of edges, spanning tree $T$, pass limit $q_2$
   Output: a (long) path in $G$
1  compute longest path $P$ in $T$ with Dijkstra algorithm;
2  for $q_2$ times do
3      rewind the stream to its beginning;
4      while not at the end of the stream do
5          get next edge $e = vw$ from stream;
6          if $v \in V(P)$ and $w \in V(P)$ then discard and continue with next iteration;
7          $T' := T + e$;
8          compute fundamental cycle $C$ in $T'$;
9          $\ell^* := \max_{f \in E(C) \setminus \{e\}} \ell(T' - f)$;
10         if $\ell^* > |P|$ then
11             pick any $e'$ from the set $\{f \in E(C) \setminus \{e\} ;\ \ell(T' - f) = \ell^*\}$;
12             $T := T' - e'$;
13             update $P$ with longest path in $T$;
14 return $P$;
```

4 Properties of Our Streaming Algorithm

If the cycle C is of length $\Omega(n)$, then a naive implementation requires $\Omega(n^2)$ to find an edge e' to remove (temporarily remove each edge on the cycle and invoke the Dijkstra algorithm). However, we have:

▶ **Theorem 1.** *Phase (2) can be implemented with per-edge processing time $\mathcal{O}(n)$.*

Proof. An $\mathcal{O}(n)$ bound is clear for all lines of Algorithm 2, except line 9 and line 11. Denote

$$\ell' := \max_{f \in E(C) \setminus \{e\}} \max \{|P| \,;\ P \text{ is path in } T' - f \text{ and } e \in E(P)\}$$

and let $R' \subseteq E(C) \setminus \{e\}$ be the set of edges where this maximum is attained. Then the following implications hold: $\ell' \leq |P| \implies \ell^* \leq |P|$ and $\ell' > |P| \implies \ell' = \ell^*$. This is because if a longest path in $T' - f$ is supposed to be longer than P, it must use e (since otherwise it would be a path in T). Hence it suffices to determine ℓ', and if $\ell' > |P|$, to find an element of R'.

Denote $C = (v_1, \dots, v_k)$ the fundamental cycle for some $k \in \mathbb{N}$ written so that $e = v_1 v_k$. When computing ℓ', we can restrict to paths in T' of the form

$$(\dots, v_s, v_{s-1}, \dots, v_1, v_k, v_{k-1}, \dots, v_t, \dots) \tag{1}$$

for $1 \leq s < t \leq k$, where v_s is the first and v_t is the last common vertex, respectively, of the path and C. For each i, let T_i be the connected component of v_i in $T - E(C)$, i. e., T_i is the part of T that is reachable from v_i without using the edges of C. Denote $\ell(T_i)$ the length of a longest path in T_i that starts at v_i and denote $c_i := \ell(T_i) + i - 1$ and $a_i := \ell(T_i) + k - i$. Then a longest path entering C at v_s and leaving it at v_t, as in (1), has length exactly $c_s + a_t$. Hence we have to determine a pair (s, t) such that $c_s + a_t$ is maximum (this maximum value is ℓ'); we call such a pair an *optimal pair*. If the so determined value ℓ' is not greater than $|P|$, then nothing further has to be done (the edge e cannot give an improvement). Otherwise, having constructed our optimal pair (s, t), we pick an arbitrary edge (e. g., uniformly at random) from $\{v_i v_{i+1} \; ; \; s \leq i < t\}$, which are the edges between v_s and v_t on C. We show that the following algorithm computes the value ℓ' and an optimal pair in $\mathcal{O}(n)$.

```
compute $c_1, \ldots, c_{k-1}$ and $a_2, \ldots, a_k$ using DFS;
$M := 0$; $L := 0$;
for $i = 1, \ldots, k-1$ do
    if $c_i > M$ then
        $M := c_i$;
        $s := i$;
    if $M + a_{i+1} > L$ then
        $L := M + a_{i+1}$;
        $t := i + 1$;
return $(s, t)$;
```

The total of computations in line 1 can be done by DFS in $\mathcal{O}(n)$, and the loop in $\mathcal{O}(k) \leq \mathcal{O}(n)$. We prove that the final (s, t) is optimal. For fixed t, the best possible length $c_s + c_t$ is obtained if t is combined with an $s < t$ where $c_s \geq c_j$ for all $j < t$. In the algorithm, for each t (when $t = i + 1$ in the loop) we combine a_t with the maximum $\max_{j<t} c_j$ (stored in the variable M). Thus, when the algorithm terminates, $L = \ell'$ and $c_s + c_t = \ell'$. ◀

▶ **Corollary 2.** *Our streaming algorithm (with the two phases as in Algorithm 1 and Algorithm 2) can be implemented with a per-edge processing time of $\mathcal{O}(n)$.*

We turn to the memory requirement. Denote b the amount of RAM required to store one vertex or one pointer (e. g., $b = 32$ bit or $b = 64$ bit) and call $n \cdot b$ one *unit*.

▶ **Theorem 3.** *Our streaming algorithm (with the two phases as in Algorithm 1 and Algorithm 2) conducts at most $2q_1 + q_2$ passes. Moreover, the algorithm can be implemented such that the RAM requirement is at most $(\max\{4\tau, 2\tau + 4\} \cdot n + c) \cdot b$ with a constant c.*

Proof. The construction of each of the initial trees $T_1, \ldots, T_\tau$ can be fed from the same passes, so we obtain those τ trees within at most q_1 passes. After isolating the path P, we need at most q_1 more passes to get back to a spanning tree. A bound of q_2 for phase (2) is obvious. We turn to the memory requirement.

Phase (1). All the adjacency lists of one tree together require 2 units, plus 1 unit for an array of pointers to each of the lists. We need 1 additional unit per tree to store connectivity information during tree construction. This amounts to 4τ units for the main data structures at any time so far, plus a few extra bits required for bookkeeping (loop variables, etc) that are covered by the constant c. The graph U can be stored in $2\tau + 1$ units (adjacency lists plus pointer array). For the Warnsdorf algorithm, we need 1 unit to store DFS information (e. g., store the DFS tree as a predecessor relation) and 1 unit for the best path so far. To determine the next vertex to visit (according to Warnsdorf's rule), we need $\Delta b \leq nb$ bits, where Δ is the maximum degree in the graph. This amounts to $2\tau + 4$ units for the main data structures for the Warnsdorf algorithm on U. The rest of phase (1) is clearly covered by this as well.

Phase (2). We need 3 units to store the tree, 1 unit to store the longest path so far, 1 unit for the fundamental cycle, and 1 unit for DFS. This amounts to 6 units during this phase plus bookkeeping, which is covered by the stated bound. ◀

▶ Remark. On a graph with average degree d, the Warnsdorf, Pohl-Warnsdorf, and Pongrácz algorithms each requires at least $(d+3)\cdot nb$ bits of memory.

Proof. Since those algorithms perform special variants of DFS (and Pongrácz also BFS), we cannot restrict them to sequential access and thus we have to load the instance into RAM as adjacency lists.[2] Hence, $d+1$ units are required to store the graph. Two more units must be allotted to store DFS information and the longest path found so far, in the case of Pongrácz need one more unit for the distance information. ◀

▶ **Corollary 4.** *Not counting the additive constant c from Theorem 3, the RAM algorithms require $\frac{d+3}{\max\{4\tau,2\tau+4\}}$ times more RAM than our streaming algorithm, on a graph with average degree d. For $\tau=2$, this ratio is $\frac{d+3}{8}$.*

5 Test Instances

Connected Random. We denote this model by $\mathcal{G}^*(n,p)$. A graph is constructed by starting with a random tree on n vertices (via a randomly chosen Prüfer sequence) and then adding further edges as in $\mathcal{G}(n,p)$. The average degree in such a graph is slightly larger than np due to the $n-1$ initial tree edges.

Chains. Parameters for a chain graph are n,p, and k, with n being a multiple of k. We create k graphs $G_1,\dots,G_k$, the *clusters*, according to $\mathcal{G}^*(n,p)$, each on n/k vertices. Then we insert an edge v_iw_i with randomly chosen $v_i\in V(G_i)$ and $w_i\in V(G_{i+1})$ for each $1\le i<k$, making sure that $w_i\ne v_{i+1}$. Such graphs pose a particular challenge to DFS-based LPP algorithms, since if the DFS visits the connecting point to the next cluster (w_i or v_i) too early, it will eventually miss out on a large number of vertices in the current cluster.

Preferential Attachment and Small World. Preferential attachment graphs are created as per the Barabási-Albert model [3]: parameters are $n,n_0,d\in\mathbb{N}$, where n is total the number of vertices, n_0 is the size of the initial tree, and in each step the new vertex is connected by d new edges. This model guarantees connectedness. Small world graphs are created as per the Watts-Strogatz model [31], with a small modification. Parameters are $n,d\in\mathbb{N}$, with d even, and $0\le\beta\le1$. We start with a ring lattice where each vertex is connected to each $d/2$ vertices on either side, then each edge vw with v and w not being next to each other on the ring is replaced with a random edge vu with probability β (the *rewiring probability*). Our modification (not to rewire certain edges) guarantees that the result is Hamiltonian (and in particular connected).

These two models were chosen since they yield very different degree distributions: for preferential attachment, we have a power-law and there exist a few *hubs*, i. e., vertices with high degree. In the small world model on the other hand, vertices tend to have similar degree.

[2] This is unless we invoke external-memory techniques, which is unexplored for the LPP at this time.

Hyperbolic Geometric. Hyperbolic geometric graphs are a very interesting new class of graphs, for which efficient generators were recently given by von Looz, Staudt, Meyerhenke, and Prutkin [30]. They are constructed in hyperbolic space of constant negative curvature. Vertices correspond to points that are randomly inserted into this space, and an edge between two vertices is inserted if the corresponding points are within a certain distance from each other. This model has been shown to exhibit many features of complex real-world networks. We refer to [20, 30] for details. Parameters are number of vertices n, average degree d, and the exponent γ of the power-law degree distribution. We use the generator implementation from [30]. Connectedness is ensured by initializing the graph with a random tree.

6 Experimental Setup

Each algorithm was implemented in C++14. Each graph stream is realized as a `std::vector` of pairs of 32 bit integers. We keep those vectors in RAM for the sake of faster running times and hence more experiments conducted – but it is guaranteed that we access those vectors only sequentially and all other data structures are $\mathcal{O}(n)$. Our implementation also allows to process graphs stored in a file on disk, without copying the contents of the file into RAM (it is accessed via a `std::ifstream`). Using the *Valgrind* tool *Massif*,[3] we verified that RAM consumption of our algorithm is indeed independent of the number of edges. For each instance, the stream of edges is randomized once and the order does not change between passes or between the invocations of the algorithms. Each implementation concludes immediately when a Hamilton path is found.

For each random graph model under consideration, we test three settings: $n = 16{,}000$ and nominal average degree $d = 14$ (*sparse*); $n = 16{,}000$ and nominal average degree $d = \sqrt[3]{n}$ (*dense*); and $n = 100{,}000$ and nominal average degree $d = 10$ (*large*). (Note that chain and hyperbolic graphs will have a slightly larger average degree than the given d due to the additional tree that is used to guarantee connectedness.) The *dense* graphs have $\Omega(n^{4/3})$ edges and are thus beyond the theoretical RAM capacity of the semi-streaming model. More on the practical side, note that by Corollary 4 (not counting the small additive constant), even for average degree $d = 14$, the RAM algorithms require more than two times more memory than ours when configured with $\tau \leq 2$. Due to lack of space we skip the details for *sparse* and *dense* small world graphs, and we only use a selection of algorithms for the *large* graphs. The study of larger and more instances is deferred to the full version, due to time constraints.

We run Warnsdorf, Pohl-Warnsdorf, Pongrácz, the simple randomized DFS, and different variants of our algorithm on 100 randomly generated instances for each parameter set (only 50 instances for *large* graphs in order to save time) and record the length of the path that is found and the running time. Variants of our algorithm are denoted in the form $\tau/q_1/q_2$, where τ is the number of trees in the beginning, q_1 is the maximum number of passes used to construct a spanning tree using degree limiting, and q_2 is the number of improvement passes. In order to save time, for fixed τ and q_1, we obtain results for $\tau/q_1/0$ up to $\tau/q_1/q_2$ by running $\tau/q_1/q_2$ and recording intermediate results.

Solution quality is analyzed in terms of *relative solution quality.* For an instance I and algorithm A, denote $\ell(A, I)$ the length of the path delivered by A on I. Then we define $\rho(A, I) := \frac{\ell(A,I)}{\max_{A'} \ell(A',I)} \in [0, 1]$, where A' runs over all algorithms under investigation. That

[3] `http://valgrind.org/docs/manual/ms-manual.html`

is the result of A divided by the best result on any of the algorithms. Clearly, one algorithm per instance will always have relative solution quality 100%.

7 Data and Discussion

Tables with detailed experimental data can be found in section 8. The column labeled 'ℓ' gives statistics (mean value μ and standard deviation σ) for the lengths of the paths found and is intended as a general orientation in which range our solutions are located. The column labeled 'wins' counts how many times this algorithm delivered the best solution, i. e., how many times it achieved relative solution quality $\rho = 100\%$. Detailed statistics are given for the relative performance in the following columns: mean value, standard deviation, minimum, 5th and 10th percentile, and median. We use percentile notation everywhere: P_0 for the minimum, P_5 and P_{10} for the 5th and 10th percentile, and P_{50} for the median. In the final two columns, we give the running time in seconds. The algorithm marked with a star (2/4/3*) uses the randomized criterion for skipping edges in the improvement phase, whereas all other variants of our algorithm use the path criterion as stated in Algorithm 2. In the following, we distill the data from the tables into several observations and conclusions.

- The fact that the simple randomized DFS algorithm (denoted 'DFS' in the tables) delivers clearly inferior results in many cases is an indication that at least those instances are not 'too easy'.
- Warnsdorf and Pohl-Warnsdorf are generally the best, except for chain graphs. For many of the instances, they find a Hamilton path, and then they are very fast, sometimes below one second. Note that this advantage could easily be removed by making the graphs non-Hamiltonian, e. g., by connecting two additional vertices as leafs to the same vertex.
- Warnsdorf and Pohl-Warnsdorf are close to each other in terms of solution quality, but unsurprisingly the former is faster.
- In terms of the average path length $\mu(\ell)$, for each set of parameters there is one algorithm that delivers at least $0.84 \cdot n$, i. e., 84% of a Hamilton path. It follows that a good relative performance also means a good absolute performance.
- Our strongest variant, 2/4/3, with the exception of preferential attachment graphs, always delivers a relative solution quality of at least 71%. For preferential attachment, we record a minimum of 49% in Table 3. In terms of the 5th percentile, i. e., after removing the 5% worst cases, and omitting preferential attachment graphs, our minimum relative solution quality is 83%. In terms of the 10th percentile and including preferential attachment graphs, we still have at least 71%. In terms of mean and median, we have at least 83%.
- Regarding running time, we compare our variant 2/4/3 with Warnsdorf, which is the fastest RAM algorithm, not counting the simple randomized DFS. Clearly, we cannot compete in cases where Warnsdorf finds a Hamilton path within a second, but as remarked before, this advantage of Warnsdorf could easily be removed by making the graph non-Hamiltonian. Apart from those cases, in the *sparse* and *dense* sets, the biggest difference is for *sparse* hyperbolic graphs, where Warnsdorf only needs about 56% of our running time on average. For *dense* chains, we are faster than Warnsdorf. For the *large* set, our variant 2/4/1 has similar running times as Warnsdorf, while delivering at least 71% in terms of P_{10}, and when excluding preferential attachment graphs it delivers 82% in terms of P_5. More than one improvement pass here only gives incremental gain, so in order to save time on large graphs, the variant 2/4/1 is recommended over 2/4/2 or 2/4/3.
- Using $\tau = 2$ has a clear advantage over $\tau = 1$, in particular compare 1/2/0 with 2/2/0 in terms of ℓ in Table 1 and Table 2.

- The degree-limiting technique yields substantial improvements. For $q_1 = 2$ (i.e., for variants of the form $\tau/2/q_2$), we use the sequence $D = (2, \infty)$, i.e., in the first pass we limit the degree to 2 and in the second pass we have no limit. In the configuration with $q_1 = 4$ we use $D = (2, 2, 3, \infty)$. Comparing for example 1/2/0 with 1/4/0 with respect to ℓ in Table 2 for preferential attachment and hyperbolic graphs, we see that 1/2/0 delivers roughly $50 - 60\%$ length on average compared to 1/4/0. Comparing 2/2/3 with 2/4/3 in particular with respect to P_0, P_5, and P_{10} for preferential attachment graphs in Table 1, we see that $q_1 = 4$ brings an improvement even on top of the improvement gained by using $\tau = 2$ and by the improvement phase.
- The improvement phase (phase (2)) can bring further improvements, in particular with respect to P_0. This is seen for example by comparing 2/4/0 with 2/4/3 for preferential attachment and hyperbolic graphs in Table 1.
- Comparing the runtimes of 2/2/3 and 2/4/3 over all tables, we find that consistently the former is slower, while delivering inferior solutions. The same goes for 1/4/3 and 2/4/3; here the difference in running time is very high for preferential attachment graphs. This shows that a lack of effort in phase (1) can make phase (2) substantially slower. An explanation is that more improvement steps have to be carried out.
- Comparing 2/4/3 with 2/4/3*, we find the former being consistently better in terms of solution quality, but requiring up to roughly 30% more time.
- Our biggest advantage (using 2/4/3) over the other algorithms is for chain graphs.

In particular, we conclude from those observations that none of the three features (namely using multiple trees in the beginning, degree-limiting, and improvement) should be missed. The combination of all those features makes our algorithm competitive.

8 Tables of Experimental Data

On the following pages please find tables of results for the experiments as discussed in Section 7. By μ we denote the mean value and by σ the standard deviation. By P_i we denote the ith percentile, in particular P_0 is the minimum and P_{50} is the median. By ℓ we denote the path length and by ρ the relative performance. Running times t (last two columns) are in seconds. For further explanations, please see Section 7.

Acknowledgments. We thank the German Research Foundation (DFG) for financial support through Grant SR7/15-1 *Algorithmic Foundations for Genome Assembly* within Priority Programme 1736 *Algorithms for Big Data*. We thank Ole Kliemann for substantially improving our C++ implementation and helpful discussions.

Abstract

Spectral clustering is a popular and successful approach for partitioning the nodes of a graph into clusters for which the ratio of outside connections compared to the volume (sum of degrees) is small. In order to partition into k clusters, one first computes an approximation of the bottom k eigenvectors of the (normalized) Laplacian of G, uses it to embed the vertices of G into k-dimensional Euclidean space $\mathbb{R}^k$, and then partitions the resulting points via a k-means clustering algorithm. It is an important task for theory to explain the success of spectral clustering.

Peng et al. (COLT, 2015) made an important step in this direction. They showed that spectral clustering provably works if the gap between the $(k+1)$-th and the k-th eigenvalue of the normalized Laplacian is sufficiently large. They proved a structural and an algorithmic result. The algorithmic result needs a considerably stronger gap assumption and does not analyze the standard spectral clustering paradigm; it replaces spectral embedding by heat kernel embedding and k-means clustering by locality sensitive hashing.

We extend their work in two directions. Structurally, we improve the quality guarantee for spectral clustering by a factor of k and simultaneously weaken the gap assumption. Algorithmically, we show that the standard paradigm for spectral clustering works. Moreover, it even works with the same gap assumption as required for the structural result.

1 Introduction

A *cluster* in an undirected graph $G = (V, E)$ is a set S of nodes whose volume is large compared to the number of outside connections. Formally, we define the *conductance* of S by $\phi(S) = \left|E(S, \overline{S})\right| / \mu(S)$, where $\mu(S) = \sum_{v \in S} \deg(v)$ is the *volume* of S. The k-way partitioning problem for graphs asks to partition the vertices of a graph such that the conductance of each block of the partition is small (formal definition below). This problem arises in many applications, e.g., image segmentation and exploratory data analysis. We refer to the survey [10] for additional information. A popular and very successful approach to clustering [4, 8, 10] is *spectral clustering*. One first computes an approximation of the bottom k eigenvectors of the (normalized) Laplacian of G, uses it to embed the vertices of G into k-dimensional Euclidean space $\mathbb{R}^k$, and then partitions the resulting points via a

[*] The full version of the paper is available at http://arxiv.org/abs/1509.09188.

k-means clustering algorithm. It is an important task for theory to explain the success of spectral clustering. Recently, Peng et al. [7] made an important step in this direction. They showed that spectral clustering provably works if the $(k+1)$-th and the k-th eigenvalue of the normalized Laplacian differ sufficiently. In order to explain their result, we need some notation.

Let $\mathcal{L}_G = I - D^{-1/2}AD^{-1/2}$ be the normalized Laplacian matrix of G, where D is the diagonal degree matrix and A is the adjacency matrix, and let $f_j \in \mathbb{R}^V$ be the eigenvector corresponding to the j-th smallest eigenvalue λ_j of $\mathcal{L}_G$. The *spectral embedding map* $F : V \to \mathbb{R}^k$ is defined by

$$F(u) = \frac{1}{\sqrt{d_u}} \left(f_1(u), \ldots, f_k(u)\right)^{\mathrm{T}}, \quad \text{for all vertices } u \in V. \tag{1}$$

Peng et al. [7] construct a k-means instance $\mathcal{X}_V$ by inserting d_u many copies of the vector $F(u)$ into $\mathcal{X}_V$, for every vertex $u \in V$.

Let $\mathcal{X}$ be a set of vectors of the same dimension. Then

$$\triangle_k(\mathcal{X}) \triangleq \min_{\text{partition } (X_1,\ldots,X_k) \text{ of } \mathcal{X}} \sum_{i=1}^{k} \sum_{x \in X_i} \|x - c_i\|^2, \quad \text{where} \quad c_i = \frac{1}{|X_i|} \sum_{x \in X_i} x,$$

is the optimal cost of clustering $\mathcal{X}$ into k sets. An α-approximate clustering algorithm returns a k-way partition $(A_1, \ldots, A_k)$ and centers $c_1, \ldots, c_k$ such that

$$\mathrm{Cost}(\{A_i, c_i\}_{i=1}^k) \triangleq \sum_{i=1}^{k} \sum_{x \in A_i} \|x - c_i\|^2 \leqslant \alpha \cdot \triangle_k(\mathcal{X}). \tag{2}$$

The *order k conductance constant* $\rho(k)$ is a well studied worst case guarantee for k-way partitioning that is defined by

$$\rho(k) = \min_{\text{disjoint nonempty } Z_1,\ldots,Z_k} \Phi(Z_1, \ldots, Z_k), \quad \text{where} \quad \Phi(Z_1, \ldots, Z_k) = \max_{i \in [1:k]} \phi(Z_i). \tag{3}$$

Lee et al. [3] connected $\rho(k)$ and the k-th smallest eigenvalue of the normalized Laplacian matrix $\mathcal{L}_G$ through the relation, also known as higher order Cheeger inequality,

$$\lambda_k/2 \leqslant \rho(k) \leqslant O(k^2)\sqrt{\lambda_k}. \tag{4}$$

In this work, we focus attention on the *order k partition constant* $\widehat{\rho}(k)$ of G, defined by

$$\widehat{\rho}(k) \triangleq \min_{\text{partition } (P_1,\ldots,P_k) \text{ of } V} \Phi(P_1, \ldots P_k), \quad \text{where} \quad \Phi(Z_1, \ldots, Z_k) = \max_{i \in [1:k]} \phi(Z_i).$$

In a consecutive work, inspired by partitioning graphs into expanders, Oveis Gharan and Trevisan [6] proved the following relation

$$\rho(k) \leqslant \widehat{\rho}(k) \leqslant k\rho(k). \tag{5}$$

We are now ready to state the main structural result by Peng et al [7].

▶ **Theorem 1.1** ([7, Theorem 1.2]). *Let $k \geqslant 3$ and $(P_1, \ldots, P_k)$ be a k-way partition of V with $\Phi(P_1, \ldots, P_k) = \widehat{\rho}(k)$. Let G be a graph that satisfies the gap assumption*[1]

$$\delta = \frac{2 \cdot 10^5 \cdot k^3}{\Upsilon} \in (0, 1/2], \quad \textit{where} \quad \Upsilon \triangleq \frac{\lambda_{k+1}}{\widehat{\rho}(k)}. \tag{6}$$

[1] Note that $\lambda_k/2 \leqslant \widehat{\rho}(k)$, see (4,5). Thus the assumption implies $\lambda_k/2 \leqslant \widehat{\rho}(k) = \delta\lambda_{k+1}/(2 \cdot 10^5 \cdot k^3)$, i.e., there is a substantial gap between the k-th and the $(k+1)$-th eigenvalue.

Let $(A_1, \ldots, A_k)$ be the k-way partition[2] *of V returned by an α-approximate k-means algorithm applied to $\mathcal{X}_V$. Then the following statements hold (after suitable renumbering of one of the partitions):*

1. $\mu(A_i \triangle P_i) \leqslant \alpha\delta \cdot \mu(P_i)$*, and*
2. $\phi(A_i) \leqslant (1 + 2\alpha\delta) \cdot \phi(P_i) + 2\alpha\delta$*,*

where the symmetric difference $A_i \triangle P_i = (A_i \backslash P_i) \cup (P_i \backslash A_i)$.

Under the stronger gap assumption $\delta = 2 \cdot 10^5 \cdot k^5 / \Upsilon \in (0, 1/2]$, they showed how to obtain a partition in time $O(m \cdot \operatorname{poly}\log(n))$ with essentially the guarantees stated in Theorem 1.1, where $m = |E|$ is the number of edges in G and $n = |V|$ is the number of nodes.

However, their algorithmic result does not analyze the standard spectral clustering paradigm, since it replaces spectral embedding by heat kernel embedding and k-means clustering by locality sensitive hashing. Therefore, their algorithmic result does not explain the success of the standard spectral clustering paradigm.

Our Results

We strengthen the approximation guarantees in Theorem 1.1 by a factor of k and simultaneously weaken the gap assumption. As a consequence, the variant of Lloyd's k-means algorithm analyzed by Ostrovsky et al. [5] applied to[3] $\widetilde{\mathcal{X}_V}$ achieves the improved approximation guarantees in time $O(m(k^2 + \frac{\ln n}{\lambda_{k+1}}))$ with constant probability. Table 1 summarizes these results.

Let $\mathcal{O}$ be the set of all k-way partitions $(P_1, \ldots, P_k)$ with $\Phi(P_1, \ldots, P_k) = \widehat{\rho}(k)$, i.e., the set of all partitions that achieve the order k partition constant. Let

$$\widehat{\rho}_{\text{avr}}(k) \triangleq \min_{(P_1,\ldots,P_k)\in\mathcal{O}} \frac{1}{k}\sum_{i=1}^{k} \phi(P_i)$$

be the *minimal average conductance* over all k-way partitions in $\mathcal{O}$. The minimal average conductance can be considerably smaller than the order k partition constant. Consider a graph consisting of one clique of size $S_k = f(n) = o(n/k^{3/2})$, $k-1$ cliques of size $(n - f(n))/(k-1)$ each, and k additional edges that connect the cliques in the form of a ring. Then $\phi(S_i) \approx k^2/n^2$ for $1 \leqslant i \leqslant k-1$ and $\phi(S_k) \approx 1/f(n)^2$. Thus $\widehat{\rho}(k) = \max_i \phi(S_i) = \phi(S_k) \approx 1/f(n)^2$ and $\widehat{\rho}_{\text{avr}}(k) = (1/k)\sum_{1 \leqslant i \leqslant k} \phi(S_k) \approx k^2/n^2 + (1/k) \cdot (1/f(n)^2) \approx \widehat{\rho}(k)/k$.

For the remainder of this paper we denote by $(P_1, \ldots, P_k)$ a k-way partition of V that achieves $\widehat{\rho}_{\text{avr}}(k)$. In the full version of the paper, we give an analogous relation to (5) for $\widehat{\rho}_{\text{avr}}(k)$. We state now our main result.

▶ **Theorem 1.2** (Main Theorem).

(a) (Existence of a Good Clustering) *Let $k \geqslant 3$. Let G be a graph satisfying the gap assumption*

$$\delta = \frac{20^4 \cdot k^3}{\Psi} \in (0, 1/2], \quad \textit{where} \quad \Psi \triangleq \frac{\lambda_{k+1}}{\widehat{\rho}_{\text{avr}}(k)}. \tag{7}$$

Let $(A_1, \ldots, A_k)$ be the k-way partition returned by an α-approximate clustering algorithm applied to the spectral embedding $\mathcal{X}_V$. Then for every $i \in [1 : k]$ the following two statements hold (after suitable renumbering of one of the partitions):

[2] The k-means algorithm returns a partition of $\mathcal{X}_V$. One may assume w.l.o.g. that all copies of $F(u)$ are put into the same cluster of $\mathcal{X}_V$. Thus the algorithm also partitions V.

[3] $\widetilde{\mathcal{X}_V}$ is defined as $\mathcal{X}_V$ but in terms of approximate eigenvectors, see Subsection 2.3.

Table 1 A comparison of the results in Peng et al. [7] and our results. The parameter $\delta \in (0, 1/2]$ relates the approximation guarantees with the gap assumption.

	Gap Assumption	Partition Quality	Running Time
Peng et al. [7]	$\delta = 2 \cdot 10^5 \cdot k^3/\Upsilon$	$\mu(A_i \triangle P_i) \leqslant \alpha\delta \cdot \mu(P_i)$ $\phi(A_i) \leqslant (1 + 2\alpha\delta)\,\phi(P_i) + 2\alpha\delta$	Existential result
This paper	$\delta = 20^4 \cdot k^3/\Psi$	$\mu(A_i \triangle P_i) \leqslant \frac{\alpha\delta}{10^3 k} \cdot \mu(P_i)$ $\phi(A_i) \leqslant \left(1 + \frac{2\alpha\delta}{10^3 k}\right) \phi(P_i) + \frac{2\alpha\delta}{10^3 k}$	Existential result
Peng et al. [7]	$\delta = 2 \cdot 10^5 \cdot k^5/\Upsilon$	$\mu(A_i \triangle P_i) \leqslant \frac{\delta \log^2 k}{k^2} \cdot \mu(P_i)$ $\phi(A_i) \leqslant \left(1 + \frac{2\delta \log^2 k}{k^2}\right) \phi(P_i) + \frac{2\delta \log^2 k}{k^2}$	$O\,(m \cdot \operatorname{poly}\log(n))$
This paper	$\delta = 20^4 \cdot k^3/\Psi$ $\delta \leqslant k/10^9$ $\triangle_k(\mathcal{X}_V) \geqslant n^{-O(1)}$	$\mu(A_i \triangle P_i) \leqslant \frac{2\delta}{10^3 k} \cdot \mu(P_i)$ $\phi(A_i) \leqslant \left(1 + \frac{4\delta}{10^3 k}\right) \phi(P_i) + \frac{4\delta}{10^3 k}$	$O\left(m\left(k^2 + \frac{\ln n}{\lambda_{k+1}}\right)\right)$

1. $\mu(A_i \triangle P_i) \leqslant \frac{\alpha\delta}{10^3 k} \cdot \mu(P_i)$, *and*
2. $\phi(A_i) \leqslant \left(1 + \frac{2\alpha\delta}{10^3 k}\right) \cdot \phi(P_i) + \frac{2\alpha\delta}{10^3 k}$.

(b) (An Efficient Algorithm) *If in addition* $\delta \leqslant k/10^9$ *and*[4] $\triangle_k(\mathcal{X}_V) \geqslant n^{-O(1)}$, *then the variant of Lloyd's algorithm analyzed by Ostrovsky et al. [5] applied to* $\widetilde{\mathcal{X}_V}$ *returns in time* $O(m(k^2 + \frac{\ln n}{\lambda_{k+1}}))$ *with constant probability a partition* $(A_1, \ldots, A_k)$ *such that for every* $i \in [1 : k]$ *the following two statements hold (after suitable renumbering of one of the partitions):*

3. $\mu(A_i \triangle P_i) \leqslant \frac{2\delta}{10^3 k} \cdot \mu(P_i)$, *and*
4. $\phi(A_i) \leqslant \left(1 + \frac{4\delta}{10^3 k}\right) \cdot \phi(P_i) + \frac{4\delta}{10^3 k}$.

Part (b) of Theorem 1.2 gives a theoretical support for the practical success of spectral clustering based on approximate spectral embedding followed by k-means clustering. Moreover, if $k \leqslant \operatorname{poly}(\log n)$ and $\lambda_{k+1} \geqslant \operatorname{poly}(\log n)$, our algorithm works in nearly linear time. Previous papers [3, 7, 9] replaced k-means clustering by other techniques for their algorithmic results.

The k-means algorithm in [5] is efficient only for inputs $\mathcal{X}$ for which some partition into k clusters is much better than any partition into $k-1$ clusters. The authors proved that the algorithm is efficient for inputs $\mathcal{X}$ satisfying $\triangle_k(\mathcal{X}) \leqslant \varepsilon^2 \triangle_{k-1}(\mathcal{X})$ for some $\varepsilon \in (0, \varepsilon_0]$, where $\varepsilon_0 = 6/10^7$, stated that the result should also hold for a larger ε_0, and mentioned that they did not attempt to maximize ε_0. For the proof of part (b) of Theorem 1.2, we show in Section 5 that $\widetilde{\mathcal{X}_V}$ satisfies this assumption. In this proof, we need $\delta \leqslant k \cdot \varepsilon_0/600 = k/10^9$.

One of the reviewers suggested to include a numerical example. Consider a graph consisting of k cliques of size n/k each plus k additional edges that connect the cliques in the form of a ring. Such a graph is about the easiest input for a clustering algorithm. Then $\widehat{\rho}_{\text{avr}}(k) = \widehat{\rho}(k) \approx (k/n)^2$. For the gap assumption to hold we need $\lambda_{k+1} \geqslant 2 \cdot 20^4 \cdot k^3 \cdot \widehat{\rho}_{\text{avr}}(k)$. Since $\lambda_{k+1} \leqslant 2$, this implies $n \geqslant 400 \cdot k^{2.5}$. For small k, this is a modest requirement on the size of the graph.

[4] The case $\triangle_k(\mathcal{X}_V) \leqslant n^{-O(1)}$ constitutes a trivial clustering problem. For technical reasons, we have to exclude too easy inputs.

For the algorithmic result, we need in addition $\delta \leqslant k \cdot \varepsilon_0/600$. For the gap condition to hold, we need $2 \geqslant \lambda_{k+1} \geqslant (600/\varepsilon_0 k) \cdot 20^4 \cdot k^3 \cdot (k^2/n^2)$ or $n \geqslant 4\sqrt{3} \cdot 10^3 \cdot k^2/\sqrt{\varepsilon_0}$. For $\varepsilon_0 = 6/10^7$, this amounts to $n \geqslant 4\sqrt{5} \cdot 10^6 \cdot k^2$, a quite large lower bound on n.

Our statement above that Part (b) of Theorem 1.2 gives a theoretical support for the practical success of spectral clustering based on approximate spectral embedding followed by k-means clustering therefore has to be taken with a grain of salt. It is only an asymptotic statement and does not explain the good behavior on small graphs.

2 Highlights of Our Technical Contribution

2.1 Exact Spectral Embedding – Notation

We use the notation adopted by Peng et al. [7]. Let $f_j \in \mathbb{R}^V$ be the eigenvector corresponding to the j-th smallest eigenvalue λ_j of $\mathcal{L}_G$, and let $\overline{g_i} = \frac{D^{1/2}\chi_{P_i}}{\|D^{1/2}\chi_{P_i}\|}$ be the normalized indicator vector associated with the i-th optimal cluster $P_i \subset V$.

Since the eigenvectors $\{f_i\}_{i=1}^n$ form an orthonormal basis of $\mathbb{R}^n$, each normalized indicator vector $\overline{g_i}$ can be expressed as $\overline{g_i} = \sum_{j=1}^n \alpha_j^{(i)} f_j$, for all $i \in [1:k]$. Its *projection* into the subspace spanned by the bottom k eigenvectors is given by $\widehat{f_i} = \sum_{j=1}^k \alpha_j^{(i)} f_j$. Peng et al. [7] proved that if the gap parameter Υ is large enough then $\mathrm{span}(\{\widehat{f_i}\}_{i=1}^k) = \mathrm{span}(\{f_i\}_{i=1}^k)$ and hence the bottom k eigenvectors can be expressed by $f_i = \sum_{j=1}^k \beta_j^{(i)} \widehat{f_j}$, for all $i \in [1:k]$. We show that similar statements hold with substituted gap parameter Ψ.

A corner stone in the analysis of spectral clustering is to prove the existence of exactly k directions near which all spectrally embedded vectors are closely concentrated. These estimation centers are defined by

$$p^{(i)} = \frac{1}{\sqrt{\mu(P_i)}} \left(\beta_i^{(1)}, \ldots, \beta_i^{(k)}\right)^{\mathrm{T}}. \tag{8}$$

Our analysis crucially relies on the isometric properties of the following square matrix. Let $\mathbf{B} \in \mathbb{R}^{k \times k}$ be a matrix defined by $\mathbf{B}_{j,i} = \beta_j^{(i)}$, for every $i, j \in [1:k]$.

2.2 Exact Spectral Embedding – Structural Results

The proof of Theorem 1.2 (a) follows the proof-structure of [7, Theorem 1.2] in Peng et al., but improves upon it in essential ways.

Our key technical insight is that the matrices $\mathbf{B}\mathbf{B}^{\mathrm{T}}$ and $\mathbf{B}^{\mathrm{T}}\mathbf{B}$ are close to the identity matrix. The proof of Theorem 2.1 appears in the full version of the paper.

▶ **Theorem 2.1** (Matrix $\mathbf{B}\mathbf{B}^{\mathrm{T}}$ is Close to Identity Matrix). *If $\Psi \geqslant 10^4 \cdot k^3/\varepsilon^2$ and $\varepsilon \in (0,1)$ then for all distinct $i, j \in [1:k]$ it holds*

$$1 - \varepsilon \leqslant \langle \mathbf{B}_{i,:}, \mathbf{B}_{i,:} \rangle \leqslant 1 + \varepsilon \quad \textit{and} \quad |\langle \mathbf{B}_{i,:}, \mathbf{B}_{j,:} \rangle| \leqslant \sqrt{\varepsilon}.$$

Informally, Theorem 2.1 implies that each normalized indicator vector $\overline{g_i}$ is close to the corresponding eigenvector f_i. This gives a simple and intuitive explanation for the success of spectral clustering.

To see this, let $\mathbf{F}_k, \widehat{\mathbf{F}}_k \in \mathbb{R}^{k \times k}$ be matrices whose i-th column is f_i and $\widehat{f_i}$, respectively. The projection matrix $\mathbf{P}_k$ into the k-th principle subspace of $\mathcal{L}_G$ is given by $\mathbf{P}_k = \mathbf{F}_k \mathbf{F}_k^{\mathrm{T}}$ and since $\widehat{\mathbf{F}}_k \mathbf{B} = \mathbf{F}_k$, by Theorem 2.1 it follows that $\widehat{\mathbf{F}}_k \widehat{\mathbf{F}}_k^{\mathrm{T}} \approx \mathbf{F}_k \mathbf{F}_k^{\mathrm{T}}$. Therefore, each projected indicator vector satisfies $\widehat{f_i} \approx f_i$. This implies $\alpha^{(i)} \approx \boldsymbol{\chi}_i$ and hence we have $\overline{g_i} \approx f_i$.

Formally, Theorem 2.1 allows us to improve the separation guarantee between any pair of estimation centers by a factor of k over [7, Lemma 4.3], measured in terms of the Euclidean distance.

▶ **Lemma 2.2.** *If $\delta = 20^4 \cdot k^3/\Psi \in (0,1]$ then for every $i \in [1:k]$ it holds that $\left\|p^{(i)}\right\|^2 \in \left[1 \pm \sqrt{\delta}/4\right] \frac{1}{\mu(P_i)}$.*

Proof. By definition $p^{(i)} = \frac{1}{\sqrt{\mu(P_i)}} \cdot \mathbf{B}_{i,:}$ and Theorem 2.1 yields $\|\mathbf{B}_{i,:}\|^2 \in [1 \pm \sqrt{\delta}/4]$. ◀

▶ **Lemma 2.3** (Larger Distance Between Estimation Centers)**.** *If $\delta = 20^4 \cdot k^3/\Psi \in (0,1/2]$ then for any distinct $i,j \in [1:k]$ it holds that $\left\|p^{(i)} - p^{(j)}\right\|^2 \geqslant \left[2 \cdot \min\left\{\mu(P_i), \mu(P_j)\right\}\right]^{-1}$.*

Proof. Since $p^{(i)}$ is a row of matrix B, Theorem 2.1 with $\varepsilon = \sqrt{\delta}/4$ yields

$$\left\langle \frac{p^{(i)}}{\left\|p^{(i)}\right\|}, \frac{p^{(j)}}{\left\|p^{(j)}\right\|} \right\rangle = \frac{\langle \mathbf{B}_{i,:}, \mathbf{B}_{j,:}\rangle}{\|\mathbf{B}_{i,:}\| \, \|\mathbf{B}_{j,:}\|} \leqslant \frac{\sqrt{\varepsilon}}{1-\varepsilon} = \frac{2\delta^{1/4}}{3}.$$

W.l.o.g. assume that $\left\|p^{(i)}\right\|^2 \geqslant \left\|p^{(j)}\right\|^2$, say $\left\|p^{(j)}\right\| = \alpha \cdot \left\|p^{(i)}\right\|$ for some $\alpha \in (0,1]$. Then by Lemma 2.2 we have $\left\|p^{(i)}\right\|^2 \geqslant (1 - \sqrt{\delta}/4) \cdot \left[\min\left\{\mu(P_i), \mu(P_j)\right\}\right]^{-1}$, and hence

$$\begin{aligned}\left\|p^{(i)} - p^{(j)}\right\|^2 &= \left\|p^{(i)}\right\|^2 + \left\|p^{(j)}\right\|^2 - 2\left\langle \frac{p^{(i)}}{\left\|p^{(i)}\right\|}, \frac{p^{(j)}}{\left\|p^{(j)}\right\|} \right\rangle \left\|p^{(i)}\right\| \left\|p^{(j)}\right\| \\ &\geqslant \left(\alpha^2 - \frac{4\delta^{1/4}}{3} \cdot \alpha + 1\right) \left\|p^{(i)}\right\|^2 \geqslant \left[2 \cdot \min\left\{\mu(P_i), \mu(P_j)\right\}\right]^{-1}.\end{aligned}$$ ◀

The observation that Υ can be replaced by Ψ in all statements in [7] is technically easy. However, this is crucial for Theorem 1.2 (b), since it yields an improved version of [7, Lemma 4.5] showing that a weaker by a factor of k assumption is sufficient. Due to space limitation, we defer the proof of Lemma 2.4 to the full version of the paper.

▶ **Lemma 2.4.** *Let $(P_1, \ldots, P_k)$ and $(A_1, \ldots, A_k)$ are partitions of the vector set. Suppose for every permutation $\pi : [1:k] \to [1:k]$ there is an index $i \in [1:k]$ such that*

$$\mu(A_i \triangle P_{\pi(i)}) \geqslant \frac{2\varepsilon}{k} \cdot \mu(P_{\pi(i)}), \tag{9}$$

where $\varepsilon \in (0,1)$ is a parameter. If $\delta = 20^4 \cdot k^3/\Psi \in (0,1/2]$ and $\varepsilon \geqslant 64\alpha \cdot k^3/\Psi$ then

$$\mathrm{Cost}(\{A_i, c_i\}_{i=1}^k) > \frac{2k^2}{\Psi}\alpha.$$

With the above Lemmas in place, the proof of Theorem 1.2 (a) is then completed as in [7]. We give more details in Section 3.

Before we turn to Theorem 1.2 (b), we consider the variant of Lloyd's algorithm analyzed by Ostrovsky et al. [5] applied to $\mathcal{X}_V$. This algorithm is efficient for inputs $\mathcal{X}$ satisfying: some partition into k clusters is much better than any partition into $k-1$ clusters.

▶ **Theorem 2.5.** *[5, Theorem 4.15] Assuming that $\triangle_k(\mathcal{X}) \leqslant \varepsilon^2 \triangle_{k-1}(\mathcal{X})$ for $\varepsilon \in (0, 6/10^7]$, there is an algorithm that returns a solution of cost at most $[(1-\varepsilon^2)/(1-37\varepsilon^2)]\triangle_k(\mathcal{X})$ with probability at least $1 - O(\sqrt{\varepsilon})$ in time $O(nkd + k^3 d)$.*

In Section 4, we establish the assumption of Ostrovsky et al. [5] for $\mathcal{X}_V$.

▶ **Theorem 2.6** (Normalized Spectral Embedding is ε-separated). *Let G be a graph that satisfies the gap assumption $\delta = 20^4 \cdot k^3/\Psi \in (0, 1/2]$ and $\delta \leqslant k \cdot \varepsilon/600$, where $\varepsilon = 6/10^7$ is the Ostrovsky et al.'s constant. Then it holds*

$$\triangle_k(\mathcal{X}_V) \leqslant \varepsilon^2 \triangle_{k-1}(\mathcal{X}_V). \tag{10}$$

However, Theorem 2.6 is insufficient for Theorem 1.2 (b), since we need a similar result for the set $\widetilde{\mathcal{X}_V}$ formed by approximate eigenvectors. To overcome this issue we build upon the recent work by Boutsidis et al. [1] which shows that running an approximate k-means clustering algorithm on approximate eigenvectors obtained via the power method, yields an additive approximation to solving the k-means clustering problem on exact eigenvectors.

In order to state the connection, we need to introduce some of their notation.

2.3 Approximate Spectral Embedding – Notation

Let $Z \in \mathbb{R}^{n\times k}$ be a matrix whose rows represent n vectors that are to be partitioned into k clusters. For every k-way partition we associate an indicator matrix $X \in \mathbb{R}^{n\times k}$ that satisfies $X_{ij} = 1/\sqrt{|C_j|}$ if the i-th row $Z_{i,:}$ belongs to the j-th cluster C_j, and $X_{ij} = 0$ otherwise. We denote the optimal indicator matrix X_{opt} by

$$X_{\text{opt}} = \arg \min_{X\in\mathbb{R}^{n\times k}} \left\|Z - XX^{\mathrm{T}}Z\right\|_F^2 = \arg \min_{X\in\mathbb{R}^{n\times k}} \sum_{j=1}^{k} \sum_{u\in X_j} \|Z_{u,:} - c_j\|_2^2, \tag{11}$$

where $c_j = (1/|X_j|) \sum_{u\in X_j} Z_{u,:}$ is the center point of cluster C_j.

The normalized Laplacian matrix $\mathcal{L}_G \in \mathbb{R}^{n\times n}$ of a graph G is define by $\mathcal{L}_G = I - \mathcal{A}$, where $\mathcal{A} = D^{-1/2}AD^{-1/2}$ is the normalized adjacency matrix. Let $U_k \in \mathbb{R}^{n\times k}$ be a matrix composed of the bottom k orthonormal eigenvectors of $\mathcal{L}_G$ corresponding to the smallest eigenvalues $\lambda_1, \ldots, \lambda_k$. We define by $Y \triangleq U_k$ the canonical spectral embedding.

Our approximate spectral embedding is computed by the so called "**Power method**". Let $S \in \mathbb{R}^{n\times k}$ be a matrix whose entries are i.i.d. samples from the standard Gaussian distribution $N(0, 1)$ and p be a positive integer. Then the approximate spectral embedding $\widetilde{Y}$ is defined by the following process:

$$1)\ \mathcal{B} \triangleq I + \mathcal{A}; \quad 2)\ \text{Let } \widetilde{U}\widetilde{\Sigma}\widetilde{V}^{\mathrm{T}} \text{ be the SVD of } \mathcal{B}^p S; \quad \text{and} \quad 3)\ \widetilde{Y} \triangleq \widetilde{U} \in \mathbb{R}^{n\times k}. \tag{12}$$

We proceed by defining the normalized (approximate) spectral embedding. We construct a matrix $Y' \in \mathbb{R}^{m\times k}$ such that for every vertex $u \in V$ we add $\deg(u)$ many copies of the normalized row $U_k(u, :)/\sqrt{\deg(u)}$ to Y'. Formally, the normalized (approximate) spectral embedding Y' ($\widetilde{Y'}$) is defined by

$$Y' = \begin{pmatrix} \mathbf{1}_{\deg(1)} \frac{U_k(1,:)}{\sqrt{\deg(1)}} \\ \cdots \\ \mathbf{1}_{\deg(n)} \frac{U_k(n,:)}{\sqrt{\deg(n)}} \end{pmatrix}_{m\times k} \quad \text{and} \quad \widetilde{Y'} = \begin{pmatrix} \mathbf{1}_{\deg(1)} \frac{\widetilde{U}(1,:)}{\sqrt{\deg(1)}} \\ \cdots \\ \mathbf{1}_{\deg(n)} \frac{\widetilde{U}(n,:)}{\sqrt{\deg(n)}} \end{pmatrix}_{m\times k}, \tag{13}$$

where $\mathbf{1}_{\deg(i)}$ is all-one column vector with dimension $\deg(i)$.

Similarly to (11) we associate to Y' ($\widetilde{Y'}$) an indicator matrix X' ($\widetilde{X'}$) that satisfies $X'_{ij} = 1/\sqrt{\mu(C_j)}$ if the i-th row $Y'_{i,:}$ belongs to the j-th cluster C_j, and $X'_{ij} = 0$ otherwise. We may assume w.l.o.g. that a k-means algorithm outputs an indicator matrix X' such that all copies of row $U_k(v, :)/\sqrt{\deg(v)}$ belong to the same cluster, for every vertex $v \in V$.

We associate to matrices Y' and $\widetilde{Y'}$ the sets of points $\mathcal{X}_V$ and $\widetilde{\mathcal{X}_V}$ respectively. We present now a key connection between the spectral embedding map $F(\cdot)$, the optimal k-means cost $\triangle_k(\mathcal{X}_V)$ and matrices Y', X'_{opt}:

$$\left\|Y' - X'_{\text{opt}}\left(X'_{\text{opt}}\right)^{\mathrm{T}} Y'\right\|_F^2 = \sum_{j=1}^{k} \sum_{v \in C_j^\star} \deg(v) \left\|F(v) - c_j^\star\right\|_F^2 = \triangle_k(\mathcal{X}_V), \tag{14}$$

where each center satisfies $c_j^\star = \mu(C_j^\star)^{-1} \cdot \sum_{v \in C_j^\star} \deg(v) F(v)$ and $F(v) = Y_{v,:}/\sqrt{\deg(v)}$.

2.4 Approximate Spectral Embedding – Algorithmic Results

Our analysis relies on the proof techniques developed in [1, 2]. By adjusting these techniques (c.f. [1, Lemma 5] and [2, Lemma 7]) to our setting, we prove (in the full version of the paper) the following result for the symmetric positive semi-definite matrix $\mathcal{B}$ whose largest k singular values (eigenvalues) correspond to the eigenvectors $u_1, \ldots, u_k$ of $\mathcal{L}_G$.

▶ **Lemma 2.7.** *Let $\widetilde{U}\widetilde{\Sigma}\widetilde{V}^{\mathrm{T}}$ be the SVD of $\mathcal{B}^p S \in \mathbb{R}^{n \times k}$, where $p \geqslant 1$ and S is an $n \times k$ matrix of i.i.d. standard Gaussians. Let $\gamma_k = \frac{2-\lambda_{k+1}}{2-\lambda_k} < 1$ and fix $\delta, \epsilon \in (0,1)$. Then for any $p \geqslant \ln(8nk/\epsilon\delta) \big/ \ln(1/\gamma_k)$ with probability at least $1 - 2e^{-2n} - 3\delta$ it holds*

$$\left\|U_k U_k^{\mathrm{T}} - \widetilde{U}\widetilde{U}^{\mathrm{T}}\right\|_F \leqslant \epsilon.$$

We establish several technical Lemmas that combined with Lemma 2.7 allow us to apply the proof techniques in [1, Theorem 6]. More precisely, we prove in Subsection 5.1 that running an approximate k-means algorithm on a normalized approximate spectral embedding $\widetilde{Y'}$ computed by the power method, yields an approximate clustering of the normalized spectral embedding Y'.

▶ **Theorem 2.8.** *Compute matrix $\widetilde{Y'}$ via the power method with $p \geqslant \ln(8nk/\epsilon\delta) \big/ \ln(1/\gamma_k)$, where $\gamma_k = (2 - \lambda_{k+1})/(2 - \lambda_k) < 1$. Run on the rows of $\widetilde{Y'}$ an α-approximate k-means algorithm with failure probability δ_α. Let the outcome be a clustering indicator matrix $\widetilde{X'_\alpha} \in \mathbb{R}^{n \times k}$. Then with probability at least $1 - 2e^{-2n} - 3\delta_p - \delta_\alpha$ it holds*

$$\left\|Y' - \widetilde{X'_\alpha}\left(\widetilde{X'_\alpha}\right)^{\mathrm{T}} Y'\right\|_F^2 \leqslant (1 + 4\varepsilon) \cdot \alpha \cdot \left\|Y' - X'_{\text{opt}}\left(X'_{\text{opt}}\right)^{\mathrm{T}} Y'\right\|_F^2 + 4\varepsilon^2.$$

Our main technical contribution is to prove, in Subsection 5.2, that $\widetilde{\mathcal{X}_V}$ satisfies the assumption of Ostrovsky et al. [5]. Our analysis builds upon Theorem 2.6 and Theorem 2.8.

▶ **Theorem 2.9** (Approximate Normalized Spectral Embedding is ε-separated)**.** *Let G be a graph that satisfies the gap assumption $\delta = 20^4 \cdot k^3/\Psi \in (0, 1/2]$ and $\delta \leqslant k \cdot \varepsilon/600$, where $\varepsilon = 6/10^7$ is the Ostrovsky et al.'s constant. If the optimum cost*[5] *$\left\|Y' - X'_{\text{opt}}(X'_{\text{opt}})^{\mathrm{T}} Y'\right\|_F \geqslant n^{-O(1)}$ and the matrix $\widetilde{Y'}$ is constructed via the power method with $p \geqslant \Omega(\frac{\ln n}{\lambda_{k+1}})$, then w.h.p it holds $\triangle_k\left(\widetilde{\mathcal{X}_V}\right) < 5\varepsilon^2 \cdot \triangle_{k-1}\left(\widetilde{\mathcal{X}_V}\right)$.*

Based on the preceding results, we prove Theorem 1.2 (b) in Subsection 5.3.

[5] $\left\|Y' - X'_{\text{opt}}(X'_{\text{opt}})^{\mathrm{T}} Y'\right\|_F \geqslant n^{-O(1)}$ asserts a multiplicative approximation guarantee in Theorem 2.8.

3 The Proof of Part (a) of Theorem 1.2

The proof of part $(a.1)$ builds upon the following Lemmas. Recall that $\mathcal{X}_V$ contains d_u copies of $F(u)$ for each $u \in V$. W.l.o.g. we may restrict attention to clusterings of $\mathcal{X}_V$ that put all copies of $F(u)$ into the same cluster and hence induce a clustering of V. Let $(A_1, \dots, A_k)$ with cluster centers c_1 to c_k be a clustering of V. Its k-means cost is

$$\mathrm{Cost}(\{A_i, c_i\}_{i=1}^k) = \sum_{i=1}^{k} \sum_{u \in A_i} d_u \left\| F(u) - c_i \right\|^2 .$$

The proofs of Lemma 3.1 and Lemma 3.2 appear in the full version of the paper.

▶ **Lemma 3.1** ($(P_1, \dots, P_k)$ is a good k-means partition)**.** *If $\Psi > 4 \cdot k^{3/2}$ then there are vectors $\{p^{(i)}\}_{i=1}^k$ such that* $\mathrm{Cost}(\{P_i, p^{(i)}\}_{i=1}^k) \leqslant (1 + \frac{3k}{\Psi}) \cdot \frac{k^2}{\Psi}$.

▶ **Lemma 3.2** (Only partitions close to $(P_1, \dots, P_k)$ are good)**.** *Under the hypothesis of Theorem 1.2, the following holds. If for every permutation $\sigma : [1:k] \to [1:k]$ there exists an index $i \in [1:k]$ such that*

$$\mu(A_i \triangle P_{\sigma(i)}) \geqslant \frac{8\alpha\delta}{10^4 k} \cdot \mu(P_{\sigma(i)}), \quad \textit{then it holds} \quad \mathrm{Cost}(\{A_i, c_i\}_{i=1}^k) > \frac{2\alpha k^2}{\Psi}.$$

We note that Lemma 3.2 follows directly by applying Lemma 2.4 with $\varepsilon = 64\alpha \cdot k^3/\Psi$. Substituting these bounds into (2) yields a contradiction, since

$$\frac{2\alpha k^2}{\Psi} < \mathrm{Cost}(\{A_i, c_i\}_{i=1}^k) \leqslant \alpha \cdot \triangle_k(\mathcal{X}_V) \leqslant \alpha \cdot \mathrm{Cost}(\{P_i, p^{(i)}\}_{i=1}^k) \leqslant \left(1 + \frac{3k}{\Psi}\right) \cdot \frac{\alpha k^2}{\Psi}.$$

Therefore, there exists a permutation π (the identity after suitable renumbering of one of the partitions) such that $\mu(A_i \triangle P_i) < \frac{8\alpha\delta}{10^4 k} \cdot \mu(P_i)$ for all $i \in [1:k]$.

Part $(a.2)$ follows from part $(a.1)$. Indeed, for $\delta' = 8\delta/10^4$ we have

$$\mu(A_i) \geqslant \mu(P_i \cap A_i) = \mu(P_i) - \mu(P_i \setminus A_i) \geqslant \mu(P_i) - \mu(A_i \triangle P_i) \geqslant \left(1 - \frac{\alpha\delta'}{k}\right) \cdot \mu(P_i)$$

and $|E(A_i, \overline{A_i})| \leqslant |E(P_i, \overline{P_i})| + \mu(A_i \Delta P_i)$ since every edge that is counted in $|E(A_i, \overline{A_i})|$ but not in $|E(P_i, \overline{P_i})|$ must have an endpoint in $A_i \Delta P_i$. Thus

$$\Phi(A_i) = \frac{|E(A_i, \overline{A_i})|}{\mu(A_i)} \leqslant \frac{|E(P_i, \overline{P_i})| + \frac{\alpha\delta'}{k} \cdot \mu(P_i)}{(1 - \frac{\alpha \cdot \delta'}{k}) \cdot \mu(P_i)} \leqslant \left(1 + \frac{2\alpha\delta'}{k}\right) \cdot \phi(P_i) + \frac{2\alpha\delta'}{k}.$$

This completes the proof of Theorem 1.2 (a).

4 The Normalized Spectral Embedding is ε-separated

In this section, we prove that the normalized spectral embedding $\mathcal{X}_V$ is ε-separated.

Proof of Theorem 2.6

We establish first a lower bound on $\triangle_{k-1}(\mathcal{X}_V)$.

▶ **Lemma 4.1.** *Let G be a graph that satisfies the gap assumption $\delta = 20^4 \cdot k^3/\Psi \in (0, 1/2]$. Then for $\delta' = 2\delta/20^4$ it holds $\triangle_{k-1}(\mathcal{X}_V) \geqslant 1/12 - \delta'/k$.*

Before we prove Lemma 4.1 we show that it implies (10). By Lemma 3.1 we have $\triangle_k(\mathcal{X}_V) \leqslant 2k^2/\Psi = \delta'/k$. Then, we apply Lemma 4.1 with $\delta \leqslant k \cdot \varepsilon/600$, where $\varepsilon = 6/10^7$ is the Ostrovsky et al.'s constant, yielding

$$\triangle_{k-1}(\mathcal{X}_V) \geqslant \frac{1}{12} - \frac{\delta'}{k} = \frac{1}{12} - \frac{2}{20^4}\cdot\frac{\delta}{k} \geqslant \frac{10^{10}}{9\cdot 2^5}\cdot\frac{\delta}{k} = \frac{1}{\varepsilon^2}\cdot\frac{\delta'}{k} \geqslant \frac{1}{\varepsilon^2}\cdot\triangle_k(\mathcal{X}_V).$$

Proof of Lemma 4.1

Let $(P_1,\ldots,P_k)$ and $(Z_1,\ldots,Z_{k-1})$ be partitions of V. We define a mapping $\sigma : [1:k-1] \mapsto [1:k]$ by

$$\sigma(i) = \arg\max_{j\in[1:k]} \frac{\mu(Z_i\cap P_j)}{\mu(P_j)}, \quad \text{for every } i \in [1:k-1].$$

We lower bound now the clusters overlapping in terms of the volume between any k-way and $(k-1)$-way partitions of V.

▶ **Lemma 4.2.** *Suppose $(P_1,\ldots,P_k)$ and $(Z_1,\ldots,Z_{k-1})$ are partitions of V. Then for any index $\ell \in [1:k]\setminus\{\sigma(1),\ldots,\sigma(k-1)\}$ (there is at least one such ℓ) and for every $i \in [1:k-1]$ it holds*

$$\left\{\mu(Z_i\cap P_{\sigma(i)}), \mu(Z_i\cap P_\ell)\right\} \geqslant \tau_i\cdot\min\left\{\mu(P_\ell), \mu(P_{\sigma(i)})\right\},$$

where $\sum_{i=1}^{k-1}\tau_i = 1$ and $\tau_i \geqslant 0$.

Proof. By pigeonhole principle there is an index $\ell \in [1:k]$ such that $\ell \notin \{\sigma(1),\ldots,\sigma(k-1)\}$. Thus, for every $i \in [1:k-1]$ we have $\sigma(i) \neq \ell$ and

$$\frac{\mu(Z_i\cap P_{\sigma(i)})}{\mu(P_{\sigma(i)})} \geqslant \frac{\mu(Z_i\cap P_\ell)}{\mu(P_\ell)} \triangleq \tau_i,$$

where $\sum_{i=1}^{k-1}\tau_i = 1$ and $\tau_i \geqslant 0$ for all i. Hence, the statement follows. ◀

Proof of Lemma 4.1. Let $(Z_1,\ldots,Z_{k-1})$ be a $(k-1)$-way partition of V with centers $c'_1,\ldots,c'_{k-1}$ that achieves $\triangle_{k-1}(\mathcal{X}_V)$, and $(P_1,\ldots,P_k)$ be a k-way partition of V achieving $\widehat{\rho}_{\mathrm{avr}}(k)$. Our goal now is to lower bound the optimal $(k-1)$-means cost

$$\triangle_{k-1}(\mathcal{X}_V) = \sum_{i=1}^{k-1}\sum_{j=1}^{k}\sum_{u\in Z_i\cap P_j} d_u \left\|F(u)-c'_i\right\|^2. \tag{15}$$

By Lemma 4.2 there is an index $\ell \in [1:k]\setminus\{\sigma(1),\ldots,\sigma(k-1)\}$. For $i \in [1:k-1]$ let

$$p^{\gamma(i)} = \begin{cases} p^\ell & \text{, if } \left\|p^\ell - c'_i\right\| \geqslant \left\|p^{\sigma(i)} - c'_i\right\|; \\ p^{\sigma(i)} & \text{, otherwise.}\end{cases}$$

Then by combining Lemma 2.3 and Lemma 4.2, we have

$$\left\|p^{\gamma(i)} - c'_i\right\|^2 \geqslant \left[8\cdot\min\left\{\mu(P_\ell),\mu(P_{\sigma(i)})\right\}\right]^{-1} \text{ and } \mu(Z_i\cap P_{\gamma(i)}) \geqslant \tau_i\cdot\min\left\{\mu(P_\ell),\mu(P_{\sigma(i)})\right\}, \tag{16}$$

where $\sum_{i=1}^{k-1}\tau_i = 1$. We now lower bound the expression in (15). Since

$$\left\|F(u)-c'_i\right\|^2 \geqslant \frac{1}{2}\left\|p^{\gamma(i)}-c'_i\right\|^2 - \left\|F(u)-p^{\gamma(i)}\right\|^2,$$

it follows for $\delta' = 2\delta/20^4$ that

$$\begin{aligned}\triangle_{k-1}(\mathcal{X}_V) &= \sum_{i=1}^{k-1}\sum_{j=1}^{k}\sum_{u\in Z_i\cap P_j} d_u \left\|F(u)-c_i'\right\|^2 \geqslant \sum_{i=1}^{k-1}\sum_{u\in Z_i\cap P_{\gamma(i)}} d_u \left\|F(u)-c_i'\right\|^2 \\ &\geqslant \frac{1}{2}\sum_{i=1}^{k-1}\sum_{u\in Z_i\cap P_{\gamma(i)}} d_u \left\|p^{\gamma(i)}-c_i'\right\|^2 - \sum_{i=1}^{k-1}\sum_{u\in Z_i\cap P_{\gamma(i)}} d_u \left\|F(u)-p^{\gamma(i)}\right\|^2 \\ &\geqslant \frac{1}{2}\sum_{i=1}^{k-1}\frac{\mu(Z_i\cap P_{\gamma(i)})}{8\cdot\min\left\{\mu(P_{\gamma(i)}),\mu(P_{\sigma(i)})\right\}} - \sum_{i=1}^{k}\sum_{u\in P_i} d_u \left\|F(u)-p^i\right\|^2 \\ &\geqslant \frac{1}{16}-\frac{\delta'}{k},\end{aligned}$$

where the last inequality holds due to (16) and Lemma 3.1. ◀

5 An Efficient Spectral Clustering Algorithm

Here, we apply the proof techniques developed by Boutsidis et al. [1, 2] to our setting. More precisely, we prove that any α-approximate k-means algorithm that runs on an approximate normalized spectral embedding $\widetilde{Y'}$ computed by the power method, yields an approximate clustering $\widetilde{X'_\alpha}$ of the normalized spectral embedding Y'.

Furthermore, we prove under our gap assumption that $\widetilde{Y'}$ is ε-separated. This allows us to apply the variant of Lloyd's k-means algorithm analyzed by Ostrovsky et al. [5] to efficiently compute $\widetilde{X'_\alpha}$. Then we use Theorem 1.2 (a) to establish the desired statement.

This section is organized as follows. In Subsection 5.1, we prove Theorem 2.8. Then in Subsection 5.2, we present the proof of Theorem 2.9. Based on the results from the preceding two subsections, we prove Theorem 1.2 (b) in Subsection 5.3.

5.1 Proof of Theorem 2.8

Due to space limits, we defer the proofs of the next Lemmas to the full version of the paper.

▶ **Lemma 5.1.** *$X'X'^{\mathrm{T}}$ is a projection matrix.*

▶ **Lemma 5.2.** *It holds that $Y'^{\mathrm{T}}Y' = I_{k\times k} = \widetilde{Y'}^{\mathrm{T}}\widetilde{Y'}$.*

▶ **Lemma 5.3.** *It holds that $\left\|Y'Y'^{\mathrm{T}} - \widetilde{Y'}\widetilde{Y'}^{\mathrm{T}}\right\|_F = \left\|YY^{\mathrm{T}} - \widetilde{Y}\widetilde{Y}^{\mathrm{T}}\right\|_F$.*

▶ **Lemma 5.4.** *For any matrix U with orthonormal columns and every matrix A it holds*

$$\left\|UU^{\mathrm{T}} - AA^{\mathrm{T}}UU^{\mathrm{T}}\right\|_F = \left\|U - AA^{\mathrm{T}}U\right\|_F. \tag{17}$$

Proof Sketch of Theorem 2.8. By combining Lemma 2.7 and Lemma 5.3, with probability at least $1-2e^{-2n}-3\delta_p$ we have $\left\|Y'Y'^{\mathrm{T}} - \widetilde{Y'}\widetilde{Y'}^{\mathrm{T}}\right\|_F = \left\|YY^{\mathrm{T}} - \widetilde{Y}\widetilde{Y}^{\mathrm{T}}\right\|_F \leqslant \varepsilon$.

Let $Y'Y'^{\mathrm{T}} = \widetilde{Y'}\widetilde{Y'}^{\mathrm{T}} + E$ such that $\|E\|_F \leqslant \varepsilon$. Based on Lemma 5.2 and Lemma 5.4 we have that (17) holds for the matrices Y' and $\widetilde{Y'}$. Hence, by Lemma 5.1 we can apply the proof in [1, Theorem 6] to obtain $\left\|Y' - \widetilde{X'_\alpha}\left(\widetilde{X'_\alpha}\right)^{\mathrm{T}}Y'\right\|_F \leqslant \sqrt{\alpha}\cdot\left(\left\|Y' - X'_{\mathrm{opt}}\left(X'_{\mathrm{opt}}\right)^{\mathrm{T}}Y'\right\|_F + 2\varepsilon\right)$. The desired statement follows by simple algebraic manipulations. ◀

5.2 Proof of Theorem 2.9

In this subsection, we show under our gap assumption that the approximate normalized spectral embedding $\widetilde{Y'}$ is ε-separated, i.e. $\triangle_k(\widetilde{\mathcal{X}_V}) < 5\varepsilon^2 \cdot \triangle_{k-1}(\widetilde{\mathcal{X}_V})$. Our analysis builds upon Theorem 2.6, Theorem 2.8 and the proof techniques in [1, Theorem 6].

We use interchangeably X'_{opt} and $X'^{(k)}_{\text{opt}}$ to denote the optimal indicator matrix for the k-means problem on $\mathcal{X}_V$ that is induced by the rows of matrix Y'. Similarly, we denote by $X'^{(k-1)}_{\text{opt}}$ the optimal indicator matrix for the $(k-1)$-means problem on $\mathcal{X}_V$.

Proof Sketch of Theorem 2.9. By Theorem 2.6 we have

$$\left\| Y' - X'^{(k)}_{\text{opt}} \left(X'^{(k)}_{\text{opt}} \right)^{\mathrm{T}} Y' \right\|_F \leqslant \varepsilon \left\| Y' - X'^{(k-1)}_{\text{opt}} \left(X'^{(k-1)}_{\text{opt}} \right)^{\mathrm{T}} Y' \right\|_F . \tag{18}$$

We set the approximation parameter in Theorem 2.8 to

$$\varepsilon' \triangleq \frac{1}{4}\sqrt{\triangle_k(\mathcal{X}_V)} = \frac{1}{4} \left\| Y' - X'^{(k)}_{\text{opt}} \left(X'^{(k)}_{\text{opt}} \right)^{\mathrm{T}} Y' \right\|_F \geqslant n^{-O(1)}, \tag{19}$$

and we note that by Theorem 2.6 it holds $\varepsilon' \leqslant \frac{\varepsilon}{4}\sqrt{\triangle_{k-1}(\mathcal{X}_V)}$.

We construct now matrix $\widetilde{Y}$ via the power method with $p \geqslant \Omega(\frac{\ln n}{\lambda_{k+1}})$. By Lemma 5.3 we have $\left\| Y'Y'^{\mathrm{T}} - \widetilde{Y'}\widetilde{Y'}^{\mathrm{T}} \right\|_F = \left\| YY^{\mathrm{T}} - \widetilde{Y}\widetilde{Y}^{\mathrm{T}} \right\|_F$ and thus by Lemma 2.7 with high probability it holds that $\left\| Y'(Y')^{\mathrm{T}} - \widetilde{Y'}\widetilde{Y'}^{\mathrm{T}} \right\|_F \leqslant \varepsilon'$.

Let $Y'(Y')^{\mathrm{T}} = \widetilde{Y'}\widetilde{Y'}^{\mathrm{T}} + E$ such that $\|E\|_F \leqslant \varepsilon'$. By combining Lemma 5.1, Lemma 5.2, Lemma 5.3 and by applying the proof techniques in [1, Theorem 6] we obtain

$$\sqrt{\triangle_k\left(\widetilde{\mathcal{X}_V}\right)} \leqslant \|E\|_F + \left\| Y' - \widetilde{X'^{(k)}_{\text{opt}}} \left(\widetilde{X'^{(k)}_{\text{opt}}} \right)^{\mathrm{T}} Y' \right\|_F .$$

Furthermore, we can show that $\ln\left(\frac{2-\lambda_k}{2-\lambda_{k+1}}\right) \geqslant \frac{1}{2}\left(1 - \frac{4\delta}{20^4 k^2}\right)\lambda_{k+1}$. Then Theorem 2.8 yields

$$\left\| Y' - \widetilde{X'^{(k)}_{\text{opt}}} \left(\widetilde{X'^{(k)}_{\text{opt}}} \right)^{\mathrm{T}} Y' \right\|_F^2 \leqslant (1+4\varepsilon') \cdot \left\| Y' - X'^{(k)}_{\text{opt}} \left(X'^{(k)}_{\text{opt}} \right)^{\mathrm{T}} Y' \right\|_F^2 + 4\varepsilon'^2.$$

Also, we can show $\left\| Y' - X'^{(k)}_{\text{opt}} \left(X'^{(k)}_{\text{opt}} \right)^{\mathrm{T}} Y' \right\|_F^2 \leqslant \frac{1}{8 \cdot 10^{13}}$ and by the definition of ε' it follows

$$\sqrt{\triangle_k\left(\widetilde{\mathcal{X}_V}\right)} \leqslant 2\sqrt{\triangle_k(\mathcal{X}_V)} \leqslant 2\varepsilon \cdot \sqrt{\triangle_{k-1}(\mathcal{X}_V)}. \tag{20}$$

Moreover, by applying similar arguments as in the proof of [1, Theorem 6] we can prove that

$$\sqrt{\triangle_{k-1}(\mathcal{X}_V)} \leqslant \left(1 + \frac{\varepsilon}{2}\right) \sqrt{\triangle_{k-1}\left(\widetilde{\mathcal{X}_V}\right)}. \tag{21}$$

The statement follows by combining (20) and (21). ◀

5.3 Proof of Part (b) of Theorem 1.2

Let $p = \Theta(\frac{\ln n}{\lambda_{k+1}})$. We can compute the matrix $\mathcal{B}^p S$ in time $O(mkp)$ and its singular value decomposition $\widetilde{U}\widetilde{\Sigma}\widetilde{V}^{\mathrm{T}}$ in time $O(nk^2)$. Based on it, we construct in time $O(mk)$ matrix $\widetilde{Y'}$ (c.f. (13)).

By Theorem 2.9, $\widetilde{\mathcal{X}_V}$ is ε-separated for $\varepsilon = 6/10^7$, i.e. $\triangle_k\left(\widetilde{\mathcal{X}_V}\right) < 5\varepsilon^2 \cdot \triangle_{k-1}\left(\widetilde{\mathcal{X}_V}\right)$. Hence, by Theorem 2.5 there is an algorithm that outputs in time $O(mk^2 + k^4)$ a clustering with indicator matrix $\widetilde{X'_\alpha}$ satisfying

$$\left\|\widetilde{Y'} - \widetilde{X'_\alpha}\left(\widetilde{X'_\alpha}\right)^{\mathrm{T}}\widetilde{Y'}\right\|_F^2 \leqslant \left(1 + \frac{1}{10^{10}}\right) \cdot \left\|\widetilde{Y'} - \widetilde{X'_{\mathrm{opt}}}\left(\widetilde{X'_{\mathrm{opt}}}\right)^{\mathrm{T}}\widetilde{Y'}\right\|_F^2$$

with constant probability (close to 1), where $\alpha = 1 + 1/10^{10}$.

Moreover, by applying Theorem 2.8 with $\varepsilon' = \frac{1}{4 \cdot 10^3}\left\|Y' - X'_{\mathrm{opt}}\left(X'_{\mathrm{opt}}\right)^{\mathrm{T}} Y'\right\|_F$ we can prove that the indicator matrix $\widetilde{X'_\alpha}$ yields a multiplicative approximation of $\mathcal{X}_V$, i.e.

$$\left\|Y' - \widetilde{X'_\alpha}\left(\widetilde{X'_\alpha}\right)^{\mathrm{T}} Y'\right\|_F^2 \leqslant \left(1 + \frac{1}{10^6}\right)\left\|Y' - X'_{\mathrm{opt}}\left(X'_{\mathrm{opt}}\right)^{\mathrm{T}} Y'\right\|_F^2. \tag{22}$$

The statement follows by Theorem 1.2 (a) applied to the partition $(A_1, \ldots, A_k)$ of V that is induced by the indicator matrix $\widetilde{X'_\alpha}$.

Acknowledgement. We would like to thank the anonymous reviewers for their constructive comments.

Abstract

The Rainbow k-Coloring problem asks whether the edges of a given graph can be colored in k colors so that every pair of vertices is connected by a rainbow path, i.e., a path with all edges of different colors. Our main result states that for any $k \geq 2$, there is no algorithm for Rainbow k-Coloring running in time $2^{o(n^{3/2})}$, unless ETH fails. Motivated by this negative result we consider two parameterized variants of the problem. In the Subset Rainbow k-Coloring problem, introduced by Chakraborty *et al.* [STACS 2009, J. Comb. Opt. 2009], we are additionally given a set S of pairs of vertices and we ask if there is a coloring in which all the pairs in S are connected by rainbow paths. We show that Subset Rainbow k-Coloring is FPT when parameterized by $|S|$. We also study Maximum Rainbow k-Coloring problem, where we are additionally given an integer q and we ask if there is a coloring in which at least q anti-edges are connected by rainbow paths. We show that the problem is FPT when parameterized by q and has a kernel of size $O(q)$ for every $k \geq 2$, extending the result of Ananth *et al.* [FSTTCS 2011]. We believe that our techniques used for the lower bounds may shed some light on the complexity of the classical Edge Coloring problem, where it is a major open question if a $2^{O(n)}$-time algorithm exists.

1 Introduction

The Rainbow k-Coloring problem asks whether the edges of a given graph can be colored in k colors so that every pair of vertices is connected by a rainbow path, i.e., a path with all edges of different colors. A minimum such k, called the *rainbow connection number* can be viewed as yet another measure of graph connectivity. The concept of rainbow coloring was introduced by Chartrand, Johns, McKeon, and Zhang [7] in 2008, while also featured in an earlier book of Chartrand and Zhang [8]. Chakraborty, Fischer, Matsliah, and Yuster [3] describe an interesting application of rainbow coloring in telecommunications. The problem

[*] Work partially supported by the National Science Centre of Poland, grant number 2013/09/B/ST6/03136 (Ł.K., A.S.), and by the Emil Aaltonen Foundation (J.L.). This is an extended abstract; for the full version see the technical report at arxiv [17].

is intensively studied from the combinatorial perspective, with over 100 papers published by now (see the survey of Li, Shi, and Sun [20] for an overview). However, the computational complexity of the problem seems less explored. It was conjectured by Caro, Lev, Roditty, Tuza, and Yuster [2] that the Rainbow k-Coloring problem is NP-complete for $k = 2$. This conjecture was confirmed by Chakraborty *et al.* [3]. Ananth, Nasre, and Sarpatwar [1] noticed that the proof of Chakraborty *et al.* in fact proves NP-completeness for every even $k > 1$, and complemented this by showing NP-completeness of the odd cases as well. An alternative hardness proof for every $k > 1$ was provided by Le and Tuza [19]. For complexity results on restricted graph classes, see e.g., [4, 5, 6, 12].

For many NP-complete graph problems there are algorithms running in time $2^{O(n)}$ for an n-vertex graph. This is obviously the case for problems asking for a set of vertices, like Clique or Vertex Cover, or more generally, for problems which admit polynomially (or even subexponentially) checkable $O(n)$-bit certificates. However, there are $2^{O(n)}$-time algorithms also for some problems for which such certificates are not known, including e.g., Hamiltonicity [13] and Vertex Coloring [18]. Unfortunately it seems that the best known worst-case running time bound for Rainbow k-Coloring is $k^m 2^k n^{O(1)}$, where m is the number of edges, which is obtained by checking each of the k^m colorings by a simple $2^k n^{O(1)}$-time dynamic programming algorithm [23]. Even in the simplest variant of just two colors, i.e., $k = 2$, this algorithm takes $2^{O(n^2)}$ time if the input graph is dense. It raises a natural question: is this problem really much harder than, say, Hamiltonicity, or have we just not found the right approach yet? Questions of this kind have received considerable attention recently. For example, the existence of a $2^{O(n)}$-time algorithm for Edge Coloring is a notorious question, appearing in numerous open problem lists. On the other hand, it was shown that unless the Exponential Time Hypothesis fails, there is no algorithm running in time $2^{o(n \log n)}$ for Channel Assignment [21], Subgraph Homomorphism, and Subgraph Isomorphism [9]. Let us recall the precise statement of the Exponential Time Hypothesis (ETH).

▶ **Hypothesis 1** (Exponential Time Hypothesis [14]). *There exists a constant $c > 0$, such that there is no deterministic algorithm solving* 3-SAT *in time $O^*(2^{cn})$.*

Note that some kind of a complexity assumption, like ETH, is hard to avoid when we prove exponential lower bounds, unless one aims at proving P $\neq$ NP.

Main Result. Our main result is the following theorem.

▶ **Theorem 2.** *For any $k \geq 2$,* Rainbow k-Coloring *can be solved neither in $2^{o(n^{3/2})}$ nor $2^{o(m/\log m)}$ time where n and m are the number of vertices and edges respectively, unless ETH fails.*

Hence, this is an NP-complete graph problem which does not admit a $2^{o(n^{1+\epsilon})}$-time algorithm (under reasonable complexity assumptions), for an $\epsilon > 0$. Such lower bounds are fairly rare in the literature. The best known algorithm for Rainbow k-Coloring just verifies all possible colorings and thus it runs in time $2^{O(m)}$ for any fixed k. Our lower bounds mean that one cannot hope for substantial improvements in this running time.

Remaining Lower Bounds. We also study a natural generalized problem, called Subset Rainbow k-Coloring, introduced by Chakraborty *et al.* [3] as a natural intermediate step in reductions from 3-SAT to Rainbow k-Coloring. In Subset Rainbow k-Coloring, we are given a connected graph G, and a set of pairs of vertices $S \subseteq \binom{V(G)}{2}$. Elements of S

are called *requests*. For a given coloring of $E(G)$ we say that a request $\{u, v\}$ is *satisfied* if u and v are connected by a rainbow path. The goal in Subset Rainbow k-Coloring is to determine whether there is a k-coloring of $E(G)$ such that every pair in S is satisfied. Our main result implies that Subset Rainbow k-Coloring admits no algorithm running in time $2^{o(n^{3/2})}$, under ETH. We show also two more lower bounds, as follows.

▶ **Theorem 3.** *For any $k \geq 2$,* Subset Rainbow k-Coloring *can be solved neither in time $2^{o(n^{3/2})}$, nor in time $2^{o(m)}$, nor in time $2^{o(s)}$ where n is the number of vertices, m is the number of edges, and s is the number of requests, unless ETH fails.*

An interesting feature here is that for $k = 2$ the $2^{o(m)}$ and $2^{o(s)}$ bounds are *tight* up to a polynomial factor (a $2^m n^{O(1)}$ algorithm is immediate, and a $2^{|S|}n^{O(1)}$-time algorithm is discussed in the next paragraph).

New Algorithms. In the context of the hardness results mentioned above it is natural to ask for FPT algorithms for Subset Rainbow k-Coloring. We show that for every fixed k, Subset Rainbow k-Coloring parameterized by $|S|$ is FPT:

▶ **Theorem 4.** *For every integer k,* Subset Rainbow k-Coloring *is FPT and it has an algorithm running in time $|S|^{O(|S|)}n^{O(1)}$.*

For the 2 color case we are able to show a different, faster algorithm running in time $2^{|S|}n^{O(1)}$, which is tight up to a polynomial factor.

We also study the Maximum Rainbow k-Coloring problem, introduced by Ananth, Nasre, and Sarpatwar [1]. Intuitively, the idea is to parameterize the problem by the number of pairs to satisfy. However, all pairs of adjacent vertices are trivially satisfied by any edge-coloring. Hence, we parameterize by the number of anti-edges to satisfy. More formally, in Maximum Rainbow k-Coloring we are given a graph $G = (V, E)$, an integer q, and asked whether there is a coloring of E that satisfies at least q anti-edges. First, we show that the maximization version of the problem (find maximum such q) admits a constant factor approximation algorithm for every fixed value of k. Second, we show that Maximum Rainbow k-Coloring is FPT for every $k \geq 2$, which generalizes the result of Ananth *et al.* [1] who showed this claim for the $k = 2$ case. Our algorithm runs in time $2^{q \log q}n^{O(1)}$ for any k, which is faster than the algorithm of Ananth *et al.* for 2 colors. For 2 colors we give an even faster algorithm, running in time $8^q n^{O(1)}$. We also show that the problem admits a kernel size $O(q)$, i.e., that there is a polynomial-time algorithm that returns an equivalent instance with $O(q)$ vertices. (For more background on kernelization see e.g., [10].) Before, this was known only for $k = 2$ (due to Ananth *et al.* [1]). Our main results for Maximum Rainbow k-Coloring are summarized in the following theorem.

▶ **Theorem 5.** Maximum Rainbow k-Coloring *parameterized by the number of anti-edges q is FPT for every $k \geq 2$. Moreover, it admits a kernel of linear size.*

Notation. For standard graph-theoretic notions, we refer the reader to [11]. All graphs we consider in this paper are simple and undirected. We denote $\Delta_1(G) = \max\{\Delta(G), 1\}$.

By $\bar{E}$ we denote the set of anti-edges, i.e., $\bar{E} = \binom{V}{2} \setminus E$. When $G = (V, E)$ is a graph then $\bar{G} = (V, \bar{E})$ is its *complement graph.* By $x^{\underline{k}}$ we denote the falling factorial, i.e., $x^{\underline{k}} = x(x-1)\cdots(x-k+1)$. For an integer k, we denote $[k] = \{1, \ldots, k\}$. For a (partial) function c, by $\mathrm{Dom}(c)$ we denote its domain.

If I and J are instances of decision problems P and R, respectively, then we say that I and J are *equivalent*, when either both I and J are YES-instances or both are NO-instances.

Organization of the paper. In Section 2 we present our hardness results. The main difficulties we encountered are sketched at the beginning of that section. Due to space constraints proofs of the claims marked by ★ are skipped and can be found in the full version [17]. Next, in Section 3 we present our algorithms for SUBSET RAINBOW k-COLORING. Again because of the space limitations, our algorithms for MAXIMUM RAINBOW k-COLORING are skipped in this extended abstract and are available in the full version [17].

2 Hardness of rainbow coloring

2.1 Overview

The main goal of this section is to show that for any $k \geq 2$ RAINBOW k-COLORING does not admit an algorithm running in time $2^{o(n^{3/2})}$, unless the Exponential Time Hypothesis fails. Let us give a high-level overview of our proof. A natural idea would be to begin with a 3-SAT formula ϕ with n variables and then transform it in time $2^{o(n)}$ to an equivalent instance $G = (V, E)$ of RAINBOW k-COLORING with $O(n^{2/3})$ vertices. Then indeed a $2^{o(|V|^{3/2})}$-time algorithm that solves RAINBOW 2-COLORING can be used to decide 3-SAT in time $2^{o(n)}$. Note that in a typical NP-hardness reduction, we observe some polynomial blow-up of the instance size. For example, one can verify that in the reduction of Chakraborty *et al.* [3], the initial 3-SAT formula with n variables and m clauses is transformed into a graph with $\Theta(n^4 + m^4)$ vertices and edges. In our case, instead of a blow-up we aim at *compression*: the number of vertices needs to be much smaller than the number of variables in the input formula ϕ. As usual in reductions, variables and clauses in ϕ are going to correspond to some structures in G, called gadgets. The compression requirement means that our gadgets need to share vertices. To make our lives slightly easier, we apply the following well-known Sparsification Lemma, which allows for assuming that the number of clauses is $O(n)$.

▶ **Lemma 6** (Sparsification Lemma [15]). *For each $\varepsilon > 0$ there exist a constants c_ε, such that any* 3-SAT *formula φ with n variables can be expressed as $\varphi = \vee_{i=1}^{t} \psi_i$, where $t \leq 2^{\varepsilon n}$ and each ψ_i is a* 3-SAT *formula with the same variable set as φ, but contains at most $c_\varepsilon n$ clauses. Moreover, this disjunction can be computed in time $O^*(2^{\varepsilon n})$.*

Note that by using the Sparsification Lemma we tweak our general plan a bit: instead of creating one equivalent instance, we are going to create $2^{\varepsilon n}$ instances (for arbitrarily small ϵ), each with $O(n^{2/3})$ vertices. The following lemma further simplifies the instance.

▶ **Lemma 7** ([22]). *Given a* 3-SAT *formula φ with m clauses one can transform it in polynomial time into a formula φ' with $O(m)$ variables and $O(m)$ clauses, such that φ' is satisfiable iff φ' is satisfiable, and moreover each clause of φ' contains exactly three different variables and each variable occurs in at most 4 clauses of φ'.*

Now our goal is to transform a 3-SAT formula ϕ with n variables such that every variable occurs in at most 4 clauses, to a graph with $O(n^{2/3})$ vertices — an equivalent instance of RAINBOW k-COLORING. We do it in three steps (see Fig 1).

In the first step we transform ϕ to an instance $I = (G, S, c_0)$ of Subset Rainbow 2-Coloring Extension, which is a generalization of Subset Rainbow 2-Coloring, where c_0, called a *precoloring*, is a partial coloring of the edges of G into two colors and the goal is to determine if there is an edge-coloring of $E(G)$ which extends c_0 and such that all pairs of S are satisfied. The first step is crucial, because here the compression takes place: $|V(G)| = O(n^{2/3})$ and $E(G) = O(n)$. The major challenge in the construction is avoiding interference between gadgets that share a vertex: to this end we define various conflict graphs and we show that they can be vertex-colored in a few colors. This reduction is described in Section 2.2.

In the second step (Lemma 9) we reduce Subset Rainbow 2-Coloring Extension to Subset Rainbow k-Coloring, for every $k \geq 2$. In fact, in the full version this is done in two sub-steps, via Subset Rainbow k-Coloring Extension. The number of the vertices in the resulting instance does not increase more than by a constant factor. This step is rather standard, though some technicalities appear because we need to guarantee additional properties of the output instance, which are needed by the reduction in the third step.

The last step (Section 2.3), where we reduce an instance $(G = (V, E), S)$ of Subset Rainbow k-Coloring to an instance G' of Rainbow k-Coloring, is yet another challenge. We would like to get rid of the set of requests somehow. For simplicity, let us focus on the $k = 2$ case now. Here, the natural idea, used actually by Chakraborty *et al.* [3] is to create, for every $\{u, v\} \notin S$, a path (u, x_{uv}, v) through a new vertex x_{uv}. Such a path cannot help any of the requests $\{u', v'\} \in S$ to get satisfied (since if it creates a new path P' between u' and v', then P' has length at least 3), and by coloring it into two different colors we can satisfy $\{u, v\}$. Unfortunately, in our case we cannot afford for creating a new vertex for every such $\{u, v\}$, because that would result in a quadratic blow up in the number of vertices. However, one can observe that for any biclique (a complete bipartite subgraph) in the graph $(V, \binom{V}{2} \setminus S)$ it is sufficient to use just one such vertex x (connected to all the vertices of the biclique). By applying a result of Jukna [16] we can show that in our specific instance of Subset Rainbow 2-Coloring which results from a 3-SAT formula, the number of bicliques needed to cover all the pairs in $\binom{V}{2} \setminus S$ is small enough. We show a $2^{|V(G)|}|V(G)|^{O(1)}$-time algorithm to find such a cover. Although this algorithm does not seem fast, in our case $|V(G)| = O(n^{2/3})$, so this complexity is *subexponential* in the number of variables of the input formula, which is enough for our goal. The case of $k \geq 3$ is similar, i.e., we also use the biclique cover. However, the details are much more technical because for each biclique we need to introduce a much more complex gadget.

2.2 From 3-SAT to Subset Rainbow k-Coloring

Let Subset Rainbow k-Coloring Extension be a generalization of Subset Rainbow k-Coloring, where c_0 is a partial k-coloring of the edges of G and the goal is to determine if there is an edge-coloring of $E(G)$ which extends c_0 and such that all pairs of S are satisfied. In this section we show a reduction (Lemma 8) from 3-SAT to Subset Rainbow 2-Coloring Extension.

For an instance $I = (G, S, c_0)$ of Subset Rainbow k-Coloring Extension (for any $k \geq 2$), let us define a *precoloring conflict graph* CG_I. Its vertex set is the set of colored edges, i.e., $V(CG_I) = \mathrm{Dom}(c_0)$. Two different colored edges e_1 and e_2 (treated as vertices of CG_I) are adjacent in CG_I when they are incident in G or there is a pair of endpoints $u \in e_1$ and $v \in e_2$ such that $uv \in E(G) \cup S$.

In what follows the reduction in Lemma 8 is going to be pipelined with further reductions going through Subset Rainbow k-Coloring Extension and Subset Rainbow k-

Coloring to Rainbow k-Coloring. In these three reductions we need to keep the instance small. To this end, the instance of Subset Rainbow 2-Coloring Extension resulting in Lemma 8 has to satisfy some additional properties, which are formulated in the claim of Lemma 8. Their role will become clearer later on.

▶ **Lemma 8.** *Given a* 3-SAT *formula φ with n variables such that each clause of φ contains exactly three variables and each variable occurs in at most four clauses, one can construct in polynomial time an equivalent instance (G, S, c_0) of* Subset Rainbow 2-Coloring Extension *such that G has $O(n^{2/3})$ vertices and $O(n)$ edges. Moreover, $\Delta(G) = O(n^{1/3})$, $\Delta(V(G), S) = O(n^{1/3})$, $|\mathrm{Dom}(c_0)| = O(n^{2/3})$ and along with the instance $I = (G, S, c_0)$ the algorithm constructs a proper vertex 4-coloring of $(V(G), E \cup S)$ (so also of $(V(G), S)$) and a proper vertex $O(n^{1/3})$-coloring of the precoloring conflict graph CG_I.*

Proof. Let m denote the number of clauses in φ. Observe that $m \leq \frac{4}{3}n$. Let Var and Cl denote the sets of variables and clauses of φ. For more clarity, the two colors of the partial coloring c_0 will be called T and F. Let us describe the graph G along with a set of anti-edges S. Graph G consists of two disjoint vertex subsets: the variable part and the clause part. The intuition is that in any 2-edge coloring of G that extends c_0 and satisfies all pairs in S

- edge colors in the variable part represent an assignment of the variables of φ,
- edge colors in the clause part represent a choice of literals that satisfy all the clauses, and
- edge colors between the two parts make the values of the literals from the clause part consistent with the assignment represented by the variable part.

The variable part. The vertices of the variable part consist of the *middle set* M and $\lceil n^{1/3} \rceil$ layers $L_1 \cup L_2 \cdots \cup L_{\lceil n^{1/3} \rceil}$. The middle set M consists of vertices m_i for each $i = 1, \ldots, \lceil n^{2/3} \rceil + 9$. For every $i = 1, \ldots, \lceil n^{1/3} \rceil$ the layer L_i consists of two parts: upper $L_i^{\uparrow} = \{u_{i,j} \ : \ j = 1, \ldots, \lceil n^{1/3} \rceil + 3\}$ and lower $L_i^{\downarrow} = \{l_{i,j} \ : \ j = 1, \ldots, \lceil n^{1/3} \rceil + 3\}$.

We are going to define four functions: mid : Var $\to M$, lay, up, low : Var $\to [\lceil n^{1/3} \rceil]$. Then, for every variable $x \in$ Var we add two edges $u_{\mathrm{lay}(x),\mathrm{up}(x)}\mathrm{mid}(x)$ and $\mathrm{mid}(x)l_{\mathrm{lay}(x),\mathrm{low}(x)}$. Moreover, we add the pair $p_x = \{u_{\mathrm{lay}(x),\mathrm{up}(x)}, l_{\mathrm{lay}(x),\mathrm{low}(x)}\}$ to S. In other words, x corresponds to the 2-path $u_{\mathrm{lay}(x),\mathrm{up}(x)}\mathrm{mid}(x)l_{\mathrm{lay}(x),\mathrm{low}(x)}$. Now we describe a careful construction of the four functions, that guarantee several useful properties (for example edge-disjointness of paths corresponding to different variables).

Let us define the *variable conflict graph* $G_V = (\mathrm{Var}, E_{G_V})$, where for two variables $x, y \in$ Var we have xy are adjacent iff they both occur in the same clause. Since every variable occurs in at most 4 clauses, $\Delta(G_V) \leq 8$. It follows that there is a proper vertex 9-coloring $\alpha : Var \to [9]$ of G_v, and it can be found by a simple linear time algorithm. Next, each of the 9 color classes $\alpha^{-1}(i)$ is partitioned into $\lceil |\alpha^{-1}(i)| / \lceil n^{1/3} \rceil \rceil$ disjoint groups, each of size at most $\lceil n^{1/3} \rceil$. It follows that the total number n_g of groups is at most $\lceil n^{2/3} \rceil + 9$. Let us number the groups arbitrarily from 1 to n_g and for every variable $x \in$ Var, let $g(x)$ be the number of the group that contains x. Then we define $\mathrm{mid}(x) = m_{g(x)}$. Since any group contains only vertices of the same color we can state the following property:

($\mathbf{P_1}$) If variables x and y occur in the same clause then $\mathrm{mid}(x) \neq \mathrm{mid}(y)$.

Now, for every variable x we define its layer, i.e., the value of the function lay(x). Recall that for every $i = 1, \ldots, \lceil n^{2/3} \rceil + 9$ the i-th group $\mathrm{mid}^{-1}(m_i)$ contains at most $\lceil n^{1/3} \rceil$ variables. Inside each group, number the variables arbitrarily and let lay(x) be the number of variable x in its group, $\mathrm{lay}(x) \in [n^{1/3}]$. This implies another important property.

($\mathbf{P_2}$) If variables x and y belong to the same layer then $\mathrm{mid}(x) \neq \mathrm{mid}(y)$.

Observe that every layer gets assigned at most $\lceil n^{2/3} \rceil + 9$ variables. For every layer L_i pick any injective function $h_i : \mathrm{lay}^{-1}(i) \to [\lceil n^{1/3} \rceil + 3]^2$. Then, for every variable $x \in \mathrm{Var}$ we put $(\mathrm{up}(x), \mathrm{low}(x)) = h_{\mathrm{lay}(x)}(x)$. Note that by (P$_2$) we have the following.

(P$_3$) For every variable x there is exactly one 2-path in G connecting p_x, namely $(u_{\mathrm{lay}(x),\mathrm{up}(x)}, \mathrm{mid}(x), l_{\mathrm{lay}(x),\mathrm{low}(x)})$.

(P$_4$) For every pair of variables x, y the two unique paths connecting p_x and p_y are edge-disjoint.

Although we are going to add more edges and vertices to G, none of these edges has any endpoint in $\bigcup_i L_i$, so P_3 will stay satisfied.

The clause part. The vertices of the clause part are partitioned into $O(m^{1/3})$ clusters. Similarly as in the case of variables, each clause is going to correspond to a pair of vertices in the same cluster. Again, the assignment of clauses to clusters has to be done carefully. To this end we introduce the *clause conflict graph* $G_C = (\mathrm{Cl}, E_{G_C})$. Two different clauses C_1 and C_2 are adjacent in G_C if C_1 contains a variable x_1 and C_2 contains a variable x_2 such that $\mathrm{mid}(x_1) = \mathrm{mid}(x_2)$. Fix a variable x_1. Since $|\mathrm{mid}^{-1}(\mathrm{mid}(x_1))| \leq \lceil n^{1/3} \rceil$, there are at most $\lceil n^{1/3} \rceil$ variables x_2 such that $\mathrm{mid}(x_1) = \mathrm{mid}(x_2)$. Since every clause contains 3 variables, and each of them is in at most 4 clauses, $\Delta(G_C) \leq 12 \lceil n^{1/3} \rceil$. It follows that in polynomial time we can find a proper coloring β of the vertices of G_C into at most $12 \lceil n^{1/3} \rceil + 1$ colors. Moreover, if for any color j its color class $\beta^{-1}(j)$ is larger than $\lceil n^{2/3} \rceil$ we partition it into $\lceil |\beta^{-1}(j)| / \lceil n^{2/3} \rceil \rceil$ new colors. Clearly, in total we produce at most $\frac{4}{3} \lceil n^{1/3} \rceil$ new colors in this way because $m \leq \frac{4}{3} n \leq \frac{4}{3} \lceil n^{1/3} \rceil \cdot \lceil n^{2/3} \rceil$. Hence, in what follows we assume that each color class of β is of size at most $\lceil n^{2/3} \rceil$, and the total number of colors $s \leq 14 \lceil n^{1/3} \rceil + 1$. In what follows we construct s clusters $Q_1, \ldots, Q_s$. Every clause $C \in \mathrm{Cl}$ is going to correspond to a pair of vertices in the cluster $Q_{\beta(C)}$.

Fix $i = 1, \ldots, s$. Let us describe the subgraph induced by cluster Q_i. Define *cluster conflict graph* $G_i = (\beta^{-1}(i), E_{G_i})$. Two different clauses $C_1, C_2 \in \beta^{-1}(i)$ are adjacent in G_i if there are three variables x_1, x_2, and x_3 such that *(i)* C_1 contains x_1, *(ii)* C_2 contains x_2, *(iii)* $(\mathrm{lay}(x_1), \mathrm{up}(x_1)) = (\mathrm{lay}(x_3), \mathrm{up}(x_3))$ and *(iv)* $\mathrm{mid}(x_2) = \mathrm{mid}(x_3)$. Fix a variable x_1 which appears in a clause $C_1 \in \beta^{-1}(i)$. By our construction, there are at most $\lceil n^{1/3} \rceil + 2$ other variables x_3 that map to the same pair as x_1 by functions lay and up. For each such x_3 there are at most $\lceil n^{1/3} \rceil$ variables x_2 such that $\mathrm{mid}(x_2) = \mathrm{mid}(x_3)$; however, at most one of these variables belongs to a clause C_2 from the same cluster $\beta^{-1}(i)$, by the definition of the coloring β. It follows that $\Delta(G_i) \leq 12(\lceil n^{1/3} \rceil + 2)$. Hence in polynomial time we can find a proper coloring γ_i of the vertices of G_i into at most $12(\lceil n^{1/3} \rceil + 2) + 1$ colors. Similarly as in the case of the coloring β, we can assume that each of the color classes of γ_i has at most $\lceil n^{1/3} \rceil$ clauses, at the expense of at most $\lceil n^{1/3} \rceil$ additional colors. It follows that we can construct in polynomial time a function $g : \mathrm{Cl} \to [\lceil n^{1/3} \rceil]$ such that for every cluster $i = 1, \ldots, s$ and for every color class S of γ_i g is injective on S. Let $n_i \leq 13 \lceil n^{1/3} \rceil + 25$ be the number of colors used by γ_i. For notational convenience, let us define a function $\gamma : \mathrm{Cl} \to [\max_i n_i]$ such that for any clause C we have $\gamma(C) = \gamma_{\beta(C)}(C)$.

We are ready to define the vertices and edges of Q_i. It is a union of three disjoint vertex sets A_i, B_i, and C_i. We have $A_i = \{a_{i,j} \ : \ j = 1, \ldots, \lceil n^{1/3} \rceil\}$, $B_i = \{b^k_{i,j} \ : \ j = 1, \ldots, n_i, k = 1, 2, 3\}$, and $C_i = \{c_{i,j} \ : \ j = 1, \ldots, n_i\}$. For every $j = 1, \ldots, n_i$ and for every $k = 1, 2, 3$ we add edge $c_{i,j} b^k_{i,j}$ to G, and we color it by c_0 to color F. (These are the only edges pre-colored in the whole graph G.) For every clause $C \in \beta^{-1}(i)$ we do the following. For each $k = 1, 2, 3$, add the edge $(a_{i,g(C)}, b^k_{i,\gamma(C)})$ to G. Finally, add the pair $\{a_{i,g(C)}, c_{i,\gamma(C)}\}$ to S. Clearly, the following holds:

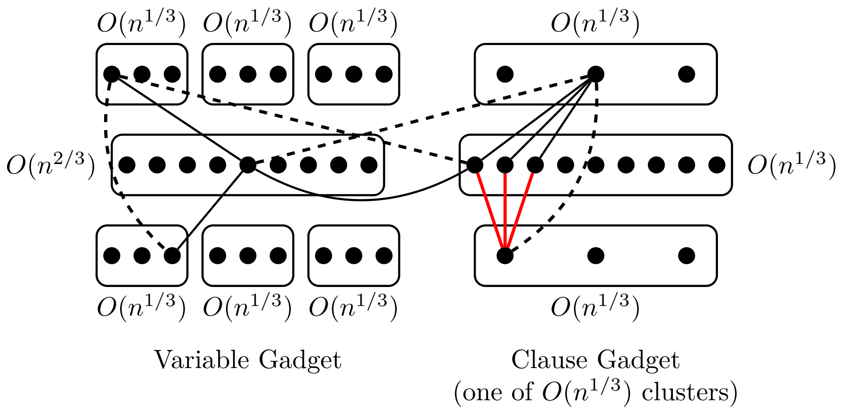

Figure 2 A simplified view of the obtained instance. Edges (solid lines) and requests (dashed lines) representing one variable and one clause that contains this variable are presented on the picture.

($\mathbf{P_5}$) Let C be any clause. Let $i = \beta(C)$ and let $j = g(C)$. Then there are exactly three 2-paths between $a_{\beta(C),g(C)}$ and $c_{\beta(C),\gamma(C)}$, each going through $b^k_{\beta(C),\gamma(C)}$ for $k = 1, 2, 3$.

Connections between the two parts. Consider a clause $C = \{\ell_1, \ell_2, \ell_3\}$ and its k-th literal ℓ_k for each $k = 1, 2, 3$. Then for some variable x we have $\ell_k = x$ or $\ell_k = \bar{x}$. We add the edge $b^k_{\beta(C),\gamma(C)}\mathrm{mid}(x)$ and we add the pair $\{\mathrm{mid}(x), a_{\beta(C),g(C)}\}$ to S. If $\ell_k = x$, we also add the pair $\{b^k_{\beta(C),\gamma(C)}, u_{\mathrm{lay}(x),\mathrm{up}(x)}\}$ to S; otherwise we add the pair $\{b^k_{\beta(C),\gamma(C)}, l_{\mathrm{lay}(x),\mathrm{low}(x)}\}$ to S. We claim the following.

($\mathbf{P_6}$) Every edge between the two parts was added exactly once, i.e., for every edge uv such that u is in the clause part and v is in the variable part, there is exactly one clause C and exactly one literal $\ell_k \in C$ such that $u = b^k_{\beta(C),\gamma(C)}$ and $v = \mathrm{mid}(x)$, where x is the variable in ℓ_k.

Indeed, assume for a contradiction that there is a clause C_1 with its k_1-th literal containing x_1 and a clause C_2 with its k_2-th literal containing x_2 such that $b^{k_1}_{\beta(C_1),\gamma(C_1)} = b^{k_2}_{\beta(C_2),\gamma(C_2)}$ and $\mathrm{mid}(x_1) = \mathrm{mid}(x_2)$. Then $C_1 \neq C_2$ by (P$_1$). Since $\mathrm{mid}(x_1) = \mathrm{mid}(x_2)$, C_1 and C_2 are adjacent in the clause conflict graph G_C. It follows that $\beta(C_1) \neq \beta(C_2)$, so two different clusters share a vertex, a contradiction.

This finishes the description of the instance (G, S, c_0). (See Fig. 2.)

From an assignment to a coloring. Let $\xi : \mathrm{Var} \to \{T, F\}$ be a satisfying assignment of φ. We claim that there is a coloring c of $E(G)$ which extends c_0 and satisfies all pairs in S. We define c as follows. Denote $\overline{F} = T$, $\overline{T} = F$ and $\xi(\overline{x}) = \overline{\xi(x)}$. For every variable $x \in \mathrm{Var}$ we put $c(u_{\mathrm{lay}(x),\mathrm{up}(x)}\mathrm{mid}(x)) = \xi(x)$ and $c(\mathrm{mid}(x)l_{\mathrm{lay}(x),\mathrm{low}(x)}) = \overline{\xi(x)}$. By (P$_3$) and (P$_4$) each edge is colored exactly once. Note that it satisfies all the pairs in S between vertices in the variable part.

For each clause C and each of its literals ℓ_k do the following. Let us color the edge $a_{\beta(C),g(C)}b^k_{\beta(C),\gamma(C)}$ with the color $\xi(\ell_k)$. Since g is injective on color classes of $\gamma_{\beta(C)}$, after processing all the literals in all the clauses, no edge is colored more than once. Recall that for every clause C we added exactly one pair to S, namely $\{a_{\beta(C),g(C)}, c_{\beta(C),\gamma(C)}\}$. Pick any of C's satisfied literals, say ℓ_k. Note that the pair $\{a_{\beta(C),g(C)}, c_{\beta(C),\gamma(C)}\}$ is then satisfied, because edge $a_{\beta(C),g(C)}b^k_{\beta(C),\gamma(C)}$ is colored by T and $b^k_{\beta(C),\gamma(C)}c_{\beta(C),\gamma(C)}$ is colored by F. Hence all the pairs in S between vertices in the clause part are satisfied.

Now let us color the edges between the clause part and the variable part. Consider any such edge uv, i.e., u is in the clause part and v is in the variable part. By (P$_6$), there is exactly one clause C and exactly one literal $\ell_k \in C$ such that $u = b^k_{\beta(C),\gamma(C)}$ and $v = \mathrm{mid}(x)$, where x is the variable in ℓ_k. Color the edge $b^k_{\beta(C),\gamma(C)}\mathrm{mid}(x)$ with the color $\overline{\xi(\ell_k)}$. Then the pair $\{\mathrm{mid}(x), a_{\beta(C),g(C)}\}$ is satisfied by the path $(\mathrm{mid}(x), b^k_{\beta(C),\gamma(C)}, a_{\beta(C),g(C)})$, since $c(b^k_{\beta(C),\gamma(C)}a_{\beta(C),g(C)}) = \xi(\ell_k)$. Assume $\ell_k = x$. Then the pair $\{b^k_{\beta(C),\gamma(C)}, u_{\mathrm{lay}(x),\mathrm{up}(x)}\}$ is satisfied by the path $(b^k_{\beta(C),\gamma(C)}, \mathrm{mid}(x), u_{\mathrm{lay}(x),\mathrm{up}(x)})$, since its first edge is colored by $\overline{\xi(\ell_k)} = \overline{\xi(x)}$ and its second edge is colored by $\xi(x)$. Analogously, when $\ell_k = \bar{x}$, then the pair $\{b^k_{\beta(C),\gamma(C)}, l_{\mathrm{lay}(x),\mathrm{low}(x)}\}$ is satisfied by the path $(b^k_{\beta(C),\gamma(C)}, \mathrm{mid}(x), l_{\mathrm{lay}(x),\mathrm{low}(x)})$, since its first edge is colored by $\overline{\xi(\ell_k)} = \xi(x)$ and its second edge is colored by $\overline{\xi(x)}$.

It follows that we colored all the edges and all the pairs in S are satisfied, so (G, S, c_0) is a YES-instance, as required.

From a coloring to an assignment. Let $c : E(G) \to \{T, F\}$ be a coloring which extends c_0 and satisfies all pairs in S. Consider the following variable assignment: for every $x \in \mathrm{Var}$, we put $\xi(x) = c(u_{\mathrm{lay}(x),\mathrm{up}(x)}\mathrm{mid}(x))$. We claim that ξ satisfies all the clauses of φ. Consider an arbitrary clause $C = \{\ell_1, \ell_2, \ell_3\}$.

Since the pair $\{a_{\beta(C),g(C)}, c_{\beta(C),\gamma(C)}\}$ is satisfied, there is a 2-color 2-path P between $a_{\beta(C),g(C)}$ and $c_{\beta(C),\gamma(C)}$. Recall that $N(c_{\beta(C),\gamma(C)}) = \{b^k_{\beta(C),\gamma(C)} : k = 1, 2, 3\}$, so there is $k = 1, 2, 3$ such that $b^k_{\beta(C),\gamma(C)}$ is the internal vertex on P. Since c extends c_0 and $c_0(b^k_{\beta(C),\gamma(C)}c_{\beta(C),\gamma(C)}) = F$, we infer that $c(a_{\beta(C),g(C)}b^k_{\beta(C),\gamma(C)}) = T$. Let x be the variable in the literal ℓ_k.

Since the pair $\{\mathrm{mid}(x), a_{\beta(C),g(C)}\}$ is satisfied, there is a 2-color 2-path Q between $\mathrm{mid}(x)$ and $a_{\beta(C),g(C)}$. Then the internal vertex of Q is $b^{k'}_{\beta(C'),\gamma(C')}$, for some clause C' and integer $k' = 1, 2, 3$. Let y be the variable in the k'-th literal of C'. Since there is an edge between $\mathrm{mid}(x)$ and $b^{k'}_{\beta(C'),\gamma(C')}$, from (P$_6$) we infer that $\mathrm{mid}(y) = \mathrm{mid}(x)$. If $C = C'$ and $k' \neq k$, then by (P$_1$) we get that $\mathrm{mid}(x) \neq \mathrm{mid}(y)$, a contradiction. If $C \neq C'$, since $\mathrm{mid}(y) = \mathrm{mid}(x)$, the clauses C and C' are adjacent in the clause conflict graph G_C, so $\beta(C') \neq \beta(C)$. However, then the edge $b^{k'}_{\beta(C'),\gamma(C')}a_{\beta(C),g(C)}$ of Q goes between two clusters, a contradiction. Hence $C' = C$ and $k' = k$, i.e., $Q = (\mathrm{mid}(x), b^k_{\beta(C),\gamma(C)}, a_{\beta(C),g(C)})$. Since $c(b^k_{\beta(C),\gamma(C)}a_{\beta(C),g(C)}) = T$, we get $c(\mathrm{mid}(x)b^k_{\beta(C),\gamma(C)}) = F$. Now assume w.l.o.g. that $\ell_k = x$, the case $\ell_k = \bar{x}$ is analogous.

Since the pair $\{b^k_{\beta(C),\gamma(C)}, u_{\mathrm{lay}(x),\mathrm{up}(x)}\}$ is satisfied, there is a 2-color 2-path R between $b^k_{\beta(C),\gamma(C)}$ and $u_{\mathrm{lay}(x),\mathrm{up}(x)}$. Then the internal vertex z of R belongs to M. By (P$_6$) there is a literal ℓ_k which belongs to a clause C_2 and contains a variable x_2 such that $z = \mathrm{mid}(x_2)$ and $b^k_{\beta(C),\gamma(C)} = b^k_{\beta(C_2),\gamma(C_2)}$. In particular, $\beta(C) = \beta(C_2)$ and $\gamma(C) = \gamma(C_2)$. Assume $C_2 \neq C$. There is a variable, say x_3, corresponding to edge $\mathrm{mid}(x_2)u_{\mathrm{lay}(x),\mathrm{up}(x)}$, i.e., $\mathrm{mid}(x_2) = \mathrm{mid}(x_3)$ and $u_{\mathrm{lay}(x),\mathrm{up}(x)} = u_{\mathrm{lay}(x_3),\mathrm{up}(x_3)}$. It follows that C and C_2 are adjacent in $G_{\beta(C)}$, which contradicts the fact that $\gamma(C) = \gamma(C_2)$. Hence $C_2 = C$, i.e., there is exactly one 2-path between $b^k_{\beta(C),\gamma(C)}$ and $u_{\mathrm{lay}(x),\mathrm{up}(x)}$, and it goes through $\mathrm{mid}(x)$. Since $c(\mathrm{mid}(x)b^k_{\beta(C),\gamma(C)}) = F$ and the path is 2-color, we get that $c(u_{\mathrm{lay}(x),\mathrm{up}(x)}\mathrm{mid}(x)) = T$. Hence $\xi(\ell_k) = \xi(x) = T$, so clause C is satisfied, as required.

It finishes the proof. (The analysis of the size of the resulting instance and its other properties described in the claim is not immediate; because of the space constraints we skip them here.) ◀

The proof of the following lemma is non-trivial, but standard (see lemmas 4 and 5 in the full version [17].)

▶ **Lemma 9** (★). *For any fixed $k \geq 2$, there is a polynomial time algorithm which given an instance $I = (G = (V, E), S, c_0)$ of* Subset Rainbow 2-Coloring Extension *constructs an equivalent instance $(G' = (V', E'), S')$ of* Subset Rainbow k-Coloring *such that $|V'| = O(k|V|k^2\ell)$, $|E'| = |E| + O(k|V|) + |\mathrm{Dom}(c_0)| + O(k^2\ell)$, $|S'| = |S| + |E| + 2|\mathrm{Dom}(c_0)| + O(k^2\ell)$. Let $G_S = (V, S)$ and $G_{S'} = (V', S')$. Then $\Delta(G_{S'}) = O(\Delta(G_S) + \Delta(G) + |\mathrm{Dom}(c_0)|/\ell)$. Moreover if we are given a proper vertex p-coloring of the graph $G_S = (V, S)$ then we can output also a proper vertex $(p + 3)$-coloring of the graph $G_{S'} = (V', S')$.*

2.3 From Subset Rainbow k-Coloring to Rainbow k-Coloring

The basic idea of our reduction from Subset Rainbow k-Coloring to Rainbow k-Coloring is to modify the graph so that the pairs of vertices from $\bar{E} \setminus S$ can be somehow trivially satisfied, without affecting the satisfiability of S. To this end we use a notion of biclique covering number (called also bipartite dimension). The *biclique covering number* $\mathrm{bc}(G)$ of a graph G is the smallest number of biclique subgraphs of G that cover all edges of G. The following proposition is well-known.

▶ **Proposition 10** (Folklore). *It holds that $\mathrm{bc}(K_n) = \lceil \log n \rceil$, and the corresponding cover can be constructed in polynomial time.*

Proof. Assume $V(K_n) = \{0, \ldots, n-1\}$. The i-th biclique contains edges between the vertices that have 0 at the i-th bit and the vertices that have 1 at the i-th bit. ◀

Let $G = (V_1, V_2, E)$ be a bipartite graph. Then $\hat{G}$ denotes the bipartite complement of G, i.e, the bipartite graph $(V_1, V_2, \{v_1v_2 \ : \ v_1 \in V_1,\ v_2 \in V_2, \text{ and } v_1v_2 \notin E\})$. We will use the following result of Jukna. Recall that we denote $\Delta_1(G) = \max\{\Delta(G), 1\}$.

▶ **Theorem 11** (Jukna [16]). *If G is an n-vertex bipartite graph, then $\mathrm{bc}(\hat{G}) = O(\Delta_1(G) \log n)$.*

Let us call the cover from Theorem 11 the *Jukna cover*. In our application we need to be able to *compute* the Jukna cover fast.

▶ **Lemma 12.** *The Jukna cover can be constructed in (i) expected polynomial time, or (ii) deterministic $2^n n^{O(1)}$ time.*

Proof. Denote $\Delta = \Delta(G)$. If $\Delta = 0$ the claim follows from Proposition 10, so in what follows assume $\Delta \geq 1$. Jukna [16] shows a simple worst-case linear time algorithm which samples a biclique in G. Then it is proved that after sampling t bicliques, the probability that there is an edge not covered by one of the bicliques is at most $n^2 e^{-t/(\Delta e)}$. It follows that the probability that more than $\Delta e(2 \ln n + 1)$ samples are needed is at most e^{-1}. If after $\Delta e(2 \ln n + 1)$ samples some edges is not covered, we discard all the bicliques found and repeat the whole algorithm from the scratch. The expected number of such restarts is $1/(1 - e^{-1}) = O(1)$.

Now we proceed to the second part of the claim. Let $G = (V_1, V_2, E)$. For every subset $A \subseteq V_1$ we define the biclique $B_A = (A, B, E_A)$, where B is the set of vertices of V_2 adjacent in $\hat{G}$ to all vertices of A. Clearly, B_A is a subgraph of $\hat{G}$ and for every subset $A \subseteq V_1$ it can be found in time linear in the size of $\hat{G}$. Our deterministic algorithm works as follows: as long as not all edges of $\hat{G}$ are covered, it picks the biclique B_A which maximizes the number of new covered edges of $\hat{G}$. Since all the bicliques in the set $\{B_A \ : \ A \subseteq V_1\}$ can be listed in time $O(2^n|E(\hat{G})|)$, the total running time is $t2^n n^{O(1)}$, where t is the size of the returned cover. It suffices to show that $t = O(\Delta \log n)$.

Jukna [16] shows that if set A is chosen by picking every vertex of V_1 independently with probability $\frac{1}{\Delta}$, then for any edge $uv \in E(\hat{G})$, $\Pr[uv \in E_A] \geq \frac{1}{\Delta e}$. Consider any step of our algorithm and let $R \subseteq E(\hat{G})$ be the set of the edges of $\hat{G}$ which are not covered yet. By the bound on $\Pr[uv \in E_A]$ and the linearity of expectation a set A sampled as described above covers at least $|R|/(\Delta e)$ new edges in expectation. In particular, it implies that there exists a set $A \subseteq V_1$ that covers at least $|R|/(\Delta e)$ new edges. Let $\alpha = (1 - \frac{1}{\Delta e})^{-1}$. By the Taylor expansion of $\log(1-x)$, it follows that $t = O(\log_\alpha |E(\hat{G})|) = O(\log n / \log \alpha) = O(\Delta \log n)$. ◀

▶ **Lemma 13.** *Let G be an n-vertex graph with a given proper vertex p-coloring. Then the edges of $\bar{G}$ can be covered by $O(p^2\Delta_1(G)\log n)$ bicliques from $\bar{G}$ so that any edge of G and any biclique have at most one common vertex. This cover can be constructed in (i) expected polynomial time, or (ii) deterministic $2^n n^{O(1)}$ time.*

Proof. The edges of $\bar{G}$ between the vertices of any color class form a clique, so by Proposition 10 we can cover its edges using $O(\log n)$ bicliques. If an edge of G has both endpoints in such a biclique, these endpoints have the same color, contradiction. For two different colors i and j the edges of G between their color classes form a bipartite graph of maximum degree at most $\Delta(G)$. Hence by Lemma 12 we can cover the edges of its bipartite complement using $O(\Delta_1(G)\log n)$ bicliques. If an edge uv of G has both endpoints in such a biclique, then either (i) these endpoints have the same color, contradiction, or (ii) these endpoints belong to two different parts of the biclique, so uv is in the biclique and hence $uv \in E(\bar{G})$, a contradiction. Summing over all color classes and pairs of color classes, we use $O(p^2\Delta_1(G)\log n)$ bicliques, as required. ◀

Now we proceed to the actual reduction.

▶ **Lemma 14.** *Given an instance $(G = (V,E), S)$ of* Subset Rainbow 2-Coloring *together with a proper p-coloring of the graph $G_S = (V,S)$, one can construct an equivalent instance G' of* Rainbow 2-Coloring *such that $|V(G')| = O(|V| + kp^2\Delta_1(G_S)\log|V|)$, $|E(G')| = O(|E(G)|+(|V|+p^2\Delta_1(G_S)\log|V|)\cdot p^2\Delta_1(G_S)\log|V|)$. The construction algorithm can run in (i) expected polynomial time, or (ii) deterministic $2^{|V|}|V|^{O(1)}$ time.*

Proof. Here we focus on the $k = 2$ case. The $k \geq 3$ case is significantly more technical — see the details in the full version. Let us consider a biclique covering of the complement of the graph G_S with $q = O(p^2\Delta_1(G_S)\log n)$ bicliques $(U_1, V_1; E_1), (U_2, V_2; E_2), \ldots, (U_q, V_q; E_q)$ as in Lemma 13. Let $W = \{w_1, w_2, \ldots, w_q\}$, $T = \{t_1, t_2, t_3\}$, $V(G') = V \cup W \cup T$ and $E(G') = E(G) \cup (W \times W) \cup (T \times T) \cup (\{t_2\} \times W) \cup (\{t_3\} \times (V \cup W)) \cup \left(\bigcup_{1 \leq i \leq q} \{w_i\} \times (U_i \cup V_i)\right)$ (we abuse the notation assuming that $\times$ operator returns *unordered* pairs minus loops). Because of the space limitation the equivalence proof is deferred to the full version. ◀

2.4 Putting everything together

By pipelining lemmas 7, 8, and 9 we get the following corollary.

▶ **Corollary 15.** *Fix $k \geq 2$. Given a* 3-SAT *formula φ with m clauses one can construct in polynomial time an equivalent instance $(G = (V,E), S)$ of* Subset Rainbow *k-*Coloring *such that $|V| = O(m^{2/3})$, $|E| = O(m)$, $\Delta((V,S)) = O(m^{1/3})$, and the graph $G_S = (V,S)$ is $O(1)$-colorable.*

Note that in Corollary 15 we have $|S| = |V|\Delta((V,S)) = O(m)$. It follows that the Sparsification Lemma (Lemma 6) and Corollary 15 imply Theorem 3.

Pipelining Corollary 15 and Lemma 14 gives the following corollary.

▶ **Corollary 16.** *Fix $k \geq 2$. Given a 3-SAT formula φ with $O(m)$ clauses one can construct an equivalent instance G of* Rainbow k-Coloring *with $O(m^{2/3})$ vertices and $O(m \log m)$ edges. The construction algorithm can run in (i) expected polynomial time, or (ii) deterministic $2^{O(m^{2/3})}$ time.*

Again, the above and the Sparsification Lemma immediately imply Theorem 2.

3 Algorithms for Subset Rainbow k-Coloring

In this section we study FPT algorithms for Subset Rainbow k-Coloring parameterized by $|S|$. We provide two such algorithms, based on different approaches: one for $k = 2$ case, and one (slightly slower) for the general case. Consider an instance (G, S) of the Subset Rainbow k-Coloring problem. Note that we can assume that $S \subseteq \bar{E}$, since any constraint $\{u, v\} \in E$ is satisfied in every edge coloring. Moreover, we say that a pair $\{u, v\}$ is *feasible* when the distance between u and v is at most k. The set of all feasible pairs is denoted by $F(G)$. Clearly, when S contains a request which is not feasible, then (G, S) is a trivial NO-instance. Hence, throughout this section we assume $S \subseteq \bar{E} \cap F(G)$.

3.1 The $k = 2$ case

For any $X \subseteq S$ let $\mathcal{P}_X$ be the set of all 2-edge paths between the pairs of vertices in X. Denote $E(\mathcal{P}_X) = \bigcup_{P \in \mathcal{P}_X} E(P)$. For two edges $e_1, e_2 \in E(G)$ we say that e_1 and e_2 are *linked by* X, denoted as $e_1 \sim_X e_2$ when there are two paths $P_1, P_2 \in \mathcal{P}_X$ (possibly $P_1 = P_2$) such that $e_1 \in E(P_1)$, $e_2 \in E(P_2)$ and $E(P_1) \cap E(P_2) \neq \emptyset$. Let $\approx_X$ be the transitive closure of $\sim_X$. Then $\approx_X$ is an equivalence relation. Recall that $E(G)/\approx_X$ denotes the quotient set of the relation $\approx_X$. The main observation of this section is the following theorem.

▶ **Theorem 17.** *The number of 2-colorings of $E(G)$ that satisfy all the pairs in S is equal to $\sum_{X \subseteq S} (-1)^{|X|} 2^{|E(G)/\approx_X|}$.*

In the proof we make use of the well-known inclusion-exclusion principle. Below we state it in the intersection version (see, e.g., [10])

▶ **Theorem 18** (Inclusion–exclusion principle, intersection version)**.** *Let $A_1, \ldots, A_n \subseteq U$, where U is a finite set. Denote $\bigcap_{i \in \emptyset}(U \setminus A_i) = U$. Then*

$$|\bigcap_{i \in [n]} A_i| = \sum_{X \subseteq [n]} (-1)^{|X|} |\bigcap_{i \in X} (U \setminus A_i)|.$$

Proof of Theorem 17. Let us define, for every pair $\{u, v\} \in S$ (say, $u < v$), the set $A_{u,v}$ of 2-edge colorings of G that satisfy $\{u, v\}$. Note that the number of rainbow 2-colorings of G that satisfy all the pairs in S is equal to $|\bigcap_{\{u,v\} \in S} A_{u,v}|$. By Theorem 18 it suffices to show that, for any subset $X \subseteq S$, the number $\#_X$ of 2-colorings such that *none* of the pairs in X is satisfied, equals $2^{|E(G)/\approx_X|}$.

Fix any coloring c that does not satisfy any pair from X. Then every path from $\mathcal{P}_X$ has both edges of the same color. Hence, for two edges $e_1, e_2 \in E(G)$, if $e_1 \sim_X e_2$ then e_1 and e_2 are colored by c with the same color. It follows that for any equivalence class A of $\approx_X$, all edges of A are have the same color in c. This proves that $\#_X \leq 2^{|E(G)/\approx_X|}$.

For every function $c_0 : (E(G)/\approx_X) \to \{1,2\}$ we can define the coloring $c : E(G) \to \{1,2\}$ by putting $c(e) = c_0([e]_{\approx_X})$ for every edge $e \in E(G)$. (Note that the edges that do not belong to any path in $\mathcal{P}_X$ form singleton equivalence classes.) Then, c does not satisfy any pair from X, because if some pair $\{u,v\}$ is satisfied then there is a 2-color path uxv; but $ux \sim_X xv$, so $[ux]_{\approx_X} = [xv]_{\approx_X}$ and $c(ux) = c(xv)$, a contradiction. It follows that $\#_X \geq 2^{|E(G)/\approx_X|}$. ◀

Since it is a standard exercise to compute the relation $X \subseteq S$ in $O(|E| + |S| \cdot |V|)$ time (see the full version), we get the following corollary. (Let us remark here that the algorithm from Corollary 19 only decides whether the coloring exists, without finding it. However, by a minor modification of the algorithm it can construct the coloring; see the full version.)

▶ **Corollary 19.** *For any graph $G = (V,E)$ and a set of requests S the number of 2-colorings of E that satisfy all the pairs in S can be computed in $O(2^{|S|}(|E| + |S| \cdot |V|))$ time and polynomial space. In particular,* Subset Rainbow 2-Coloring *can be decided within the same time.*

3.2 The general case

In this section we use partial colorings. For convenience, a partial coloring is represented as a function $c : E \to [k] \cup \{\perp\}$, where the value $\perp$ corresponds to an uncolored edge. By $\mathrm{Dom}(c)$ we denote the domain of the corresponding partial function, i.e., $\mathrm{Dom}(c) = c^{-1}([k])$. The partial coloring which does not color anything, i.e., is constantly equal to $\perp$ is denoted by $c_\perp$.

For a graph $G = (V,E)$ consider a partial edge coloring $c : E \to [k] \cup \{\perp\}$. A *guide function* is any function of the form $f : S \to \binom{\mathrm{Dom}(c)}{\leq k}$, i.e., any function that assigns sets of at most k colored edges to all requests in S. A constant guide function equal to $\emptyset$ for every request in S is denoted by $g_{S,\emptyset}$. Pick any pair $\{u,v\} \in S$. We say that a walk W connecting u and v is f-guided if every color appears at most once on W, and $f(\{u,v\}) \subseteq E(W)$. We say that a coloring c is (f,S)-rainbow when for every pair $\{u,v\} \in S$ there is an f-guided walk between u and v. Note that (G,S) is a YES-instance of Subset Rainbow k-Coloring iff there is an $(g_{S,\emptyset}, S)$-rainbow coloring. Indeed, every rainbow walk contains a rainbow path.

The following lemma is going to be useful in our branching algorithm.

▶ **Lemma 20.** *Let $G = (V,E)$ be a graph, and let S be a set of requests. Let $c_0 : E \to [k]$ be a partial edge coloring and let $f : S \to \binom{\mathrm{Dom}(c_0)}{\leq k}$ be a guide function. Then, given a pair $\{u,v\} \in S$ in time $2^k n^{O(1)}$ one can find an f-guided u-v walk of length at most k, if it exists.*

Proof. The algorithm is as follows. We can assume that $f(\{u,v\})$ does not contain two edges of the same color, for otherwise the requested walk does not exist. For every $e \in f(\{u,v\})$ we remove all the edges of color $c_0(e)$. Next, we put back edges of $f(\{u,v\})$. Then it suffices to find in the resulting graph G' any u-v path of length at most k and with no repeated colors that visits all the colors of the edges in $f(\{u,v\})$. This is done using dynamic programming. For every vertex $x \in V$, subset $X \subseteq [k]$ and integer $\ell = 0, \ldots, k$ we find the boolean value $T[x,X,\ell]$ which is true iff there is a u-x walk of length ℓ which does not repeat colors and visits all the colors from X, but not more. We initialize $T[u,\emptyset,0] = \texttt{true}$ and $T[x,\emptyset,0] = \texttt{false}$ for every $x \neq u$. Next we iterate through the remaining triples (x,X,ℓ), in the nondecreasing order of ℓ and X's cardinalities. The value of $T[x,X,\ell]$ is then computed using the formula

$$T[x,X,\ell] = \bigvee_{yx \in c_0^{-1}(X \cup \{\perp\}) \cap E(G')} T[y, X \setminus \{c_0(yx)\}, \ell - 1].$$

Pseudocode 1: FindColoring(S_0, c_0, f)

```
if $S_0 = \emptyset$ then
    return $c_0$
if for some $r \in S_0$ there are edges $e_1, e_2 \in f(r)$ with $c_0(e_1) = c_0(e_2)$ then
    return null
Pick any $\{u, v\} \in S_0$;
Find any $f$-guided $u$-$v$ walk $W$ of length at most $k$ using Lemma 20;
if $W$ does not exist then
    return null
Let $c_1$ be obtained from $c_0$ by coloring the uncolored edges of $W$ to get a rainbow walk;
if FindColoring($S_0 \setminus \{u, v\}, c_1, f|_{S_0 \setminus \{u,v\}}$) $\neq$ null then return the coloring found;
for $e \in E(W) \setminus \mathrm{Dom}(c_0)$ do
    for $\alpha \in [k]$ do
        for $r \in S_0 \setminus \{\{u, v\}\}$ do
            Let $c_{e,\alpha}$ be obtained from $c_0$ by coloring $e$ with $\alpha$;
            Let $f_{e,r}$ be obtained from $f$ by putting $f(r) := f(r) \cup \{e\}$;
            if FindColoring($S_0, c_{e,\alpha}, f_{e,r}$) $\neq$ null then return the coloring found;
return null
```

The requested walk exists iff $T[v, X, \ell] = \texttt{true}$ for any $\ell = 0, \ldots, k$ and X such that $c_0(f(\{u, v\})) \subseteq X$. The walk is retrieved using standard DP methods. ◀

Now we are ready to describe our branching algorithm. Let $(G = (V, E), S)$ be the input instance. Our algorithm consists of a recursive procedure FindColoring which gets three parameters: S_0 (a set of requests), $c_0 : E \to [k] \cup \{\perp\}$ (a partial coloring), and a guide function $f : S \to \binom{\mathrm{Dom}(c_0)}{\leq k}$. It is assumed that for every request $r \in S$, every pair of different edges $e_1, e_2 \in f(r)$ is colored differently by c_0. The goal of the procedure FindColoring is to find an (f, S_0)-rainbow coloring $c : E \to [k]$ which extends c_0. Thus the whole problem is solved by invoking FindColoring($S, c_\perp, g_{S,\emptyset}$). A rough description of FindColoring is as follows. We pick any pair $\{u, v\} \in S_0$ and we find any f-guided u-v walk W of length at most k using Lemma 20. Let c_1 be obtained from c_0 by coloring the uncolored edges of W to get a rainbow walk. If FindColoring($S_0 \setminus \{u, v\}, c_1, f|_{S_0 \setminus \{u,v\}}$) returns a coloring, we are done. But if no such coloring exists then we know that we made a wrong decision: coloring some of the uncolored edges e of W into $c_1(e)$ (instead of some color α) makes some other request $r \in S_0 \setminus \{\{u, v\}\}$ impossible to satisfy. For every possible triple (e, α, r) we invoke FindColoring with the same set of requests S_0, partial coloring c_0 extended by coloring e with α, and the guide function f extended by putting $f(r) := f(r) \cup \{e\}$.

A precise description of procedure FindColoring can be found in Pseudocode 1. The following lemma proves its correctness.

▶ **Lemma 21.** *Procedure* FindColoring *invoked with parameters* (S_0, c_0, f) *finds an* (f, S_0)*-rainbow coloring* $c : E \to [k]$ *which extends* c_0*, whenever it exists.*

Proof. The proof is by induction on the sum of $|S_0|$ and the number of uncolored edges. It is clear that if $|S_0| = 0$ or all the edges are colored then the algorithm behaves correctly. In the induction step, the only non-trivial thing to check is whether any of the calls in lines 10 or 16 returns a coloring, provided that there is a solution, i.e., an (f, S_0)-rainbow coloring $c : E \to [k]$ which extends c_0. Assume that no coloring is returned in Line 16. Then for every edge $e \in E(W) \setminus \mathrm{Dom}(c_0)$, and request $r \in S_0 \setminus \{\{u, v\}\}$ coloring c is not a $(f_{e,r}, S_0)$-rainbow coloring, for otherwise the call FindColoring($S_0, c_{e,c(e)}, f_{e,r}$) returns a coloring. If follows that for every edge $e \in E(W) \setminus \mathrm{Dom}(c_0)$ and request $r \in S_0 \setminus \{\{u, v\}\}$ the walk that realizes the request r in the coloring c does not contain e. Hence, the following coloring

$$c'(e) = \begin{cases} c(e) & \text{if } e \notin E(W), \\ c_1(e) & \text{if } e \in E(W). \end{cases}$$

is another (f, S_0)-rainbow coloring, and it extends c_1. It follows that the call in Line 10 returns a coloring, as required. ◀

▶ **Theorem 22.** *For every integer k, there is an FPT algorithm for* Subset Rainbow k-Coloring *parameterized by $|S|$. The algorithm runs in time $(k^2|S|)^{k|S|}2^k n^O(1)$, in particular in $|S|^{O(|S|)}n^{O(1)}$ time for every fixed k.*

Proof. By Lemma 21 Subset Rainbow k-Coloring is solved by invoking FindColoring($S, c_\perp, g_{S,\emptyset}$). Note that whenever we go deeper in the recursion either some request of S_0 gets satisfied, or $|f(r)|$ increases for some $r \in S_0$. When $|f(r)|$ increases to $k+1$, the corresponding recursive call returns `null` immediately (because the condition in Line 3 holds). It follows that the depth of the recursion is at most $|S|k$. Since in every call of Subset Rainbow k-Coloring the algorithm uses time $2^k n^{O(1)}$ (by Lemma 21) and branches into at most $1 + k^2(|S| - 1) \leq k^2|S|$ recursive calls, the total time is $(k^2|S|)^{k|S|}2^k n^O(1)$, as required. ◀

4 Further Work

We believe that this work only initiates the study of fine-grained complexity of variants of Rainbow k-Coloring. In particular, many open questions are still unanswered. The ultimate goal is certainly to get tight bounds. We pose the following two conjectures.

▶ **Conjecture 23.** *For any integer $k \geq 2$, there is no $2^{o(|E|)}n^{O(1)}$-time algorithm for* Rainbow k-Coloring*, unless ETH fails.*

▶ **Conjecture 24.** *For any integer $k \geq 2$, there is no $2^{o(n^2)}n^{O(1)}$-time algorithm for* Rainbow k-Coloring*, unless ETH fails.*

Note that in this work we have settled Conjecture 23 for Subset Rainbow k-Coloring, and for Rainbow k-Coloring we showed a slightly weaker, $2^{o(|E|/\log|E|)}n^{O(1)}$ bound. However, avoiding this $\log|E|$ factor seems to constitute a considerable technical challenge.

In this paper we gave two algorithms for Subset Rainbow k-Coloring parameterized by $|S|$, one working in $2^{|S|}n^{O(1)}$ time for $k = 2$ and another, working in time $|S|^{O(|S|)}n^{O(1)}$ for every fixed k. We conjecture that there exists an algorithm running in time $2^{O(|S|)}n^{O(1)}$ for every fixed k.

Finally, we would like to propose yet another parameterization of Rainbow k-Coloring. Assume we are given a graph $G = (V, E)$ and a subset of vertices $S \subseteq V$. In the Steiner Rainbow k-Coloring problem the goal is to determine whether there is a rainbow k-coloring such that every pair of vertices in S is connected by a rainbow path. By our Theorem 2, Steiner Rainbow k-Coloring has no algorithm running in time $2^{o(|S|^{3/2})}$, under ETH. On the other hand, our algorithm for Subset Rainbow k-Coloring implies that Steiner Rainbow k-Coloring parameterized by $|S|$ admits an FPT algorithm with running time of $2^{O(|S|^2 \log|S|)}n^{O(1)}$. It would be interesting make the gap between these bounds smaller.

A Randomized Polynomial Kernelization for Vertex Cover with a Smaller Parameter

Stefan Kratsch

Universität Bonn, Institut für Informatik, Bonn, Germany
kratsch@cs.uni-bonn.de

Abstract

In the VERTEX COVER problem we are given a graph $G = (V, E)$ and an integer k and have to determine whether there is a set $X \subseteq V$ of size at most k such that each edge in E has at least one endpoint in X. The problem can be easily solved in time $\mathcal{O}^*(2^k)$, making it fixed-parameter tractable (FPT) with respect to k. While the fastest known algorithm takes only time $\mathcal{O}^*(1.2738^k)$, much stronger improvements have been obtained by studying *parameters that are smaller than* k. Apart from treewidth-related results, the arguably best algorithm for VERTEX COVER runs in time $\mathcal{O}^*(2.3146^p)$, where $p = k - LP(G)$ is only the excess of the solution size k over the best fractional vertex cover (Lokshtanov et al. TALG 2014). Since $p \leq k$ but k cannot be bounded in terms of p alone, this strictly increases the range of tractable instances.

Recently, Garg and Philip (SODA 2016) greatly contributed to understanding the parameterized complexity of the VERTEX COVER problem. They prove that $2LP(G) - MM(G)$ is a lower bound for the vertex cover size of G, where $MM(G)$ is the size of a largest matching of G, and proceed to study parameter $\ell = k - (2LP(G) - MM(G))$. They give an algorithm of running time $\mathcal{O}^*(3^\ell)$, proving that VERTEX COVER is FPT in ℓ. It can be easily observed that $\ell \leq p$ whereas p cannot be bounded in terms of ℓ alone. We complement the work of Garg and Philip by proving that VERTEX COVER admits a randomized polynomial kernelization in terms of ℓ, i.e., an efficient preprocessing to size polynomial in ℓ. This improves over parameter $p = k - LP(G)$ for which this was previously known (Kratsch and Wahlström FOCS 2012).

1 Introduction

A *vertex cover* of a graph $G = (V, E)$ is a set $X \subseteq V$ such that each edge $e \in E$ has at least one endpoint in X. The VERTEX COVER problem of determining whether a given graph G has a vertex cover of size at most k has been an important benchmark problem in parameterized complexity for both *fixed-parameter tractability* and *(polynomial) kernelization*,[1] which are the two notions of tractability for parameterized problems. Kernelization, in particular, formalizes the widespread notion of efficient preprocessing, allowing a rigorous study (cf. [14]). We present a randomized polynomial kernelization for VERTEX COVER for the to-date smallest parameter, complementing a recent fixed-parameter tractability result by Garg and Philip [10].

[1] Definitions can be found in the full version. Note that we use ℓ, rather than k, as the default symbol for parameters and use VERTEX COVER(ℓ) to refer to the VERTEX COVER problem with parameter ℓ.

Let us first recall what is known for the so-called *standard parameterization* VERTEX COVER(k), i.e., with parameter $\ell = k$: There is a folklore $\mathcal{O}^*(2^k)$ time[2] algorithm for testing whether a graph G has a vertex cover of size at most k, proving that VERTEX COVER(k) is fixed-parameter tractable (FPT); this has been improved several times with the fastest known algorithm due to Chen et al. [4] running in time $\mathcal{O}^*(1.2738^k)$. Under the Exponential Time Hypothesis of Impagliazzo et al. [11] there is no algorithm with runtime $\mathcal{O}^*(2^{o(k)})$. The best known kernelization for VERTEX COVER(k) reduces any instance (G, k) to an equivalent instance (G', k') with $|V(G')| \leq 2k$; the total size is $\mathcal{O}(k^2)$ [3]. Unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$ and the polynomial hierarchy collapses there is no kernelization to size $\mathcal{O}(k^{2-\varepsilon})$ [8].

At first glance, the FPT and kernelization results for VERTEX COVER(k) seem essentially best possible. This is true for parameter $\ell = k$, but there are *smaller parameters* ℓ' for which both FPT-algorithms and polynomial kernelizations are known. The motivation for this is that even when $\ell' = \mathcal{O}(1)$, the value $\ell = k$ may be as large as $\Omega(n)$, making both FPT-algorithm and kernelization for parameter k useless for such instances (time $2^{\Omega(n)}$ and size guarantee $\mathcal{O}(n)$). In contrast, for $\ell' = \mathcal{O}(1)$ an FPT-algorithm with respect to ℓ' runs in polynomial time (with only leading constant depending on ℓ'). Let us discuss the relevant type of smaller parameter, which relates to *lower bounds on the optimum* and was introduced by Mahajan and Raman [19]; two other types are discussed briefly under related work.

Two well-known lower bounds for the size of vertex covers for a graph $G = (V, E)$ are the maximum size of a matching of G and the smallest size of fractional vertex covers for G; we (essentially) follow Garg and Philip [10] in denoting these two values by $MM(G)$ and $LP(G)$. Note that the notation $LP(G)$ comes from the fact that fractional vertex covers come up naturally in the linear programming relaxation of the VERTEX COVER problem, where we must assign each vertex a fractional value such that each edge is incident with total value of at least 1. In this regard, it is useful to observe that the LP relaxation of the MAXIMUM MATCHING problem is exactly the dual of this. Accordingly, we have $MM(G) \leq LP(G)$ since each integral matching is also a fractional matching, i.e., with each vertex incident to a total value of at most 1. Similarly, using $VC(G)$ to denote the minimum size of vertex covers of G we get $VC(G) \geq LP(G)$ and, hence, $VC(G) \geq LP(G) \geq MM(G)$.

A number of papers have studied vertex cover with respect to "above lower bound" parameters $\ell' = k - MM(G)$ or $\ell'' = k - LP(G)$ [24, 23, 7, 21, 17]. Observe that $k \geq k - MM(G) \geq k - LP(G)$. For the converse, note that k can be unbounded in terms of $k - MM(G)$ and $k - LP(G)$, whereas $k - MM(G) \leq 2(k - LP(G))$ holds [16, 12]. Thus, from the perspective of achieving fixed-parameter tractability (and avoiding large parameters) both parameters are equally useful for improving over parameter k. Razgon and O'Sullivan [24] proved fixed-parameter tractability of ALMOST 2-SAT(k), which implies that VERTEX COVER(k − MM) is FPT due to a reduction to ALMOST 2-SAT(k) by Mishra et al. [20]. Using $k - MM(G) \leq 2(k - LP(G))$, this also entails fixed-parameter tractability of VERTEX COVER(k − LP).

After several improvements [23, 7, 21, 17] the fastest known algorithm, due to Lokshtanov et al. [17], runs in time $\mathcal{O}^*(2.3146^{k-MM(G)})$. The algorithms of Narayanaswamy et al. [21] and Lokshtanov et al. [17] achieve the same parameter dependency also for parameter $k - LP(G)$. The first (and to our knowledge only) kernelization result for these parameters is a randomized polynomial kernelization for VERTEX COVER(k − LP) by Kratsch and Wahlström [16], which of course applies also to the larger parameter $k - MM(G)$.

Recently, Garg and Philip [10] made an important contribution to understanding the

[2] We use $\mathcal{O}^*$ notation, which suppresses polynomial factors.

parameterized complexity of the VERTEX COVER problem by proving it to be FPT with respect to parameter $\ell = k - (2LP(G) - MM(G))$. Building on an observation of Lovász and Plummer [18] they prove that $VC(G) \geq 2LP(G) - MM(G)$, i.e., that $2LP(G) - MM(G)$ is indeed a lower bound for the minimum vertex covers size of any graph G. They then design a branching algorithm with running time $\mathcal{O}^*(3^\ell)$ that builds on the well-known Gallai-Edmonds decomposition for maximum matchings to guide its branching choices.

VERTEX COVER$(k - (2\text{LP} - \text{MM}))$
Input: A graph $G = (V, E)$ and an integer $k \in \mathbb{N}$.
Parameter: $\ell = k - (2LP(G) - MM(G))$ where $LP(G)$ is the minimum size of fractional vertex covers for G and $MM(G)$ is the maximum cardinality of matchings of G.
Question: Does G have a vertex cover of size at most k, i.e., a set $X \subseteq V$ of size at most k such that each edge of E has at least one endpoint in X?

Since $LP(G) \geq MM(G)$, we clearly have $2LP(G) - MM(G) \geq LP(G)$ and hence $\ell = k - (2LP(G) - MM(G))$ is indeed at most as large as the previously best parameter $k - LP(G)$. We can easily observe that $k - LP(G)$ cannot be bounded in terms of ℓ: For any odd cycle C of length $2s + 1$ we have $LP(C) = \frac{1}{2}(2s + 1)$, $VC(C) = s + 1$, and $MM(C) = s$. Thus, a graph G consisting of t vertex-disjoint odd cycles of length $2s + 1$ has $LP(G) = \frac{1}{2}t(2s + 1)$, $VC(G) = t(s + 1)$, and $MM(G) = ts$. For $k = VC(G) = t(s + 1)$ we get

$$\ell = k - (2LP(G) - MM(G)) = t(s + 1) - t(2s + 1) + ts = 0$$

whereas

$$k - LP(G) = t(s + 1) - \frac{1}{2}t(2s + 1) = \frac{1}{2}t(2s + 2) - \frac{1}{2}t(2s + 1) = \frac{1}{2}t.$$

Generally, it can be easily proved that $LP(G)$ and $2LP(G) - MM(G)$ differ by exactly $\frac{1}{2}$ on any *factor-critical* graph (cf. Proposition 4).

As always in parameterized complexity, when presented with a new fixed-parameter tractability result, the next question is whether the problem also admits a polynomial kernelization. It is well known that decidable problems are fixed-parameter tractable if and only if they admit a (not necessarily polynomial) kernelization.[3] Nevertheless, not all problems admit polynomial kernelizations and, in the present case, both an extension of the methods for parameter $k - LP(G)$ [16] or a lower bound proof similar to Cygan et al. [6] or Jansen [12, Section 5.3] (see related work) are conceivable.

Our result. We give a randomized polynomial kernelization for VERTEX COVER$(k - (2\text{LP} - \text{MM}))$. This improves upon parameter $k - LP(G)$ by giving a strictly smaller parameter for which a polynomial kernelization is known. At high level, the kernelization takes the form of a (randomized) polynomial parameter transformation from VERTEX COVER$(k - (2\text{LP} - \text{MM}))$ to VERTEX COVER$(k - \text{MM})$, i.e., a polynomial-time many-one (Karp) reduction with *output parameter polynomially bounded in the input parameter*. It is well known (cf. Bodlaender et

[3] We sketch this folklore fact for VERTEX COVER$(k - (2\text{LP} - \text{MM}))$: If the input is larger than 3^ℓ, where $\ell = k - (2LP(G) - MM(G))$, then the algorithm of Garg and Philip [10] runs in polynomial time and we can reduce to an equivalent small yes- or no-instance; else, the instance size is bounded by 3^ℓ; in both cases we get size at most 3^ℓ in polynomial time. The converse holds since a kernelization followed by any brute-force algorithm on an instance of, say, size $g(\ell)$ gives an FPT running time in terms of ℓ.

al. [2]) that this implies a polynomial kernelization for the source problem, i.e., for VERTEX COVER($k-(2\text{LP}-\text{MM})$) in our case. Let us give some more details of this transformation.

Since the transformation is between different parameterizations of the same problem, it suffices to handle parts of any input graph G where the input parameter $\ell = k-(2LP(G)-MM(G))$ is (much) smaller than the output parameter $k-MM(G)$. After the well-known LP-based preprocessing (cf. [10]), the difference in parameter values is equal to the number of vertices that are exposed (unmatched) by any maximum matching M of G. Consider the Gallai-Edmonds decomposition $V = A \mathbin{\dot\cup} B \mathbin{\dot\cup} D$ of $G=(V,E)$, where D contains the vertices that are exposed by at least one maximum matching, $A = N(D)$, and $B = V \setminus (A \cup D)$. Let M be a maximum matching and let t be the number of exposed vertices. There are t components of $G[D]$ that have exactly one exposed vertex each. The value $2LP(G)-MM(G)$ is equal to $|M|+t$ when $LP(G) = \frac{1}{2}|V|$, as implied by LP-based preprocessing.

To reduce the difference in parameter values we will remove all but $\mathcal{O}(\ell^4)$ components of $G[D]$ that have an exposed vertex; they are called *unmatched components* for lack of a matching edge to A and we can ensure that they are not singletons. It is known that any such component C is factor-critical and hence has no vertex cover smaller than $\frac{1}{2}(|C|+1)$; this exactly matches its contribution to $|M|+t$: It has $\frac{1}{2}(|C|-1)$ edges of M and one exposed vertex. Unless the instance is trivially **no** all but at most ℓ of these components C have a vertex cover of size $\frac{1}{2}(|C|+1)$, later called a *tight vertex cover*. The only reason not to use a tight vertex cover for C can be due to adjacent vertices in A that are not selected; this happens at most ℓ times. A technical lemma proves that this can always be traced to at most three vertices of C and hence at most three vertices in A that are adjacent with C.

In contrast, there are (matched, non-singleton) components C of $G[C]$ that together with a matched vertex $v \in A$ contribute $\frac{1}{2}(|C|+1)$ to the lower bound due to containing this many matching edges. To cover them at this cost requires not selecting vertex v. This in turn propagates along M-alternating paths until the cover picks both vertices of an M-edge, which happens at most ℓ times, or until reaching an unmatched component, where it may help prevent a tight vertex cover. We translate this effect into a two-way separation problem in an auxiliary directed graph. Selecting both vertices of an M-edge is analogous to a adding a vertex to the separator. Relative to a separator the question becomes which sets of at most three vertices of A that can prevent tight vertex covers are still reachable by propagation. At this point we can apply representative set tools from Kratsch and Wahlström [16] to identify a small family of such triplets that works for all separators (and hence for all so-called *dominant* vertex covers) and keep only the corresponding components.

Related work. Let us mention some further kernelization results for VERTEX COVER with respect to nonstandard parameters. There are two further types of interesting parameters:

1. *Width-parameters:* Parameters such as treewidth allow dynamic programming algorithms running in time, e.g., $\mathcal{O}^*(2^{\text{tw}})$, independently of the size of the vertex cover. It is known that there are no polynomial kernels for VERTEX COVER (or most other NP-hard problems) under such parameters [1]. The treewidth of a graph is upper bounded by the smallest vertex cover, whereas graphs of bounded treewidth can have vertex cover size $\Omega(n)$.
2. *"Distance to tractable case"-parameters:* VERTEX COVER can be efficiently solved on forests. By a simple enumeration argument it is fixed-parameter tractable when ℓ is the minimum number of vertices to delete such that G becomes a forest. Jansen and Bodlaender [13] gave a polynomial kernelization to $\mathcal{O}(\ell^3)$ vertices. Note that the vertex cover size is an upper bound on ℓ, whereas trees can have unbounded vertex cover size. The FPT-result can be carried over to smaller parameters corresponding to distance from

larger graph classes on which VERTEX COVER is polynomial-time solvable, however, Cygan et al. [6] and Jansen [12, Section 5.3] ruled out polynomial kernels for some of them. E.g., if ℓ is the deletion-distance to an outerplanar graph then there is no kernelization for VERTEX COVER(ℓ) to size polynomial in ℓ unless the polynomial hierarchy collapses [12].

Organization. Section 2 gives some preliminaries. In Section 3 we discuss vertex covers of factor-critical graphs and prove the claimed lemma about critical sets. Section 4 introduces a relaxation of the Gallai-Edmonds decomposition, called *nice decomposition*, and Section 5 explores the relation between nice decompositions and vertex covers. The kernelization for VERTEX COVER($k - (2\text{LP} - \text{MM})$) is given in Section 6. We conclude in Section 7.

2 Preliminaries

Parameterized complexity. We use standard definitions from parameterized complexity, with the difference of using ℓ as the default symbol for the parameter. We use VERTEX COVER(ℓ) to refer to the VERTEX COVER problem parameterized by ℓ, e.g., $\ell = k$ for the *standard parameterization* or $\ell = k - LP(G)$. For a detailed introduction to parameterized complexity we recommend the recent books by Downey and Fellows [9] and Cygan et al. [5].

Graphs. We require both directed and undirected graphs; all graphs are finite and simple, i.e., they have no parallel edges or loops. Accordingly, an undirected graph $G = (V, E)$ consists of a finite set V of vertices and a set $E \subseteq \binom{V}{2}$ of edges; a directed graph $H = (V, E)$ consists of a finite set V and a set $E \subseteq V^2 \setminus \{(v, v) \mid v \in V\}$. For clarity, all undirected graphs are called G and all directed graphs are called H (possibly with indices etc.). For a graph $G = (V, E)$ and vertex set $X \subseteq V$ we use $G - X$ to denote the graph induced by $V \setminus X$; we also use $G - v$ if $X = \{v\}$. Analogous definitions are used for directed graphs H.

Let $H = (V, E)$ be a directed graph and let S and T be two not necessarily disjoint vertex sets in H. A set $X \subseteq V$ is an *S, T-separator* if in $G - X$ there is no path from $S \setminus X$ to $T \setminus X$; note that X may overlap both S and T and that $S \cap T \subseteq X$ is required. The set T is *closest to* S if there is no S, T-separator X with $X \neq T$ and $|X| \leq |T|$, i.e., if T is the unique minimum S, T-separator in G (cf. [16]). Both separators and closeness have analogous definitions in undirected graphs but they are not required here.

▶ **Proposition 1** (cf. [16]). *Let $H = (V, E)$ be a directed graph and let $S, T \subseteq V$ such that T is closest to S. For any vertex $v \in V \setminus T$ that is reachable from S in $H - T$ there exist $|T| + 1$ (fully) vertex-disjoint paths from S to $T \cup \{v\}$.*

Proof. Assume for contradiction that such $|T| + 1$ directed paths do not exist. By Menger's Theorem there must be an $S, T \cup \{v\}$-separator X of size at most $|T|$. Observe that $X \neq T$ since v is reachable from S in $H - T$. Thus, X is an S, T-separator of size at most $|T|$ that is different from T; this contradicts closeness of T. ◀

For an undirected graph $G = (V, E)$, a *matching* is any set $M \subseteq E$ such that no two edges in M have an endpoint in common. If M is a matching in $G = (V, E)$ then we will say that a path is M-alternating if its edges are alternatingly from M and from $\overline{M} := E \setminus M$. An M, M-path is an M-alternating path whose first and last edge are from M; it must have odd length. Similarly, we define $\overline{M}, M$-paths, $M, \overline{M}$-paths (both of even length), and $\overline{M}, \overline{M}$-paths (of odd length). If M is a matching of G and v is incident with an edge of M then we use $M(v)$ to denote the other endpoint of that edge, i.e., the *mate* or *partner* of v. Say that a vertex v is *exposed by M* if it is not incident with an edge of M; we say that

v is *exposable* if it is exposed by some maximum matching of G. A graph $G = (V, E)$ is *factor-critical* if for each vertex $v \in V$ the graph $G - v$ has a perfect matching (a *near-perfect matching of* G); observe that all factor-critical graphs must have an odd number of vertices.

We denote by $LP(G)$ the optimum value of fractional vertex covers, which are exactly the feasible solutions of the well-known LP-relaxation of VERTEX COVER. It is known that the extremal points x of that linear program are half-integral, i.e., $x \in \{0, \frac{1}{2}, 1\}^V$. With this in mind, we will tacitly assume that all considered fractional vertex covers are half-integral. We use the shorthand $[n] := \{1, \ldots, n\}$. By $A \dot\cup B$ to denote the disjoint union of A and B.

Gallai-Edmonds decomposition. We will now recall the Gallai-Edmonds decomposition following the well-known book of Lovász and Plummer [18].[4]

▶ **Definition 2.** Let $G = (V, E)$ be a graph. The *Gallai-Edmonds decomposition* of G is a partition of V into three sets A, B, and D where

- D consists of all vertices v of G such that there is a maximum matching M of G that contains no edge incident with v, i.e., that leaves v exposed,
- A is the set of neighbors of D, i.e., $A := N(D)$, and
- B contains all remaining vertices, i.e., $B := V \setminus (A \cup D)$.

It is known (and easy to verify) that the Gallai-Edmonds decomposition of any graph G is unique and can be computed in polynomial time. The Gallai-Edmonds decomposition has a number of useful properties; the following theorem states some of them.

▶ **Theorem 3** (cf. [18, Theorem 3.2.1]). *Let $G = (V, E)$ be a graph and let $V = A \dot\cup B \dot\cup D$ be its Gallai-Edmonds decomposition. The following properties hold:*

1. *The connected components of $G[D]$ are factor-critical.*
2. *The graph $G[B]$ has a perfect matching.*
3. *Every maximum matching M of G consists of a perfect matching of $G[B]$, a near-perfect matching of each component of $G[D]$, and a matching of A into D.*

3 Tight vertex covers of factor-critical graphs

In this section we study vertex covers of factor-critical graphs, focusing on those that are of smallest possible size (later called tight vertex covers). We first recall the fact that any factor-critical graph with $n \geq 3$ vertices has no vertex cover of size less than $\frac{1}{2}(n+1)$. By a similar argument such graphs have no fractional vertex cover of cost less than $\frac{1}{2}n$.

▶ **Proposition 4** (folklore). *Let $G = (V, E)$ be a factor-critical graph with at least three vertices. Every vertex cover X of G has cardinality at least $\frac{1}{2}(|V|+1)$ and every fractional vertex cover $x\colon V \to \mathbb{R}_{\geq 0}$ of G has cost at least $\frac{1}{2}|V|$.*

Proof. Let $X \subseteq V$ be a vertex cover of G. Since G has at least three vertices and is factor-critical, it has a maximum matching M of size $\frac{1}{2}(|V|-1) \geq 1$. It follows that X has size at least one. (This is not true for graphs consisting of a single vertex, which are also factor-critical. All other factor-critical graphs have at least three vertices.) Pick any vertex $v \in X$. Since G is factor-critical, there is a maximum matching M_v of $G - v$ of size $\frac{1}{2}(|V|-1)$. It follows that X must contain at least one vertex from each edge of M_v, and no

[4] We use B instead of C for $V \setminus (A \cup D)$ to leave the letter C for cycles and connected components.

vertex is contained in two of them. Together with v, which is not in any edge of M_v, this gives a lower bound of $1 + \frac{1}{2}(|V| - 1) = \frac{1}{2}(|V| + 1)$, as claimed.

Let $x\colon V \to \mathbb{R}_{\geq 0}$ be a fractional vertex cover of G. We use again the matching M of size at least one from the previous case; let $\{u, v\} \in M$. It follows that $x(u) + x(v) \geq 1$; w.l.o.g. we have $x(v) \geq \frac{1}{2}$. Let M_v be a maximum matching of $G - v$ of size $\frac{1}{2}(|V| - 1)$. For each edge $\{p, q\} \in M_v$ we have $x(p) + x(q) \geq 1$. Since the matching edges are disjoint we get a lower bound of $\sum_{p \in V \setminus \{v\}} x(p) \geq \frac{1}{2}(|V| - 1)$. Together with $x(v) \geq \frac{1}{2}$ we get the claimed lower bound of $\frac{1}{2}|V|$ for the cost of x. ◀

Note that Proposition 4 is tight for example for all odd cycles of length at least three, all of which are factor-critical. We now define tight vertex covers and critical sets.

▶ **Definition 5** (tight vertex covers, critical sets)**.** Let $G = (V, E)$ be a factor-critical graph with $|V| \geq 3$. A vertex cover X of G is *tight* if $|X| = \frac{1}{2}(|V| + 1)$. Note that this is different from a minimum vertex cover, and a factor-critical graph need not have a tight vertex cover; e.g., odd cliques with at least five vertices are factor-critical but have no tight vertex cover.

A set $Z \subseteq V$ is called a *bad set* of G if there is no tight vertex cover of G that contains Z. The set Z is a *critical set* if it is a minimal bad set, i.e., no tight vertex cover of G contains Z but for all proper subsets Z' of Z there is a tight vertex cover containing Z'.

Observe that a factor-critical graph $G = (V, E)$ has no tight vertex cover if and only if $Z = \emptyset$ is a critical set of G. It may be interesting to note that a set $X \subseteq V$ of size $\frac{1}{2}(|V| + 1)$ is a vertex cover of G if and only if it contains no critical set. (We will not use this fact and hence leave its two line proof to the reader.) The following lemma proves that all critical sets of a factor-critical graph have size at most three; this is of central importance for our kernelization. For the special case of odd cycles, the lemma has a much shorter proof and we point out that all critical sets of odd cycles have size exactly three.

▶ **Lemma 6.** *Let $G = (V, E)$ be a factor-critical graph with at least three vertices. All critical sets Z of G have size at most three.*

Proof. Let $\ell \in \mathbb{N}$ with $\ell \geq 1$ such that $|V| = 2\ell + 1$; recall that all factor-critical graphs have an odd number of vertices.

Assume for contradiction that there is a critical set Z of G of size at least four. Let $w, x, y, z \in Z$ be any four pairwise different vertices from Z. Let M be a maximum matching of $G - w$. Since G is factor-critical, we get that M is a perfect matching of $G - w$ and has size $|M| = \ell$. Observe that any tight vertex cover of G that contains w must contain exactly one vertex from each edge of M, since its total size is $\frac{(}{|}V| + 1) = \ell + 1$. We will first analyze G and show that the presence of certain structures would imply that some proper subset Z' of Z is bad, contradicting the assumption that Z is critical. Afterwards, we will use the absence of these structures to find a tight vertex cover that contains Z, contradicting the fact that it is a critical set.

If there is an M, M-path from x to y then $\{w, x, y\}$ is a bad set, i.e., no tight vertex cover of G contains all three vertices w, x, and y, contradicting the choice of Z: Let $P = (v_1, v_2, \ldots, v_{p-1}, v_p)$ denote an M, M-path from $v_1 = x$ to $v_p = y$. Accordingly, we have $\{v_1, v_2\}, \ldots, \{v_{p-1}, v_p\} \in M$ and the path P has odd length. Assume that X is a tight vertex cover containing w, x, and y. It follows, since $w \in X$, that X contains exactly one vertex per edge in M; in particular it contains exactly one vertex per matching edge on the path P. Since $v_1 = x \in X$ we have $v_2 \notin X$. Thus, as $\{v_2, v_3\}$ is an edge of G, we must have $v_3 \in X$ to cover this edge; this in turn implies that $v_4 \notin X$ since it already contains v_3 from the matching edge $\{v_3, v_4\}$. Continuing this argument along the path P we conclude that $v_{p-1} \in X$ and $v_p \notin X$, contradicting the fact that $v_p = y \in X$. Thus, if there is an M, M-path from x to y then there is no tight vertex cover of G that contains w, x, and y, making $\{w, x, y\}$ a bad set and contradicting the assumption that Z is a critical set. It follows that there can be no M, M-path from x to y. The same argument can be applied also to x and z, and to y and z, ruling out M, M-paths connecting them.

Similarly, if there is an edge $\{u, v\} \in M$ such that z reaches both u and v by (different, not necessarily disjoint) $M, \overline{M}$-paths then no tight vertex cover of G contains both w and z, contradicting the choice of Z: Let $P = (v_1, v_2, \ldots, v_{p-1}, v_p)$ denote an $M, \overline{M}$-path from $v_1 = z$ to $v_p = u$ with $\{v_1, v_2\}, \{v_3, v_4\}, \ldots, \{v_{p-2}, v_{p-1}\} \in M$. Let X be a tight vertex cover of G that contains w and z. It follows (as above) that $v_1, v_3, \ldots, v_{p-2} \in X$ and $v_2, v_4, \ldots, v_{p-1} \notin X$, by considering the induced M, M-path from $z = v_1$ to v_{p-1}. The fact that $v_{p-1} \notin X$ directly implies that $v_p = u \in X$ in order to cover the edge $\{v_{p-1}, v_p\}$. Repeating the same argument on an $M, \overline{M}$-path from z to v we get that $v \in X$. Thus, we conclude that u and v are both in X, contradicting the fact that X must contain exactly one vertex of each edge in X. Hence, there is no tight vertex cover of G that contains both w and z. We conclude that $\{w, z\}$ is a bad set, contradicting the choice of Z. Hence, there is no edge $\{u, v\} \in M$ such that z has $M, \overline{M}$-paths (not necessarily disjoint) to both u and v.

Now we will complete the proof by using the established properties, i.e., the non-existence of certain M-alternating paths starting in z, to construct a tight vertex cover of G that contains all of Z, giving the final contradiction. Using minimality of Z, let X be a tight vertex cover of G that contains $Z \setminus \{z\}$; by choice of Z we have $z \notin X$. We construct the claimed vertex cover $X' \supseteq Z$ from $X' = X$ as follows:

1. Add vertex z to X and remove $M(z)$, i.e., remove the vertex that z is matched to.
2. Add all vertices v to X' that can be reached from z by an $M, \overline{M}$-path.
3. Remove all vertices from X' that can be reached from z by an M, M-path of length at least three. (There is a single such path of length one from z to $M(z)$ which, for clarity, was handled already above.)

We need to check four things: (1) The procedure above is well-defined, i.e., no vertex can be reached by both M, M- and $M, \overline{M}$-paths from z. (2) The size of X' is at most $|X| = \ell + 1$. (3) X' is a vertex cover. (4) The set X' contains w, x, y, and z.

(1) Assume that there is a vertex v such that z reaches v both by an M, M-path $P = (v_1, v_2, \ldots, v_p)$ with $v_1 = z$ and $v_p = v$, and by an $M, \overline{M}$-path P'. Observe that $\{v_{p-1}, v_p\} \in M$ since P is an M, M-path and, hence, that $P'' = (v_1, \ldots, v_{p-1})$ is an $M, \overline{M}$-path from v to v_{p-1}. Together, P' and P'' constitute two $M, \overline{M}$-paths from z to both endpoints v_{p-1} and v_p of the matching edge $\{v_{p-1}, v_p\}$; a contradiction (since we ruled out this case earlier).

(2) In the first step, we add z and remove $M(z)$. Note that $z \notin X$ implies that $M(z) \in X$ (we start with $X' = X$). Thus the size of X' does not change. Consider a vertex v that is added in the second step, i.e., with $v \notin X$: There is an $M, \overline{M}$-path P from z to v. Since $w \in X$ we know that $v \neq w$. Thus, since M is a perfect matching of $G - w$, there is a vertex u with $u = M(v)$. The vertex $u := M(v)$ must be in X to cover the edge $\{v, u\} \in M$, as $v \notin X$. Moreover, u cannot be on P since that would make it incident with a second matching edge other than $\{u, v\}$. Thus, by extending P with $\{v, u\}$ we get an M, M-path from z to u, implying that u is removed in the second step. Since $u \in X$ the total size change is zero. Observe that the vertex $u = M(v)$ used in this argument is not used for any other vertex v' added in the second step since it is only matched to v. Similarly, due to (1), the vertex u is not also added in the second step since it cannot be simultaneously have an $M, \overline{M}$-path from z.

(3) Assume for contradiction that some edge $\{u, v\}$ is not covered by X', i.e., that $u, v \notin X'$. Since $w \in X'$ is the only unmatched vertex it follows that both u and v are incident with some edge of M. We distinguish two cases, namely (a) $\{u, v\} \in M$ and (b) $\{u, v\} \notin M$.

(3.a) If $\{u, v\} \in M$ then without loss of generality assume $u \in X$ (as X is a vertex cover). By our assumption we have $u \notin X'$, which implies that we have removed it on account of having an M, M-path P from z to u. Since $\{u, v\} \in M$ the path P must visit v as its penultimate vertex; there is no other way for an M, M-path to reach u. This, however, implies that there is an $M, \overline{M}$-path from z to v, and that we have added v in the second step; a contradiction.

(3.b) In this case we have $\{u, v\} \notin M$. Again, without loss of generality, assume that $u \in X$. Since $u \notin X'$ there must be an M, M-path P from z to u. If P does not contain v then extending P by edge $\{u, v\} \notin M$ would give an $M, \overline{M}$-path from z to v and imply that $v \in X'$; a contradiction. In the remaining case, the vertex v is contained in P; let P' denote the induced path from z to v (not containing u as it is the final vertex of P). Since $v \notin X'$ we know that P' cannot be an $M, \overline{M}$-path, or else we would have $v \in X'$, and hence it must be an M, M-path. Now, however, extending P' via $\{v, u\} \notin M$ yields an $M, \overline{M}$-path from z to u, contradicting (1). Altogether, we conclude that X' is indeed a vertex cover.

(4) Clearly, $z \in X'$ by construction. Similarly, $w \in X'$ since it is contained in X and it cannot be removed since there is no incident M-edge (i.e., no M, M-paths from z can end in w). Finally, regarding x and y, we proved earlier that there are no M, M-paths from z to x or from z to y. Thus, since both x and y are in X they must also be contained in X'.

We have showed that under the assumption of minimality of Z and using $|Z| \geq 4$ one can construct a vertex cover X' of optimal size $\ell + 1$ that contains Z entirely. This contradicts the choice of Z and completes the proof. ◀

4 Nice decompositions

The well-known Gallai-Edmonds decomposition plays an important role in the FPT-algorithm of Garg and Philip [10]. It is, in principle, also very useful for our kernelization result, but it is much more convenient to use a form that is both relaxed (in part) but also includes a certain maximum matching of the graph, called *nice decomposition*. Due to space restrictions, we give the definition directly rather than first defining a natural intermediate form.

▶ **Definition 7** (nice decomposition)**.** Let $G = (V, E)$ be a graph. A *nice decomposition of* G is a tuple (A, B, D, M) where $V = A \,\dot\cup\, B \,\dot\cup\, D$ and M is a maximum matching of G such that

1. $A = N(D)$, i.e., all vertices not in D that are adjacent to D,
2. each connected component of $G[D]$ is factor-critical,
3. M restricted to B is a perfect matching of $G[B]$,
4. M restricted to any component C of $G[D]$ is a near-perfect matching of $G[C]$,
5. each vertex of A is matched by M to a vertex of D, and
6. for each singleton component $\{v\}$ of $G[D]$ there is a vertex $u \in A$ with $\{u, v\} \in M$.

For a nice decomposition (A, B, D, M) of G it will be of importance for us which components of $G[D]$ are matched to a vertex in A. Since M induces a near-perfect matching on each component of $G[D]$, there is always at most one such vertex per component of $G[D]$.

▶ **Definition 8** (matched/unmatched components of $G[D]$)**.** Let $G = (V, E)$ be a graph and let (A, B, D, M) be a nice decomposition of G. We say that a connected component C of $G[D]$ is *matched* if there are vertices $v \in C$ and $u \in N(C) \subseteq A$ such that $\{u, v\} \in M$; we will also say that u and C are matched to one another. Otherwise, we say that C is *unmatched*. Note that edges of M with both ends in C have no influence on whether C is matched or unmatched.

We use $\mathcal{C}_1$ to denote the set of matched singleton components in $G[D]$; a nice decomposition has no unmatched singleton components. We use $\mathcal{C}_3$ and $\hat{\mathcal{C}}_3$ for matched and unmatched non-singleton components. By A_1 and A_3 we denote the set of vertices in A that are matched to singleton respectively non-singleton components of $G[D]$; note that $A = A_1 \dot\cup A_3$.

Our main reason for preferring nice decompositions is captured in the following lemma, namely that deleting certain types of components, e.g., in a reduction rule, allows the obtained graph G' to effectively inherit a nice decomposition.

▶ **Lemma 9.** *Let $G = (V, E)$ be a graph, (A, B, D, M) a nice decomposition, and $C \in \hat{\mathcal{C}}_3$ an unmatched component of $G[D]$. Then (A, B, D', M') is a nice decomposition of $G' = G - C$ where M' is M restricted to $V(G') = V \setminus C$ and where $D' := D \setminus C$. The corresponding sets A_1, A_3, $\mathcal{C}_1$, and $\mathcal{C}_3$ are the same as for G. For $\hat{\mathcal{C}}_3$ we have $\hat{\mathcal{C}}'_3 = \hat{\mathcal{C}}_3 \setminus \{C\}$.*

5 Nice decompositions and vertex covers

Due to space restrictions, this section gives a brief summary of the relation between a nice decomposition (A, B, D, M) of a graph G and (certain) vertex covers of G. We first prove a lower bound on $VC(G)$ in terms of (A, B, D, M) and relate it to $2LP(G) - MM(G)$. Note that Garg and Philip [10] proved that $2LP(G) - MM(G)$ is a lower bound for the vertex cover size for every graph G, but we require the bound of $|M| + |\hat{\mathcal{C}}_3|$ related to our decompositions, and the equality to $2LP(G) - MM(G)$ is "only" required to complete the kernelization later.

▶ **Lemma 10.** *Let $G = (V, E)$ be a graph and let (A, B, D, M) be a nice decomposition of G. Each vertex cover of G has size at least $|M| + |\hat{\mathcal{C}}_3| = 2LP(G) - MM(G)$.*

Intuitively, a vertex cover X of size at most $|M| + |\hat{\mathcal{C}}_3| + \ell$ can "overpay" only ℓ times as compared to spending one vertex per edge of M and $\frac{1}{2}(|C| + 1)$ for any component $C \in \hat{\mathcal{C}}_3$. Conversely, X must induce tight vertex covers of all but at most ℓ components $C \in \hat{\mathcal{C}}_3$.

▶ **Definition 11** (active component)**.** Let $G = (V, E)$ be a graph, let (A, B, D, M) be a nice decomposition of G, and let X be a vertex cover of G. A component $C \in \hat{\mathcal{C}}_3$ is *active (w.r.t. X)* if X contains more than $\frac{1}{2}(|C| + 1)$ vertices of C, i.e., if $X \cap C$ is not a tight vertex cover of $G[C]$.

▶ **Definition 12** (set X_{op})**.** Let $G = (V, E)$ be a graph and let (A, B, D, M) be a nice decomposition of G. For $X \subseteq V$ define $X_{\mathsf{op}} = X_{\mathsf{op}}(A_1, A_3, M, X) \subseteq A \cap X$ to contain all vertices v that fulfill either of the following two conditions:

1. $v \in A_1$ and X contains both v and $M(v)$.
2. $v \in A_3$ and X contains v.

Both conditions of Definition 12 capture parts of the graph where X contains more vertices than implied by the lower bound. To see this for the second condition, note that if $v \in A_3 \cap X$ then X still needs at least $\frac{1}{2}(|C|+1)$ vertices of the component $C \in \mathcal{C}_3$ that v is matched to; since there are $\frac{1}{2}(|C|+1)$ matching edges that M has between vertices of $C \cup \{v\}$ we find that X (locally) exceeds the lower bound, as $|X \cap (C \cup \{v\})| \geq 1 + \frac{1}{2}(|C|+1)$. Conversely, if X does match the lower bound on $C \cup \{v\}$ then it cannot contain v.

We now prove formally that a vertex cover X of size close to the lower bound of Lemma 10 has only few active components and only a small set $X_{\mathsf{op}} \subseteq X$.

▶ **Lemma 13.** *Let $G = (V, E)$ be a graph, let (A, B, D, M) be a nice decomposition of G, let X be a vertex cover of G, and let $X_{\mathsf{op}} = X_{\mathsf{op}}(A_1, A_3, M, X)$. The set X_{op} has size at most ℓ and there are at most ℓ active components in $\hat{\mathcal{C}}_3$ with respect to X where $\ell = |X| - (|M| + |\hat{\mathcal{C}}_3|) = |X| - (2LP(G) - MM(G))$.*

The central question is of course how the different structures where X exceeds the lower bound interact. We are only interested in aspects that are responsible for not allowing a tight vertex cover for any (unmatched, non-singleton) components $C \in \hat{\mathcal{C}}_3$. This happens exactly due to vertices in A that are adjacent to C and that are not selected by X. Between components of $G[B]$ and non-singleton components of $G[D]$ there are M-alternating paths with vertices alternatingly from A and from singleton components of $G[D]$ since vertices in A are all matched to D and singleton components in $G[D]$ have all their neighbors in A. Unless X contains both vertices of a matching edge, it contains the A- or the D-vertices of such a path. Unmatched components of $G[D]$ and components of $G[B]$ have all neighbors in A. Matched components C in $G[D]$ with matched neighbor $v \in A$ enforce not selecting v for X unless X spends more than the lower bound; in this way, they lead to selection of D-vertices on M-alternating paths. Intuitively, this leads to two "factions" that favor either A- or D-vertices and that are effectively separated when X selects both A- and D-endpoint of a matching edge. An optimal solution need not separate all neighbors in A of any component $C \in \hat{\mathcal{C}}_3$, and C may still have a tight vertex cover or paying for a larger cover of C is overall beneficial. The following auxiliary directed graph H captures this situation and for certain vertex covers X reachability of $v \in A$ in $H - X_{\mathsf{op}}$ will be proved to be equivalent with $v \notin X$.

▶ **Definition 14** (auxiliary directed graph H). Let $G = (V, E)$ be a graph and let (A, B, D, M) be a nice decomposition of G. Define a *directed graph* $H = H(G, A, B, D, M)$ on vertex set A by letting (u, v) be a directed edge of H, for $u, v \in A$, whenever there is a vertex $w \in D$ with $\{u, w\} \in E \setminus M$ and $\{w, v\} \in M$.

There are three important properties of vertex covers in relation to the corresponding graph H. Two of them hold only for what we call *dominant* vertex covers and their proofs build on a fairly technical replacement argument. We will define dominant vertex covers next and then summarize the properties in a single lemma.

▶ **Definition 15** (dominant vertex cover). Let $G = (V, E)$ be a graph and let (A, B, D, M) be a nice decomposition of G. A vertex cover $X \subseteq V$ of G is *dominant* if G has no vertex cover of size less than $|X|$ and no vertex cover of size $|X|$ contains fewer vertices of D.

▶ **Lemma 16.** *Let $G = (V, E)$ be a graph, let (A, B, D, M) be a nice decomposition of G, and X a vertex cover of G. Let $H = H(G, A, B, D, M)$ and let $X_{\mathsf{op}} = X_{\mathsf{op}}(A_1, A_3, M, X)$. The following properties hold:*

1. *If X is dominant then X_{op} is closest to A_3 in H.*
2. *If $v \in A$ is reachable from A_3 in $H - X_{\mathsf{op}}$ then X does not contain v.*
3. *If X is dominant and $v \in A$ is not reachable from A_3 in $H - X_{\mathsf{op}}$ then X contains v.*

All three properties are crucial for applying the matroid tools of Kratsch and Wahlström [16]. Closeness of X_{op} is needed to translate between reachability and independence in an appropriate matroid. The latter two properties are required to translate between the directed graph, where the tools are applied, and the undirected input graph G.

6 Randomized polynomial kernelization

In this section, we describe our randomized polynomial kernelization for VERTEX COVER($k-(2\text{LP}-\text{MM})$). For convenience, let us fix an input instance (G,k,ℓ), i.e., $G=(V,E)$ is a graph for which we want to know whether it has a vertex cover of size at most k; the parameter is $\ell = k-(2LP(G)-MM(G))$, where $LP(G)$ is the minimum cost of a fractional vertex cover of G and $MM(G)$ is the size of a largest matching.

From previous work of Garg and Philip [10] we know that the well-known linear program-based preprocessing for VERTEX COVER (cf. [5]) can also be applied to VERTEX COVER($k-(2\text{LP}-\text{MM})$); the crucial new aspect is that this operation does not increase the value $k-(2LP-MM)$. The LP-based preprocessing builds on the half-integrality of fractional vertex covers and a result of Nemhauser and Trotter [22] stating that all vertices with value 1 and 0 in an optimal fractional vertex cover $x\colon V\to\{0,\frac{1}{2},1\}$ are included respectively excluded in at least one minimum (integral) vertex cover. Thus, only vertices with value $x(v)=\frac{1}{2}$ remain and the best LP solution costs exactly $\frac{1}{2}$ times number of (remaining) vertices. For our kernelization we only require the fact that if G is reduced under this reduction rule then $LP(G)=\frac{1}{2}(|V(G)|)$; e.g., we do not require $x\colon V\to\{\frac{1}{2}\}$ to be the unique optimal fractional vertex cover. Without loss of generality, we assume that our given graph $G=(V,E)$ already fulfills $LP(G)=\frac{1}{2}|V|$.

▶ **Observation 17.** *If $LP(G)=\frac{1}{2}|V|$ then $2LP(G)-MM(G)=|V|-MM(G)$. In other words, if M is a maximum matching of G then the lower bound $2LP(G)-MM(G)=|V|-MM(G)=|V|-|M|$ is equal to cardinality of M plus the number of isolated vertices.*

As a first step, let us compute the Gallai-Edmonds decomposition $V=A\,\dot\cup\,B\,\dot\cup\,D$ of G; this can be done in polynomial time.[5] Using $LP(G)=\frac{1}{2}|V|$ we can find a maximum matching M of G such that (A,B,D,M) is a nice decomposition of G.

▶ **Lemma 18.** *Given $G=(V,E)$ with $LP(G)=\frac{1}{2}|V|$ and a Gallai-Edmonds decomposition $V=A\,\dot\cup\,B\,\dot\cup\,D$ of G one can in polynomial time compute a maximum matching M of G such that (A,B,D,M) is a nice decomposition of G.*

We fix a nice decomposition (A,B,D,M) of G obtained via Lemma 18. We have already learned about the relation of dominant vertex covers X, their intersection with the set A, and separation of A vertices from A_3 in $H-X_{\mathsf{op}}$, where $H=H(G,A,B,D,M)$. It is safe to assume that solutions are dominant vertex covers as among minimum vertex covers there is a minimum intersection with D. We would now like to establish that most components of $\hat{\mathcal{C}}_3$ can be deleted (while reducing k by the cost for corresponding tight vertex covers). Clearly, since any vertex cover pays at least for tight covers of these components, we cannot turn a yes- into a no-instance this way. However, if the instance is no then it might become yes.

[5] The main expenditure is finding the set D. A straightforward approach is to compute a maximum matching M_v of $G-v$ for each $v\in V$. If $|M_v|=MM(G)$ then v is in D as M_v is maximum and exposes v; otherwise $v\notin D$ as no maximum matching exposes v.

In the following, we will try to motivate both the selection process for components of $\hat{\mathcal{C}}_3$ that are deleted as well as the high-level proof strategy for establishing correctness. We will tacitly ignore most technical details, like parameter values, getting appropriate nice decompositions, etc., and refer to the formal proof instead. Assume that we are holding a no-instance (G, k, ℓ). Consider for the moment, the effect of deleting all components $C \in \hat{\mathcal{C}}_3$ that have tight vertex covers and updating the budget accordingly; for simplicity, say they all have such vertex covers. Let (G_0, k_0, ℓ) be the obtained instance; if this instance is no as well, then deleting any subset of $\hat{\mathcal{C}}_3$ also preserves the correct answer (namely: no). Else, if (G_0, k_0, ℓ) is yes then pick any dominant vertex cover X^0 for it. We could attempt to construct a vertex cover of G of size at most k by adding back the components of C and picking a tight vertex cover for each; crucially, these covers must also handle edges between C and A. Since (G, k, ℓ) was assumed to be a no-instance, there must be too many components $C \in \hat{\mathcal{C}}_3$ for which this approach fails. For any such component, the adjacent vertices in $A \setminus X^0$ force a selection of their neighbors $Z_A = N(A) \cap C$ that cannot be completed to a tight vertex cover of C. To avoid turning the no-instance (G, k, ℓ) into a yes-instance (G', k', ℓ) we have to keep enough components of $\hat{\mathcal{C}}_3$ in order to falsify any suggested solution X' of size at most k' for G. The crux is that there may be an exponential number of such solutions and that we do not know any of them. This is where the auxiliary directed graph and related technical lemmas as well as the matroid-based tools of Kratsch and Wahlström [16] are essential.

Let us outline how we arrive at an application of the matroid-based tools. Crucially, if C (as above) has no tight vertex cover containing $Z_A = N(A) \cap C$ then, by Lemma 6, there is a set $Z \subseteq Z_A$ of size at most three such that no tight vertex cover contains Z. Accordingly, there is a set $T \subseteq A \setminus X^0$ of size at most three whose neighborhood in C contains Z. Thus, the fact that X^0 contains no vertex of T is responsible for not allowing a tight vertex cover of C. This in turn, by Lemma 16 means that all vertices in T are reachable from A_3 in $H - X^0_{\mathsf{op}}$. Recalling that a set X^0_{op} corresponding to a dominant vertex cover is also closest to A_3, we can apply a result from [16] that generates a sufficiently small representative set of sets T corresponding to components of $\hat{\mathcal{C}}_3$. If a dominant vertex cover has any reachable sets T then the lemma below guarantees that at least one such set is in the output. For each set we select a corresponding component $C \in \hat{\mathcal{C}}_3$ and then start over on the remaining components. After $\ell + 1$ iterations we can prove that for any not selected component C, which we delete, and any proposed solution X' for the resulting graph that does not allow a tight vertex cover for C, there are $\ell + 1$ other selected components on which X' cannot be tight. This is a contradiction as there are at most ℓ such active components by Lemma 13.

Concretely, we will use the following lemma about representative sets of vertex sets of size at most three regarding reachability in a directed graph (modulo deleting a small set of vertices). Notation of the lemma is adapted to the present application. The original result is for pairs of vertices in a directed graph (see [15, Lemma 2]) but extends straightforwardly to sets of fixed size q and to sets of size at most q. We provide a proof in the full version for completeness. Note that the lemma is purely about reachability of small sets in a directed graph (like the DIGRAPH PAIR CUT problem studied in [15, 16]) and we require the structural lemmas proved so far to negotiate between this an VERTEX COVER$(k - (2\text{LP} - \text{MM}))$.

▶ **Lemma 19.** *Let $H = (V_H, E_H)$ be a directed graph, let $S_H \subseteq V_H$, let $\ell \in \mathbb{N}$, and let $\mathcal{T}$ be a family of nonempty vertex sets $T \subseteq V_H$ each of size at most three. In randomized polynomial time, with failure probability exponentially small in the input size, we can find a set $\mathcal{T}^* \subseteq \mathcal{T}$ of size $\mathcal{O}(\ell^3)$ such that for any set $X_H \subseteq V_H$ of size at most ℓ that is closest to S_H if there is a set $T \in \mathcal{T}$ such that all vertices $v \in T$ are reachable from S_H in $H - X_H$ then there is a corresponding set $T^* \in \mathcal{T}^*$ satisfying the same properties.*

Using the lemma we will be able to identify a small set $\mathcal{C}_{\texttt{rel}}$ of components of $\hat{\mathcal{C}}_3$ that contains for each dominant vertex cover X of G of size at most k all active components with respect to X. Conversely, if there is no solution of size k, we will have retained enough components of $\hat{\mathcal{C}}_3$ to preserve this fact. Concretely, the set $\mathcal{C}_{\texttt{rel}}$ is computed as follows:

1. Let $\mathcal{C}^0_{\texttt{rel}}$ contain all components $C \in \hat{\mathcal{C}}_3$ that have no vertex cover of size at most $\frac{1}{2}(|C|+1)$. Clearly, these components are active for every vertex cover of G. We know from Lemma 13 that there are at most ℓ such components if the instance is **yes**. We can use the algorithm of Garg and Philip [10] to test in polynomial time whether any $C \in \hat{\mathcal{C}}_3$ has a vertex cover of size at most $k_C := \frac{1}{2}(|C|+1)$: We have parameter value
$$k_C - (2LP(G[C]) - MM(G[C])) = \frac{1}{2}(|C|+1) - (|C| - \frac{1}{2}(|C|-1)) = 0.$$
We could of course also use an algorithm for VERTEX COVER parameterized above maximum matching size, where we would have parameter value 1. If there are more than ℓ components C with no vertex cover of size $\frac{1}{2}(|C|+1)$ then we can safely reject the instance. Else, as indicated above, let $\mathcal{C}^0_{\texttt{rel}}$ contain all these components and continue.
2. Let $i = 1$. We will repeat the following steps for $i \in \{1, \ldots, \ell+1\}$.
3. Let $\mathcal{T}^i$ contain all nonempty sets $T \subseteq A$ of size at most three such that there is a component $C \in \hat{\mathcal{C}}_3 \setminus (\mathcal{C}^0_{\texttt{rel}} \cup \ldots \cup \mathcal{C}^{i-1}_{\texttt{rel}})$ such that:
   a. There is a set $Z \subseteq N_G(T) \cap C$ of at most three neighbors of T in C such that no vertex cover of $G[C]$ of size $\frac{1}{2}(|C|+1)$ contains Z. Note that $Z \neq \emptyset$ since $C \notin \mathcal{C}^0_{\texttt{rel}}$ implies that it has at least some vertex cover of size $\frac{1}{2}(|C|+1)$.
   b. For each C and $Z \subseteq C$ of size at most three, existence of a vertex cover of $G[C]$ of size $k_C := \frac{1}{2}(|C|+1)$ containing Z can be tested by the algorithm of Garg and Philip [10] since the parameter value is constant. Concretely, run the algorithm on $G[C \setminus Z]$ and solution size $k_C - |Z|$ and observe that the parameter value is
   $$(k_C - |Z|) - (2LP(G[C \setminus Z]) - MM(G[C \setminus Z])).$$
   Using that $LP(G[C \setminus Z]) \geq LP(G[C]) - |Z|$ and $MM(G[C \setminus Z]) \leq MM(G[C]) = \frac{1}{2}(|C|-1)$ this value can be upper bounded by
   $$\begin{aligned} & k_C - |Z| - 2LP(G[C]) + 2|Z| + MM(G[C]) \\ = & \frac{1}{2}(|C|+1) - |Z| - |C| + 2|Z| + \frac{1}{2}(|C|-1) = |Z|. \end{aligned}$$
   Since $|Z| \leq 3$ the parameter value is at most three and the FPT-algorithm of Garg and Philip [10] runs in polynomial time.

   Intuitively, C must always be active for vertex covers not containing T, but for the formal correctness proof that we give later the above description is more convenient.
4. Apply Lemma 19 to graph $H = H(G, A, B, D, M)$ on vertex set $V_H = A$, set $S_H = A_3 \subseteq A$, integer ℓ, and family $\mathcal{T}^i$ of nonempty subsets of A of size at most three to compute a subset $\mathcal{T}^{i*}$ of $\mathcal{T}^i$ in randomized polynomial time. The size of $|\mathcal{T}^{i*}|$ is $\mathcal{O}(\ell^3)$.
5. Select a set $\mathcal{C}^i_{\texttt{rel}}$ as follows: For each $T \in \mathcal{T}^{i*}$ add to $\mathcal{C}^i_{\texttt{rel}}$ a component $C \in \hat{\mathcal{C}}_3 \setminus (\mathcal{C}^0_{\texttt{rel}} \cup \ldots \cup \mathcal{C}^{i-1}_{\texttt{rel}})$ such that C fulfills the condition for T in Step 3, i.e., such that:
   a. There is a set $Z \subseteq N_G(T) \cap C$ of at most three neighbors of T in C such that no vertex cover of $G[C]$ of size $\frac{1}{2}(|C|+1)$ contains Z. (We know that Z must be nonempty.)

   Clearly, the size of $|\mathcal{C}^i_{\texttt{rel}}|$ is $\mathcal{O}(\ell^3)$. Note that the same component C can be chosen for multiple sets $T \in \mathcal{T}^{i*}$ but we only require an upper bound on $|\mathcal{C}^i_{\texttt{rel}}|$

6. If $i < \ell+1$ then increase i by one and return to Step 3. Else return the set $\mathcal{C}_{\texttt{rel}} := \bigcup_{i=0}^{\ell+1} \mathcal{C}^i_{\texttt{rel}}$. The size of $\mathcal{C}_{\texttt{rel}}$ is $\mathcal{O}(\ell^4)$ since it is the union of $\ell+2$ sets that are each of size $\mathcal{O}(\ell^3)$.

In particular, we will be interested in the components $C \in \hat{\mathcal{C}}_3$ that are not in $\mathcal{C}_{\texttt{rel}}$. We call these *irrelevant components* and let $\mathcal{C}_{\texttt{irr}} := \hat{\mathcal{C}}_3 \setminus \mathcal{C}_{\texttt{rel}}$ denote the set of all irrelevant components. (Of course we still need to prove that they are true to their name.)

▶ **Lemma 20.** *Let G' be obtained by deleting from G all vertices of irrelevant components, i.e., $G' := G - \bigcup_{C\in\mathcal{C}_{\texttt{irr}}} C$, and let $k' = k - \sum_{C\in\mathcal{C}_{\texttt{irr}}} \frac{1}{2}(|C|+1)$, i.e., k' is equal to k minus the lower bounds for vertex covers of the irrelevant components. Then G has a vertex cover of size at most k if and only if G' has a vertex cover of size at most k'. Moreover, $k - (2LP(G) - MM(G)) = k' - (2LP(G') - MM(G'))$, i.e., the instances (G, k, ℓ) and (G', k, ℓ') of* VERTEX COVER$(k - (2\text{LP} - \text{MM}))$ *have the same parameter value $\ell = \ell'$.*

We can now complete our kernelization. According to Lemma 20 we may delete all irrelevant components and update k. We obtain a graph G' and integer k' such that:

1. G' has a vertex cover of size at most k' if and only if G has a vertex cover of size at most k, i.e., the instances (G, k) and (G', k') for VERTEX COVER are equivalent.
2. As a part of the proof of Lemma 20 we showed that $k' = |M'| + |\hat{\mathcal{C}}'_3| + \ell$ where $\hat{\mathcal{C}}'_3$ is the set of unmatched non-singleton components of $G'[D']$ with respect to M'.
3. From Lemma 9 we know that $\hat{\mathcal{C}}'_3$ is equal to the set $\hat{\mathcal{C}}_3$ minus the components $C \in \mathcal{C}_{\texttt{irr}}$ that were removed to obtain G'. In other words, $\hat{\mathcal{C}}'_3 = \hat{\mathcal{C}}_3 \setminus \mathcal{C}_{\texttt{irr}} = \mathcal{C}_{\texttt{rel}}$.
4. We know from Step 6 that $|\mathcal{C}_{\texttt{rel}}| = \mathcal{O}(\ell^4)$. Hence, $|\hat{\mathcal{C}}'_3| = \mathcal{O}(\ell^4)$.
5. Let us consider $p := k' - |M'|$, which is the parameter value of (G', k') when considered as an instance of VERTEX COVER parameterized above the size of a maximum matching. Clearly, $p = k' - |M'| = |M'| + |\hat{\mathcal{C}}'_3| + \ell - |M'| = \ell + \mathcal{O}(\ell^4) = \mathcal{O}(\ell^4)$.
6. We can now apply the randomized polynomial kernelization for VERTEX COVER$(k - \text{MM})$ [16] to get a polynomial kernelization for VERTEX COVER$(k - (2\text{LP} - \text{MM}))$. On input of (G', k', p) it returns an equivalent instance (G^*, k^*, p^*) of size $\mathcal{O}(p^c)$ for some constant c. We may assume that $k^* = \mathcal{O}(p^c)$ since else it would exceed the number of vertices in G^* and we may as well return a **yes**-instance of constant size. Let $\ell^* = k^* - (2LP(G^*) - MM(G^*))$, i.e., the parameter value of the instance (G^*, k^*, ℓ^*) of VERTEX COVER$(k - (2\text{LP} - \text{MM}))$. Clearly, $\ell^* \leq k^* = \mathcal{O}(p^c)$. Thus, (G^*, k^*, ℓ^*) has size and parameter value $\mathcal{O}(p^c)$.

▶ **Theorem 21.** VERTEX COVER$(k - (2\text{LP} - \text{MM}))$ *has a randomized polynomial kernelization with error probability exponentially small in the input size.*

7 Conclusion

We have presented a randomized polynomial kernelization for VERTEX COVER$(k - (2\text{LP} - \text{MM}))$ by giving a (randomized) polynomial parameter transformation to VERTEX COVER$(k - \text{MM})$. This improves upon the smallest parameter, namely $k - LP(G)$, for which such a result was known [16]. The kernelization for VERTEX COVER$(k - \text{MM})$ [16] involves reductions to and from ALMOST 2-SAT(k), which can be done without affecting the parameter value (cf. [23]). We have not attempted to optimize the total size. Given an instance (G, k, ℓ) for VERTEX COVER(k-(2LP-MM)) we get an equivalent instance of ALMOST 2-SAT(k) with $\mathcal{O}(k^{24})$ variables and size $\mathcal{O}(k^{48})$, which still needs to be reduced to a VERTEX COVER instance.

It seems likely that the kernelization can be improved if one avoids the blackbox use of the kernelization for VERTEX COVER$(k - \text{MM})$ and the detour via ALMOST 2-SAT(k). In particular, the underlying kernelization for ALMOST 2-SAT(k) applies, in part, the same representative set machinery to reduce the number of a certain type of clauses. Conceivably the two applications can be merged, thus avoiding the double blow-up in size. As a caveat, it appears to be likely that this would require a much more obscure translation into a directed separation problem. Moreover, the kernelization for ALMOST 2-SAT(k) requires an approximate solution, and it is likely that the same would be true for this approach. It would of course also be interesting whether a deterministic polynomial kernelization is possible, but this is, e.g., already not known for ALMOST 2-SAT(k) and VERTEX COVER($k-\text{MM}$).

We find the appearance of a notion of critical sets of size at most three and the derived separation problem in the auxiliary directed graph quite curious. For the related problem of separating at least one vertex from each of a given set of triples from some source s by deleting at most ℓ vertices (a variant of DIGRAPH PAIRCUT [16]) there is a natural $\mathcal{O}^*(3^\ell)$ time algorithm that performs at most ℓ three-way branchings before finding a solution (if possible). It would be interesting whether a complete encoding of VERTEX COVER($k-(2\text{LP}-\text{MM})$) into a similar form would be possible, since that would imply an algorithm that exactly matches the running time of the algorithm of the algorithm by Garg and Philip [10].

The Strongly Stable Roommates Problem

Adam Kunysz[*]

Institute of Computer Science, University of Wrocław, Wrocław, Poland
aku@cs.uni.wroc.pl

Abstract

An instance of the strongly stable roommates problem with incomplete lists and ties (SRTI) is an undirected non-bipartite graph $G = (V, E)$, with an adjacency list being a linearly ordered list of ties, which are vertices equally good for a given vertex. Ties are disjoint and may contain one vertex. A matching M is a set of vertex-disjoint edges. An edge $\{x, y\} \in E \setminus M$ is a *blocking edge* for M if x is either unmatched or strictly prefers y to its current partner in M, and y is either unmatched or strictly prefers x to its current partner in M or is indifferent between them. A matching is *strongly stable* if there is no blocking edge with respect to it. We present an $O(nm)$ time algorithm for computing a strongly stable matching, where we denote $n = |V|$ and $m = |E|$. The best previously known solution had running time $O(m^2)$ [16]. We also give a characterisation of the set of all strongly stable matchings. We show that there exists a partial order with $O(m)$ elements representing the set of all strongly stable matchings, and we give an $O(nm)$ algorithm for constructing such a representation. Our algorithms are based on a simple reduction to the bipartite version of the problem.

1 Introduction

An instance of the STABLE ROOMMATES PROBLEM WITH TIES AND INCOMPLETE LISTS (SRTI) involves a non-bipartite graph $G = (V, E)$, where an adjacency list of each vertex is a linearly ordered list of ties, which are subsets of vertices equally good for a given vertex. Ties are disjoint and may contain one vertex. Thus if vertices b_1 and b_2 are neighbours of a in G then one of the following holds:

- a strictly prefers b_1 to b_2, which we denote by $b_1 \succ_a b_2$
- b_1 and b_2 are tied on the preference list of a, which we denote by $b_1 =_a b_2$
- a strictly prefers b_2 to b_1, which we denote by $b_1 \prec_a b_2$

If vertex a strictly prefers b_1 to b_2 or is indifferent between them, then we say that a *weakly prefers* b_1 to b_2 and we denote it by $b_1 \succeq_a b_2$. A matching M is a set of edges, no two of which share an endpoint. Let $e = (v, w)$ be an edge contained in a matching M. Then we say that vertices v and w are matched in M and that v is the partner of w in M, which we also denote as $v = M(w)$. If a vertex v has no edge of M incident to it, then we say that v is *free* or *unmatched* in M. An edge $(x, y) \in E \setminus M$ is a *blocking edge* for M if x is either unmatched or strictly prefers y to its current partner in M, and y is either unmatched or weakly prefers x to its current partner. A matching is *strongly stable* if there is no edge blocking it. The goal is to determine a strongly stable matching of a given instance or to

report that no such matching exists. The STABLE MARRIAGE PROBLEM WITH TIES AND INCOMPLETE LISTS (SMTI) is a version of the problem, such that the underlying graph G is bipartite.

Motivation. As the problem name suggests, applications of SRTI arise in the context of assigning students to dormitories [13], [14]. In the problem we try to assign students to share two-person rooms. An instance of SRTI arises in a natural way based on students preferences over one another. The notion of strong stability allows us to prevent the following scenarios. Suppose that we assign a student a to share a room with a student $M(a)$ and a student b to share a room with a student $M(b)$. Assume also that a and b accept each other as a potential rommmates and that a prefers b to $M(a)$ but b is indifferent between a and $M(b)$. Then to improve their situation student a may try to bribe student b, in order to convince b to accept them. Since b is indifferent between a and $M(b)$, they may be happy to share a room with a, denying our assignment.

Previous results. Several algorithms for computing a strongly stable matching in bipartite instances of SMTI have already been given. Let us denote $n = |V|$, $m = |E|$. Irving [5] gave an $O(n^4)$ algorithm for computing strongly stable matchings for instances of SMTI in which the graph is complete. In [9] Manlove extended the algorithm to general SMTI instances, obtaining $O(m^2)$ runtime. In [7] Kavitha, Mehlhorn, Michail and Paluch gave an $O(nm)$ algorithm for the problem. Several structural results related to the problem in instances of SMTI have been given. In [10] the set of strongly stable matchings has been shown to form a distributive lattice (defined in Preliminaries). Recently, in [8] Ghosal, Kunysz and Paluch characterised the set of strongly stable matchings. They described an $O(nm)$ algorithm for constructing a partial order with $O(m)$ elements representing the set of solutions to the problem.

Contrary to the bipartite version of the problem, its non-bipartite generalisation has not received much attention in the literature. The problem of computing a strongly stable matching in non-bipartite instances of SRTI was first solved by Scott [16]. He obtained an $O(m^2)$ algorithm for the problem (The algorithm contained some flaws that can be removed using results from this paper). To the best of our knowledge no structural results related to the problem have been published so far.

Our results. Scott [16] and Manlove [11] asked whether it was possible to use techniques from [7] in order to speed up Scott's algorithm for computing a single strongly stable matching in instances of SRTI from $O(m^2)$ time to $O(nm)$ time. We describe an $O(nm)$ time algorithm for the problem, however we would like to remark that our algorithm is not an extension of Scott's algorithm. Our approach is based on a simple reduction to the bipartite version of the problem. Let $\mathcal{I}$ be an instance of SRTI, and $G = (V, E)$ be an underlying graph. We define an auxiliary instance $\mathcal{I}'$ of SMTI along with its underlying graph $G' = (A \cup B, E')$ as follows. We make two copies $v^p \in A$ and $v^r \in B$ of each vertex $v \in V$. For each edge $\{v, w\} \in E$ we add (v^p, w^r) and (w^p, v^r) to E'. Preference lists in $\mathcal{I}'$ are inherited from preference lists in $\mathcal{I}$. Most of the strongly stable matchings in G' correspond to certain cycles in G, however a deep understanding of the structure of the bipartite instance $\mathcal{I}'$ allows us to filter out matchings which do not correspond to strongly stable matchings in G. This approach allows us not only to obtain a faster algorithm for computing a single strongly stable matching, but also to characterise the set of all strongly stable matchings in instances of SRTI. Our characterisation is based on the construction of a certain partial order with

$O(m)$ elements which allows us to represent all the strongly stable matchings. No such characterisation has been known so far in this setting, however we would like to remark that our construction resembles the one given by Gusfield and Irving [3] for instances of SRI. The presented characterisation can be used to solve a number of problems connected with strongly stable matchings such as enumeration of strongly stable matchings, the minimum regret matching problem and the problem of computing all strongly stable pairs. We would like to point out that we do not address these problems in the paper. The main advantage of our approach is its simplicity. Due to the complicated nature of the problem, it would require a lot of effort to extend Scott's algorithm in order to achieve an $O(nm)$ running time for finding a single strongly stable matching and construct a representation of all the strongly stable matchings. Our algorithms completely avoid the need for low level technical details. The reduction to the bipartite version of the problem allows us also to construct an alternative version of Irving's algorithm [4] for computing stable matchings in instances of SRI. We remark that this has already been observed by Dean and Munshi in [1], where they also use the bipartite formulation of the problem to obtain their results.

Related work. Depending on the way we define a blocking edge in an instance of SRTI we can get two other versions of the stable matching problem. In the weakly stable matching problem an edge $e = (x, y)$ is blocking if by getting matched to each other both x and y would become better off. In the super stable matching problem an edge e is said to be blocking if neither x nor y would become worse off. A matching is respectively *weakly stable* or *super stable* if no blocking edge exists with respect to it.

Super stable matchings in instances of SRTI were investigated by Irving and Manlove [6]. They gave an $O(m)$ time algorithm for finding a super stable matching or reporting that no such matching exists. The algorithm is an extension of Irving's algorithms for finding stable matching in the SRI setting [4] and for finding super stable matching in instances of SMTI [5]. Using a polynomial time reduction from SRTI under super stability to 2-SAT, Fleiner, Irving and Manlove [2] deduced a number of structural results involving super stable matchings. These structural results allowed authors to give algorithms for computing all super stable pairs, enumeration of super stable matchings and finding a minimum regret super stable matching.

In contrast to strongly stable matchings and super stable matchings, the problem of determining whether a weakly stable matching exists in a non-bipartite graph was proven to be NP-complete by Ronn [15]. He proved that NP-completeness holds even if each preference list is either strictly ordered or contains a tie of length 2 at the head.

2 Preliminaries

We start with some additional notation. Let $\mathcal{I}$ be an instance of either SMTI or SRTI. Denote the set of all strongly stable matchings in $\mathcal{I}$ by $\mathcal{M}(\mathcal{I})$. Denote by $V(\mathcal{I})$, $E(\mathcal{I})$ the set of vertices and edges respectively of the underlying graph of $\mathcal{I}$. We say that an instance $\mathcal{I}$ is solvable if there is a strongly stable matching in the underlying graph. We define the rank of w in v's preference list, denoted by $rank(v, w)$, to be 1 plus the number of ties which are preferred to w by v. If $\mathcal{I}$ is a an instance of SMTI, then the underlying bipartite graph is of the form $G = (A \cup B, E)$. As is customary we call the vertices of A and B respectively men and women.

Below we give an overview of known structural results related to strongly stable matchings in bipartite graphs.

▶ **Theorem 1** ([7]). *There is an $\mathcal{O}(nm)$ algorithm to determine a man-optimal strongly stable matching of the given instance or report that no such matching exists.*

We say that a matching is *man-optimal* if every man gets the best partner among all his possible partners in any strongly stable matching. It can be proven that such a matching always exists if a given instance is solvable.

▶ **Theorem 2** (Rural Hospitals Theorem [9]). *In a given instance of* SMTI*, the same vertices are matched in all strongly stable matchings.*

We define an equivalence relation $\sim$ on $\mathcal{M}(\mathcal{I})$ as follows.

▶ **Definition 3.** For two strongly stable matchings M and N, $M \sim N$ if and only if each man m is indifferent between $M(m)$ and $N(m)$. Denote by $[M]$ the equivalence class containing M and denote by $\mathcal{X}$ the set of equivalence classes of $\mathcal{M}(\mathcal{I})$ under $\sim$.

Note that if there are no ties in the instance i.e. $\mathcal{I}$ is an instance of SMI, then each equivalence class of $\sim$ contains exactly one matching. It turns out that if ties are present in the instance, then an equivalence class can contain exponentially many matchings. To see that consider any bipartite graph G which admits a perfect matching. We construct an instance $\mathcal{J}$ of SMTI from G such that the preference list of every vertex is a single tie. Note that perfect matchings in G are strongly stable in $\mathcal{J}$ and all perfect matchings belong to the same equivalence class. If G admits exponentially many perfect matchings, then there are exponentially many strongly stable matchings in $\mathcal{J}$ as well.

Strongly stable matchings belonging to the same equivalence class can be easily characterised (more details in [10]). Thus we focus on structural results related to the set of equivalence classes of $\sim$.

For two strongly stable matchings M and N we say that M dominates N and write $N \preceq M$ if each man m weakly prefers $M(m)$ to $N(m)$. If M dominates N and there exists a man m who prefers $M(m)$ to $N(m)$ then we say that M strictly dominates N and we call N a successor of M.

Next we define a partial order $\preceq^*$ on $\mathcal{X}$.

▶ **Definition 4.** For any two equivalence classes $[M]$ and $[N]$, $[M] \preceq^* [N]$ if and only if $M \preceq N$.

Let M and N be two strongly stable matchings. Consider the symmetric difference $M \oplus N$. By Theorem 2 this set contains only alternating cycles. These cycles display an interesting property captured in:

▶ **Lemma 5** ([10]). *Let M and N be two strongly stable matchings. Consider any alternating cycle C of $M \oplus N$. Let $(m_0, w_0, m_1, w_1, ..., m_{k-1}, w_{k-1})$ be the sequence of vertices of C where m_i are men and w_i are women. Then there are only three possibilities:*
- $(\forall m_i) w_i =_{m_i} w_{i+1}$ *and* $(\forall w_i) m_i =_{w_i} m_{i-1}$
- $(\forall m_i) w_i \prec_{m_i} w_{i+1}$ *and* $(\forall w_i) m_i \succ_{w_i} m_{i-1}$
- $(\forall m_i) w_i \succ_{m_i} w_{i+1}$ *and* $(\forall w_i) m_i \prec_{w_i} m_{i-1}$

Subscripts are taken modulo k.

Below we introduce two operations transforming pairs of strongly stable matchings into other strongly stable matchings.

▶ **Definition 6.** Let M and N be two strongly stable matchings. Consider any man m and his partners $M(m)$ and $N(m)$.

By $M \wedge N$ we denote the matching such that:

- if $M(m) \succeq_m N(m)$ then $(m, M(m)) \in M \wedge N$
- if $M(m) \prec_m N(m)$ then $(m, N(m)) \in M \wedge N$

Similarly by $M \vee N$ we denote the matching such that:
- if $M(m) \succ_m N(m)$ then $(m, N(m)) \in M \vee N$
- if $M(m) \preceq_m N(m)$ then $(m, M(m)) \in M \vee N$

From [10] it follows that both $M \vee N$ and $M \wedge N$ are strongly stable matchings, and $M, N \succeq M \vee N$ and $M, N \preceq M \wedge N$.

We extend operations $\vee$ and $\wedge$ to the set $\mathcal{X}$ of equivalence classes. Let $[M], [N] \in \mathcal{X}$. Denote $[M] \vee [N] = [M \vee N]$, $[M] \wedge [N] = [M \wedge N]$.

A *lattice* is a partially ordered set in which every two elements a, b have a unique infimum (denoted $a \vee b$) and a unique supremum (denoted $a \wedge b$). A lattice L with operations join $\vee$ and meet $\wedge$ is *distributive* if for any three elements x, y, z of L the following holds: $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$.

▶ **Theorem 7** ([10]). *The partial order $(\mathcal{X}, \preceq^*)$ with operations meet $\vee$ and join $\wedge$ defined above forms a distributive lattice.*

It is easy to give an example such that $\mathcal{X}$ is of exponential size. It turns out that it is possible to build a representation of the lattice which is of polynomial size. In order to describe its construction a few more definitions are needed.

▶ **Definition 8.** Let M and N be two strongly stable matchings such that $N \prec M$. We say that N is a **strict successor** of M if and only if there is no strongly stable matching M' such that $N \prec M' \prec M$.

Let M_0 be a man-optimal strongly stable matching, and let M_z be a woman optimal strongly stable matching. We call a sequence $(M_0, M_1, \ldots, M_z)$ such that $M_0 \succ M_1 \succ \ldots \succ M_z$ and M_{i+1} is a strict successor of M_i, a *maximal sequence of strongly stable matchings.*

▶ **Theorem 9** ([8]). *There is an $\mathcal{O}(nm)$ time algorithm to compute a maximal sequence of strongly stable matchings.*

This algorithm works as follows. We first compute a man-optimal matching M_0 in $\mathcal{O}(nm)$ time using the standard algorithm [7], then given a matching M_i we find a strict successor M_{i+1} or determine that M_i is a woman-optimal matching (more details in [8]). We iterate over i until we reach a woman-optimal matching. Using amortized analysis it can be proven that the algorithm runs in $\mathcal{O}(nm)$ time. The algorithm can be easily modified so that it starts with an arbitrary strongly stable matching instead of a man-optimal one.

▶ **Corollary 10.** *Let M_0 be a strongly stable matching. There is an $\mathcal{O}(nm)$ algorithm to compute a sequence of strongly stable matchings $(M_0, M_1, \ldots, M_k)$ such that M_k is a woman-optimal matching, and M_{i+1} is a strict successor of M_i for each i.*

An important property of this algorithm is that in successive matchings each vertex either stays matched to the same partner or gets a partner of a different rank.

▶ **Corollary 11.** *Let $\mathcal{S} = (M_0, M_1, \ldots, M_z)$ be any sequence of strongly stable matchings produced by the algorithm of Corollary 10. Then for each $v \in V(\mathcal{I})$ and $i < z$ we have either $M_i(v) = M_{i+1}(v)$ or $rank(v, M_i(v)) \neq rank(v, M_{i+1}(v))$.*

Let M and N be two strongly stable matchings such that N is a strict successor of M. Recall that $M \oplus N$ is a set of alternating cycles. Consider some matchings $M' \in [M]$, $N' \in [N]$. Depending on the choice of matchings M' and N' it might happen that $M \oplus N \neq M' \oplus N'$. Note that from the definition of $\sim$ it follows that for every vertex v we have $rank(v, M(v)) - rank(v, N(v)) = rank(v, M'(v)) - rank(v, N'(v))$. In other words when we transform a matching from $[M]$ into some matching from $[N]$ the change of v's rank does not depend on the choice of matchings from equivalence classes. This observation motivates the following definition.

▶ **Definition 12.** Let M and N be two strongly stable matchings such that N is a strict successor of M. For any vertex v denote $r_v = rank(v, M(v))$ and $r'_v = rank(v, N(v))$. We say that a set of triples $\rho([M], [N]) = \{(v, r_v, r'_v) : v \in V(\mathcal{I}), r_v \neq r'_v\}$ is a **rotation** transforming $[M]$ into $[N]$.

Let ρ be a rotation and M, N be two strongly stable matchings such that N is a strict successor of M. We say that the set of alternating cycles $M \oplus N$ *realizes* a rotation ρ if $\rho = \rho([M], [N])$. As noted above there are potentially many sets of cycles realizing a given rotation. A rotation ρ is *exposed* in $[M]$ if $\rho = \rho([M], [N])$ for some N which is a strict successor of M. We say that such a rotation *transforms* $[M]$ into $[N]$. Note that a given rotation may be exposed in many equivalence classes.

▶ **Theorem 13** ([8]). *Let $\mathcal{S} = (M_0, M_1, \ldots, M_z)$ be a maximal sequence of strongly stable matchings. For $i \in \{0, 1, \ldots, z-1\}$ denote $\rho_i = \rho([M_i], [M_{i+1}])$. Then the set $D(\mathcal{I}) = \{\rho_0, \rho_1, \ldots, \rho_{z-1}\}$ does not depend on the choice of $\mathcal{S}$, and $\rho_i \neq \rho_j$ for $i \neq j$.*

Note that given a maximal sequence of strongly stable matchings $(M_0, M_1, \ldots, M_z)$ we can easily compute rotations $(\rho_0, \rho_1, \ldots, \rho_{z-1})$ where $\rho_i = \rho([M_i], [M_{i+1}])$. Moreover the set $C_{\rho_i} = M_i \oplus M_{i+1}$ realizes ρ_i for each i. It is important to note that depending on the choice of the maximal sequence $\mathcal{S}$ alternating cycles in C_{ρ_i} may differ.

Let $v \in V(\mathcal{I})$, and let ρ be a rotation. If $(v, f, s) \in \rho$, then we say that ρ *moves* v from rank f to rank s. If a particular maximal sequence of strongly stable matchings $\mathcal{S}$ is given and $\rho = \rho([M_i], [M_{i+1}])$ for some i then we say that a rotation ρ moves v from $M_i(v)$ to $M_{i+1}(v)$.

Note that in an instance of SMI for each rotation there is exactly one set of alternating cycles realizing this rotation. This follows easily from the definition of a rotation and the fact that each equivalence class consists of exactly one matching. It can be proven that in this setting a set of cycles realizing a given rotation always consists of one cycle. Thus in an instance of SMI a rotation can be viewed as a single cycle. In the more general SMTI setting it may happen that a set of cycles realizing a given rotation consists of more than one cycle (Figure 1).

▶ **Definition 14.** Let $D(\mathcal{I})$ be the set of all rotations in a given instance $\mathcal{I}$. We define the order $\prec$ on elements of $D(\mathcal{I})$ as follows. We say that a rotation ρ precedes rotation ρ' and write $\rho \prec \rho'$ if and only if for every maximal sequence $\mathcal{S} = (M_0, M_1, \ldots, M_z)$ of strongly stable matchings we have $\rho = \rho([M_i], [M_{i+1}])$ and $\rho' = \rho([M_j], [M_{j+1}])$ for some i, j such that $i < j$.

Let Z be a subset of $D(\mathcal{I})$. We say that Z is a *closed set* if there is no $\rho \in D(\mathcal{I}) \setminus Z$ such that $\rho \prec \rho'$ for some $\rho' \in Z$. It turns out that each closed set corresponds to an equivalence class of $\sim$. Moreover given such a set we can efficiently find an equivalence class corresponding to it. We briefly explain how to do it.

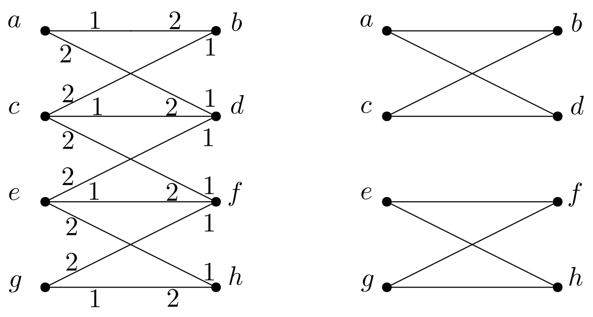

Figure 1 An example instance of SMTI is presented on the left hand side. Natural numbers denote ranks of the corresponding edges. This instance admits two strongly stable matchings $M_1 = \{(a,b),(c,d),(e,f),(g,h)\}$ and $M_2 = \{(a,d),(c,b),(e,h),(g,f)\}$. Cycles realizing the only rotation are presented on the right hand side.

First assume that we are given some particular maximal sequence $\mathcal{S} = (M_0, M_1, \ldots, M_z)$ of strongly stable matchings, the set of rotations $D(\mathcal{I})$, and for each rotation $\rho_i = \rho([M_i],[M_{i+1}])$ a set of cycles $C_{\rho_i} = M_i \oplus M_{i+1}$ realizing it.

▶ **Definition 15.** Let $Z = \{\rho_{a_0}, \rho_{a_1}, \ldots, \rho_{a_{k-1}}\}$ be a closed set. We order its elements so that there are no i, j such that $i < j$ and $\rho_{a_i} \succ \rho_{a_j}$. Let $N_0 = M_0$, $N_{i+1} = N_i \oplus C_{\rho_{a_i}}$. We denote $f_{\mathcal{S}}(Z) = N_k$.

Note that the sequence $\{N_i\}$ depends on the ordering of elements of Z, however its last element $f_{\mathcal{S}}(Z) = M_0 \oplus C_{\rho_{a_0}} \oplus C_{\rho_{a_1}} \oplus \ldots \oplus C_{\rho_{a_{k-1}}}$ is the same regardless of the ordering.

Intuition behind this definition is as follows. We start with an equivalence class $[N_0]$ ($N_0 = M_0$), and some ordering of elements of Z. First we apply a rotation ρ_{a_0} and get a matching $N_1 = N_0 \oplus C_{\rho_{a_0}}$ belonging to $[N_1]$. Then we apply ρ_{a_1} to N_1 and get $N_2 = N_1 \oplus C_{\rho_{a_1}}$ belonging to $[N_2]$. We continue this process until we apply all the rotations. In the end we get a matching $f_{\mathcal{S}}(Z) = N_k$, and a class $[N_k]$. Note that depending on the ordering of Z, sequences $\{N_i\}$ may go through different equivalence classes, however all possible orderings result in the same matching N_k, and an equivalence class $[N_k]$.

The next lemma says that every equivalence class can be obtained in this way from some closed set of rotations.

▶ **Lemma 16.** *For each equivalence class $[M]$ there is a closed set X such that $f_{\mathcal{S}}(X) \in [M]$. Let Z_1 and Z_2 be closed sets. Then $Z_1 \neq Z_2$ implies that $[f_{\mathcal{S}}(Z_1)] \neq [f_{\mathcal{S}}(Z_2)]$.*

For each closed set Z we define $g_{\mathcal{S}}(Z) = [f_{\mathcal{S}}(Z)]$. It can be proven that $g_{\mathcal{S}}$ does not depend on the choice of $\mathcal{S}$ and that $g_{\mathcal{S}}$ is a bijection between closed sets of $D(\mathcal{I}, \prec)$ and the set $\mathcal{X}$. The above discussion is summarized in the following theorem.

▶ **Theorem 17** ([8]). *There is a one-to-one correspondence between the set $\mathcal{X}$ of equivalence classes of $\sim$ and the closed sets of $(D(\mathcal{I}), \prec)$.*

It is important to note that given the function $f_{\mathcal{S}}$ we can get one strongly stable matching from each equivalence class and that depending on the choice of $\mathcal{S}$ these matchings may differ. In other words if $\mathcal{S} \neq \mathcal{S}'$ then it may happen that $f_{\mathcal{S}}(Z) \neq f_{\mathcal{S}'}(Z)$ for some Z, however regardless of the choice of $\mathcal{S}$ and $\mathcal{S}'$ we have $[f_{\mathcal{S}}(Z)] = [f_{\mathcal{S}'}(Z)]$. We emphasize this fact as our algorithm for the non-bipartite version of the problem is based on it.

Note that from Definition 14 alone it is non-trivial how to efficiently construct the relation $\prec$ on $D(\mathcal{I})$. Construction of an explicit representation of the relation $\prec$ would take $\Omega(m^2)$

time, because $D(\mathcal{I})$ might have $\Omega(m)$ elements. It can be proven that we can efficiently construct a sparse subgraph of $(D(\mathcal{I}), \prec)$ such that the closed sets of these two posets are identical.

▶ **Theorem 18** ([8]). *There is a graph $G' = (D(\mathcal{I}), E')$ such that $|E'| = \mathcal{O}(m)$, and the closed sets in G' are exactly the same as the closed sets in the poset $(D(\mathcal{I}), \prec)$. Such a graph can be constructed in $\mathcal{O}(nm)$ time.*

3 The Strongly Stable Roommates Problem

Let $\mathcal{I}$ be an instance of SRTI and let $G = (V, E)$ be the underlying graph. We define an auxiliary instance $\mathcal{I}'$ of SMTI and its underlying bipartite graph $H = (A \cup B, E')$. We make two copies of each vertex $v \in V(G)$, $v^p \in A$ – a *proposing node* and $v^r \in B$ – a *responding node*. For each edge $\{v, w\} \in E$ we add two edges (v^p, w^r) and (w^p, v^r) to E'. Each node in H inherits its preference list from the original instance i.e. for each edge $\{v, w\} \in E$ we have $rank(v^p, w^r) = rank(v, w)$ and $rank(w^r, v^p) = rank(w, v)$. Following the notation from [3] we denote edges of non-bipartite graphs as $\{x, y\}$ rather than (x, y) to emphasise the fact that pairs are unordered.

In the next few lemmas we show that we can derive some useful properties of the structure of strongly stable matchings in $\mathcal{I}$ from the structure of $\mathcal{I}'$. Throughout this section we assume that $\mathcal{I}$ is an instance of SRTI and that $\mathcal{I}'$ is defined as above.

▶ **Definition 19.** Let M be a matching in $\mathcal{I}'$. We say that M is a **symmetric matching** if for each edge $(v, w) \in E$ we have $(v^p, w^r) \in M \iff (w^p, v^r) \in M$.

▶ **Lemma 20.** *There is a one-to-one correspondence between strongly stable matchings in $\mathcal{I}$ and symmetric strongly stable matchings in $\mathcal{I}'$.*

Proof. Let M be a strongly stable matching in $\mathcal{I}$. Let M' be a symmetric matching such that for each $\{v, w\} \in M$ we add (v^p, w^r) and (w^p, v^r) to M'. We can easily see that M' is strongly stable. If there was some edge (x^p, y^r) blocking M' then M would be blocked by $\{x, y\}$. Similarly we can see that for each symmetric strongly stable matching M in $\mathcal{I}'$ there is a corresponding strongly stable matching M' in $\mathcal{I}$. For each $(v^r, w^p) \in M$ we add $\{v, w\}$ to M'. Stability of M' is simple to establish. It is obvious that it is a one-to-one correspondence. ◀

Let M be a strongly stable matching M in $\mathcal{I}$. We denote its symmetric counterpart in $\mathcal{I}'$ by $s(M)$. One can easily see that the equivalence class $[s(M)]$ might contain some matchings which are not symmetric. Moreover, some classes may not contain any symmetric matchings. For instance let M be a matching in $\mathcal{I}'$ such that for some vertex $v \in V(\mathcal{I})$ we have $rank(v^p, M(v^p)) \neq rank(v^r, M(v^r))$. It is clear that none of the matchings from $[M]$ can be symmetric. This observation leads to the following definition.

▶ **Definition 21.** Let M be a strongly stable matching in $\mathcal{I}'$. We say that the class $[M]$ is **symmetric** if for each $v \in V(\mathcal{I})$ we have $rank(v^p, M(v^p)) = rank(v^r, M(v^r))$.

It is obvious that if M is a symmetric matching then $[M]$ is also symmetric. Note that if a matching belongs to a symmetric equivalence class it does not imply that it is actually a symmetric matching. Do all the symmetric equivalence classes contain at least one symmetric matching? It turns out that the answer to this question is negative. A counterexample is presented in Figure 2. It turns out that the following theorem holds:

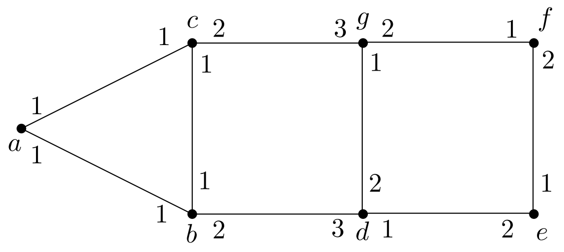

Figure 2 An example of an unsolvable instance $\mathcal{I}$ of SRTI. There are four strongly stable matchings in the corresponding auxiliary instance $\mathcal{I}'$ of SMTI:

- $M_1 = \{(a^p, b^r), (b^p, c^r), (c^p, a^r), (d^p, e^r), (e^p, f^r), (f^p, g^r), (g^p, d^r)\}$
- $M_2 = \{(a^p, b^r), (b^p, c^r), (c^p, a^r), (d^p, e^r), (e^p, d^r), (f^p, g^r), (g^p, f^r)\}$
- $M_3 = \{(a^p, b^r), (b^p, c^r), (c^p, a^r), (d^p, g^r), (g^p, d^r), (e^p, f^r), (f^p, e^r)\}$
- $M_4 = \{(a^p, b^r), (b^p, c^r), (c^p, a^r), (d^p, g^r), (g^p, f^r), (f^p, e^r), (e^p, d^r)\}$

Matchings M_2 and M_3 belong to symmetric equivalence classes but neither of them is symmetric.

▶ **Theorem 22.** *An instance $\mathcal{I}$ is solvable if and only if the following hold:*
- *at least one symmetric equivalence class exists in $\mathcal{I}'$*
- *each symmetric equivalence class in $\mathcal{I}'$ contains at least one symmetric strongly stable matching*

The above theorem implies that if we find a symmetric equivalence class which does not contain any symmetric matching, then the instance is unsolvable. Moreover if we find a strongly stable matching in a given instance $\mathcal{I}$ then every single symmetric equivalence class of $\mathcal{I}'$ contains at least one symmetric matching. Note that the above theorem is somewhat trivial in the case of strict preferences. In an instance of SMI each equivalence class contains exactly one matching. There are no ties, thus M is symmetric if and only if $[M]$ is symmetric.

In order to prove Theorem 22 we are going to make use of the function $f_{\mathcal{S}}$ (Definition 15). It turns out that if an instance $\mathcal{I}$ is solvable, then we can pick a maximal sequence $\mathcal{S}$ such that if a closed set Z corresponds to a symmetric equivalence class, then $f_{\mathcal{S}}(Z)$ is a symmetric matching. Below we give a candidate for such a sequence.

Denote $q(v^r) = v^p$ and $q(v^p) = v^r$ for $v \in V(\mathcal{I})$. For a given matching M in $\mathcal{I}'$ we denote $S(M) = \{(q(w), q(v)) : (v, w) \in M\}$.

▶ **Definition 23.** We say that a maximal sequence of strongly stable matchings $\mathcal{S} = (M_0, M_1, \ldots M_{2k})$ is **symmetric** if M_k is a symmetric matching and $S(M_i) = M_{2k-i}$ for each i.

It turns out that if a given instance of $\mathcal{I}'$ admits a symmetric strongly stable matching, then there is a symmetric maximal sequence of strongly stable matchings containing this matching.

▶ **Lemma 24.** *Let M_k be a woman-optimal matching in $\mathcal{I}'$, M_0 be a symmetric strongly stable matching, and let $(M_0, M_1, \ldots, M_k)$ be a sequence of strongly stable matchings such that M_{i+1} is a strict successor of M_i. Then the sequence:*

$$\mathcal{Q} = (S(M_k), S(M_{k-1}), \ldots, S(M_1), M_0, M_1, \ldots, M_k)$$

is a symmetric maximal sequence of strongly stable matchings.

Proof. It suffices to prove that for each i the matching $S(M_i)$ is strongly stable, $S(M_k)$ is man-optimal, and that $S(M_{i-1})$ is a strict successor of $S(M_i)$. Strong stability of $S(M_i)$

follows easily from strong stability of M_i. If there was an edge (v^p, w^r) blocking $S(M_i)$ then (w^p, v^r) would block M_i. It can be easily proven that for any two strongly stable matchings N, N' we have $N \prec N' \iff S(N') \prec S(N)$. If there was a matching N such that $S(M_k) \prec N$, then $S(N) \prec M_k$ would hold, thus M_k would not be woman-optimal. Similarly if there was a strongly stable matching M' such that $S(M_i) \succ M' \succ S(M_{i-1})$, then there would be $M_{i-1} \succ S(M') \succ M_i$. This would contradict the assumption that M_i is a strict successor of M_{i-1}. Thus for each i the matching $S(M_{i-1})$ is a strict successor of $S(M_i)$. Hence $\mathcal{Q}$ is a symmetric maximal sequence of strongly stable matchings. ◀

Corollary 10 along with the proof of Lemma 24 imply that given a symmetric strongly stable matching M in $\mathcal{I}'$ we can compute a symmetric maximal sequence of strongly stable matchings.

▶ **Corollary 25.** *Assume that we are given a symmetric strongly stable matching M in $\mathcal{I}'$. Then there exists a symmetric maximal sequence of strongly stable matchings $(M_0, M_1, \ldots, M_{2k})$ such that $M_k = M$. We can compute such a sequence in $\mathcal{O}(nm)$ time.*

Before we prove Theorem 22 we need to investigate the structure of the set of rotations $D(\mathcal{I}')$. Let M be a symmetric strongly stable matching. Consider a symmetric sequence of strongly stable matchings $\mathcal{S} = (M_0, M_1, \ldots, M_{2k})$ such that $M_k = M$. Let $\rho_i = \rho([M_i], [M_{i+1}])$ for each i. Theorem 13 implies that $D(\mathcal{I}') = \{\rho_0, \rho_1, \ldots, \rho_{2k-1}\}$. From Theorem 17 we know that the set $Z = \{\rho_0, \rho_1, \ldots, \rho_{k-1}\}$ is closed and it corresponds to the equivalence class $[M]$. It turns out that the set of remaining rotations $D(\mathcal{I}') \setminus Z$ has very similar structure to Z. In order to see this we consider matchings M_i, M_{i+1} and their symmetric counterparts $M_{2k-i} = S(M_i)$, $M_{2k-i-1} = S(M_{i+1})$. Let $v \in V(\mathcal{I})$, $w_1^r = M_i(v^p)$, and $w_2^r = M_{i+1}(v^p)$. Observe that rotation ρ_i moves v^p from w_1^r to w_2^r. We can easily see that ρ_{2k-i-1} moves v^r from w_2^p to w_1^p. This observation motivates the following definition.

For a given rotation ρ in $\mathcal{I}'$ we denote $\overline{\rho} = \{(q(v), s, f) : (v, f, s) \in \rho\}$. Similarly for a given cycle C in $\mathcal{I}'$ we denote $\overline{C} = \{(q(w), q(v)) : (v, w) \in C\}$. We say that $\overline{\rho}$ is the *rotation dual* to ρ. Analogously for a given cycle C we say that $\overline{C}$ is the *cycle dual* to C. Note that the rotation dual to $\overline{\rho}$ is equal to ρ. Similarly the cycle dual to $\overline{C}$ is equal to C. We say that the set of all rotations $D(\mathcal{I}')$ is *symmetric* if for each $\rho \in D(\mathcal{I}')$ both $\overline{\rho} \in D(\mathcal{I}')$ and $\rho \neq \overline{\rho}$ hold.

▶ **Theorem 26.** *If $\mathcal{I}$ is solvable, then the set of rotations $D(\mathcal{I}')$ is symmetric.*

Proof. Let $\mathcal{S} = (M_0, M_1, \ldots, M_{2k})$ be a symmetric maximal sequence of strongly stable matchings. Such a sequence exists from Corollary 25. Denote $\rho_i = \rho([M_i], [M_{i+1}])$ for each i. From Theorem 13 we know that $D(\mathcal{I}') = \{\rho_0, \rho_1, \ldots, \rho_{2k-1}\}$, and that $\rho_i \neq \rho_j$ for $i \neq j$. One can easily check that ρ_i is dual to ρ_{2k-i-1} for each i. Thus $D(\mathcal{I}')$ is symmetric. ◀

From the above theorem we know that if $D(\mathcal{I}')$ is not symmetric, then for sure $\mathcal{I}$ does not admit any strongly stable matching. From Theorems 9 and 13 we know how to compute the set $D(\mathcal{I}')$ in $\mathcal{O}(nm)$ time. We can easily check if this set is symmetric.

▶ **Corollary 27.** *There is an $\mathcal{O}(nm)$ algorithm to determine if $D(\mathcal{I}')$ is symmetric.*

It turns out that if the set $D(\mathcal{I}')$ is symmetric then we can characterise the set of symmetric equivalence classes of $\mathcal{I}'$. We say that a set $Z \subseteq D(\mathcal{I}')$ is *complete* if for each rotation $\rho \in D(\mathcal{I}')$ either $\rho \in Z$ or $\overline{\rho} \in Z$. Similarly to Lemma 16, for a given maximal sequence $\mathcal{S}$ we consider the function $f_{\mathcal{S}}$ (Definition 15) however this time we restrict its domain to the set of complete closed sets.

▶ **Lemma 28.** *Let $D(\mathcal{I}')$ be symmetric, $\mathcal{S} = (M_0, M_1, \dots, M_z)$ be any maximal sequence of strongly stable matchings. For each set $Z \subseteq D(\mathcal{I}')$ which is complete and closed $f_\mathcal{S}(Z)$ belongs to a symmetric equivalence class. Moreover for each symmetric equivalence class $[M]$ there is a closed and complete set Z such that $f_\mathcal{S}(Z) \in [M]$.*

Proof. Let Z be a complete and closed set of rotations. We prove that $f_\mathcal{S}(Z)$ belongs to a symmetric equivalence class. First let us order rotations of $Z = \{\rho_0, \rho_1, \dots, \rho_k\}$, so that if $i < j$, then $\rho_i \not\succ \rho_j$. Then we denote $N_0 = M_0$, $N_{i+1} = N_i \oplus C_{\rho_i}$ for $0 \leq i < k$. From the definition of rotation it follows that N_{i+1} is a strict successor of N_i. Consider an arbitrary vertex $v \in V(\mathcal{I})$. In order to prove that $f_\mathcal{S}(Z)$ belongs to a symmetric equivalence class we need to show that $rank(v^p, N_k(v^p)) = rank(v^r, N_k(v^r))$. For each i the rotation ρ_i moves v^p from $N_i(v^p)$ to $N_{i+1}(v^p)$, thus Z moves v^p from $N_0(v^p)$ to $N_k(v^p)$. From the definition of dual rotation we know that $\overline{\rho_i}$ moves v^r from $q(N_{i+1}(v^p))$ to $q(N_i(v^p))$, hence $D(\mathcal{I}') \setminus Z$ moves v^r from $q(N_k(v^p))$ to $q(N_0(v^p))$ From the completeness of Z we obtain that Z moves v^r from $N_0(v^r)$ to $q(N_k(v^p))$. Thus $rank(v^r, N_k(v^r)) = rank(v^r, q(N_k(v^p)) = rank(v^p, N_k(v^p))$, hence $f_\mathcal{S}(Z)$ belongs to a symmetric equivalence class.

Let $[M]$ be a symmetric equivalence class. We prove that there is a closed and complete set Z such that $f_\mathcal{S}(Z) \in [M]$. From Lemma 24 there exists a symmetric maximal sequence of strongly stable matchings $(M_0, M_1, \dots, M_{2k})$ such that $M = M_k$. Analogously to the proof of Theorem 26 we denote $\rho_i = \rho([M_i], [M_{i+1}])$ for each i. From Theorem 13 we know that $D(\mathcal{I}') = \{\rho_0, \rho_1, \dots, \rho_{2k-1}\}$. Consider the set $Z = \{\rho_0, \rho_1, \dots, \rho_{k-1}\}$. This set is obviously closed. One can easily check that ρ_i is dual to ρ_{2k-i-1}, thus Z is complete. From Theorem 17 we have $f_\mathcal{S}(Z) \in [M]$. ◀

Analogously to Theorem 17 we consider a function $g_\mathcal{S}(Z) = [f_\mathcal{S}(Z)]$ and obtain the following theorem.

▶ **Theorem 29.** *There is a one-to-one correspondence between the symmetric equivalence classes and the complete closed subsets of rotations in $(D(\mathcal{I}'), \prec)$.*

It may happen that the set of rotations is symmetric but none of the symmetric classes contains a symmetric strongly stable matching (Figure 2). If an instance $\mathcal{I}$ is solvable, then we can pick a maximal sequence $\mathcal{S}$ of strongly stable matchings, such that all values of the function $f_\mathcal{S}$ are symmetric strongly stable matchings. Note that this implies Theorem 22 and allows us to characterise strongly stable matchings in a non-bipartite instance $\mathcal{I}$. Below we prove that it suffices to take a sequence obtained from Corollary 25 as $\mathcal{S}$.

▶ **Theorem 30.** *Let $\mathcal{Q} = (M_0, M_1, \dots, M_{2k})$ be a symmetric maximal sequence of strongly stable matchings obtained as in Corollary 25. For each complete and closed set Z of rotations $f_\mathcal{Q}(Z)$ is a symmetric matching.*

Proof. Let Z be a closed and complete set of rotations. Denote $M = f_\mathcal{Q}(Z)$. Let $v \in V(\mathcal{I})$ be any vertex, and let $M(v^p) = w^r$. Our goal is to prove that $M(v^r) = w^p$. From Lemma 28 we know that M belongs to a symmetric equivalence class, thus $rank(v^p, M(v^p)) = rank(v^r, M(v^r))$. Denote this rank by r. From the definition of $f_\mathcal{Q}$ if an edge belongs to M then it must belong to one of the matchings M_i. Recall that since $\mathcal{Q}$ is a sequence obtained from Corollary 25 we have that for each i, and a vertex x either $M_i(x) = M_{i+1}(x)$ or $rank(x, M_i(x)) \neq rank(x, M_{i+1}(x))$ (Corollary 11). This observation, and the fact that $M_0 \succ M_1 \succ \dots \succ M_{2k}$ imply that there exists exactly one vertex of rank r matched to v^p amongst all vertices matched to v^p in matchings of $\mathcal{Q}$. Let us denote this vertex by w^r, and assume that $M_j(v^p) = w^r$ for some j. Similarly it can be proven that there exists exactly

Algorithm 1 for computing a symmetric equivalence class

```
1: let $\mathcal{I}'$ be an auxiliary symmetric instance of SMTI
2: if $\mathcal{I}'$ is unsolvable or $D(\mathcal{I}')$ is not symmetric then
3:     return no

one vertex of rank r matched to v^r amongst all vertices matched to v^r in matchings of $\mathcal{Q}$. The fact that $\mathcal{Q}$ is symmetric implies that $M_{2k-j}(v^r) = w^p$, so v^r must be matched to w^p in M. This implies that M is a symmetric matching. ◀

Assuming that we are given one symmetric matching in $\mathcal{I}'$ we can efficiently construct $f_{\mathcal{Q}}$ as shown in Corollary 25. It remains to show how to find some symmetric equivalence class and check if there exists a symmetric matching belonging to this class. If such a matching does not exist then Theorem 22 implies that $\mathcal{I}$ is unsolvable.

Algorithm 1 for determining a symmetric equivalence class works as follows. We first build the symmetric instance $\mathcal{I}'$. If this instance is unsolvable or $D(\mathcal{I}')$ is not symmetric then $\mathcal{I}$ is unsolvable from Theorem 26. From now on we assume that $D(\mathcal{I}')$ is symmetric. We prove that in this case we can find a symmetric equivalence class in $\mathcal{I}'$. The intuition behind the algorithm is very simple. We first construct a set Z which is closed and complete. Initially we set $Z = \emptyset$. During each step of the algorithm we add to Z some rotations ρ such that there does not exist any rotation $\rho' \notin Z$ such that $\rho' \prec \rho$. It is enough to make sure that Z is closed at all times of the execution. In order to make sure that the resulting set is complete, when we add a rotation ρ to Z we mark $\overline{\rho}$, and never add any marked rotations to Z. Once the set Z is constructed we use Theorem 29 to obtain a symmetric equivalence class corresponding to it. Before we prove the correctness of the algorithm we need the following technical lemma.

▶ **Lemma 31.** *Let $\rho, \rho' \in D(\mathcal{I}')$ be two rotations such that $\rho \prec \rho'$. Then $\overline{\rho'} \prec \overline{\rho}$ holds.*

Proof. Assume that $\overline{\rho'} \prec \overline{\rho}$ does not hold. From the definition of $\prec$ we know that there exists a maximal sequence of strongly stable matchings $\mathcal{S} = (M_0, M_1, \ldots, M_{2k})$ such that $\overline{\rho'} = \rho_j$, $\overline{\rho} = \rho_l$ for some $l < j$, where we denote $\rho_i = \rho([M_i], [M_{i+1}])$ for each i. One can easily see that $\mathcal{S}' = (S(M_{2k}), S(M_{2k-1}), \ldots, S(M_0))$ is also a maximal sequence of strongly stable matchings. It can be proven that $\overline{\rho_i} = \rho([S(M_{i+1})], [S(M_i)])$ for each i. Thus $\rho' = \overline{\rho_j}$ and $\rho = \overline{\rho_l}$ – a contradiction with the definition of $\prec$. ◀

Correctness of the algorithm is proven in the following theorem.

▶ **Theorem 32.** *Let $\mathcal{I}$ be an instance of* SRTI*, and let $\mathcal{I}'$ be the auxiliary instance of* SMTI*. Algorithm 1 determines a matching belonging to a symmetric equivalence class of $\mathcal{I}'$ or reports that such a matching does not exist. The runtime of the algorithm is bounded by $\mathcal{O}(nm)$.*

Proof. It is clear from Theorem 26 that if the algorithm returns *no* in line 4, then $\mathcal{I}$ is unsolvable.

We first prove that Z is closed. Closed sets in the poset $(D(\mathcal{I}'), \prec)$, and in G' are identical, hence it suffices to prove that Z is closed in G'. At the start of the execution we have $Z = \emptyset$, so Z is closed. A rotation can be added to Z only if all its immediate predecessors in G' have already been added to Z. It implies that when a rotation is added to Z this set remains closed, hence Z is closed during the entire execution of the algorithm.

We prove that Z is complete when we exit the *while* loop (lines $14 - 23$). Assume to the contrary that Z is not complete. Then there is some rotation ρ such that $\rho, \overline{\rho} \notin Z$. From the pseudocode we can see that neither ρ nor $\overline{\rho}$ is marked. Since $\rho \notin Z$ there exists some rotation ρ' such that $(\rho', \rho) \in G'$ and $\rho' \notin Z$, otherwise at some point ρ would have been added to Q in the line 23, and either ρ or $\overline{\rho}$ would be added to Z. If ρ' is marked then $\overline{\rho'} \in Z$. From Lemma 31 we know that $\rho' \prec \rho$ implies that $\overline{\rho} \prec \overline{\rho'}$ – a contradiction with the fact that Z is closed. Hence ρ' cannot be marked. The rotation $\overline{\rho'}$ is also unmarked, because $\rho' \notin Z$. We can do the same reasoning for ρ' and $\overline{\rho'}$ and get another rotation $\rho'' \notin Z$, such that $\overline{\rho''} \notin Z$ and neither ρ'' nor $\overline{\rho''}$ is marked. We continue this process building a sequence of rotations $\rho \succ \rho' \succ \rho'' \succ \ldots$, and we eventually get a contradiction because our poset is finite. Thus Z is complete, and it corresponds to a symmetric equivalence class.

Let us estimate the complexity of the algorithm. From Corollary 27 we know that computations in lines $3 - 4$ take $\mathcal{O}(nm)$ time. Then we build a graph G' in time $\mathcal{O}(nm)$ (Theorem 18). Number of operations performed in lines $14 - 23$ is proportional to the number of edges of G', which is bounded by $\mathcal{O}(nm)$. Thus the algorithm runs in $\mathcal{O}(nm)$ time overall. ◀

The last step of the algorithm is to show how to determine if a symmetric matching exists in a given symmetric equivalence class.

▶ **Theorem 33.** *Let M be a strongly stable matching belonging to a symmetric equivalence class. We can determine in $\mathcal{O}(\sqrt{n}m)$ time if there is a symmetric strongly stable matching belonging to $[M]$.*

Proof. We will construct a subgraph $G' = (V', E')$ of G (recall that G is the underlying graph of $\mathcal{I}$) such that perfect matchings in G' correspond to symmetric matchings in $[M]$. Let us consider a matching M. For each $v \in V(\mathcal{I})$ such that v^p and v^r are matched in M we add v to V'. We also add to E' each edge (v, w) such that $rank(v, M(v)) = rank(v, w)$ and $rank(w, v) = rank(w, M(w))$. Similarly to the proof of Lemma 20 it can be shown that each symmetric matching in $[M]$ corresponds to a perfect matching in G'. It remains to compute a maximum matching in the non-bipartite graph G' [12]. ◀

The algorithm for computing a single strongly stable matching follows easily from the above discussion. Given an instance $\mathcal{I}$ of SRTI, we first use Algorithm 1 in order to compute a strongly stable matching M belonging to a symmetric equivalence class in an auxiliary instance $\mathcal{I}'$. Then from Theorem 33 we determine a symmetric matching belonging to $[M]$, and output its counterpart in $\mathcal{I}$. Thus we obtain the following theorem:

▶ **Theorem 34.** *There is an $O(nm)$ time algorithm to determine a single strongly stable matching in an instance of* SRTI *or to report that no such matching exists.*

In the Introduction we mentioned that Scott's $O(m^2)$ algorithm contained some flaws. We explain the problem with his algorithm using our terminology. Scott's algorithm can correctly determine whether a symmetric equivalence class exists in an auxiliary instance $\mathcal{I}'$. He claims that a symmetric strongly stable matching can always be found in a given symmetric equivalence class (Lemma 3.3.4 in [16]). This is a false statement as we can see in Figure 2. The algorithm can be repaired using for instance Theorem 33, however an analogue of Theorem 22 is needed to prove its correctness.

Given a single strongly stable matching we can easily construct a representation of the set of all strongly stable matchings. Using Corollary 25 we compute a symmetric maximal sequence of strongly stable matchings and then construct the poset of rotations as in Theorem 17. Closed and complete subsets of rotations correspond to strongly stable matchings from Theorem 29 hence the following holds:

▶ **Theorem 35.** *There is an $O(nm)$ time algorithm to construct a poset $(D(\mathcal{I}'), \prec)$, such that closed and complete subsets of $D(\mathcal{I}')$ correspond to symmetric equivalence classes of an auxiliary instance $\mathcal{I}'$.*

Abstract

The suffix array, perhaps the most important data structure in modern string processing, needs to be augmented with the longest-common-prefix (LCP) array in many applications. Their construction is often a major bottleneck especially when the data is too big for internal memory. We describe two new algorithms for computing the LCP array from the suffix array in external memory. Experiments demonstrate that the new algorithms are about a factor of two faster than the fastest previous algorithm.

1 Introduction

The suffix array [22, 10], a lexicographically sorted list of the suffixes of a text, is the most important data structure in modern string processing. It is frequently augmented with the longest-common-prefix (LCP) array, which stores the lengths of the longest common prefixes between lexicographically adjacent suffixes. Together they are the basis of powerful text indexes such as enhanced suffix arrays [1] and many compressed full-text indexes [25]. Modern textbooks spend dozens of pages in describing their applications, see e.g. [28, 21].

The construction of the suffix and LCP arrays has been heavily studied over the years. Recently, several algorithms and implementations for constructing the suffix array in external memory have been published [7, 4, 6, 11, 27, 26, 19, 15]. Such algorithms are frequently needed for handling large texts or text collections that are too big to process in RAM. Some of the algorithms can also compute the LCP array simultaneously with the suffix array [4, 6] and others could probably be modified to do so. However, such a modification is unique to each algorithm and can significantly increase the construction time as well as the disk space usage of the algorithm [4].

A better solution for constructing the LCP array is to construct the suffix array separately first and then compute the LCP array from the suffix array. This has been a standard practice in internal memory for 15 years [18] but became possible in external memory only recently with the introduction of the LCPscan algorithm [12, 13]. This led to a significant improvement in construction time as well as in disk space usage over previous approaches.

Furthermore, since LCPscan can be combined with any suffix array construction algorithm, it can immediately benefit from any progress in the fast developing field of suffix array construction. For example, the recent pSAscan algorithm [15] can often construct the suffix

Table 1 The time and I/O complexities of LCPscan and the new algorithms in the standard external memory model [34]. The parameters are the text length n, the alphabet size σ, the available RAM M (in units of $\log n$ bits), and the disk block size B (in units of $\log n$ bits).

Algorithm	Time complexity	I/O complexity
LCPscan	$\mathcal{O}\left(\frac{n^2}{M(\log_\sigma n)^2} + n\log_{\frac{M}{B}}\frac{n}{B}\right)$	$\mathcal{O}\left(\frac{n^2}{MB(\log_\sigma n)^2} + \frac{n}{B}\log_{\frac{M}{B}}\frac{n}{B}\right)$
SPARSE-Φ	$\mathcal{O}\left(\frac{n^2}{M} + n\log_{\frac{M}{B}}\frac{n}{B}\right)$	$\mathcal{O}\left(\frac{n^2}{MB(\log_\sigma n)^2} + \frac{n}{B}\log_{\frac{M}{B}}\frac{n}{B}\right)$
SUCCINCTIRREDUCIBLE	$\mathcal{O}\left(\frac{n^2}{M(\log_\sigma n)^2} + n\log n\right)$	$\mathcal{O}\left(\frac{n^2}{MB(\log_\sigma n)^2} + \frac{n\log\sigma}{B} + \frac{n}{B}\log_{\frac{M}{B}}\frac{n}{B}\right)$

array significantly faster than the LCPscan algorithm can construct the LCP array [13, Table IX]. Thus there is a need for even faster LCP array construction in external memory.

Our contribution. In this paper, we describe two new external memory algorithms for constructing the LCP array from the suffix array. Although the new algorithms share some features with LCPscan their more immediate ancestors are two semi-external algorithms introduced in [16]. The semi-external algorithms need to keep the text and some additional small data structures in RAM but the larger suffix and LCP arrays are kept on disk and are accessed sequentially only. When there is enough RAM, these algorithms are many times faster than LCPscan.

We show how the requirement to keep the text (and some additional data structures) can be removed from the algorithms. Although this adds a significant amount of computation and I/O, the resulting algorithms are still about a factor of two faster than LCPscan in our experiments. Asymptotically, LCPscan has a slight advantage over the new algorithms (see Table 1). The main disadvantage of LCPscan is that it relies heavily on external memory sorting, which is completely avoided by the new algorithms.

The advantage of the new algorithms over LCPscan is particularly large when the text is only slightly larger than the available RAM. This is a common situation when dealing with compressed full-text self-indexes [25]. A compressed index can be significantly smaller than an uncompressed text and fit in RAM even though the text does not. However, the construction of the index still requires external memory computation.

Related work. Kasai et al. [18] introduced the first (internal memory) algorithm for computing the LCP array from the suffix array. It is simple and fairly fast but requires a lot of space. Thus a lot of the later work focused on reducing the space [20, 23, 30, 16, 33, 9, 3]. A culmination of this line of work are semi-external algorithms that keep most of the data structures on disk but need to have at least the text in RAM [30, 16]. There is also recent research on speeding up LCP computation by using parallelism [8, 32].

External memory algorithms for constructing the suffix array have been around since the early days [10], but until recently the only way to construct the LCP array when the text does not fit in RAM was as byproduct of a suffix array construction algorithm [17, 4, 6, 2]. To the best of our knowledge, LCPscan [12] is still the only external memory algorithm that can construct the LCP array from the suffix array independently of how it was constructed.

2 Basic Data Structures

Throughout we consider a string $\mathsf{X} = \mathsf{X}[0..n) = \mathsf{X}[0]\mathsf{X}[1]\ldots\mathsf{X}[n-1]$ of $|\mathsf{X}| = n$ symbols drawn from an alphabet of size σ. Here and elsewhere we use $[i..j)$ as a shorthand for

Table 2 Examples of the arrays used by the algorithms for the text $\mathsf{X} = \texttt{babaabbabbab}$.

i	0	1	2	3	4	5	6	7	8	9	10	11	12
$\mathsf{X}[i]$	b	a	b	a	a	b	b	a	b	b	a	b	-
$\mathrm{SA}[i]$	12	3	10	1	7	4	11	2	9	0	6	8	5
$\mathrm{BWT}[i]$	b	b	b	b	b	a	a	a	b	$	b	a	a
$\Phi[i]$	9	10	11	12	7	8	0	1	6	2	3	4	-
$\mathrm{LCP}[i]$	-	0	1	2	2	5	0	1	2	3	3	1	4
$\mathrm{PLCP}[i]$	3	2	1	0	5	4	3	2	1	2	1	0	-
$i + \mathrm{PLCP}[i]$	3	3	3	3	9	9	9	9	9	11	11	11	-
$\Phi[i] + \mathrm{PLCP}[i]$	12	12	12	12	12	12	3	3	7	4	4	4	-

$[i..j-1]$. For $i \in [0..n]$, we write $\mathsf{X}[i..n)$ to denote the *suffix* of X of length $n-i$, that is $\mathsf{X}[i..n) = \mathsf{X}[i]\mathsf{X}[i+1]\ldots\mathsf{X}[n-1]$. We will often refer to suffix $\mathsf{X}[i..n)$ simply as "suffix i".

The *suffix array* [22, 10] SA of X is an array $\mathrm{SA}[0..n]$ which contains a permutation of the integers $[0..n]$ such that $\mathsf{X}[\mathrm{SA}[0]..n) < \mathsf{X}[\mathrm{SA}[1]..n) < \cdots < \mathsf{X}[\mathrm{SA}[n]..n)$. In other words, $\mathrm{SA}[j] = i$ iff $\mathsf{X}[i..n)$ is the $(j+1)^{\mathrm{th}}$ suffix of X in ascending lexicographical order. Another representation of the permutation is the Φ *array* [16] $\Phi[0..n)$ defined by $\Phi[\mathrm{SA}[j]] = \mathrm{SA}[j-1]$ for $j \in [1..n]$. In other words, the suffix $\Phi[i]$ is the immediate lexicographical predecessor of the suffix i, and thus $\mathrm{SA}[n-k] = \Phi^k[\mathrm{SA}[n]]$ for $k \in [0..n]$. An example illustrating the arrays is given in Table 2.

Let $\mathrm{lcp}(i,j)$ denote the length of the longest-common-prefix (LCP) of suffix i and suffix j. For instance, in the example of Table 2, $\mathrm{lcp}(0,6) = 3 = |\texttt{bab}|$ and $\mathrm{lcp}(7,4) = 5 = |\texttt{abbab}|$. The *longest-common-prefix array* [22, 18], $\mathrm{LCP}[1..n]$, is defined such that $\mathrm{LCP}[i] = \mathrm{lcp}(\mathrm{SA}[i], \mathrm{SA}[i-1])$ for $i \in [1..n]$. The *permuted LCP array* [16] $\mathrm{PLCP}[0..n)$ is the LCP array permuted from the lexicographical order into the text order, i.e., $\mathrm{PLCP}[\mathrm{SA}[j]] = \mathrm{LCP}[j]$ for $j \in [1..n]$. Then $\mathrm{PLCP}[i] = \mathrm{lcp}(i, \Phi[i])$ for all $i \in [0..n)$. Table 2 shows example LCP and PLCP arrays. The last two rows in Table 2 illustrate the following property of the PLCP array, which is the basis of all efficient algorithms for LCP array construction.

▶ **Lemma 1** ([13]). *Let $i, j \in [0..n)$. If $i \leq j$, then $i + \mathrm{PLCP}[i] \leq j + \mathrm{PLCP}[j]$. Symmetrically, if $\Phi[i] \leq \Phi[j]$, then $\Phi[i] + \mathrm{PLCP}[i] \leq \Phi[j] + \mathrm{PLCP}[j]$.*

The *succinct PLCP array* [31] $\mathrm{PLCP}_{\mathrm{succ}}[0..2n)$ represents the PLCP array using $2n$ bits. Specifically, $\mathrm{PLCP}_{\mathrm{succ}}[j] = 1$ if $j = 2i + \mathrm{PLCP}[i]$ for some $i \in [0..n)$, and $\mathrm{PLCP}_{\mathrm{succ}}[j] = 0$ otherwise. Notice that the value $2i + \mathrm{PLCP}[i]$ must be unique for each i by Lemma 1. Any lcp value can be recovered by the equation $\mathrm{PLCP}[i] = \mathrm{select}(\mathrm{PLCP}_{\mathrm{succ}}, i) - 2i$, where $\mathrm{select}(\mathrm{PLCP}_{\mathrm{succ}}, i)$ returns the location of the $(i+1)^{\mathrm{th}}$ 1-bit in $\mathrm{PLCP}_{\mathrm{succ}}$. The select query can be answered in $\mathcal{O}(1)$ time given a precomputed data structure of $o(n)$ bits [5, 24].

For $q \geq 1$, the *sparse PLCP array* $\mathrm{PLCP}_q[0..\lceil n/q \rceil)$ is defined by $\mathrm{PLCP}_q[i] = \mathrm{PLCP}[iq]$, i.e., it contains every qth entry of PLCP. It can be used as a compact representation of the full PLCP array because the other entries can be bounded using the following lemma.

▶ **Lemma 2** ([16]). *For any $i \in [0..n)$, let $a = \lfloor i/q \rfloor$ and $b = i \bmod q$, so that $i = aq + b$. If $(a+1)q \leq n-1$, then $\mathrm{PLCP}_q[a] - b \leq \mathrm{PLCP}[i] \leq \mathrm{PLCP}_q[a+1] + q - b$. If $(a+1)q > n-1$, then $\mathrm{PLCP}_q[a] - b \leq \mathrm{PLCP}[i] \leq n - i \leq q$.*

Let the slack, denoted by $\mathrm{slack}_q(i)$, be the difference of the upper and lower bounds for $\mathrm{PLCP}[i]$ given by Lemma 2. Although there is no non-trivial bound on an individual slack, the sum of the slacks is bounded by the following lemma.

▶ **Lemma 3** ([16]). $\sum_{i\in[0..n)} \mathrm{slack}_q(i) \le (q-1)n + q^2$.

The *Burrows–Wheeler transform* $\mathrm{BWT}[0..n]$ of X is defined by $\mathrm{BWT}[i] = \mathsf{X}[\mathrm{SA}[i]-1]$ if $\mathrm{SA}[i] > 0$ and otherwise $\mathrm{BWT}[i] = \$$, where $\$$ is a special symbol that does not appear in the text. We say that that an lcp value $\mathrm{LCP}[i] = \mathrm{PLCP}[\mathrm{SA}[i]]$ is *reducible* if $\mathrm{BWT}[i] = \mathrm{BWT}[i-1]$ and *irreducible* otherwise. The significance of reducibility is summarized in the following two lemmas.

▶ **Lemma 4** ([16]). *If* $\mathrm{PLCP}[i]$ *is reducible, then* $\mathrm{PLCP}[i] = \mathrm{PLCP}[i-1]-1$ *and* $\Phi[i] = \Phi[i-1]+1$.

▶ **Lemma 5** ([16, 14]). *The sum of all irreducible lcp values is* $\le n\log n$.

3 Basic Semi-External Algorithms

We will next describe the two semi-external algorithms introduced by Kärkkäinen, Manzini and Puglisi [16]. The semi-external versions are only briefly mentioned in [16] but they are essentially the same as the space-efficient versions. Both algorithms need enough RAM for the text and for either the succinct or the sparse PLCP array. The larger data structures SA and LCP are stored on disk in the semi-external algorithms.

The first algorithm, which we call SPARSE-Φ, performs the following main steps:

1. Compute a sparse version Φ_q of the Φ-array defined so that $\mathrm{PLCP}_q[i] = \mathrm{lcp}(qi, \Phi_q[i])$.
2. Compute PLCP_q using Φ_q. When computing $\mathrm{PLCP}_q[i]$, we take advantage of the fact that $\mathrm{PLCP}_q[i] \ge \mathrm{PLCP}_q[i-1]-q$ (Lemma 1).
3. Compute LCP using PLCP_q based on Lemma 2.

The first two steps need $\mathcal{O}(n)$ time and the third step $\mathcal{O}(qn)$ time. The pseudocode for SPARSE-Φ is given in Figure 1. All accesses to SA and LCP are sequential allowing them to be stored on disk.

The second algorithm is called SUCCINCTIRREDUCIBLE and has the following steps:

1. Compute irreducible lcp values and store them in the succinct PLCP array $\mathrm{PLCP}_{\mathrm{succ}}$.
2. Compute the reducible lcp values using Lemma 4 and store them in $\mathrm{PLCP}_{\mathrm{succ}}$.
3. Compute LCP from $\mathrm{PLCP}_{\mathrm{succ}}$.

During steps 1 and 2 we also need a bitvector $\mathsf{R}[0..n]$ for marking the irreducible positions in PLCP. The first step needs $\mathcal{O}(n\log n)$ time by Lemma 5, and the other steps need $\mathcal{O}(n)$ time. Again, all accesses to SA and LCP are sequential.

The algorithm also uses BWT (line 4). Since $\mathrm{BWT}[i] = \mathsf{X}[\mathrm{SA}[i]-1]$ (unless $\mathrm{SA}[i] = 0$), we can compute the values on-the-fly when the text X is in RAM as was done in [16]. However, we want to get rid of the requirement that the text is in RAM and instead assume that the BWT is available on disk and is accessed sequentially during the algorithm.

4 Moving Text into External Memory

The semi-external algorithms described above need to have the text X in RAM. While a single comparison of two suffixes is sequential, the first character accesses in each comparison are random accesses often enough so that any straightforward way to deal with texts larger than RAM will not work. Instead, the computation in the steps involving text accesses have to be completely reorganized as will be described in this section. Here we still assume that Φ_q, PLCP_q, $\mathrm{PLCP}_{\mathrm{succ}}$ and R fit in RAM; handling them in a fully external memory algorithm is covered in the next section.

```
SPARSE-Φ
 — Step 1: Compute $\Phi_q$
1:  for $i \leftarrow 1$ to $n$ do
2:      if $\mathrm{SA}[i] \bmod q = 0$ then
3:          $\Phi_q[\mathrm{SA}[i]/q] \leftarrow \mathrm{SA}[i-1]$
 — Step 2: Compute $\mathrm{PLCP}_q$ using $\Phi_q$
4:  $\ell \leftarrow 0$
5:  for $i \leftarrow 0$ to $\lceil n/q \rceil - 1$ do
6:      $j \leftarrow \Phi_q[i]$
7:      while $\mathsf{X}[qi+\ell] = \mathsf{X}[j+\ell]$ do
8:          $\ell \leftarrow \ell+1$
9:      $\mathrm{PLCP}_q[i] \leftarrow \ell$
10:     $\ell \leftarrow$ max $(\ell - q, 0)$
 — Step 3: Compute LCP using $\mathrm{PLCP}_q$
11: for $i \leftarrow 1$ to $n$ do
12:     $j \leftarrow \mathrm{SA}[i-1]$
13:     $k \leftarrow \mathrm{SA}[i]$
14:     $k' \leftarrow \lfloor k/q \rfloor$
15:     $\ell \leftarrow \mathrm{PLCP}_q[k'] - (k - k'q)$
16:     $\ell \leftarrow$ max $(\ell, 0)$
17:     while $\mathsf{X}[k+\ell] = \mathsf{X}[j+\ell]$ do
18:         $\ell \leftarrow \ell+1$
19:     $\mathrm{LCP}[i] \leftarrow \ell$
```

```
SUCCINCTIRREDUCIBLE
 — Step 1: Compute irreducible lcps
1:  $\mathrm{PLCP}_{\mathrm{succ}}[0..2n) \leftarrow (0, 0, \ldots, 0)$
2:  $\mathsf{R}[0..n] \leftarrow (0, 0, \ldots, 0, 1)$
3:  for $i \leftarrow 1$ to $n$ do
4:      if $\mathrm{BWT}[i] \neq \mathrm{BWT}[i-1]$ then
5:          $j \leftarrow \mathrm{SA}[i-1]$; $k \leftarrow \mathrm{SA}[i]$
6:          $\mathsf{R}[k] \leftarrow 1$
7:          $\ell \leftarrow 0$
8:          while $\mathsf{X}[k+\ell] = \mathsf{X}[j+\ell]$ do
9:              $\ell \leftarrow \ell+1$
10:         $\mathrm{PLCP}_{\mathrm{succ}}[2k + \ell] \leftarrow 1$
 — Step 2: Fill in reducible lcps
11: $i \leftarrow 0$; $j \leftarrow 0$
12: while $i < n$ do
13:     while $\mathrm{PLCP}_{\mathrm{succ}}[j] = 0$ do $j \leftarrow j + 1$
      — Now $j = \mathrm{PLCP}[i] + 2i$
14:     $i \leftarrow i + 1$; $j \leftarrow j + 1$
15:     while $\mathsf{R}[i] = 0$ do
16:         $\mathrm{PLCP}_{\mathrm{succ}}[j] \leftarrow 1$
17:         $i \leftarrow i + 1$; $j \leftarrow j + 1$
 — Step 3: Compute LCP from $\mathrm{PLCP}_{\mathrm{succ}}$
18: Construct select-structure for $\mathrm{PLCP}_{\mathrm{succ}}$
19: for $j \leftarrow 1$ to $n$ do
20:     $i \leftarrow \mathrm{SA}[j]$
21:     $\mathrm{LCP}[j] \leftarrow \mathrm{select}(\mathrm{PLCP}_{\mathrm{succ}}, i) - 2i$
```

Figure 1 Two semi-external algorithms.

We will analyze the algorithms in the standard external memory model [34], where the memory system consists of a fast random access memory (RAM) of size M and a slow (disk) memory of unbounded size divided into blocks of size B, both measured in units of $\mathcal{O}(\log n)$ bits. We are primarily interested in the I/O complexity which measures the number of blocks read from or written to disk. Notice that we can fit $\mathcal{O}(M \log_\sigma n)$ characters in RAM and $\mathcal{O}(B \log_\sigma n)$ characters in a disk block.

All text accesses in both algorithms happen in loops where the goal is to compute $\mathrm{lcp}(i, \Phi[i])$ for some i. The basic idea is to divide the text into segments of size at most $m = \mathcal{O}(M \log_\sigma n)$ such that two segments fit in RAM. For each pair of segments at a time, we load them into RAM and compute $\mathrm{lcp}(i, \Phi[i])$ for each i such that i and $\Phi[i]$ are in those two segments. Further details we will consider separately for each step involving text accesses.

Step 1 in SuccinctIrreducible. The computation on lines 1–10 in SUCCINCTIRREDUCIBLE including the text access loop on line 8 is replaced by the following steps:

1.1. Scan SA and BWT to form a pair $(i, \Phi[i])$ for each i such that $\mathrm{PLCP}[i]$ is irreducible. The pairs are written to disk where there is a separate file for each pair of text segments. Simultaneously, compute the bitvector R, which is kept in RAM during the step and written to disk at the end of the step.

1.2. For each pair of text segments, load them to RAM and compute $\mathrm{PLCP}[i] = \mathrm{lcp}(i, \Phi[i])$ for each pair $(i, \Phi[i])$ obtained from the associated file. For each computed $\mathrm{PLCP}[i]$, we store the value $2i + \mathrm{PLCP}[i]$ to disk.

1.3. With $\mathrm{PLCP}_{\mathrm{succ}}$ in RAM, read the output of the previous step and set the corresponding bits of $\mathrm{PLCP}_{\mathrm{succ}}$ to 1. Then read R from disk.

The rest of the algorithm is as in Section 3. The total number of additional I/Os resulting from this procedure is $\mathcal{O}((n/\log_\sigma n)^2/(MB))$.

An additional detail to consider in step 1.2 is that although i and $\Phi[i]$ are in the segments in RAM, the common prefix of those suffixes may continue beyond the end of the segments. To deal with this, we also keep the first $B\log_\sigma n$ symbols after the segments in RAM. These are called *overflow buffers*. If the comparison continues beyond the overflow buffers, we read the relevant parts of the text from disk sequentially. Since the total length of the irreducible lcps is $\mathcal{O}(n\log n)$, the additional number of I/Os from this is never more than $\mathcal{O}((n\log n)/(B\log_\sigma n)) = \mathcal{O}((n\log\sigma)/B)$.

Step 3 in Sparse-Φ. The loop on lines 11-19 in Sparse-Φ including the text access loop on line 17 is replaced with the following steps:

3.1. Scan SA to generate all $(i, \Phi[i])$ pairs. For each pair use PLCP_q (stored in RAM) to compute the lower bound $\ell_{\min}$ (and the upper bound $\ell_{\max}$) for PLCP$[i]$. Write the pair $(i+\ell_{\min}, \Phi[i]+\ell_{\min})$ to disk, where there is a separate file for each pair of text segments.

3.2. For each pair of text segments, load them to RAM and compute $\mathrm{lcp}(i,j)$ for each pair (i,j) obtained from the associated file. The resulting value $\mathrm{lcp}(i,j)$ is written to disk to a separate file for each pair of text segments. The order of the lcp values in the output file must be the same as the order of the pairs in the input file.

3.3. Scan SA to generate all $(i, \Phi[i])$ pairs. For each pair, compute $\ell_{\min}$ as in step 1 and read the value $\ell' = \mathrm{lcp}(i+\ell_{\min}, \Phi[i]+\ell_{\min})$ from the appropriate file. Then $\mathrm{PLCP}[i] = \ell_{\min}+\ell'$ is the next value in the LCP array.

The total number of additional I/Os from reading text segments is $\mathcal{O}((n/\log_\sigma n)^2/(MB))$.

Again, we have to deal with lcp comparisons continuing beyond the end of the segments in step 3.2. In step 3.1, we use the upper bound $\ell_{\max}$ to determine whether such an overflow is possible, and if it is, we generate additional pairs/triples for each possible boundary crossing. For example, if for some $\ell' \in [\ell_{\min}..\ell_{\max}]$ we find out that $i+\ell'$ is at a segment boundary, we generate the triple $(i+\ell', \Phi[i]+\ell', \ell_{\max}-\ell')$. The third value is used as an upper bound for the length of the comparison, which might be needed in the case where $\mathrm{lcp}(i,\Phi[i]) < \ell'$. Otherwise, the triple is treated as a normal pair in step 3.2. All the comparisons in step 3.2 end at a segment boundary. In step 3.3, we generate pairs and triples as in step 3.1, read the corresponding lcp values from the appropriate files, and combine them to obtain the final lcp value. The total number of the extra triples is at most $\mathcal{O}(n + qn/(M\log_\sigma n))$. Also notice that the total number of character comparisons is still bounded by $\mathcal{O}(qn)$.

Step 2 in Sparse-Φ. The third and final place with a text access loop is on line 7 in algorithm Sparse-Φ. In this case, the text segment size is $2m$ and only one segment is kept in RAM while the rest of the text is scanned sequentially. The loop on lines 5–10 is replaced with the following steps:

2.1. Scan Φ_q to generate all pairs $(i, \Phi[i])$ such that i is a multiple of q. Write the pairs to disk into the file associated with the text segment that contains $\Phi[i]$. Notice that the pairs in each file are sorted by i.

2.2. For each segment, load the segment into RAM. Read the pairs $(i, \Phi[i])$ from the associated file while simultaneously scanning the text so that the position $\mathsf{X}[i]$ is reached when the pair $(i, \Phi[i])$ is processed. For each pair, compute $\mathrm{lcp}(i, \Phi[i])$ and write it to disk into a separate file for each segment. When computing $\ell = \mathrm{lcp}(i,\Phi[i])$ we use the fact that $\ell \geq \mathrm{lcp}(i', \Phi[i']) - (i-i')$, where $(i', \Phi[i'])$ is the pair processed just previously. This ensures that the text scan never needs to backtrack.

2.3. Scan Φ_q and for each $i \in [0..\lceil n/q \rceil)$ read $\mathrm{PLCP}_q[i]$ from the file associated with the text segment containing $\Phi_q[i]$.

The total number of additional I/Os from scanning the text is $\mathcal{O}((n/\log_\sigma n)^2/(MB))$.

Here too, we have the possibility that the position $\Phi[i] + \ell$ moves beyond the end of the segment during the comparison. We deal with this again by having an overflow buffer of $\mathcal{O}(B \log_\sigma n)$ characters and by reading text from disk when the overflow buffer is not enough. Then the extra I/Os for reading the positions $\Phi[i] + \ell$ is never more than the regular I/Os for reading the positions $i + \ell$.

As a final note, both algorithms distribute pairs into $\mathcal{O}(s^2)$ files at some point, where $s = \mathcal{O}(n/(M \log_\sigma n))$ is the number of segments. To do this efficiently we need to have enough RAM for $\mathcal{O}(s^2)$ buffers of size $\mathcal{O}(B)$ each, which means that we must have $s = \mathcal{O}(\sqrt{M/B})$ and thus $n = \mathcal{O}\left(M\sqrt{M/B}\log_\sigma n\right)$. We can get rid of this constraint by doing the distribution in multiple rounds. That is, we first distribute the pairs into $\mathcal{O}(M/B)$ files and then those files are divided into smaller files and so on. The I/O complexity of the multiround distribution is the same as for external memory sorting, $\mathcal{O}((n/B)\log_{M/B}(n/B))$, and the time complexity is $\mathcal{O}(n \log_{M/B}(n/B))$.

5 Fully External Memory Algorithms

Let us now complete the transformation of the semi-external algorithms into external memory algorithms by describing how to deal with Φ_q, PLCP_q, $\mathrm{PLCP}_{\mathrm{succ}}$ and R.

Consider first Sparse-Φ. We set $q = \min\{n/M, M \log_\sigma n\}$. This choice ensures that the number of extra triples generated in Step 3 is $\mathcal{O}(n + qn/(M \log_\sigma n)) = \mathcal{O}(n)$. When $n \le M^2 \log_\sigma n$, we have $q = \Theta(n/M)$ so that Φ_q and PLCP_q fit in RAM and the algorithm is exactly as described above. When $n > M^2 \log_\sigma n$, we divide Φ_q and PLCP_q into $s = \mathcal{O}(n/(M^2 \log_\sigma n))$ segments that fit in RAM. In Steps 1 and 3, instead of scanning SA once, we scan it s times, once for each segment. Step 3 also produces s subsequences of LCP which are then merged with the help of one more scan of SA. The additional I/O from the extra scans is $\mathcal{O}(n^2/(M^2 B \log_\sigma n))$, which is less than the I/O for text scanning (assuming $M = \Omega(\log_\sigma n)$).

The time complexity has three main components: $\mathcal{O}(qn)$ time for comparing suffixes, $\mathcal{O}(n^2/(M(\log_\sigma n)^2))$ for loading text segments and scanning the text, and $\mathcal{O}(n \log_{M/B}(n/B))$ time for multiround distribution. This gives the following result.

▶ **Theorem 6.** *Given a text of length n over an integer alphabet $[0..\sigma)$ and its suffix array, the associated* LCP *array is computed by* Sparse-Φ *in*

$$\mathcal{O}\left(\min\left\{\frac{n^2}{M}, nM\log_\sigma n\right\} + \frac{n^2}{M(\log_\sigma n)^2} + n\log_{\frac{M}{B}}\frac{n}{B}\right) = \mathcal{O}\left(\frac{n^2}{M} + n\log_{\frac{M}{B}}\frac{n}{B}\right) \text{ time}$$

and $\mathcal{O}\left(\frac{n^2}{MB(\log_\sigma n)^2} + \frac{n}{B}\log_{\frac{M}{B}}\frac{n}{B}\right)$ *I/Os using* $\mathcal{O}(n/B)$ *blocks of disk space.*

Consider then SuccinctIrreducible. Since we cannot make $\mathrm{PLCP}_{\mathrm{succ}}$ and R arbitrarily small, we must be able to handle them even if they do not fit in RAM. We do this by dividing them into segments that are small enough. Consider first the computation of R. While scanning BWT and SA we create a list of irreducible positions, which are then distributed into files corresponding to segments of R. Then each segment of R can be computed by scanning the corresponding file. Similarly, the irreducible bits in $\mathrm{PLCP}_{\mathrm{succ}}$ are set one segment at a time by reading the $2i + \mathrm{PLCP}[i]$ values from disk, which are now in separate files for each segment. The reducible bits in $\mathrm{PLCP}_{\mathrm{succ}}$ can be easily set by scanning $\mathrm{PLCP}_{\mathrm{succ}}$ and R simultaneously. None of this increases the complexity of the algorithm.

Finally, the last stage of SuccinctIrreducible is performed as follows when $\mathrm{PLCP}_{\mathrm{succ}}$ does not fit in RAM:

3.1. Scan SA and store each value $\mathrm{SA}[i]$ into the file corresponding to the $\mathrm{PLCP}_{\mathrm{succ}}$ segment that contains the $(\mathrm{SA}[i] + 1)^{\mathrm{th}}$ 1-bit in $\mathrm{PLCP}_{\mathrm{succ}}$.

3.2. For each segment of $\mathrm{PLCP}_{\mathrm{succ}}$ read the $\mathrm{SA}[i]$ values from the corresponding file, compute $\mathrm{LCP}[i]$ by a select query, and write it to a separate file for each segment.

3.3. Scan SA and for each element $\mathrm{SA}[i]$ determine which segment file contains $\mathrm{LCP}[i]$ and move it to the final output file.

Again, none of this increases the complexity of the algorithm.

The following theorem summarizes the complexities of SuccinctIrreducible. The $\mathcal{O}(n \log n)$ and $\mathcal{O}((n \log \sigma)/B)$ terms come from the irreducible lcp comparisons.

▶ **Theorem 7.** *Given a text of length n over an integer alphabet $[0..\sigma)$ and its suffix array and BWT, the associated LCP array is computed by* SuccinctIrreducible *in*

$$\mathcal{O}\left(\frac{n^2}{M(\log_\sigma n)^2} + n \log n\right) \text{ time and } \mathcal{O}\left(\frac{n^2}{MB(\log_\sigma n)^2} + \frac{n \log \sigma}{B} + \frac{n}{B} \log_{\frac{M}{B}} \frac{n}{B}\right) \text{ I/Os}$$

using $\mathcal{O}(n/B)$ blocks of disk space.

In practice, we have noticed that the n select queries performed at the last stage of SuccinctIrreducible often dominate the time. In the implementation, we have replaced $\mathrm{PLCP}_{\mathrm{succ}}$ with the plain PLCP array, but only in the last stage. That is, instead of loading a segment of $\mathrm{PLCP}_{\mathrm{succ}}$ into RAM, we construct a segment of PLCP in RAM by reading a part of $\mathrm{PLCP}_{\mathrm{succ}}$ from disk. Then we use simple accesses to PLCP instead of select queries on $\mathrm{PLCP}_{\mathrm{succ}}$. This modification does not affect the time or I/O complexities of the algorithm.

As a final note, SuccinctIrreducible needs the BWT. Any suffix array construction algorithm can be modified to compute the BWT too with little overhead by storing $\mathrm{BWT}[i]$ together with $\mathrm{SA}[i]$. Since the algorithm has to access $\mathsf{X}[\mathrm{SA}[i]]$ at some point, we can compute $\mathrm{BWT}[i]$ at the same time. We have also implemented a simple external memory algorithm for computing BWT from SA and show its performance in the next section.

6 Experimental Results

Algorithms. We performed experiments using the following algorithms:

- LCPscan, the fastest external-memory LCP array construction algorithm in previous studies [13]. The number of rounds of partial processing in LCPscan was set to 4, as this gives a similar peak disk space usage ($\sim 16n$ bytes) to the new algorithms presented in this paper (see [13] for more details). In our experiments LCPscan serves as a baseline.
- SE-SΦ, the semi-external version of the Sparse-Φ algorithm described by Kärkkäinen et al. [16] (see also Section 3 of this paper).
- EM-SΦ, the fully external-memory version of the Sparse-Φ algorithm described in Sections 3–5. The algorithm is the first contribution of this paper.
- EM-PLCP, the external-memory version of SuccinctIrreducible algorithm described in this paper restricted to perform only Step 1 and 2, i.e., the algorithm produces the $\mathrm{PLCP}_{\mathrm{succ}}$ array but does not convert it to LCP array. We separately consider the construction of $\mathrm{PLCP}_{\mathrm{succ}}$ because first, for some applications computing $\mathrm{PLCP}_{\mathrm{succ}}$ is sufficient

Table 3 Statistics of data used in the experiments. In addition to basic parameters, we show the percentage of irreducible lcp values among all lcp values (expression $100r/n$, where r denotes the number of irreducible lcps) and the average length of the irreducible lcp value (Σ_r/r, where Σ_r is the sum of all irreducible lcps).

Name	$n/2^{30}$	σ	$100r/n$	Σ_r/r
kernel	128.0	229	0.09	1494.76
geo	128.1	211	0.15	1221.49
wiki	128.7	213	16.71	29.40
dna	128.0	6	18.46	23.79
dna	512.0	6	16.13	27.25
debruijn	128.0	2	99.26	35.01

and avoiding the conversion to LCP array is a big time save, and second, this allows us to visualize differences in the methods that convert $\mathrm{PLCP}_{\mathrm{succ}}$ to LCP. Note: small files than can be handled by the original semi-external version of SuccinctIrreducible are processed using the original algorithm from [16]. The increase in I/O and runtime that occurs when we switch to fully-external procedure is discussed in one of the experiments.

- SE-SI, the semi-external version of the SuccinctIrreducible algorithm. It first runs EM-PLCP and then converts $\mathrm{PLCP}_{\mathrm{succ}}$ (held in RAM) to LCP using select queries as originally described [16]. To implement the select queries, we use the variant of the *darray* data structure [29] described in [16]. We set the darray overhead to 6.25% as we did not observe a significant speedup from using more space (e.g., increasing the overhead to 50% speeds up select queries only by about 10%).
  This algorithm is essentially identical to the original semi-external algorithm in [16] when the text and the bitvectors $\mathsf{R}[0..n]$ and $\mathrm{PLCP}_{\mathrm{succ}}[0..2n)$ fit in RAM, but it can also extend beyond that limit since it uses EM-PLCP. It is still a semi-external algorithm though as it needs to have enough RAM for $\mathrm{PLCP}_{\mathrm{succ}}[0..2n)$ in the last stage.
- EM-SI, the fully-external version of the SuccinctIrreducible algorithm described in Sections 3–5. It first uses EM-PLCP to compute $\mathrm{PLCP}_{\mathrm{succ}}$ and then computes LCP using plain accesses to PLCP segments instead of select queries on $\mathrm{PLCP}_{\mathrm{succ}}$ segments as described in Section 5. The time and I/O of EM-PLCP is included in the runtime and I/O volume of EM-SI. Together with EM-PLCP this algorithm is the second contribution of this paper.

All algorithms use 8 bits to represent characters and 40 bits to represent integers. The implementations of all LCP array construction algorithms used in experiments are available at `http://www.cs.helsinki.fi/group/pads/`.

Datasets. For the experiments we used the following files varying in the number of repetitions and alphabet size (see Table 3 for some statistics):

- kernel: a concatenation of ∼10.7 million source files from over 300 versions of Linux kernel [1]. This is an example of highly repetitive file;
- geo: a concatenation of all versions (edit history) of Wikipedia articles about all countries and 10 largest cities in the XML format. The resulting file is also highly repetitive;

[1] `http://www.kernel.org/`

- wiki: a concatenation of English Wiki dumps (Wikipedia, Wikisource, Wikibooks, Wikinews, Wikiquote, Wikiversity, and Wikivoyage [2]) dated 20160203 in XML;
- dna: a collection of DNA reads (short fragments produced by a sequencing machine) from multiple human genomes[3] filtered from symbols other than $\{\mathtt{A}, \mathtt{C}, \mathtt{G}, \mathtt{T}, \mathtt{N}\}$ and newline;
- debruijn: a binary De Bruijn sequence of order k is an artificial sequence of length $2^k + k - 1$ than contains all possible binary k-length substrings. A file of length n is obtained as a prefix of a De Bruijn sequence of order $\lceil \log n \rceil$. It contains nearly n irreducible lcps with total length of nearly $n \log n$ (see [16, Lemma 5]) which is the worst case for LCPscan, SE-SI and EM-SI algorithms.

Setup. We performed experiments on a machine equipped with two six-core 1.9 GHz Intel Xeon E5-2420 CPUs with 15 MiB L3 cache and 120 GiB of DDR3 RAM. For experiments we limited the RAM in the system (with the kernel boot flag) to 4 GiB and all algorithms were allowed to use 3.5 GiB. The machine had 6.8 TiB of free disk space striped with RAID0 across four identical local disks achieving a (combined) transfer rate of about 480 MiB/s.

The OS was Linux (Ubuntu 12.04, 64bit) running kernel 3.13.0. All programs were compiled using `g++` version 4.9.2 with `-O3 -DNDEBUG` options. All tested LCP array construction algorithms are sequential, i.e., only a single thread of execution was used for computation. In the last experiment we used parallel algorithms to compute SA and BWT in order to demonstrate the performance of currently fastest methods but those measurements have no bearing on the findings of this paper. All reported runtimes are wallclock (real) times.

Experiments. In the first experiment we compare the scalability of the new external-memory LCP array construction algorithms described in this paper (EM-SΦ, EM-SI) to LCPscan. We executed the algorithms on increasing length prefixes of testfiles using 3.5 GiB of RAM and measured the runtime and the I/O volume.

The results are presented in Figure 2. The performance of EM-SI, similarly to LCPscan, is related to the number of irreducible lcp values (see Table 3). However, avoiding the external-memory sorting gives EM-SI a consistent speed and I/O advantage (of about $60n$ bytes) over LCPscan. The EM-SI algorithm is at least two times faster than LCPscan and even more on highly repetitive data. The computation time can be further reduced by 30–65% if one stops at the $\mathrm{PLCP}_{\mathrm{succ}}$ array. Overall, if the BWT is given as input alongside the text and the suffix array, EM-SI is the fastest way to compute the LCP array. Even if we include the cost of the standalone construction of BWT from the suffix array, the algorithm still outperforms LCPscan.

The performance of EM-SΦ is also related to the number of irreducible lcp values though in a different way than EM-SI. Whenever during step 3.1 the exact value of $\mathrm{PLCP}[i]$ can be deduced from the lower/upper bounds on $\mathrm{PLCP}[i]$ (i.e., $\ell_{\min} = \ell_{\max}$), the algorithm does not write any data to disk. All other pairs are written to disk and processed in step 3.2, which usually dominates the runtime. From Lemma 4 we expect the number of skipped pairs to be high if the number of irreducible lcp values is low, and thus the algorithm runs faster and uses less I/O (by about $20n$ bytes) on kernel and geo testfiles. However, even on the non-repetitive data, EM-SΦ is still about two times faster than LCPscan. Furthermore, when BWT is not available it usually also outperforms EM-SI, making it the algorithm of choice in this case.

[3] `http://www.1000genomes.org/`

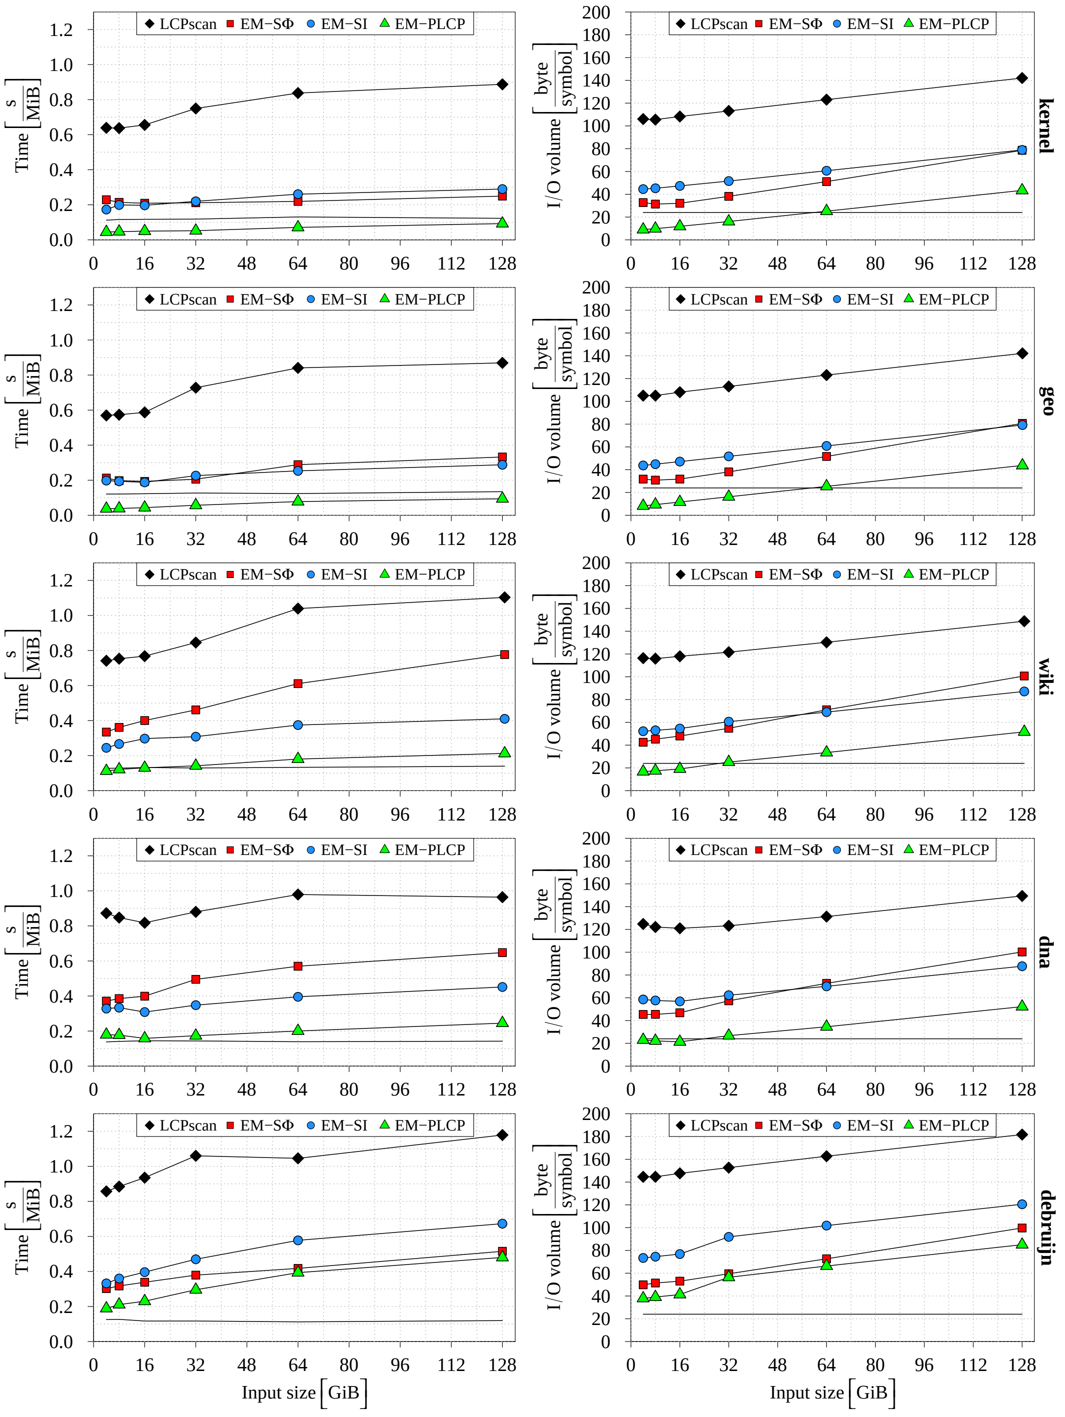

Figure 2 Comparison of the runtime (left; in seconds per MiB of input text) and I/O volume (right; in bytes per input symbol) of the new external-memory LCP array construction algorithms (EM-SΦ, EM-SI) to LCPscan. All algorithms were allowed to use 3.5 GiB of RAM. The unlabeled curve shows the runtime and I/O volume of the standalone external-memory construction of BWT from SA.

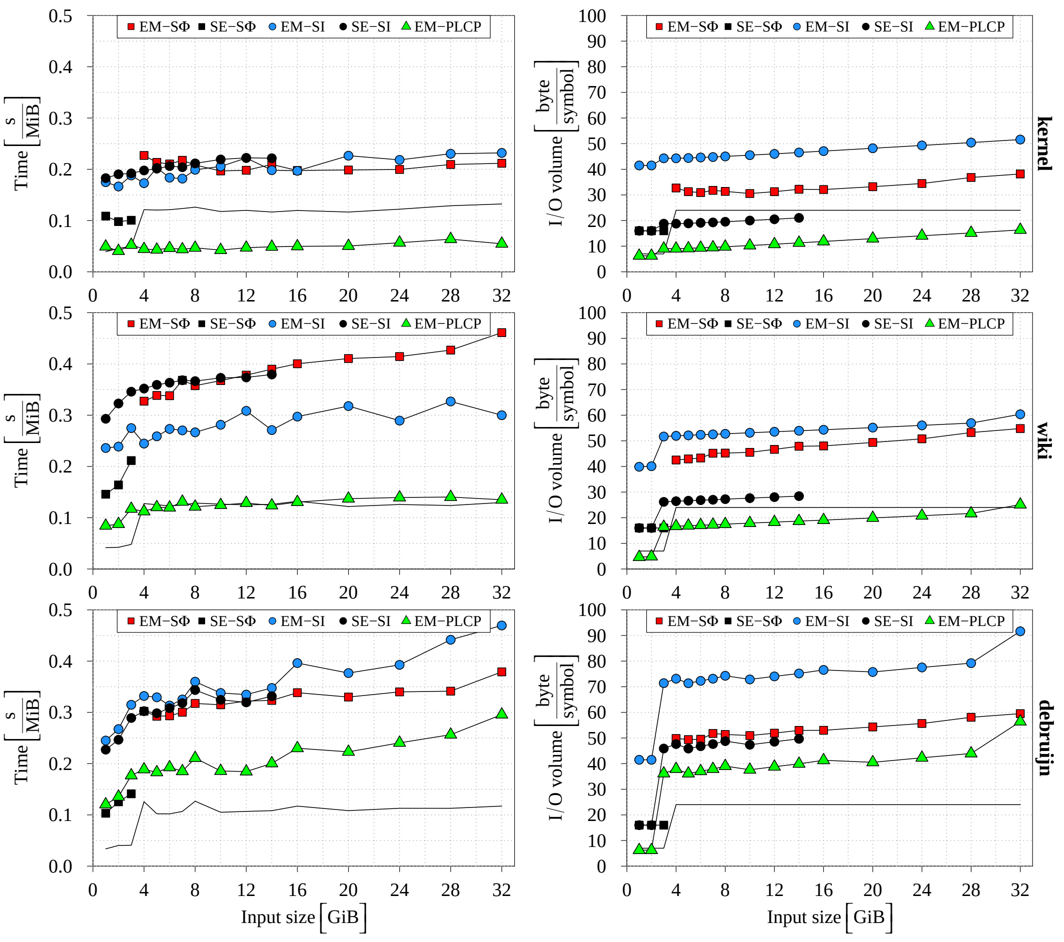

Figure 3 Comparison of the runtime and I/O volume of the new external-memory LCP array construction algorithms (EM-SΦ, EM-SI), to their original semi-external counterparts (SE-SΦ, SE-SI) [16]. The setup is analogous to Figure 2, i.e., all algorithms are using 3.5 GiB of RAM. The unlabeled curve shows the runtime and I/O volume of the standalone external-memory construction of BWT from SA (when the text fits in RAM, we run a semi-external version that needs less I/O).

In the second experiment we compare the EM-SΦ and EM-SI algorithms to their semi-external counterparts SE-SΦ and SE-SI. More precisely, we analyse the transition between semi-external and fully-external algorithms in terms of runtime and I/O volume.

The results are given in Figure 3. First, observe that at the point where we no longer can accommodate the text and bitvectors $\mathrm{PLCP}_{\mathrm{succ}}$ and R in RAM (i.e., between 2 and 3 GiB prefixes) the I/O volume of EM-PLCP (and thus also SE-SI and EM-SI) increases proportionally to the number of irreducible lcp values (up to $30n$ bytes for debruijn). The extra I/O accounts mostly for scanning and does not significantly affect the runtime. Second, note the difference of $25n$ bytes in the I/O volume of SE-SI and EM-SI. While SE-SI uses the original semi-external method that performs select-queries over $\mathrm{PLCP}_{\mathrm{succ}}$ bitvector (kept in RAM) to convert $\mathrm{PLCP}_{\mathrm{succ}}$ into LCP array [16], EM-SI uses the fully external-memory (and thus more I/O-demanding) method that does not require $\mathrm{PLCP}_{\mathrm{succ}}$ to fit in RAM, and furthermore, replaces the select-queries with simple lookups (see Section 5). The I/O increase is however compensated by faster computation and the fully-external method is either comparable (kernel, debruijn) or faster (wiki) than the semi-external method.

Table 4 Experimental results on the 512 GiB instance of dna testfile using 120 GiB of RAM. The disk usage column gives a peak disk space usage including the input and output of the given algorithm. pEM-BWT is a simple external-memory algorithm constructing BWT from SA. For comparison with pSAscan we also parallelized the computation in pEM-BWT.

Algorithm	Runtime	I/O volume	Disk usage
pSAscan	2.51 days	16.63 TiB	3.75 TiB
pEM-BWT	0.54 days	12.00 TiB	5.50 TiB
LCPscan	5.04 days	62.22 TiB	6.33 TiB
EM-SI	2.16 days	25.89 TiB	6.12 TiB
EM-SΦ	2.69 days	20.77 TiB	5.50 TiB
EM-PLCP	0.77 days	8.27 TiB	4.36 TiB

The transition between the SE-SΦ algorithm and EM-SΦ shows an increase in I/O by a factor 2–3 at the point where the text no longer fits in RAM. This is due to the fact that SE-SΦ reads the text once while EM-SΦ reads it in steps 2.2 and 3.2. Similarly, while SE-SΦ reads SA once in Step 3, EM-SΦ needs two scans (steps 3.1 and 3.3). Moreover EM-SΦ computes the values $\ell_{\min}$ and $\ell_{\max}$ twice for every processed pair (step 3.1 and 3.3), whereas SE-SΦ does it only once. This causes a slowdown by a factor 1.6–2.3 at the transition point, since these computations involve random accesses to the PLCP_q array and thus attract multiple cache misses. Note however that the increase in runtime and I/O volume is much bigger if we consider the transition from SE-SΦ to LCPscan.

In the last experiment we compare the performance of the new external-memory algorithms EM-SI and EM-SΦ to LCPscan on a full 512 GiB instance of the dna file using all 120 GiB of RAM available on our test machine. Unlike in previous experiments, here we use LCPscan with six rounds of processing since the four-round version ran out of disk space. The performance of both modes is very similar.

The results are given in Table 4. For comparison we also present the resources used by pSAscan [15] – currently the fastest practical way to construct suffix arrays in external memory, and pEM-BWT – a simple parallel BWT-from-SA construction. Note that in all previous experiments the algorithm for computing BWT from SA was sequential. Here we decided to use the parallel version to make it comparable to pSAscan. The results are consistent with previous experiments, i.e., both EM-SI and EM-SΦ are about two times faster than LCPscan. When BWT is available alongside the suffix array, the processing time is smaller for EM-SI. Otherwise, we need to additionally run a separate BWT construction and as a result EM-SΦ has a slight edge over EM-SI. Finally, if one wishes to only compute the PLCP array the processing time of EM-SI is reduced by about 65%.

Lastly, note that the new algorithms use a fairly moderate disk space. For EM-PLCP a peak disk space usage is either achieved after step 1.1 where in addition to input, we have $2r$ integers and the R bitvector stored on disk (recall that r is the number of irreducible lcp values) or after step 2.3 where in addition to input we store the $\mathrm{PLCP}_{\mathrm{succ}}$ bitvector on disk. The resulting disk usage is $7.125n + \max(10r, 0.125n)$ bytes, assuming 40-bit integers. Given that for the input instance we have $10r = 1.61n$ (see Table 3), the peak disk usage is $8.735n$, i.e., 4.36 TiB. For EM-SI we obtain the full LCP array in the last stage and thus the disk usage increases to $7.125n + \max(10r, 5.125n)$ bytes, i.e., $12.25n$ for the tested input. For EM-SΦ the disk usage is either maximized after step 3.1 or at the end of computation and is equal to at most $16n$ bytes (we ignore the space needed for PLCP_q). In practice it can be less due to skipped $(i, \Phi[i])$ pairs (see the discussion above) but it cannot be easily expressed in terms and n and r. In our experiment 55% of all pairs were skipped resulting in a peak disk usage of about $11n$ bytes or 5.5 TiB. We leave details for the full version of the paper.

7 Concluding Remarks

We have described two new external memory algorithms for LCP array construction. Our experiments show that the new algorithms are about two times faster than the state of the art. A common feature of the new algorithms is their avoidance of external-memory sorting.

One of the possible avenues for future work is reducing the disk space usage. In LCPscan this is accomplished by splitting and processing the input text in multiple parts. Similar partitioning techniques can be applied to reduce the disk space usage of the presented algorithms. Although the new algorithms are already quite disk space efficient, with partitioning their peak disk space usage can be guaranteed to be little more than what is needed for the input and the output.

Another possibility for improvement is to use parallelism. Both of the new algorithms are compute-bound rather than I/O-bound in some stages of the computation. Parallel computation in such stages can reduce the running time further.

Abstract

It is an open problem whether Yao-Yao graphs YY_k (also known as sparse-Yao graphs) are all spanners when the integer parameter k is large enough. In this paper we show that, for any integer $k \geq 42$, the Yao-Yao graph YY_{2k} is a t_k-spanner, with stretch factor $t_k = 6.03 + O(k^{-1})$ when k tends to infinity. Our result generalizes the best known result which asserts that all YY_{6k} are spanners for $k \geq 6$ [Bauer and Damian, SODA'13]. Our proof is also somewhat simpler.

1 Introduction

Let $\mathcal{P}$ be a set of points on the Euclidean plane $\mathbb{R}^2$. A simple undirected graph $G = (V, E)$ with vertex set $V = \mathcal{P}$ is called a *geometric t-spanner*, if for any pair of vertices (u, v) there is a path $uu_1 \dots u_s v$ in G such that the total length of the path $|uu_1| + |u_1u_2| + \dots + |u_s v|$ is at most t times the Euclidean distance $|uv|$, where t is a constant, called the *stretch factor*. The concept of geometric spanners was first proposed in [7], and can be considered as a special case of general graph spanners [21] if we consider the complete graph with edge lengths defined by the Euclidean metric.

Yao graph was first introduced by Andrew Yao in his seminal work on high-dimensional Euclidean minimum spanning trees [23]. Let $C_u(\gamma_1, \gamma_2)$ be the cone with apex u and consisting of the rays with polar angles in $[\gamma_1, \gamma_2)$. Given a positive integer parameter k, the construction of Yao graph Y_k is described in the following process.

```
Initially $\mathsf{Y}_k$ is an empty graph.
For each point $u$:
    For each $j = 0, \dots, k-1$:
        Let $C = C_u(2j\pi/k, 2(j+1)\pi/k)$;
        Select $v \in C \cap \mathcal{P}$ such that $|uv|$ is the shortest;
        Add edge $\overrightarrow{uv}$ into $\mathsf{Y}_k$.
```

* JL and WZ are supported in part by the National Basic Research Program of China grants 2015CB358700, 2011CBA00300, 2011CBA00301, and the National NSFC grants 61033001, 61361136003.

In the above process, ties are broken in an arbitrary but consistent manner. The above process is usually referred to as a “Yao step”. Note that the edges $\overrightarrow{uv}$ we added are directed edges (the directions are useful in the construction of Yao-Yao graphs).

Besides the usefulness in constructing minimum spanning trees, Yao graphs are also sparse graphs with surprisingly nice spanning properties. It is known that Yao graph Y_k has a stretch factor $(1-2\sin(\pi/k))^{-1}$ when $k \geq 6$ (see e.g., [18] and [5]). Later, the spanning properties of Y_4, Y_6 and Y_5 are proved in a series of work [10, 11, 2]. Due to the spanning properties and the simplicity of the construction, they have important applications in networking and wireless communication; we refer to [20] and [16] for more details.

One may notice that a Yao graph may not have a bounded degree. This is a serious drawback in certain wireless networking applications, since a wireless node can only communicate with a bounded number of neighbors. The issue was initially realized by Li et al. [18]. To address the issue, they proposed a modified construction with two Yao steps: the first Yao step produces a Yao graph Y_k, and the second step, called the “reverse Yao step”, eliminates a subset of edges of Y_k to ensure the maximum degree is bounded. The reverse Yao step can be described by the following procedure:

```
Initially $\mathsf{YY}_k$ is an empty graph.
For each point $u$:
    For each $j = 0, \dots, k-1$:
        $C = C_u(2j\pi/k, 2(j+1)\pi/k)$;
        Select $v \in C \cap \mathcal{P}$, $\overrightarrow{vu} \in \mathsf{Y}_k$ such that $|uv|$ is the shortest;
        Add edge $\overrightarrow{vu}$ into $\mathsf{YY}_k$.
```

The resulting graph, YY_k, is named as “Yao-Yao graph” or “Sparse-Yao graph” in the literature. The node degrees in YY_k are clearly upper-bounded by $2k$. It has long been conjectured that YY_k are also geometric spanners when k is larger than some constant threshold [18, 16, 3]:

► **Conjecture 1.** *There exists a constant k_0 such that for any integer $k > k_0$, YY_k is a geometric spanner.*

In sharp contrast to Yao graphs, our knowledge about the spanning properties of Yao-Yao graphs is still quite limited. Li et al. [18] proved that YY_k is connected for $k > 6$, and provided extensive experimental evidence suggesting YY_k are indeed spanners for larger k. Jia et al. [14] and Damian [9] showed that YY_k is spanner in certain special cases (the underlying point set satisfies certain restrictions). It is also known that for small constant k's, none of YY_k with $2 \leq k \leq 6$ admits a constant stretch factor [2, 10, 13]. Recently, a substantial progress was made by Bauer and Damian [3], who showed that YY_{6k} are spanners with stretch factor 11.76 for all integer $k \geq 6$ and the factor drops to 4.75 when $k \geq 8$. In fact, a closer examination of the proofs in their paper actually implies an asymptotic stretch factor of $2 + O(k^{-1})$. None of YY_k with other k values have been proved or disproved to be spanners. We note here that some of the aforementioned work [18, 9] focused on *UDGs (unit disk graphs).* But their arguments can be easily translated to general planar point sets as well. [1]

[1] Suppose a spanning property holds for any UDG. For a general set of points, we first scale it so that its diameter is less than 1. We can see that the UDG defined over the scaled set is a complete graph. So the spanning property also holds for the set of points.

In this paper, we improve the current knowledge of Yao-Yao graphs and make a step towards the resolution of Conjecture 1, by showing that almost all Yao-Yao graphs with even k are geometric spanners for k large enough. Formally, our results is as follows:

▶ **Theorem 2.** *For any $k \geq 42$, YY_{2k} is a t_k-spanner, where $t_k = 6.03 + O(k^{-1})$.*

Our Technique Our proof contains two major steps.

1. (Section 3) We first introduce two classes of intermediate graphs, called *overlapping Yao graphs* (denoted as OY_k) and *trapezoidal Yao graphs* (denoted as TY_k). The construction of overlapping Yao graphs is similar to that of Yao graphs, except that the cones incident on a vertex overlap with each other. We can easily show that OY_k is a geometric spanner. The definition of trapezoidal Yao graphs is also similar to Yao graphs, but takes advantage of a shape called *curved trapezoid* (defined in Section 2). We can show that OY_k is a subgraph of TY_k, implying TY_k is a geometric spanner as well.
2. (Section 4) In the second step, we show that YY_{2k} spans TY_{2k} (i.e., for any $u, v \in \mathcal{P}$, the shortest u-v path in YY_{2k} is at most a constant times longer than the shortest u-v path in TY_{2k}).

Our proof makes crucial use of the properties of curved trapezoids. Roughly speaking, curved trapezoids are more flexible than triangles which were used in [3]), which is the main reason for the improvement from YY_{6k} to more general YY_{2k}.

Related Works Replacing the Euclidean distance $|\cdot|$ by a power $|\cdot|^\kappa$ with a constant $\kappa \geq 2$ leads to the definition of *power spanners*. Since the power of length models the energy consumed in wireless transmissions, power spanners have important implications in wireless networking applications. In this setting, Yao-Yao graphs YY_k have been proved to be power spanners for any $\kappa \geq 2$ when $k > 6$ [14, 22]. It is clear that when a graph is a geometric spanner, it must also be a power spanner (See [17, Lemma 1]), however the reverse does not hold.

We also note that neither Yao graphs nor Yao-Yao graphs can be guaranteed to be planar graphs [22, 15], whereas Delaunay triangulation provides another type of spanner which is planar but without bounded degree [12, 4]. In order to facilitate network design in certain applications, some previous work [6, 19] made use of both Yao graphs and Delaunay graphs to produce degree-bounded and planar geometric spanners.

The paper is organized as follows. We introduce some standard notations and useful tools, including the shape of curved trapezoid, in Section 2. We introduce overlapping Yao graphs, trapezoidal Yao graphs, and prove their spanning properties in Section 3. We prove our main result in Section 4. Finally, we conclude with some future work in Section 5.

2 Preliminaries

$\mathcal{P}$ is the underlying set of points in $\mathbb{R}^2$. $D(a, \rho)$ denotes an open disk centered at point a with radius ρ. The boundary and closure of a region R are denoted by ∂R and $\overline{R}$, respectively. Let $S(a, \rho) = \partial D(a, \rho)$ be the circle centered at a with radius ρ. The length of shortest u-v path in a graph G is denoted by $d_G(u, v)$.

On $\mathbb{R}^2$, a point u with coordinates (x, y) is denoted by $u(x, y)$. Let $o(0, 0)$ be the origin of $\mathbb{R}^2$. The positive direction of x-axis is fixed as the polar axis throughout the construction and analysis. For a point $a \in \mathbb{R}^2$, we use x_a to denote its x-coordinate and y_a its y-coordinate. We use $\varphi(uv)$ to represent the polar angle of vector $\overrightarrow{uv}$. The angle computations are all under the modulo of 2π, and angle subtraction is regarded as the

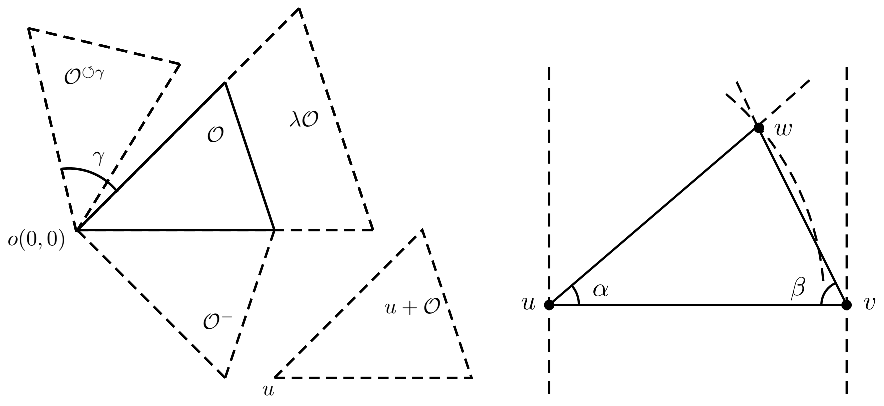

Figure 1 Left: Affine transformations. Right: Proof for Lemma 3.

counterclockwise difference. A cone between polar angles $\gamma_1 < \gamma_2$ with apex at the origin is denoted as $C(\gamma_1, \gamma_2) = \{u \mid \varphi(ou) \in [\gamma_1, \gamma_2)\}$.

It is also necessary to introduce some notations of standard affine transformations on a geometric object $\mathcal{O}$ in the plane:

- (Dilation) If $\mathcal{O}$ is uniformly scaled by factor λ with the origin as the center, the result is denoted by $\lambda\mathcal{O} = \{\lambda z \mid z \in \mathcal{O}\}$.
- (Translation) If $\mathcal{O}$ is translated so that the original point goes to point u, the result is denoted by $u + \mathcal{O} = \{u + z \mid z \in \mathcal{O}\}$.
- (Rotation) If $\mathcal{O}$ rotated an angle γ counterclockwise with respect to the origin, the result is denoted by $\mathcal{O}^{\circlearrowleft\gamma}$.
- (Reflection) If $\mathcal{O}$ is reflected through the x-axis, the result is denoted by $\mathcal{O}^-$.

By the above notations, we can denote the cone with apex u by $u + C(\gamma_1, \gamma_2)$ (abbreviated as $C_u(\gamma_1, \gamma_2)$).

Geometric Inequalities

In order to attain a constant stretch factor for Yao graphs and their variants, one often needs to bound a certain geometric ratio. Here we present a simple yet general lemma for this purpose. Let the *open strip* on the segment uv be the collection of points

▶ **Lemma 3.** *Suppose $\tau \geq 1$ is a constant. Let w be a point with $\angle wuv, \angle wvu \in [0, \pi/2)$ (see Figure 1). When $\tau|vw| < |uv|$, the following statements about the ratio $|uw|/(|uv| - \tau|vw|)$ hold:*

1. *If w is restricted within a compact segment of an arc centered at u, the ratio is maximized when $|vw|$ is the largest;*
2. *If w is restricted within a compact segment of a ray from v, the ratio is maximized when $|vw|$ is the largest;*
3. *If w is restricted within a compact segment of a ray originated from u, the maximum ratio is achieved when w makes $|uw|$ the largest or smallest;*

Proof. The first statement is straightforward since both $|uv|$ and $|uw|$ are fixed. Now, we show the last two properties. Let $\alpha = \angle wuv$ and $\beta = \angle wvu$. By the law of sines and the fact that $\sin(\alpha + \beta) = \sin\alpha\cos\beta + \cos\alpha\sin\beta$, we can see that

$$\frac{|uw|}{|uv| - \tau|vw|} = \frac{\sin\beta}{\sin(\alpha+\beta) - \tau\sin(\alpha)} = \frac{1}{\cos\alpha - \sin\alpha \cdot (\tau - \cos\beta)/\sin\beta}. \tag{1}$$

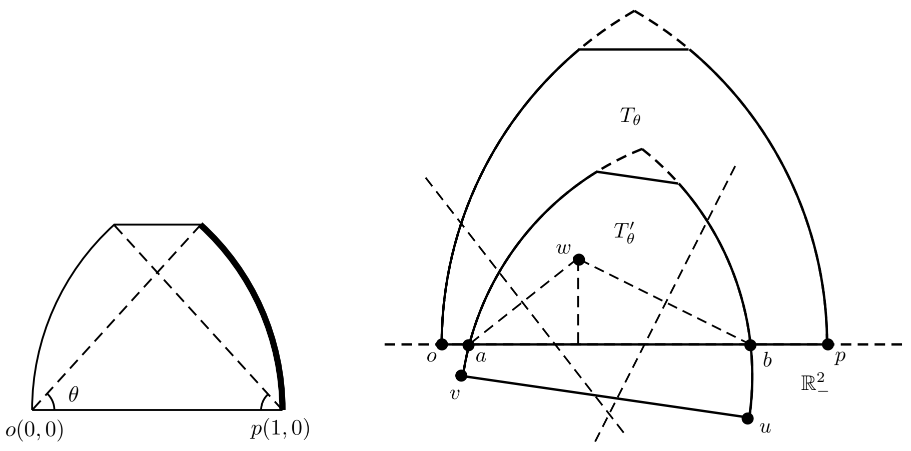

Figure 2 Left: The curved trapezoid. The critical arc is shown in bold. Right: An illustration of Lemma 6 with its proof.

One can see the ratio is maximized when α is maximized, which implies the second statement. Moreover, $(\tau - \cos\beta)/\sin\beta$ is a convex function of β for $\beta \in (0, \pi/2)$. Hence, it is maximized when β is maximized or minimized, which implies the last statement. ◀

Due to Lemma 3, to compute an upper bound for $|uw|/(|uv| - |vw|)$ in a region, it suffices to consider a small number of extreme positions. In particular, the following corollary is an immediately consequence, which is an improvement of a classical result mentioned in [8]:

▶ **Corollary 4.** *$R = \overline{D(u, |uv|) \cap C_u(\gamma_1, \gamma_2)}$ is a sector with apex u and with v on its arc. Suppose $\alpha = \max\{\varphi(uv) - \gamma_1, \gamma_2 - \varphi(uv)\} < \pi/3$. Then, for all $w \in R \setminus \{u\}$, it holds that*

$$\frac{|uw|}{|uv| - |vw|} \leq \left(1 - 2\sin\frac{\alpha}{2}\right)^{-1}.$$

Proof. Take $\tau = 1$ in Lemma 3. By considering the rays from u and the arcs centered at u, and applying the first and third cases in Lemma 3, we can see that the ratio can only be maximized when w is at the two corners of the sector with $\beta = (\pi - \alpha)/2$, or when w approaches u with $\beta = 0$. The two upper bounds in equality 1 in these cases are $(1 - 2\sin(\alpha/2))^{-1}$ and $(\cos\alpha)^{-1}$, and the former one is larger. ◀

Curved Trapezoid T_θ

To construct the trapezoidal Yao Graphs TY_k, we need to define an open shape, called *curved trapezoid*, as follows.

▶ **Definition 5** (Curved Trapezoid T_θ)**.** Fix two points $o(0, 0)$ and $p(1, 0)$. Given $\theta \in [\pi/4, \pi/3)$, we define the curved trapezoid T_θ as:

$$T_\theta = \{u(x, y) \mid 0 < x < 1, 0 < y < \sin\theta, |ou| < 1, |pu| < 1\}.$$

Intuitively, it is the convex hull of two sectors with apices at o and p respectively. We regard T_θ as a shape attached to the origin o, and the closed arc not incident on o is called the *critical arc*. See Figure 2 for an example.

We list some useful properties of T_θ here. It is straightforward to show that T_θ is symmetric with respect to the vertical line $x = \frac{1}{2}$. For any $u \in T_\theta$ it holds that $0 < \varphi(ou) < \pi/2$. If u is on the critical arc, it holds that $0 < \varphi(ou) < \theta$. The following crucial lemma, illustrated in Figure 2, is also an immediate consequence from the definition.

▶ **Lemma 6.** *Denote $\mathbb{R}^2_-$ as the lower half-plane $\{(x, y) \mid y \le 0\}$. Consider any two points $u, v \in \mathbb{R}^2_-$ satisfying $0 < x_u < 1$, $|\varphi(uv) - \pi| < \frac{1}{6}\pi$, and $|ou|, |pv| \in [|uv|, 1)$. We construct a similar shape $T'_\theta := u + |uv|(T^-_\theta)^{\circlearrowleft\varphi(uv)}$. We have that $T'_\theta - T_\theta$ is completely contained in lower half plane $\mathbb{R}^2_-$.*

Proof. We first consider the extreme case when $\theta = \pi/3$. Since $u, v \in \mathbb{R}^2_-$, if the two arcs of T'_θ do not intersect with the line $y = 0$, then T_θ is fully contained in $\mathbb{R}^2_-$ and the proof is done.

Now suppose the two intersections are a, b, illustrated in the RHS of Figure 2. Notice that $|ua| = |uv| \le |ou|$ and $|vb| = |uv| \le |pv|$. Combining with the condition that $0 < x_u < 1$, we can see that both a and b lie in the segment op. For any point $w \in T'_\theta - \mathbb{R}^2_-$, it suffices to prove $|ow|, |pw| < 1$ so that w is in T_θ. This is done by examining the perpendicular bisector of aw and bw: since $|ua| > |uw|$, u is in the upper half-plane of the bisector of aw, and so is p. Thus $|pw| < |pa| \le |op| = 1$. The same arguments hold for $|ow| < 1$.

The above shows that $T'_\theta - T_\theta \subset \mathbb{R}^2_-$ when $\theta = \pi/3$, and if θ is smaller, we only need to show that the distance $d(w, op)$ from w to line $y = 0$ is less than $\sin\theta$. This is done by the observation that $d(w, ab) \le d(w, uv)$ in T'_θ, and $d(w, uv) < |uv| \sin\theta < \sin\theta$. This completes the proof for Lemma 6. ◀

3 Overlapping Yao Graphs and Trapezoidal Yao Graphs

In this section we consider two variants of Yao graphs, overlapping Yao graphs and trapezoidal Yao graphs.

▶ **Definition 7** (Overlapping Yao Graph OY_k). Let $\gamma = \left\lceil \frac{k}{4} \right\rceil \frac{2\pi}{k}$. For every $u \in \mathcal{P}$ and $j = 0, \ldots, k-1$, select shortest $\overrightarrow{uv}$ with $v \in C_u(2j\pi/k, 2j\pi/k + \gamma)$. The chosen edges form the *overlapping Yao graph* $\mathsf{OY}_k(\mathcal{P})$.

The angle γ in the definition is actually the smallest multiple of $2\pi/k$ which is no less than $\pi/2$. We note here that the term “overlapping" comes from the fact that the cones with the same apex overlap with each other, while in the original Yao graphs they are disjoint. First we claim that OY_k is a spanner when k is large.

▶ **Lemma 8.** *If $k > 24$, then OY_k is a τ_k-spanner where $\tau_k = \left(1 - 2\sin\left(\frac{\pi}{k} + \frac{\pi}{8}\right)\right)^{-1}$.*

Proof. We prove $d_{\mathsf{OY}}(u, v) \le \tau_k |uv|$ by induction on the length $|uv|$ for $u, v \in \mathcal{P}$. Notice that it is always possible to find j so that $v \in C_u\left(2j\pi/k + \pi/4, 2(j+1)\pi/k + \pi/4\right)$. See Figure 3 for an illustration. This cone is contained in $C_u(\gamma_1, \gamma_2)$, where $\gamma_1 = 2j\pi/k$ and $\gamma_2 = 2j\pi/k + \gamma$, since $k > 24$ and thus $\gamma \ge \pi/2$. If $\overrightarrow{uv}$ is the shortest in $C_u(\gamma_1, \gamma_2)$, then $\overrightarrow{uv} \in \mathsf{OY}_k$ and we are done with the proof.

Now, suppose that in the construction of construction of OY_k, we choose $\overrightarrow{uw}$ for $C_u(\gamma_1, \gamma_2)$ with $w \ne v$. Since $k > 24$, one shall see that

$$\begin{aligned} \alpha \quad &:= \quad \max\{\varphi(uv) - \gamma_1, \gamma_2 - \varphi(uv)\} \\ &\le \quad \max\{2\pi/k + \pi/4, \gamma - \pi/4\} = 2\pi/k + \pi/4 < \pi/3. \end{aligned}$$

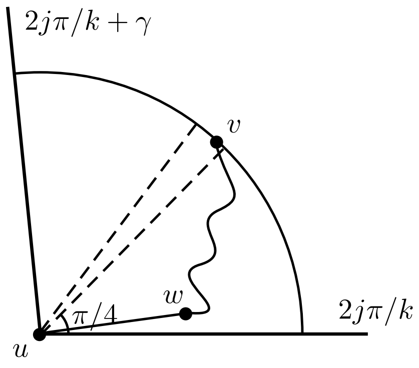

Figure 3 Illustration of the proof of Lemma 8. The outer cone is $C_u(\gamma_1,\gamma_2)$ where $\gamma_1 = 2j\pi/k$ and $\gamma_2 = 2j\pi/k+\gamma$ The cone defined by two dashed lines is $C_u\,(2j\pi/k+\pi/4, 2(j+1)\pi/k+\pi/4)$.

Hence, we can apply Corollary 4 on the sector $R = \overline{D(u,|uv|)\cap C_u(\gamma_1,\gamma_2)}$, which claims

$$\frac{|uw|}{|uv|-|vw|} \le \tau_k = \left(1-2\sin\frac{\alpha}{2}\right)^{-1}.$$

Since $\alpha < \pi/3$, we have $|vw| < |uv|$. By the induction hypothesis, we can see that

$$d_{\mathsf{OY}}(u,v) \le |uw| + d_{\mathsf{OY}}(v,w) \le |uw| + \tau_k|vw| \le \tau_k(|uv|-|vw|) + \tau_k|vw| = \tau_k|uv|,$$

which completes the proof. ◀

We also note that Barba et al. proposed the so-called *continuous Yao graphs* in [1], which play a similar role as OY_k. By adapting their method, it might be possible to prove a slightly smaller stretch factor for OY_k. However the constant is not our primary goal in this paper, and we leave it to the future work.

Now we define the trapezoidal Yao graphs based on the curved trapezoid T_θ (Definition 5).

▶ **Definition 9** (Trapezoidal Yao Graph TY_k). Let $\theta = \left\lceil \frac{k}{8} \right\rceil \frac{2\pi}{k}$. For every $u \in \mathcal{P}$ and $j = 0,\ldots,k-1$, define two curved trapezoids

$$\Gamma_{j1} = (T_\theta)^{\circlearrowleft 2j\pi/k} \qquad \text{and} \qquad \Gamma_{j2} = (T_\theta^-)^{\circlearrowleft 2j\pi/k}.$$

Note that their bottom sides lie on the ray of angle $2j\pi/k$. For each $i = 1,2$, we do the following: We grow a curved trapezoid $u + \lambda\Gamma_{ji}$ by gradually increasing λ (initially 0) until its boundary hits some point v. If the critical arc hits v, we select $\overrightarrow{uv}$. Otherwise, we select nothing. All the selected edges form the graph $\mathsf{TY}_k(\mathcal{P})$.

▶ **Lemma 10.** *For any integer $k > 24$, TY_k is a τ_k-spanner where* $\tau_k = \left(1-2\sin\left(\frac{\pi}{k}+\frac{\pi}{8}\right)\right)^{-1}$.

Proof. Note that in Definition 5, we require that $\theta \in [\pi/4, \pi/3)$. When $k > 24$, we can see that

$$\frac{\pi}{4} \le \theta = \left\lceil \frac{k}{8} \right\rceil \frac{2\pi}{k} \le \frac{k+7}{k}\cdot\frac{\pi}{4} < \frac{\pi}{3}.$$

Hence, the value θ in Definition 9 satisfies the requirement of θ in Definition 5.

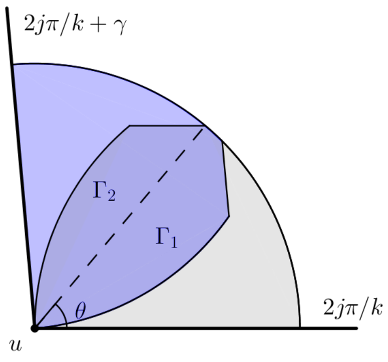

Figure 4 Illustration for Lemma 10: Two curved trapezoids cover a sector.

We show that the overlapping Yao graph OY_k is actually a subgraph of TY_k, from which the lemma is an immediate consequence. Given any j and one cone $C_u(2j\pi/k, 2j\pi/k+\gamma)$, we choose two copies of T_θ: $\Gamma_1 = (T_\theta)^{\circlearrowleft 2j\pi/k}$, and $\Gamma_2 = (T_\theta^-)^{\circlearrowleft 2j\pi/k+\gamma}$. See Figure 4. Since $2\theta \geq \gamma \geq \pi/2$, it is clear that Γ_1 and Γ_2 exactly cover the interior of sector $D(o,1) \cap C_o(2j\pi/k, 2j\pi/k+\gamma)$. Now, for any edge $\overrightarrow{uv} \in \mathsf{OY}_k$ selected within this cone, both $u+|uv|\Gamma_1$ and $u+|uv|\Gamma_2$ must have empty interior ($|uv|$ is the shortest within the cone). Therefore, if $\varphi(uv) - 2j\pi/k \leq \theta$, it should be selected into TY_k with respect to Γ_1. Otherwise it should be selected with respect to Γ_2. This implies that OY_k is a subgraph of TY_k, and by Lemma 8, TY_k is a τ_k-spanner as well. ◀

4 Yao-Yao Graphs YY_{2k} are Spanners

In this section, we prove our main result that YY_{2k} has a constant stretch factor for large k, by show that YY_{2k} spans TY_{2k}.

To begin with, we prove an important property of TY_{2k}, which will be useful later. The property can be seen as an analogue of the property of Θ_6 shown in [3, Lemma 2]. One of the reasons we can improve YY_{6k} to more general YY_{2k} is that we can take advantage of the curved trapezoid rather than the regular triangle. We state this property by assuming, that without loss of generality, a curved trapezoid T_θ is placed at its normal position, i.e., T_θ lies in the first quadrant with two vertices $o(0,0)$ and $p(1,0)$. From now on, we work with trapezoidal Yao graphs TY_{2k}. Hence, the associated parameter θ (see Definition 9) is $\theta = \left\lceil \frac{2k}{8} \right\rceil \frac{2\pi}{2k} = \left\lceil \frac{k}{4} \right\rceil \frac{\pi}{k}$.

▶ **Lemma 11.** *Suppose $o \in \mathcal{P}$ and T_θ has an empty interior. If there is a point $a \in \mathcal{P}$ such that $0 < x_a < 1$, $y_a \leq 0$ and $0 < \varphi(ap) < \pi/6$, then*

$$d_{\mathsf{TY}}(oa) \leq x_a + (2\tau_{2k}+1)|y_a|$$

where τ_k is as defined in Lemma 10, and there is a path in TY_{2k} from a to o where each edge is shorter than $|oa|$.

Proof. Note that simply applying Lemma 10 is insufficient to achieve the guarantee. Instead, we present an iterative algorithm for finding a path from a to o. The path found by the iterative algorithm is not necessarily a shortest path from a to o. Nevertheless, we can bound its length as in the lemma.

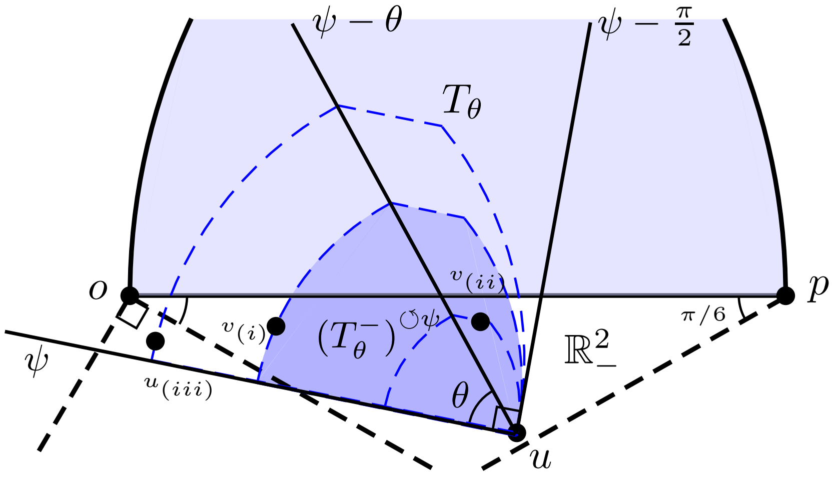

Figure 5 Illustration of three cases in the proof of Lemma 11.

```
Let $u$ be the current point in $\mathcal{P}$; Initially $u$ is set to be $a$.
While $u \neq o$ and $\varphi(ou) > -\frac{\pi}{6}$ do
    Let $\psi = \min\{j\pi/k \mid j\pi/k > \varphi(uo), j = 0, 1, \ldots, 2k-1\}$;
    Grow a curved trapezoid $u + \lambda(T_\theta^-)^{\circlearrowleft\psi}$ until its boundary hits some point $v$.
    If $v \in C_u(\psi - \frac{\pi}{2}, \psi - \theta)$:
        (i) $\mathsf{TY}_{2k}$ must contain the edge $\overrightarrow{uv}$. We add $\overrightarrow{uv}$ to our path;
    Otherwise:
        (ii) Add the path from $u$ to $v$ in $\mathsf{OY}_{2k}$ constructed in Lemma 8;
    Set the current point $u$ to be $v$ and proceed to the next iteration.
If now $u = o$, the path is already found;
(iii) Otherwise take the path from $u$ to $o$ in $\mathsf{OY}_{2k}$ constructed in Lemma 8.
```

See Figure 5 for an illustration of the three cases (i),(ii) and (iii). Let $l(u)$ be the length of the path from u to o generated by the algorithm above. To analyze its behaviour, we define a potential function

$$\Phi(u) = x_u + (2\tau_{2k} + 1)|y_u| - l(u).$$

We claim that the potential function never increases as the algorithm proceeds and is eventually 0. The potential only changes in the three labeled steps (i),(ii) and (iii). When executing step (i) and (ii), it is clear that $\varphi(uo) \in \left(\frac{5}{6}\pi, \pi\right]$, $\varphi(up) \in \left[0, \frac{1}{6}\pi\right)$. Therefore ψ also falls in the range $\left(\frac{5}{6}\pi, \pi\right]$. Moreover, v must be contained in $\mathbb{R}^2_-$ due to Lemma 6, that is, $y_v \leq 0$.

- In step (i), v is simply the nearest neighbor in the cone $C_u(\psi - \theta, \psi)$. Since $\varphi(up) < \pi/6$, we know $|uv| < |vp|$. Since $\psi - \theta > \pi/2$ and $\psi \leq \pi$, we can see that $x_v \leq x_u$ and $|y_v| < |y_u|$. Hence the change in potential is

$$\begin{aligned}\Delta\Phi = \Phi(v) - \Phi(u) &= |uv| - (x_u - x_v) - (2\tau_{2k} + 1)(|y_u| - |y_v|)\\ &\leq |uv| - (x_u - x_v) - (|y_u| - |y_v|) \leq 0.\end{aligned}$$

- In step (ii), since $\varphi(uv) \in [\psi - \frac{\pi}{2}, \psi - \theta)$, we know $|\varphi(uv) - \pi/2|$ is at most $\pi/4$, so $|y_v| < |y_u|$ and $|x_v - x_u| < |y_u| - |y_v|$. That further implies $|uv| < 2(|y_u| - |y_v|)$, and thus $d_{\mathsf{TY}}(uv) \le \tau_{2k}|uv| < 2\tau_{2k}(|y_u| - |y_v|)$. Therefore the change in potential is

$$\begin{aligned}\Delta\Phi = \Phi(v) - \Phi(u) &= d_{\mathsf{TY}}(uv) - (x_u - x_v) - (2\tau_{2k} + 1)(|y_u| - |y_v|) \\ &= (d_{\mathsf{TY}}(uv) - 2\tau_{2k}(|y_u| - |y_v|)) + (x_v - x_u - (|y_u| - |y_v|)) \le 0.\end{aligned}$$

- In step (iii), suppose the node arrived before u is u', with $\varphi(u'o) > \frac{5}{6}\pi$. Since $\overrightarrow{u'u}$ is chosen, it must be the case that $|u'u| \le |u'o|$. It is immediate that $\varphi(uo) \in \left(\frac{\pi}{3}, \frac{5}{6}\pi\right]$, and thus $|uo| \le 2|y_u|$, $-x_u \le |y_u|$. Therefore, we have that

$$\Delta\Phi = \Phi(o) - \Phi(u) = (d_{\mathsf{TY}}(uo) - 2\tau_{2k}|y_u|) + (-x_u - |y_u|) \le 0.$$

Now that $\Phi(o) = 0$, and the above arguments show that the potential cannot increase during the path from u to o, we can conclude that $\Phi(a) \ge 0$. That is, $l(a) \le x_a + (2\tau_{2k} + 1)|y_a|$.

Also notice that in steps (i) and (ii), it is ensured that $|uv| < |ou|$ and $|ov| < |ou|$ since v is contained in the curved trapezoid. On the other hand, the paths from OY_{2k} in steps (ii) and (iii), which are constructed according to Lemma 8, contains only edges shorter than the direct distance. Thus the edges we selected are all shorter than $|oa|$. ◀

▶ **Lemma 12.** *On a Yao-Yao graph $\mathsf{YY}_{2k}(\mathcal{P})$ with $k \ge 42$, if $\overrightarrow{uv} \in \mathsf{TY}_{2k}$, then $d_{\mathsf{YY}}(uv) \le \tau'_k|uv|$, where $\tau'_k = \sqrt{2} + O(k^{-1})$ is a constant depending only on k.*

Proof. Let $\tau'_k \ge 1$ be a constant to be fixed later. Our proof is by induction on the length $|uv|$. The base case is simple: the shortest edge is in both TY_{2k} and YY_{2k}. Now, consider an edge $\overrightarrow{uv} \in \mathsf{TY}_{2k}$. Without loss of generality, we assume that $|uv| = 1$. We further assume that T_θ, which generates $\overrightarrow{uv}$ in TY_{2k}, in its normalized position, i.e., u is $o(0,0)$ and another vertex is $p(1,0)$. See Figure 6. Noticing that θ is a multiple of π/k, we can see that v must be the nearest neighbor of u in its corresponding cone of YY_{2k}.

If $\overrightarrow{uv} \in \mathsf{YY}_{2k}$, then $d_{\mathsf{YY}}(uv) = |uv|$ and we are done with the proof. Otherwise, there must be another edge $\overrightarrow{wv} \in \mathsf{YY}_{2k}$ where u and w are in the same v-apex cone, and $|vw| \le |uv|$ (this is due to the construction of Yao-Yao graph). It follows that $|uw| < |uv|$ since $k \ge 42$.

Now, we prove by induction that $d_{\mathsf{YY}}(uv) \le \tau'_k|uv|$. Now noticing that T_θ has an empty interior, there are only two cases for w we need to consider. See Figure 6 for an example.

1. $y_w > 0$: See the left part of Figure 6. By Lemma 3, we can see that within all possible positions of w, $|vw|/(|uv| - \tau_{2k}|uw|)$ can only be maximized when $|vw| = |uv|$ or when w is on the left boundary of T_θ. Since when $k \ge 42$, it holds $2\tau_{2k}\sin\frac{\pi}{2k} < 1$, therefore

$$\frac{|vw|}{|uv| - \tau_{2k}|uw|} \le \frac{1}{1 - 2\tau_{2k}\sin\frac{\pi}{2k}}.$$

   Hence, if $\tau'_k \ge 1/(1 - 2\tau_{2k}\sin\frac{\pi}{2k})$, we have that $|vw| \le \tau'_k(|uv| - \tau_{2k}|uw|)$. Consider the shortest path from u to w in TY_{2k}. Notice that $d_{\mathsf{TY}}(uw) \le \tau_{2k}|uw| < |uv|$. Applying the induction hypothesis to every edge of the shortest path, we can see $d_{\mathsf{YY}}(uw) \le \tau'_k d_{\mathsf{TY}}(uw)$. Combining the above inequalities, we can finally obtain that

$$d_{\mathsf{YY}}(uv) \le d_{\mathsf{YY}}(uw) + |vw| \le \tau'_k(d_{\mathsf{TY}}(uw) + |uv| - \tau_{2k}|uw|) \le \tau'_k|uv|.$$

2. $y_w \le 0$: See the middle and right parts of Figure 6. Consider the two cases of angle $\varphi(uv)$:

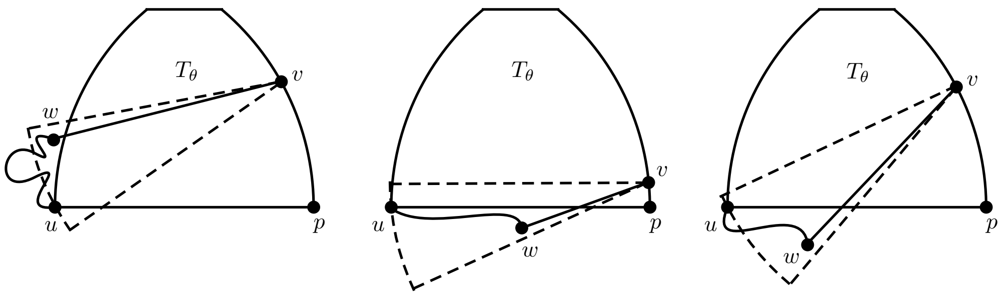

Figure 6 Proof for Lemma 12. Left: w is in the upper half-plane; Middle: w is in the lower half-plane and $\varphi(uv) \le \pi/k$; Right: w is in the lower half-plane and $\varphi(uv) > \pi/k$.

- If $0 \le \varphi(uv) \le \pi/k$, then $\varphi(wp) \le \varphi(wv) \le \pi/k$;
- If $\pi/k < \varphi(uv) \le \theta$, then $\angle upv \le \frac{(k-1)\pi}{2k} \le \angle uwv$. Thus p is outside the circumcircle of $\triangle uvw$, and $\varphi(wp) = \angle upw \le \angle uvw \le \pi/k$.

Therefore in both cases, we have $0 < x_w < x_p$ and $0 \le \varphi(wp) \le \pi/k$. We notice the following two inequalities:

$$|y_w| \le (x_p - x_w) \tan \varphi(wp) \le (|uv| - x_w) \tan \frac{\pi}{k},$$
$$|vw| \le (x_v - x_w) \sec \varphi(wv) \le (|uv| - x_w) \sec \left(\theta + \frac{\pi}{k}\right).$$

Consider the path from w to u as we constructed in Lemma 11 (w and u correspond to a and o in the lemma, respectively). Since all edges in the constructed path are shorter than $|wu|$ (thus shorter than $|uv|$ as well), we can apply the induction hypothesis to get $d_{\mathsf{YY}}(uw) \le \tau'_k d_{\mathsf{TY}}(uw)$. Applying Lemma 11, we have

$$\begin{aligned} d_{\mathsf{YY}}(uv) &\le d_{\mathsf{YY}}(uw) + |vw| \le \tau'_k d_{\mathsf{TY}}(uw) + |vw| \\ &\le \tau'_k (x_w + (2\tau_{2k} + 1)|y_w|) + |vw| \\ &\le \tau'_k x_w + \left(\tau'_k (2\tau_{2k} + 1) \tan \frac{\pi}{k} + \sec\left(\theta + \frac{\pi}{k}\right)\right)(|uv| - x_w). \end{aligned}$$

Suppose we choose τ'_k such that $\tau'_k(2\tau_{2k}+1)\tan\frac{\pi}{k} + \sec(\theta+\frac{\pi}{k}) \le \tau'_k$, (which is equivalent to $\tau' \ge ((1-(2\tau_{2k}+1)\tan\frac{\pi}{k})\cos(\theta+\frac{\pi}{k}))^{-1}$). Note that the above holds also because $(2\tau_{2k}+1)\tan\frac{\pi}{k} < 1$ when $k \ge 42$. Finally, we can conclude that

$$d_{\mathsf{YY}}(uv) \le \tau'_k |uv|.$$

We can conclude from the above two cases that τ'_k can be chosen to be $\sec\frac{\pi}{4} + O(k^{-1}) = \sqrt{2} + O(k^{-1})$. ◀

Combining Lemma 10 and 12, with the observation that $\tau_k = (1 - 2\sin(\pi/8))^{-1} + O(k^{-1})$, we can get our main result that almost all YY_{2k} are spanners.

▶ **Theorem 2** (restated). *For any integer $k \ge 42$, YY_{2k} is a t_k-spanner, where $t_k = \tau'_k \tau_{2k} = \sqrt{2}(1-2\sin(\pi/8))^{-1} + O(k^{-1}) = 6.03 + O(k^{-1})$.*

5 Conclusion and Future Work

In this paper we proved that Yao-Yao graphs YY_{2k} are geometric spanners for k large enough, making a positive progress to the long-standing Conjecture 1. For Yao-Yao graphs with odd parameters, the resolution of the conjecture is still elusive and seems to require additional new ideas.

We did not try very hard to optimize the constant stretch ratio for different k values. Hence, the constant claimed in Theorem 2 may well be further improved. One potential approach is to use techniques developed in [1]. Obtaining tighter bounds (and lower bounds as well!) is left as an interesting future work.

We propose some other potential future directions, which are interesting in their own rights and might lead to sparse spanners with bounded degrees and small stretch factors.

- Consider the variant of Yao-Yao graphs where the cones are not divided uniformly. One could expect that such variants are spanners if the apex angles of the cones are all small. It seems that our techniques in the paper can be adapted to this situation if the separated cones are *centrosymmetric*: every separation ray of polar angle φ has a corresponding one at polar angle $\pi + \varphi$. But the more general case is still open.
- Instead of insisting on one polar division for every node, we can let each point choose its polar axis individually by uniformly and independently randomizing a direction. We conjecture that such graphs are also spanners (in expectation or with high probability) for k large enough.

Abstract

Resource augmentation is a well-established model for analyzing algorithms, particularly in the online setting. It has been successfully used for providing theoretical evidence for several heuristics in scheduling with good performance in practice. According to this model, the algorithm is applied to a more powerful environment than that of the adversary. Several types of resource augmentation for scheduling problems have been proposed up to now, including speed augmentation, machine augmentation and more recently rejection. In this paper, we present a framework that unifies the various types of resource augmentation. Moreover, it allows generalize the notion of resource augmentation for other types of resources. Our framework is based on mathematical programming and it consists of extending the domain of feasible solutions for the algorithm with respect to the domain of the adversary. This, in turn allows the natural concept of duality for mathematical programming to be used as a tool for the analysis of the algorithm's performance. As an illustration of the above ideas, we apply this framework and we propose a primal-dual algorithm for the online scheduling problem of minimizing the total weighted flow time of jobs on unrelated machines when the preemption of jobs is not allowed. This is a well representative problem for which no online algorithm with performance guarantee is known. Specifically, a strong lower bound of $\Omega(\sqrt{n})$ exists even for the offline unweighted version of the problem on a single machine. In this paper, we first show a strong negative result even when speed augmentation is used in the online setting. Then, using the generalized framework for resource augmentation and by combining speed augmentation and rejection, we present an $(1+\epsilon_s)$-speed $O(\frac{1}{\epsilon_s\epsilon_r})$-competitive algorithm if we are allowed to reject jobs whose total weight is an ϵ_r-fraction of the weights of all jobs, for any $\epsilon_s > 0$ and $\epsilon_r \in (0,1)$. Furthermore, we extend the idea for analysis of the above problem and we propose an $(1+\epsilon_s)$-speed ϵ_r-rejection $O\left(\frac{k^{(k+3)/k}}{\epsilon_r^{1/k}\epsilon_s^{(k+2)/k}}\right)$-competitive algorithm for the more general objective of minimizing the weighted ℓ_k-norm of the flow times of jobs.

1 Introduction

A well-identified issue in algorithms and, in particular, in online computation is the weakness of the worst case paradigm. Summarizing an algorithm by a pathological worst case can underestimate its performance on most inputs. Many practically well-performed algorithms admit a mediocre theoretical guarantee whereas theoretically established algorithms behave poorly even on simple instances in practice. The need of more accurate models is crucial and is considered as an important question in algorithmic community. Several models have been proposed in this direction.

A *first* type of models study online problems assuming nice properties on the inputs. For example, several models, in which arrivals of requests are assumed to follow a given distribution, an unknown distribution, a Markov chain, a random order, etc, have been studied for fundamental online problems such as paging, k-server, matching, Steiner tree. Other models that assume properties on inputs include the access graph model [5], the diffuse adversary model [22], the statistical adversary model [25], the working set model [1, 10]. A *second* type of models consists of giving more power to online algorithms and compare the online algorithm (with additional power) to the offline optimum (without additional power). This class consists of the model with advice [12, 13] and the resource augmentation model [20, 24]. A *third* type of models aim at comparing an online algorithm to some benchmark different from the offline optimum. This class includes the comparative analysis [22], the bijective analysis [3], etc. Each model has successfully explained the performance of algorithms in certain contexts but it has limits against other classes of problems. The lack of appropriate tools is a primary obstacle for the advance of most of the above models.

In this paper, we are interested in studying the resource augmentation model that compares online algorithms to a weaker adversary. Kalyanasundaram and Pruhs [20] proposed a *speed augmentation* model, where an online algorithm is compared against an adversary with slower processing speed. Phillips et al. [24] proposed the *machine augmentation* model in which the algorithm has more machines than the adversary. Recently, Choudhury et al. [8] introduced the *rejection model* where an online algorithm is allowed to discard a small fraction of jobs. The power of these models lies in the fact that many natural scheduling algorithms can be analyzed with respect to them, as well as, they have successfully provided theoretical evidence for heuristics in scheduling with good performance in practice. Although the models give more power to online algorithms, the connection especially between the latter and the two formers is unclear and the disconnection is emphasized by the fact that some algorithms have good performance in a model but have moderate behavior in others (for example, the problem of minimizing maximum flow-time [8]).

1.1 Generalized Resource Augmentation and Approach

In this paper, we introduce a generalized resource augmentation model that unifies all the previous ones. We also consider an approach based on duality for the systematic study of algorithms in this new model. To see that the duality is particularly appropriate, we first explain the model and the approach intuitively.

The weak duality in mathematical programming can be interpreted as a game between an algorithm and an adversary (the primal program against the dual one). The game is $L(x, \lambda)$, the standard Lagrangian function completely defined for a given problem, in which x and λ are primal and dual variables, respectively. The primal and dual variables are controlled and correspond to the strategies of the adversary and the algorithm, respectively. The goal of the algorithm is to choose a strategy λ among its feasible sets so as to minimize $L(x, \lambda)$ for whatever feasible strategy x of the adversary. The algorithm is c-competitive if it can choose dual variables λ^* in such a way that whatever the strategy (choice on x) of the adversary, the value $\min_x L(x, \lambda^*)$ is always within a desirable factor c of the objective due to the algorithm.

The resource augmentation models [8, 20] consist in giving more power to the algorithm. This idea could be perfectly interpreted as a game between an algorithm and an adversary in which additional power for the algorithm is reflected by better choices over its feasible strategy set.

Concretely, let us illustrate this idea for the speed augmentation and the rejection models. In several scheduling problems, a constraint originally states that the speed of a given machine is at most one. In the speed augmentation model, this constraint is relaxed such that the algorithm executes jobs at higher speed than that of the adversary. On other hand, the relaxation is of a different nature in the rejection model. Specifically, there are usually constraints ensuring that all jobs should be completed. In the rejection model, the algorithm is allowed to systematically reject a fraction of constraints whereas adversary should satisfy all of them. In both models, the algorithm optimizes the objective over a feasible domain whereas the adversary optimizes the same objective over a sub-domain with respect to the algorithm. This naturally leads to a more general model of resource augmentation.

▶ **Definition 1** (Generalized Resource Augmentation)**.** Consider an optimization problem that can be formalized by a mathematical program. Let $\mathcal{P}$ be the set of feasible solutions of the program and let $\mathcal{Q}$ be a subset of $\mathcal{P}$. In *generalized resource augmentation*, the performance of an algorithm is measured by the worst ratio between its objective over $\mathcal{P}$ and that of a solution which is optimized over $\mathcal{Q}$.

Based on the above definition, the polytope of the adversary in speed augmentation model is a strict subset of the algorithm's polytope since the speed constraint for the adversary is tighter. In the rejection model, the polytope of the adversary is also a strict subset of the algorithm's one since it contains more constraints. In addition, the generalized model allows us to introduce different kind of relaxations to the set of feasible solutions – each corresponding to different type of augmentations.

Together with the generalized model, we consider the following duality-based approach for the systematic design and analysis of algorithms. Let $\mathcal{P}$ and $\mathcal{Q}$ be the sets of feasible solutions for the algorithm and the adversary, respectively. By resource augmentation, $\mathcal{Q} \subset \mathcal{P}$. In order to study the performance of an algorithm, we consider the dual of the mathematical program consisting of the objective function optimized over $\mathcal{Q}$. By weak duality, the dual is a lower bound for any solution. Then, we bound the algorithm's cost by that of this dual. We exploit the resource augmentation properties (relation between $\mathcal{P}$ and $\mathcal{Q}$) to derive effective bounds. Intuitively, one needs to take the advantage from resource augmentation so as to raise the dual as much as possible — an impossible procedure without resource augmentation. As it has been shown in previous works and as we will see below, the duality approach is particularly appropriate to study problems with resource augmentation.

1.2 Our Contributions

We illustrate the applicability of the generalized model and the duality-based approach through a scheduling problem, in which jobs arrive online and they have to be scheduled non-preemptively on a set of unrelated machines. The objective is to minimize the average weighted time a job remains in the system (average weighted flow-time), where the weights represent the importance of the jobs. This is a well representative hard problem since no online algorithm with performance guarantee is known. Specifically, a strong lower bound of

$\Omega(\sqrt{n})$ exists even for the offline unweighted version of the problem on a single machine [21], where n is the number of jobs. For the online setting, any algorithm without resource augmentation has at least $\Omega(n)$ competitive ratio, even for single machine (as mentioned in [7]). Moreover, in contrast to the preemptive case, our first result (Lemma 2) shows that no deterministic algorithm has bounded competitive ratio when preemptions are not allowed even if we consider a single machine which has arbitrary large speed augmentation. However, the non-preemptive scheduling is a natural setting and it is important to have algorithms with theoretical explanation on their performance or a mean to classify algorithms.

In this paper, we present a competitive algorithm in a model which combines speed augmentation and the rejection model. Specifically, for arbitrary $0 < \epsilon_r < 1$ and $\epsilon_s > 0$, there exists a $O(1/(\epsilon_r \cdot \epsilon_s))$-competitive algorithm that uses machines with speed $(1 + \epsilon_s)$ and rejects jobs with at most ϵ_r-fraction of the total weight of all jobs. The design and analysis of the algorithm follow the duality approach. At the release time of any job j, the algorithm defines the dual variables associated to the job and assigns the job to some machine based on this definition. The value of the dual variables associated to a job j are selected in order to satisfy two key properties: (i) comprise the marginal increase of the total weighted flow-time due to the arrival of the job — the property that has been observed [2, 26] and has become more and more popular in dual-fitting for online scheduling; and (ii) capture the information for a future decision of the algorithm whether job j will be completed or rejected — a *novel* point in the construction of dual variables to exploit the power of rejection. Informally, to fulfill the second property, we introduce *prediction* terms to dual variables that at some point in the future will indicate whether the corresponding job would be rejected. Moreover, these terms are chosen so as to stabilize the schedule such that the properties of the assignment policy are always preserved (even with job rejections in the future). This allows us to maintain a non-migratory schedule.

Our algorithm dispatches jobs immediately at their release time — a desired property in scheduling. Besides, the algorithm processes jobs in the highest density first manner and interrupts a job only if it is rejected. In other words, no completed job has been interrupted during its execution. The algorithm is relatively simple, particularly for a single machine setting as there is no assignment policy. Therefore, the analysis of the algorithm in the generalized resource augmentation could be considered as a first step toward the theoretical explanation for the well-known observation that simple scheduling algorithms usually behave well and are widely used in practice.

Finally, we extend the above ideas to the more general objective of minimizing the weighted ℓ_k-norm of flow-time of jobs on unrelated machines. The ℓ_k-norm captures the notion of fairness between jobs since it removes the extreme outliers and hence it is more appropriate to balance the difference among the flow-times of individual jobs than the average function, which corresponds to the ℓ_1-norm (see for example [23]). For the ℓ_k-norm objective, we propose a primal-dual algorithm which is $(1 + \epsilon_s)$-speed $O\left(\frac{k^{(k+3)/k}}{\epsilon_r^{1/k}\epsilon_s^{(k+2)/k}}\right)$-competitive and it rejects jobs of total weight at most ϵ_r-fraction of the total weight of all jobs. The analysis for this problem is more technical and it is given in the Appendix.

1.3 Related Work

Duality based techniques have been extensively developed in approximation algorithms [27] and in online algorithms [6]. Specifically, Buchbinder and Naor [6] gave a general framework for online covering/packing LPs that applies to several fundamental problems in online computation. However, this framework encounters different issues to design competitive algorithms for online scheduling problems. Recently, Anand et al. [2] have proposed the use of dual-fitting techniques to study scheduling problems in the speed augmentation model. After this seminal paper, the duality approaches in online scheduling have been extended to a variety of problems, and has rapidly become standard techniques. The duality approaches have also led to the development of newer techniques for analyzing algorithm (see for example [2, 11, 15, 16, 18, 17, 26]). Informally, in the approach proposed in [2], the key step relies on the construction of a dual feasible solution in such a way that its dual objective is up to some bounded factor from that of the algorithm. In [2], the dual variables are carefully designed in order to encode the power of speed augmentation. Later on, Nguyen [26] explicitly formalized the comparison through the mean of Lagrangian functions between the algorithm and the adversary, with a tighter feasible domain due to speed augmentation. That point of view makes the framework in [2] effective to study non-convex formulations.

For the online non-preemptive scheduling problem of minimizing total weighted flow-time, no competitive algorithm for unrelated machines even with resource augmentation is known; that is in contrast to the preemptive version which has been well studied [2, 11, 16, 18, 17, 26]. For identical machines, Phillips et al. [24] gave a constant competitive algorithm that uses $m \log P$ machines (recall that the adversary uses m machines), where P is the ratio of the largest to the smallest processing time. Moreover, an $O(\log n)$-machine $O(1)$-speed algorithm that returns the optimal schedule has been presented in [24] for the unweighted flow-time objective. Epstein and van Stee [14] proposed an ℓ-machines $O(\min\{\sqrt[\ell]{P}, \sqrt[\ell]{n}\})$-competitive algorithm for the unweighted case on a single machine. This algorithm is optimal up to a constant factor for constant ℓ. For the offline non-preemptive single machine setting, Bansal et al. [4] gave a 12-speed $(2+\epsilon)$-approximation polynomial time algorithm. Recently, Im et al. [19] gave a $(1+\epsilon)$-speed $(1+\epsilon)$-approximation quasi-polynomial time algorithm for the setting of identical machines.

For the online non-preemptive scheduling problem of minimizing the weighted ℓ_k-norm of flow-time, to the best of our knowledge, no competitive algorithm is known. However, the problem in the preemptive setting has been widely studied. With speed augmentation, Anand et al. [2] gave a $(1+\epsilon)$-speed, $O(k/\epsilon^{2+1/k})$-competitive algorithm but the algorithm needs to know the speed $(1+\epsilon)$ in advance. Later on, Nguyen [26] derived an improved $(1+\epsilon)$-speed, $k/\epsilon^{1+1/k}$-competitive algorithm which does not need information on ϵ a priori. Recently, Choudhury et al. [9] have considered the (preemptive) problem in the restricted assignment setting in the rejection model. They have presented a $1/\epsilon^{O(1)}$-competitive algorithm that rejects at most ϵ fraction of the total job weight.

2 Problem Definition and Notation

We are given a set $\mathcal{M}$ of m unrelated machines. The jobs arrive *online*, that is we learn about the existence and the characteristics of a job only after its release. Let $\mathcal{J}$ denote the set of all jobs of our instance, which is not known a priori. Each job $j \in \mathcal{J}$ is characterized by its *release time* r_j, its *weight* w_j and if job j is executed on machine $i \in \mathcal{M}$ then it has a *processing time* p_{ij}. We study the *non-preemptive* setting, meaning that a job is considered to be completed only if it is fully processed in one machine without interruption during its execution. This definition allows the interruption of jobs. However, if the execution of a job is interrupted then it has to be processed entirely later on in order to be considered as completed. In this paper, we consider a stronger non-preemptive model according to which we are only allowed to interrupt a job if we reject it, i.e., we do not permit restarts. Moreover, each job has to be dispatched to one machine at its arrival and migration is not allowed. Given a schedule $\mathcal{S}$, we denote by C_j the *completion time* of the job j. Then, its *flow-time* is defined as $F_j = C_j - r_j$, that is the total time that j remains in the system. Our objective is to create a non-preemptive schedule that minimizes the total weighted flow-times of all jobs, i.e., $\sum_{j \in \mathcal{J}} w_j F_j$. A more general objective that implies fairness between jobs is the minimization of the weighted ℓ_k-norm of the flow-time of all jobs, i.e., $(\sum_{j \in \mathcal{J}} w_j F_j^k)^{1/k}$, where $k \geq 1$.

Let $\delta_{ij} = \frac{w_j}{p_{ij}}$ be the *density* of a job $j \in \mathcal{J}$ on machine $i \in \mathcal{M}$. Moreover, let $q_{ij}(t)$ be the remaining processing time at time t of a job $j \in \mathcal{J}$ which is dispatched at machine $i \in \mathcal{M}$. A job $j \in \mathcal{J}$ is called *pending* at time t, if it is already released at t but not yet completed, i.e., $r_j \leq t < C_j$. Finally, let $P = \max_{j,j' \in \mathcal{J}} \{p_j / p_{j'}\}$ and $W = \max_{j,j' \in \mathcal{J}} \{w_j / w_{j'}\}$.

3 Scheduling to Minimize Total Weighted Flow-time

In this section, we describe our primal-dual method for the online non-preemptive scheduling problem of minimizing the total weighted flow-time on unrelated machines. This problem admits no competitive algorithm even with speed augmentation as shown by the following lemma.

▶ **Lemma 2.** *For any speed augmentation $s \leq P^{1/10}$ or $s < W^{1/6}$, every deterministic algorithm has competitive ratio at least $\Omega(P^{1/10})$ or $\Omega(W^{1/6})$, respectively, even for the single machine problem.*

Proof. Let $s > 1$ be the speed of the machine; without loss of generality we assume that the machine speed for the adversary is 1. Let $R > s^2$ be an arbitrary (large) constant and fix an algorithm.

We consider the following instance. At time 1, a *long* job of processing time $2sR^3$ and weight 1 is released. After that, the phase 1 starts: at any time aR^3, starting with $a = 1$, a *short* job of processing time 1 and weight R is released. If the algorithm processes the long job during the whole interval $[aR^3, (a+1)R^3]$, then the adversary stops releasing jobs and the instance halts. Otherwise, the adversary will release a new short job at time $(a+1)R^3$ and so on, until $a = 2s - 1$. Then, the phase 2 begins immediately after phase 1: at any time aR^3 for $a \geq 2s$, a *small* job of processing time 1 and weight R^2 is released. Similarly, if the algorithm keeps processes the long job during the whole interval $[aR^3, (a+1)R^3]$, the instance halts. Otherwise, the adversary will release a new small job at time $(a+1)R^3$, until $a = 2sR^2$.

In the instance, we have at most $2s$ short jobs and $2sR^2$ small jobs. Observe that by using speed s, the algorithm cannot complete the long job between two consecutive release times of short or small jobs. We analyze the performance of the algorithm by considering different cases.

Case 1: the instance halts during phase 1. In this case, there is a $a \in \{1, 2, \ldots, 2s-1\}$ for which the algorithm keeps processing the long job during the whole interval $[aR^3, (a+1)R^3]$ and hence the short job released at aR^3 is not processed during that time interval. Thus, the weighted flow-time of the short job is at least $R \cdot R^3$. However, the adversary can execute immediately all short jobs at their release times and process the long job in the end. The total weighted flow-time of all short jobs is at most $2sR$. The long job would be started no later than the time where phase 1 terminates, which is $(2s-1)R^3 + 1$. So the weighted flow-time of the long job is at most $4sR^3$. Therefore, the competitive ratio is at least $\Omega(R/s)$.

Case 2: the instance halts during phase 2. In this case, there is a $a \in \{2s, 2s+1, \ldots, 2sR^2\}$ for which the algorithm keeps processing the long job during the whole interval $[aR^3, (a+1)R^3]$ and hence the small job released at aR^3 is not processed during that time interval. We proceed similarly as in the previous case. The weighted flow-time of this small job is at least $R^2 \cdot R^3$. Nevertheless, the adversary can process the long job during $[1, 2sR^3 + 1]$, execute small jobs at their release time (except the first one which starts 1 unit of time after its release time) and execute all short jobs during the interval $[2sR^3 + 2, 5sR^3]$ whenever a small job is not executed. This is a feasible schedule since the number of short jobs is $(2s - 1) < 3R^3 - 5$ (note that there are 2 small jobs released during $[2sR^3 + 2, 5sR^3]$). By this strategy, the weighted flow-time of the long job is $2sR^3 + 1$. The total weighted flow-time of small jobs is at most $2sR^2 \cdot R^2$. The total weighted flow-time of short jobs is at most $2s \cdot R \cdot 5sR^3$. Hence, the cost of the adversary is at most $14s^2R^4$ and the competitive ratio is at least $\Omega(R/s^2)$.

Case 3: the instance halts at the end of phase 2. The algorithm executes the long job after the end of phase 2 and hence this job is completed at later than $2sR^5$; so its weighted flow-time is at least $2sR^5$. The adversary can apply the same strategy as in Case 2 with total cost $14s^2R^4$. Therefore, the competitive ratio is at least $\Omega(R/s)$.

In summary, the competitive ratio is at least $\Omega(R/s^2)$. Recall that P and W are the largest ratio between processing times and that between weights, respectively. In this instance, $P = 2sR^3$ and $W = R^2$ respectively. By a simple estimation (setting $R = s^3$), for any speed $s \leq P^{1/10}$ the competitive ratio is at least $\Omega(P^{1/10})$; and for $s \leq W^{1/6}$, the competitive ratio is at least $\Omega(W^{1/6})$. ◀

In the following, we study the problem in the resource augmentation model with speed augmentation and rejection.

3.1 Linear Programming Formulation

For each machine $i \in \mathcal{M}$, job $j \in \mathcal{J}$ and time $t \geq r_j$, we introduce a binary variable $x_{ij}(t)$ which indicates if j is processed on i at time t. We consider the following linear programming formulation. Note that the objective value of this linear program is at most twice that of the optimal preemptive schedule.

$$\min \sum_{i\in\mathcal{M}} \sum_{j\in\mathcal{J}} \int_{r_j}^{\infty} \delta_{ij}\,(t - r_j + p_{ij}) x_{ij}(t)dt$$

$$\sum_{i\in\mathcal{M}} \int_{r_j}^{\infty} \frac{x_{ij}(t)}{p_{ij}} dt \geq 1 \quad \forall j \in \mathcal{J} \tag{1}$$

$$\sum_{j\in\mathcal{J}} x_{ij}(t) \leq 1 \quad \forall i \in \mathcal{M}, t \tag{2}$$

$$x_{ij}(t) \in \{0,1\} \quad \forall i \in \mathcal{M}, j \in \mathcal{J}, t \geq r_j$$

After relaxing the integrality constraints, we get the following dual program.

$$\max \sum_{j\in\mathcal{J}} \lambda_j - \sum_{i\in\mathcal{M}} \int_0^{\infty} \gamma_i(t)dt$$

$$\frac{\lambda_j}{p_{ij}} - \gamma_i(t) \leq \delta_{ij}\,(t - r_j + p_{ij}) \quad \forall i \in \mathcal{M}, j \in \mathcal{J}, t \geq r_j \tag{3}$$

We will interpret the resource augmentation models in the above primal and dual programs as follows. In the speed augmentation model, we assume that all machines in the schedule of our algorithm run with speed 1, while in adversary's schedule they run at a speed $a < 1$. This can be interpreted in the primal linear program by modifying the constraint (2) to be $\sum_{j\in\mathcal{J}} x_{ij}(t) \leq a$. Intuitively, each machine in the adversary's schedule can execute jobs with speed at most a at each time t. The above modification in the primal program reflects to the objective of the dual program which becomes $\sum_{j\in\mathcal{J}} \lambda_j - a\sum_{i\in\mathcal{M}} \int_0^\infty \gamma_i(t)dt$. In the rejection model, we assume that the algorithm is allowed to reject some jobs. This can be interpreted in the primal linear program by summing up only on the set of the non rejected jobs, i.e., the algorithm does not have to satisfy the constraint (1) for rejected jobs. Hence the objective becomes $\sum_{i\in\mathcal{M}}\sum_{j\in\mathcal{J}\setminus\mathcal{R}} \int_{r_j}^\infty \delta_{ij}\left(t - r_j + p_{ij}\right)dt$. Concluding, our algorithm rejects a set $\mathcal{R}$ of jobs, uses machines with speed $1/a$ times faster than that of the adversary and, by using weak duality, has a competitive ratio at most

$$\frac{\sum_{i\in\mathcal{M}}\sum_{j\in\mathcal{J}\setminus\mathcal{R}} \int_{r_j}^\infty \delta_{ij}(t - r_j + p_{ij})dt}{\sum_{j\in\mathcal{J}} \lambda_j - a\sum_{i\in\mathcal{M}} \int_0^\infty \gamma_i(t)dt}.$$

3.2 Algorithm and Dual Variables

We describe next the scheduling, the rejection and the dispatching policies of our algorithm which we denote by $\mathcal{A}$. In parallel, we give the intuition about the definition of the dual variables in a primal-dual way. Let $\epsilon_s > 0$ and $0 < \epsilon_r < 1$ be constants arbitrarily small. Intuitively, ϵ_s and ϵ_r stand for the speed augmentation and the rejection fraction of our algorithm, respectively. In what follows, we assume that in the schedule created by $\mathcal{A}$ all machines run with speed 1, while in the adversary's schedule they run by speed $\frac{1}{1+\epsilon_s}$.

Each job is immediately dispatched to a machine upon its arrival. We denote by $Q_i(t)$ the set of pending jobs at time t dispatched to machine $i \in \mathcal{M}$, i.e., the set of jobs dispatched to i that have been released but not yet completed and have not been rejected at t. Our *scheduling policy* for each machine $i \in \mathcal{M}$ is the following: at each time t when the machine i becomes idle or has just completed or interrupted some job, we start executing on i the job $j \in Q_i(t)$ such that j has the largest density in $Q_i(t)$, i.e., $j = \text{argmax}_{j'\in Q_i(t)}\{\delta_{ij'}\}$. In case of ties, we select the job that arrived earliest.

When a machine $i \in \mathcal{M}$ starts executing a job $k \in \mathcal{J}$, we introduce a counter v_k (associated to job k) which is initialized to zero. Each time when a job $j \in \mathcal{J}$ with $\delta_{ij} > \delta_{ik}$ is released during the execution of k and j is dispatched to i, we increase v_k by w_j. Then, the *rejection policy* is the following: we interrupt the execution of the job k and we reject it the first time where $v_k > \frac{w_k}{\epsilon_r}$.

Let Δ_{ij} be the increase in the total weighted flow-time occurred in the schedule of our algorithm if we assign a new job $j \in \mathcal{J}$ to machine i, following the above scheduling and rejection policies. Assuming that the job $k \in \mathcal{J}$ is executed on i at time r_j, we have that

$$\Delta_{ij} = \begin{cases} w_j\left(q_{ik}(r_j) + \displaystyle\sum_{\substack{\ell\in Q_i(r_j)\setminus\{k\}:\\ \delta_{i\ell}\geq\delta_{ij}}} p_{i\ell}\right) + p_{ij}\displaystyle\sum_{\substack{\ell\in Q_i(r_j)\setminus\{k\}:\\ \delta_{i\ell}<\delta_{ij}}} w_\ell & \text{if } v_k + w_j \leq \frac{w_k}{\epsilon_r}, \\ w_j\displaystyle\sum_{\substack{\ell\in Q_i(r_j):\\ \delta_{i\ell}\geq\delta_{ij}}} p_{i\ell} + \left(p_{ij}\displaystyle\sum_{\substack{\ell\in Q_i(r_j):\\ \delta_{i\ell}<\delta_{ij}}} w_\ell - q_{ik}(r_j)\displaystyle\sum_{\substack{\ell\in Q_i(r_j)\cup\{k\}:\\ \ell\neq j}} w_\ell\right) & \text{otherwise.} \end{cases}$$

where, in both cases, the first term corresponds to the weighted flow-time of the job j if it is dispatched to i and the second term corresponds to the change of the weighted flow-time for the jobs in $Q_i(r_j)$. Note that, the second case corresponds to the rejection of k and hence we remove the term $w_j q_{ik}(r_j)$ in the weighted flow-time of j, while the flow-time of each pending job is reduced by $q_{ik}(r_j)$.

In the definition of the dual variables, we aim to charge to job j the increase Δ_{ij} in the total weighted flow-time occurred by the dispatching of j in machine i, except from the quantity $w_j q_{ik}(r_j)$ which will be charged to job k, if $\delta_{ij} > \delta_{ik}$. However, we will use the dual variables (in the primal-dual sense) to guide the assignment policy. Hence the charges have to be distributed in a consistent manner to the assignment decisions of jobs to machines in the past. So in order to do the charging, we introduce a *prediction term*: at the arrival of each job j we charge to it an additional quantity of $\frac{w_j}{\epsilon_r} p_{ij}$. By doing this, the consistency is maintained by the rejection policy: if the charge from future jobs exceeds the prediction term of some job then the latter will be rejected.

Based on the above, we define

$$\lambda_{ij} = \begin{cases} \frac{w_j}{\epsilon_r} p_{ij} + w_j \sum\limits_{\ell \in Q_i(r_j):\delta_{i\ell} \geq \delta_{ij}} p_{i\ell} + p_{ij} \sum\limits_{\ell \in Q_i(r_j)\setminus\{k\}:\delta_{i\ell} < \delta_{ij}} w_\ell & \text{if } \delta_{ij} > \delta_{ik} \\ \frac{w_j}{\epsilon_r} p_{ij} + w_j \left(q_{ik}(r_j) + \sum\limits_{\ell \in Q_i(r_j)\setminus\{k\}:\delta_{i\ell} \geq \delta_{ij}} p_{i\ell} \right) + p_{ij} \sum\limits_{\ell \in Q_i(r_j):\delta_{i\ell} < \delta_{ij}} w_\ell & \text{otherwise} \end{cases}$$

which represents the total charge for job j if it is dispatched to machine i. Note that the only difference in the two cases of the definition of λ_{ij} is that we charge the quantity $w_j q_{ik}(r_j)$ to j only if $\delta_{ij} \leq \delta_{ik}$. Moreover, we do not consider the negative quantity that appears in the second case of Δ_{ij}. Intuitively, we do not decrease our estimation for the completion times of pending jobs when a job is rejected. The *dispatching policy* is the following: dispatch j to the machine $i^* = \text{argmin}_{i \in \mathcal{M}}\{\lambda_{ij}\}$. Intuitively, a part of Δ_{ij} may be charged to job k, and more specifically to the prediction part of λ_{ik}. However, we do not allow to exceed this prediction by applying rejection. In other words, the rejection policy can be re-stated informally as: we reject k just before we exceed the prediction charging part in λ_{ik}.

In order to keep track of the negative terms in Δ_{ij}, for each job $j \in \mathcal{J}$ we denote by D_j the set of jobs that are rejected by the algorithm after the release time of j and before its completion or rejection (including j in case it is rejected), that is the jobs that cause a decrease to the flow time of j. Moreover, we denote by j_k the job released at the moment we reject a job $k \in \mathcal{R}$. Then, we say that a job $j \in \mathcal{J}$ which is dispatched to machine $i \in \mathcal{M}$ is *definitively finished* $\sum_{k \in D_j} q_{ik}(r_{j_k})$ time after its completion or rejection. Let $U_i(t)$ be the set of jobs that are dispatched to machine $i \in \mathcal{M}$, they are already completed or rejected at a time before t, but they are not yet definitively finished at t.

It remains to formally define the dual variables. At the arrival of a job $j \in \mathcal{J}$, we set $\lambda_j = \frac{\epsilon_r}{1+\epsilon_r} \min_{i \in \mathcal{M}}\{\lambda_{ij}\}$ and we never change λ_j again. Let $W_i(t)$ be the total weight of jobs dispatched to machine $i \in \mathcal{M}$ in the schedule of $\mathcal{A}$, and either they are pending at t or they are not yet definitively finished at t, i.e., $W_i(t) = \sum_{\ell \in Q_i(t) \cup U_i(t)} w_\ell$. Then, we define $\gamma_i(t) = \frac{\epsilon_r}{1+\epsilon_r} W_i(t)$. Note that $\gamma_i(t)$ is updated during the execution of $\mathcal{A}$. Specifically, given any fixed time t, $\gamma_i(t)$ may increase if a new job j' arrives at any time $r_{j'} \in [r_j, t)$. However, $\gamma_i(t)$ does never decrease in the case of rejection since the jobs remain in $U_i(t)$ for a sufficient time after their completion or rejection.

3.3 Analysis

We first prove the following lemma which guarantees the feasibility of the dual constraint using the above definition of the dual variables.

▶ **Lemma 3.** *For every machine $i \in \mathcal{M}$, job $j \in \mathcal{J}$ and time $t \geq r_j$, the dual constraint is feasible, that is*

$$\frac{\lambda_j}{p_{ij}} - \gamma_i(t) - \delta_{ij}\left(t - r_j + p_{ij}\right) \leq 0\,.$$

Proof. Fix a machine i. We have observed above that, for any fixed time $t \geq r_j$, as long as new jobs arrive, the value of $\gamma_i(t)$ may only increase. Then, it is sufficient to prove the dual constraints for the job j using the values of $\gamma_i(t)$, $Q_i(t)$, $U_i(t)$ and $W_i(t)$ as these are defined at time r_j. Let k be the job executed in machine i at r_j. We have the following cases.

Case 1: $\delta_{ij} > \delta_{ik}$

In this case we may have rejected the job k at r_j. By the definitions of λ_j and λ_{ij}, we have

$$\begin{aligned}\frac{\lambda_j}{p_{ij}} &\leq \frac{\epsilon_r}{(1+\epsilon_r)}\frac{\lambda_{ij}}{p_{ij}} = \frac{\epsilon_r}{1+\epsilon_r}\left(\frac{w_j}{\epsilon_r} + \delta_{ij}\sum_{\ell\in Q_i(r_j):\delta_{i\ell}\geq\delta_{ij}} p_{i\ell} + \sum_{\ell\in Q_i(r_j)\setminus\{k\}:\delta_{i\ell}<\delta_{ij}} w_\ell\right)\\ &= \frac{\epsilon_r}{1+\epsilon_r}\left(\frac{w_j}{\epsilon_r} + \delta_{ij}\sum_{\ell\in Q_i(r_j)\setminus\{j\}:\delta_{i\ell}\geq\delta_{ij}} p_{i\ell} + w_j + \sum_{\ell\in Q_i(r_j)\setminus\{k\}:\delta_{i\ell}<\delta_{ij}} w_\ell\right)\\ &= w_j + \frac{\epsilon_r}{1+\epsilon_r}\left(\delta_{ij}\sum_{\ell\in Q_i(r_j)\setminus\{j\}:\delta_{i\ell}\geq\delta_{ij}} p_{i\ell} + \sum_{\ell\in Q_i(r_j)\setminus\{k\}:\delta_{i\ell}<\delta_{ij}} w_\ell\right)\end{aligned}$$

By the definition of $\gamma_i(t)$ we get

$$\begin{aligned}\gamma_i(t) + \delta_{ij}(t - r_j + p_{ij}) &= \frac{\epsilon_r}{1+\epsilon_r}\sum_{\ell\in Q_i(t)\cup U_i(t)} w_\ell + \delta_{ij}(t-r_j) + w_j\\ &\geq \frac{\epsilon_r}{1+\epsilon_r}\left(\sum_{\ell\in Q_i(t)\cup U_i(t)} w_\ell + \delta_{ij}(t-r_j)\right) + w_j\end{aligned}$$

Thus, it remains to show that

$$\delta_{ij}\cdot\sum_{\substack{\ell\in Q_i(r_j)\setminus\{j\}:\\ \delta_{i\ell}\geq\delta_{ij}}} p_{i\ell} + \sum_{\substack{\ell\in Q_i(r_j)\setminus\{k\}:\\ \delta_{i\ell}<\delta_{ij}}} w_\ell \leq \sum_{\ell\in Q_i(t)\cup U_i(t)} w_\ell + \delta_{ij}(t-r_j) \qquad (4)$$

Let $\tilde{C}_j = r_j + \sum_{\ell\in Q_i(r_j):\delta_{i\ell}\geq\delta_{ij}} p_{i\ell}$ (if k is rejected) or $\tilde{C}_j = r_j + q_{ik}(r_j) + \sum_{\ell\in Q_i(r_j):\delta_{i\ell}\geq\delta_{ij}} p_{i\ell}$ (otherwise) be the estimated completion time of j at time r_j if it is dispatched to machine i.

Case 1.1: $t \leq \tilde{C}_j$. By the definition of $U_i(t)$, all jobs in $Q_i(r_j)$ with $\delta_{i\ell} < \delta_{ij}$ still exist in $Q_i(t)\cup U_i(t)$. Moreover, for every job $\ell \in Q_i(r_j)\setminus(Q_i(t)\cup U_i(t)\cup\{k\})$ it holds that $\delta_{i\ell}\geq\delta_{ij}$, since ℓ is processed before j by the algorithm. Then, by splitting the first term of the left-hand side of (4) we get

$$\begin{aligned}
&\delta_{ij} \cdot \sum_{\ell \in Q_i(r_j)\setminus\{j\}:\delta_{i\ell}\geq\delta_{ij}} p_{i\ell} + \sum_{\ell\in Q_i(r_j)\setminus\{k\}:\delta_{i\ell}<\delta_{ij}} w_\ell \\
&\quad = \delta_{ij} \sum_{\ell\in Q_i(r_j)\setminus(Q_i(t)\cup U_i(t)\cup\{k\})} p_{i\ell} + \delta_{ij} \sum_{\substack{\ell\in(Q_i(r_j)\cap(Q_i(t)\cup U_i(t)))\setminus\{j\}:\\ \delta_{i\ell}\geq\delta_{ij}}} p_{i\ell} \\
&\qquad\qquad + \sum_{\substack{\ell\in(Q_i(r_j)\cap(Q_i(t)\cup U_i(t)))\setminus\{k\}:\\ \delta_{i\ell}<\delta_{ij}}} w_\ell \\
&\quad \leq \delta_{ij} \sum_{\ell\in Q_i(r_j)\setminus(Q_i(t)\cup U_i(t)\cup\{k\})} p_{i\ell} + \sum_{\substack{\ell\in(Q_i(t)\cup U_i(t))\setminus\{j\}:\\ \delta_{i\ell}\geq\delta_{ij}}} w_\ell + \sum_{\substack{\ell\in(Q_i(t)\cup U_i(t))\setminus\{k\}:\\ \delta_{i\ell}<\delta_{ij}}} w_\ell \\
&\quad \leq \delta_{ij}(t-r_j) + \sum_{\ell\in Q_i(t)\cup U_i(t)} w_\ell
\end{aligned}$$

where the first inequality is due to $\delta_{ij}p_{i\ell} \leq w_\ell$ for each $\ell \in Q_i(t)\cup U_i(t)$ with $\delta_{i\ell}\geq\delta_{ij}$, while the latter one holds since the set of jobs $Q_i(r_j)\setminus(Q_i(t)\cup U_i(t)\cup\{k\})$ corresponds to the set of pending jobs at r_j that start their execution after r_j and are definitively finished before t.

Case 1.2: $t > \tilde{C}_j$. By splitting the second term of the left-hand side of (4) we get

$$\begin{aligned}
&\delta_{ij} \cdot \sum_{\ell \in Q_i(r_j)\setminus\{j\}:\delta_{i\ell}\geq\delta_{ij}} p_{i\ell} + \sum_{\ell\in Q_i(r_j)\setminus\{k\}:\delta_{i\ell}<\delta_{ij}} w_\ell \\
&\quad = \delta_{ij} \sum_{\substack{\ell\in Q_i(r_j)\setminus\{j\}:\\ \delta_{i\ell}\geq\delta_{ij}}} p_{i\ell} + \sum_{\substack{\ell\in Q_i(r_j)\setminus(Q_i(t)\cup U_i(t)\cup\{k\}):\\ \delta_{i\ell}<\delta_{ij}}} w_\ell + \sum_{\substack{\ell\in Q_i(r_j)\cap(Q_i(t)\cup U_i(t)):\\ \delta_{i\ell}<\delta_{ij}}} w_\ell \\
&\quad \leq \delta_{ij}(\tilde{C}_j - r_j) + \delta_{ij} \sum_{\ell\in Q_i(r_j)\setminus(Q_i(t)\cup U_i(t)\cup\{k\}):\delta_{i\ell}<\delta_{ij}} p_{i\ell} + \sum_{\ell\in Q_i(t)\cup U_i(t)} w_\ell \\
&\quad \leq \delta_{ij}(\tilde{C}_j - r_j) + \delta_{ij}(t-\tilde{C}_j) + \sum_{\ell\in Q_i(t)\cup U_i(t)} w_\ell
\end{aligned}$$

where the first inequality follows by the definition of $\tilde{C}_j$ and since $w_\ell < \delta_{ij}p_{i\ell}$ for each $\ell \in Q_i(r_j)$ with $\delta_{i\ell} < \delta_{ij}$, while the second inequality follows since the set of jobs in $Q_i(r_j)\setminus(Q_i(t)\cup U_i(t)\cup\{k\})$ with $\delta_{i\ell}<\delta_{ij}$ corresponds to the pending jobs at r_j which at time r_j have been scheduled to be executed during the interval $[\tilde{C}_j, t)$.

Case 2: $\delta_{ij} \leq \delta_{ik}$

In this case the job k is not rejected at the arrival of job j. By using the same arguments as in Case 1, we have

$$\frac{\lambda_j}{p_{ij}} \leq w_j + \frac{\epsilon_r}{1+\epsilon_r}\left(\delta_{ij}q_{ik}(r_j) + \delta_{ij}\sum_{\ell\in Q_i(r_j)\setminus\{k,j\}:\delta_{i\ell}\geq\delta_{ij}} p_{i\ell} + \sum_{\ell\in Q_i(r_j):\delta_{i\ell}<\delta_{ij}} w_\ell\right)$$

Let $\tilde{C}_k = r_j + q_{ik}(r_j)$ be the estimated completion time of k at time r_j. We consider different scenarios.

Case 2.1: $t \le \tilde{C}_k$. In this case, it holds that $w_k \ge \delta_{ij} p_k \ge \delta_{ij} q_{ik}(r_j)$. Then,

$$\gamma_i(t) + \delta_{ij}\left(t - r_j + p_{ij}\right) \ge \frac{\epsilon_r}{1+\epsilon_r} \sum_{\ell \in Q_i(t) \cup U_i(t)} w_\ell + w_j \ge \frac{\epsilon_r}{1+\epsilon_r} \sum_{\ell \in Q_i(r_j)} w_\ell + w_j$$

$$\ge \frac{\epsilon_r}{1+\epsilon_r} \left(\sum_{\ell \in Q_i(r_j) \setminus \{k\}} w_\ell + w_k \right) + w_j \ge \frac{\epsilon_r}{1+\epsilon_r} \left(\sum_{\ell \in Q_i(r_j) \setminus \{k\}} w_\ell + \delta_{ij} q_{ik}(r_j) \right) + w_j$$

Hence, it remains to show

$$\delta_{ij} \sum_{\ell \in Q_i(r_j) \setminus \{k,j\} : \delta_{i\ell} \ge \delta_{ij}} p_{i\ell} + \sum_{\ell \in Q_i(r_j) : \delta_{i\ell} < \delta_{ij}} w_\ell - \sum_{\ell \in Q_i(r_j) \setminus \{k\}} w_\ell \le 0$$

which directly holds as $\delta_{ij} p_{i\ell} \le w_\ell$ for any job $j \in Q_i(r_j)$ with $\delta_{i\ell} \ge \delta_{ij}$.

Case 2.2: $t > \tilde{C}_k$. By the definition of $\gamma_i(t)$ we get

$$\gamma_i(t) + \delta_{ij}\left(t - r_j + p_{ij}\right) \ge \frac{\epsilon_r}{1+\epsilon_r} \left(\sum_{\ell \in Q_i(t) \cup U_i(t)} w_\ell + \delta_{ij} q_{ik}(r_j) + \delta_{ij}(t - r_j) \right) + w_j$$

Hence it suffices again to prove (4), which has been proved previously. ◀

The following lemma guarantees that, by the rejection policy, the algorithm rejects at most a small fraction of the total job weight.

▶ **Lemma 4.** *For the set $\mathcal{R}$ of jobs rejected by the algorithm $\mathcal{A}$ it holds that $\sum_{j \in \mathcal{R}} w_j \le \epsilon_r \sum_{j \in \mathcal{J}} w_j$.*

Proof. Each job $j \in \mathcal{J}$ dispatched to machine $i \in \mathcal{M}$ may increase only the counter v_k of the job $k \in \mathcal{J}$ that was executed on i at r_j. In other words, each job j may be charged to at most one other job. Besides, we reject a job k the first time where $v_k > \frac{w_k}{\epsilon_r}$, meaning that the total weight of jobs charged to k is at least $\frac{w_k}{\epsilon_r}$. Hence, the total weight of rejected jobs is at most an ϵ_r-fraction of the total weight of all jobs in the instance. ◀

▶ **Theorem 5.** *Given any $\epsilon_s > 0$ and $\epsilon_r \in (0,1)$, $\mathcal{A}$ is a $(1+\epsilon_s)$-speed $\frac{2(1+\epsilon_r)(1+\epsilon_s)}{\epsilon_r \epsilon_s}$-competitive algorithm that rejects jobs of total weight at most $\epsilon_r \sum_{j \in \mathcal{J}} w_j$.*

Proof. By Lemma 3, the proposed dual variables constitute a feasible solution for the dual program. By definition, the algorithm $\mathcal{A}$ uses for any machine at any time a factor of $1+\epsilon_s$ higher speed than that of the adversary. By Lemma 4, $\mathcal{A}$ rejects jobs of total weight at most $\epsilon_r \sum_{j \in \mathcal{J}} w_j$. Hence, it remains to give a lower bound for the dual objective based on the proposed dual variables.

We denote by $F_j^{\mathcal{A}}$ the flow-time of a job $j \in \mathcal{J} \setminus \mathcal{R}$ in the schedule of $\mathcal{A}$. By slightly abusing the notation, for a job $k \in \mathcal{R}$, we will also use $F_k^{\mathcal{A}}$ to denote the total time passed after r_k until deciding to reject a job k, that is, if k is rejected at the release of the job $j \in \mathcal{J}$ then $F_k^{\mathcal{A}} = r_j - r_k$. Denote by j_k the job released at the moment we decided to reject k, i.e., for the counter v_k before the arrival of job j_k we have that $w_k/\epsilon_r - w_{j_k} < v_k < w_k/\epsilon_r$.

Let Δ_j be the total increase in the flow-time caused by the arrival of the job $j \in \mathcal{J}$, i.e., $\Delta_j = \Delta_{ij}$, where $i \in \mathcal{M}$ is the machine to which j is dispatched by $\mathcal{A}$. By the definition of

λ_j's, we have

$$\begin{aligned}\sum_{j\in\mathcal{J}}\lambda_j &\geq \frac{\epsilon_r}{1+\epsilon_r}\left(\sum_{j\in\mathcal{J}}\Delta_j + \sum_{k\in\mathcal{R}}\left(q_{ik}(r_{j_k})\sum_{\ell\in Q_i(r_{j_k})\cup\{k\}:\ell\neq j_k} w_\ell\right)\right)\\ &= \frac{\epsilon_r}{1+\epsilon_r}\left(\sum_{j\in\mathcal{J}} w_jF_j^{\mathcal{A}} + \sum_{j\in\mathcal{J}}\left(w_j\sum_{k\in D_j} q_{ik}(r_{j_k})\right)\right)\end{aligned}$$

where the inequality comes from the fact that if $\delta_{ij} > \delta_{ik}$ then in the prediction part of the running job k at r_j we charge the quantity w_jp_k instead of $w_jq_k(r_j)$ which is the real contribution of k to the weighted flow-time of job j. By the definition of $\gamma_i(t)$'s, we have

$$\begin{aligned}\sum_{i\in\mathcal{M}}\int_0^\infty \gamma_i(t)dt &= \frac{\epsilon_r}{1+\epsilon_r}\left(\sum_{i\in\mathcal{M}}\int_0^\infty\sum_{\ell\in Q_i(t)} w_\ell dt + \sum_{i\in\mathcal{M}}\int_0^\infty\sum_{\ell\in U_i(t)} w_\ell dt\right)\\ &= \frac{\epsilon_r}{1+\epsilon_r}\left(\sum_{j\in\mathcal{J}} w_jF_j^{\mathcal{A}} + \sum_{j\in\mathcal{J}}\left(w_j\sum_{k\in D_j} q_{ik}(r_{j_k})\right)\right)\end{aligned}$$

since the set $Q_i(t)$ contains the pending jobs at time t dispatched on machine i, while each job $j\in\mathcal{J}$ appears by definition in $U_i(t)$ for $\sum_{k\in D_j} q_{ik}(r_{j_k})$ time after its completion or rejection.

Therefore, the proposed assignment for the dual variables leads to the following value of the dual objective

$$\begin{aligned}&\sum_{j\in\mathcal{J}}\lambda_j - \frac{1}{1+\epsilon_s}\sum_{i\in\mathcal{M}}\int_0^\infty\gamma_i(t)dt\\ &\geq \frac{\epsilon_r\epsilon_s}{(1+\epsilon_r)(1+\epsilon_s)}\left(\sum_{j\in\mathcal{J}} w_jF_j^{\mathcal{A}} + \sum_{j\in\mathcal{J}}\left(w_j\sum_{k\in D_j} q_{ik}(r_{j_k})\right)\right)\\ &\geq \frac{\epsilon_r\epsilon_s}{(1+\epsilon_r)(1+\epsilon_s)}\sum_{j\in\mathcal{J}} w_jF_j^{\mathcal{A}} \geq \frac{\epsilon_r\epsilon_s}{(1+\epsilon_r)(1+\epsilon_s)}\sum_{j\in\mathcal{J}\setminus\mathcal{R}} w_jF_j^{\mathcal{A}}\end{aligned}$$

Since the objective value of our linear program is at most twice the value of an optimal non-preemptive schedule, the theorem follows. ◀

4 ℓ_k-norm on Unrelated Machines

In this section, we study the objective of minimizing the weighted ℓ_k-norm of flow-times. Let $\epsilon_s > 0$ and $0 < \epsilon_r < 1$ be the speed augmentation and the rejection fraction of our algorithm, respectively. For each machine $i\in\mathcal{M}$, job $j\in\mathcal{J}$ and time $t\geq r_j$, we introduce a binary variable $x_{ij}(t)$ which indicates if j is processed on i at time t. We consider the following linear programming formulation. Note that the optimal objective value of this linear program is at most $\frac{4(20k)^{k+3}}{\epsilon_s^{k+1}}$ times the total weighted k-th power of flow-time of jobs in an optimal preemptive schedule.

$$\min \sum_{i\in\mathcal{M}}\sum_{j\in\mathcal{J}}\int_{r_j}^{\infty} \frac{2(20k)^{k+3}}{\epsilon_s^{k+1}}\delta_{ij}\left[(t-r_j)^k + p_{ij}^k\right]x_{ij}(t)dt$$
$$\sum_{i\in\mathcal{M}}\int_{r_j}^{\infty}\frac{x_{ij}(t)}{p_{ij}}dt \geq 1 \quad \forall j\in\mathcal{J}$$
$$\sum_{j\in\mathcal{J}} x_{ij}(t) \leq 1 \quad \forall i\in\mathcal{M}, t$$
$$x_{ij}(t)\in\{0,1\} \quad \forall i\in\mathcal{M}, j\in\mathcal{J}, t\geq r_j$$

After relaxing the integrality constraints, we get the following dual program.

$$\max \sum_{j\in\mathcal{J}}\lambda_j - \sum_{i\in\mathcal{M}}\int_0^{\infty}\gamma_i(t)dt$$
$$\frac{\lambda_j}{p_{ij}} - \gamma_i(t) \leq \frac{2(20k)^{k+3}}{\epsilon_s^{k+1}}\delta_{ij}\left[(t-r_j)^k + p_{ij}^k\right] \quad \forall i\in\mathcal{M}, j\in\mathcal{J}, t\geq r_j$$
$$\lambda_j, \gamma_i(t) \geq 0 \quad \forall i\in\mathcal{M}, j\in\mathcal{J}, t$$

The algorithm follows the same ideas as the one in the previous section for the objective of minimizing the total weighted flow-time. Each job is immediately dispatched to a machine upon its arrival. Recall that $Q_i(t)$ is the set of pending jobs at time t dispatched to machine $i\in\mathcal{M}$, i.e., the set of jobs dispatched to i that have been released but not yet completed and have not been rejected at t. Our *scheduling policy* for each machine $i\in\mathcal{M}$ is the same as the previous one: at each time t when the machine i becomes idle or has just completed or interrupted some job, we start executing on i the job $j\in Q_i(t)$ of largest density, i.e., $j = \text{argmax}_{j'\in Q_i(t)}\{\delta_{ij'}\}$. In case of ties, we select the job that arrived the earliest.

When a machine $i\in\mathcal{M}$ starts executing a job $u\in\mathcal{J}$, a counter v_u associated to job u is initialized to zero. Each time when a job $j\in\mathcal{J}$ with $\delta_{ij}>\delta_{iu}$ is released during the execution of u and j is dispatched to i, we increase v_u by w_j. Then, the *rejection policy* is the following: we interrupt the execution of the job k and we reject it the first time where $v_u > \frac{w_u}{\epsilon_r}$. As before we define the set of rejected jobs D_j which causes a decrease to the flow time of j and we say that j is *definitively finished* $\sum_{u\in D_j} q_{iu}(r_{j_u})$ time after its completion or rejection. However, j does not appear to the set of pending jobs $Q_i(t)$ for any t after its completion or rejection. Recall that $U_i(t)$ is the set of jobs that have been marked finished at a time before t in machine i but they have not yet been definitively finished at t. For a job $j\in Q_i(t)\cup U_i(t)$, let $F_j(t)$ be the *remaining time* of j from t to to the moment it is definitively finished.

Let Δ_{ij} be the increase in the total weighted k-th power of flow-time occurred in the schedule of our algorithm if we assign a new job $j\in\mathcal{J}$ to machine i, following the above scheduling and rejection policies. Assuming that the job $u\in\mathcal{J}$ is executed on i at time r_j, we have that, if $v_u + w_j \leq \frac{w_u}{\epsilon_r}$ then

$$\Delta_{ij} = w_j\Bigg(q_{iu}(r_j) + \sum_{\substack{a\in Q_i(r_j)\cup\{j\}\setminus\{u\}:\\ \delta_{ia}\geq\delta_{ij}}} p_{ia}\Bigg)^k + \sum_{\substack{a\in Q_i(r_j)\setminus\{u\}:\\ \delta_{ia}<\delta_{ij}}} w_a\left[\big(F_a(r_j)+p_{ij}\big)^k - F_a(r_j)^k\right],$$

otherwise,

$$\Delta_{ij} = w_j\Bigg(\sum_{\substack{a\in Q_i(r_j)\cup\{j\}:\\ \delta_{ia}\geq\delta_{ij}}} p_{ia}\Bigg)^k + \sum_{\substack{a\in Q_i(r_j)\setminus\{u\}:\\ \delta_{ia}<\delta_{ij}}} w_a\left[\big(F_a(r_j)+p_{ij}-q_{iu}(r_j)\big)^k - F_a(r_j)^k\right],$$

where, in both cases, the first term corresponds to the weighted k-th power of the flow-time of job j if it is dispatched to i and the second term corresponds to the change of the weighted k-th power of flow-time for the jobs in $Q_i(r_j)$. Note that, the second case corresponds to the rejection of u and hence we do not have the term $q_{iu}(r_j)$ in the weighted flow-time of j, while the flow-time of each pending job is reduced by $q_{iu}(r_j)$.

Based on the above, we define λ_{ij} as follows. If $\delta_{ij} > \delta_{iu}$ then λ_{ij} equals to

$$\frac{2^k(10k)^k}{\epsilon_s^k}\frac{1+\epsilon_r}{\epsilon_r}w_j p_{ij}^k + \left(1+\frac{\epsilon_s}{5}\right)w_j\Bigg(\sum_{\substack{a\in Q_i(r_j)\cup\{j\}\setminus\{u\}:\\ \delta_{ia}\geq\delta_{ij}}} p_{ia}\Bigg)^k + \sum_{\substack{a\in Q_i(r_j)\setminus\{u\}:\\ \delta_{ia}<\delta_{ij}}} w_a\left[\big(F_a(r_j)+p_{ij}\big)^k - F_a(r_j)^k\right],$$

otherwise, λ_{ij} equals to

$$\frac{2^k(10k)^k}{\epsilon_s^k}\frac{1+\epsilon_r}{\epsilon_r}w_j p_{ij}^k + \left(1+\frac{\epsilon_s}{5}\right)w_j\Bigg(q_{iu}(r_j) + \sum_{\substack{a\in Q_i(r_j)\cup\{j\}\setminus\{u\}:\\ \delta_{ia}\geq\delta_{ij}}} p_{ia}\Bigg)^k + \sum_{\substack{a\in Q_i(r_j)\setminus\{u\}:\\ \delta_{ia}<\delta_{ij}}} w_a\left[\big(F_a(r_j)+p_{ij}\big)^k - F_a(r_j)^k\right].$$

Intuitively, the value of λ_{ij}'s captures the marginal increase of the total weighted k-th power of flow-times due to the arrival of job j and additionally a prediction term. Note that we do not consider the negative quantity $q_{iu(r_j)}$ that appears in the second case of Δ_{ij}.

The *dispatching policy* of the algorithm is the following: dispatch j to the machine $i^* = \operatorname{argmin}_{i\in\mathcal{M}}\{\lambda_{ij}\}$.

It remains to formally define the dual variables. At the arrival of a job $j \in \mathcal{J}$, we set $\lambda_j = \frac{\epsilon_r}{1+\epsilon_r}\min_{i\in\mathcal{M}}\{\lambda_{ij}\}$ and we will never change the value of λ_j again. Define $\gamma_i(t)$ as

$$\gamma_i(t) = \frac{\epsilon_r}{1+\epsilon_r}\left(1+\frac{\epsilon_s}{2}\right)\left(1+\frac{\epsilon_s}{5}\right)\cdot k \sum_{a\in Q_i(t)\cup U_i(t)} w_a F_a(t)^{k-1}$$

Note that $\gamma_i(t)$ is updated during the execution of $\mathcal{A}$. More specifically, given any fixed time t, $\gamma_i(t)$ may increase if a new job j' arrives at any time $r_{j'} \in [r_j, t)$. However, $\gamma_i(t)$ does never decrease in the case of rejection since the jobs remain in $U_i(t)$ for a sufficient time after their completion or rejection.

Using the above definition of the dual variables, the following theorem holds by a quite more technical analysis than that of the previous section for the total weighted flow-time objective.

▶ **Theorem 6.** *Given any $\epsilon_s > 0$ and $\epsilon_r \in (0,1)$, there is a $(1+\epsilon_s)$-speed $O\left(\frac{k^{(k+3)/k}}{\epsilon_r^{1/k}\epsilon_s^{(k+2)/k}}\right)$-competitive algorithm that rejects jobs of total weight at most $\epsilon_r\sum_{j\in\mathcal{J}} w_j$.*

5 Conclusion

In this paper, we presented a generalized model of resource augmentation through the lens of the duality in mathematical programming. The model unifies previous ones and opens up possibilities for different types of resource augmentation. As shown in the paper, the generalized model can be used to explain the competitiveness of algorithms for certain problems that currently admit no algorithm with performance guarantee even in the resource augmentation context. Besides, an advantage in studying problems in the generalized model is that one can benefit the power of duality-based techniques which have been widely developed for the analysis of approximation and online algorithms. In this context, it would be interesting to consider different problems under the new model. Another interesting question is whether rejection is more powerful than speed. Or, more specifically, can we eliminate the speed augmentation or replace it by a new rejection rule in the presented results? Note that, the power of speed augmentation is that it affects proportionally all jobs, while the difficulty in the rejection case consists in deciding which jobs to reject and how to charge parts of the objective of the non-rejected jobs to the rejected ones.

Abstract

Turaev-Viro invariants are amongst the most powerful tools to distinguish 3-manifolds. They are invaluable for mathematical software, but current algorithms to compute them rely on the enumeration of an extremely large set of combinatorial data defined on the triangulation, regardless of the underlying topology of the manifold.

In the article, we propose a finer study of these combinatorial data, called *admissible colourings*, in relation with the cohomology of the manifold. We prove that the set of admissible colourings to be considered is substantially smaller than previously known, by furnishing new upper bounds on its size that are aware of the topology of the manifold. Moreover, we deduce new topology-sensitive enumeration algorithms based on these bounds.

The paper provides a theoretical analysis, as well as a detailed experimental study of the approach. We give strong experimental evidence on large manifold censuses that our upper bounds are tighter than the previously known ones, and that our algorithms outperform significantly state of the art implementations to compute Turaev-Viro invariants.

1 Introduction

In geometric topology, testing if two manifolds are equivalent is one of the most fundamental algorithmic problems. In fact, the task of comparing the topology of two given manifolds often stands at the very beginning of a question, and solving it is essential for conducting research in the field. In the active field of research of 3-manifold topology, this task is remarkably difficult. As a result, practitioners in computational topology rely on simpler invariants – properties of a topological space that can tell different spaces apart.

In the discrete setting, among the most useful invariants for 3-manifolds are the *Turaev-Viro invariants* [16]. They derive from quantum field theory but can be computed by purely combinatorial means – much like the famous Jones polynomial for knots. They are implemented in the major software packages *Regina* [4] and the *Manifold Recogniser* [12, 13],

* This work is supported by the Australian Research Council (DP140104246) and the Department of Industry and Science, Australia under the Australia-India Strategic Research Fund (AISRF06660).

and they play a key role in developing census databases, which are analogous to the well-known dictionaries of knots [1, 12]. Their main difficulty is that they are slow to compute: the best implementations rely on the enumeration of exponentially large sets of combinatorial data defined on a triangulation.

The Turaev-Viro invariants are a family of invariants (TV_r) indexed by an integer $r \geq 3$. For a triangulation $\mathfrak{T}$, the Turaev-Viro invariant is based on *colourings* of the triangulation $\mathfrak{T}$, which are assignements of one of $r-1$ distinct colours to each of the edges of $\mathfrak{T}$. Only a subset of colourings satisfy *admissibility constraints* – which are of combinatorial nature –, and each *admissible colouring* defines a *weight*. The Turaev-Viro invariant $\mathrm{TV}_r(\mathfrak{T})$ is equal to the sum of these weights over all admissible colourings.

For any $r \geq 3$, a naive algorithm to compute $\mathrm{TV}_r(\mathfrak{T})$ on a triangulation $\mathfrak{T}$, with m edges, consists of a simple backtracking procedure enumerating all of the $(r-1)^m$ edge colourings, checking each of them for admissibility and summing the weights, resulting in a memory efficient but very slow implementation. More recently, Burton and the authors introduced a *fixed parameter tractable (FPT)* algorithm which is *linear* in the size of the input, and only singly exponential in the treewidth of the dual graph of $\mathfrak{T}$ [5]. This is possible by using the structure of the input to process large groups of admissible colourings simultaneously. Despite good performance in practice, this approach requires exponential memory and the running time is very sensitive to the combinatorial structure of the input triangulation, as opposed to the topology of the underlying manifold.

Algorithmic results exist for specific values of r. For $r = 3$, the Turaev-Viro invariant $\mathrm{TV}_3(\mathfrak{T})$ can be interpreted in terms of the cohomology of the manifold, which results in a polynomial time algorithm [5, 12]. For $r = 4$ however, the computation of the invariant is known to be hard for the *counting complexity class* #P [5, 11]. This gives evidence that a general efficient solution (for example polynomial) for computing TV_r is unlikely to exist.

In this article, we elaborate on the cohomology interpretation of the Turaev-Viro invariants, successful for the case $r = 3$, to design more efficient implementations for TV_r relying on an optimised enumeration of admissible colourings. More precisely, we use the admissibility constraints to connect colourings and cohomology classes of the manifold, and reduce a priori the number of colourings to be considered algorithmically in order to find all admissible colourings.

Using this technique, we study the structure of the set of admissible colourings for $r = 3$ and $r = 4$. We design new sharper upper bounds on the number of admissible colourings of a triangulation for $r = 4$, and deduce an algorithm to compute TV_4 which is linear in these new bounds. This is of particular interest considering the #P-hardness of this computation. We give experimental evidence on large censuses of triangulations that these upper bounds are sharp in many cases and significantly better than the naive ones.

We then study in more details admissible colourings that reduce to the trivial cohomology class. This is a special case of particular importance, as it allows the study of homology spheres – manifolds involved in the 3-sphere recognition problem – and later becomes a key ingredient for an improved algorithm to compute TV_r, with r odd, on any manifold. We deduce new sharp upper bounds on the number of colourings of homology spheres for $r \leq 7$.

Finally, building on this study at the trivial cohomology class, and work by Kirby and Melvin [10] and Matveev [12], we introduce an improved algorithm to compute the Turaev-Viro invariants for odd values of r. By embedding it within existing algorithms, our method allows a significant exponential speed-up on both backtracking algorithm and FPT algorithm to compute Turaev-Viro invariants. We provide large scale experiments to show the interest of the method. In particular, our new enumeration of colourings, combined with the FPT algorithm to compute Turaev-Viro, performs up to two orders of magnitude faster than state of the art implementation, hence opening notably the range of possible practical computations in 3-manifold topology.

These implementations will appear as features in the 3-manifold software `Regina` [4].

2 Background

Manifolds and generalised triangulations: Let M be a closed 3-manifold. A *generalised triangulation* $\mathfrak{T}$ of M is a collection of n abstract tetrahedra $\Delta_1, \ldots, \Delta_n$ together with $2n$ *gluing maps* identifying their $4n$ triangular faces in pairs, such that the underlying topological space is homeomorphic to M.

As a consequence of the gluings, vertices, edges or triangles of the same tetrahedron may be identified. It follows from an Euler characteristic argument, that any n-tetrahedra v-vertex triangulation of a closed 3-manifold must have $2n$ triangles and $n+v$ edges. It is common in practical applications to have a *one-vertex triangulation*, in which all vertices of all tetrahedra are identified to a single point. We refer to an equivalence class defined by the gluing maps as a single *face of the triangulation*. The number of tetrahedra n of $\mathfrak{T}$ is often referred to as the *size* of the triangulation. We denote by V, E, F and T the vertices, edges, triangles and tetrahedra, respectively, of a generalised triangulation.

Generalised triangulations are widely used in 3-manifold topology. They are more general than simplicial complexes, and can encode a wide range of manifolds, and very complex topologies, with very few tetrahedra. For instance, one can build 13 400 *distinct* prime manifolds with less than 11 tetrahedra [12], and the number of distinct manifolds represented by generalised triangulations with less than n tetrahedra grows super-exponentially with n.

We refer to [9] for more details on generalised triangulations.

Homology and cohomology: In the following section we give a very brief introduction to (co)homology theory. For more details see [7].

Let $\mathfrak{T}$ be a generalised 3-manifold triangulation. For the field of coefficients $\mathbb{Z}_2 := \mathbb{Z}/2\mathbb{Z}$, the *group of p-chains*, $0 \le p \le 3$, denoted $\mathbf{C}_p(\mathfrak{T}, \mathbb{Z}_2)$, of $\mathfrak{T}$ is the group of formal sums of p-faces with $\mathbb{Z}_2$ coefficients. The *boundary operator* is a linear operator $\partial_p : \mathbf{C}_p(\mathfrak{T}, \mathbb{Z}_2) \to \mathbf{C}_{p-1}(\mathfrak{T}, \mathbb{Z}_2)$ such that $\partial_p \sigma = \partial_p \{v_0, \cdots, v_p\} = \sum_{j=0}^{p} \{v_0, \cdots, \widehat{v_j}, \cdots, v_p\}$, where σ is a face of $\mathfrak{T}$, $\{v_0, \ldots, v_p\}$ represents σ as a face of a tetrahedron of $\mathfrak{T}$ in local vertices $v_0, \ldots, v_p$, and $\widehat{v_j}$ means v_j is deleted from the list. Denote by $\mathbf{Z}_p(\mathfrak{T}, \mathbb{Z}_2)$ and $\mathbf{B}_{p-1}(\mathfrak{T}, \mathbb{Z}_2)$ the kernel and the image of ∂_p respectively. Observing $\partial_p \circ \partial_{p+1} = 0$, we define the *$p$-th homology group* $\mathbf{H}_p(\mathfrak{T}, \mathbb{Z}_2)$ of $\mathfrak{T}$ by the quotient $\mathbf{H}_p(\mathfrak{T}, \mathbb{Z}_2) = \mathbf{Z}_p(\mathfrak{T}, \mathbb{Z}_2)/\mathbf{B}_p(\mathfrak{T}, \mathbb{Z}_2)$. These structures are vector spaces.

The concept of *cohomology* is in many ways dual to homology, but more abstract and endowed with more algebraic structure. It is defined in the following way: The *group of p-cochains* $\mathbf{C}^p(\mathfrak{T}, \mathbb{Z}_2)$ is the formal sum of linear maps of p-faces of $\mathfrak{T}$ into $\mathbb{Z}_2$. The *coboundary operator* is a linear operator $\delta^p : \mathbf{C}^{p-1}(\mathfrak{T}, \mathbb{Z}_2) \to \mathbf{C}^p(\mathfrak{T}, \mathbb{Z}_2)$ such that for all $\phi \in \mathbf{C}^{p-1}(\mathfrak{T}, \mathbb{Z}_2)$ we have $\delta^p(\phi) = \phi \circ \partial_p$. As above, *$p$-cocycles* are the elements in the kernel of δ^{p+1}, *p-coboundaries* are elements in the image of δ^p, and the *p-th cohomology group* $\mathbf{H}^p(\mathfrak{T}, \mathbb{Z}_2)$ is defined as the p-cocycles factored by the d-coboundaries.

We denote by $\beta_1(\mathfrak{T}, \mathbb{Z}_2)$ the dimension of $\mathbf{H}_1(\mathfrak{T}, \mathbb{Z}_2)$, called the first *Betti number* of the manifold. By duality, this is also the dimension of homology and cohomology groups of dimension $p \in \{1, 2\}$, with $\mathbb{Z}_2$ coefficients.

In Section 3.1 we discuss how 1-cocycles correspond to (sets of) *admissible colourings* of the edges of $\mathfrak{T}$ used in the definition of Turaev-Viro invariants.

Turaev-Viro invariants: In this section we briefly describe *invariants of Turaev-Viro type* TV_r, parameterised by an integer $r \geq 3$. We then have a closer look at the more specialised original *Turaev-Viro invariants* $\mathrm{TV}_{r,q}$, which also depend on a second integer $0 < q < 2r$.

Let $\mathfrak{T}$ be a generalised triangulation of a closed 3-manifold M, and let $r \geq 3$, be an integer. Let V, E, F and T denote the set of vertices, edges, triangles and tetrahedra of the triangulation $\mathfrak{T}$ respectively. Let $I = \{0, 1/2, 1, 3/2, \ldots, (r-2)/2\}$ be the set of the first $r-1$ non-negative half-integers. A *colouring* of $\mathfrak{T}$ is defined to be a map $\theta : E \to I$; that is, θ "colours" each edge of $\mathfrak{T}$ with an element of I. A colouring θ is *admissible* if, for each triangle of $\mathfrak{T}$, the three edges e_1, e_2, and e_3 bounding the triangle satisfy the

- *parity condition* $\theta(e_1) + \theta(e_2) + \theta(e_3) \in \mathbb{Z}$;
- *triangle inequalities* $\theta(e_i) \leq \theta(e_j) + \theta(e_k)$, $\{i,j,k\} = \{1,2,3\}$; and
- *upper bound constraint* $\theta(e_1) + \theta(e_2) + \theta(e_3) \leq r-2$.

For a triangulation $\mathfrak{T}$ and $r \geq 3$, its set of admissible colourings is denoted by $\mathrm{Adm}(\mathfrak{T}, r)$.

For each admissible colouring θ and for each vertex $w \in V$, edge $e \in E$, triangle $f \in F$ or tetrahedron $t \in T$ we define *weights* $|w|_\theta, |e|_\theta, |f|_\theta, |t|_\theta \in \mathbb{C}$. The weights of vertices are constant, and the weights of edges, triangles and tetrahedra only depend on the colours of edges they are incident to. Using these weights, we define the *weight of the colouring* to be

$$|\mathfrak{T}|_\theta = \prod_{w \in V} |w|_\theta \times \prod_{e \in E} |e|_\theta \times \prod_{f \in F} |f|_\theta \times \prod_{t \in T} |t|_\theta, \tag{1}$$

Invariants of Turaev-Viro types of $\mathfrak{T}$ are defined as sums of the weights of all admissible colourings of $\mathfrak{T}$, that is $\mathrm{TV}_r(\mathfrak{T}) = \sum_{\theta \in \mathrm{Adm}(\mathfrak{T},r)} |\mathfrak{T}|_\theta$.

In [16], Turaev and Viro show that, when the weighting system satisfies some identities, $\mathrm{TV}_r(\mathfrak{T})$ is indeed an invariant of the manifold; that is, if $\mathfrak{T}$ and $\mathfrak{T}'$ are generalised triangulations of the same closed 3-manifold M, then $\mathrm{TV}_r(\mathfrak{T}) = \mathrm{TV}_r(\mathfrak{T}')$ for all r. We thus sometimes abuse notation and write $\mathrm{TV}_r(M)$, meaning the Turaev-Viro type invariant computed for a triangulation of M.

We refer to [5] for a precise definition of the weights of the original Turaev-Viro invariant at $sl_2(\mathbb{C})$, which not only depend on r but also on a second integer $0 < q < 2r$. The exact definition of these weights is rather involved, but not at all important in order to understand the findings presented in this article, we thus continue to denote these weights by $|\cdot|_\theta$ despite the fact that they not only depend on θ, but also on r and q. We use these weights in our experiments in Section 4.

For an n-tetrahedra triangulation $\mathfrak{T}$ with v vertices there is a simple backtracking algorithm to compute $\mathrm{TV}_{r,q}(\mathfrak{T})$ by testing the $(r-1)^{v+n}$ possible colourings for admissibility and computing their weights. The case $r = 3$ can however be computed in polynomial time, due to a connection between $\mathrm{Adm}(\mathfrak{T}, 3)$ and cohomology, see Section 3.1 and [5, 12].

Classical results about Turaev-Viro invariants: Note that the Turaev-Viro invariants $\mathrm{TV}_{r,q}$ are closely related to the more general invariant of Witten and Reshetikhin-Turaev $\tau_{r,q}$ ($\in \mathbb{C}$), due to the following result.

▶ **Theorem 1** (Turaev [15], Roberts [14]). *For the invariants of Witten and Reshetikhin-Turaev $\tau_{r,q}$, and the Turaev-Viro invariants, the following equality holds*

$$\mathrm{TV}_{r,q} = | \tau_{r,q} |^2 \ .$$

Theorem 1 enables us to translate a number of key results about the Witten and Reshetikhin-Turaev invariants in terms of Turaev-Viro invariants. Namely, the following statement holds.

▶ **Theorem 2** (Based on Kirby and Melvin [10]). *Let M and N be closed compact 3-manifolds, and let $r \geq 3$, $1 \leq q \leq r-1$. Then there exist $\gamma_r \in \mathbb{C}$, such that for $\mathrm{TV}'_{r,1} = \gamma_r \mathrm{TV}_{r,1}$ we have*

$$\mathrm{TV}'_{r,1}(M \# N) = \mathrm{TV}'_{r,1}(M) \cdot \mathrm{TV}'_{r,1}(N).$$

Additionally, when a manifold M is represented by a triangulation with n tetrahedra, the normalising factor γ_r can be computed in polynomial time in n.

Using Turaev-Viro invariants at the trivial cohomology class we have the following identity for odd degree r.

▶ **Theorem 3** (Based on Kirby and Melvin [10]). *Let M be a closed compact 3-manifold, and let $r \geq 3$ be an odd integer. Then*

$$\mathrm{TV}_{r,1}(M) = \mathrm{TV}_{3,1}(M) \cdot \mathrm{TV}_{r,1}(M, [0]).$$

3 Reduction of colourings at cohomology classes

Let $\mathfrak{T}$ be a 3-manifold triangulation with v vertices, $n+v$ edges, $2n$ triangles and n tetrahedra. Following the definitions in Section 2 above, there are at most $(r-1)^{n+v}$ admissible colourings for $\mathrm{Adm}(\mathfrak{T}, r)$. Due to the admissibility constraints for colourings, as described in Section 2, this bound is usually far from being sharp. However, current enumeration algorithms for admissible colourings do not try to capitalise on this fact (including the parameterised algorithm from [5]).

In this section we discuss methods that incorporate these constraints in a controlled fashion when enumerating admissible colourings. More precisely, we present improved upper bounds on the number of admissible colourings in important special cases (thus reducing a priori the number of options an enumeration algorithm needs to consider). Moreover, we give a number of examples where these new upper bounds are actually attained. The bounds are then used to construct a structure sensitive algorithm to enumerate $\mathrm{Adm}(\mathfrak{T}, 4)$, and to achieve a significant exponential speed-up for the computation of the Turaev-Viro invariants $\mathrm{TV}_{r,1}$ where r is odd.

3.1 Turaev-Viro invariants for r=3 and cohomology

There is a close connection between the first cohomology group of a 3-manifold triangulation $\mathfrak{T}$ and the admissible colourings of the Turaev-Viro invariants for $r = 3$. We discuss this connection under the viewpoint of triangulations which helps setting the scene for improved bounds on the number of admissible colourings for higher values of r, as presented in Sections 3.2 and 3.4 below.

▶ **Proposition 4.** *Let $\mathfrak{T}$ be a 3-manifold triangulation with v vertices. Then there is a bijection between $\mathrm{Adm}(\mathfrak{T}, 3)$ and the 1-cocycles of $\mathfrak{T}$, and we have $|\mathrm{Adm}(\mathfrak{T}, 3)| = 2^{v+\beta_1(\mathfrak{T},\mathbb{Z}_2)-1}$.*

Proof. An edge colouring $\theta : E \to \{0, 1/2\}$ defines a 1-cochain α_θ with coefficients in $\mathbb{Z}_2$ evaluating to 1 on edges coloured 1/2 and to 0 otherwise. The parity condition on θ is then equivalent to the boundary of α_θ (which is a 2-chain) vanishing over $\mathbb{Z}_2$. Moreover, note that every colouring $\theta : E \to \{0, 1/2\}$ satisfying the parity condition is admissible for $r = 3$. Thus θ is admissible if and only if α_θ is a cocycle. This proves the first statement. The second statement follows from the observation that $\mathfrak{T}$ has exactly $2^{v+\beta_1(\mathfrak{T},\mathbb{Z}_2)-1}$ cocycles. ◀

Let $\mathbf{H}^1(\mathfrak{T},\mathbb{Z}_2) = (\mathbb{Z}_2)^{\beta_1(\mathfrak{T},\mathbb{Z}_2)}$ be the first cohomology group of $\mathfrak{T}$. Since every 1-cocycle α in $\mathfrak{T}$ is a representative of a cohomology class $[\alpha] \in \mathbf{H}^1(\mathfrak{T},\mathbb{Z}_2)$, every admissible colouring in $\mathrm{Adm}(\mathfrak{T},3)$ can be associated to a cohomology class. This correspondence can be generalised to arbitrary $r \geq 3$ with the help of the following observation.

▶ **Proposition 5.** *Let $\mathfrak{T}$ be a 3-manifold triangulation with edge set E, $r \geq 3$, and $\theta \in \mathrm{Adm}(\mathfrak{T},r)$. Then the* reduction of θ*, defined by $\theta' : E \to \{0, 1/2\}$; $e \mapsto \theta(e) - \lfloor \theta(e) \rfloor$, is an admissible colouring in $\mathrm{Adm}(\mathfrak{T},3)$.*

Proof. Let f be a triangle of $\mathfrak{T}$ with edges e_1, e_2, and e_3. Since $\theta \in \mathrm{Adm}(\mathfrak{T},r)$ is admissible, we have $\theta(e_1)+\theta(e_2)+\theta(e_3) \in \mathbb{Z}$. Thus, there are either no or two half-integers amongst the colours of the edges of f and $\theta' \in \mathrm{Adm}(\mathfrak{T},3)$. ◀

We have seen that every colouring $\theta \in \mathrm{Adm}(\mathfrak{T},r)$ can be associated to a 1-cohomology class of $\mathfrak{T}$ via its reduction $\theta' \in \mathrm{Adm}(\mathfrak{T},3)$ and Proposition 4. We know from [12, 16] that this construction can be used to split $\mathrm{TV}_r(\mathfrak{T})$ (and thus also $\mathrm{TV}_{r,q}(\mathfrak{T})$) into simpler invariants indexed by the elements of $\mathbf{H}^1(\mathfrak{T},\mathbb{Z}_2)$. More precisely, let $[\alpha] \in \mathbf{H}^1(\mathfrak{T},\mathbb{Z}_2)$ be a cohomology class, then

$$\mathrm{TV}_r(\mathfrak{T},[\alpha]) = \sum_{\substack{\theta \in \mathrm{Adm}(\mathfrak{T},r) \\ \theta \bmod 2 \in [\alpha]}} |\mathfrak{T}|_\theta,$$

where θ mod 2 denotes the reduction of θ, is an invariant of $\mathfrak{T}$. The special case $\mathrm{TV}_r(\mathfrak{T},[0])$ is of particular importance for computations as explained in further detail in Section 3.4.

3.2 Admissible colourings for r=4

We have seen in Proposition 4 that admissible colourings for $r = 3$ are in one-to-one correspondence to the 1-cocycles of a triangulated 3-manifold $\mathfrak{T}$. This basic but very useful observation has consequences for the structure of $\mathrm{Adm}(\mathfrak{T},4)$. This is particularly interesting as computing $\mathrm{TV}_{4,1}$ is known to be $\#P$-hard [5, 11]. More precisely, the following statement holds.

▶ **Theorem 6.** *Let $\mathfrak{T}$ be an n-tetrahedron 3-manifold triangulation with v vertices, and let $\theta \in \mathrm{Adm}(\mathfrak{T},3)$. Furthermore, let $\ker_\theta$ be the number of edges coloured 0 by θ. Then*

$$|\mathrm{Adm}(\mathfrak{T},4)| \leq \left(\Sigma_{\theta\in\mathrm{Adm}(\mathfrak{T},3)\setminus\{\mathbf{0}\}} 2^{\ker_\theta}\right) + 2^{v+\beta_1(\mathfrak{T},\mathbb{Z}_2)-1} \quad (2)$$

$$\leq (|\mathrm{Adm}(\mathfrak{T},3)|-1)(2^{n+v-1}+1)+1, \quad (3)$$

where **0** *denotes the all zero colouring. Moreover, both bounds are sharp.*

Proof. Let $\theta \in \mathrm{Adm}(\mathfrak{T},4)$, and let θ' be its reduction, as defined in Proposition 5. If θ' is the trivial colouring (that is, if no colour of θ is coloured by $1/2$) the colouring $\theta/2$, obtained by dividing all of the colours of θ by two, must be in $\mathrm{Adm}(\mathfrak{T},3)$. It follows from Proposition 4 that exactly $2^{v+\beta_1(\mathfrak{T},\mathbb{Z}_2)-1}$ colourings in $\mathrm{Adm}(\mathfrak{T},4)$ reduce to the trivial colouring.

If θ' is not the trivial colouring then θ colours some edges by $1/2$. In particular it is not the trivial colouring. Since the only colours in θ are 0, $1/2$, and 1, all edges coloured by $1/2$

in θ are coloured by $1/2$ in θ' and vice versa. Thus, $\ker_{\theta'}$ denotes all edges coloured by 0 or 1 in θ. Naturally, there are at most $2^{\ker_{\theta'}}$ such colourings. The result now follows by adding these upper bounds $2^{\ker_{\theta'}}$ over all non-trivial reductions $\theta' \in \mathrm{Adm}(\mathfrak{T}, 3)$, and adding the $2^{v+\beta_1(\mathfrak{T},\mathbb{Z}_2)-1}$ extra colourings with trivial reduction.

For Equation (3) note that each non-trivial colouring in $\mathrm{Adm}(\mathfrak{T}, 3)$ has at least one edge coloured $1/2$ and thus $\ker_{\theta'}$ is at most the number of edges minus one.

It follows that for $\beta_1(\mathfrak{T}, \mathbb{Z}_2)$ or v sufficiently large this bound cannot be tight. For 1-vertex triangulations $\mathfrak{T}$ with $\beta_1(\mathfrak{T}, \mathbb{Z}_2) = 0$ this bound is sharp as explained in Proposition 7. Looking at all 1-vertex triangulations with $\beta_1(\mathfrak{T}, \mathbb{Z}_2) = 1$ up to six tetrahedra, the cases of equality in Inequality (3) are summarised in Table 2. See Table 1 for a large number of cases of equality for Inequality (2). ◀

3.3 A structure-sensitive algorithm to compute $\mathrm{Adm}(\mathfrak{T}, 4)$

In this section we describe an algorithm to compute $\mathrm{TV}_{4,q}$ – a problem known to be $\#P$-hard – exploiting the combinatorial structure of the input triangulation. The algorithm is a direct consequence of the proof of Theorem 6.

Input. A v-vertex n-tetrahedra triangulation of a closed 3-manifold $\mathfrak{T}$ with set of edges E

1. Compute $\mathrm{Adm}(\mathfrak{T}, 3)$. Following the proof of Proposition 4, it is enough to compute a basis of the 1-cohomology of $\mathfrak{T}$ with coefficients in the field with two elements $\mathbb{Z}_2$. Then every cocycle naturally defines an admissible colouring and vice versa. This can be done in polynomial time by solving a linear system of equations. $\mathrm{Adm}(\mathfrak{T}, 3)$ can then be enumerated using the cohomology basis.
2. For all $\theta \in \mathrm{Adm}(\mathfrak{T}, 3)$, enumerate the set of edges $\ker_\theta \subset E$ of $\mathfrak{T}$ coloured zero in θ.
3. For each non-trivial $\theta \in \mathrm{Adm}(\mathfrak{T}, 3)$, for each subset $A \subseteq \ker_\theta$: Let θ' be the edge colouring that colours (i) all edges in A by 1, (ii) all edges in $(E \setminus \ker_\theta)$ by $1/2$, and (iii) all edges in $(\ker_\theta \setminus A)$ by 0. For each non-trivial θ, set up a backtracking procedure to check all such θ' for admissibility. Add the admissible colourings θ' to $\mathrm{Adm}(\mathfrak{T}, 4)$.
4. For all colourings $\theta \in \mathrm{Adm}(\mathfrak{T}, 3)$, double all colours of θ and add the result to $\mathrm{Adm}(\mathfrak{T}, 4)$.

Correctness of the algorithm and running time. Due to Theorem 6 we know that the above procedure enumerates all colourings in $\mathrm{Adm}(\mathfrak{T}, 4)$. Computing $\mathrm{TV}_{4,q}(\mathfrak{T})$ thus runs in

$$O\left(\left(\Sigma_{\theta\in\mathrm{Adm}(\mathfrak{T},3)\setminus\{\mathbf{0}\ \}}\ 2^{\ker_\theta}\right) \cdot n + 2^{v+\beta_1(\mathfrak{T},\mathbb{Z}_2)-1}\right)$$

arithmetic operations. This upper bound is much smaller than the worst case running time $(r-1)^{n+v}$ of the naive backtracking procedure.

In Section 4.3, we provide experimental evidence on a large census of triangulations that the new upper bounds on the number of admissible colourings from Theorem 6 are tight in many cases and close to being tight in average, and that our new algorithm to enumerate the colourings of $\mathrm{Adm}(\mathfrak{T}, 4)$ experimentally exhibits an output-sensitive nature.

3.4 Computing Turaev-Viro invariants at the zero cohomology class

Following Proposition 4 the complexity of enumerating admissible colourings of a 3-manifold triangulation $\mathfrak{T}$ not only depends on the size n of $\mathfrak{T}$, but also on (i) the number of vertices, and (ii) the first Betti number of $\mathfrak{T}$.

Regarding (i) we show in Section 3.5 that, given $\mathfrak{T}$, we can efficiently find a triangulation $\mathfrak{T}'$ of the same 3-manifold of same or smaller size with only one vertex. Regarding (ii) the first Betti number of $\mathfrak{T}$ is a topological invariant and hence an unchangeable part of the input. Thus, when computing $\mathrm{TV}_{r,q}(\mathfrak{T})$ by enumerating colourings, this layer of complexity can not be avoided. However, this observation does not hold for the invariant $\mathrm{TV}_{r,q}(\mathfrak{T},[0])$ which is a useful tool for various reasons.

1. First of all and most prominently, in order to compute $\mathrm{TV}_{r,q}(\mathfrak{T},[0])$ we only need to consider admissible colourings which correspond to the zero cohomology class. Following Proposition 4 for a one-vertex triangulation $\mathfrak{T}$, the colourings corresponding to the zero cohomology class are precisely the ones which reduce to the all zero colouring and thus can only have integer colours. A similar statement for the case of special spines can be found in [12, Remark 8.1.2.2].
2. One of the most important tasks of 3-manifold invariants is to distinguish between a 3-manifold triangulation $\mathfrak{T}$ and the 3-sphere (this task is known as the 3-*sphere recognition problem*). Whenever the homology groups of $\mathfrak{T}$ and the 3-sphere are different, this distinction can efficiently be made (i.e., in polynomial time). Hence, 3-sphere recognition is most interesting when homology fails, that is, when $\mathfrak{T}$ has the (trivial) homology of the 3-sphere $\mathbf{H}^1(\mathfrak{T},\mathbb{Z}_2)=\{[0]\}$. In this important case we have $\mathrm{TV}_{r,q}(\mathfrak{T})=\mathrm{TV}_{r,q}(\mathfrak{T},[0])$.
3. There are several non-trivial further cases when $\mathrm{TV}_{r,q}(\mathfrak{T})$ can be obtained from $\mathrm{TV}_{r,q}(\mathfrak{T},[0])$ in polynomial time, see Section 3.5 for details.

For the remainder of this section, instead of considering $\mathrm{TV}_{r,q}(\cdot,[0])$, we follow the related approach of considering $\mathrm{TV}_{r,q}(\cdot)$ and triangulations with vanishing first Betti number. We will use this study in the next section to derive a faster algorithm to compute $\mathrm{TV}_{r,q}(\cdot)$ on *all* manifold triangulations for r odd and $q=1$. The following facts follow from the observations made in Sections 3.1 and 3.2.

▶ **Proposition 7.** *Let $\mathfrak{T}$ be a 1-vertex triangulation such that $\beta_1(\mathfrak{T},\mathbb{Z}_2)=0$. Then*
(i) $|\mathrm{Adm}(\mathfrak{T},r)|=1$ *for $r\le 4$;*
(ii) *Let $\theta\in\mathrm{Adm}(\mathfrak{T},r)$, then all colours in θ must be integers;*
(iii) $|\mathrm{Adm}(\mathfrak{T},r)|\le\lfloor\frac{r}{2}\rfloor^{n+1}$.

In particular, $\mathrm{TV}_{r,q}(\mathfrak{T})$, $r\le 4$, must be trivial, and manifolds with trivial $\mathbb{Z}_2$-cohomology (a large group of 3-manifolds) can never be distinguished from the 3-sphere by $\mathrm{TV}_{r,q}$, $r\le 4$.

Proof.
(i) It follows from Proposition 4 that $\mathrm{Adm}(\mathfrak{T},3)=\{\mathbf{0}\}$ and the statement follows from Theorem 6.
(ii) Since $\mathrm{Adm}(\mathfrak{T},3)=\{\mathbf{0}\}$ all colourings must reduce to the all zero colouring.
(iii) Since all colours in θ must be (a) integers, (b) sum to at most $r-2$ on each triangle, and (c) satisfy the triangle inequality. It follows that all colours must be integers between 0 and $\lfloor\frac{r-2}{2}\rfloor$. The statement now follows from the fact that $\mathfrak{T}$ has $n+1$ edges. ◀

The bound from Proposition 7 cannot be sharp since not all triangle colourings $(a,b,c)\in\{0,1,\dots,\lfloor\frac{r-2}{2}\rfloor\}^3$ are admissible. For $5\le r\le 7$ we have the following situation.

▶ **Theorem 8.** *Let $\mathfrak{T}$ be a 1-vertex n-tetrahedron triangulation such that $\beta_1(\mathfrak{T},\mathbb{Z}_2)=0$, then*

$$|\mathrm{Adm}(\mathfrak{T},5)|\le 2^n+1;\qquad |\mathrm{Adm}(\mathfrak{T},6)|\le 3^n+1;\qquad |\mathrm{Adm}(\mathfrak{T},7)|\le 3^n+1.$$

Moreover, all these upper bounds are sharp.

Proof. For $r = 5$ the admissible triangle colourings are $(0, 0, 0)$, $(1/2, 1/2, 0)$, $(1, 1, 0)$, $(1, 1/2, 1/2)$, $(1, 1, 1)$, $(3/2, 3/2, 0)$, $(3/2, 1, 1/2)$, up to permutations. By Proposition 5, no colouring in $\mathrm{Adm}(\mathfrak{T}, 5)$ can contain an edge colour $1/2$ or $3/2$: Otherwise the reduction of such a colouring would be a non-trivial colouring in $\mathrm{Adm}(\mathfrak{T}, 3)$, which does not exist (cf. Proposition 4 and Corollary 7 with $v = 1$ and $\beta_1(\mathfrak{T}, \mathbb{Z}_2) = 0$). Hence, all edge colours must be 0 or 1, leaving triangle colourings $(0, 0, 0)$, $(1, 1, 0)$, and $(1, 1, 1)$.

By an Euler characteristic argument, a 1-vertex n-tetrahedron 3-manifold has $n+1$ edges. Hence the number of colourings of $\mathrm{TV}_{5,q}$ is trivially bounded above by 2^{n+1}. Furthermore, let $\theta \in \mathrm{Adm}(\mathfrak{T}, 5)$, then either θ is constant 0 on the edges, constant 1 on the edges, or θ contains a triangle coloured $(1, 1, 0)$. In the last case, the complementary colouring θ', obtained by flipping the colour on all the edges, contains a triangle coloured $(0, 0, 1)$ and thus $\theta' \notin \mathrm{Adm}(\mathfrak{T}, 5)$. It follows that $|\mathrm{Adm}(\mathfrak{T}, 5)| \leq 2^n + 1$.

For $r = 6$ the admissible triangle colourings are the ones from the case $r = 5$ above plus $(3/2, 3/2, 1)$, $(2, 1, 1)$, $(2, 2, 0)$, $(2, 3/2, 1/2)$. Again, due to Proposition 5, no half-integers can occur in any colouring. Thus, the only admissible triangle colourings are $(0, 0, 0)$, $(1, 1, 0)$, $(1, 1, 1)$, $(2, 1, 1)$, and $(2, 2, 0)$.

We trivially have $|\mathrm{Adm}(\mathfrak{T}, 6)| \leq 3^{n+1}$. Let $\theta \in \mathrm{Adm}(\mathfrak{T}, 6)$. We want to show, that at most a third of all non-constant assignment of colours 0, 1, 2 to the edges of $\mathfrak{T}$ can be admissible. For this, let $\theta \in \mathrm{Adm}(\mathfrak{T}, 6)$ and let θ' be defined by adding 1 (mod 3) to every edge colour. For θ' to be admissible, all triangles of θ must be of type $(0, 0, 0)$ and $(2, 1, 1)$. If at least one triangle has colouring $(0, 0, 0)$, θ must be the trivial colouring. Hence, all triangles are of type $(2, 1, 1)$ in θ. Replacing 2 by 0 and 1 by $1/2$ in θ yields a non-trivial admissible colouring in $\mathrm{Adm}(\mathfrak{T}, 3)$, a contradiction by Corollary 7. Hence, for every non-trivial admissible colouring θ, the colouring θ' cannot be admissible.

Analogously, let θ'' be defined by adding 2 (mod 3) to every edge colour of θ. For θ'' to be admissible, all triangles of θ must be of the type $(1, 1, 1)$, or $(2, 2, 0)$. A single triangle of type $(1, 1, 1)$ in θ forces θ to be constant. Hence, all triangles must be of type $(2, 2, 0)$. Dividing θ by four defines a non-trivial colouring in $\mathrm{Adm}(\mathfrak{T}, 3)$, a contradiction.

Combining these observations, at most every third non-trivial assignment of colours 0, 1, 2 to the edges of θ can be admissible. Adding the two admissible constant colourings yields $|\mathrm{Adm}(\mathfrak{T}, 6)| \leq 3^n + 1$.

The proof for $r = 7$ follows from a slight adjustment of the proof for $r = 6$. Admissible triangle colourings for colourings in $\mathrm{Adm}(\mathfrak{T}, 7)$ are the ones from $r = 6$ plus $(2, 2, 1)$. Again, we want to show that at most every third non-trivial assignment of colours 0, 1, 2 to the edges of $\mathfrak{T}$ can be admissible. For this let $\theta \in \mathrm{Adm}(\mathfrak{T}, 7)$ and let θ' and θ'' be defined as above. For θ' to be admissible θ must consist of triangle colourings of type $(0, 0, 0)$, $(1, 1, 0)$ and $(2, 1, 1)$. Whenever θ is non-constant replacing 2 by 0, and 1 by $1/2$ yields a non-trivial colouring in $\mathrm{Adm}(\mathfrak{T}, 3)$ which is not possible. The argument for θ'' is the same as in the case $r = 6$. It follows that $|\mathrm{Adm}(\mathfrak{T}, 7)| \leq 3^n + 1$.

All of the above bounds are attained by a number of small 3-sphere triangulations. See Table 2 for more details about 1-vertex triangulations $\mathfrak{T}$ with $\beta_1(\mathfrak{T}, \mathbb{Z}_2) = 0$ with up to six tetrahedra and their average number of admissible colourings $|\mathrm{Adm}(\mathfrak{T}, r)|$, $5 \leq r \leq 7$. ◀

There are 27,202 1-vertex triangulations with vanishing first Betti number and up to 6 tetrahedra. Exactly 142 of them attain equality in all three bounds. For more details about these cases of equality and the average number of colourings for $5 \leq r \leq 7$ in the census, see Table 2.

Note that the sharp bounds from Theorem 8 suggest that the over count of the general bound from Proposition 7(iii) is only linear in r.

3.5 An algorithm to compute $\mathrm{TV}_{r,1}$, r odd

In this section we describe a significant exponential speed-up for computing $\mathrm{TV}_{r,1}(\mathfrak{T})$ in the case where r is odd and $\mathfrak{T}$ does not contain any two-sided projective planes[1]. Note that the case of r odd is of importance for 3-sphere recognition problem. The main ingredients for this speed-up are:

- The *crushing and expanding procedure* for closed 3-manifolds as described by Burton, and Burton and Ozlen, which turns an arbitrary v-vertex triangulation into a number of smaller 1-vertex triangulations in polynomial time [3, 6];
- A classical result about Turaev-Viro invariants due to Turaev [15], Roberts [14], and Kirby and Melvin [10] stating that there exists a scaled version $\mathrm{TV}'_{r,1} = \gamma_r \mathrm{TV}_{r,1}$ which is multiplicative under taking *connected sums*[2], i.e., $\mathrm{TV}'_{r,1}(M\#N) = \mathrm{TV}'_{r,1}(M)\mathrm{TV}'_{r,1}(N)$ (see Theorem 2);
- Another classical result due to the same authors and publications stating that, for r odd, we have

$$\mathrm{TV}_{r,1}(\mathfrak{T}) = \mathrm{TV}_{3,1}(\mathfrak{T}) \cdot \mathrm{TV}_{r,1}(\mathfrak{T}, [0]),$$

  and thus $\mathrm{TV}_{r,1}(\mathfrak{T}, [0])$ and $\mathrm{TV}_{3,1}(\mathfrak{T})$ are sufficient to compute $\mathrm{TV}_{r,1}(\mathfrak{T})$ (see Theorem 3);
- Proposition 7(ii) stating that computing $\mathrm{TV}_{r,1}(\mathfrak{T}, [0])$ of a 1-vertex closed 3-manifold triangulation can be done by only enumerating colourings with all integer colours.

Input. A v-vertex n-tetrahedra triangulation of a closed 3-manifold $\mathfrak{T}$

1. If $\mathfrak{T}$ has more than one vertex, apply the crushing and expanding procedure to $\mathfrak{T}$ as described in [3] and [6] respectively. It is not necessary to understand this procedure in detail. We only need this step to efficiently transform an arbitrary v-vertex n-tetrahedra triangulation $\mathfrak{T}$ into a number of triangulations $\mathfrak{T}_i$, $1 \le i \le s$, such that the following properties hold.
   - For $m \le s$, every triangulation $\mathfrak{T}_i$, $1 \le i \le m$, is a 1-vertex n_i-tetrahedron triangulation;
   - For $m < \ell \le s$, the topological type of every triangulation $\mathfrak{T}_\ell$ can be detected in polynomial time, and must be one of only three types (for which Turaev-Viro invariants can be pre-computed in constant time);
   - We have $(s-m) + \sum_{i=1}^{m} n_i \le n$;
   - We have $\mathfrak{T} \cong \mathfrak{T}_1 \# \ldots \# \mathfrak{T}_s$, i.e., $\mathfrak{T}$ is the connected sum of the $\mathfrak{T}_i$, $1 \le i \le s$.

   If $\mathfrak{T}$ contains a two-sided projective plane the crushing procedure will detect this fact and the computation is cancelled. The total running time of this step is polynomial.
2. For $1 \le i \le m$, compute $\mathrm{TV}_{r,1}(\mathfrak{T}_i, [0])$. This is the only step of this algorithm with an exponential running time. All other steps can be completed in polynomial time.
3. For all $\mathfrak{T}_i$, compute $\mathrm{TV}_{3,1}(\mathfrak{T}_i)$ – a polynomial time procedure, due to the one-to-one correspondence between admissible colourings in $\mathrm{Adm}(\mathfrak{T}, 3)$ and 1-cocycles of $\mathfrak{T}$.
4. Use Theorem 3 (for r odd we have $\mathrm{TV}_{r,1}(\cdot) = \mathrm{TV}_{3,1}(\cdot)\ \mathrm{TV}_{r,1}(\cdot, [0])$) to obtain $\mathrm{TV}_{r,1}(\mathfrak{T}_i)$.
5. Scale all values from the previous step to $\mathrm{TV}'_{r,1}$, multiply them and re-scale the product. The result equals $\mathrm{TV}_{r,1}(\mathfrak{T})$, by Theorem 2.

[1] This is a technical pre-condition for the procedure to succeed. Triangulations not satisfying this pre-condition are extremely rare.

[2] Building the connected sum $M\#N$ of two manifolds M and N consists of removing a small ball from M and N respectively, and glue them together along their newly created boundaries.

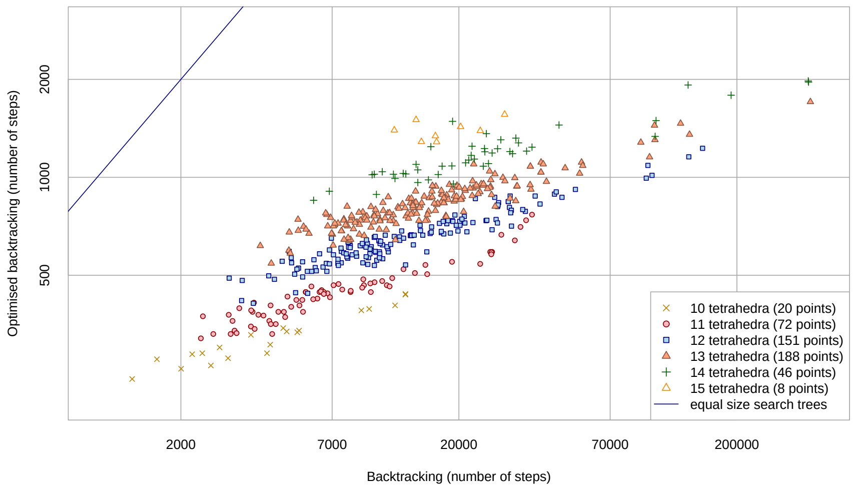

Figure 1 Number of nodes in the search tree visited by the naive algorithm and the optimised backtracking procedure for the 500 first 1-vertex triangulations of the Hodgson-Weeks census.

Running time of the proposed algorithm. The crushing and expanding procedure, computing $\mathrm{TV}_{3,1}(\mathfrak{T})_i$, $1 \leq i \leq s$, computing $\mathrm{TV}_{r,1}(\mathfrak{T}_i, [0])$, $m < i \leq s$, and scaling and multiplying the invariants are all polynomial time procedures [3, 6]. Following Proposition 7(iii) the running time to compute $\mathrm{TV}_{r,1}(\mathfrak{T}_i, [0])$, $1 \leq i \leq m$, is $O(\lfloor r/2 \rfloor^{n_i+1})$ (remember, $\mathfrak{T}_i$ is a 1-vertex triangulation). The overall running time is thus $O(\lfloor r/2 \rfloor^{n+1})$. The same procedure can be applied to improve the fixed parameter tractable algorithm as presented in [5] – which is also based on enumerating colourings – to get the running time $O(n \lfloor r/2 \rfloor^{6(k+1)} k^2 \log r)$, where k is the treewidth of the dual graph of $\mathfrak{T}$.

In Sections 4.1 and 4.2 we show that this improvement has also strong practical implications. In particular, the proposed algorithms allow computations up to several orders of magnitude faster than state of the art procedures to compute Turaev-Viro invariants.

4 Experiments

Here we run large scale experiments to illustrate the interest and performance of the methods introduced above. Implementations will appear within the 3-manifold software `Regina` [4].

We use two data sets for our experiments, both taken from large "census databases" of 3-manifolds to ensure that the experiments are comprehensive and not cherry-picked. The first census contains all 50 817 closed minimal triangulations that can be formed from $n \leq 11$ tetrahedra [2, 12]. This simulates "real-world" computation – the Turaev-Viro invariants were used to build this census. The second data set contains the triangulations from the Hodgson-Weeks census of closed hyperbolic manifolds [8]. This shows performance on larger triangulations, with n ranging from 9 to 20.

The admissible colouring weights may be computed symbolically or numerically, which acts substantially on running times. In the following, we either avoid this difficulty by measuring "discrete data" (like size of search spaces) to represent performance, or we indicate which weight representation we use.

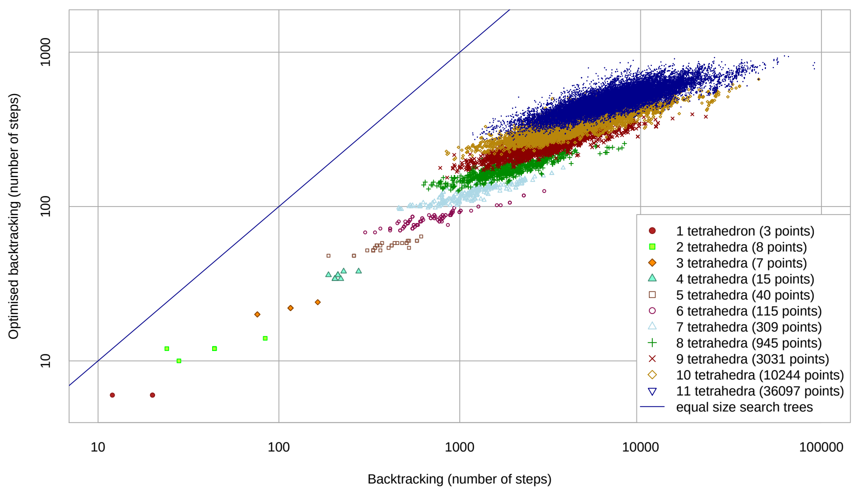

Figure 2 Number of nodes in the search tree visited by the optimised backtracking procedure over the naive algorithm for the 1-vertex minimal closed triangulations.

4.1 Computing $\mathrm{TV}_{r,1}$ with the backtracking method, r odd

We compare experimentally the performance of the naive backtracking algorithm with our proposed backtracking algorithm (Section 3.5) enumerating only colouring at the cohomology class [0]. To do so, we count the number of nodes in the backtracking search tree visited by both algorithms for computing $\mathrm{TV}_{5,1}$ (i) for all triangulations with ≤ 11 tetrahedra in the census of closed minimal triangulations [2] (see Figure 2), and (ii) for the first 500 triangulations of the Hodgson-Weeks census, with $10 \leq n \leq 15$, [8] (see Figure 1). These triangulations all have one vertex, and the improvement is solely due to the reduction of the space of colourings studied above (in particular, the crushing step is not applied).

Because a colouring may be declared non-admissible before colouring all edges of the triangulation, the standard backtracking algorithm visits generally fewer nodes than the $O((r-1)^{n+1})$, for a triangulation with n tetrahedra, predicted by the worst case complexity analysis. Despite this fact, the improvements of our algorithm for the minimal triangulations census range from factors 2 to 117. Improvements in the Hodgson-Weeks census, which contains much larger triangulations, range from factors 5.6 to 215. On both data sets, the range of improvements rapidly grows larger as the size of the triangulations increase. We confirm this observation below.

4.2 Computing $\mathrm{TV}_{r,1}$ with the FPT algorithm, r odd

As demonstrated in [5], the fixed parameter tractable (FPT) algorithm is the most efficient procedure to compute Turaev-Viro invariants experimentally. Improving the running time of this implementation is thus highly significant in practice.

We compare the running times of the FPT algorithm from [5] with the optimised FPT algorithm relying on the enumeration of colourings at the trivial cohomology class, as presented in Section 3.5. Here, the enumeration of colourings is done within the bags of the tree decomposition of the dual graph of the triangulation [5]. Turaev-Viro invariants are computed with floating point arithmetic. Figure 4 represents the running time of both algorithms on the census of closed minimal triangulations of up to 11 tetrahedra, for $r = 5$. All triangulations only have one vertex. We have removed from the timings triangulations with

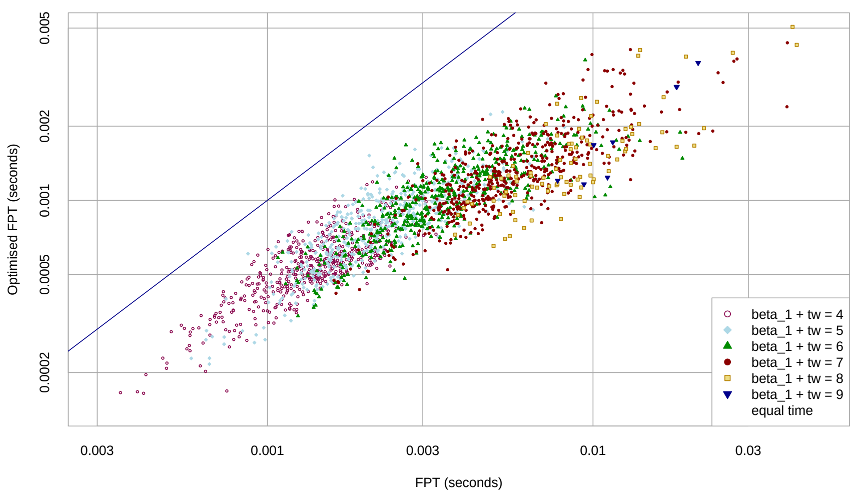

Figure 3 Comparison of the running times of the FPT algorithm presented in [5] and the FPT algorithm with the enumeration procedure introduced in Section 3.5, to compute $\mathrm{TV}_{5,1}$ on the Hodgson-Weeks census with $n \leq 20$ tetrahedra (with one vertex and $\mathrm{TV}_{3,1} \neq 0$). We use the parameter $\mathrm{tw} + \beta_1$ as a measure of "difficulty" for the computation. For readability, the plot presents a sparsified cloud (500 uniform random samples for each parameter value).

$\mathrm{TV}_{3,1} = 0$, as we can conclude in polynomial time, in our implementation, that $\mathrm{TV}_{r,1} = 0$ using the formula involving $\mathrm{TV}_{3,1}$ in Section 3.5. Consequently, Figure 4 illustrates the improvement solely due to the enumeration of colourings at the trivial cohomology class. For our implementation of the FPT algorithm, we include the timings of *all* steps of the algorithm presented in Section 3.5; the dominating step is naturally the computation of $\mathrm{TV}_{r,1}(\mathfrak{T}, [0])$ (step 2), which is the only exponential step of the procedure.

Figure 4 shows a clear improvement of the running time of our algorithm. Most interestingly, this range of improvement seems to increase (points getting further away from the diagonal) for triangulations on which the standard FPT algorithm is slower.

To confirm this tendency on larger scales, we run the computational power-intensive computation of $\mathrm{TV}_{11,1}$ on the first 1000 triangulations of the Hodgson-Weeks census (Figure 3), with triangulations with up to 20 tetrahedra. We observe that 40% of the total running time of the standard FPT algorithm over the 1000 triangulations is spent on only 10 of them. On these 10 inputs, our implementation is up to 130 times faster, and 29 times faster in average, reducing the total running time for these "hardest" 10 triangulations from several hours to a few minutes of computation.

4.3 Experiments for computing $\mathrm{Adm}(\mathfrak{T}, 4)$

In this section, we study experimentally the bounds on the number of admissible colourings for $r = 4$, and the efficiency of the algorithm for $\mathrm{TV}_{4,1}$, introduced in Sections 3.2 and 3.3, depending on them. Table 1 gives details on the bounds given by Theorem 6, and hence the worst case number of steps of our algorithm to compute $\mathrm{TV}_{4,1}$, and the average number of steps the backtracking algorithm requires to compute $\mathrm{TV}_{4,1}$. We run the experiments on all minimal triangulations with up to 6 tetrahedra, sorted by Betti number β_1.

We note that the actual number of nodes visited by the backtracking algorithm is smaller than the worst case bound, but it is significantly larger than the upper bound of Equation (2) in Theorem 6. Additionally, the bound given by Equation (2) is very close

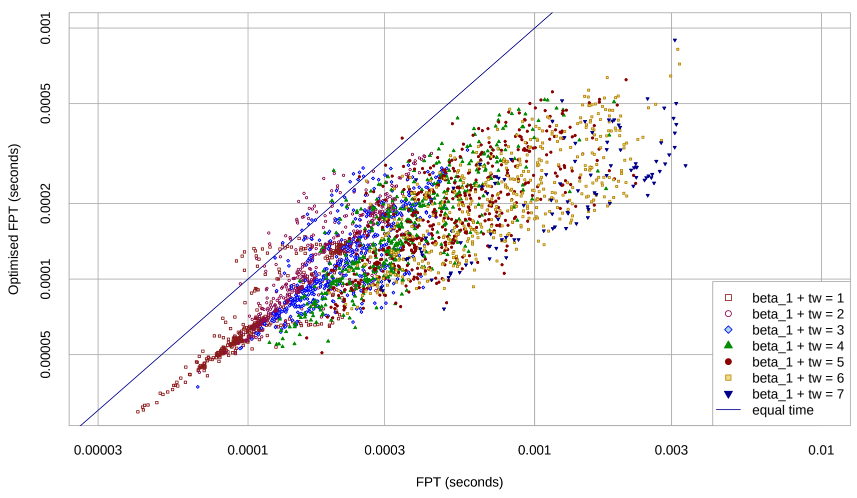

Figure 4 Comparison of the running times of the FPT algorithm from [5] and the FPT algorithm with the enumeration procedure introduced in Section 3.5, to compute $\mathrm{TV}_{5,1}$ on the census of minimal triangulations with $n \leq 11$ tetrahedra (with one vertex and $\mathrm{TV}_{3,1} \neq 0$). We use the parameter $\mathrm{tw} + \beta_1$ as a measure of "difficulty" for the computation. For readability, the plot presents sparsified cloud (500 uniform random samples for each parameter value).

Table 1 "$\#\mathfrak{T}$" lists the number of triangulations contained in the n-tetrahedra census of minimal triangulations with first Betti number $\beta_1(\mathfrak{T}, \mathbb{Z}_2)$, "# eq. (2)" lists the number of triangulations satisfying equality in Inequality (2). Below, the average number of nodes of the search tree visited by the backtracking algorithm ("# tree"), the bound "Eqn. (2)" given by Inequality (2), and the average number "Av." of admissible colourings in $\mathrm{Adm}(\mathfrak{T}, 4)$ are listed.

(n, β_1)	$(1,1)$	$(2,1)$	$(2,2)$	$(3,1)$	$(3,2)$	$(4,1)$	$(4,2)$	$(5,1)$	$(5,2)$	$(6,1)$	$(6,2)$	$(6,3)$
$\#\mathfrak{T}$	1	5	1	27	3	205	19	1858	184	21459	2516	34
#eq. (2)	1	5	1	14	1	67	4	261	10	1574	47	0

Av.	4.0	6.0	10.0	6.3	11.3	8.7	15.3	9.3	18.6	10.7	22.0	41.4

to the average number of admissible colourings of the triangulations, which underlines the fact that our algorithm for $\mathrm{TV}_{4,1}$ has a practical output-sensitive behaviour in the number of admissible colourings. Finally, our bounds on $|\mathrm{Adm}(\mathfrak{T}, 4)|$ are sharp on 1985 out of the 26,312 triangulations of the experiment.

5 Experiments on triangulations with vanishing β_1

In this section we provide experimental details on the number of admissible colourings of triangulations with $\beta_1 = 0$, and the ability of $\mathrm{TV}_{r,1}$ to distinguish between these manifolds and the 3-sphere, which is of particular importance in 3-manifold topology.

In Table 2 we provide details on the number of admissible colourings of triangulations with up to 6 tetrahedra and $\beta_1 = 0$. In particular, the table shows that the bounds from Proposition 8 are tight, and much finer in general than the naive bound $(r-1)^{n+v}$.

As evidence for the interest of the algorithm to compute $\mathrm{TV}_{r,1}$, r odd, introduced in Section 3.5, we analyse the ability of $\mathrm{TV}_{r,1}$, $r \in \{3,5,7,9\}$, to distinguish 3-manifolds

Table 2 Number "# trigs." of 1-vertex triangulations $\mathfrak{T}$ of manifolds with $\beta_1(\mathfrak{T}, \mathbb{Z}_2) = 0$ and n tetrahedra, $1 \leq n \leq 6$. Number "#sharp" of such triangulations satisfying equality in all bounds from Theorem 8 (third column), and the average number "$\overline{|\mathrm{Adm}(\mathfrak{T}, r)|}$" of admissible colourings in $\mathrm{Adm}(\mathfrak{T}, r)$, $5 \leq r \leq 7$ (columns 6, 9, and 12), compared to the naive upper bound "$(r-1)^{v+n}$" (columns 4, 7, and 10) and the new upper bounds given by Theorem 8 (columns 5, 8, and 11).

n	#trig.	#sharp	$(5-1)^{n+v}$	2^n+1	$\overline{\lvert\mathrm{Adm}(\mathfrak{T},5)\rvert}$	$(6-1)^{n+v}$	3^n+1	$\overline{\lvert\mathrm{Adm}(\mathfrak{T},6)\rvert}$	$(7-1)^{n+v}$	3^n+1	$\overline{\lvert\mathrm{Adm}(\mathfrak{T},7)\rvert}$

Table 3 Summary of the ability of $\mathrm{TV}_{r,1}$, $3 \leq r \leq 9$, to distinguish 3-manifolds with trivial (integral) homology up to complexity 11 from the 3-sphere. X/Y denotes the success rate, i.e., there are Y manifolds, X of which can be distinguished from the 3-sphere by the respective invariant.

n	$\mathrm{TV}_{3,1}$	$\mathrm{TV}_{4,1}$	$\mathrm{TV}_{5,1}$	$\mathrm{TV}_{6,1}$	$\mathrm{TV}_{7,1}$	$\mathrm{TV}_{8,1}$	$\mathrm{TV}_{9,1}$	$\mathrm{TV}_{5,1}$ and $\mathrm{TV}_{7,1}$
5	0/1	0/1	**1/1**	0/1	**1/1**	1/1	1/1	**1/1**
7	0/1	0/1	**1/1**	0/1	**1/1**	0/1	1/1	**1/1**
8	0/3	0/3	**1/3**	0/3	**3/3**	3/3	3/3	**3/3**
9	0/4	0/4	**3/4**	0/4	**3/4**	1/4	3/4	**4/4**
10	0/8	0/8	**5/8**	0/8	**7/8**	3/8	6/8	**8/8**
11	0/19	0/19	**11/19**	0/19	**16/19**	13/19	16/19	**18/19**

from the 3-sphere. Since homology can be computed in polynomial time, we only consider 3-manifolds M which cannot be distinguished from the 3-sphere using integral homology (i.e., $\beta_1(M, \mathbb{F}) = 0$, for any choice of field $\mathbb{F}$). There are 36 distinct such 3-manifolds of *complexity* at most 11, meaning, they can be triangulated with 11 tetrahedra or less. Due to Proposition 7(i) we already know that none of them can be distinguished from the 3-sphere by $\mathrm{TV}_{3,1}$. $\mathrm{TV}_{5,1}$, $\mathrm{TV}_{7,1}$, and $\mathrm{TV}_{9,1}$ distinguish 22, 31, and 30, a combination of $\mathrm{TV}_{5,1}$ and $\mathrm{TV}_{7,1}$ only fails once, and a combination of all three invariants never fails to distinguish them from the 3-sphere. See Table 3 for details.

Together with the favourable timings presented in Section 4, this indicates that our new approach to compute the Turaev-Viro invariants for odd values of r gives a practical fast way to distinguish manifolds with $\beta_1 = 0$ from the 3-sphere in many cases.

Abstract

A key question in biological systems is whether genetic diversity persists in the long run under evolutionary competition, or whether a single dominant genotype emerges. Classic work by Kalmus in 1945 [14] has established that even in simple diploid species (species with chromosome pairs) diversity can be guaranteed as long as the heterozygous[1] individuals enjoy a selective advantage. Despite the classic nature of the problem, as we move towards increasingly polymorphic traits (e.g., human blood types) predicting diversity (and its implications) is still not fully understood. Our key contribution is to establish complexity theoretic hardness results implying that even in the textbook case of single locus (gene) diploid models, predicting whether diversity survives or not given its fitness landscape is algorithmically intractable.

Our hardness results are structurally robust along several dimensions, e.g., choice of parameter distribution, different definitions of stability/persistence, restriction to typical subclasses of fitness landscapes. Technically, our results exploit connections between game theory, nonlinear dynamical systems, and complexity theory and establish hardness results for predicting the evolution of a deterministic variant of the well known multiplicative weights update algorithm in symmetric coordination games; finding one Nash equilibrium is easy in these games. In the process we characterize stable fixed points of these dynamics using the notions of Nash equilibrium and negative semidefiniteness. This as well as hardness results for decision problems in coordination games may be of independent interest. Finally, we complement our results by establishing that under randomly chosen fitness landscapes diversity survives with significant probability. The full version of this paper is available at `http://arxiv.org/abs/1411.6322`.

[1] Having different alleles for a gene on two chromosomes.

1 Introduction

The beauty and complexity of natural ecosystems have always been a source of fascination and inspiration for the human mind. The exquisite biodiversity of Galapagos' ecosystem, in fact, inspired Darwin to propose his theory of natural selection as an explanatory mechanism for the origin and evolution of species. This revolutionary idea can be encapsulated in the catch phrase "survival of the fittest"[2]. Natural selection promotes the survival of those genetic traits that provide to their carriers an evolutionary advantage.

A marker of the true genius behind any paradigm is its longevity and in this respect the success of natural selection is without precedent. The formalized study of evolution, dating back to the work of Fisher, Haldane, and Wright in the beginning of the twentieth century, still and to a large extent focuses on simple, almost toy-like, alas concrete, models of this famous aphorism and the experimental and theoretical analysis of them. Arguably, the most influential result in the area of mathematical biology is Fisher's fundamental theorem of natural selection (1930) [9]. It states that the rate of increase in fitness of any organism at any time is equal to its genetic variance in fitness at that time. In the classical model of population genetics (Fisher-Wright-Haldane, discrete or continuous version) of single locus (one gene) multi-allele diploid models[3] it implies that the average fitness of the species populations is always strictly increasing unless we are at an equilibrium. In fact, convergence to equilibrium is point-wise even if there exist continuum of equilibria (See [21] and references therein). From a dynamical systems perspective, this is a rather strong characterization, since it establishes that the average fitness acts as a Lyapunov function for the system and that every trajectory converges to an equilibrium.

Besides the purely dynamical systems interpretation, an alternative, more palpable, game theoretic interpretation of these genetic systems is possible. Specifically, these systems can be interpreted as symmetric coordination/partnership two-agent games[4] where both agents, starting with the same mixed initial strategy, apply (discrete) replicator dynamics[5]. The analogies are as follows: The two players correspond each to a locus (or gene) on a pair of homologous chromosomes[6] and the alleles are their strategies. When both players choose a strategy, say i and j, an individual (i, j) is defined whose fitness, say A_{ij}, is the payoff to both players, hence we have a coordination game. Furthermore, allele pairs are unordered so we have $A_{ij} = A_{ji}$, *i.e.*, A is symmetric and so is the game. The frequencies of the alleles in the initial population, namely $\boldsymbol{x} := (x_1, ..., x_n) \in \Delta_n$[7] of n different alleles, corresponds to the initial common mixed strategy of both players. In each generation, every individual from the population mates with another individual picked at random from the population, and the updates of the mixed strategies/allele frequencies are captured by replicator/MWUA dynamics, *i.e.*,

$$x'_i = x_i \frac{\sum_j A_{ij} x_j}{\boldsymbol{x}^T A \boldsymbol{x}} \tag{1}$$

[2] The phrase "survival of the fittest" was coined by Herbert Spencer.
[3] We present information related to biology in Section A.1.
[4] A coordination/partnership game is a game where at each outcome all agents receive the same utility.
[5] Replicator dynamics (as well as their discrete variants) are close analogues to the well known multiplicative updates (MWUA) family of dynamics [19].
[6] Most multicellular organisms have two sets of chromosomes; *i.e.*, they are diploid. These chromosomes are referred to as homologous chromosomes. If both alleles at a locus (or gene) on the homologous chromosomes are the same, they and the organism are homozygous with respect to that gene. If the alleles are different, they and the organism are heterozygous with respect to that gene. See section A.
[7] Δ_n denotes the simplex of dimension n.

where x_i' is the proportion of allele i in the next generation (for details see Section 4). In game theoretic language, the fundamental theorem of natural selection implies that the social welfare $\boldsymbol{x}^T A \boldsymbol{x}$ (average fitness in biology terms) of the game acts as potential for the game dynamics. This implies convergence to fixed points. Fixed points are superset of Nash equilibria where each strategy played with positive probability has the same average payoff.

We say that population is genetically diverse if at least two alleles have non-zero proportion in the population, *i.e.,* allele frequencies form a *mixed (polymorphic) strategy*. The game theoretic results do not provide insight on the survival of genetic diversity. One way to formalize this question is whether there exists a mixed fixed point that the dynamics converges to with positive probability, given a uniformly random starting point in Δ_n. The answer to this question for the minimal case of $n = 2$ alleles (alleles b/B, individuals $bb/bB/BB$) is textbook knowledge and can be traced back to the classic work of Kalmus (1945) [14]. The intuitive answer here is that diversity can survive when the heterozygote individuals, bB, have a fitness advantage. Intuitively, this can be explained by the fact that even if evolution tries to dominate the genetic landscape by bB individuals, the random genetic mixing during reproduction will always produce some bb, BB individuals, so the equilibrium that this process is bound to reach will be mixed. On the other hand, it is trivial to create instances where homozygote individuals are the dominant species regardless of the initial condition.

As we increase the size/complexity of the fitness landscape, not only is not clear that a tight characterization of the diversity-inducing fitness landscape exists (a question about global stability of nonlinear dynamical systems), but also, it is even less clear whether one can decide efficiently whether such conditions are satisfied by a given fitness landscape (a computational complexity consideration). How can one address this challenge and moreover, how can one account for the apparent genetic diversity of the ecosystems around us?

In a nutshell, we establish that the decision version of the problem is computationally hard, by sandwiching limit points of the dynamics between various stability notions. This core result is shown to be robust across a number of directions. Deciding the existence of stable (mixed) polymorphic equilibria remains hard under a host of different definitions of stability examined in the dynamical systems literature. The hardness results persist even if we restrict the set of allowable landscape instances to reflect typical instance characteristics. Despite the hardness of the decision problems, randomly chosen fitness landscapes are shown to support polymorphism with significant probability (at least 1/3). The game theoretic interpretation of our results allow for proving hardness results for understanding standard game theoretic dynamics in symmetric coordination games. We believe that this is an important result of independent interest as it points out at a different source of complexity in understanding social dynamics.

2 Technical Overview

To study survival of diversity in diploidy, we need to characterize limiting population under evolutionary pressure. We focus on the simplest case of single locus (one gene) species. For this case, evolution under natural selection has been shown to follow replicator dynamics in symmetric two-player coordination games [21], where the genes on two chromosomes are players and alleles are their strategies as described in the introduction. Losert and Akin established point-wise convergence for this dynamics through a potential function argument [21]; here average fitness $\boldsymbol{x}^T A \boldsymbol{x}$ is the potential. The limiting population corresponds to fixed points (FP), and so to make predictions about diversity (if the limiting population has support size at least 2) we need to characterize and compute these limiting FPs.

Let $\mathcal{L}$ denote the set of fixed points (FP) with region of attraction[8] of positive (Lebesgue) measure. Hence, given a random starting point replicator dynamics converges to such a FP with positive probability, *i.e.,* the set of FP with region of attraction of positive measure. It seems that an exact characterization of $\mathcal{L}$ is unlikely. Establishing necessary and sufficient conditions so that a FP has a region of attraction of positive measure in classes of nonlinear systems is a rather formidable task. Instead we try to capture this property as closely as possible through different stability notions. First we consider two standard notions defined by Lyapunov, the *stable* and *asymptotically stable* FP. Informally, if we start close to a *stable* FP then we stay close to it forever, while in case of *asymptotically stable* FP furthermore the dynamics converges to it (see Section 4.3). Thus *asymptotically stable* $\subseteq \mathcal{L}$ follows, *i.e.,* an asymptotically stable FP has region of attraction of positive measure (*e.g.*, a small ball around the FP). Note that $\mathcal{L}$ may have points that are not (asymptotically) stable.

There exist some well known connections between stability notions and properties of the (absolute) eigenvalues (EVal) of the Jacobian of the update rule (function) of the dynamics are well known: if the Jacobian at a FP has an Eval > 1 then the FP is *un-stable* (not *stable*), and if all Eval < 1 then it is asymptotically stable. The case when all Eval ≤ 1 with equality holding for some, is the ambiguous one. In that case we can say nothing about the stability because the Jacobian does not suffice. We will call these FPs *linearly-stable.* At a FP, say $\boldsymbol{x}$, if some EVal > 1 then the direction of corresponding eigenvector is repelling, and therefore any starting vector with a component of this vector can never converge to $\boldsymbol{x}$. Thus points converging to $\boldsymbol{x}$ can not have positive measure. Using this as an intuition we show that in our dynamical systems $\mathcal{L} \subseteq$ *linearly-stable* FPs. In other words the set of initial points so that the dynamics converges to linearly-*un*-stable FPs has zero measure (Theorem 13). This theorem is heavily utilized to understand the (non-)existence of diversity.

Efficient computation requires efficient verification. However, note that whether a given FP is (asymptotically) stable or not does not seem easy to verify. To achieve this, one of the contributions of this paper is the definition of two more notions: *Nash stable* and *strict Nash stable.*[9] It is straightforward to check that Nash equilibria (NE) of the corresponding coordination game described in introduction are FPs of the replicator dynamics (Equations 1,2) but not vice-versa. Keeping this in mind we define *Nash stable* FP, which is a NE with the additional property that the sub-matrix corresponding to its support satisfies certain negative semi-definiteness. The latter condition is derived from the fact that *stability* is related to local optima of $\boldsymbol{x}^T A \boldsymbol{x}$ and also from Sylvester's law of inertia [38] (see Section 5 and proofs). For *strict Nash stable* both conditions are strict, namely strict NE and negative definiteness. Combining all of these notions we show the following:

▶ **Theorem 1.**

$$\begin{array}{ccccccccc} \textit{Strict Nash stable} & \subseteq & \textit{Asymptotically stable} & \subseteq & \mathcal{L} & \subseteq & \textit{linearly-stable} & = & \textit{Nash stable} \\ & & \cap\!\mid & & & & & & \\ & & \textit{stable} \subseteq & \textit{linearly-stable} & = & \textit{Nash stable} & & & \end{array}$$

We note that the sets of asymptotically stable, stable, $\mathcal{L}$ and linearly stable FPs of Theorem 1 do not coincide in general.[10] For example, let x_{t+1} be the next step for the

[8] Region of attraction of an FP is the set of all initial points so that dynamics converges to it.

[9] These two notions are not the same as evolutionary stable strategies/states.

[10] We also note that generically these sets coincide. It can be shown [22] that given a fitness matrix, its entries can be perturbed to ensure no eigenvalue on the unit circle for the Jacobian at any fixed point. Such fixed points are called *hyperbolic.* Formally, if we consider the dynamics as an operator (called *Fisher* operator) then the set of hyperbolic operators is dense in the space of Fisher operators.

following update rules:

$$f(x_t) = \frac{1}{2}x_t, g(x_t) = x_t - \frac{1}{2}x_t^2, h(x_t) = x_t + \frac{x_t^3}{2}, d(x_t) = x_t.$$

Then for dynamics governed by f, 0 is asymptotically stable, stable and linearly stable, and hence is also in $\mathcal{L}$. While for g it is linearly stable and is in $\mathcal{L}$, but is not stable or asymptotically stable. For d it is linearly stable and stable, but not asymptotically stable and is not in $\mathcal{L}$. Finally, for h it is only linearly-stable, and does not belong to any other class. Our primary goal was to see if diversity is going to survive. We formalize this by checking whether set $\mathcal{L}$ contains a mixed point, *i.e.,* where more than one alleles have non-zero proportion, implying that *diversity survives with some positive probability*, where the randomness is w.r.t the random initial $\boldsymbol{x} \in \Delta_m$. In Section 7 we show that for all five notions of stability, checking existence of mixed stable FP is NP-hard.

Our reductions are from k**-clique** - given an undirected graph check if it has a clique of size k; a well known NP-hard problem. Given an instance G of k*-clique*, we will construct a symmetric matrix A as shown in Figure 1, and consider coordination game (A, A). We show game (A, A) has the following two properties.

(i) If G has a clique of size k then (A, A) has a mixed *strict* Nash stable equilibrium. Therefore, it has a mixed stable FP for any notions of the (strict) Nash stability, (asymptotic) stability, linearly-stability, and $\mathcal{L}$ because of Theorem 1.

(ii) If (A, A) has a mixed Nash stable equilibrium then G has a clique of size k. Therefore, if (A, A) has a mixed stable FP for all notions of the (strict) Nash stability, (asymptotic) stability, linearly-stability, and $\mathcal{L}$ then G has a clique of size k because of Theorem 1.

Note that the above two properties imply NP-hardness for checking existence of mixed stable FP for all five notions of stability as well as set $\mathcal{L}$. The latter implies NP-hardness for checking survival of diversity in diploid species even with single gene.

▶ **Theorem 2** (Informal). *Given a symmetric matrix A, it is NP-hard to check if replicator dynamics with payoff A has mixed (asymptotically) stable, linear-stable, or (strict) Nash stable fixed points. A common reduction for all together with Theorem 1 will imply that it is NP-hard to check whether diversity survives for a given fitness matrix.*

The main idea in the construction of matrix A (Figure 1) is to use a modified version of the adjacency matrix E of the graph as one of the blocks in the payoff matrix such that the existence of a clique of size k or more implies a stable Nash equilibrium in that block, and all stable mixed equilibria are only in that block. Here E' is the modification of E where off-diagonal zeros are replaced with $-h$ where h is a large (polynomial-size number). Note that A is $2n \times 2n$, where the first n strategies correspond to the n nodes of the graph. To argue (i), given a k-clique we construct a maximal clique containing it, say of size m, and then show that the distribution that assigns probability $\frac{1}{m}$ to the strategies corresponding to nodes in the clique, and zero otherwise, is a (strict Nash) stable FP. To show (ii), we use the negative semi-definiteness property of Nash stable (which contains all other notions), which implies $A_{ii} \leq 2A_{ij}$ for all i, j in the support a Nash stable FP. Therefore if $h > 2(k-1)$, then none of $\{n+1, \ldots, 2n\}$ can be in the support. Next we concentrate only on strategies that have big enough probability, call it set S. The Nash equilibrium property of Nash stable states can be shown to force each non-zero probability to be $\leq \frac{1}{k}$. Using these facts we show that $|S| \geq k$ and the corresponding vertices in G form a clique. Thus, we prove the existence of a k-clique.

The fitness matrix constructed for the hardness results is rather specific. Do these hardness results carry over to "typical" (at least not completely worst case) instances of fitness landscapes? What is the complexity of checking if a given allele survives? We show that our computational intractability results still apply to these settings.

There has been a lot of work on NP-hardness for decision versions of Nash equilibrium in general games [11, 5, 34, 10], where finding one equilibrium is also PPAD-hard [3]. Whereas to the best of our knowledge these are the first NP-hardness results for coordination games, where finding one Nash equilibrium is easy, and therefore may be of independent interest. Finally, in Section 6 we show that even though checking the survival of diversity is hard, on average diversity persists.

▶ **Theorem 3** (Informal). *If the entries of a fitness matrix are i.i.d. on a continuous distribution then with significantly high probability, at least $\frac{1}{3}$, diversity will surely survive.*

Survival is ensured if every fixed point in $\mathcal{L}$ is mixed. This itself is guaranteed as long as every diagonal entry (i, i) of the fitness matrix is dominated by some entry in its row or column. We can lower bound the probability of the latter *by a constant* for a random symmetric matrix (from continuous distribution) of *any size*. The tricky part is to avoid correlation arising due to symmetry and we achieve this using inclusion-exclusion arguments.

3 Related Work

In the last few years we have witnessed a rapid cascade of theoretical results on the intersection of computer science and evolution. Livnat *et al.* [20] introduced the notion of mixability, the ability of an allele to combine itself successfully with other alleles within a specific population. In [2, 1] connections were established between haploid evolution and game theoretic dynamics in coordination games. Even more recently Meir and Parkes [24] provided a more detailed examination of these connections. These dynamics are close variants of the standard (discrete) replicator dynamics [12]. Replicator dynamics is closely connected to the multiplicative weights update algorithm [19]. Analogous game theoretic interpretations are known for diploids [21].

Analyzing limit sets of dynamical systems is a critical step towards understanding the behavior of processes that are inherently dynamic, like evolution. There has been an upsurge in studying the complexity of computing these sets. Quite few works study such questions for dynamical systems governed by arbitrary continuous functions or ODEs [15, 16, 35]. Limit cycles are inherently connected to dynamical systems and recent works by Papadimitriou and Vishnoi [29] showed that computing a point on an approximate limit cycle is PSPACE-complete. Cyclic limit sets also arise in game theoretic dynamics [18, 32, 31, 28]. On the positive side, in [27], it was shown that a class of evolutionary Markov chains mix rapidly, where techniques from dynamical systems were used.

The complexity of checking if a game has an evolutionary stable strategy (ESS) has been studied first by Nissan and then by Etessami and Lochbihler [26, 8] and has been nailed down to be Σ_2^P-complete by Conitzer [4]. Unlike our setting here the game is between different species to survive in a common environment. These problems are orthogonal to understanding issues of genetic diversity, and thus not directly comparable to our work.

Other connections between computational complexity and ecology/evolution examine the complexity of finding local/global minima of structured fitness landscapes [37, 17, 39], as well as, complexity questions in regards to the probability that a new invader (or a new mutant) will take over a resident population [33]. The sexual dynamics and the questions about diversity considered here are not captured in any of the settings above.

In [23] Mehta, Panageas and Piliouras examine the question of diversity for haploid species. Despite the systems' superficial similarities the two analyses come to starkly different conclusions. In haploids systems all mixed (polymorphic) equilibria are unstable and evolution converges to monomorphic states. In the case of diploid systems the answer to whether diversity survives or not depends crucially on the geometry of the fitness landscape.

4 Preliminaries

Notations: We use boldface letters, like $\boldsymbol{x}$, to denote column vectors, and x_i is its i^{th} coordinate. Vectors $\mathbf{0}_n$ and $\mathbf{1}_n$ are n-D vectors with all zeros and ones. For matrix A, A_{ij} is the entry in i^{th} row and j-th column and we denote $(A\boldsymbol{x})_i = \sum_j A_{ij}x_j$. By norm $||.||$ we mean $||.||_\infty$. $[n]$ denotes set $\{1,\dots,n\}$, and Δ_n denotes n-D simplex, and let $SP(\boldsymbol{x})$ be $\{i \mid x_i > 0\}$.

4.1 Evolutionary dynamics

Consider a diploid single locus species, *i.e.,* a species with a chromosome pair and single gene. Every gene has a set of representative alleles, e.g., gene for eye color has different alleles for brown, black and blue eyes. Let n be the number of alleles for the single gene of our species, and let these be numbered $1,\dots,n$. An individual is represented by an unordered pair of alleles (i,j) one in each chromosome, and we denote its fitness by A_{ij}; clearly A is symmetric. Here fitness represents its ability to reproduce during a mating. In every generation two individuals are picked uniformly at random from the population, say (i,j) and (i',j'), and they mate. The allele pair of the offspring can be any of the four possible combinations, namely $(i,i'),(i,j'),(i',j),(j,j')$, with equal probability. Let x_i be a random variable that denotes the proportion of the population with allele i. After one generation, the expected number of offsprings with allele i is proportional to $x_i \cdot x_i \cdot (A\boldsymbol{x})_i + 2\frac{1}{2}(1-x_i)x_i \cdot (A\boldsymbol{x})_i = x_i(A\boldsymbol{x})_i$ (x_i^2 stands for the probability that first individual has both his alleles i, *i.e.,* is represented by (i,i) - and thus the offspring will inherit allele i - and $2\frac{1}{2}(1-x_i)x_i$ stands for the probability that the first individual has allele i exactly once in his representation and the offspring will inherit). Hence, if $\boldsymbol{x}$ denote the frequencies of the alleles in the population in the next generation (random variables)

$$E[x_i'|\boldsymbol{x}] = \frac{x_i(A\boldsymbol{x})_i}{\boldsymbol{x}^T A\boldsymbol{x}}.$$

We focus on the *deterministic* version of the equations above, which captures the infinite population model. Thus if $\boldsymbol{x} \in \Delta_n$ represents the proportions of alleles in the current population. Under the evolutionary process of natural-selection (the reproduction happens as described) this proportion changes as per the following multi-variate function $f : \Delta_n \to \Delta_n$ under the infinite population model [21]; in the literature this is often called *Discrete Replicator Dynamics.*

$$\boldsymbol{x}' = f(\boldsymbol{x}) \quad \text{where} \quad x_i' = f_i(\boldsymbol{x}) = x_i\frac{(A\boldsymbol{x})_i}{\boldsymbol{x}^T A\boldsymbol{x}}, \quad \forall i \in [n] \tag{2}$$

where $\boldsymbol{x}'$ are the proportions of the next generation. f is a continuous function with convex, compact domain (= range), and therefore always has a fixed point [13]. Furthermore, limit points of f have to be fixed points, *i.e.,* $\boldsymbol{x}$ such that $f(\boldsymbol{x}) = \boldsymbol{x}$.

▶ **Fact 4.** *Profile $\boldsymbol{x}$ is a fixed point of f iff $\forall i \in [n],\ x_i > 0 \Rightarrow (A\boldsymbol{x})_i = \boldsymbol{x}^T A\boldsymbol{x}$.*

One of the fundamental questions is: starting from arbitrary population of alleles how does the population look like in the limit under evolutionary pressures? Does the system converge? If so, then what are the properties of these limit points? Fisher's Fundamental Theorem of Natural Selection [21, 22] says that mean fitness function $\pi(\boldsymbol{x}) = \boldsymbol{x}^T A \boldsymbol{x}$ (potential function in game theory terms) satisfies the inequality $\pi(f(\boldsymbol{x})) \geq \pi(\boldsymbol{x})$ and the equality holds iff $\boldsymbol{x}$ is a fixed point. Losert and Akin [21, 22] showed that the dynamics above converge point-wise to fixed points and that f is a diffeomorphism in Δ_n.

4.2 Games, Nash equilibria and symmetries

In this paper we consider two-player (locus) games, where each player has finitely many pure strategies (alleles). Let $S_i,\ i = 1, 2$ be the set of strategies for player i, and let $m \overset{\text{def}}{=} |S_1|$ and $n \overset{\text{def}}{=} |S_2|$, then such a game can be represented by two payoff matrices A and B of dimension $m \times n$. Players may randomize amongst their strategies. The set of mixed strategies are Δ_m and Δ_n respectively.

▶ **Definition 5.** Nash Equilibrium [36] A strategy profile is said to be a Nash equilibrium (NE) if no player can achieve a better payoff by a unilateral deviation [25]. Formally, $(\boldsymbol{x}, \boldsymbol{y}) \in \Delta_m \times \Delta_n$ is a NE iff $\forall \boldsymbol{x}' \in \Delta_m,\ \boldsymbol{x}^T A \boldsymbol{y} \geq \boldsymbol{x}'^T A \boldsymbol{y}$ and $\forall \boldsymbol{y}' \in \Delta_n,\ \boldsymbol{x}^T B \boldsymbol{y} \geq \boldsymbol{x}^T B \boldsymbol{y}'$.

Game (A, B) is said to be symmetric if $B = A^T$. In a symmetric game the strategy sets of both players are identical, *i.e.,* $m = n$, and $S_1 = S_2$. We will use n, S and Δ_n to denote the strategy related quantities. Strategy $\boldsymbol{x} \in \Delta_n$ is a symmetric NE, both play $\boldsymbol{x}$, iff

$$\forall i \in S, x_i > 0 \Rightarrow (A\boldsymbol{x})_i = \max_k (A\boldsymbol{x})_k \tag{3}$$

▶ **Definition 6.** NE $\boldsymbol{x}$ is **strict** if $\forall k \notin SP(\boldsymbol{x}),\ (A\boldsymbol{x})_k < (A\boldsymbol{x})_i$, where $i \in SP(\boldsymbol{x})$.

Symmetric Coordination Game. In a coordination/partnership game $B = A$, *i.e.,* both the players get the same payoff always. Thus if A is symmetric then (A, A) is a symmetric coordination game. The next lemma follows using (3) and Fact 4

▶ **Lemma 7.** *If $\boldsymbol{x}$ is a symmetric NE of game (A, A), it is a fixed point of dynamics (2).*

From now on, by *mixed* (fixed point) strategy we mean strictly mixed (fixed point) strategy, *i.e.,* $\boldsymbol{x}$ such that $|SP(\boldsymbol{x})| > 1$, and non-mixed are called *pure.*

4.3 Basics in Dynamical Systems

Next we describe well-known stability notions in dynamical systems.

▶ **Definition 8.** A fixed point $\mathbf{r}$ of $f : \mathbb{R}^n \to \mathbb{R}^n$ is called **stable** if, for every $\epsilon > 0$, there exists a $\delta = \delta(\epsilon) > 0$ such that, for all $\boldsymbol{p} \in \mathbb{R}^n$ with $||\boldsymbol{p} - \mathbf{r}||| < \delta$ we have that $||f^n(\boldsymbol{p}) - \mathbf{r}|| < \epsilon$ for every $n \geq 0$, otherwise it is called **unstable**.

▶ **Definition 9.** A fixed point $\mathbf{r}$ of $f : \mathbb{R}^n \to \mathbb{R}^n$ is called **asymptotically stable** if it is stable and there exists a (neighborhood) $\delta > 0$ such that, for all $\boldsymbol{p} \in \mathbb{R}^n$ with $||\boldsymbol{p} - \mathbf{r}|| < \delta$ we have that $||f^n(\boldsymbol{p}) - \mathbf{r}|| \to 0$ as $n \to \infty$.

By definition it follows that if $\boldsymbol{x}$ is asymptotically stable w.r.t. dynamics f (2), then the set of initial conditions in Δ so that the dynamics converge to $\boldsymbol{x}$ has positive measure. Using that under f the potential function $\pi(\boldsymbol{x}) = \boldsymbol{x}^T A \boldsymbol{x}$ strictly decreases unless $\boldsymbol{x}$ is a fixed point, the next theorem was derived in [22].

▶ **Theorem 10** ([22], § 9.4.7)**.** *A fixed point $\boldsymbol{r}$ of dynamics (2) is stable if and only if it is a local maximum of π, and is asymptotically stable if and only if it is a strict local maximum.*

As the domain of π is closed and bounded, there exists a global maximum of π in Δ_n, which by Theorem 10 is a stable fixed point, and therefore its existence follows. However, existence of asymptotically stable fixed point is not guaranteed, for example if $A = [1]_{m\times n}$ then no $\boldsymbol{x} \in \Delta_n$ is attracting under f.

4.3.1 Stability and Eigenvalues

To analyze limiting points of f with respect to the notion of stability in terms of perturbation resistent, we need to use the eigenvalues of the Jacobian of f at fixed points. Let $J^{\mathbf{r}}$ denote the Jacobian at $\mathbf{r} \in \Delta_n$. The following theorem in dynamics/control theory relates (asymptotically) stable fixed points with the eigenvalue of its Jacobian.

▶ **Theorem 11** ([30])**.** *At fixed point $\boldsymbol{x}$ if $J^{\boldsymbol{x}}$ has at least one eigenvalue with absolute value > 1, then $\boldsymbol{x}$ is unstable. If all the eigenvalues have absolute value < 1 then it is asymptotically stable.*

▶ **Definition 12.** A fixed point $\mathbf{r}$ is called linearly stable, if the eigenvalues $J^{\mathbf{r}}$ are at most 1 in absolute value. Otherwise, it is called linearly unstable.

Theorem 11 implies that eigenvalues of the Jacobian at a stable fixed point have absolute value at most 1, however the converse may not hold. Using properties of $J^{\boldsymbol{x}}$ and [21], we prove next: (see the full version for Jacobian equations).

▶ **Theorem 13.** *The set of initial conditions in Δ_n so that the dynamics (2) converge to linearly unstable fixed points has measure zero.*

In Theorem 13 we manage to discard only those fixed points whose Jacobian has eigenvalue with absolute value > 1, while characterizing limiting points of f; the latter is finally used to argue about the survival of diversity.

5 Convergence, Stability, and Characterization

As established in Section 4.1, evolution in single locus diploid species is governed by dynamics f of (2). Understanding survival of diversity requires to analyze the following set,

$$\mathcal{L} = \{\boldsymbol{x} \in \Delta_n \mid \text{positive measure of starting points converge to } \boldsymbol{x} \text{ under } f\} \tag{4}$$

The next lemma follows from Definition 9 and Theorem 13.

▶ **Lemma 14.** *asymptotically stable $\subseteq \mathcal{L} \subseteq$ linearly stable.*

In this section we try to characterize $\mathcal{L}$ using various notions of stability, which have game theoretic and combinatorial interpretation. These notions sandwich set-wise the classical notions of stability given in Section 4.3, and thereby give us a partial characterization of $\mathcal{L}$. This characterization turns out to be crucial for our hardness results as well as results on survival in random instances.

Given a symmetric matrix A, a two-player game (A, A) forms a symmetric coordination game. In this section we identify special symmetric NE of this game to characterize stable fixed points of f. Given a profile $\boldsymbol{x} \in \Delta_n$, define a transformed matrix $T(A, \boldsymbol{x})$ of dimension $(k-1) \times (k-1)$, where $k = |SP(\boldsymbol{x})|$, as follows.

$$\text{Let } SP(\boldsymbol{x}) = \{i_1, \dots, i_k\},\ B = T(A, \boldsymbol{x}).\ \forall a, b < k,\ B_{ab} = A_{i_a i_b} + A_{i_k i_k} - A_{i_a i_k} - A_{i_k i_b} \quad (5)$$

Since A is symmetric it is easy to check that B is also symmetric, and therefore has real eigenvalues. Recall the Definition 6 of strict symmetric NE.

▶ **Definition 15.** A strategy $\boldsymbol{x}$ is called (strict) Nash stable if it is a (strict) symmetric NE of the game (A, A), and $T(A, \boldsymbol{x})$ is negative (definite) semi-definite.

▶ **Lemma 16.** *For any given $\boldsymbol{x} \in \Delta_n$, $T(A, \boldsymbol{x})$ is negative (definite) semi-definite iff ($\boldsymbol{y}^T A \boldsymbol{y} < 0$) $\boldsymbol{y}^T A \boldsymbol{y} \leq 0$, $\forall y \in \mathbb{R}^n$ such that $\sum_i y_i = 0$ and $x_i = 0 \Rightarrow y_i = 0$.*

Using that stable fixed point are local optima, we map them to Nash stable strategies.

▶ **Lemma 17.** *Every stable fixed point $\boldsymbol{r}$ of f is a Nash stable of game (A, A).*

Since stable fixed points always exist, so do Nash stable strategies (Lemma 17). Next we map strict Nash stable strategies to asymptotically stable fixed points, as the negative definiteness and strict symmetric Nash of the former implies strict local optima, and the next lemma follows.

▶ **Lemma 18** ([22] § 9.2.5)**.** *Every strict Nash stable is asymptotically stable.*

The above two lemmas show that strict Nash stable $\subseteq$ asymptotically stable (by definition) $\subseteq$ stable (by definition) $\subseteq$ Nash stable. Further, by Theorem 11 and the definition of *linearly stable* fixed points we know that stable $\subseteq$ linearly-stable. What remains is the relation between Nash stable and linearly stable. The next lemma answers this.

▶ **Lemma 19.** *Strategy $\boldsymbol{r}$ is Nash stable iff it is a linearly stable fixed point.*

Using Theorems 10 and 13, and Lemmas 14, 17, 18 and 19 we get the following characterization among all the notions of stability that we have discussed so far.

▶ **Theorem 20.** *Given a symmetric matrix A, we have*

$$\begin{array}{ccccccccc} \textit{Strict Nash stable} & \subseteq & \textit{Asymptotically stable} & \subseteq & \mathcal{L} & \subseteq & \textit{linearly-stable} & = & \textit{Nash stable} \\ & & \cap\!\shortmid & & & & & & \\ & & \textit{stable} \subseteq & \textit{linearly-stable} & = & \textit{Nash stable} & & & \end{array}$$

As stated before, generically (random fitness matrix) we have hyperbolic fixed points and all the previous notions coincide.

6 Survival of Diversity

In this section we characterize two extreme cases of fitness matrix for the survival of diversity, namely where diversity always survives and where diversity disappears regardless of the starting population. Using this characterization we analyze the chances of survival of diversity when fitness matrix and starting populations are picked uniformly at random from continuous distributions.

Given a fitness (positive) matrix A, let $\boldsymbol{x}$ be a limit point of dynamics f governed by (2) If it is not pure, *i.e.,* $|SP(\boldsymbol{x})| > 1$ then at least two alleles survive among the population, and we say the population is diverse in the limit.

▶ **Definition 21.** We say that *diversity survives* in the limit if there exists $\boldsymbol{x} \in \mathcal{L}$ such that $\boldsymbol{x}$ is not pure. And *diversity survives surely* if no $\boldsymbol{x} \in \mathcal{L}$ is pure.

Since $\mathcal{L} \subseteq$ Nash stable = linearly stable (Theorem 20), there has to be at least one mixed Nash (or linearly) stable strategy for diversity to survive.

Next we give a definition that captures the homozygote/heterozygote advantage and a lemma which uses it to identify instances that lack mixed Nash stable strategies.

▶ **Definition 22.** Diagonal entry A_{ii} is called *dominated* if and only if $\exists j$, such that $A_{ij} > A_{ii}$. And it is called *dominating* if and only if $A_{ii} > A_{ij}$ for all $j \neq i$.

In full version we show that diversity dies for matrices with all *dominating* diagonals. Next we show sure survival of diversity when diagonals are *dominated*.

▶ **Lemma 23.** *Let $\boldsymbol{r}$ be a fixed point of f with $r_t = 1$. If A_{tt} is dominated, then $\boldsymbol{r}$ is linearly unstable.*

If all pure fixed points are linearly unstable, then all linearly stable fixed points are mixed, and thus the next theorem follows using Theorem 20 and Lemma 23.

▶ **Theorem 24.** *If every diagonal of A is dominated then no $\boldsymbol{x} \in \mathcal{L}$ is pure, i.e., diversity survives almost surely.*

The following lemma shows that when the entries of a fitness matrix are picked uniformly independently from a continuous distribution, there is a positive probability (bounded away from zero for all n) so that every diagonal in A is dominated. This essentially means that generically, diversity survives with positive probability, bounded away from zero, where the randomness is taken with respect to both the payoff matrix and initial conditions.

▶ **Lemma 25.** *Let entries of A be chosen i.i.d from a continuous distribution. The probability that all diagonals of A are dominated is at least $\frac{1}{3} - o(1)$.*

The next theorem follows using Theorem 24 and Lemma 25.

▶ **Theorem 26.** *Assume that the fitness matrix has entries picked independently from a continuous distribution then with probability, at least $\frac{1}{3}$, diversity will survive almost surely.*

▶ Remark 27 (Typical instance). Observe that letting X_i be the indicator random variable that A_{ii} is dominating and $X = \sum_i X_i$ we get that $E[X] = \sum_i E[X_i] = \sum_i \Pr[E_i] = n \times \frac{1}{n} = 1$ so in expectation we will have one dominating element. Also from the above proof of Lemma 25 we get that $E[X^2] = \sum_i E[X_i] + 2\sum_{i<j} E[X_iX_j] = 1 + n(n-1)\Pr[E_i \cap E_j] \approx 2 - o(1)$ (namely $Var[X] \approx 1 - o(1)$) so by Chebyshev's inequality $\Pr[|X-1| > k]$ is $O(\frac{1}{k^2})$.

7 NP-Hardness Results

Positive chance of survival of phenotypic (allele) diversity in the limit under the evolutionary pressure of selection (dynamics (2)), implies existence of a mixed linearly stable fixed point (Theorem 13). This notion encompasses all the other notions of stability (Theorem 20), and may contain points that are not attracting. Whereas, strict Nash stable and asymptotically stable are attracting.

In this section we show that checking if there exists a mixed stable profile, for any of the five notions of stability (Definitions 8, 9, 12 and 15), may not be easy. In particular, we show that the problem of checking if there exists a mixed profile that satisfies any of the stability

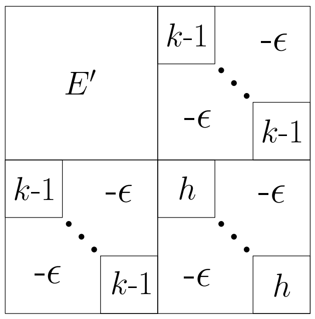

Figure 1 Matrix A as defined in (6), where E' is modification of E where off-diagonal zeros are replaced with $-h$ where h is a large (polynomial-size number).

conditions is NP-hard. In order to obtain hardness for checking survival of diversity, in other words checking if set $\mathcal{L}$ has a mixed strategy, we need to obtain a unifying reduction.

Our reduction also gives NP-hardness for checking if a given pure strategy is played with non-zero probability (subset) at these. In other words, it is NP-hard to check if a particular allele is going to survive in the limit under the evolution. Finally we extend all the results to the typical class of matrices, where exactly one diagonal entry is dominating (see Remark 27). All the reductions are from **k-Clique**, a well known NP-complete problem [6].

▶ **Definition 28. (k-Clique)** Given an undirected graph $G = (V, E)$, with V vertices and E edges, and an integer $0 < k < |V| - 1 = n - 1$, decide if G has a clique of size k.

Properties of G. Given a simple graph $G = (V, E)$ if we create a new graph $\bar{G}$ by adding a vertex u and connecting it to all the vertices $v \in V$, then it is easy to see that graph G has a clique of size k if and only if $\bar{G}$ has a clique of size $k + 1$. Therefore, w.l.o.g we can assume that there exists a vertex in G which is connected to all the other vertices. Further, if $n = |V|$, then for us such a vertex is the n^{th} vertex. By abuse of notation we will use E an adjacency matrix of $\bar{G}$ too, $E_{ij} = 1$ if edge (i, j) present in $\bar{G}$ else it is zero.

7.1 Hardness for checking stability

In this section we show NP-hardness (completeness for some) results for decision versions on (strict) Nash stable strategies and (asymptotically) stable fixed points. Given graph $G = (V, E)$ and integer $k < n$, we construct the following symmetric $2n \times 2n$ matrix A (see Figure 1), where E' is modification of E where off-diagonal zeros are replaced with $-h$ where $h > 2n^2 + 5$.

$$\forall i \leq j,\ A_{ij} = A_{ji} = \begin{cases} E'_{ij} & \text{if } i, j \leq n \\ k-1 & \text{if } |i-j| = n \\ h & \text{if } i, j > n \text{ and } i = j, \text{ where } h > 2n^2 + 5 \\ -\epsilon & \text{otherwise, where } 0 < \epsilon \leq \frac{1}{10n^3} \end{cases} \tag{6}$$

A is a symmetric but is not non-negative. The next lemma maps a k-clique to a mixed-strategy that is also strict Nash stable fixed point (FP). Note that such a FP satisfies all other stability notions as well, and hence implies existence of mixed limit point in $\mathcal{L}$.

▶ **Lemma 29.** *If there exists a clique of size at least k in graph G, then the game (A, A) has a mixed strategy $\mathbf{p}$ that is strict Nash stable.*

Since strict Nash stable is contained in all other sets, the above lemma implies existence of mixed-strategy for all of them if there is a clique in G. Next we want to show the converse for all notions of stability. That is if mixed-strategy exists for any notion of the five notions of stability then there is a clique of size at least k in the graph G. Since each of the five stability implies Nash stability, it suffices to map mixed Nash stable strategy to clique of size k. For this, and reductions that follow, we will use the following property due to negative semi-definiteness of Nash stability extensively.

▶ **Lemma 30.** *Given a fixed point $\boldsymbol{x}$, if $T(A,\boldsymbol{x})$ is negative semi-definite, then $\forall i \in SP(\boldsymbol{x}), A_{ii} \leq 2A_{ij},\ \forall j \neq i \in SP(\boldsymbol{x})$. Moreover if $\boldsymbol{x}$ is a mixed Nash stable then it has in its support at most one strategy t with A_{tt} is dominating.*

Nash stable also implies symmetric Nash equilibrium. The next lemma maps (special) symmetric NE to k-clique.

▶ **Lemma 31.** *Let $\boldsymbol{p}$ be a symmetric NE of game (A,A). If $SP(\boldsymbol{p}) \subset [n]$ and $|SP(\boldsymbol{p})| > 1$, then there exists a clique of size k in graph G.*

We obtain the following lemma essentially using Lemmas 30 and 31.

▶ **Lemma 32.** *If game (A,A) has a mixed Nash stable strategy, then graph G has a clique of size k.*

Note that adding a constant to A does not change its set of strict Nash stable and Nash stable.

▶ **Lemma 33.** *Let A be a symmetric matrix, and $B = A + c$ for a $c \in \mathbb{R}$, then the set of (strict) Nash stable strategies of B are identical to that of A.*

The next theorem follows using Theorem 20, Lemmas 29 and 32, and the property observed in Lemma 33. Since there is no polynomial-time checkable condition for (asymptotically) stable fixed points[11] its containment in NP is not clear, while for (strict) Nash stable strategies containment in NP follows from the Definition 15.

▶ **Theorem 34.** *Given a symmetric matrix A,*

- *it is NP-complete to check if game (A,A) has a mixed Nash stable (or linearly stable) strategy.*
- *it is NP-complete to check if game (A,A) has a mixed strict Nash stable strategy.*
- *it is NP-hard to check if dynamics (2) applied on A has a mixed stable fixed-point.*
- *it is NP-hard to check if dynamics (2) applied on A has a mixed asymptotically stable fixed-point.*

even if A is a assumed to be positive.

As we note in Remark 27, matrix with i.i.d entries from any continuous distribution has in expectation exactly one row with dominating diagonal. One could ask does the problem become easier for this typical case. We answer negatively by extending all the NP-hardness results of Theorem 34 to this case as well. Consider the following modification of matrix A

[11] These are same as (strict) local optima of function $\pi(\boldsymbol{x}) = \boldsymbol{x}^T A\boldsymbol{x}$, and checking if a given $\boldsymbol{p}$ is a local optima can be inconclusive if hessian at $\boldsymbol{p}$ is (negative) semi-definite.

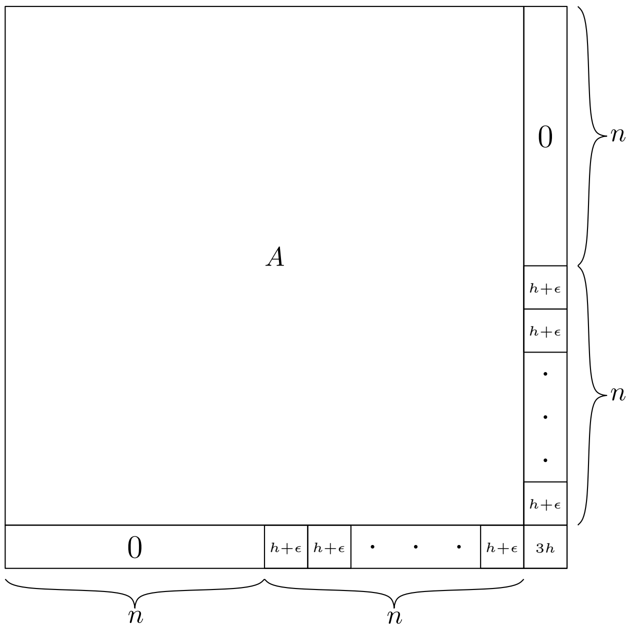

Figure 2 Matrix M as defined in (7).

from (6), where we add an extra row and column. Matrix M is of dimension $(2n+1)\times(2n+1)$ (See Figure (2)). Recall that $h > 2n^2 + 5$ and k is the given integer.

$$\begin{array}{ll} M_{ij} = A_{ij} & \text{if } i,j \le 2n \\ M_{(2n+1)i} = M_{i(2n+1)} = 0 & \text{if } i \le n \\ M_{(2n+1)i} = M_{i(2n+1)} = h+\epsilon & \text{if } n < i \le 2n, \text{ where } 0 < \epsilon < 1 \\ M_{(2n+1)(2n+1)} = 3h & \end{array} \tag{7}$$

Note that M has exactly one row whose diagonal entry dominates all other entries of the row, *i.e.*, $\exists i: \ M_{ii} > M_{ij}, \ \forall j \neq i$. See the full version of paper for details, and thus the next theorem holds.

▶ **Theorem 35.** *Given a symmetric matrix M such that exactly one row/column in M has a dominating diagonal,*

- *it is NP-complete to check if game (M,M) has a mixed Nash stable (or linearly stable) strategy.*
- *it is NP-complete to check if game (M,M) has a mixed strict Nash stable strategy.*
- *it is NP-hard to check if dynamics (2) applied on M has a mixed stable fixed-point.*
- *it is NP-hard to check if dynamics (2) applied on M has a mixed asymptotically stable fixed-point.*

even if M is a assumed to be positive.

Hardness for Subset. Another natural question is whether a particular allele is going to survive with positive probability in the limit for a given fitness matrix. In full version we show that this may not be easy either, by proving hardness for checking if there exists a stable strategy $\boldsymbol{p}$ such that $i \in SP(\boldsymbol{p})$ for a given i. In general, given a subset S of pure strategies it is hard to check if $\exists$ a stable profile $\boldsymbol{p}$ with $S \subseteq SP(\boldsymbol{p})$.

Survival of Diversity and Hardness. As discussed in Section 5 checking if diversity survives in the limiting population of single locus diploid organism reduces to checking "if f converges to a *mixed* fixed point with positive probability". In absence of clear characterization of the *mixed* limit points of f in terms of any of the stability definition, the hardness does not follow directly from the above result. In full version we explain how above results can be combined to obtain the following theorem. Also see the following remark on complexity of decision problem for general Nash equilibrium in coordination games.

▶ **Theorem 36.** *Given a fitness matrix A for a diploid organism with single locus, it is NP-hard to decide if, under evolution, diversity will survive (by converging to a specific mixed equilibrium with positive probability) when starting allele frequencies are picked i.i.d from from a continuous distribution. Also, deciding if a given allele will survive is NP-hard.*

▶ Remark 37. As noted in Section 4.2, coordination games are very special and they always have a pure Nash equilibrium which is easy to find; NE computation in general game is PPAD-complete [7]. Thus, it is natural to wonder if decision versions on coordination games are also easy to answer.

In the process of obtaining the above hardness results, we stumbled upon NP-hardness for checking if a symmetric coordination game has a NE (not necessarily symmetric) where each player randomizes among at least k strategies. Again the reduction is from k-clique. Thus, it seems highly probable that other decision version on (symmetric) coordination games are also NP-complete.

A Terms Used in Biology

A.1 Terms in Biology

We provide brief non-technical definitions of a few biological terms that we use in this paper.

Gene. A unit that determines some characteristic of the organism, and passes traits to offsprings. All organisms have genes corresponding to various biological traits, some of which are instantly visible, such as eye color or number of limbs, and some of which are not, such as blood type.

Allele. Allele is one of a number of alternative forms of the same gene, found at the same place on a chromosome. Different alleles can result in different observable traits, such as different pigmentation.

Genotype. The genetic constitution of an individual organism.

Phenotype. The set of observable characteristics of an individual resulting from the interaction of its genotype with the environment.

Diploid. Diploid means having two copies of each chromosome. Almost all of the cells in the human body are diploid.

Haploid. A cell or nucleus having a single set of unpaired chromosomes. Our sex cells (sperm and eggs) are haploid cells that are produced by meiosis. When sex cells unite during fertilization, the haploid cells become a diploid cell.

A.2 Heterozygote Advantage (Overdominance)

Cases of heterozygote advantage have been demonstrated in several organisms. The first confirmation of heterozygote advantage was with a fruit fly, Drosophila melanogaster. Kalmus demonstrated in a classic paper [14] how polymorphism can persist in a population through heterozygote advantage. In humans, sickle-cell anemia is a genetic disorder caused by the presence of two recessive alleles. Where malaria is common, carrying a single sickle-cell allele (trait) confers a selective advantage, *i.e.,* being a heterozygote is advantageous. Specifically, humans with one of the two alleles of sickle-cell disease exhibit less severe symptoms when infected with malaria.

Approximation and Hardness of Token Swapping

Abstract

Given a graph $G = (V, E)$ with $V = \{1, \ldots, n\}$, we place on every vertex a token $T_1, \ldots, T_n$. A swap is an exchange of tokens on adjacent vertices. We consider the algorithmic question of finding a shortest sequence of swaps such that token T_i is on vertex i. We are able to achieve essentially matching upper and lower bounds, for exact algorithms and approximation algorithms. For exact algorithms, we rule out any $2^{o(n)}$ algorithm under the ETH. This is matched with a simple $2^{O(n \log n)}$ algorithm based on a breadth-first search in an auxiliary graph. We show one general 4-approximation and show APX-hardness. Thus, there is a small constant $\delta > 1$ such that every polynomial time approximation algorithm has approximation factor at least δ.

Our results also hold for a generalized version, where tokens and vertices are colored. In this generalized version each token must go to a vertex with the same color.

1 Introduction

In the theory of computation, we regularly encounter the following type of problem: Given two configurations, we wish to transform one to the other. In these problems we also need to fix a family of operations that we are allowed to perform. Then, we need to solve two problems: (1) Determine if one can be transformed to the other; (2) If so, find a shortest sequence of such operations. Motivations come from the better understanding of solution spaces, which is beneficial for design of local-search algorithms, enumeration, and probabilistic analysis. See [9] for example. The study of *combinatorial reconfigurations* is a young growing field [2].

Among problem variants in combinatorial reconfiguration, we study the *token swapping problem* on a graph. The problem is defined as follows. We are given an undirected connected graph with n vertices $v_1, \ldots, v_n$. Each vertex v_i holds exactly one token $T_{\pi(i)}$, where π is a permutation of $\{1, \ldots, n\}$. In one step, we are allowed to swap tokens on a pair of adjacent

vertices, that is, if v_i and v_j are adjacent, v_i holds the token T_k, and v_j holds the token T_ℓ, then the swap between v_i and v_j results in the configuration where v_i holds T_ℓ, v_j holds T_k, and all the other tokens stay in place. Our objective is to determine the minimum number of swaps so that every vertex v_i holds the token T_i. It is known (and not difficult to observe) that such a sequence of swaps always exists [22].

The problem was introduced by Yamanaka et al. [22] in its full generality, but special cases had been studied before. When the graph is a path, the problem is equivalent to counting the number of adjacent swaps in bubble sort, and it is folklore that this is exactly the number of inversions of π (see Knuth [16, Section 5.2.2]). When the graph is complete, it was already known by Cayley [4] that the minimum number is equal to n minus the number of cycles in π (see also [14]). Note that the number of inversions and the number of cycles can be computed in $O(n \log n)$ time. Thus, the minimum number of swaps can be computed in $O(n \log n)$ time for paths and complete graphs. Jerrum [14] gave an $O(n^2)$-time algorithm to solve the problem for cycles. When the graph is a star, a result by Pak [19] implies an $O(n \log n)$-time algorithm. Exact polynomial-time algorithms are also known for complete bipartite graphs [22] and complete split graphs [24]. Polynomial-time approximation algorithms are known for trees with factor two [22] and for squares of paths with factor two [12]. Since Yamanaka et al. [22], it has remained open whether the problem is polynomial-time solvable or NP-complete, even for general graphs, and whether there exists a constant-factor polynomial-time approximation algorithm for general graphs.

Our results. In this paper, we resolve the open problems above from Yamanaka et al. [22]. Namely, we prove that the token swapping problem is NP-complete, and give a polynomial-time approximation algorithm with factor 4 for general graphs and factor 2 for trees. For the NP-completeness, we consider a more general problem, called the *colored token swapping problem*. In the colored token swapping problem, each token has a color, each vertex of the graph has a color, and we are asked to move the tokens to the vertices of the same color. This can also be seen as a graph-theoretic generalization of bubble sort on a multiset. Yamanaka et al. [23] proved that the colored token swapping problem is NP-complete. We strengthen their result in the sense that our hardness results hold for instances with special structure. Furthermore we design a gadget called an *even permutation* network (not to be confused with a sorting network). This can be regarded as a special class of instances of the token swapping problem. It allows us to achieve *any* even permutation of the tokens between dedicated input and output vertices. Using even permutation networks allows us to reduce further from the colored token swapping problem to the more specific uncolored version. We believe that this gadget is of general interest and we hope that similar gadgets will prove useful in other situations too. A close look at the hardness proof gives APX-hardness. Therefore we have that the constant approximation, we provide, is essentially tight (up to the constant). In addition, the proof rules out any $2^{o(n)}$-time algorithm under the Exponential Time Hypothesis, where n is the number of vertices of the input graph. To complement this, we provide a simple $2^{O(n \log n)}$-time exact algorithm. Therefore, our algorithmic results are almost *tight*. Even though our exact algorithm is completely straightforward, our reductions show that we cannot hope for much better results. The approximation algorithm we suggest makes deep use of the structure of the problem and is nice to present. Our reductions are quite technical and, so, we try to modularize them as much as possible. In the process, we show hardness for a number of intermediate problems. Due to space limitations, some of the proofs are missing. A self-contained full version of this paper can be found online [17].

Organization. In Section 2, we provide a simple exact algorithm. Section 3 describes a 4-approximation algorithm of the token swapping problem. In Section 4, we show a general technique to attain approximation algorithms for the colored token swapping problem from the uncolored version. In this way, we attain a 4-approximation for the colored token swapping problem. In Section 5, we define and construct even permutation networks, which are interesting in their own right. The hardness results are modularized into four sections. In Section 6, we show a reduction from 3SAT to a problem of finding disjoint paths in a structured graph. (A precise definition can be found in the section.) Section 7 shows how to reduce further to the colored token swapping problem. Section 8 is committed to the reduction from the colored to the ordinary token swapping problem. For this purpose, we attach an even permutation network to each color class. Section 9 finally puts the three previous reductions together in order to attain the main results.

Related concepts. The famous 15-puzzle is similar to the token swapping problem, and indeed a graph-theoretic generalization of the 15-puzzle was studied by Wilson [21]. The 15-puzzle can be modeled as a token-swapping problem by regarding the empty square of the 4×4 grid as a distinguished token, but there remains an important difference from our problem: in the 15-puzzle, two adjacent tokens can be swapped only if one of them is the distinguished token. For the 15-puzzle and its generalization, the reachability question is not trivial, but by the result of Wilson [21] we can determine if the tokens can be moved to the right vertices in polynomial time. However, it is NP-hard to find the minimum number of swaps even for grids [20].

The token swapping problem can be seen as an instantiation of the minimum generator sequence problem of permutation groups. There, a permutation group is given by a set of generators $\pi_1, \dots, \pi_k$, and we want to find a shortest sequence of generators whose composition is equal to a given target permutation τ. Indeed, this is the problem that Jerrum [14] studied, where he gave an $O(n^2)$-time algorithm for the token swapping problem on cycles. He proved that the minimum generator sequence problem is PSPACE-complete [14]. To formulate the token swapping problem as the minimum generator sequence problem of permutation groups, for a given connected graph G, we consider the symmetric group on $\{1, \dots, n\}$ (the set of all permutations on $\{1, \dots, n\}$) that is given by the set of transpositions determined by the edges of G.

In the literature, we also find the problem of *token sliding*, but this is different from the token swapping problem. In the token sliding problem on a graph G, we are given two independent sets I_1 and I_2 of G of the same size. We place one token on each vertex of I_1, and we perfom a sequence of the following sliding operations: We may move a token on a vertex v to another vertex u if v and u are adjacent, u has no token, and after the movement the set of vertices with tokens forms an independent set of G. The goal is to determine if a sequence of sliding operations can move the tokens on I_1 to I_2. The problem was introduced by Hearn and Demaine [11], and they proved that the problem is PSPACE-complete even for planar graphs of maximum degree three. Subsequent research showed that the token sliding problem is PSPACE-complete for perfect graphs [15] and graphs of bounded treewidth [18]. Polynomial-time algorithms are known for cographs [15], claw-free graphs [3], trees [6] and bipartite permutation graphs [8].

Several other models of swapping have been studied in the literature, e.g. [10, 7, 5].

2 Simple Exact Algorithms

We start presenting our results with the simplest one. There is an exact, exponential time algorithm which, after the hardness results that we obtain in Section 9, will prove to be almost tight to the lower bounds.

▶ **Theorem 1.** *Let I be an instance of the token swapping problem on a graph $G = (V, E)$ with n vertices and m edges. There exists a simple algorithm for finding an optimal sequence in time $O(n!\ m) = 2^{O(n \log n)}$.*

Proof. The algorithm is breadth first search in the configuration graph. The vertices $\mathcal{V}$ of the configuration graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ consist of all $n! = 2^{O(n \log n)}$ possible configurations of tokens on vertices V of G. Two configurations A and B are adjacent if there is a single swap that transforms A to B. Each configuration has $m \leq \binom{n}{2} = O(n^2)$ adjacent configurations. Thus the total number of edges is $n!\ m/2 \leq O(n^2) \cdot 2^{O(n \log n)} = 2^{O(n \log n)}$. It is easy to see that any shortest path in $\mathcal{G}$ from the start to the target configuration gives a shortest sequence of swaps. Breadth first search finds this shortest path. The running time of breadth first search is $O(|\mathcal{V}| + |\mathcal{E}|) = 2^{O(n \log n)}$. ◀

3 A 4-Approximation Algorithm

In this section, we describe an approximation algorithm for the token swapping problem, which has approximation factor 4 on general graphs and 2 on trees. Firstly, we state the following simple lemma.

▶ **Lemma 2.** *Let $d(T_i)$ be the distance of token T_i to the target vertex i. Let L be the sum of distances of all tokens to their target vertices:*

$$L := \sum_{i=1}^{n} d(T_i).$$

Then any solution needs at least $L/2$ swaps.

Proof. Every swap reduces L by at most 2. ◀

We are now ready to describe our algorithm. It has two atomic operations. The first one is called an *unhappy swap*: This is an edge swap where one of the tokens swapped is already on its target and the other token reduces its distance to its target vertex (by one).

The second operation is called a *happy swap chain.* Consider a path of $\ell + 1$ distinct vertices $v_1, \ldots, v_{\ell+1}$. We swap the tokens over edge (v_1, v_2), then (v_2, v_3), etc., performing ℓ swaps in total. The result is that the token that was on vertex v_1 is now on vertex $v_{\ell+1}$ and all other tokens have moved from v_j to v_{j-1}. If every swapped token reduces its distance by at least 1, we call this a happy swap chain of length ℓ. A single swap that is part of a happy swap chain is called a *happy swap.* When our algorithm applies a happy swap chain, there will be an edge between $v_{\ell+1}$ and v_1, closing a cycle. In this case, the happy swap chain performs a cyclic shift. Figure 1 illustrates this definition with an example. Note that a happy swap chain might consist of a single swap. We leave it to the reader to find such an example.

▶ **Lemma 3.** *Let G an undirected graph $G = (V, E)$ with a token placement where not every token is at its target vertex. Then, there is a happy swap chain or an unhappy swap.*

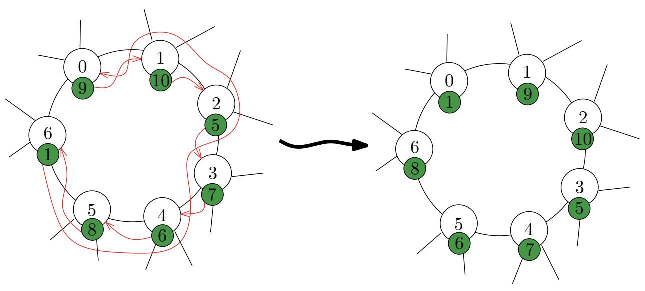

Figure 1 Before and after a happy swap chain. The swap sequence is, in this order, 6 – 5, 5 – 4, 4 – 3, 3 – 2, 2 – 1, 1 – 0. Token 1 swaps with every other token, moving counter-clockwise; every other token moves one step clockwise.

Proof. Given a token placement on a graph $G = (V, E)$ we define the auxiliary directed graph F on V as follows. For each undirected edge $e = \{v, w\}$ of G we define a directed edge from v to w if the token on v reduces its distance to its target vertex by swapping along e. Note that for a pair of vertices both directed edges might be part of the graph F. We can perform a happy swap chain whenever we find a directed cycle in F. The outdegree of a vertex v in F is 0 if and only if the token on v has target vertex v. Assume that not every token is in its target position. Choose any vertex v that does not hold the right token and perform a depth first search from v in F. This search ends with either revisiting a vertex and we get a directed cycle or we encounter a vertex with outdegree 0 and we get an unhappy swap. ◀

The above lemma gives rise to our algorithm: Search for a happy swap chain or unhappy swap; when one is found it is performed, until none remains. If there is no such swap, the final placement of every token is reached. This algorithm is polynomial time (follows from the proof of Lemma 3). Moreover, it correctly swaps the tokens to their target position with at most $2L$ swaps.

▶ **Lemma 4.** *Let T_i be a token on vertex i. If T_i participates in an unhappy swap, then the next swap involving T_i will be a happy swap.*

Proof. Refer to Figure 2. Let the vertices i, j be the ones participating in the unhappy swap and let e be the edge that connects them. On vertex j is token T_i that got unhappily removed from its target vertex and on vertex j is token S' whose target is neither i nor j. Based on Lemma 3, our algorithm performs either unhappy swaps or happy swap chains. Note that, currently, edge e cannot participate in an unhappy swap. This is because none of its endpoints holds the right token. Moreover, token T_i cannot participate in an unhappy swap that does not involve edge e, as that would not decrease its distance. Therefore, there has to be a happy swap chain that involves token T_i. ◀

▶ **Theorem 5.** *Any sequence of happy swap chains and unhappy swaps is at most 4 times as long as an optimal sequence of swaps on general graphs and 2 times as long on trees.*

Proof. Let L be the sum of all distances of tokens to its target vertex. We know that the optimal solution needs at least $L/2$ swaps as every swap reduces L by at most 2 (Lemma 2). We will show that our algorithm needs at most $2L$ swaps, and this implies the claim.

A happy swap chain of length ℓ reduces the sum of total distances by $\ell + 1$ and involves ℓ happy swaps. Thus, #(happy swaps) $< L$. By Lemma 4, #(unhappy swaps) $\leq$

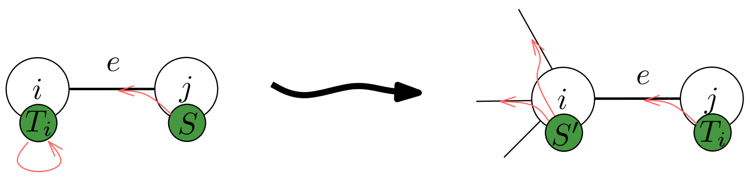

Figure 2 After a Token T_i makes an unhappy swap along edge e, T_i wants to go back to vertex i and is not willing to go to any other vertex. Also whatever token S' will be on vertex i, it has no desire to stay there. This implies that the next swap involving T_i will be part of a happy swap chain.

#(happy swaps), this implies: #(swaps) = #(unhappy swaps) + #(happy swaps) $\leq$ 2 #(happy swaps) $< 2L$. This algorithm is a 2-approximation algorithm on trees as the longest possible cycle in F (as in Lemma 3) has length 2 and thus every happy swap chain consists of only one happy swap that reduces L by *two*. This implies #(happy swaps) $= L/2$. ◀

4 The Colored Version of the Problem

In this section, we consider the *colored* token swapping problem as defined in the introduction. We will see that all approximation bounds from the previous sections carry over to this problem. Our approach to the problem is easy:

1. We first decide which token goes to which target vertex.
2. We then apply one of the algorithms from the previous sections for n distinct tokens.

The details can be found in the full version.

▶ **Theorem 6.** *There is a* 4*-approximation of the colored token swapping problem on general graphs and a* 2*-approximation on trees.*

5 Even Permutation Networks

Before we dive in the details of the reductions for token swapping (Sections 6–8), we introduce our even permutation network PN, the gadget that we advertised in the introduction. We consider it stand-alone and we present it independently of the other parts of the reduction.

The vertices of PN are partitioned into the sets V_{in}, V_{out}, and V_{PN}, where $|V_{\text{in}}| = |V_{\text{out}}|$, together with a bijection $\varphi\colon V_{\text{in}} \to V_{\text{out}}$ and a bijection $\psi\colon V_{\text{out}} \cup V_{\text{PN}} \to V_{\text{in}} \cup V_{\text{PN}}$, defining for each token on $V_{\text{PN}} \cup V_{\text{out}}$ a fixed target vertex in $V_{\text{in}} \cup V_{\text{PN}}$. We place on each $v \in V_{\text{out}} \cup V_{\text{PN}}$ the token $T_{\psi(v)}$. (The goal of token T_v is to be on vertex v.)

The target vertices of V_{in} lie in V_{out}, and they are specified by an additional variable permutation π of V_{in}. The instance $I(\pi)$ corresponding to π is obtained by placing on each $v \in V_{\text{in}}$ the token $T_{\varphi(\pi(v))}$.

This *even* permutation network has the property that the optimal number of swaps to solve $I(\pi)$ is the same for every even permutation π, see Figure 3. We will refer to the composition $\varphi \circ \pi$ as an *assignment*. Recall that a permutation is even if the number of inversions of the permutation is even. Realizing *all* permutations at the same cost is impossible, since every swap changes the parity, and hence all permutations reachable by a given number of swaps have the same parity.

We will later use even permutation networks to reduce from the *colored* token swapping problem on a network H to the token swapping problem, see Lemma 10. We will attach an even permutation network PN to each layer (color class) of H by identifying that layer with the input vertices V_{in} of PN. This permutation network will bring the colored tokens of H,

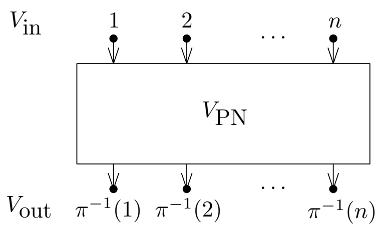

Figure 3 The interface of a permutation network PN. The permutation φ is not indicated; it maps each vertex of V_{in} to the vertex of V_{out} of that is vertically below.

which have arrived in V_{in} in a first phase, to their individual final destinations in V_{out}. To ensure that even permutations suffice, we use the simple trick of doubling the whole input graph before attaching the permutation networks: the product of two permutations of the same parity is always even.

▶ **Lemma 7.** *For every n, there is a permutation network* PN *with n input vertices* V_{in}*, n output vertices* V_{out}*, and $O(n^3)$ additional vertices* V_{PN}*, which has the following properties, for some value T:*

- *For every target assignment π between the inputs* V_{in} *and the outputs* V_{out} *that is an even permutation, the shortest swapping sequence has length T.*
- *For any other target assignment, the shortest realizing sequence has length at least $T+1$.*
- *The same statement holds for any extension of the network PN, which is the union of PN with another graph H that shares only the vertices* V_{in} *with PN, and in which the starting positions of the tokens assigned to* V_{out} *may be anywhere in H.*

The last clause concerns not only all assignments between V_{in} and V_{out} that are odd permutations, but also all other conceivable situations where the tokens destined for V_{out} do not end up in V_{in}, but somewhere else in the graph H. The lemma confirms that such non-optimal solutions for H cannot be combined with solutions for PN to yield better swapping sequences than the ones for which the network was designed.

Proof. (Sketch. For the complete proof with diagrams of the gadgets, see the full version.)

The even permutation network will be built up hierarchically from small gadgets. Each gadget is built in a layered manner, subject to the following rules.

1. There is a strict layer structure: The vertices are partitioned into layers $V_1, \dots, V_t$ of the same size.
2. Each gadget has its own input layer V_{in} at the top and its output layer V_{out} at the bottom, just as the overall network PN.
3. Edges may run between two vertices of the same layer (*horizontal edges*), or between adjacent layers (*downward edges*).
4. Every vertex has at most one neighbor in the successor layer and at most one neighbor in the predecessor layer.

The goal is to bring the input tokens from the input layer V_{in} to the output layer V_{out}. By Rule 3, the cheapest conceivable way to achieve this is by using only the downward edges, and then every such edge is used precisely once. Our first gadget is the so-called *swapping gadget*, which can either realize the identity permutation, or swap a specified input vertex with one of two others at a cost of one additional swap. Our second gadget, the *shift gadget*, consists of two swapping gadgets chained together in such a way that both the identity permutation and a cyclic shift of three input vertices can be realized in the same minimal number of swaps, but every other permutation takes more swaps. Both of these constructions involve some auxiliary input tokens that have set destinations within the gadget. We then chain these shifting gadgets together in a cascading fashion, so that any even permutation of the input vertices can be realized as a composition of the cyclic shifts of three vertices. In this way, all the even permutations can be achieved with the same amount of swaps, and all other permutations are more costly. ◀

6 Reduction to a Disjoint Paths Problem

For the lower bounds of the Token Swapping problem, we study some auxiliary problems. The first problem is a special multi-commodity flow problem.

Disjoint Paths on a Directed Acyclic Graph (DP)
Input: A directed acyclic graph $G = (V, E)$ and a bijection $\varphi\colon V^- \to V^+$ between the sources V^- (vertices without incoming arcs) and the sinks V^+ (vertices without outgoing arcs), with the following properties:

1. The vertices can be partitioned into layers $V_1, V_2, \ldots, V_t$ such that, for every vertex in some layer V_j, all incoming arcs (if any) come from the same layer V_i, with $i < j$. Note that i need not be the same for every vertex in V_j.
2. Every layer contains at most 10 vertices.
3. For every $v \in V^-$, there is a path from v to $\varphi(v)$ in G. Let $n(v)$ denote the number of vertices on the shortest path from v to $\varphi(v)$.
4. The total number of vertices is $|V| = \sum_{v \in V^-} n(v)$.

Question: Is there a set of vertex-disjoint directed paths $P_1, \ldots, P_k$ with $k = |V^-| = |V^+|$, such that P_i starts at some vertex $v \in V^-$ and ends at $\varphi(v)$?

By Property 4, the k paths must completely cover the vertices of the graph. The graphs that we will construct in our reduction have in fact the stronger property that *any* directed path from $v \in V^-$ to $\varphi(v)$ contains the same number $n(v)$ of vertices.

In our construction, we will label the source and the sink that should be connected by a path by the same symbol X, and "the path X" refers to this path. In the drawings, the arcs will be directed from top to bottom.

▶ **Lemma 8.** *There is a linear-size reduction from 3SAT to the Disjoint Paths Problem on a Directed Acyclic Graph (DP).*

Proof. Let $x_1, \ldots, x_n$ be the variables and $C_1, \ldots, C_m$ the clauses of the 3SAT formula. Each variable x_i is modeled by a variable path, which has a choice between two tracks. The track is determined by the choice of the first vertex on the path after x_i: either x_i^T or x_i^F . This choice models the truth assignment. There is also a path for each clause. In addition, there will be supplementary paths that fill the unused variable tracks. Figure 4 shows an example of a variable x_i that appears in three clauses C_u, C_v, and C_w. Consequently, the two tracks x_i^T and x_i^F, which run in parallel, pass through three *clause* gadgets, which are shown schematically as gray boxes in Figure 4 and which are drawn in greater detail in Figure 5. The bold path in Figure 4 corresponds to assigning the value *false* to x_i: the path follows the track x_i^F. For a variable that appears in ℓ clauses, there are $\ell + 1$ supplementary paths. In Figure 4, they are labeled $s_1, \ldots, s_4$. The path s_j covers the unused track (x_i^T in the example) between the $(j-1)$-st and the j-th clause in which the variable x_i is involved.

Initially, the path x_i can choose between the tracks x_i^T and x_i^F; the other track will be covered by a path starting at s_1. This choice is made possible by a *crossing* gadget. Each variable has two crossing gadgets attached, one at the beginning of the variable path and

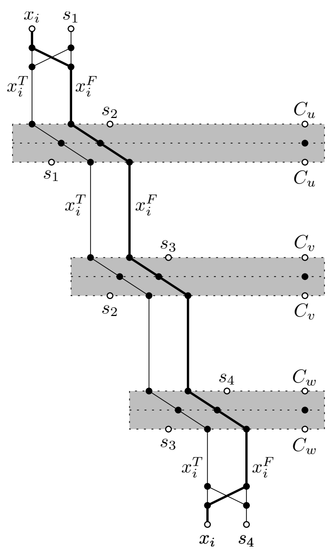

Figure 4 Schematic representation of a variable x_i. Sources and sinks are marked by white vertices, and their labels indicated the one-to-one correspondence φ between sources and sinks.

one at the end. Those gadgets consist of 6 vertices: x_i, s_1, x_i^T, x_i^F and two auxiliary vertices that allow the variable to change tracks. In Figure 4, the crossing gadgets appear at the top and the bottom. Note, that a variable can only change tracks in the crossing gadgets; the last supplementary path $s_{\ell+1}$ allows the path x_i to reach its target sink.

Figure 5 shows a clause gadget C_z in greater detail. It consists of three successive layers and connects the three variables that occur in the clause. The clause itself is represented by a clause path that spans only these three layers. A supplementary path starts at the first layer and one ends at the third layer of each clause gadget. Each layer of the clause gadget has at most 10 vertices: three for each variable, two that are on the tracks x_i^T, x_i^F, one for the supplementary path of the variable. There is at most three variables per clause. Finally, there is a vertex that corresponds to the clause itself.

Let C_z be the current clause which is the jth clause in which x_i appears, and it does so as a positive literal (as in Figure 5a). Each track, say x_i^T, connects to the corresponding vertex in the middle and bottom layer of the clause gadget and to s_j (the end of the supplementary path). The track of the literal that does not appear in this clause (x_i^F in this case) is also connected to the vertex of the clause on the middle layer (z in Figure 5). Moreover, the middle layer vertex of this track is connected to the top and bottom layer vertices that correspond to the clause. The supplementary path s_{j+1} starts in this clause gadget and goes through the middle layer and then connects to the vertices of both tracks on the bottom layer. Figure 5 depicts all these connections.

We can make the following observations about the interaction between the variable x_i and the clause C_z. We, further, illustrate those in Figure 5.

1. A variable path (shown in black) that enters on the track x_i^T or x_i^F must leave the gadget on the same track. Equivalently, a path cannot change track except in the crossing gadgets.
2. The clause path (in red) can make a detour through vertex v (w.r.t. Figure 5) only if the variable x_i makes the clause true, according to the track chosen by the variable path. In this case, the supplementary path s_j covers the intermediate vertex z of the clause.
3. If variable x_i makes the clause true, the clause path may also choose a different detour, in case more variables make the clause true.

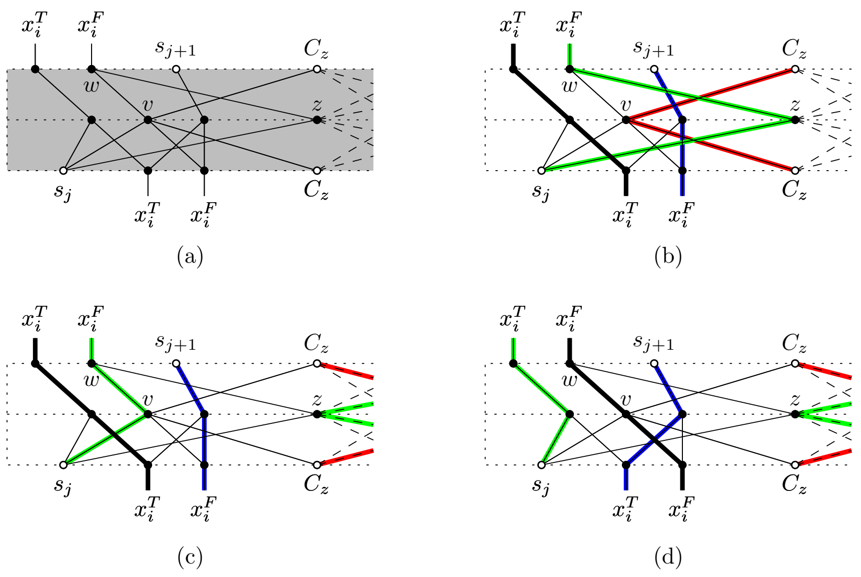

Figure 5 (a) Gadget for a clause C_z containing a variable x_i as a positive literal. The clause involves two other variables, whose connections are indicated by dashed lines. (b–d) The possibilities of paths passing through the gadget: (b) $x_i = \mathit{true}$, the clause is fulfilled, and the clause path makes its detour via the vertex v. (c) $x_i = \mathit{true}$, the clause is fulfilled, and the clause path makes its detour via another vertex. (d) $x_i = \mathit{false}$, this variable does not contribute to fulfilling the clause, and the clause path *has to* make its detour via another vertex. For a negative literal, the detour vertex v and the upper neighbor w of z would be placed on the other track, x_i^T.

4. The supplementary path s_j (shown in green) can reach its sink vertex.
5. The supplementary path s_{j+1} (in blue) can reach the track the track x_i^T or x_i^F which is not used by the variable path.

Since each clause path *must* make a detour into one of the variables, it follows from Property 2 that a set of disjoint source-sink paths exists if and only if all clauses are satisfiable.

The special properties of the graph that are required for the Disjoint Paths Problem on a Directed Acyclic Graph (DP) can be checked easily. Whenever a vertex has one or more incoming arcs, they come from the previous layer of the same clause gadget. We can assign three distinct layers to each clause gadget and to each crossing gadget. Thereby, we ensure that every layer contains at most 10 vertices. It follows from the construction that the graph has just enough vertices that the shortest source-sink paths can be disjointly packed, but we can also check this explicitly. (See the full version for an explicit calculation.) ◀

7 Reduction to Colored Token Swapping

We have shown in Lemma 8 how to reduce 3SAT to the Disjoint Paths Problem on a Directed Acyclic Graph (DP) in linear time. Now, we show how to reduce from this problem to the colored token swapping problem.

▶ **Lemma 9.** *There exists a linear reduction from DP to the colored token swapping problem.*

Proof. Let G be a directed graph and φ be a bijection, as in the definition of DP. We place k tokens $t_1, \ldots, t_k$ of distinct colors on the vertices in V^-, see Figure 6. Their target positions are in V^+ as determined by the assignment φ. We define a color for each layer $V_1, \ldots, V_{t-1}$. Each vertex in layer V_i which is not a sink is colored by the corresponding color.

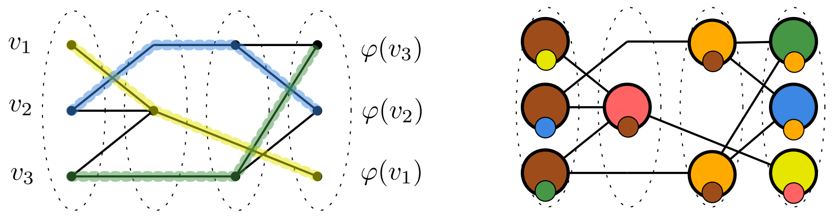

Figure 6 left: an instance of the disjoint paths problem with $t = 4$ and $k = 3$, together with a solution; right: an equivalent instance of the colored token swapping problem.

Recall that for each vertex v all ingoing edges come from the same layer, which we denote by L_v. On each vertex v which is not a source, we place a token with the color of layer L_v. We call these tokens *filler tokens*.

We set the threshold T to $|V(G)| - k$. This equals the number of filler tokens.

We have to show that there are k paths with the properties above if and only if there is a sequence of at most T swaps that brings every token to its target position (see the full version). ◀

We conclude that the Colored Token Swapping Problem is NP-hard. This has already been proved by Yamanaka et al. [23], even when there are only three colors.

The reduction in Lemma 9 produces instances of the colored token swapping problem with additional properties, which are directly derived from the properties of DP. A precise definition of the *structured token swapping problem* can be found in the full version.

8 Reduction to the Token Swapping Problem

In this section we describe the final reduction which results in an instance of the token swapping problem. To achieve this we make use of the even permutation network gadget from Section 5. For adhering to space constraints we omit from here an illustration of the reduction, the the full version for details.

▶ **Lemma 10.** *There exists a linear reduction from the structured colored token swapping problem to the token swapping problem.*

Proof. Let I be an instance of the structured colored token swapping instance. We denote the graph by G, the layers by $V_1, \ldots, V_t$, the sources by V^-, the sinks by V^+ and the threshold for the number of swaps by k.

We construct an instance J of the token swapping problem. The graph $\overline{G}$ consists of two copies of G. For each set $V_j \setminus V^+$, we add *one* even permutation network to the union of both copies. In other words, the two copies of $V_j \setminus V^+$ serve as inputs of the permutation network. We denote the output vertices of the permutation network attached to the copies of $V_j \setminus V^+$ by V_j'. The filler tokens that were are destined for $V_j \setminus V^+$ in I have V_j' as their new final destination in J, see the full version for illustrations and details. It is not important how we assign each token to a target vertex, as long as this assignment is consistent between the two copies of G (that is, for the bijection φ_j between the input and output vertices of the permutation network, we have that the tokens in the first copy are sent to the image under φ_j of the vertices in the first copy, while the tokens in the second are sent to the corresponding vertices in the image of the second copy).

Further each token gets a unique label. The threshold $\overline{k}$ for the number of swaps is defined by $2k$ plus the number of swaps needed for the permutation networks.

We show at first that this reduction is linear. For this it is sufficient to observe that the size of each layer is constant. And thus also the permutation network attached to these layers have constant size each.

Now we show correctness. Let I be an instance of the structured colored token swapping problem and J the constructed instance as described above.

[$\Rightarrow$] Let S be a valid sequence of swaps that brings every token on G to a correct target position within k swaps. We need to show that there is a sequence of $\overline{k}$ swaps that brings each token in $\overline{G}$ to its unique target position. We perform S on each copy of G. Thereafter every token is swapped through the permutation network to its target position. Note that the permutation between the input and output is an *even* permutation. This is because we doubled the graph G. Therefore, the number of swaps in the permutation network is constant regardless of the permutation of the filler tokens in layer V_i, by Lemma 7. This also implies that the total number of swaps is $\overline{k}$.

[$\Leftarrow$] Assume that there is a sequence S' of $\overline{k}$ swaps that brings each token of J to its target position. This implies that each filler token went through the permutation network to its correct target vertex. In order to do that each filler token must have gone to some input vertex of its corresponding permutation network. As the number of swaps inside each permutation network is independent of the permutation of the tokens on the input vertices, there remain exactly $2k$ swaps to put all tokens in each copy of G at its right place. This implies that each token in G can be swapped to its correct position in I in k swaps as claimed. ◀

9 Hardness of the Token Swapping Problem

In this section we put together all the reductions. They imply the following theorem.

▶ **Theorem 11.** *The token swapping problem has the following properties:*

1. *It is NP-complete.*
2. *It cannot be solved in time $2^{o(n)}$ unless ETH fails, where n is the number of vertices.*
3. *It is APX-hard.*

These properties also hold, when we restrict ourselves to instances of bounded degree.

Proof. For the NP-completeness, we reduce from 3SAT. For the lower bound under ETH, we need to use the Sparsification Lemma, see [13], and reduce from 3SAT instances where the number of clauses is linear in the number of variables. This prevents a potential quadratic blow up of the construction. For the inapproximability result, we reduce from 5-OCCURRENCE-MAX-3SAT. (In this variant of 3SAT each variable is allowed to have at most 5 *occurrences*.) This gives us some additional structure that we use for the argument later on. In all three cases the reduction is exactly the same.

Let f be a 3SAT instance. We denote by $K(f)$ the instance of the token swapping problem after applying the reduction of Lemma 8, Lemma 9 and Lemma 10 in this order. (It is easy to see that the graph of $K(f)$ has bounded degree.)

As all three reductions are correct, we can immediately conclude that the problem is NP-hard. NP-membership follows easily from the fact that a valid sequence of swaps is at most quadratic in the size of the input and can be checked in polynomial time.

The Exponential Time Hypothesis (ETH) asserts that 3SAT cannot be solved in $2^{o(n')}$, where n' is the number of variables. The Sparsification Lemma implies that 3SAT cannot be solved in $2^{o(m')}$, where m' is the number of clauses. As the reductions are linear the number of vertices in $K(f)$ is linear in the number of clauses of f. Thus a subexponential-time algorithm for the token swapping problem implies a subexponential-time algorithm for 3SAT and contradicts ETH.

To show APX-hardness, we do the same reductions as before, but we reduce from 5-OCCURRENCE-MAX-3SAT. Thus we can assume that each variable in f appears in at most 5 clauses. This variant of 3SAT is also APX-hard, see [1]. Assume a constant fraction of the clauses of f are not satisfiable. We have to show that we need an additional constant fraction on the total number of swaps. For this, we assume that the reader is familiar with the proofs of Lemma 8, 9 and 10. It follows from these proofs that there is a constant sized gadget in $K(f)$ for each clause of f. Also there are certain tokens that represent variables and the paths they take correspond to a variable assignment. We denote with x, y, z the variables of some clause C, and we denote with T_x, T_y, T_z the tokens corresponding to these variables and G_C the gadget corresponding to C. We need two crucial observations. In the case where the paths taken by the tokens T_x, T_y and T_z do not correspond to an assignment that makes C true, at least one more swap is needed. This swap can be attributed to the clause gadget G_C. In case that a token T_x changes its track, which corresponds to another assignment of the variable, then at least one more swap needs to be performed that can be attributed to all its clauses with value 1/5. These two observations follow from the proofs of the above lemmas, as otherwise it would be possible to "cheat" at each clause gadget and the above lemmas would be incorrect. The observations also imply the claim. Let f be a 3SAT formula with a constant fraction of the clauses not satisfiable. Assume at first that the swaps are "honest" in the sense that the variable tokens T_x does not change its track and corresponds consistently with the same assignment. In this case, by the first observation, we need at least one extra swap per clause. And thus a constant fraction of extra swaps, compared to the total number of swaps. In a dishonest sequence of swaps, changing the track of some variable token T_x fixes at most five clauses. This implies at least one extra swap for every five unsatisfied clauses, which is a constant fraction of all the swaps as the total number of swaps is linear in the number of clauses of f. This finishes the APX-hardness proof. ◀

Abstract

We consider the minimum-weight feedback vertex set problem in tournaments: given a tournament with non-negative vertex weights, remove a minimum-weight set of vertices that intersects all cycles. This problem is NP-hard to solve exactly, and Unique Games-hard to approximate by a factor better than 2. We present the first 7/3 approximation algorithm for this problem, improving on the previously best known ratio 5/2 given by Cai et al. [FOCS 1998, SICOMP 2001].

1 Introduction

Among the most basic concepts in graph theory is the notion of a *feedback vertex set (FVS)* of a digraph: a subset of the vertices S such that removing S makes the digraph acyclic. The computational problem of finding a FVS of minimum size is known as the Feedback Vertex Set problem. A fundamental problem with numerous applications (e.g., in deadlock recovery in operating systems), the Feedback Vertex Set problem is among Karp's 21 original NP-complete problems [13]. Karp's proof of NP-hardness also implies that the problem is APX-hard. Obtaining a constant factor polynomial-time approximation algorithm for the Feedback Vertex Set problem seems elusive and is a major open problem. The best known approximation factor achievable in polynomial time is $O(\log n \log\log n)$ [8, 21].

The Feedback Vertex Set problem is particularly interesting for the special case when the input graph is a *tournament*, i.e., an orientation of the complete graph. The problem restricted to tournaments has many interesting applications, most notably in social choice theory where it is essential to the definition of a certain type of election winners called the Banks set [1].

The Feedback Vertex Set problem remains NP-complete and APX-hard in tournaments. Moreover, Speckenmeyer [22] gave an approximation-ratio preserving polynomial time reduction from the Vertex Cover problem in general undirected graphs to the Feedback Vertex Set problem in tournaments. Consequently, the FVS problem in tournaments cannot be approximated in polynomial time within a factor better than 1.3606, unless $\mathsf{P} = \mathsf{NP}$ [6], and not within a factor better than 2 assuming the Unique Games Conjecture (UGC) [14].

On the upper bound side, the Feedback Vertex Set problem in tournaments admits an easy 3-approximation algorithm: while the tournament contains a directed triangle, place all the triangle vertices in the FVS and remove them from the tournament (see also Bar-Yehuda and Rawitz [2] for another simple 3-approximation algorithm). Cai, Deng and Zang [4] improved the simple algorithm and gave a polynomial time algorithm with approximation guarantee 5/2, even in the case when vertices have non-negative weights and one seeks a solution of approximate minimum weight.

In this paper we develop a 7/3-approximation algorithm for the minimum weight Feedback Vertex Set problem in tournaments, obtaining the first improvement over the eighteen year old result of Cai et al. [4]. Our result shows that the 2.5-approximation ratio is not best possible, and gives hope that a 2-approximation algorithm, that would be optimal under the UGC, might be achievable.

▶ **Theorem 1.** *There exists a polynomial-time* 7/3*-approximation algorithm for finding a minimum-weight feedback vertex set in a tournament.*

In the process of proving the above theorem, we uncover a structural theorem about tournament graphs that has interesting connections to the tournament colouring problem investigated by Berger et al. [3]. We explain these connections in Sect. 5.

1.1 Overview

Let us first give an overview of Cai et al.'s result [4]. Let $\mathcal{T}_5$ denote the set of tournaments on 5 vertices where the minimum FVS has size 2 (note that every tournament on 5 vertices has a FVS of size at most 2). Cai et al. showed that for any tournament free of subtournaments from $\mathcal{T}_5$, the minimum-weight FVS problem becomes polynomial-time solvable. They in fact show that the natural LP relaxation of the problem is integral in $\mathcal{T}_5$-free tournaments: the minimum weight of a FVS equals the maximum value of a fractional directed triangle packing.

For the special case of unit weights only, their 5/2-approximation algorithm starts by greedily choosing subtournaments in $\mathcal{T}_5$, and including all 5 vertices in the FVS. Once the remaining tournament admits no more subtournaments in $\mathcal{T}_5$, the optimal covering algorithm is used. The algorithm returns a 5/2-approximate solution, since every step of removing a subtournament decreases the optimum value by at least 2, and includes 5 vertices in the FVS. The algorithm extends to non-negative weights using the local ratio technique.

We now give an overview of our approach. We define the set $\mathcal{T}_7$ as the set of 7-vertex tournaments where the minimum size of a FVS is 3. The algorithm comprises two stages. The first stage uses the iterative rounding technique, and removes all subtournaments in $\mathcal{T}_7$; the weight of the vertices included at this stage will be at most 7/3-times the decrease in the optimum weight. In the second stage, we give a 7/3-approximate combinatorial algorithm for the remaining $\mathcal{T}_7$-free tournament.

The analogous first stage of Cai et al. obtains a worse factor 5/2. In the second stage, their algorithm delivers an optimal solution. In contrast, we only give an approximation algorithm in the second stage, but that is sufficient for the overall approximation guarantee.

We now provide some more detail of the two stages. In the first stage we use the iterative rounding technique. We formulate the natural LP relaxation of the minimum-weight FVS problem in the given tournament T, including a covering constraint for every directed triangle of T, and further we include that every subtournament of T belonging to $\mathcal{T}_7$ must be covered by at least three vertices. We consider an optimal solution of the LP relaxation. If there is a vertex of T with fractional value at least $3/7$, we include it in our FVS and remove it from T. We then resolve the LP on the remaining tournament, and again include a vertex with fractional value at least $3/7$, if there exists one. We iterate until there are no more such vertices. At this point, the tournament will be $\mathcal{T}_7$-free, and the fractional optimum value equals exactly one third of the total weight of the vertices (see Lemma 6).

In the second stage, we develop a polynomial time combinatorial algorithm that delivers a FVS of weight at most $7/9$ times the *total weight* of the vertices in a $\mathcal{T}_7$-free tournament (Theorem 4). This algorithm implies our main theorem, since an optimal FVS in the remaining $\mathcal{T}_7$-free tournament is of size at least the optimum fractional value, which by the previous paragraph is exactly a third of the total weight of the nodes, which itself is at least $1/3 \cdot 9/7 = 3/7$ of the size of the FVS returned.

To prove Theorem 4, we decompose the vertex set into "layers". Our algorithm divides the vertices into $\mathcal{T}_5$-free layers, while also identifying a certain vertex set S to be included in the FVS right away. Our final FVS will be composed of the initially selected S, every second layer, and the optimal FVS's inside the remaining layers. To obtain these, we use Cai et al.'s algorithm as a subroutine to find an optimal solution on a $\mathcal{T}_5$-free layer. The layering idea is inspired by Cai et al.'s structural analysis of $\mathcal{T}_5$-free tournaments; nevertheless, we use it quite differently.

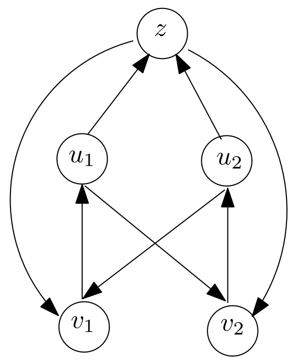
It is natural to conjecture that our approach can be extended to lead to a $(2 + \varepsilon)$-approximation for the FVS problem in tournaments, for all $\varepsilon > 0$. At this point it is unclear how to improve the approximation ratio in the above second stage. Nevertheless, our paper provides the next substantial step towards reaching the UGC-based lower bound.

1.2 Related work

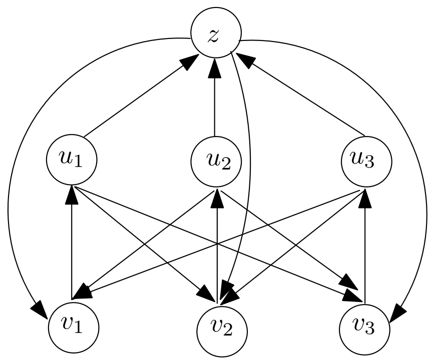
Feedback vertex sets in tournaments are a well-studied subject. Dom et al. [7] showed how to decide existence of an FVS of size at most k in time $2^k \cdot n^{O(1)}$, and gave a kernel with $O(k^2)$ vertices. An exponential-time algorithm by Fomin et al. [10] finds an FVS of minimum size in time $O(1.674^n)$, improving on earlier algorithms [18, 7, 11, 16]. Gaspers and Mnich [11] gave a polynomial-space algorithm to enumerate all minimal FVS of a given tournament with polynomial delay; the currently best upper bound on their number is $O(1.6667^n)$ [10].

The related question of FVS in *bipartite* tournaments has also been studied, i.e., orientations of the complete bipartite graph. First, Cai et al. [5] using a similar framework to their 5/2-approximation algorithm [4], developed a 7/2-approximation algorithm for FVS in bipartite tournaments. This was improved by Sasatte [20] giving a 3-approximation, and finally, by van Zuylen [23] who developed a polynomial time 2-approximation algorithm.

Iterative rounding is a standard and powerful method in approximation algorithms; we refer the reader to the book by Lau et al. [17]. The approach was made popular by Jain's groundbreaking 2-approximation for survivable network design [12], and the main application area is network design. However, the same principle was already used earlier for various



(a) S_5



(b) S_7

Figure 1 Examples of tournaments from $\mathcal{T}_5$ and $\mathcal{T}_7$.

problems. In particular, Krivelevich used implicitly iterative rounding for the undirected triangle cover problem [15]; our application is similar to his argument. Van Zuylen [23] used iterative rounding for FVS in bipartite tournaments.

The Cluster Vertex Deletion problem is another restrictions of the vertex cover problem in 3-uniform hypergraphs. Here the goal is to cover all induced paths of length 2 in an undirected graph. A very recent paper by Fiorini et al. [9] provides a 7/3-approximation algorithm for Cluster Vertex Deletion, improving on the previous best ratio 2.5. An approximation-preserving reduction from the Vertex Cover problem shows that the best possible factor is 2 under the Unique Games Conjecture. Despite these similarities, no approximation-preserving reduction is known between Cluster Vertex Deletion and FVS in Tournaments. The techniques used are also quite different.

2 Description of the Algorithm

Let $T = (V, A)$ be a tournament, equipped with a weight function $w : V \to \mathbb{R}_{\geq 0}$. An arc between $u, v \in V$ will be denoted by $(u, v) \in A$ or $u \to v$. The tournament T is *transitive* if it does not contain any directed cycles, or equivalently, its vertices admit a topological order. A vertex set $S \subseteq V$ is a *feedback vertex set* if $T[V \setminus S]$ is transitive. For a vertex set $S \subseteq V$, let $T - S$ denote the tournament resulting from the removal of the vertex set S from T. If $S = \{v\}$ has a single element, we also use the notation $T - v$.

The following straightforward characterization of FVS's in tournaments is well-known.

▶ **Proposition 2.** *For any tournament T, a set S is a feedback vertex set for T if and only if S intersects every directed triangle of T.*

Let $\mathcal{T}_5$ denote the family of tournaments T' on 5 vertices that do not contain a transitive subtournament on 4 vertices; equivalently, every FVS of T' has size at least 2. The set $\mathcal{T}_5$ contains 3 tournaments, the same ones used by Cai et al. [4]. Characterizations of many related classes of tournaments were given by Sanchez-Flores [19].

Our main focus will be the set $\mathcal{T}_7$ defined as follows. Let $\mathcal{T}_7$ denote the family of tournaments on 7 vertices that do not contain a transitive subtournament on 5 vertices. This is equivalent to the property that every FVS is of size at least 3. We remark that $\mathcal{T}_7$ consists of 121 tournaments.

Fig. 1 gives important examples of tournaments $S_5 \in \mathcal{T}_5$ and $S_7 \in \mathcal{T}_7$. The arcs not included in the figures can be oriented arbitrarily; hence both figures represent multiple

Algorithm 1 TOURNAMENT FVS

```
Input: A tournament $T = (V, A)$ with weight function $w : V \to \mathbb{Q}_{\geq 0}$.
Output: A feedback vertex set of $T$ of weight at most $\frac{7}{3}OPT(T)$.
1: Initialize $F = \emptyset$, $T' = T$.
2: Find an optimal solution $x^*$ to (LP).
3: while $T' \neq \emptyset$ and there exists a vertex $v \in V(T')$ with $x^*_v \geq \frac{3}{7}$ do
4:     Set $F := F \cup \{v : x^*_v \geq \frac{3}{7}\}$ and $T' := T' \setminus \{v : x^*_v \geq \frac{3}{7}\}$.
5:     Remove every vertex from $T'$ not contained in any directed triangle; denote this
       resulting tournament also by $T'$.
6:     Solve (LP) for $T'$ to obtain an optimal solution $x^*$.
7: If $T' \neq \emptyset$ then run Algorithm LAYERS (Algorithm 2) for $T'$, returning a FVS $F'$ of $T'$.
8: return $F \cup F'$.
```

tournaments. Tournament S_5 is identical to F_1 of Cai et al. [4]. We leave the proof of the following simple claim to the reader.

▶ **Proposition 3.** *For the tournaments in Fig. 1, $S_5 \in \mathcal{T}_5$ and $S_7 \in \mathcal{T}_7$.*

For a tournament T, let $\Delta(T)$ denote the family of vertex sets of directed triangles in T. According to Proposition 2, T is transitive if and only if $\Delta(T) = \emptyset$. Similarly, $\mathcal{T}_5(T)$ and $\mathcal{T}_7(T)$ denote the family of vertex sets of the subtournaments of T isomorphic to a tournament in $\mathcal{T}_5$ and $\mathcal{T}_7$, respectively. We say that T is $\mathcal{T}_5$*-free* if $\mathcal{T}_5(T) = \emptyset$ and $\mathcal{T}_7$*-free* if $\mathcal{T}_7(T) = \emptyset$.

We use iterative rounding for the following LP relaxation of the FVS problem in a tournament $T = (V, A)$ with weight function $w : V \to \mathbb{Q}_{\geq 0}$. For a vector $x : V \to \mathbb{R}$ and a set $S \subseteq V$, let $x(S) = \sum_{v \in S} x_v$.

$$\begin{aligned} &\min\ w^T x \\ &x(R) \geq 1 \quad \forall R \in \Delta(T) \\ &x(Q) \geq 3 \quad \forall Q \in \mathcal{T}_7(T) \\ &\quad x \geq 0 \end{aligned} \tag{LP}$$

Notice that (LP) does not impose any constraints for subtournaments in $\mathcal{T}_5(T)$. This is an LP of polynomial size. Let $OPT(T)$ denote the optimum value of (LP).

Our algorithm (Algorithm 1), iteratively builds a FVS F of T, initialized empty. We find an optimal solution x^* to (LP), and as long as there exist vertices v such that $x^*_v \geq \frac{3}{7}$, we include all of them in F and remove them from T. We iterate this process, by resolving the LP for the smaller tournament T'. By the first stage of the algorithm we mean the sequence of these iterative rounding steps, which terminate once T' becomes empty (in which case we are done), or every fractional value x^*_v satisfies $x^*_v < \frac{3}{7}$.

In this case, the current tournament T' must be $\mathcal{T}_7$-free. Indeed, the constraint on the elements of $\mathcal{T}_7(T')$ guarantees that in every $\mathcal{T}_7$ subtournament at least one element must have fractional value at least 3/7. Note that this is true already after the very first iteration. The analogous task of removing all subtournaments from $\mathcal{T}_5(T')$ is done by Cai et al. [4] using the local ratio technique. As shown by Bar-Yehuda and Rawitz [2], this could also be done via a primal-dual algorithm. The local ratio and primal-dual techniques easily give a 3-approximation for the formulation with triangles only (given as (P) in the next section). However, these do not seem to easily extend for our second goal with the iterative rounding, when we only have triangle constraints left, and we proceed as long as there is a vertex of fractional value at least 3/7.

In the second stage we apply Algorithm Layers (Algorithm 2). That is the algorithm described in the following theorem.

▶ **Theorem 4.** *There is an algorithm that, given any $\mathcal{T}_7$-free tournament $T' = (V', A')$ with weight function $w : V' \to \mathbb{Q}_{\geq 0}$, in polynomial time finds a FVS F' of T' of weight at most $\frac{7}{9}w(V')$.*

We defer the description of Algorithm Layers as well as the proof of Theorem 4 to Sect. 4. We now prove the validity of Algorithm 1, provided this result.

3 Proof of Theorem 1

It is straightforward to see that the set $F \cup F'$ returned by the algorithm is a FVS of T. The next simple lemma shows that in every iterative rounding step, the weight of the elements added to F can be bounded by the decrease of $OPT(T)$.

▶ **Lemma 5.** *In every iteration during the first stage of the algorithm with current tournament T' and set F, we have*

$$w(F) \leq \frac{7}{3}(OPT(T) - OPT(T')) \ .$$

Proof. We prove the claim by induction. It is clearly true at the beginning when $T' = T$. Whenever we remove a vertex not contained in any triangle, the left-hand side remains unchanged and the right-hand side may only increase. It is sufficient to prove that if x^* is an optimal solution to (LP) for T' and $S = \{v : x^*_v \geq \frac{3}{7}\} \neq \emptyset$, then $OPT(T' \setminus S) + \frac{3}{7}w(S) \leq OPT(T')$.

Note that x^* restricted to $T' \setminus S$ is feasible to (LP) for $T' \setminus S$, and thus $OPT(T' \setminus S) \leq OPT(T') - \sum_{v \in S} w(v)x^*_v \leq OPT(T') - \frac{3}{7}w(S)$, as required. ◀

As observed above, the tournament T' at the end of the first stage is $\mathcal{T}_7$-free. Theorem 4 guarantees that the FVS F' of T' returned by Algorithm Layers has weight $w(F') \leq \frac{7}{9}w(T')$.

▶ **Lemma 6.** *At the end of the first stage, $OPT(T') = \frac{1}{3}w(T')$.*

Before proving this lemma, let us see how it concludes the proof of Theorem 1. According to Theorem 4 and Lemma 6, $w(F') \leq \frac{7}{9}w(T') \leq \frac{7}{3}OPT(T')$. Using Lemma 5, we see that the weight of the constructed FVS $F \cup F'$ is $w(F \cup F') \leq \frac{7}{3}OPT(T)$.

The proof of Lemma 6 analyzes the LP relaxation with triangle constraints only. At the end of the first stage, T' is $\mathcal{T}_7$-free. Hence, the second set of constraints in (LP) for T' is empty. Let us omit these constraints and write (LP) together with its dual:

$$\begin{aligned} \min \quad & w^T x \\ & x(R) \geq 1 \quad \forall R \in \Delta(T') \\ & x : V \to \mathbb{R}_+ \end{aligned} \qquad \text{(P)} \qquad\qquad \begin{aligned} & \max \mathbf{1}^T y \\ & \sum_{R: v \in R} y_R \leq w_v \quad \forall v \in V' \\ & y : \Delta(T') \to \mathbb{R}_+ \end{aligned} \qquad \text{(D)}$$

Proof of Lemma 6. If $\Delta(T') \neq \emptyset$, then T' is empty and the statement of the lemma holds. Therefore, we can assume that $\Delta(T') \neq \emptyset$, and that $x^*_v \leq \frac{3}{7}$ for every $v \in V'$, where $V' = V(T')$ is the vertex set of T'.

▶ **Claim 7.** *$x^*_v > 0$ for every $v \in V'$.*

Proof. For sake of contradiction, suppose that $x_v^* = 0$ for some $v \in V'$. Every vertex in T' is contained in a directed triangle; say $\{v, u, z\} \in \Delta(T')$. The relaxation (LP) includes a constraint $x_v^* + x_u^* + x_z^* \geq 1$, and therefore $x_u^* \geq \frac{1}{2}$ or $x_z^* \geq \frac{1}{2}$, a contradiction to $x_v^* \leq \frac{3}{7}$ for all $v \in V'$. ◀

By primal-dual slackness, we must have $\sum_{u \in R} y_R = w(u)$ for all $u \in V'$. Then

$$w(V') = \sum_{u \in V'} \sum_{R: u \in R} y_R = \sum_{R \in \Delta(T')} y_R \sum_{u \in R} 1 = 3 \sum_{R \in \Delta(T')} y_R = 3 \cdot OPT(T'),$$

completing the proof. In the third equation, we used that every triangle contains exactly three vertices. ◀

4 The Algorithm Layers

In this section, we present Algorithm Layers and prove Theorem 4. First, we need the following result by Cai et al. [4, Sect. 4].

▶ **Theorem 8** ([4]). *There exists an algorithm that, given any $\mathcal{T}_5$-free tournament $\hat{T}$ with non-negative vertex weights, finds in polynomial time a minimum weight FVS in $\hat{T}$.*

We shall refer to the algorithm as the Cai-Deng-Zang algorithm. We also need a property of $\mathcal{T}_5$-free tournaments established by Cai et al. [4, Thm. 3.2].

▶ **Proposition 9** ([4]). *For any $\mathcal{T}_5$-free tournament $\hat{T}$ with non-negative vertex weights, the minimum weight of a FVS equals the maximum value of a fractional triangle packing.*

Observe that computing the maximum value of a fractional triangle packing amounts to solving (D) to optimality.

The next simple lemma bounds the cost of the FVS found by the Cai-Deng-Zang algorithm in terms of the total weight of the vertices $w(\hat{V})$.

▶ **Lemma 10.** *Let $\hat{T} = (\hat{V}, \hat{A})$ be a $\mathcal{T}_5$-free tournament with weight function $w : \hat{V} \to \mathbb{Q}_{\geq 0}$, and let $\hat{F}$ be an FVS of $\hat{T}$ returned by the Cai-Deng-Zang algorithm applied to $(\hat{T}, w)$. Then $w(\hat{F}) \leq w(\hat{V})/3$.*

Proof. By Proposition 9, the polyhedron (P) applied to $T' = \hat{T}$, and w is integral. Setting $x_v = \frac{1}{3}$ for every $v \in \hat{V}$ is a feasible solution, and hence $w(\hat{F}) \leq w(\hat{V})/3$. ◀

4.1 Layers from a vertex

Recall that Theorem 4 takes as input a $\mathcal{T}_7$-free tournament $T' = (V', A')$ with weight function $w : V' \to \mathbb{Q}_{\geq 0}$. For a set $S \subseteq V'$, let $N(S) = \{v \notin S \mid \exists u \in S, v \to u\}$ denote the set of its in-neighbours; let $N(u) := N(\{u\}) = \{v \mid v \to u\}$.

For any vertex $z \in V'$ and $\ell \in \{1, \ldots, n\}$, let us define $V_\ell(z)$ as the set of vertices v such that the shortest directed path from v to z has length exactly $\ell - 1$. Equivalently, let $V_1(z) = \{z\}$, $V_2(z) = N(z)$, and for $\ell \geq 2$ let

$$V_{\ell+1}(z) := \{v \in V' \setminus (V_1(z) \cup \ldots \cup V_\ell(z)) \mid \exists u \in V_\ell(z), v \to u\} \ .$$

These correspond to the layers of the BFS algorithm starting from z. We will prove the following structural result. For two disjoint sets $S, Z \subseteq V'$, let us say that Z *in-dominates* S if for every $s \in S$ there exists a $z \in Z$ with $s \to z$. We say that Z *2-in-dominates* S if Z has a subset $Z' \subseteq Z$ with $|Z'| \leq 2$ such that Z' in-dominates S.

▶ **Theorem 11.** *For every vertex z of positive in-degree, the following hold:*

(a) *The set $V_3(z)$ is $\mathcal{T}_5$-free, and is 2-in-dominated by $V_2(z)$.*

(b) *The set $V_4(z)$ is $\mathcal{T}_5$-free, and is 2-in-dominated by $V_3(z)$.*

(c) *If z is a minimum in-degree vertex in the tournament, then $V_3(z) \neq \emptyset$, and $V_2(z)$ is also $\mathcal{T}_5$-free.*

The proof of Theorem 11 is given in Sect. 4.4. Let us now provide some context and motivation. Cai et al. [4] showed that for any $\mathcal{T}_5$-free tournament, if we select a minimum in-degree vertex z, then every layer $V_i(z)$ induces a transitive tournament and is 1-in-dominated by $V_{i-1}(z)$. This is an important step in their algorithm for finding the exact optimal solution in $\mathcal{T}_5$-free tournaments.

Assume that the analogous property held for $\mathcal{T}_7$-free tournaments T': starting from a minimum in-degree vertex z, every layer $V_{i-1}(z)$ is $\mathcal{T}_5$-free. Then one could get a FVS of T' with weight at most $\frac{2}{3}w(V')$ as follows. Compare the total weight of the even and odd layers, and include in the FVS whichever of the two is smaller. Let us assume the total weight of the odd layers is smaller; the argument is same for the other case. For every remaining even layer $V_i(z)$, run the Cai-Deng-Zang algorithm to obtain a FVS F_i of $V_i(z)$. Form the final FVS F' of T' as the union of all odd layers and the union of the F_i's for the even layers. Using Proposition 10, it is easy to verify that $w(F') \leq \frac{2}{3}w(V')$. Further, F' will be a FVS of T', since by the construction of the $V_i(z)$'s, every triangle must fall on consecutive layers. That is, it is, if a triangle T intersects layers $V_i(z)$ and $V_j(z)$ with $i < j$, then $j \leq i + 2$, and if $j = i + 2$ then T must also intersect layer $V_{i+1}(z)$.

However, Theorem 11 only claims $\mathcal{T}_5$-freeness of layers $V_i(z)$ for $i \leq 4$. This property might not hold for higher values of i. To overcome this difficulty, we modify the layering procedure. While the layers are constructed, we already include certain vertices in the final FVS. This is to make sure that for every layer U_i, it holds that $U_i = V_j(z')$ in some subtournament of T, for a certain vertex z' in a previous layer and $j = 3$ or $j = 4$. Hence Theorem 11 guarantees that all constructed layers are $\mathcal{T}_5$-free. The construction of the final FVS will be a modification of the simple argument above.

4.2 Description of the layering algorithm

The algorithm (Algorithm 2) first partitions the vertex set V' into $S \cup \bigcup_{j=1}^{2k} U_j$ for some $2k \leq n$. We now describe how the layers are constructed in Steps 1-11. We start by setting $U_1 = \{z_1\}$ for a vertex z_1 of minimum in-degree. We let $U_2 = N(z_1)$ be the set of in-neighbours of z_1. The set W will denote the set of vertices not yet included in some U_k or in S; at this point, $W = V' \setminus (U_1 \cup U_2)$.

While W is not empty, we construct an odd layer U_{2k+1}, an even layer U_{2k+2}, and S_{2k+1} as follows. First consider the case when U_{2k} has at least one in-neighbour in W. We set $U_{2k+1} = N(U_{2k}) \cap W$, and remove U_{2k+1} from W. Let U' be the set of in-neighbours of U_{2k+1} in W. We note that $U' = \emptyset$ is possible. We partition U' into U_{2k+2} and S_{2k+2}, and remove U' from W. To obtain this partitioning, we pick a vertex $z_{2k+1} \in U_{2k+1}$ such that $w(N(z_{2k+1}) \cap U') \geq w(U')/2$. The existence of such a vertex z_{2k+1} is non-trivial, and will be proved in Lemma 12(c). We set $U_{2k+2} = N(z_{2k+1}) \cap U'$, and $S_{2k+2} = U' \setminus U_{2k+2}$; the set S_{2k+2} will be part of S.

Let us now address the case when U_{2k} does not have any in-neighbours in W. In this case, we select $U_{2k+1} = \{z\}$ for a vertex $z \in W$ that has minimum in-degree inside W. We refer to the latter scenario as a *fresh start.* We set U_{2k+2} as the set of in-neighbours of z in W, and remove these vertices from W; here $U_{2k+2} = \emptyset$ is possible.

Algorithm 2 LAYERS

```
Input: A $\mathcal{T}_7$-free tournament $T' = (V', A')$ with weight function $w : V' \to \mathbb{Q}_{\geq 0}$.
Output: A feedback vertex set $F'$ of $T'$ of weight at most $\frac{7}{9}w(V')$.
1: Choose $z_1$ as a vertex of minimum in-degree.
2: Set $U_1 := \{z_1\}$,
3: Set $U_2 := N(z_1)$, $W := V' \setminus (U_1 \cup U_2)$, $k := 1$.
4: while $W \neq \emptyset$ do
5:     if $N(U_{2k}) \cap W \neq \emptyset$ then
6:         Set $U_{2k+1} := N(U_{2k}) \cap W$,
7:         $W := W \setminus U_{2k}$.
8:         Set $U' := N(U_{2k+1}) \cap W$, $W := W \setminus U'$.
9:         Choose $z_{2k+1} \in U_{2k+1}$ such that $w(U' \cap N(z_{2k+1})) \geq w(U')/2$.
10:        Set $U_{2k+2} := U' \cap N(z_{2k+1})$; $S_{2k+2} := U' \setminus N(z_{2k+1})$.
11:    else        //fresh start
12:        Choose $z \in W$ with $|N(z) \cap W|$ minimal.
13:        Set $U_{2k+1} := \{z\}$, $U_{2k+2} := N(z) \cap W$, and $S_{2k+2} := \emptyset$.
14:        Set $W := W \setminus (U_{2k+1} \cup U_{2k+2})$.
15:    Set $k := k + 1$.
16: Set $L_0 := \cup_{j=1}^{k} U_{2j}$, $L_1 := \cup_{j=0}^{k-1} U_{2j+1}$, and $S := \cup_{j=1}^{k} S_{2j}$.
17: if $w(L_0) \geq w(L_1)$ then
18:    Run the CAI-DENG-ZANG algorithm for every $U_{2j}$ to obtain a FVS $F_{2j}$ of $U_{2j}$.
19:    Set $F' := (\cup_{j=1}^{k} F_{2j}) \cup S \cup L_1$.
20: else
21:    Run the CAI-DENG-ZANG algorithm for every $U_{2j+1}$ to obtain a FVS $F_{2j+1}$ of $U_{2j+1}$.
22:    Set $F' := (\cup_{j=0}^{k-1} F_{2j+1}) \cup S \cup L_0$.
23: return $F'$.
```

The layering procedure finishes once $W = \emptyset$. At this point, we denote by $L_0 = \bigcup_{j=1}^{k} U_{2j}$ the set of all even and by $L_1 = \bigcup_{j=0}^{k-1} U_{2j+1}$ the set of all odd layers, and by $S = \bigcup_{j=1}^{k} S_{2j}$ the set of vertices removed during the procedure. Thus, $V' = S \cup L_0 \cup L_1$. Given the layering, the algorithm constructs a FVS in Steps 12-18 as follows. If $w(L_0) \geq w(L_1)$, then we use the CAI-DENG-ZANG algorithm to find an optimal FVS F_{2j} in all even layers U_{2j}. We set the entire FVS as $F' := (\cup_{j=1}^{k} F_{2j}) \cup S \cup L_1$. Otherwise, we use the CAI-DENG-ZANG algorithm in all odd layers to find optimal FVS's F_{2j+1}, and set $F' := (\cup_{j=0}^{k-1} F_{2j+1}) \cup S \cup L_0$.

The algorithm clearly runs in polynomial time: every while cycle decreases the size of W by at least one, and every step amounts to examining in-neighbourhoods of vertices and comparing weights of sets.

4.3 Proof of correctness

The following lemma summarizes the essential properties of the layering obtained.

▶ **Lemma 12.** *The sets S and U_i returned by Algorithm* LAYERS *satisfy the following properties.*

(a) *If $i > j + 1$, then $u \to v$ for every $u \in U_j$ and $v \in U_i$.*
(b) *Every subtournament $T'[U_i]$ is $\mathcal{T}_5$-free.*
(c) *There always exists a vertex $z_{2i+1} \in U_{2i+1}$ as required in line 9 of the algorithm.*
(d) $w(S) \leq w(L_0)$.

Proof. Part (a) is immediate, since if $u \in U_j$, then $N(u) \subseteq \cup_{\ell=0}^{j+1}(U_\ell \cup S_\ell)$ (let us use the convention $S_\ell = \emptyset$ for all odd values of ℓ).

We prove parts (b) and (c) simultaneously. We prove it for all layers before the first fresh start happens. If $N(z_1) = \emptyset$, then $U_2 = \emptyset$, hence U_1 and U_2 are trivially $\mathcal{T}_5$-free, and U_3 will be obtained by a fresh start. Otherwise, part (b) is a direct consequence of Theorem 11 for layers $1 \le i \le 4$, as z_1 was chosen as a minimum in-degree vertex; note that $V_3(z_1) \ne \emptyset$ and hence $U_3 = V_3(z_1)$ was not obtained by a fresh start. In this case, the existence of vertex $z_3 \in U_3$ follows by Theorem 11(c): $U' = V_4(z_1)$, and thus U' is 2-in-dominated by U_3. This means that there exist $z, z' \in U_3$ such that $N(z) \cup N(z') \supseteq U'$ (we allow $z = z'$). Without loss of generality, we may assume $w(U' \cap N(z)) \ge w(U' \cap N(z'))$. Then $z_3 = z$ gives an appropriate choice.

Assuming that U_5 is not obtained by a fresh start, let us apply Theorem 11 in the tournament T'' that is the restriction of T' to the ground set $\{z_3\} \cup U_4 \cup U_5 \cup (U_6 \cup S_6)$. In T'' we have $V_3(z_3) = U_5$ and $V_4(z_3) = U_6 \cup S_6$, and therefore U_5 and $U_6 \cup S_6$ are both $\mathcal{T}_5$-free. Further, $U_6 \cup S_6$ is 2-in-dominated by U_5 and therefore we can choose an appropriate $z_5 \in U_5$ as above. The same argument works for all values of $i \ge 3$: consider the restriction of T' to $\{z_{2i-1}\} \cup U_{2i} \cup U_{2i+1} \cup (U_{2i+2} \cup S_{2i+2}$, and apply Theorem 11. We obtain that U_{2i+1} and $U_{2i+2} \cup S_{2i+2}$ are $\mathcal{T}_5$-free as well as the choice of $z_{2i+1} \in U_{2i+1}$.

Assume now that a certain layer U_{2i+1} is obtained by a fresh start. Then we can apply the same argument as above to show parts (b) and (c) for all subsequent layers until the next fresh start: we restrict the tournament from V to the ground set W at the beginning of the iteration when U_{2i+1} is constructed.

Finally, part (d) is straightforward, since $w(U_{2i+2}) \ge w(S_{2i+2})$ by the choice of z_{2i+2}. ◀

We are ready to prove the correctness and approximation ratio of the algorithm.

Proof of Theorem 4. By Lemma 12(b), the CAI-DENG-ZANG algorithm can be applied in all layers U_i and finds an optimal FVS F_i in polynomial time.

First, let us show that the set F' returned by Algorithm LAYERS is indeed a FVS of T'. For a contradiction, assume $V' \setminus F'$ contains a directed triangle uvs.

Let us assume $w(L_0) \ge w(L_1)$; the other case follows similarly. In this case, $V' \setminus F' \subseteq L_0$. The three vertices u, v and s cannot fall into the same layer U_{2i}, as in every such layer we removed a FVS F_{2i}. Hence they must fall into at least two different U_{2i}'s. By Lemma 12(a), if vertices fall into different even layers, then all arcs from the lower layers point towards the higher layers, excluding the possibility of such a triangle.

The proof is complete by showing $w(F') \le \frac{7}{9}w(V')$, or equivalently, $w(V' \setminus F') \ge \frac{2}{9}w(V')$.

Case I: $w(L_0) \ge w(L_1)$. In this case, $w(V' \setminus F') = \cup_{j=1}^{k}(U_{2j} \setminus F_{2j})$. By Proposition 10, $w(F_{2j}) \le w(U_{2j})/3$ for all layers, and thus $w(V' \setminus F') \ge \frac{2}{3}w(L_0)$. Using Lemma 12(d), $w(L_0) \ge \max\{w(L_1), w(S)\}$, and thus $w(L_0) \ge w(V')/3$. Thus $w(V' \setminus F') \ge \frac{2}{9}w(V')$ follows.

Case II: $w(L_0) < w(L_1)$. Using the same argument as in the previous case, we obtain $w(V' \setminus F') \ge \frac{2}{3}w(L_1)$. Again using Lemma 12(d), $w(L_1) > w(L_0) \ge w(S)$, and therefore $w(L_1) \ge w(V')/3$, implying $w(V' \setminus F') \ge \frac{2}{9}w(V')$. ◀

4.4 Proof of Theorem 11

Let us first verify part (c):

▶ **Lemma 13.** *Let z be a minimum in-degree vertex in a $\mathcal{T}_7$-free tournament. Then $V_2(z)$ is $\mathcal{T}_5$-free. If $V_2(z) \neq \emptyset$, then $V_3(z) \neq \emptyset$.*

Proof. The claim is trivial if $V_2(z) = \emptyset$. Hence we assume $V_2(z) \neq \emptyset$ in the sequel. We first claim that for every $u \in V_2(z)$ there must exist a $v \in V_3(z)$ with $v \to u$. Indeed, assume that for some u there exists no such v. Then $N(u) \subsetneq V_2(z) = N(z)$ must hold. This is a contradiction to the choice of z with $|N(z)|$ minimum. This already shows that $V_3(z) \neq \emptyset$.

Consider a subset $H \subseteq V_3(z)$ containing at least one vertex v with $v \to u$ for every $u \in V_2$; choose H minimal for containment. If $|H| \geq 3$, then there must be three vertices $v_1, v_2, v_3 \in H$, and three vertices $u_1, u_2, u_3 \in V_2(z)$ such that $v_i \to u_i$ for $i = 1, 2, 3$, while $u_i \to v_j$ if $i \neq j$. Then z and these vertices together form an $S_7 \in \mathcal{T}_7$ subtournament as in Fig. 1(b), a contradiction.

Hence $|H| \leq 2$. For a contradiction, assume $X \subseteq V_2(z)$ forms a $\mathcal{T}_5$-graph ($|X| = 5$). There exists a $v \in H$ with $|\{s \in X : v \to s\}| \geq 3$. We claim that $X \cup \{v, z\} \in \mathcal{T}_7$. Indeed, assume it contains a transitive tournament Y on 5 vertices. Since $X \in \mathcal{T}_5$, $|X \cap Y| \leq 3$; hence $v, z \in Y$ and $|X \cap Y| = 3$. There must be a vertex $t \in X \cap Y$ with $v \to t$, and thus vtz is a directed triangle, a contradiction. ◀

For (a) and (b) of Theorem 11, we show that the 2-in-domination claim implies $\mathcal{T}_5$-freeness:

▶ **Lemma 14.** *Let z be an arbitrary vertex in a $\mathcal{T}_7$-free tournament. For $i \geq 3$, if $V_i(z)$ is 2-in-dominated by $V_{i-1}(z)$, then $V_i(z)$ is $\mathcal{T}_5$-free.*

Proof. Consider a $\mathcal{T}_5$-subtournament X in $V_i(z)$. By 2-in-domination, there must be a $v \in V_{i-1}(z)$ such that $|N(v) \cap X| \geq 3$. Let $s \in V_{i-2}(z)$ be such that $v \to s$. We obtain a contradiction as in the previous proof, showing that $X \cup \{v, s\} \in \mathcal{T}_7$. Indeed, assume that $X \cup \{v, s\}$ has a transitive subtournament Y of size 5. We have $|X \cap Y| \leq 3$ since X is $\mathcal{T}_5$; thus $|X \cap Y| = 3$, and $v, s \in Y$. But then there exists a vertex $t \in X \cap Y \cap N(v)$. We have $s \to t$ because $N(s) \cap V_{i-1}(z) = \emptyset$. Thus stv is a directed triangle. ◀

The proof of Theorem 11 is complete by the following two lemmata, that show that both $V_3(z)$ and $V_4(z)$ are 2-in-dominated by the previous layer.

▶ **Lemma 15.** *For an arbitrary vertex z in a $\mathcal{T}_7$-free tournament T', the set $V_3(z)$ is 2-in-dominated by $V_2(z)$.*

Proof. Let $H \subseteq V_2(z)$ be a minimal set for containment that in-dominates $V_3(z)$. We show that $|H| \leq 2$. Indeed, if $|H| \geq 3$, then again there must be a tournament $S_7 \in \mathcal{T}_7$ as in Fig. 1(b), formed by z, three vertices in $V_2(z)$ and three in $V_3(z)$. ◀

In the sequel, let $\{a, b\} \subseteq V_2(z)$ be a set that 2-in-dominates $V_3(z)$.

▶ **Lemma 16.** *For an arbitrary vertex z in a $\mathcal{T}_7$-free tournament T', the set $V_4(z)$ is 2-in-dominated by $V_3(z)$.*

Proof. For sake of contradiction, assume that any minimal set in $V_3(z)$ that 2-in-dominates $V_4(z)$ has size at least 3. Then there must exists vertices $u_1, u_2, u_3 \in V_3(z)$ and $v_1, v_2, v_3 \in V_4(z)$ such that $v_i \to u_i$ for $i = 1, 2, 3$, while $u_i \to v_j$ if $i \neq j$.

If all $u_1, u_2, u_3 \in N(a)$, then $\{a, u_1, u_2, u_3, v_1, v_2, v_3\}$ forms a tournament in $\mathcal{T}_7$, a contradiction. A similar argument applies for b. We may therefore assume (by possibly renaming the indices) that $u_1 \to a, u_2 \to a, u_3 \to b, a \to u_3$, and $b \to u_2$. See Fig. 2.

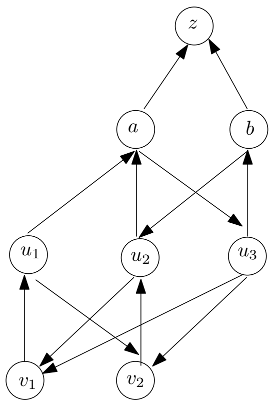


Figure 2 Illustration of the proof of Lemma 16. A few directed edges that are not portrayed are: from z to each one of $\{u_1, u_2, u_3, v_1, v_2\}$ and from each of $\{a, b\}$ to each of $\{v_1, v_2\}$.

Since T' is $\mathcal{T}_7$-free, then every 7-vertex subgraph of $\{z, a, b, u_1, u_2, u_3, v_1, v_2, v_3\}$ must contain a transitive tournament on 5 vertices. Let $Q = \{z, a, b, u_2, u_3\}$, and for $i = 1, 2$, let $Q_i = Q \cup \{u_1, v_i\}$. Let T_i be a transitive tournament on 5 nodes in Q_i.

Notice that Q forms a $\mathcal{T}_5$. Because of this, for $i = 1, 2$ it holds $\{u_1, v_i\} \subseteq T_i$. Furthermore, b, u_3, z cannot all be in T_i since they form a directed triangle; so $\{a, u_2\} \cap T_i \neq \emptyset$. A symmetric argument shows that $\{b, u_3\} \cap T_i \neq \emptyset$ as well.

Now, since either $u_2 \to u_1$ or $u_1 \to u_2$, either $u_2 u_1 v_2$ or $u_1 u_2 v_1$ forms a directed triangle. Thus, $u_2 \notin T_i$ for either $i = 1$ or $i = 2$. For the same i, $a \in T_i$ because of $\{a, u_2\} \cap T_i \neq \emptyset$. Then z cannot be in T_i because $u_1 a z$ forms a directed triangle. Hence $T_i = \{a, b, u_1, u_3, v_i\}$, and this implies that (i) $a \to b$ since $a \to u_3 \to b$, (ii) $u_1 \to u_3$ since $u_1 \to a \to u_3$, and (iii) $u_1 \to b$ since $u_1 \to a \to b$, using (i).

As noted above, $\{u_1, v_1\} \subseteq T_1$. By (ii), $v_1 u_1 u_3$ forms a directed triangle, and by (iii), $v_1 u_1 b$ forms a triangle. Hence, neither u_3 nor b can be contained in T_1, contradicting that $\{b, u_3\} \cap T_1 \neq \emptyset$. This completes the proof of Lemma 16. ◀

5 Connections to Tournament Colouring

We explore a connection to the notion of heroes and celebrities in tournaments studied by Berger, Choromanski, Chudnovsky, Fox, Loebl, Scott, Seymour and Thomassé [3]. Colouring a tournament means partitioning its vertex set into transitive subtournaments; the chromatic number of a tournament is the minimum number of colours needed. A tournament H is called a *hero*, if there exists a constant c_H such that every H-free tournament has chromatic number at most c_H. Further, H is called a *celebrity*, if for some constant $c'_H > 0$, every H-free tournament T has a transitive subtournament of size at least $c'_H |V(T)|$. Clearly, every hero is a celebrity; Berger et al. show that the converse also holds: every celebrity is a hero. Their work gives a characterization of all tournaments that are heros (or equivalently, celebrities).

In this context, our Theorem 4 shows that $\mathcal{T}_7$ collectively form a celebrity set. Further, our constant $c' = 2/9$ seems much better than the constants that could be derived using the techniques of Berger et al. [3]. The set $\mathcal{T}_7$ includes some heros as well as some non-hero tournaments. In contrast, the set $\mathcal{T}_5$ is precisely the set of heros on 5 vertices.

Berger et al.'s [3] characterization rules out the following possible modification of our algorithm to obtain a 2-approximation for the FEEDBACK VERTEX SET in tournaments problem. Instead of $\mathcal{T}_7$, one could use the single tournament ST_6, the unique 6-vertex tournament not containing a transitive subtournament of order 4 [19]. All copies ST_6 can be removed from the input tournament by losing a factor 2 in the approximation ratio only (instead of losing 7/3 by removing copies of subtournaments from $\mathcal{T}_7$). However, according to Berger et al. [3, Thm. 1.2], ST_6 is *not* a hero, and hence there is no hope to prove a version of Theorem 4 for this setting.

Abstract

The Map-Reduce computing framework rose to prominence with datasets of such size that dozens of machines on a single cluster were needed for individual jobs. As datasets approach the exabyte scale, a single job may need distributed processing not only on multiple machines, but on multiple *clusters*. We consider a scheduling problem to minimize weighted average completion time of n jobs on m distributed clusters of parallel machines. In keeping with the scale of the problems motivating this work, we assume that (1) each job is divided into m "subjobs" and (2) distinct subjobs of a given job may be processed concurrently.

When each cluster is a single machine, this is the NP-Hard *concurrent open shop* problem. A clear limitation of such a model is that a serial processing assumption sidesteps the issue of how different tasks of a given subjob might be processed in parallel. Our algorithms explicitly model clusters as pools of resources and effectively overcome this issue.

Under a variety of parameter settings, we develop two constant factor approximation algorithms for this problem. The first algorithm uses an LP relaxation tailored to this problem from prior work. This LP-based algorithm provides strong performance guarantees. Our second algorithm exploits a surprisingly simple mapping to the special case of one machine per cluster. This mapping-based algorithm is combinatorial and extremely fast. These are the first constant factor approximations for this problem.

1 Introduction

It is becoming increasingly impractical to store full copies of large datasets on more than one data center [7]. As a result, the data for a single job may be located not on multiple

machines, but on multiple *clusters* of machines. To maintain fast response-times and avoid excessive network traffic, it is advantageous to perform computation for such jobs in a completely distributed fashion [8]. In addition, commercial platforms such as AWS Lambda and Microsoft's Azure Service Fabric are demonstrating a trend of centralized cloud computing frameworks in which the user manages neither data flow nor server allocation [1, 11]. In view of these converging issues, the following scheduling problem arises:

If computation is done locally to avoid excessive network traffic, how can individual clusters on the broader grid coordinate schedules for maximum throughput?

This was precisely the motivation for Hung, Golubchik, and Yu in their 2015 ACM Symposium on Cloud Computing paper [8]. Hung et al. modeled each cluster as having an arbitrary number of identical parallel machines, and choose an objective of average job completion time. As such a problem generalizes the NP-Hard concurrent open shop problem, they proposed a heuristic approach. Their heuristic (called "SWAG") runs in $O(n^2m)$ time and performed well on a variety of data sets. Unfortunately, SWAG offers poor worst-case performance, as we show in Section 5.

Our contributions to this problem are to extend the model considered by Hung et al. and to introduce the first constant-factor approximation algorithms for this general problem. Our extensions of Hung et al.'s model are (1) to allow different machines within the same cluster to operate at different speeds, (2) to incorporate pre-specified "release times" (times before which a subjob cannot be processed), and (3) to support *weighted* average job completion time. We present two algorithms for the resulting problem. Our combinatorial algorithm exploits a surprisingly simple mapping to the special case of one machine per cluster, where the problem can be approximated in $O(n^2 + nm)$ time. We also present an LP-rounding approach with strong performance guarantees. E.g., a 2-approximation when machines are of unit speed and subjobs are divided into equally sized (but not necessary *unit*) tasks.

1.1 Formal Problem Statement

▶ **Definition 1** (Concurrent Cluster Scheduling).

- There is a set M of m clusters, and a set N of n jobs. For each job $j \in N$, there is a set of m "subjobs" (one for each cluster).
- Cluster $i \in M$ has m_i parallel machines, and machine ℓ in cluster i has speed $v_{\ell i}$. Without loss of generality, assume $v_{\ell i}$ is decreasing in ℓ.[1]
- The i^{th} subjob for job j is specified by a set of tasks to be performed by machines in cluster i, denote this set of tasks T_{ji}. For each task $t \in T_{ji}$, we have an associated processing time p_{jit} (again w.l.o.g., assume p_{jit} is decreasing in t). We will frequently refer to "the subjob of job j at cluster i" as "subjob (j, i)."
- Different subjobs of the same job may be processed concurrently on different clusters.
- Different tasks of the same subjob may be processed concurrently on different machines within the same cluster.
- A subjob is complete when all of its tasks are complete, and a job is complete when all of its subjobs are complete. We denote a job's completion time by "C_j".
- The objective is to minimize weighted average job completion time (job j has weight w_j).
- For the purposes of computing approximation ratios, it is equivalent to minimize $\sum w_j C_j$. We work with this equivalent objective throughout this paper.

[1] Where we write "decreasing", we mean "non-increasing." Where we write "increasing", we mean "non-decreasing".

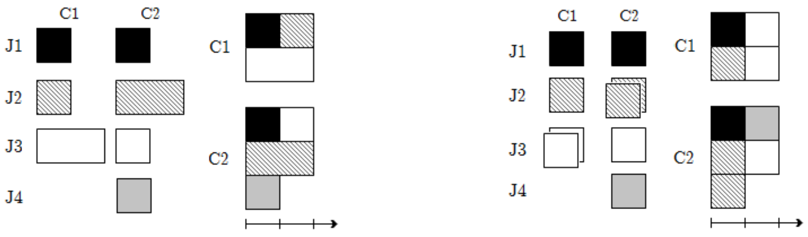

Figure 1 Two examples of our scheduling model. **Left**: Our baseline example. There are 4 jobs and 2 clusters. Cluster 1 has 2 identical machines, and cluster 2 has 3 identical machines. Note that job 4 has no subjob for cluster 1 (this is permitted within our framework). In this case every subjob has at most one task. **Right**: Our baseline example with a more general subjob framework : subjob (2,2) and subjob (3,1) both have two tasks. The tasks shown are unit length, but our framework *does not* require that subjobs be divided into equally sized tasks.

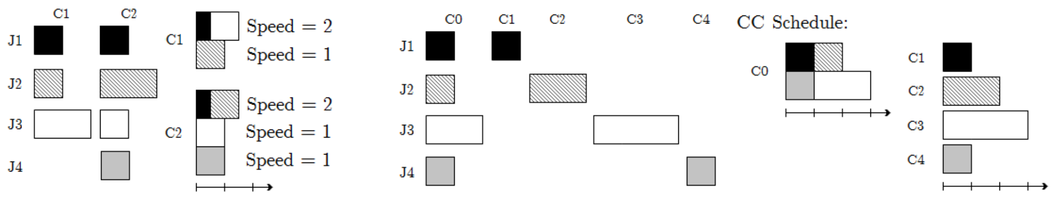

Figure 2 Two additional examples of our model. **Left**: Our baseline example, with variable machine speeds. Note that the benefit of high machine speeds is only realized for tasks assigned to those machines in the final schedule. **Right**: A problem with the peculiar structure that (1) all clusters but one have a single machine, and (2) most clusters have non-zero processing requirements for only a single job. We will use such a device for the total weighted lateness reduction in Section 6.

A machine is said to operate at *unit speed* it if can complete a task with processing requirement "p" in p units of time. More generally, a machine with speed "v" ($v \geq 1$) processes the same task in p/v units of time. Machines are said to be *identical* if they are all of unit speed, and *uniform* if they differ only in speed.

In accordance with Graham et al.'s $\alpha|\beta|\gamma$ taxonomy for scheduling problems [6] we take $\alpha = CC$ to refer to the concurrent cluster environment, and denote our problem by $CC||\sum w_j C_j$.[2] Optionally, we may associate a release time r_{ji} to every subjob. If any subjobs are released after time zero, we write $CC|r|\sum w_j C_j$.

1.1.1 Example Problem Instances

We now illustrate our model with several examples (see Figures 1 and 2). The tables at left have rows labeled to identify jobs, and columns labeled to identify clusters; each entry in these tables specifies the processing requirements for the corresponding subjob. The diagrams to the right of these tables show how the given jobs might be scheduled on clusters with the indicated number of machines.

[2] A problem $\alpha|\beta|\gamma$ implies a particular environment α, objective function γ, and optional constraints β.

1.2 Related Work

Concurrent cluster scheduling subsumes many fundamental machine scheduling problems. For example, if we restrict ourselves to a single cluster (i.e. $m = 1$) we can schedule a set of jobs on a bank of identical parallel machines to minimize makespan ($C_{\max}$) or total weighted completion time ($\sum w_j C_j$). With a more clever reduction, we can even minimize *total weighted lateness* ($\sum w_j L_j$) on a bank of identical parallel machines (see Section 6). Alternatively, with $m > 1$ but $\forall i \in M, m_i = 1$, our problem reduces to the well-studied "concurrent open shop" problem.

Using Graham et al.'s taxonomy, the concurrent open shop problem is written as $PD||\sum w_j C_j$. Three groups [3, 4, 9] independently discovered an LP-based 2-approximation for $PD||\sum w_j C_j$ using the work of Queyranne [13]. The linear program in question has an exponential number of constraints, but can still be solved in polynomial time with a variant of the Ellipsoid method. Our "strong" algorithm for concurrent cluster scheduling refines the techniques contained therein, as well as those of Schulz [14, 15] (see Section 4).

Mastrolilli et al. [10] developed a primal-dual algorithm for $PD||\sum w_j C_j$ that does not use LP solvers. "MUSSQ"[3] is significant for both its speed and the strength of its performance guarantee : it achieves an approximation ratio of 2 in only $O(n^2 + nm)$ time. Although MUSSQ does not require an LP solver, its proof of correctness is based on the fact that it finds a feasible solution to the dual a particular linear program. Our "fast" algorithm for concurrent cluster scheduling uses MUSSQ as a subroutine (see Section 5).

Hung, Golubchik, and Yu [8] presented a framework designed to improve scheduling across geographically distributed data centers. The scheduling framework had a centralized scheduler (which determined a job ordering) and local dispatchers which carried out a schedule consistent with the controllers job ordering. Hung et al. proposed a particular algorithm for the controller called "SWAG." SWAG performed well in a wide variety of simulations where each data center was assumed to have the same number of identical parallel machines. We adopt a similar framework to Hung et al., but we show in Section 5.1 that SWAG has no constant-factor performance guarantee.

1.3 Paper Outline & Algorithmic Results

Although only one of our algorithms requires *solving* a linear program, both algorithms use the same linear program in their proofs of correctness; we introduce this linear program in Section 2 before discussing either algorithm. Section 3 establishes how an ordering of jobs can be processed to completely specify a schedule. This is important because the complex work in both of our algorithms is to generate an ordering of jobs for each cluster.

Section 4 introduces our "strong" algorithm: CC-LP. CC-LP can be applied to any instance of concurrent cluster scheduling, including those with non-zero release times r_{ji}. A key in CC-LP's strong performance guarantees lay in the fact that it allows different permutations of subjobs for different clusters. By providing additional structure to the problem (but while maintaining a generalization of concurrent open shop) CC-LP becomes a 2-approximation. This is significant because it is UGC-Hard to approximate concurrent open shop (and by extension, our problem) with ratio $2 - \epsilon$ for any $\epsilon > 0$ [2].

Our combinatorial algorithm ("CC-TSPT") is presented in Section 5. The algorithm is fast, provably accurate, and has the interesting property that it can schedule all clusters

[3] A permutation of the author's names: Mastrolilli, Queyranne, Schulz, Svensson, and Uhan.

using the same permutation of jobs.[4] After considering CC-TSPT in the general case, we show how fine-grained approximation ratios can be obtained in the "fully parallelizable" setting of Zhang et al. [17]. We conclude with an extension of CC-TSPT that maintains performance guarantees while offering improved empirical performance.

The following table summarizes our results for approximation ratios. For compactness, condition Id refers to identical machines (i.e. $v_{\ell i}$ constant over ℓ), condition A refers to $r_{ji} \equiv 0$, and condition B refers to p_{jit} constant over $t \in T_{ji}$.

	(Id, A, B)	$(Id, \neg A, B)$	$(Id, A, \neg B)$	$(Id, \neg A, \neg B)$	$(\neg Id, A)$	$(\neg Id, \neg A)$
CC-LP	2	3	3	4	$2 + R$	$3 + R$
CC-TSPT	3	–	3	–	$2 + R$	–

The term R is the maximum over i of R_i, where R_i is the ratio of fastest machine to *average* machine speed at cluster i.

The most surprising of all of these results is that our scheduling algorithms are remarkably simple. The first algorithm solves an LP, and then the scheduling can be done easily on each cluster. The second algorithm is again a rather surprising simple reduction to the case of one machine per cluster (the well understood concurrent open shop problem) and yields a simple combinatorial algorithm. The proof of the approximation guarantee is somewhat involved however.

In addition to algorithmic results, we demonstrate how our problem subsumes that of minimizing total weighted lateness on a bank of identical parallel machines (see Section 6). Section 7 provides additional discussion and highlights our more novel technical contributions.

2 The Core Linear Program

Our linear program has an unusual form. Rather than introduce it immediately, we conduct a brief review of prior work on similar LP's. All the LP's we discuss in this paper have objective function $\sum w_j C_j$, where C_j is a decision variable corresponding to the completion time of job j, and w_j is a weight associated with job j.

For the following discussion only, we adopt the notation in which job j has processing time p_j. In addition, if multiple machine problems are discussed, we will say that there are m *such machines (possibly with speeds $s_i, i \in \{1, \ldots, \mathsf{m}\}$).*

The earliest appearance of a similar linear program comes from Queyranne [13]. In his paper, Queyranne presents an LP relaxation for sequencing n jobs on a single machine where all constraints are of the form $\sum_{j \in S} p_j C_j \geq \frac{1}{2}\left[\left(\sum_{j \in S} p_j\right)^2 + \sum_{j \in S} p_j^2\right]$ where S is an arbitrary subset of jobs. Once a set of optimal $\{C_j^\star\}$ is found, the jobs are scheduled in increasing order of $\{C_j^\star\}$. These results were primarily theoretical, as it was known at his time of writing that sequencing n jobs on a single machine to minimize $\sum w_j C_j$ can be done optimally in $O(n \log n)$ time.

Queyranne's constraint set became particularly useful for problems with *coupling* across distinct machines (as occurs in concurrent open shop). Four separate groups [3, 4, 9, 10] saw

[4] We call such schedules "single-σ schedules." As we will see later on, CC-TSPT serves as a constructive proof of existence of near-optimal single-σ schedules for all instances of $CC||\sum w_j C_j$, *including* those instances for which single-σ schedules are strictly sub-optimal. This is addressed in Section 7.

this and used the following LP in a 2-approximation for concurrent open shop scheduling.

$$\text{(LP0)} \quad \min \sum_{j \in N} w_j C_j \quad \text{s.t.} \quad \textstyle\sum_{j \in S} p_{ji} C_j \geq \frac{1}{2}\left[\left(\sum_{j \in S} p_{ji}\right)^2 + \left(\sum_{j \in S} p_{ji}^2\right)\right] \ \forall \substack{S \subseteq N \\ i \in M}$$

In view of its tremendous popularity, we sometimes refer to the linear program above as the *canonical relaxation* for concurrent open shop.

Andreas Schulz's Ph.D. thesis developed Queyranne's constraint set in greater depth [14]. As part of his thesis, Schulz considered scheduling n jobs on m identical parallel machines with constraints of the form $\sum_{j \in S} p_j C_j \geq \frac{1}{2\mathsf{m}}\left(\sum_{j \in S} p_j\right)^2 + \frac{1}{2}\sum_{j \in S} p_j^2$. In addition, Schulz showed that the constraints $\sum_{j \in S} p_j C_j \geq \left[2\sum_{i=1}^{\mathsf{m}} s_i\right]^{-1}\left[\left(\sum_{j \in S} p_j\right)^2 + \sum_{j \in S} p_j^2\right]$ are satisfied by any schedule of n jobs on m uniform machines. In 2012, Schulz refined the analysis for several of these problems [15]. For constructing a schedule from the optimal $\{C_j^\star\}$, Schulz considered scheduling jobs by increasing order of $\{C_j^\star\}$, $\{C_j^\star - p_j/2\}$, and $\{C_j^\star - p_j/(2\mathsf{m})\}$.

2.1 Statement of LP1

The model we consider allows for more fine-grained control of the job structure than is indicated by the LP relaxations above. Inevitably, this comes at some expense of simplicity in LP formulations. In an effort to simplify notation, we define the following constants, and give verbal interpretations for each.

$$\mu_i \doteq \textstyle\sum_{\ell=1}^{m_i} v_{\ell i} \qquad q_{ji} \doteq \min\{|T_{ji}|, m_i\} \qquad \mu_{ji} \doteq \sum_{\ell=1}^{q_{ji}} v_{\ell i} \qquad p_{ji} \doteq \sum_{t \in T_{ji}} p_{jit} \tag{1}$$

From these definitions, μ_i is the processing power of cluster i. For subjob (j, i), q_{ji} is the maximum number of machines that could process the subjob, and μ_{ji} is the maximum processing power than can be brought to bear on the same. Lastly, p_{ji} is the total processing requirement of subjob (j, i). In these terms, the core linear program, LP1, is as follows.

$$\begin{aligned}
&\text{(LP1)} \ \min \textstyle\sum_{j \in N} w_j C_j \\
&\textit{s.t.} \quad (1A) \quad \textstyle\sum_{j \in S} p_{ji} C_j \geq \frac{1}{2}\left[\left(\sum_{j \in S} p_{ji}\right)^2 / \mu_i + \sum_{j \in S} p_{ji}^2 / \mu_{ji}\right] \qquad \forall S \subseteq N, i \in M \\
&\qquad\quad (1B) \quad C_j \geq p_{jit}/v_{1i} + r_{ji} \qquad \forall i \in M,\ j \in N,\ t \in T_{ji} \\
&\qquad\quad (1C) \quad C_j \geq p_{ji}/\mu_{ji} + r_{ji} \qquad \forall j \in N,\ i \in M
\end{aligned}$$

Constraints $(1A)$ are more carefully formulated versions of the polyhedral constraints introduced by Queyranne [13] and developed by Schulz [14]. The use of μ_{ji} term is new and allows us to provide stronger performance guarantees for our framework where subjobs are composed of *sets* of tasks. As we will see, this term is one of the primary factors that allows us to parametrize results under varying machine speeds in terms of maximum to *average* machine speed, rather than maximum to *minimum* machine speed. Constraints $(1B)$ and $(1C)$ are simple lower bounds on job completion time.

The majority of this section is dedicated to proving that LP1 is a valid relaxation of $CC|r|\sum w_j C_j$. Once this is established, we prove the that LP1 can be solved in polynomial time by providing a separation oracle with use in the Ellipsoid method. Both of these proofs use techniques established in Schulz's Ph.D. thesis [14].

2.2 Proof of LP1's Validity

The lemmas below establish the basis for both of our algorithms. Lemma 2 generalizes an inequality used by Schulz [14]. Lemma 3 relies on Lemma 2 and cites an inequality mentioned in the preceding section (and proven by Queyranne [13]).

▶ **Lemma 2.** *Let $\{a_1, \dots a_z\}$ be a set of non-negative real numbers. We assume that $k \le z$ of them are positive. Let b_i be a set of decreasing positive real numbers. Then*

$$\sum_{i=1}^{z} a_i^2/b_i \ge \left(\sum_{i=1}^{z} a_i\right)^2 / \left(\sum_{i=1}^{k} b_i\right).$$

The proof (found in the full version of this paper, [12]) cites the AM-GM inequality and proceeds with induction from $z = k = 2$.

▶ **Lemma 3** (Validity Lemma). *Every feasible schedule for an instance I of $CC|r|\sum w_j C_j$ has completion times that define a feasible solution to LP1(I).*

Proof. As constraints ($1B$) and ($1C$) are clear lower bounds on job completion time, it suffices to show the validity of constraint ($1A$). Thus, let S be a non-empty subset of N, and fix an arbitrary but feasible schedule "F" for I.

Define C^F_{ji} as the completion time of subjob (j, i) under schedule F. Similarly, define $C^F_{ji\ell}$ as the first time at which tasks of subjob (j, i) scheduled on machine ℓ of cluster i are finished. Lastly, define p^ℓ_{ji} as the total processing requirement of job j scheduled on machine ℓ of cluster i. Note that by construction, we have $C^F_{ji} = \max_{\ell \in \{1,\dots,m_i\}} C^F_{ji\ell}$ and $C^F_j = \max_{i \in M} C^F_{ji}$. Since $p_{ji} = \sum_{\ell=1}^{m_i} p^\ell_{ji}$, we can rather innocuously write

$$\textstyle\sum_{j\in S} p_{ji} C^F_{ji} = \sum_{j\in S} \left[\sum_{\ell=1}^{m_i} p^\ell_{ji}\right] C^F_{ji}. \tag{2}$$

But using $C^F_{ji} \ge C^F_{ji\ell}$, we can lower-bound $\sum_{j\in S} p_{ji} C^F_{ji}$. Namely,

$$\textstyle\sum_{j\in S} p_{ji} C^F_{ji} \ge \sum_{j\in S} \sum_{\ell=1}^{m_i} p^\ell_{ji} C^F_{ji\ell} = \sum_{\ell=1}^{m_i} v_{\ell i} \sum_{j\in S} \left[p^\ell_{ji}/v_{\ell i}\right] C^F_{ji\ell} \tag{3}$$

The next inequality uses a bound on $\sum_{j\in S} \left[p^\ell_{ji}/v_{\ell i}\right] C^F_{ji\ell}$ proven by Queyranne [13] for any subset S of N jobs with processing times $\left[p^\ell_{ji}/v_{\ell i}\right]$ to be scheduled on a single machine.[5]

$$\textstyle\sum_{j\in S} \left[p^\ell_{ji}/v_{\ell i}\right] C^F_{ji\ell} \ge \frac{1}{2}\left[\left(\sum_{j\in S} \left[p^\ell_{ji}/v_{\ell i}\right]\right)^2 + \sum_{j\in S} \left(\left[p^\ell_{ji}/v_{\ell i}\right]\right)^2\right] \tag{4}$$

Combining inequalities (3) and (4), we have the following.

$$\begin{align} \textstyle\sum_{j\in S} p_{ji} C^F_{ji} &\ge \frac{1}{2} \textstyle\sum_{\ell=1}^{m_i} v_{\ell i} \left[\left(\sum_{j\in S} \left[p^\ell_{ji}/v_{\ell i}\right]\right)^2 + \sum_{j\in S} \left(\left[p^\ell_{ji}/v_{\ell i}\right]\right)^2\right] \tag{5}\\ &\ge \frac{1}{2} \left[\textstyle\sum_{\ell=1}^{m_i} \left(\sum_{j\in S} p^\ell_{ji}\right)^2 / v_{\ell i} + \sum_{j\in S} \sum_{\ell=1}^{m_i} \left(p^\ell_{ji}\right)^2 / v_{\ell i}\right] \tag{6} \end{align}$$

Next, we apply Lemma 2 to the right hand side of inequality (6) a total of $|S| + 1$ times.

$$\textstyle\sum_{\ell=1}^{m_i} \left(\sum_{j\in S} p^\ell_{ji}\right)^2 / v_{\ell i} \ge \left(\sum_{\ell=1}^{m_i} \sum_{j\in S} p^\ell_{ji}\right)^2 / \sum_{\ell=1}^{m_i} v_{\ell i} = \left(\sum_{j\in S} p_{ji}\right)^2 / \mu_i \tag{7}$$

$$\textstyle\sum_{\ell=1}^{m_i} \left(p^\ell_{ji}\right)^2 / v_{\ell i} \ge \left(\sum_{\ell=1}^{m_i} p^\ell_{ji}\right)^2 / \sum_{\ell=1}^{q_{ji}} v_{\ell i} = p^2_{ji}/\mu_{ji} \quad \forall\, j \in S \tag{8}$$

[5] Here, our machine is machine ℓ on cluster i.

Citing $C_j^F \geq C_{ji}^F$, we arrive at the desired result.

$$\textstyle\sum_{j \in S} p_{ji} C_j^F \geq \frac{1}{2}\left[\left(\sum_{j \in S} p_{ji}\right)^2 / \mu_i + \sum_{j \in S} p_{ji}^2 / \mu_{ji}\right] \qquad \text{“constraint } (1A)\text{”} \tag{9}$$

◀

2.3 Theoretical Complexity of LP1

As the first of our two algorithms requires solving LP1 directly, we need to address the fact that LP1 has $m \cdot (2^n - 1) + n$ constraints. Luckily, it is still possible to such solve linear programs in polynomial time with the Ellipsoid method; we introduce the following separation oracle for this purpose.

▶ **Definition 4** (Oracle LP1). Define the *violation*

$$V(S, i) = \frac{1}{2}\left[\left(\textstyle\sum_{j \in S} p_{ji}\right)^2 / \mu_i + \sum_{j \in S} p_{ji}^2 / \mu_{ji}\right] - \textstyle\sum_{j \in S} p_{ji} C_j \tag{10}$$

Let $\{C_j\} \in \mathbb{R}^n$ be a *potentially* feasible solution to LP1. Let σ_i denote the ordering when jobs are sorted in increasing order of $C_j - p_{ji}/(2\mu_{ji})$. Find the most violated constraint in $(1A)$ for $i \in M$ by searching over $V(S_i, i)$ for S_i of the form $\{\sigma_i(1), \ldots, \sigma_i(j-1), \sigma_i(j)\}$, $j \in \{1, \ldots, n\}$. If any of maximal $V(S_i^*, i) > 0$, then return (S_i^*, i) as a violated constraint for $(1A)$. Otherwise, check the remaining n constraints ($(1B)$ and $(1C)$) directly in linear time.

For fixed i, Oracle-LP1 finds the subset of jobs that maximizes “violation” for cluster i. That is, Oracle-LP1 finds S_i^* such that $V(S_i^*, i) = \max_{S \subset N} V(S, i)$. We prove the correctness of Oracle-LP1 by establishing a necessary and sufficient condition for a job j to be in S_i^*.

▶ **Lemma 5.** *For $\mathbb{P}_i(A) \doteq \sum_{j \in A} p_{ji}$, we have $x \in S_i^* \Leftrightarrow C_x - p_{xi}/(2\mu_{xi}) \leq \mathbb{P}_i(S_i^*)/\mu_i$.*

Proof. For given S (not necessarily equal to S_i^*), it is useful to express $V(S, i)$ in terms of $V(S \cup x, i)$ or $V(S \setminus x, i)$ (depending on whether $x \in S$ or $x \in N \setminus S$). Without loss of generality, we restrict our search to $S : x \in S \Rightarrow p_{x,i} > 0$.

Suppose $x \in S$. By writing $\mathbb{P}_i(S) = \mathbb{P}_i(S \setminus x) + \mathbb{P}_i(x)$, and similarly decomposing the sum $\sum_{j \in S} p_{ji}^2/(2\mu_{ji})$, one can show the following.

$$V(S, i) = V(S \setminus x, i) + p_{xi}\left(\frac{1}{2}\left(\frac{2\mathbb{P}_i(S) - p_{xi}}{\mu_i} + \frac{p_{xi}}{\mu_{xi}}\right) - C_x\right) \tag{11}$$

Now suppose $x \in N \setminus S$. In the same strategy as above (this time writing $\mathbb{P}_i(S) = \mathbb{P}_i(S \cup x) - \mathbb{P}_i(x)$), one can show that

$$V(S, i) = V(S \cup x, i) + p_{xi}\left(C_x - \frac{1}{2}\left(\frac{2\mathbb{P}_i(S) + p_{xi}}{\mu_i} + \frac{p_{xi}}{\mu_{xi}}\right)\right). \tag{12}$$

Note that Equations (11) and (12) hold for all S, including $S = S_i^*$. Turning our attention to S_i^*, we see that $x \in S_i^*$ implies that the second term in Equation (11) is non-negative, i.e.

$$C_x - p_{xi}/(2\mu_{xi}) \leq \left(2\mathbb{P}_i(S_i^*) - p_{xi}\right)/(2\mu_i) < \mathbb{P}_i(S_i^*)/\mu_i. \tag{13}$$

Similarly, $x \in N \setminus S_i^*$ implies the second term in Equation (12) is non-negative.

$$C_x - p_{xi}/(2\mu_{xi}) \geq \left(2\mathbb{P}_i(S_i^*) + p_{xi}\right)/(2\mu_i) \geq \mathbb{P}_i(S_i^*)/\mu_i \tag{14}$$

It follows that $x \in S_i^*$ iff $C_x - p_{xi}/(2\mu_{xi}) < \mathbb{P}_i(S_i^*)/\mu_i$. ◀

Given Lemma 5, It is easy to verify that sorting jobs in increasing order of $C_x - p_{xi}/(2\mu_{xi})$ to define a permutation σ_i guarantees that S_i^* is of the form $\{\sigma_i(1), \ldots, \sigma_i(j-1), \sigma_i(j)\}$ for some $j \in N$. This implies that for fixed i, Oracle-LP1 finds S_i^* in $O(n\log(n))$ time. This procedure is executed once for each cluster, leaving the remaining n constraints in $(1B)$ and $(1C)$ to be verified in linear time. Thus Oracle-LP1 runs in $O(mn\log(n))$ time.

By the equivalence of separation and optimization, we have proven the following theorem:

▶ **Theorem 6.** *LP1(I) is a valid relaxation of $I \in \Omega_{CC}$, and is solvable in polynomial time.*

As was explained in the beginning of this section, linear programs such as those in [3, 4, 9, 13, 14, 15] are processed with an appropriate sorting of the optimal decision variables $\{C_j^\star\}$. It is important then to have bounds on job completion times for a particular ordering of jobs. We address this next in Section 3, and reserve our first algorithm for Section 4.

3 List Scheduling from Permutations

The complex work in both of our proposed algorithms is to generate a *permutation* of jobs. The procedure below takes such a permutation and uses it to determine start times, end times, and machine assignments for every task of every subjob.

List-LPT: Given a single cluster with m_i machines and a permutation of jobs σ, introduce $\text{List}(a,i) \doteq (p_{ai1}, p_{ai2}, \ldots, p_{ai|T_{ai}|})$ as an ordered set of tasks belonging to subjob (a,i), ordered by longest processing time first. Now define $\text{List}(\sigma) \doteq \text{List}(\sigma(1),i) \oplus \text{List}(\sigma(2),i) \oplus \cdots \oplus \text{List}(\sigma(n),i)$, where $\oplus$ is the concatenation operator.

Place the tasks of $\text{List}(\sigma)$ in order- from the largest task of subjob $(\sigma(1),i)$, to the smallest task of subjob $(\sigma(n),i)$. When placing a particular task, assign it whichever machine and start time results in the task being completed as early as possible (without moving any tasks which have already been placed). Insert idle time (on all m_i machines) as necessary if this procedure would otherwise start a job before its release time.

The following Lemma is essential to bound the completion time of a set of jobs processed by List-LPT. The proof is adapted from Gonzalez et al. [5].

▶ **Lemma 7.** *Suppose n jobs are scheduled on cluster i according to List-LPT(σ). Then for $\bar{v}_i \doteq \mu_i/m_i$, the completion time of subjob $(\sigma(j),i)$ (denoted $C_{\sigma(j)i}$) satisfies*

$$C_{\sigma(j)i} \leq \max_{1\leq k\leq j} r_{\sigma(k)i} + p_{\sigma(j)i1}/\bar{v}_i + \left(\textstyle\sum_{k=1}^{j} p_{\sigma(k)i} - p_{\sigma(j)i1}\right)/\mu_i \tag{15}$$

Proof. For now, assume all jobs are released at time zero. Let the task of subjob $(\sigma(j),i)$ to finish last be denoted t^*. If t^* is not the task in $T_{\sigma(j)i}$ with least processing time, then construct a new set $T'_{\sigma(j)i} = \{t : p_{\sigma(j)it^*} \leq p_{\sigma(j)it}\} \subset T_{\sigma(j)i}$. Because the tasks of subjob $(\sigma(j),i)$ were scheduled by List-LPT (i.e. longest-processing-time-first), the sets of potential start times and machines for task t^* (and hence the set of potential completion times for task t^*) are the same regardless of whether subjob $(\sigma(j),i)$ consisted of tasks $T_{\sigma(j)i}$ or the subset $T'_{\sigma(j)i}$. Accordingly, reassign $T_{\sigma(j)i} \leftarrow T'_{\sigma(j)i}$ without loss of generality.

Let D_ℓ^j denote the total demand for machine ℓ (on cluster i) once all tasks of subjobs $(\sigma(1),i)$ through $(\sigma(j-1),i)$ and all tasks in the set $T_{\sigma(j)i} \setminus \{t^*\}$ are scheduled. Using the fact that $C_{\sigma(j)i}v_{\ell i} \leq (D_\ell^j + p_{\sigma(j)it^*})\forall \ell \in \{1,\ldots,m_i\}$, sum the left and right and sides over ℓ. This implies $C_{\sigma(j)i}\left(\sum_{\ell=1}^{m_i} v_{\ell i}\right) \leq m_i p_{\sigma(j)it^*} + \sum_{\ell=1}^{m_i} D_\ell^j$. Dividing by the sum of machine speeds and using the definition of μ_i yields

$$C_{\sigma(j)i} \;\leq\; m_i p_{\sigma(j)it^*}/\mu_i + \textstyle\sum_{\ell=1}^{m_i} D_\ell^j/\mu_i \;\leq\; p_{\sigma(j)i1}/\bar{v}_i + \left(\sum_{k=1}^{j} p_{\sigma(k)i} - p_{\sigma(j)i1}\right)/\mu_i \tag{16}$$

where we estimated $p_{\sigma(j)it^*}$ upward by $p_{\sigma(j)i1}$. Inequality (16) completes our proof in the case when $r_{ji} \equiv 0$. The alternative case is addressed in the full version of this paper. ◀

Lemma 7 is cited directly in the proof of Theorem 8 and Lemma 13. Lemma 7 is used implicitly in the proofs of Theorems 9, 10, and 15.

4 An LP-based Algorithm

In this section we show how LP1 can be used to construct near optimal schedules for concurrent cluster scheduling both when $r_{ji} \equiv 0$ and when some $r_{ji} > 0$. Although solving LP1 is somewhat involved, the algorithm itself is quite simple:

Algorithm CC-LP: Let $I = (T, r, w, v)$ denote an instance of $CC|r|\sum w_j C_j$. Use the optimal solution $\{C_j^\star\}$ of LP1(I) to define m permutations $\{\sigma_i : i \in M\}$ which sort jobs in increasing order of $C_j^\star - p_{ji}/(2\mu_{ji})$. For each cluster i, execute List-LPT(σ_i).

Each theorem in this section can be characterized by how various assumptions help us cancel an additive term[6] in an upper bound for the completion time of an arbitrary subjob (x, i). Theorem 8 is the most general, while Theorem 10 is perhaps the most surprising.

4.1 CC-LP for Uniform Machines

▶ **Theorem 8.** *Let $\hat{C}_j$ be the completion time of job j using algorithm CC-LP, and let R be as in Section 1.3. If $r_{ji} \equiv 0$, then $\sum_{j \in N} w_j \hat{C}_j \leq (2 + R)\,OPT$. Otherwise, $\sum_{j \in N} w_j \hat{C}_j \leq (3 + R)\,OPT$.*

Proof. For $y \in \mathbb{R}$, define $y^+ = \max\{y, 0\}$. Now let $x \in N$ be arbitrary, and let $i \in M$ be such that $p_{xi} > 0$ (but otherwise arbitrary). Define t^* as the last task of job x to complete on cluster i, and let j_i be such that $\sigma_i(j_i) = x$. Lastly, denote the optimal LP solution $\{C_j\}$.[7] Because $\{C_j\}$ is a feasible solution to LP1, constraint $(1A)$ implies the following (set $S_i = \{\sigma_i(1), \ldots, \sigma_i(j_i - 1), x\}$)

$$\frac{\left(\sum_{k=1}^{j_i} p_{\sigma_i(k)i}\right)^2}{2\mu_i} \leq \sum_{k=1}^{j_i} p_{\sigma_i(k)i}\left(C_{\sigma_i(k)} - \frac{p_{\sigma_i(k)i}}{2\mu_{\sigma_i(k)i}}\right) \leq \left(C_x - \frac{p_{xi}}{2\mu_{xi}}\right)\sum_{k=1}^{j_i} p_{\sigma_i(k)i} \tag{17}$$

which in turn implies $\sum_{k=1}^{j_i} p_{\sigma_i(k)i}/\mu_i \leq 2C_x - p_{xi}/\mu_{xi}$.

If all subjobs are released at time zero, then we can combine this with Lemma 7 and the fact that $p_{xit^*} \leq p_{xi} = \sum_{t \in T_{xi}} p_{xit}$ to see the following (the transition from the first inequality the second inequality uses $C_x \geq p_{xit^*}/v_{1i}$ and $R_i = v_{1i}/\bar{v}_i$).

$$\hat{C}_{xi} \leq 2C_x - \frac{p_{xi}}{\mu_{xi}} + \frac{p_{xit^*}}{\bar{v}_i} - \frac{p_{xit^*}}{\mu_i} \leq C_x(2 + [R_i(1 - 2/m_i)]^+) \tag{18}$$

When one or more subjobs are released after time zero, Lemma 7 implies that it is sufficient to bound $\max\limits_{1 \leq k \leq j_i} \{r_{\sigma_i(k)i}\}$ by some constant multiple of C_x. Since σ_i is defined by increasing $L_{ji} \doteq C_j - p_{ji}/(2\mu_{ji})$, $L_{\sigma_i(a)i} \leq L_{\sigma_i(b)i}$ implies

$$r_{\sigma_i(a)i} + \frac{p_{\sigma_i(a)i}}{2\mu_{\sigma_i(a)i}} + \frac{p_{\sigma_i(b)i}}{2\mu_{\sigma_i(b)i}} C_{\sigma_i(a)} - \frac{p_{\sigma_i(a)i}}{2\mu_{\sigma_i(a)i}} + \frac{p_{\sigma_i(b)i}}{2\mu_{\sigma_i(b)i}} \leq C_{\sigma_i(b)} \;\forall\; a \leq b \tag{19}$$

[6] "$+p_{xit^*}$"; see associated proofs.
[7] We omit the customary $\star$ to avoid clutter in notation.

and so $\max_{1\le k\le j_i}\left\{r_{\sigma_i(l)i}\right\} + p_{xi}/(2\mu_{xi}) \le C_x$. As before, combine this with Lemma 7 and the fact that $p_{xit^*} \le p_{xi} = \sum_{t\in T_{xi}} p_{xit}$ to yield the following inequalities

$$\hat{C}_{xi} \le 3C_x - \frac{3p_{xi}}{2\mu_{xi}} + \frac{p_{xit^*}}{\bar{v}_i} - \frac{p_{xit^*}}{\mu_i} \le C_x(3 + [R_i(1 - 5/(2m_i))]^+) \tag{20}$$

which complete our proof. ◀

4.2 CC-LP for Identical Machines

▶ **Theorem 9.** *If machines are of unit speed, then CC-LP yields an objective that is ...*

	$r_{ji} \equiv 0$	*some* $r_{ji} > 0$
single-task subjobs	$\le$ *2 OPT*	$\le$ *3 OPT*
multi-task subjobs	$\le$ *3 OPT*	$\le$ *4 OPT*

Proof. Define $[\cdot]^+$, x, C_x, $\hat{C}_x$, i, σ_i, and t^* as in Theorem 8. When $r_{ji} \equiv 0$, one need only give a more careful treatment of the first inequality in (18) (using $\mu_{ji} = q_{ji}$).

$$\hat{C}_{x,i} \le 2C_x + p_{xit^*} - p_{xit^*}/m_i - p_{xi}/q_{xi} \le C_x(2 + [1 - 1/m_i - 1/q_{xi}]^+) \tag{21}$$

Similarly, when some $r_{ji} > 0$, the first inequality in (20) implies the following.

$$\hat{C}_{x,i} \le 3C_x + p_{xit^*} - p_{xit^*}/m_i - 3p_{xi}/(2q_{xi}) \le C_x(3 + [1 - 1/m_i - 3/(2q_{xi})]^+) \tag{22}$$

◀

The key in the refined analysis of Theorem 9 lay in how $-p_{xi}/q_{xi}$ is used to annihilate $+p_{xit^*}$. While $q_{xi} = 1$ (i.e. single-task subjobs) is sufficient to accomplish this, it is not strictly *necessary*. The theorem below shows that we can annihilate the $+p_{xit^*}$ term whenever all tasks of a given subjob are of the same length. Note that the tasks need not be *unit*, as the lengths of tasks across different subjobs can differ.

▶ **Theorem 10.** *Suppose $v_{\ell i} \equiv 1$. If p_{jit} is constant over $t \in T_{ji}$ for all $j \in N$ and $i \in M$, then algorithm CC-LP is a 2-approximation when $r_{ji} \equiv 0$, and a 3-approximation otherwise.*

Proof. The definition of p_{xi} gives $p_{xi}/q_{xi} = \sum_{t\in T_{xi}} p_{xit}/q_{xi}$. Using the assumption that p_{jit} is constant over $t \in T_{ji}$, we see that $p_{xi}/q_{xi} = (q_{xi} + |T_{xi}| - q_{xi})p_{xit^*}/q_{xi}$, where $|T_{xi}| \ge q_{xi}$. Apply this to Inequality (21) from the proof of Theorem 9; some algebra yields

$$\hat{C}_{xi} \le 2C_x - p_{xit^*}/m_i - p_{xit^*}\left(|T_{xi}| - q_{xi}\right)/q_{xi} \le 2C_x. \tag{23}$$

The case with some $r_{ji} > 0$ uses the same identity for p_{xi}/q_{xi}. ◀

Bansal and Khot [2] showed that is is UGC-Hard to approximate $CC|m_i \equiv 1|\sum w_j C_j$ with a constant factor less than 2. Theorem 10 is significant because it shows that CC-LP can attain the same guarantee for *arbitrary* m_i, provided $v_{\ell i} \equiv 1$ and p_{jit} is constant over t.

5 Combinatorial Algorithms

In this section, we introduce an extremely fast combinatorial algorithm with performance guarantees similar to CC-LP for "unstructured" inputs (i.e. those for which some $v_{\ell i} > 1$, or some T_{ji} have p_{jit} non-constant over t). We call this algorithm *CC-TSPT*. CC-TSPT uses the MUSSQ algorithm for concurrent open shop (from [10]) as a subroutine. As SWAG (from [8]) motivated development of CC-TSPT, we first address SWAG's worst-case performance.

5.1 A Degenerate Case for SWAG

The full version of this paper [12] contains a detailed explanation of SWAG's mechanics beside pseudocode as a necessary component of making claims on worst-case performance. In this version of the paper, we omit this reference material for space considerations.

▶ **Theorem 11.** *For an instance I of $PD||\sum C_j$, let $SWAG(I)$ denote the objective function value of SWAG applied to I, and let $OPT(I)$ denote the objective function value of an optimal solution to I. Then for all $L \geq 1$, there exists an $I \in \Omega_{PD||\sum C_j}$ such that $SWAG(I)/OPT(I) > L$.*

Proof. Let $L \in \mathbb{N}^+$ be fixed but otherwise arbitrary. Construct an instance I_L^m as follows:

$N = N_1 \cup N_2$ where N_1 is a set of m jobs, and N_2 is a set of L jobs. Job $j \in N_1$ has processing time p on cluster j and zero all other clusters. Job $j \in N_2$ has processing time $p(1-\epsilon)$ on all m clusters. ϵ is chosen so that $\epsilon < 1/L$.

It is easy to verify that SWAG will generate a schedule where all jobs in N_2 precede all jobs in N_1 (due to the savings of $p\epsilon$ for jobs in N_2). We propose an *alternative* solution in which all jobs in N_1 precede all jobs in N_2. Denote the objective value for this alternative solution $ALT(I_L^m)$, noting $ALT(I_L^m) \geq OPT(I_L^m)$.

By symmetry, and the fact that all clusters have a single machine, we can see that $SWAG(I_L^m)$ and $ALT(I_L^m)$ are given by the following

$$SWAG(I_L^m) = p(1-\epsilon)L(L+1)/2 + p(1-\epsilon)Lm + pm \tag{24}$$

$$ALT(I_L^m) = p(1-\epsilon)L(L+1)/2 + pL + pm \tag{25}$$

Since L is fixed, we can take the limit with respect to m.

$$\lim_{m\to\infty} \frac{SWAG(I_L^m)}{ALT(I_L^m)} = \lim_{m\to\infty} \frac{p(1-\epsilon)Lm + pm}{pm} = L(1-\epsilon) + 1 > L \tag{26}$$

The above implies the existence of a sufficiently large number of clusters $\overline{m}$, such that $m \geq \overline{m}$ implies $SWAG(I_L^m)/OPT(I_L^m) > L$. This completes our proof. ◀

Theorem 11 demonstrates that that although SWAG performed well in simulations, it may not be reliable. The rest of this section introduces an algorithm not only with superior runtime to SWAG (generating a permutation of jobs in $O(n^2 + nm)$ time, rather than $O(n^2 m)$ time), but also a constant-factor performance guarantee.

5.2 CC-TSPT : A Fast 2 + R Approximation

Our combinatorial algorithm for concurrent cluster scheduling exploits an elegant transformation to concurrent open shop. Once we consider this simpler problem, it can be handled with MUSSQ [10] and List-LPT. Our contributions are twofold: (1) we prove that this intuitive technique yields an approximation algorithm for a decidedly more general problem, and (2) we show that a *non-intuitive* modification can be made that maintains theoretical bounds while improving empirical performance. We begin by defining our transformation.

▶ **Definition 12** (The Total Scaled Processing Time (TSPT) Transformation)**.** Let Ω_{CC} be the set of all instances of $CC||\sum w_j C_j$, and let Ω_{PD} be the set of all instances of $PD||\sum w_j C_j$. Note that $\Omega_{PD} \subset \Omega_{CC}$. Then the Total Scaled Processing Time Transformation is a mapping

$$TSPT : \Omega_{CC} \to \Omega_{PD} \quad \text{with} \quad (T, v, w) \mapsto (X, w) \; : \; x_{ji} = \textstyle\sum_{t\in T_{ji}} p_{jit}/\mu_i$$

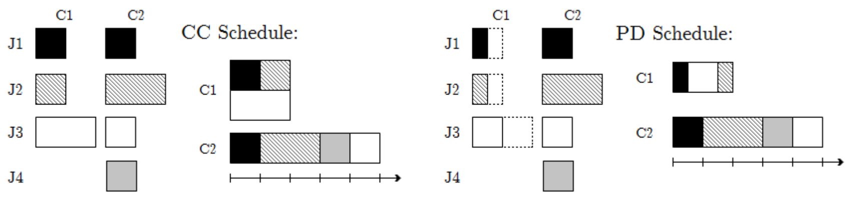

Figure 3 An instance I of $CC||\sum w_j C_j$, and its image $I' = TSPT(I)$. The schedules were constructed with List-LPT using the same permutation for I and I'.

i.e., x_{ji} is the total processing time required by subjob (j, i), scaled by the sum of machine speeds at cluster i. Throughout this section, we will use $I = (T, v, w)$ to denote an arbitrary instance of $CC||\sum w_j C_j$, and $I' = (X, w)$ as the image of I under TSPT. Figure 3 shows the result of TSPT applied to our baseline example.

We take the time to emphasize the simplicity of our reduction. Indeed, the TSPT transformation is perhaps the first thing one would think of given knowledge of the concurrent open shop problem. What is surprising is how one can attain constant-factor performance guarantees even after such a simple transformation.

Algorithm CC-TSPT: Execute MUSSQ on $I' = TSPT(I)$ to generate a permutation of jobs σ. List schedule instance I by σ on each cluster according to List-LPT.

Towards proving the approximation ratio for CC-TSPT, we will establish a critical inequality in Lemma 13. The intuition behind Lemma 13 requires thinking of every job j in I as having a corresponding representation in j' in I'. Job j in I will be scheduled in the CC environment, while job j' in I' will be scheduled in the PD environment. We consider what results when the same permutation σ is used for scheduling in both environments.

Now the definitions for the lemma: let $C^{CC}_{\sigma(j)}$ be the completion time of job $\sigma(j)$ resulting from List-LPT on an arbitrary permutation σ. Define $C^{CC\star}_{\sigma(j)}$ as the completion time of job $\sigma(j)$ in the CC environment in the optimal solution. Lastly, define $C^{PD,I'}_{\sigma(j')}$ as the completion time of job $\sigma(j')$ in I' when scheduling by List-LPT(σ) in the PD environment.

▶ **Lemma 13.** *For $I' = TSPT(I)$, let j' be the job in I' corresponding to job j in I. For an arbitrary permutation of jobs σ, we have $C^{CC}_{\sigma(j)} \leq C^{PD,I'}_{\sigma(j')} + R \cdot C^{CC\star}_{\sigma(j)}$.*

Proof. After list scheduling has been carried out in the CC environment, we may determine $C^{CC}_{\sigma(j)i}$ - the completion time of subjob $(\sigma(j), i)$. We can bound $C^{CC}_{\sigma(j)i}$ using Lemma 7 (which implies (27)), and the serial-processing nature of the PD environment (which implies (28)).

$$C^{CC}_{\sigma(j)i} \leq p_{\sigma(j)i1}\left(1/\bar{v} - 1/\mu_i\right) + \textstyle\sum_{\ell=1}^{j} p_{\sigma(\ell)i}/\mu_i \tag{27}$$

$$\textstyle\sum_{\ell=1}^{j} p_{\sigma(\ell)i}/\mu_i \leq C^{PD,I'}_{\sigma(j')} \quad \forall\ i \in M \tag{28}$$

If we relax the bound given in Inequality (27) and combine it with Inequality (28), we see that $C^{CC}_{\sigma(j)i} \leq C^{PD,I'}_{\sigma(j')} + p_{\sigma(j)i1}/\bar{v}$. The last step is to replace the final term with something more meaningful. Using $p_{\sigma(j)1}/\bar{v} \leq R \cdot C^{CC\star}_{\sigma(j)}$ (which is immediate from the definition of R) the desired result follows. ◀

While Lemma 13 is true for arbitrary σ, now we consider $\sigma = MUSSQ(X, w)$. The proof of MUSSQ's correctness established the first inequality in the chain of inequalities below. The second inequality can be seen by substituting p_{ji}/μ_i for x_{ji} in LP0(I') (this shows that the constraints in LP0(I') are weaker than those in LP1(I)). The third inequality follows from the Validity Lemma.

$$\textstyle\sum_{j\in N} w_{\sigma(j)} C^{PD,I'}_{\sigma(j)} \leq 2\sum_{j\in N} w_j C^{\text{LP0}(I')}_j \leq 2\sum_{j\in N} w_j C^{\text{LP1}(I)}_j \leq 2OPT(I) \tag{29}$$

Combining Inequality (29) with Lemma 13 allows us to bound the objective in a way that does not make reference to I'.

$$\textstyle\sum_{j\in N} w_{\sigma(j)} C^{CC}_{\sigma(j)} \leq \sum_{j\in N} w_{\sigma(j)} \left[C^{PD,I'}_{\sigma(j)} + R\cdot C^{CC\star}_{\sigma(j)}\right] \leq \ 2\cdot OPT(I) + R\cdot OPT(I) \tag{30}$$

Inequality (30) completes our proof of the following theorem.

▶ **Theorem 14.** *Algorithm CC-TSPT is a $2+R$ approximation for $CC||\sum w_jC_j$.*

5.3 CC-TSPT with Unit Tasks and Identical Machines

Consider concurrent cluster scheduling with $v_{\ell i} = p_{jit} = 1$ (i.e., all processing times are unit, although the size of the collections T_{ji} are unrestricted). In keeping with the work of Zhang, Wu, and Li [17] (who studied this problem in the single-cluster case), we call instances with these parameters "fully parallelizable," and write $\beta = fps$ for Graham's $\alpha|\beta|\gamma$ taxonomy.

Zhang et al. showed that scheduling jobs greedily by "Largest Ratio First" (decreasing w_j/p_j) results in a 2-approximation, where 2 is a tight bound. This comes as something of a surprise since the Largest Ratio First policy is *optimal* for $1||\sum w_jC_j$ - which their problem very closely resembles. We now formalize the extent to which $P|fps|\sum w_jC_j$ resembles $1||\sum w_jC_j$: define the *time resolution* of an instance I of $CC|fps|\sum w_jC_j$ as $\rho_I = \min_{j\in N, i\in M}\lceil p_{ji}/m_i\rceil$. Indeed, one can show that as the time resolution increases, the performance guarantee for LRF on $P|fps|\sum w_jC_j$ approaches that of LRF on $1||\sum w_jC_j$. We prove the analogous result for our problem.

▶ **Theorem 15.** *CC-TSPT for $CC|fps|\sum w_jC_j$ is a $(2+1/\rho_I)-$approximation.*

Proof. Applying techniques from the proof of Lemma 13 under the hypothesis of this theorem, we have $C^{CC}_{\sigma(j),i} \leq C^{PD,I'}_{\sigma(j)} + 1$. Next, use the fact that for all $j \in N$, $C^{CC,OPT}_{\sigma(j)} \geq \rho_I$ by the definition of ρ_I. These facts together imply $C^{CC}_{\sigma(j),i} \leq C^{PD,I'}_{\sigma(j)} + C^{CC,OPT}/\rho_I$. Thus

$$\textstyle\sum_{j\in N} w_j C^{CC}_{\sigma(j)} \leq \sum_{j\in N} w_j \left[C^{PD,I'}_{\sigma(j)} + C^{CC,OPT}/\rho_I\right] \leq 2\cdot OPT + OPT/\rho_I. \tag{31}$$

◀

5.4 CC-ATSPT : Augmenting the LP Relaxation

The proof of Theorem 14 appeals to a trivial lower bound on $C^{CC\star}_{\sigma(j)}$, namely $p_{\sigma(j)1}/\bar{v} \leq R\cdot C^{CC\star}_{\sigma(j)}$. We attain constant-factor performance guarantees in spite of this, but it is natural to wonder how the *need* for such a bound might come hand-in-hand with empirical weaknesses. Indeed, TSPT can make subjobs consisting of many small tasks look the same as subjobs consisting of a single very long task. Additionally, a cluster hosting a subjob with a single extremely long task might be identified as a bottleneck by MUSSQ, even if that cluster has more machines than it does tasks to process.

We would like to mitigate these issues by introducing the simple lower bounds on C_j as seen in constraints ($1B$) and ($1C$). This is complicated by the fact that MUSSQ's proof of correctness only allows constraints of the form in $(1A)$. For $I \in \Omega_{PD}$ this is without loss of generality, since $|S| = 1$ in LP0 implies $C_j \geq p_{ji}$, but since we apply LP0 to $I' = TSPT(I)$, $C_j \geq x_{ji}$ is equivalent to $C_j \geq p_{ji}/\mu_i$ (a much weaker bound than we desire).

Nevertheless, we can bypass this issue by introducing additional clusters and appropriately defined subjobs. We formalize this with the "Augmented Total Scaled Processing Time" (ATSPT) transformation. Conceptually, ATSPT creates n "imaginary clusters", where each imaginary cluster has nonzero processing time for exactly one job.

▶ **Definition 16** (The Augmented TSPT Transformation)**.** Let Ω_{CC} and Ω_{PD} be as in the definition for TSPT. Then the Augmented TSPT Transformation is likewise a mapping

$$ATSPT : \Omega_{CC} \to \Omega_{PD} \quad \text{with} \quad (T, v, w) \mapsto (X, w) \ : \ X = \left[\ X_{TSPT(I)} \ \middle| \ D \ \right].$$

Where $D \in \mathbb{R}^{n \times n}$ is a diagonal matrix with d_{jj} as any valid lower bound on the completion time of job j (such as the right hand sides of constraints $(1B)$ and $(1C)$ of LP1).

Given that d_{jj} is a valid lower bound on the completion time of job j, it is easy to verify that for $I' = ATSPT(I)$, LP1(I') is a valid relaxation of I. Because MUSSQ returns a permutation of jobs for use in list scheduling by List-LPT, these "imaginary clusters" needn't be accounted for beyond the computations in MUSSQ.

6 A Reduction for Minimizing Total Weighted Lateness on Identical Parallel Machines

The problem of minimizing total weighted lateness on a bank of identical parallel machines is typically denoted $P||\sum w_j L_j$, where the lateness of a job with deadline d_j is $L_j \doteq \max\{C_j - d_j, 0\}$. The reduction we offer below shows that $P||\sum w_j L_j$ can be stated in terms of $CC||\sum w_j C_j$ *at optimality*. Thus while a Δ approximation to $CC||\sum w_j C_j$ does not imply a Δ approximation to $P||\sum w_j L_j$, the reduction below nevertheless provides new insights on the structure of $P||\sum w_j L_j$.

▶ **Definition 17** (Total Weighted Lateness Reduction)**.** Let $I = (p, d, w, m)$ denote an instance of $P||\sum w_j L_j$. p is the set of processing times, d is the set of deadlines, w is the set of weights, and m is the number of identical parallel machines. Given these inputs, we transform $I \in \Omega_{P||\sum w_j L_j}$ to $I' \in \Omega_{CC}$ in the following way.

Create a total of $n + 1$ clusters. Cluster 0 has m machines. Job j has processing time p_j on this cluster, and $|T_{j0}| = 1$. Clusters 1 through n each consist of a single machine. Job j has processing time d_j on cluster j, and zero on all clusters other than cluster 0 and cluster j. Denote this problem I'.

We refer the reader to Figure 2 for an example output of this reduction.

▶ **Theorem 18.** *Let I be an instance of $P||\sum w_j L_j$. Let I' be an instance of $CC||\sum w_j C_j$ resulting from the transformation described above. Any list schedule σ that is optimal for I' is also optimal for I.*

The proof can be found in the full version of this paper.

7 Closing Remarks

We now take a moment to address a subtle issue in the concurrent cluster problem: what price do we pay for using the same permutation on all clusters (i.e. single-σ schedules)?

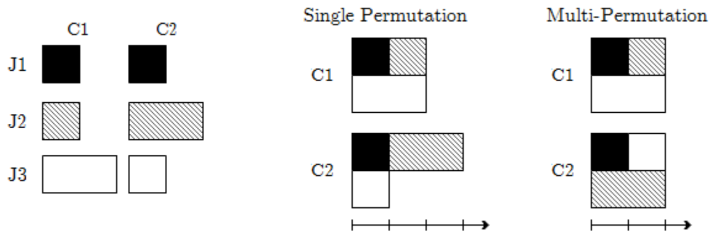

Figure 4 An instance of $CC||\sum C_j$ (i.e. $w_j \equiv 1$) for which there does not exist a single-σ schedule which attains the optimal objective value. In the single-σ case, one of the jobs necessarily becomes delayed by one time unit compared to the multi-σ case. As a result, we see a 20% optimality gap even when $v_{\ell i} \equiv 1$.

For concurrent open shop, it has been shown ([16, 10]) that single-σ schedules may be assumed without loss of optimality. As is shown in Figure 4, this does *not* hold for concurrent cluster scheduling in the general case. In fact, that is precisely why the strong performance guarantees for algorithm CC-LP rely on clusters having possibly unique permutations.

Our more novel contributions came in our analysis for CC-TSPT and CC-ATSPT. First, we could not rely on the processing time of the last task for a job to be bounded above by the job's completion time variable C_j in LP0(I'), and so we appealed to a lower bound on C_j that was not stated in the LP itself. The need to incorporate this second bound is critical in realizing the strength of algorithm CC-TSPT, and uncommon in LP rounding schemes. Second, CC-ATSPT is novel in that it introduces constraints that would be redundant for LP0(I) when $I \in \Omega_{PD}$, but become relevant when viewing $LP0(I')$ as a relaxation for $I \in \Omega_{CC}$. This approach has potential for more broad applications since it represented effective use of a limited constraint set supported by a known primal-dual algorithm.

We now take a moment to state some open problems in this area. One topic of ongoing research is developing a factor 2 purely combinatorial algorithm for the special case of concurrent cluster scheduling considered in Theorem 10. In addition, it would be of broad interest to determine the worst-case loss to optimality incurred by assuming single-permutation schedules for $CC|v \equiv 1|\sum w_j C_j$. The simple example above shows that an optimal single-σ schedule can have objective 1.2 times the globally optimal objective. Meanwhile, Theorem 14 shows that there always exists a single-σ schedule with objective no more than 3 times the globally optimal objective. Thus, we know that the worst-case performance ratio is in the interval $[1.2, 3]$, but we do not know its precise value. As a matter outside of scheduling theory, it would be valuable to survey primal-dual algorithms with roots in LP relaxations to determine which have constraint sets that are amenable to implicit modification, as in the fashion of CC-ATSPT.

Acknowledgments. Special thanks to Andreas Schulz for sharing some of his recent work with us [15]. His thorough analysis of a linear program for $P||\sum w_j C_j$ drives the LP-based results in this paper. Thanks also to Chien-Chung Hung and Leana Golubchik for sharing [8] while it was under review, and to Ioana Bercea and Manish Purohit for their insights on SWAG's performance. Lastly, our sincere thanks to William Gasarch for organizing the REU which led to this work, and to the 2015 CAAR-REU cohort for making the experience an unforgettable one; in the words of Rick Sanchez *wubalubadubdub!*

Abstract

The worst-case fastest known algorithm for the Set Cover problem on universes with n elements still essentially is the simple $O^*(2^n)$-time dynamic programming algorithm, and no non-trivial consequences of an $O^*(1.01^n)$-time algorithm are known. Motivated by this chasm, we study the following natural question: Which instances of Set Cover *can* we solve faster than the simple dynamic programming algorithm? Specifically, we give a Monte Carlo algorithm that determines the existence of a set cover of size σn in $O^*(2^{(1-\Omega(\sigma^4))n})$ time. Our approach is also applicable to Set Cover instances with exponentially many sets: By reducing the task of finding the chromatic number $\chi(G)$ of a given n-vertex graph G to Set Cover in the natural way, we show there is an $O^*(2^{(1-\Omega(\sigma^4))n})$-time randomized algorithm that given integer $s = \sigma n$, outputs NO if $\chi(G) > s$ and YES with constant probability if $\chi(G) \leq s - 1$.

On a high level, our results are inspired by the 'representation method' of Howgrave-Graham and Joux [EUROCRYPT'10] and obtained by only evaluating a randomly sampled subset of the table entries of a dynamic programming algorithm.

1 Introduction

The Set Cover problem is, after determining satisfiability of CNF formulas or Boolean circuits, one of the canonical NP-complete problems. It not only directly models many applications in practical settings, but also algorithms for it routinely are used as tools for theoretical algorithmic results (e.g., [17]). It is a problem 'whose study has led to the development of fundamental techniques for the entire field' of approximation algorithms.[1] However, the exact exponential time complexity of Set Cover is still somewhat mysterious: We know algorithms need to use super-polynomial time assuming $P \neq NP$ and (denoting n for the universe size) $O^*(2^{\Omega(n)})$ time assuming the Exponential Time Hypothesis, but how large the exponential should be is not clear. In particular, no non-trivial consequences of an $O^*(1.01^n)$-time algorithm are currently known.

Even though it is one of the canonical NP-complete problems, the amount of studies of exact algorithms for Set Cover pales in comparison with the amount of literature on exact algorithms for CNF-Sat: Many works focus on finding $O^*(c^n)$-time algorithms for $c < 2$

[1] As the Wikipedia page on Set Cover quotes the textbook by Vazirani [32, p15].

for CNF-Sat on n-variable CNF-formulas in special cases such as, among others, bounded clause width [31, 17, 12], bounded clause density [11, 25] or few projections [27, 29, 30]. Improved exponential time algorithms for special cases of problems other than CNF-Sat were also studied for e.g. Graph Coloring or Traveling Salesman on graphs bounded degree/average degree [8, 9, 15, 20].

In this paper we are interested in the exponential time complexity of Set Cover, and study which properties are sufficient to have improved exponential time algorithms. Our interest in finding faster exponential time algorithms for Set Cover does not only stem from it being a canonical NP-complete problem, but also from its unclear relation with CNF-Sat. Intriguingly, on one hand Set Cover has some similarities with the CNF-Sat: 1. Both problems take an (annotated) hypergraph as input. 2. The improvability of the worst-case complexity of CNF-Sat is essentially equivalent to the improvability of the worst-case complexity of Hitting Set [14], which is just a reparametrization[2] of Set Cover. But, on the other hand the problems are quite different to our understanding: 1. Most algorithms for Set Cover use dynamic programming or some variant of inclusion exclusion, while most algorithms for CNF-Sat are based on branching. 2. No connection between the exponential time complexities of both problems is known (see [14]). One hope would be that a better understanding of the exact complexity of Set Cover might shed more light on this unclarity. Moreover, Cygan et al. [14] also show that if we would like to improve the run time $O^*(f(k))$ of several parameterized algorithms to $O^*(f(k)^{1-\Omega(1)})$, we first need to find an $O^*(2^{(1-\Omega(1))n})$-time algorithm for Set Cover. These parameterized algorithms include the classic algorithm for Subset Sum, as well as more recent algorithms for Connected Vertex Cover and Steiner Tree.

Relevant previous work. The algorithmic results on Set Cover that are the most relevant to our work are as follows: The folklore dynamic programming algorithm runs in $O^*(2^n)$ time. A notable special case of Set Cover that can be solved in $O^*(2^{(1-\Omega(1))n})$ time is due to Koivisto [28]: He gives an algorithm that runs in time $O^*(2^{(1-\frac{1}{O(r)})n})$-time algorithm if all sets are at most of size r. Björklund et al. [10] show that the problem can be solved in $2^n \operatorname{poly}(n)$ time (which is faster if the number of sets is exponentially large in n). Björklund et al. [7] give a randomized algorithm that assumes all sets are of size q and determines whether there exist p pairwise disjoint sets in $O^*(2^{(1-\epsilon)pq})$ time where $\epsilon > 0$ depends on q.

Our Main Results. We investigate what are sufficient structural properties of instances of Set Cover, and the closely related Set Partition (in which the picked sets need to be disjoint), problems to be solvable in time significantly faster than the currently known algorithms. We will outline our main results now:

▶ **Theorem 1.1.** *There is a Monte Carlo algorithm that takes an instance of* Set Cover *on n elements and m sets and an integer s as input and determines whether there exists a set cover of size s in $O(2^{(1-\Omega(\sigma^4))n}m)$ time, where $\sigma = s/n$.*

We remark that this generalizes the result of Koivisto [28] in the sense that it solves a larger class of instances in $O^*(2^{(1-\Omega(1))n})$ time: If all set sizes are bounded by a constant r, a set partition needs to consist of at least n/r sets and Theorem 1.1 applies with $\sigma = 1/r$

[2] One way of stating Hitting Set in this context, is that we have an instance of the Set Cover problem but aim to find an $O^*(2^{(1-\Omega(1))m})$ time algorithm, where m denotes the number of sets.

(although this gives a slower algorithm than Koivisto's in this special case). Moreover, it seems hard to extend the approach of Koivisto to our more general setting.

The second result demonstrates that our techniques are also applicable to Set Cover instances with exponentially many sets, a canonical example of which being graph coloring:

▶ **Theorem 1.2.** *There is a randomized algorithm that given graph G and integer $s = \sigma n$, in $O^*(2^{(1-\Omega(\sigma^4))n})$ time outputs* **yes** *with constant probability, if $\chi(G) < s$, and* **no**, *if $\chi(G) > s$.*

Representation method for Set Cover. We feel the main technique used in this paper is equally interesting as the result, and will therefore elaborate on its origin here. Our technique is on a high level inspired by the following simple observation ingeniously used by Howgrave-Graham and Joux [23]: Suppose $\mathcal{S} \subseteq 2^{[m]}$ is a set of solutions implicitly given and we seek for a solution $X \in \mathcal{S}$ with $|X| = s$ by listing all sets of $\binom{[m]}{s/2}$ and performing pairwise checks to see which two combine to an element of $\mathcal{S}$. Then we can restrict our search in various ways since there will be as many as $\binom{s}{s/2}$ pairs guiding us to X. In [23] and all subsequent works (including [3, 4, 1, 2]), this idea was used to speed up 'meet-in-the-middle attacks' (also called 'birthday attacks' [26, Chapter 6]). We will refer to uses of this idea as the 'representation method' since it crucially relies on the fact that X has many representations as pairs. To indicate the power of this technique in the context of Set Cover and Set Partition we show that without changes it already gives an $O^*(2^{0.3399m})$-time Monte Carlo algorithm for the Set Partition problem with m sets, and even for a more general linear satisfiability problem on m variables. For the latter problem this improves the $O^*(2^{m/2})$ time algorithm based on the meet-in-the-middle attack that was the fastest known before.

At first sight the representation method seemed to be inherently only useful for improving algorithms based on the meet-in-the-middle attack. However, the main conceptual contribution of this work is to show that it is also useful in other settings, or at least for improving the dynamic programming algorithm for the Set Cover and Set Partition problems if the solution size is large. On a high level, we show this as follows in the case of Set Partition:[3] for a subset W of the elements of the Set Partition instance, define $T[W]$ to be the minimum number of disjoint sets needed to cover all elements of W. Stated slightly oversimplified, we argue that if a minimal set partition of size s is large, we have that $T[W] + T[[n] \setminus W] = s$ for $\binom{s}{s/2}$ sets W with $|W|$ close to $n/2$. To relate this to later sections, let us remark we refer to such a set W as a *witness halve*. Subsequently, we exploit the presence of many witness halves by using a dynamic programming algorithm that samples a set of the subsets with size close to $n/2$ and only evaluates table entries from this sample plus the table entries required to compute the table entries from the sample.

Organization. This paper is organized as follows: In Section 2, we recall preliminaries and introduce notation. In Section 3, we discuss new observations and basic results that we feel are useful for developing a better understanding of the complexity of Set Cover with respect to several structural properties of instances. In Section 4 we formally present the notion of witness halves and prepare tools for exploiting the existence of many witness halves. In Section 5 we prove our main results and in Section 6 we suggest further research.

[3] The algorithm for Set Cover actually reduces to Set Partition.

2 Preliminaries and Notation

For a Boolean predicate p, we let $[p]$ denote 1 if p is true and 0 otherwise. On the other hand, if p is an integer we let $[p]$ denote $\{1,\dots,p\}$. As usual, $\mathbb{N}$ denotes all positive integers. Running times of algorithms are often stated using $O^*(\cdot)$ notation which suppresses factors polynomial in the input size. To avoid superscript, we sometimes use $\exp(x)$ to denote e^x. We denote lg for the base-2 logarithm. If $G=(V,E)$ and $v \in V$ we denote $N(v)=\{w \in V : (v,w) \in E\}$ and for $X \subseteq V$ we extended this notation to $N(X)=\bigcup_{v \in X} N(v)$. For reals $a,b>0$ we let $a \pm b$ denote the interval $[a-b,a+b]$. A false positive (negative) of an algorithm is an instance on which it incorrectly outputs YES (respectively, NO). In this work we call an algorithm Monte Carlo if it has no false positives and if any instance is a false negative with probability at most 1/4. We denote vectors with boldface for clarity. For a real number $x \in [0,1]$, $h(x)=-x\lg x-(1-x)\lg(1-x)$ denotes the binary entropy of x, where $0\lg 0$ should be thought of as 0. It is well known that $\binom{b}{a} \le 2^{h(a/b)b}$ (and this can for example be proved using Stirling's approximation). It is easy to see from the definition that $h(\cdot)$ is symmetric in the sense that $h(x)=h(1-x)$.

▶ **Lemma 2.1.** *The following can be verified using standard calculus:*
1. $h(1/2-x)=h(1/2+x) \le 1-x^2$ *for all* $x \in (0,1/2)$,
2. $h(x) \le x\lg(4/x)$ *for all* $x \in (0,1)$,
3. $(1-1/n)^n \le 1/e$.

▶ **Lemma 2.2** (Hoeffding bound [21]). *If* $X_1,\dots,X_s$ *are independent,* $Y=\sum_{i=1}^s X_i$ *and* $a_i \le X_i \le b_i$ *for* $i=1,\dots,s$ *then* $\Pr[|Y-\mathbb{E}[Y]| \ge t] \le 2\cdot\exp\left(\frac{-2t^2}{\sum_{i=1}^s (b_i-a_i)^2}\right)$.

Set Cover / Set Partition. In the Set Cover problem we are given a bipartite graph $G=(F\dot{\cup}U,E)$ (where F and U shorthand 'Family' and 'Universe' respectively), together with an integer s and the task is to determine whether there exists a *solution* $S \subseteq F$ such that $N(S)=U$ and $|S| \le s$. In the Set Partition problem we are given the same input as in the Set Cover problem, but we are set to determine whether there exists $S \subseteq F$ with $N(S)=U$, $|S|=s$ and additionally $N(f)\cap N(f')=\emptyset$ for every $f,f' \in S$ with $f \ne f'$. We will refer to solutions of both problems as set covers and set partitions.

Throughout this paper, we let n,m respectively denote $|U|$ and $|F|$, and refer to instances of Set Cover or Set Partition as (n,m,s)-instances to quantify their parameters. Since this work concerns Set Cover or Set Partition with large solutions we record the following basic observation that follows by constructing for each[4] c-tuple $t=(f_1,\dots,f_c) \in F^c$ of sets in the original instance a set f^t with $N(f^t)=\bigcup_{i=1}^t f_i$ in the output instance:

▶ **Observation 2.3** ([14]). *There is a polynomial time algorithm that takes a constant* $c \ge 1$ *dividing* s*, and a* (n,m,s)*-instance of* Set Cover *(resp.* Set Partition*) as input and outputs an equivalent* $(n,m^c,s/c)$*-instance of* Set Cover *(resp.* Set Partition*).*

Often it will be useful dispense with linear sized sets. To this end, the following can be achieved by simply iterating over all $f \in F$ with $|N(f)| \ge \epsilon n$ and checking for each such set whether there is a solution containing it using the $2^n\operatorname{poly}(n)$ algorithm for Set Cover [10].

[4] For Set Partition only do this for c-tuples $(f_1,\dots,f_c)$ with $N(f_i)$ disjoint.

▶ **Observation 2.4.** *There is an algorithm that, given a real number $\epsilon > 0$, takes an (n, m, s)-instance of* Set Cover *as input and outputs an equivalent (n, m', s)-instance with $m' \le m$ satisfying $|N(f)| \le \epsilon n$ for every $f \in F$. The algorithm runs in $O(m2^{(1-\epsilon)n} \operatorname{poly}(n))$ time.*

As we will see in Theorem 3.4, it makes a difference in the Set Partition problem whether empty sets are allowed since we need to find a set partition of size exactly s. To exclude such sets, we will simply say that an instance is 'without empty sets'.

3 Observations and Basic Results on Set Cover and Set Partition

To improve our understanding of which properties of instances of Set Cover and Set Partition allow faster algorithms, and which techniques are useful for obtaining such faster algorithms, we will record some observations and basic results in this section. To stress that the proof techniques in this section are *not our main technical contribution*, we postpone all proofs to full version.

We prefer to state our results in terms of Set Cover because it is slightly more natural and common, but since Set Partition often is easier to deal with for our purposes we will sometimes use the following easy reduction, all of whose steps are contained in [14]:

▶ **Theorem 3.1.** *There is an algorithm that, given a real $0 < \epsilon < 1/2$, takes an (n, m, s)-instance of* Set Cover *as input and outputs an equivalent (n, m', s)-instance of* Set Partition *with $m' \le m2^{\epsilon n}$ sets in time $O(m2^{(1-\epsilon)n})$.*

For completeness, we show that in fact Set Cover and Set Partition are equivalent with respect to being solvable in time $O^*(2^{(1-\Omega(1))n})$. This was never stated in print to the best of our knowledge, but the proof uses standard ideas and is found in the full version.

▶ **Theorem 3.2.** *For some $\epsilon > 0$ there is an $O^*(2^{(1-\epsilon)n})$ time algorithm for* Set Cover *if and only if for some $\epsilon' > 0$ there is an $O^*(2^{(1-\epsilon')n})$ time algorithm for* Set Partition*.*

The following natural result is a rather direct consequence of a paper by Koivisto [28]. It reveals some more similarity with the k-CNF-Sat problem: Koivisto shows[5] that for maximum set size r, Set Cover can be solved in $O^*(2^{(1-\Omega(\frac{1}{r}))n})$ which is analogous to k-CNF-Sat being in $O^*(2^{(1-\Omega(\frac{1}{k}))n})$ time [31, 17, 12], and similarly the following result is the counterpart of $O^*(2^{(1-\Omega(\frac{1}{\delta}))n})$-time algorithms for CNF-formula's of density δ (i.e. at most δn clauses) [11, 25]. Again, this result was never explicitly stated in print to the best of our knowledge, and therefore is proved in the full version.

▶ **Theorem 3.3.** *There is an algorithm solving (n, m, s)-instances of* Set Cover *or* Set Partition *in time $m \cdot \mathsf{poly}(n)2^{n - \frac{n}{O(\lg(m/n))}}$.*

Relevant to our work is the following subtlety on solution sizes in Set Partition. It shows that for Set Partition with empty sets, finding large solutions is as hard as the general case. The proof is postponed to the full version.

▶ **Theorem 3.4.** *Suppose there exist $0 < \epsilon_1, \epsilon_2 < 1/2$ and an algorithm solving $(n, m, \epsilon_1 n)$-instances of* Set Partition *in time $O^*(2^{(1-\epsilon_2)n})$. Then there exists an $O^*(2^{(1-\epsilon_2/2)n})$-time algorithm for* Set Partition*.*

[5] Koivisto only showed this for Set Partition, but the straightforward reductions in this section carry this result over to Set Cover.

Finally, it is insightful to see how well the representation method performs on the Set Partition problem with few sets (e.g., we consider running times of the $O^*(2^m)$, where m is the number of sets). A straightforward approach of the meet-in-the-middle attack leads directly to an $O^*(2^{m/2})$ time algorithm. We show that the representation method combined with the analysis of [2, 1] in fact solves the more general Linear Sat problem. In Linear Sat, one is given an integer t, matrix $A \in \mathbb{Z}_2^{n\times m}$ and vectors $\boldsymbol{b} \in \mathbb{Z}_2^n$ and $\boldsymbol{\omega} \in \mathbb{N}^m$ the task is to find $\boldsymbol{x} \in \mathbb{Z}_2^m$ satisfying $A\boldsymbol{x} \equiv \boldsymbol{b}$ and $\boldsymbol{\omega} \cdot \boldsymbol{x} \leq t$.

▶ **Theorem 3.5.** *There is an $O^*(2^{0.3399m})$-time Monte Carlo algorithm solving* Linear Sat.

To our best knowledge no $O^*(2^{(0.5-\Omega(1))m})$-time algorithm for Linear Sat was known before. We get as a corollary that given a bipartite graph $G = (F\dot{\cup}U, E)$ we can determine the smallest size of a set partition in time $O^*(2^{0.3399m})$, which we take as a clear first signal that the representation method is useful for solving Set Partition (and Set Cover) for instances with small universe. To see this consequence, note we can reduce this problem to Linear Sat as follows: for every $f \in F$ add the incidence vector of $N(f)$ as a column to A, and set cost ω_i of picking this column to be $n|N(f)| + 1$. Then the minimum of $\boldsymbol{\omega} \cdot \boldsymbol{x}$ subject to $A\boldsymbol{x} \equiv \mathbf{1}$ will be $n^2 + s$ where s is the number of sets in a minimum set partition. Let us remark that [16, Page 130] solves (a counting version) of Set Partition in time $O^*(1.2561^m) = O^*(2^{0.329m})$, and Drori and Peleg [18] solve the problem in $O^*(2^{0.3212m})$ time,[6] so by no means our algorithm is the fastest in this setting. However, both use sophisticated branching and we find it intriguing that the representation method does work quite well even for the more general Linear Sat problem.

4 Exploiting the Presence of Many Witness β-halves

For convenience we will work with Set Partition in this section; the results straightforwardly extend to Set Cover but we will not need this in the subsequent section.

▶ **Definition 4.1.** Given an (n, m, s) instance of Set Partition, a subset $W \subseteq U$ is said to be a *witness β-halve* if $|W| \in (\frac{1}{2} \pm \beta)n$ and there exist disjoint subsets $S_1, S_2 \subseteq F$ such that $N(S_1 \cup S_2) = U$, $\sum_{f \in S_1 \cup S_2} |N(f)| = n$, $N(S_1) = W$, $N(S_2) = U \setminus W$ and $|S_1| + |S_2| = s$.

Note that this is similar to the intuitive definition outlined in Section 1, except that we require $|W| \in (\frac{1}{2} \pm \beta)|U|$ and we adjusted the definition to the Set Partition problem. Since $S_1 \cup S_2$ is a set partition of size s we see that if a witness β-halve exists, we automatically have a yes instance.

In this section we will give randomized algorithms that solve promise-variants of Set Partition with the promise that, if the instance is a yes-instance, there will be an exponential number of witness halves that are sufficiently balanced (i.e. of size close to $n/2$). In the first subsection we outline the basic algorithm and in the second subsection we show how tools from the literature can be combined with our approach to also give a faster algorithm if the number of sets is exponential in n.

[6] We attempted to find any more recent faster algorithm, but did not find this. Though, we would not be surprised if using more recent tools in branching algorithms as [19] one should be able to more significantly outperform our algorithm for Set Partition.

```
Algorithm A1($G = (F \dot\cup U, E), s, \zeta, \beta$).
Output: An estimate of whether there exists a set partition of size $s$.
1: for integer $l$ satisfying $\lfloor(1/2-\beta)n\rfloor < l < \lceil(1/2+\beta)n\rceil$ do
2:     Sample $\mathcal{W} \subseteq \binom{U}{l}$ by including every set of $\binom{U}{l}$ with probability $2^{-\zeta n}$.
3:     For every $W \in \mathcal{W}$ and $i \in [n]$, compute $c_i(W)$ and $c_i(U \setminus W)$.
4:     if $\exists i \in [n] : c_i(W) \wedge c_{s-i}(U \setminus W)$ then return yes.
5: return no.
```

Figure 1 High level description of the Algorithm implementing Theorem 4.2.

4.1 The basic algorithm

▶ **Theorem 4.2.** *There exists an algorithm* A1 *that takes an (n, m, s)-instance of* SET PARTITION *and real numbers $\beta, \zeta > 0$ satisfying $2\sqrt{\beta} \leq \zeta < 1/4$ as input, runs in time $2^{(1-(\zeta/2)^4)n}\text{poly}(n)m$, and has the following property: if there exist at least $\Omega(2^{\zeta n})$ witness β-halves it returns* **yes** *with at least constant probability, and if there does not exist a set partition of size s it returns* **no**.

Note that the theorem does not guarantee anything on Algorithm A1 if a partition of s sets exists and there are only few witness halves, but we will address this later. A high level description of the Algorithm A1 is given in Figure 1:

Here, we define $c_i(W)$ to be true if and only if there exists $S_1 \subseteq F$ with $|S_1| = i$, $N(S_1) = W$, and for every $f, f' \in S_1$ with $f \neq f'$, $N(f) \cap N(f') = \emptyset$. Given a set family $\mathcal{W}$, we denote $\downarrow\mathcal{W} = \{X : \exists W \in \mathcal{W} \wedge X \subseteq W\}$ for the *down-closure* of $\mathcal{W}$, and $\uparrow\mathcal{W} = \{X : \exists W \in \mathcal{W} \wedge X \supseteq W\}$ for the *up-closure* of $\mathcal{W}$. The following lemma concerns the sub-routine invoked in Algorithm 1 and can be proved via known dynamic programming techniques, and is postponed to the full version.

▶ **Lemma 4.3.** *There exists an algorithm that given a bipartite graph $G = (F \dot\cup U, E)$ and $\mathcal{W} \subseteq 2^U$ with $|U| = n$ and $|F| = m$, computes $c_i(W)$ for all $W \in \mathcal{W}$ and $i \in n$ in $O(\text{poly}(n)|\downarrow\mathcal{W}|m)$ time.*

Thus, for further preparation of the proof of Theorem 4.2, we need to analyze the maximum size of the (down/up)-closure of $\mathcal{W}$ in Algorithm A1 in Figure 1:

▶ **Lemma 4.4.** *Let ζ, β be positive real numbers satisfying $2\sqrt{\beta} \leq \zeta < 1/4$ and $|U| = n$. Suppose $\mathcal{W} \subseteq \binom{U}{(1/2+\beta)n}$ with $|\mathcal{W}| \leq 2^{(1-\zeta)n}$. Then $|\uparrow\mathcal{W}|, |\downarrow\mathcal{W}| \leq n2^{(1-(\zeta/2)^4)n}$.*

Proof. The upper bound on the up-closure is directly obtained by using Part 1 of Lemma 2.1:

$$|\uparrow\mathcal{W}| \leq n\binom{n}{1/2+\beta} \leq n2^{h(1/2+\beta)n} \leq n2^{(1-\beta^2)n} \leq n2^{(1-(\zeta/2)^4)n}.$$

We continue with upper bounding the down closure. Let $\lambda \leq \beta$ and $w_\lambda = |\{W \in \downarrow\mathcal{W} : |W| = \lambda n\}|$, so $|\downarrow\mathcal{W}| \leq n \cdot \max_\lambda w_\lambda$. Then we have the following upper bounds:

$$w_\lambda \leq \binom{n}{\lambda n} \leq 2^{h(\lambda)n}, \qquad w_\lambda \leq |\mathcal{W}|\binom{(1/2+\beta)n}{\lambda n} \leq 2^{\left((1-\zeta)+h\left(\frac{\lambda}{1/2+\beta}\right)(1/2+\beta)\right)n}.$$

To see the second upper bound, note that any set $W \in \mathcal{W}$ can have at most $\binom{\beta n}{\lambda n}$ subsets of size λn. Thus, we see that $|\downarrow\mathcal{W}|/n$ is upper bounded by $2^{f(\zeta,\beta)n}$, where

$$f(\zeta, \beta) = \max_{\lambda \leq 1/2+\beta} \min\left\{h(\lambda), (1-\zeta) + h\left(\frac{\lambda}{1/2+\beta}\right)(1/2+\beta)\right\}.$$

The remainder of the proof is therefore devoted to upper bounding $f(\zeta,\beta)$. We establish this by evaluating both terms of the minimum, setting λ to be $\lambda' = (1-\zeta^2)(1/2+\beta)$. First note that by our assumption

$$\begin{aligned} \lambda' = (1-\zeta^2)(1/2+\beta) = 1/2 - \zeta^2/2 + \beta - \zeta^2\beta \leq 1/2 - \zeta^2/2 + \zeta^2/4 - \zeta^2\beta & \quad < 1/2, \\ \lambda'/(1/2+\beta) = 1-\zeta^2 & \quad > 1/2. \end{aligned}$$

Therefore, since $h(x)$ is increasing for $x < 1/2$, $h(\lambda) \leq h(\lambda')$ for $\lambda \leq \lambda'$. Similarly, $h\left(\frac{\lambda}{1/2+\beta}\right)$ is at most $h\left(\frac{\lambda'}{1/2+\beta}\right)$ for $\lambda \geq \lambda'$, and we may upper bound $f(\zeta,\beta)$ by the maximum of the two terms of the minimum in $f(\zeta,\beta)$ obtained by setting $\lambda = \lambda'$. For the first term of the minimum, note that by Lemma 2.1, Item 1:

$$\begin{aligned} h(\lambda') = h((1-\zeta^2)(1/2+\beta)) &\leq 1 - (1/2 - (1-\zeta^2)(1/2+\beta))^2 \\ &= 1 - \left(\zeta^2/2 - \beta + \beta\zeta^2\right)^2 \\ &\leq 1 - \left(\zeta^2/2 - \beta\right)^2 \\ &\leq 1 - (\zeta^2/4)^2 = 1 - (\zeta/2)^4. \end{aligned}$$

For the second term we have

$$\begin{aligned} 1 - \zeta + h\left(\frac{\lambda'}{1/2+\beta}\right)(1/2+\beta) &= 1 - \zeta + h(1-\zeta^2)(1/2+\beta) && \text{by Lemma 2.1, Item 2} \\ &= 1 - \zeta + h(\zeta^2)(1/2+\beta) && \beta < \tfrac{1}{64} \text{ by assumption} \\ &\leq 1 - \zeta + \zeta^2 \lg\left(\frac{4}{\zeta^2}\right)\frac{33}{64} && \zeta \lg\left(\tfrac{4}{\zeta^2}\right) \leq \tfrac{3}{2} \\ &\leq 1 - \zeta + \zeta\tfrac{3}{2}\cdot\tfrac{33}{64} \\ &\leq 1 - \zeta/10. \end{aligned}$$

note for the penultimate inequality that $\zeta\lg(\frac{4}{\zeta^2})$ is monotone increasing for $0 \leq \zeta \leq 1/4$ and substituting $\zeta = 1/4$ in this expression thus upper bounds it with $3/2$. ◀

Now we are ready to wrap up this section with the proof of Theorem 4.2:

Proof of Theorem 4.2. We can implement Line 3 by invoking the algorithm of Lemma 4.3 with both $|\mathcal{W}|$ and $\mathcal{W}' = \{W : [n]\setminus W \in \mathcal{W}\}$. Since $|{\downarrow}\mathcal{W}'| = |\{X : \exists W \in \mathcal{W} \wedge X \subseteq [n]\setminus W\}| = |{\uparrow}\mathcal{W}|$, this will take time $O(\text{poly}(n)(|{\downarrow}W| + |{\uparrow}\mathcal{W}|)m)$. This is clearly the bottleneck of the algorithm, so it remains to upper bound (the expectation of) $|{\downarrow}W| + |{\uparrow}\mathcal{W}|$ by applying Lemma 4.4. To do this, note that $W \subseteq \binom{n}{l}$, and we may assume $l \geq n/2$ since we could either apply the lemma using $\mathcal{W}$ or $\mathcal{W}'$. Moreover, we have that $l \leq (1/2+\beta)n$ and $2\sqrt{\beta} \leq \zeta$ by assumption so indeed Lemma 4.4 applies. On expectation $|\mathcal{W}| \leq \binom{n}{(1/2+\beta)n}2^{-\zeta n} \leq 2^{(1-\zeta)n}$, thus the running time[7] indeed is as claimed.

For the correctness, it is easily checked that the algorithm never returns false positives. Moreover, if there exist at least $\Omega(2^{\zeta n})$ witness β-halves then for some l in the loop of Line 1, there are at least $\Omega(2^{\zeta n}/n)$ witness halves of size l. Thus in this iteration we see by Lemma 2.1, Part 3 that

$$\Pr[\nexists \text{ witness halve } W \in \mathcal{W}] \leq \left(1 - \frac{1}{2^{\zeta n}}\right)^{\Omega(2^{\zeta n}/n)} \leq e^{-1/n}. \tag{4.1}$$

[7] Due to the sampling in Line 2, we actually only get an upper bound on the expectation of the running time, but by Markov's inequality we can simply ignore iterations where $\mathcal{W}$ exceeds twice the expectation.

and if a witness halve $W \in \mathcal{W}$ exists the algorithm returns **yes** since $c_i(W) \wedge c_{s-i}(U \setminus W)$ holds for some i by the definition of witness halve. Therefore, if we perform n independent trials of Algorithm $\mathtt{A}_1$ it return **yes** with probability at least $1 - 1/e$. ◀

4.2 Improvement in the case with exponentially many input sets

In this section we show that under some mild conditions, the existence of many witness halves can also be exploited in the presence of exponentially many sets. This largely builds upon machinery developed by Björklund et al. [10, 8]. To state our result as general as possible we assume the sets are given via an oracle so our running can be sublinear in the input if the number of sets is close to 2^n.

▶ **Theorem 4.5.** *There exists an algorithm that, given oracle access to an (n, m, s)-instance of* Set Partition *and real numbers $\beta, \zeta > 0$ satisfying $2\sqrt{\beta} \leq \zeta < 1/4$, runs in time $2^{(1-(\zeta/2)^4)n}\operatorname{poly}(n)T$ and has the following property: if there exist at least $\Omega(2^{\zeta n})$ witness β-halves, it outputs* **yes** *with constant probability and if there does not exist a set partition of size s it outputs* **no**.

Here the oracle algorithm accepts $X \subseteq U$ as input, and decides whether there exists $f \in F$ with $N(f) = X$ in time T.

The proof of Theorem 4.5 is identical to the proof of Theorem 4.2 (and therefore omitted), except that here we use the following lemma instead of Lemma 4.3:

▶ **Lemma 4.6.** *There exists an algorithm that, given $\mathcal{W} \subseteq 2^U$ and oracle access to a bipartite graph $G = (F \dot\cup U, E)$, computes the values $c_i(W)$ for all $W \in \mathcal{W}$ in $O(T|{\downarrow}\mathcal{W}|\operatorname{poly}(n))$ time. Here the oracle algorithm accepts $X \subseteq U$ as input, and decides whether there exists $f \in F$ with $N(f) = X$ in time T.*

This lemma mainly reiterates previous work developed by Björklund et al. [10, 8], but since they did not prove this lemma as such we include a proof here in the full version.

5 Finding Large Set Covers Faster

In this section we will use the tools of the previous sections to prove our main results, Theorems 1.1 and 1.2. We first connect the existence of large solutions to the existence of many witness halves in the following lemma:

▶ **Lemma 5.1.** *If an (n, m, s)-instance of* Set Partition *has no empty sets and satisfies $s \geq \sigma_0 n$ and $|N(f)| \leq \sigma_0^4 n/8$ for every $f \in F$, there is a solution if and only if there exist at least $2^{\sigma_0 n}/4$ witness $(\sigma_0^2/4)$-halves.*

Proof. Note that the backward direction is trivial since by definition the existence of a witness halve implies the existence of a solution.

For the other direction, suppose $S = \{f_1, \ldots, f_s\}$ is a set partition, and denote $d_i = |N(f_i)|$. Suppose $S' \subseteq S$ is obtained by including every element of S with probability $1/2$ in S'. since $N(f_i) \cap N(f_j) = \emptyset$ for $i \neq j$, we have that the random variable $|N(S')|$ is a sum of s independent random variables that equal 0 and d_i with probability $1/2$. By the Hoeffding bound (Lemma 2.2) we see that

$$\Pr\left[\Big| |N(S')| - \mathbb{E}[|N(S')|]\Big| \geq n\sigma_0^2/4\right] \leq 2 \cdot \exp\left(\frac{-n^2\sigma_0^4/8}{\sum_{e \in S} d_e^2}\right) \leq 2 \cdot \exp\left(\frac{-n^2\sigma_0^4/8}{n^2\sigma_0^4/8}\right) < \tfrac{3}{4},$$

```
Algorithm A2($G = (F \dot\cup U, E), \sigma$).
1: Ensure $|N(f)| \leq \sigma^4 n/1000$ using Observation 2.4.
2: for every integer $s$ satisfying $\lfloor \sigma n/2 \rfloor \leq s \leq \sigma n$ do
3:     Create an $(n, m', s)$-instance $((F' \dot\cup U, E), s)$ of Set Partition where $F'$ is con-
       structed by adding a vertex $f'$ with $N(f') = X$ for all $f \in F, X \subseteq N(f)$.
4:     Let $\sigma_0 = s/n$.
5:     if A1$((F' \dot\cup U, E), s, \sigma_0, \sigma_0^2/4)$ = yes then return yes.
6: Pick an arbitrary subset $X \in \binom{U}{n/2}$.
7: Find the sizes $l$ and $r$ of the smallest set covers in the instances induced by elements
   $X$ and respectively elements $U \setminus X$ in $O(2^{n/2}\,\mathrm{poly}(n)m)$ time with standard dynamic
   programming.
8: if $l + r <= \sigma n$ then return yes else return no.
```

Figure 2 Algorithm for Set Cover large solutions (implementing Theorem 1.1).

where the second inequality follows from $d_e \leq \sigma_0^4 n/8$ and $\sum_{e \in S} d_e = n$. So for at least $2^{|S|}/4 \geq 2^{\sigma_0 n}/4$ subsets $S' \subseteq S$ we have that $|N(S')| \in (\frac{1}{2} \pm \sigma_0^2/4)n$. Thus, since for each such S', $N(S')$ determines S' and thus gives rise to a distinct witness halve, there are at least $2^{\sigma_0 n}/4$ witness $(\sigma_0^2/4)$-halves. ◀

Now we are ready to prove the first main theorem, which we recall here for convenience.

▶ **Theorem 1.1** (restated). *There is a Monte Carlo algorithm that takes an instance of* Set Cover *on n elements and m sets and an integer s as input and determines whether there exists a set cover of size s in $O(2^{(1-\Omega(\sigma^4))n}m)$ time, where $\sigma = s/n$.*

Proof. The algorithm implementing Theorem 1.1 is given in Figure 2.

We first focus on the correctness of this algorithm. It is clear that the algorithm never returns false positives on Line 5 since Algorithm A1 also has this property. If **yes** is returned on Line 8 it is also clear there exists a solution.

Now suppose that a set cover S of size at most σn exists. First suppose $\sigma n/2 \leq |S| \leq \sigma n$. We consider $s = |S|$ in some iteration of the loop on Line 2. Notice that now in Line 3 we have reduced the problem to a yes-instance of Set Partition without empty sets satisfying $|N(f)| \leq \sigma^4 n/1000$ for every $f \in F$. Therefore Lemma 5.1 applies with $\sigma_0 \geq \sigma/2$ and we see there are at least $2^{\sigma_0 n}/4$ witness $(\sigma_0^2/4)$-halves. Thus, we can apply Theorem 4.2 with $\zeta = \sigma_0$ and $\beta = \sigma_0^2/4$ to find the set S with constant probability, since $\beta \leq (\zeta/2)^2$.

Now suppose $|S| \leq \sigma n/2$. Then picking every element in S twice is a solution (as a multiset), and it implies that for every $X \subseteq U$ the sizes of the smallest set covers l and r (as defined in the algorithm) satisfy $l + r \leq \sigma n$. Thus Lines 6-8 find such a set and the algorithm returns **yes**.

For the running time, Line 1 takes at most $O(2^{(1-\sigma^4/1000)n}\,\mathrm{poly}(n)m)$ due to Observation 2.4. For Line 5, due to Theorem 4.2 this runs in time

$$\begin{aligned} O(2^{(1-(\zeta/2)^4)n}\,\mathrm{poly}(n)m') &= O(2^{(1-(\sigma_0/2)^4)n}\,\mathrm{poly}(n)2^{\sigma^4 n/1000}m) \\ &\leq O(2^{(1-(\sigma/4)^4)n}\,\mathrm{poly}(n)2^{\sigma^4 n/1000}m) \\ &= O(2^{(1+\sigma^4(1/1000-1/4^4))n}\,\mathrm{poly}(n)m) \\ &\leq O(2^{(1-\Omega(\sigma^4))n}\,\mathrm{poly}(n)m). \end{aligned}$$

as claimed in the theorem statement. ◀

As a more direct consequence of the tools of the previous section we also get the following result for Set Partition:

▶ **Theorem 5.2.** *There exists a Monte Carlo algorithm for* Set Partition *that, given oracle access to an $(n, m, \sigma n)$-instance satisfying $0 < |N(f)| \leq \sigma^4 n/8$ for every $f \in F$, runs in $2^{(1-\Omega(\sigma^4))n}\,\mathrm{poly}(n)T$ time.*

Here the oracle algorithm accepts $X \subseteq U$ as input, and decides whether there exists $f \in F$ with $N(f) = X$ in time T.

Proof. Lemma 5.1 implies the instance is a YES-instance if and only if there exist $2^{\sigma n}/4$ witness $(\sigma^2/4)$-halves. Thus Theorem 4.5 implies the theorem statement. ◀

Note that this theorem also implies an $O((m + 2^{(1-\Omega(\sigma^4))n})\,\mathrm{poly}(n))$ time algorithm for Set Partition where the sets are given explicitly because we can construct a binary search tree after which we can implement the oracle to run in $T = n$ query time. We remark that it would be interesting to see whether the assumption $|N(f)| \leq \sigma^2 n/4$ is needed, but removing this assumption seems to require more ideas than the ones from this work: For example if the solution has three sets of size $3n/10$ there will be no witness halve that is sufficiently balanced, and alternatively using Observation 2.4 seems to be too slow.

However, if we settle for a additive 1-approximation we can deal with this issue in a simple way and have as a particular consequence the second result mentioned in the beginning of this paper:

▶ **Theorem 1.2** (restated)**.** *There is a randomized algorithm that given graph G and integer $s = \sigma n$, in $O^*(2^{(1-\Omega(\sigma^4))n})$ time outputs* **yes** *with constant probability, if $\chi(G) < s$, and* **no***, if $\chi(G) > s$.*

Proof. Let $G = (V, E)$ and define a Set Partition instance where for every independent set $I \subseteq V$ of G there is an element $f \in F$ with $N(f) = I$. It is easy to see that this instance of Set Partition has a solution of size s if and only if $\chi(G) \leq s$.

Check in $\binom{n}{\sigma^4 n/8}$ time whether G has an independent set of size $\sigma^4 n/8$. If such an independent set is found, remove this set from the graph and return yes if the obtained graph has a $(k-1)$-coloring and no otherwise. Using the $O^*(2^n)$ time algorithm by Björklund et al. [10] in the second step, this procedure clearly runs in time $O^*(2^{(1-\Omega(\sigma^4))n})$, and always finds a coloring using at most one more color than the minimum number of colors if a large enough independent set exists.

On the other hand, if the maximum independent set of G is of size at most $\sigma^4 n/8$, we may apply Theorem 5.2 with $T = \mathrm{poly}(n)$ since it can be verified in polynomial time whether a given $X \subseteq V$ is an independent set, and the theorem follows. ◀

6 Directions for Further Research

In this section, we relate the work presented to some notorious open problems. The obvious open question is to determine the exact complexity of the Set Cover problem:

▶ **Open Problem 1.** *Can* Set Cover *be solved in time $O^*((2-\Omega(1))^n)$?*

This question was already stated at several places. It is known that if a version of Set Cover where the number of solutions modulo 2 is counted can be solved in $(2-\Omega(1))^n$ the Strong Exponential Time Hypothesis fails. We refer to [14], for more details.

Less ambitiously, it is natural to wonder whether our dependency on σ can be improved. Our algorithm and analysis seem loose, but we feel the gain of a sharpening this analysis does not outweigh the technical effort currently: For a better dependence, we need both a better bound in Lemma 4.4 and to reduce the set sizes more efficiently than in Observation 2.4. As further research we suggest to find a different algorithmic way to deal with the case where many witness halves are unbalanced. But this alone will not suffice to give linear dependence in σ since in Lemma 4.4 we do not expect to get linear dependence on ζ even if $\beta = 0$. It would also be interesting to see which other instances of SET COVER can be solved in $O^*((2 - \Omega(1))^n)$ time. One that might be worthwhile studying is whether this includes instances with optimal set covers in which the sum of the set sizes is at least $(1 + \Omega(1))n$; one may hope to find exponentially many (balanced) witness halves here as well.

In [14], the authors also give a reduction from SUBSET SUM to SET PARTITION. The exact complexity of SUBSET SUM with small integers is also something we explicitly like to state as open problem here, especially since the $O^*(t)$ time algorithm (where t is the target integer) is perhaps one of the most famous exponential time algorithms:

▶ **Open Problem 2.** *Can* SUBSET SUM *with target t be solved in time $O^*(t^{1-\Omega(1)})$, or can we exclude the existence of such an assuming the Strong Exponential Time Hypothesis?*

Note this question was before asked in [24] by the present author. It would be interesting to study the complexity of SUBSET SUM in a similar vein as we did in this paper: are there some special properties allowing a faster algorithm? For example, a faster algorithm for instances of high ‘density’ (e.g., $n/\lg t$) may be used for improving an algorithm of Horowitz&Sahni [22]. Note that here the ‘density’ of a SUBSET SUM instance is the inverse of what one would expect when relating to the definition of density of k-CNF formula.

Another question that has already open for a while is:

▶ **Open Problem 3.** *Can* GRAPH COLORING *be solved in time $O^*(2^{(1-\Omega(1))n})$?*

Could the techniques of this paper be used to make progress towards resolving this question? While our algorithm seems to benefit from the existence of many optimal colorings, in an interesting paper Björklund [5] actually shows that the existence of *few* optimal colorings can be exploited in graphs of small pathwidth. Related to this is also the Hamiltonicity problem. In our current understanding this problem becomes easier when there is a promise that there are few Hamiltonian cycles (see [6], but also e.g. [13] allows derandomizations of known probabilistic algorithms in this case), so a natural approach would be to deal explicitly with instances with many solutions by sampling dynamic programming table in a similar vein as done in this paper.

Acknowledgements. The author would like to thank Per Austrin, Petteri Kaski, Mikko Koivisto for their collaborations resulting in [1, 2] that mostly inspired this work, Karl Bringmann for discussions on applications of [2] to SET PARTITION, and anonymous reviewers for their useful comments.

Graph Isomorphism for Unit Square Graphs

Daniel Neuen

RWTH Aachen University, Aachen, Germany
neuen@informatik.rwth-aachen.de

Abstract

In the past decades for more and more graph classes the Graph Isomorphism Problem was shown to be solvable in polynomial time. An interesting family of graph classes arises from intersection graphs of geometric objects. In this work we show that the Graph Isomorphism Problem for unit square graphs, intersection graphs of axis-parallel unit squares in the plane, can be solved in polynomial time. Since the recognition problem for this class of graphs is NP-hard we can not rely on standard techniques for geometric graphs based on constructing a canonical realization. Instead, we develop new techniques which combine structural insights into the class of unit square graphs with understanding of the automorphism group of such graphs. For the latter we introduce a generalization of bounded degree graphs which is used to capture the main structure of unit square graphs. Using group theoretic algorithms we obtain sufficient information to solve the isomorphism problem for unit square graphs.

1 Introduction

The Graph Isomorphism Problem is one of the most famous open problems in theoretical computer science. In the past three decades the problem was intensively studied but only recently the upper bound on the complexity could be improved to quasipolynomial time [2]. However, it is still open whether the Graph Isomorphism Problem can be solved in polynomial time. In this work we focus on geometric graph classes, that is, graph classes that arise as intersection graphs of geometric objects. In an intersection graph the vertices are identified with geometric objects and two vertices are connected if the corresponding objects intersect.

One of the most basic geometric graph classes is the class of interval graphs, intersection graphs of intervals on the real line. Although this graph class is quite restrictive there are a number of practical applications and specialized algorithms for interval graphs (see e.g. [15]). The Graph Isomorphism Problem on interval graphs can be solved in linear time [11] as well as in logarithmic space [18]. However, for several generalizations of interval graphs the complexity of the Graph Isomorphism Problem is unknown. This includes for example circular arc graphs (see [12]) and triangle graphs (see [30]). On the other hand a graph class is GI-complete if the Graph Isomorphism Problem for this class is as difficult as the general problem under polynomial time reductions. An example of a GI-complete geometric class is the class of grid intersection graphs, bipartite intersection graphs of horizontal and vertical line segments in the plane [29]. As an immediate consequence the class of intersection graphs of axis-parallel rectangles is also GI-complete. Unit square graphs, intersection graphs of axis-parallel unit squares, are a natural restriction for the rectangle graphs. This raises the question for the complexity of the isomorphism problem for unit square graphs. In this work we prove that the Graph Isomorphism Problem for unit square graphs can be solved in polynomial time. Besides being a natural restriction to rectangle graphs, another central motivation to study this problem comes from unit disk graphs, intersection graphs of unit circles in the plane. Unit disk graphs where first studied by Clark, Colbourn and Johnson in [10] and for several problems specialized algorithms have been proposed (see e.g. [13]). Practical applications arise for example from broadcast networks where each broadcast station is represented by a vertex and two stations communicate with each other if the distance between them does not exceed the broadcast range. In the work of Clark et al. two problems, namely the recognition problem and the isomorphism problem, were left open. While recognition of unit disk graphs proved to be NP-hard [8], the isomorphism problem for unit disk graphs is still open. Unit square graphs present a natural variant to unit disk graphs as we just replace the Euclidean norm by the Manhattan norm. Also, going from unit disks to unit squares removes geometric intricacies and tends to simplify the structure of graphs but maintains several key aspects of the problem. In particular, for unit disk as well as unit square graphs vertices only have a bounded number of independent neighbors (set of pairwise non-adjacent neighbors) and the structure of graphs seems to be a mixture of bounded degree and planarity. Hence, solving the isomorphism problem for unit square graphs might be a step towards solving the same problem for unit disk graphs. Furthermore, in [29, 30] Uehara also asked for the complexity of graph isomorphism for unit grid intersection graphs. Unit grid intersection graphs can be seen as bipartite versions of unit square graphs in the following sense: A bipartite graph is a unit grid intersection graph if and only if it is the intersection graph of unit squares where intersections between squares belonging to vertices on the same side of the bipartition are ignored. Hence, the result presented in this work shows that in some sense the difficulty for unit grid intersection lies in recreating the information which lines are close to each other.

Another interesting point arises from the fact that, like for unit disk graphs, recognition of unit square graphs is NP-hard [7]. Hence, we obtain an example of a natural graph class with the interesting property that isomorphism tests can be performed in polynomial time whereas recognition is NP-hard. Also, the hardness result rules out the classical approach to attack the isomorphism problem. Typically, isomorphism tests for geometric graphs are based on constructing a canonical geometric representation of the graph (see e.g. [18, 20]) but, as this would also solve the recognition problem, such an approach is not possible here. Instead, our algorithm combines group theoretic techniques with geometric properties of unit square graphs. For the group theoretic machinery we extend the results developed by Luks [22] to decide isomorphism for bounded degree graphs by also allowing for example large cycles in the neighborhood of a vertex. On a geometric level this coincides in some sense with the intuition that vertices in the neighborhood of some fixed vertex are cyclically arranged around the central vertex. Using geometric properties of unit square graphs and known algorithms for other geometric graph classes such as proper circular arc graphs we can canonically (in an isomorphism-invariant way) extract such circular orderings, which can then be used by the group theoretic machinery. For this, we show a series of results giving a deep insight into the structure of neighborhoods of single vertices and neighborhoods of cliques within unit square graphs. These results not only help us to understand the structure of unit square graphs, but also we obtain significant knowledge about the structure of the automorphism group of a unit square graph. However, an obvious obstacle to this approach comes from large cliques which are connected in a uniform way to the rest of the graph and do not contain any significant structure. More precisely, such cliques may be responsible for large symmetric groups which are subgroups of the automorphism group of the whole graph. Since large symmetric groups form a clear obstacle to the group theoretic machinery and can not be handled by Luks' algorithm we have to cope with these parts of the graph in a different way. Our second main result on the structure of unit square graphs characterizes connections between cliques which are stable with respect to the color refinement algorithm (see e.g. [6, 24]), and also establishes a close connection to interval graphs. Building on this characterization we show that the color refinement algorithm can be used to cope with the symmetric parts of the graph containing no significant structure. Finally, combining the color refinement algorithm with the group theoretic machinery, we obtain an algorithm to solve the isomorphism problem for unit square graphs.

2 Preliminaries

2.1 Graphs

A *graph* is a pair $G = (V, E)$ with vertex set $V = V(G)$ and edge set $E = E(G)$. In this paper all graphs are undirected, so $E(G)$ is always irreflexive and symmetric. The *(open) neighborhood* of a vertex $v \in V(G)$ is the set $N_G(v) = N(v) = \{w \in V(G) \mid vw \in E(G)\}$ and the size of $N(v)$ is the degree of v. The *closed neighborhood* is the set $N[v] = N(v) \cup \{v\}$. Two vertices $v, w \in V(G)$ are *connected twins* if $N[v] = N[w]$. The corresponding equivalence relation, where two vertices are related if they are connected twins, will be called the *connected twins relation*. A *path* from v to w of length m is a sequence $u_0, \ldots, u_m$ of distinct vertices with $u_0 = v$ and $u_m = w$, such that $u_{i-1}u_i \in E(G)$ for each $i \in [m] := \{1, \ldots, m\}$. The *distance* between v and w, $d(v, w)$, is the length of a shortest path from v to w. A colored graph is a tuple $G = (V, E, c)$ where $c\colon V(G) \to \mathbb{N}$ assigns each vertex a unique color. For each color $i \in \mathbb{N}$ let $V_i(G) = \{v \in V(G) \mid c(v) = i\}$. Two graphs G and H are *isomorphic* ($G \cong H$) if there is a bijection $\varphi\colon V(G) \to V(H)$, such that $vw \in E(G)$ if and only if $\varphi(v)\varphi(w) \in E(H)$ for all $v, w \in V(G)$. In this case the mapping φ is an *isomorphism* from G to H. In case the input graphs are colored it is demanded that the isomorphism also preserves the coloring of the vertices. The Graph Isomorphism Problem asks whether two given graphs G and H are isomorphic. An isomorphism from a graph to itself is called an *automorphism*. The set of automorphisms of a graph G, denoted by $\mathrm{Aut}(G)$, forms a subgroup of the symmetric group over the vertex set.

2.2 Color Refinement

A very basic and fundamental method, which is a basic building block of many isomorphism tests, is the color refinement algorithm (see e.g. [24]). The basic idea is to iteratively distinguish vertices if they have a different number of neighbors in some color. A partition $\mathcal{P}$ of the vertices is *stable* if for all $X, Y \in \mathcal{P}$ and all $v, w \in X$ it holds that $|N(v) \cap Y| = |N(w) \cap Y|$. Further a partition $\mathcal{P}$ *refines* another partition $\mathcal{Q}$ if for each $X \in \mathcal{P}$ there is some $Y \in \mathcal{Q}$ with $X \subseteq Y$. The color refinement algorithm computes the unique coarsest stable partition refining the initial color partition (i.e. the partition of the vertices according to their color). The coarsest stable partition can be computed in almost linear time (see [24, 6]). We say color refinement distinguishes two graphs if there is some class in the coarsest stable partition on the disjoint union of the graphs that contains a different number of vertices from the two graphs. In this case the two input graphs are not isomorphic.

The k-dimensional Weisfeiler-Leman algorithm is a generalization of the color refinement algorithm (cf. [9]). Instead of coloring only single vertices, the Weisfeiler-Leman algorithm colors k-tuples of vertices. Initially each tuple is colored with the isomorphism type of the underlying induced subgraph and then the coloring is refined in a similar way as by the color refinement algorithm (see [9] for a detailed description). We say k-dimensional Weisfeiler-Leman *identifies* a graph class $\mathcal{C}$ if for every pair of non-isomorphic graphs G, H with $G \in \mathcal{C}$ the k-dimensional Weisfeiler-Leman distinguishes between G and H.

2.3 Group Theory

In this subsection we briefly introduce the main group theoretic tools used in this work. For a general introduction to group theory we refer to [25] whereas several group theoretic algorithms are given in [16, 27]. Since we only deal with automorphism groups of graphs we can restrict ourselves to permutation groups which throughout this work will always be represented by generating sets of size polynomial in the size of the permutation domain. For a set Ω let $\mathrm{Sym}(\Omega)$ be the symmetric group over the set Ω. In particular we require a certain subclass of permutation groups, namely groups with bounded non-abelian composition factors. Let Γ be a group. A *normal series* is a sequence of subgroups $\Gamma = \Lambda_0 \trianglerighteq \Lambda_1 \trianglerighteq \dots \trianglerighteq \Lambda_k = \{1\}$. The length of the series is k and the groups Λ_{i-1}/Λ_i are the factor groups of the series, $i \in [k]$. A *composition series* is a strictly decreasing normal series of maximal length. For every finite group Γ all composition series have the same family of factor groups considered as a multi-set (cf. [25]). A *composition factor* of a finite group Γ is a factor group of a composition series of Γ.

▶ **Definition 2.1.** Let $d \in \mathbb{N}$. The family Γ_d contains all finite groups Γ for which all non-abelian composition factors are isomorphic to subgroups of $S_d = \mathrm{Sym}([d])$.

The class of Γ_d-groups is closed under subgroups and homomorphic images. Furthermore, for groups $N \trianglelefteq \Gamma$ it holds that $\Gamma \in \Gamma_d$ if and only if $N \in \Gamma_d$ and $\Gamma/N \in \Gamma_d$ (cf. [22]). A group Γ is *solvable* if every composition factor is abelian. Two examples of solvable groups, that are particularly important for this work, are cyclic groups and dihedral groups which are the automorphism groups of directed cycles and undirected cycles. Note that every solvable group is a Γ_d-group for every $d \in \mathbb{N}$.

The Setwise Stabilizer Problem asks, given a permutation group $\Gamma \leq \mathrm{Sym}(\Omega)$ and $A \subseteq \Omega$, for a generating set of the group $\mathrm{Stab}_\Gamma(A) := \{\gamma \in \Gamma \mid A = A^\gamma\}$, where $A^\gamma = \{\alpha^\gamma \mid \alpha \in A\}$ and α^γ is the image of α under the permutation γ. A central motivation to consider Γ_d-groups is the following result.

▶ **Theorem 2.2.** *Let $d \in \mathbb{N}$. The Setwise Stabilizer Problem for groups in Γ_d can be solved in polynomial time.*

A weaker version of this statement was proved by Luks in [22] considering only groups where all composition factors are isomorphic to subgroups of S_d. For the more general version stated above we refer to [1]. This result is for example used by Luks to solve graph isomorphism for graphs of bounded degree [22], but it can also be applied to more general graph classes such as t-bounded graphs (see e.g. [4]). For this work we introduce a slight variation, namely graphs which we call *t-circle-bounded* graphs. For a graph G and a set $X \subseteq V(G)$ we write $G[X]$ to denote the induced subgraph of G with vertex set X.

▶ **Definition 2.3.** A colored graph $G = (V, E, c)$ with $c\colon V(G) \to [k]$ is *t-circle-bounded* if for each $i \in [k]$ and $X \subseteq V_{<i} := \bigcup_{j<i} V_j(G)$ the graph

$$G_{i,X} := G[\{v \in V_i(G) \mid N(v) \cap V_{<i} = X\}]$$

is the disjoint union of at most t connected graphs of maximum degree two.

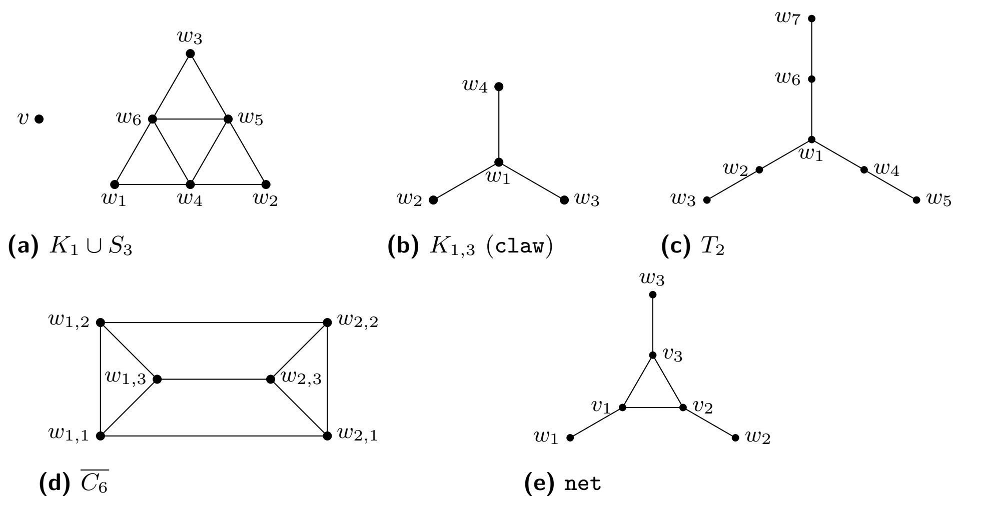

Figure 1 Some forbidden induced subgraphs of proper circular arc graphs.

The t-circle-bounded graphs are closely related to t-bounded graphs which are similarly defined with the size of $G_{i,X}$ bounded by t (see [4]). From an algorithmic point of view we can use very similar methods for the isomorphism problem on t-circle-bounded graphs as for t-bounded graphs.

▶ **Theorem 2.4.** *Let G be a t-circle-bounded graph. Then* $\text{Aut}(G) \in \Gamma_t$.

▶ **Theorem 2.5.** *The Graph Isomorphism Problem for t-circle-bounded graphs can be solved in polynomial time.*

Both theorems can be proved in very similar fashion as the respective statements for t-bounded graphs. In fact the only additional argument required for t-circle-bounded graphs is that the automorphism groups of connected graphs of maximum degree two are solvable and thus elements of Γ_t.

2.4 Proper circular arc graphs

A graph G is a *unit interval graph* if G is the intersection graph of unit intervals on the real line. A graph G is a *proper circular arc graph* if G is the intersection graph of arcs on a circle, such that for no two arcs one is properly contained in the other. A characterization of unit interval graphs and proper circular arc graphs in terms of forbidden induced subgraphs is given in [28]. For our purposes the following statements are sufficient. Some relevant forbidden induced subgraphs are also depicted in Figure 1.

▶ **Theorem 2.6.** *A graph G is a unit interval graph if and only if there are no induced subgraphs isomorphic to C_{n+4} for $n \geq 0$, S_3, $K_{1,3}$ and* `net`.

Here, C_n denotes a cycle of length n. Furthermore we denote by $G \cup H$ the disjoint union of G and H and the graph $\overline{G}$ is the complement graph of G.

▶ **Lemma 2.7.** *Let G be a graph, such that $N_G[v]$ induces a unit interval graph for every $v \in V(G)$ and there are no induced subgraphs isomorphic to $K_1 \cup C_{n+4}$ for $n \geq 0$, $K_1 \cup S_3$, $\overline{T_2}$, $\overline{C_6}$ and* `net`. *Then G is a proper circular arc graph.*

We also require the following characterization for proper circular arc graphs. A vertex is *universal* if it is adjacent to all other vertices. A graph G is *twin-free* if it does not contain connected twins and G is *co-bipartite* if $\overline{G}$ is bipartite.

▶ **Theorem 2.8** ([19], Theorem 3)**.** *Let G be a graph without universal vertices. Then G is a proper circular arc graph if and only if there is a cycle H with $V(G) = V(H)$, such that*

1. *$N_G[v]$ induces a connected subgraph in H for each $v \in V(G)$*
2. *For all $v, w \in V(G)$ it holds that if $N_G[v] \subseteq N_G[w]$ then the two paths share an endpoint in H.*

Furthermore, if G is connected, twin-free and not co-bipartite, the cycle H is unique [17]. Additionally, given some proper circular arc graph, a cycle H can be computed in polynomial time (see [19]). This gives us the following result.

▶ **Theorem 2.9.** *Let G be a connected proper circular arc graph, such that $\overline{G}$ is not bipartite. Further let $\sim_G$ be the connected twins relation and $\mathcal{P}$ the corresponding partition into equivalence classes. Then one can compute in polynomial time a canonical connected graph H, such that $V(H) = \mathcal{P}$ and H has maximum degree two.*

3 Basic Properties

For unit square graphs there are several possible definitions. The most obvious one is to describe vertices by axis-parallel unit squares with edges connecting two vertices if the unit squares intersect. Alternatively it can also be demanded that vertices represented by unit squares are connected if the center of the first square is contained in the other square. Another possibility is to describe vertices by points in the plane. Note that two squares with unit side length intersect if and only if the distance between their centers using the maximum norm is at most one. Thus, two vertices are connected if the distance between the points is at most one using the maximum norm. Furthermore, a unit square contains the center point of another unit square if and only if the distance between both centers is at most one half using the maximum norm. By applying a scaling argument this also gives us the equivalence to the second definition. In this paper we work with the last definition, that is we represent vertices by points in the plane. For a point $p \in \mathbb{R}^k$ we denote by p_i the i-th component of p, $i \in [k]$. The L_∞-norm is defined as $\|p\|_\infty = \max_{i\in[k]} |p_i|$.

▶ **Definition 3.1.** A *k-dimensional L_∞-realization* of a graph G is a mapping $f : V(G) \to \mathbb{R}^k$ such that $vw \in E(G)$ if and only if $\|f(v) - f(w)\|_\infty \leq 1$ for all $v, w \in V(G)$. A *unit square graph* is a graph having a two-dimensional L_∞-realization.

Observe that graphs with 1-dimensional L_∞-realization are exactly the unit interval graphs. For the remainder of this paper we focus on unit square graphs and just use the term realization for a two-dimensional L_∞-realization. Following our previous notation, for a realization $f : V(G) \to \mathbb{R}^2$ and a vertex $v \in V(G)$, we denote by $(f(v))_i$ the i-th component of $f(v)$. This is also abbreviated by $f(v)_i$, $i \in [2]$. We start by listing some basic properties for unit square graphs.

▶ **Observation 3.2.** *Let G be a unit square graph and $f\colon V(G) \to \mathbb{R}^2$ a realization. Further let $X \subseteq V(G)$, such that there are $a_1, b_1, a_2, b_2 \in \mathbb{R}$ with $a_1 \leq b_1 \leq a_1 + 1$, $a_2 \leq b_2$ and $f(v) \in [a_1, b_1] \times [a_2, b_2]$ for every $v \in X$. Then $G[X]$ is a unit interval graph.*

▶ **Lemma 3.3.** *Let G be a unit square graph. Then the following properties hold:*

1. *There is some $v \in V(G)$, such that $G[N[v]]$ is a unit interval graph.*

2. *For every two non-adjacent $u, v \in V(G)$ the set $N(u) \cap N(v)$ induces a unit interval graph with at most two independent vertices.*
3. *G has no induced subgraph isomorphic to $K_{1,5}$, $K_{2,3}$ or $\overline{3K_2}$ ($3K_2$ is the disjoint union of three K_2).*

Proof. Let $f\colon V(G) \to \mathbb{R}^2$ be a realization. Pick $v = \operatorname{argmin}_{v \in V(G)} f(v)_1$. Further let $a_1 = f(v)_1$, $b_1 = a_1 + 1$, $a_2 = f(v)_2 - 1$ and $b_2 = f(v)_2 + 1$. Then $f(w) \in [a_1, b_1] \times [a_2, b_2]$ for every $w \in N[v]$. So $G[N[v]]$ is a unit interval graph by Observation 3.2.

Now let $u, v \in V(G)$ be two non-adjacent vertices. Without loss of generality assume $f(u)_1 + 1 \leq f(v)_1$. For $w \in N(u) \cap N(v)$ we obtain $f(u)_1 \leq f(w)_1 \leq f(v)_1$. Without loss of generality let $f(u) = (0, 0)$. Then $f(w) \in [0, 1] \times [-1, 1]$ for every $w \in N(u) \cap N(v)$. So $N(u) \cap N(v)$ defines a unit interval graph according to Observation 3.2. Furthermore in this area there can be at most two independent vertices.

For the third item first observe that the class of unit square graphs is hereditary (i.e. it is closed under taking induced subgraphs) so it suffices to show that the listed graphs are not unit square graphs. We first consider the graph $K_{1,5}$. Suppose towards a contradiction that there is a realization $f : V(G) \to \mathbb{R}^2$. Without loss of generality let $f(v) = (0, 0)$ where v is the center vertex connected to the other vertices $w_1, \ldots, w_5$. Then there is some quadrant containing two vertices w_i and w_j for distinct $i, j \in [5]$. But then $w_i w_j \in E(G)$ which is a contradiction.

For $K_{2,3}$ the two vertices on the left side have three independent common neighbors. The graph $\overline{3K_2}$ contains two non-adjacent vertices whose common neighborhood is a 4-cycle. So in both cases it follows from the second statement that the graph is not a unit square graph. ◀

We also require some properties of maximal cliques. A clique is a set $C \subseteq V(G)$, such that $vw \in E(G)$ for every two distinct $v, w \in C$. A maximal clique is a clique so that there is no larger clique containing it. For a graph G the set of maximal cliques of G is denoted by $\mathcal{M}(G)$.

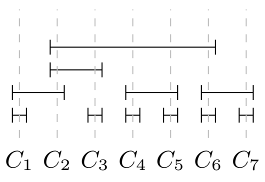
▶ **Lemma 3.4.** *Let G be a unit square graph and C be a maximal clique of G. Then there are $v_1, \ldots, v_4 \in V(G)$, such that $C = \bigcap_{i \in [4]} N[v_i]$.*

Proof. Let $f : V(G) \to \mathbb{R}^2$ be a realization of G. Let $v_{2i-1} = \operatorname{argmin}_{v \in C} f(v)_i$ and $v_{2i} = \operatorname{argmax}_{v \in C} f(v)_i$ for $i \in [2]$. Clearly $C \subseteq \bigcap_{i \in [4]} N[v_i]$. So let $w \in \bigcap_{i \in [4]} N[v_i]$ and $v \in C$. In order to prove $w \in C$ it suffices to show that $\|f(v) - f(w)\|_\infty \leq 1$, since v is chosen arbitrarily from C. For $i \in [2]$ it holds that $f(v_{2i-1})_i \leq f(v_{2i})_i$. If $f(w)_i \leq f(v_{2i})_i$ then $-1 \leq f(v_{2i})_i - 1 - f(v)_i \leq f(w)_i - f(v)_i \leq f(v_{2i})_i - f(v)_i \leq 1$. Otherwise $f(w)_i \geq f(v_{2i-1})_i$ and $-1 \leq f(v_{2i-1})_i - f(v)_i \leq f(w)_i - f(v)_i \leq f(v_{2i-1})_i + 1 - f(v)_i \leq 1$. ◀

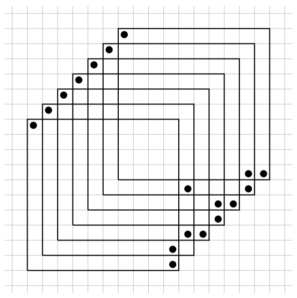
In particular all maximal cliques can be computed in polynomial time.

4 Local structure

The basic approach for our algorithm is group-theoretic. A main obstacle for group theoretic approaches comes from large symmetric or alternating groups that appear in the automorphism group of the given graph. For unit square graphs the central observation is that these groups can in a way only arise from cliques. In this section we show how to cope with possibly very symmetric parts of the graphs and give a corresponding reduction to get rid of them.



(a) An interval graph G



(b) The constructed realization for $G_{\mathcal{M}}$

Figure 2 From interval to unit square graphs.

We start by giving a central class of examples to obtain a better understanding of how the symmetric parts may look like. Let G be a graph. Define the colored graph $G_{\mathcal{M}} = (V(G) \cup \mathcal{M}(G), E(G_{\mathcal{M}}), c_{G_{\mathcal{M}}})$ with

$$E(G_{\mathcal{M}}) = \{vC \mid C \in \mathcal{M}(G), v \in C\} \cup \{vw \mid v \neq w \in V(G)\} \cup \{CD \mid C \neq D \in \mathcal{M}(G)\}$$

and $c_{G_{\mathcal{M}}}(v) = c_G(v) + 1$ for $v \in V(G)$, $c_{G_{\mathcal{M}}}(C) = 1$ for $C \in \mathcal{M}(G)$. For a group $\Gamma \leq \mathrm{Sym}(\Omega)$ and a set $A \subseteq \Omega$ the *pointwise stabilizer* is the group $\mathrm{Stab}^{\bullet}_{\Gamma}(A) := \{\gamma \in \Gamma \mid \forall \alpha \in A \colon \alpha^{\gamma} = \alpha\}$. If A is invariant under Γ (i.e. $A^{\gamma} = A$ for every $\gamma \in \Gamma$) we define the restriction of Γ to A as $\Gamma|_A := \{\gamma|_A \mid \gamma \in \Gamma\}$ where $\gamma|_A \colon A \to A$ with $\gamma|_A(\alpha) = \gamma(\alpha)$.

▶ **Observation 4.1.** *For every two graphs G and H it holds that*
1. *$G \cong H$ if and only if $G_{\mathcal{M}} \cong H_{\mathcal{M}}$,*
2. *$\mathrm{Stab}^{\bullet}_{\mathrm{Aut}(G_{\mathcal{M}})}(V(G)) = \{1\}$ (here 1 denotes the identify mapping),*
3. *$\mathrm{Aut}(G_{\mathcal{M}})|_{V(G)} = \mathrm{Aut}(G)$.*

In particular $\mathrm{Aut}(G) \cong \mathrm{Aut}(G_{\mathcal{M}})$ by combining the second and third part of the observation. We now show that for each interval graph G the graph $G_{\mathcal{M}}$ is a unit square graph. For this we use the following characterization of interval graphs: A graph G is an interval graph if and only if there is a linear order on the maximal cliques, such that each vertex appears in consecutive maximal cliques [14]. For a vertex $v \in V(G)$ let $\mathcal{M}_G(v) = \mathcal{M}(v) = \{C \in \mathcal{M}(G) \mid v \in C\}$.

▶ **Lemma 4.2.** *Let G be an interval graph. Then $G_{\mathcal{M}}$ is a colored unit square graph.*

Proof. Let $<$ be a linear order on $\mathcal{M}(G)$, such that each vertex appears in consecutive maximal cliques. Let $k = |\mathcal{M}(G)|$ and $C_1 < C_2 < \cdots < C_k$ be the maximal cliques of G. For each $v \in V(G)$ define $a_v, b_v \in [k]$ in such a way that $\mathcal{M}(v) = \{C_i \mid a_v \leq i \leq b_v\}$. Consider the following realization $f : V(G_{\mathcal{M}}) \to \mathbb{R}^2$ with $f(C_i) = (\frac{i}{k} - 1, \frac{i}{k})$ and $f(v) = (\frac{a_v}{k}, \frac{b_v}{k} - 1)$ for all $v \in V(G)$. Clearly all vertices are connected to each other as well as all maximal cliques. So let $v \in V(G)$. Then $|\frac{a_v}{k} - \frac{i}{k} + 1| = |\frac{a_v - i}{k} + 1| \leq 1$ if and only if $a_v \leq i$. Further $|\frac{i}{k} - \frac{b_v}{k} + 1| = |\frac{i - b_v}{k} + 1| \leq 1$ if and only if $i \leq b_v$. So there is an edge between $v \in V(G)$ and $C_i \in \mathcal{M}$ if and only if $a_v \leq i \leq b_v$ if and only if $v \in C_i$. ◀

A visualization of the presented realization is also given in Figure 2. In Figure 2b the vertices of $G_{\mathcal{M}}$ are represented by points. The squares are only for visualization purposes and indicate which vertices are connected. Each square describes a maximal clique of the original interval graph and contains exactly the vertex which corresponds to the given clique and the vertices being in the clique.

▶ **Corollary 4.3.** *For each colored interval graph G one can compute in polynomial time some colored unit square graph H with* $\mathrm{Aut}(G) \cong \mathrm{Aut}(H)$.

In particular this construction implies that there are twin-free unit square graphs where the automorphism group contains arbitrarily large symmetric groups which can not be handled by the group theoretic approach due to Luks. For example consider the following graph $G_{n,k}$ for $n, k \in \mathbb{N}$. The vertex set $V(G_{n,k}) = [n]^{\leq k}$ is the set of all words over the alphabet $[n]$ of length at most k and there is an edge $vw \in E(G_{n,k})$ if v is a prefix of w (this is interpreted for an undirected graph). First, $G_{n,k}$ is an interval graph. To verify this consider the set $[n]^k$ of words of length k with the natural lexicographic order. Then each vertex $v \in V(G_{n,k})$ can be represented by the interval $I_{n,k}(v) = \{w \in [n]^k \mid v \text{ is prefix of } w\}$. It is easy to check that two vertices are connected if and only if the corresponding intervals intersect. The automorphism group of $G_{n,k}$ is a wreath product of the automorphism group of $G_{n,k-1}$ by a symmetric group on n points.

One of the main contributions of this work is to show that within automorphism groups of unit square graphs large symmetric groups only appear in a local setting. Here, local refers to a small area in the realization of a unit square graph G. In the presented example the vertices of each color class are close together and in particular they induce a clique. The main target for this section is to present a method how to cope with the local parts of the graph that may admit large symmetric groups in the automorphism group. For this purpose we have to analyze the structure of clique-partitions of the vertices.

▶ **Definition 4.4.** Let G be a graph and $\mathcal{P}$ be a partition of the vertices. We call $\mathcal{P}$ a *clique-partition* if X is a clique for each $X \in \mathcal{P}$.

Let G be a unit square graph with realization $f : V(G) \to \mathbb{R}^2$. We first define the graph $G^*_{\mathcal{M}} = (V(G) \cup \mathcal{M}(G), E(G^*_{\mathcal{M}}), c_{G^*_{\mathcal{M}}})$ with $E(G^*_{\mathcal{M}}) = \{vC \mid C \in \mathcal{M}(G), v \in C\} \cup E(G)$ and $c_{G^*_{\mathcal{M}}} = c_{G_{\mathcal{M}}}$ as defined above. Let $\mathcal{P}$ be a clique-partition of $V(G)$, which is refined by the color refinement algorithm applied to the graph $G^*_{\mathcal{M}}$. More precisely let $\mathcal{P}^*$ be the unique coarsest partition of $V(G) \cup \mathcal{M}(G)$ that is stable with respect to $G^*_{\mathcal{M}}$ and refines the partition $\mathcal{P} \cup \{\mathcal{M}(G)\}$. The partition $\mathcal{P}$ is called *clique-stable* if $\mathcal{P}^* \cap 2^{V(G)} = \mathcal{P}$.

▶ **Lemma 4.5.** *Let G be a twin-free unit square graph and let $\mathcal{P}$ be a clique-stable partition. Further let $f : V(G) \to \mathbb{R}^2$ be a realization. Then the following properties hold:*

1. *For each $X \in \mathcal{P}$ there exists $b \in \{-1, 1\}$, such that*
$$f(v)_1 \leq f(w)_1 \;\Leftrightarrow\; b \cdot f(v)_2 \leq b \cdot f(w)_2 \tag{1}$$
for all $v, w \in X$. The value b is called the orientation of X, *which is denoted by* $\mathrm{ori}_{G,f}(X)$ *(the value b is unique unless $|X| = 1$, in this case we define* $\mathrm{ori}_{G,f}(X) = 1$*).*
2. *Let $X, Y \in \mathcal{P}$ with* $\mathrm{ori}_{G,f}(X) \neq \mathrm{ori}_{G,f}(Y)$. *Then either $xy \in E(G)$ for all $x \in X, y \in Y$ or there is no $x \in X, y \in Y$ with $xy \in E(G)$.*
3. *Let $X, Y \in \mathcal{P}$ with* $\mathrm{ori}_{G,f}(X) = \mathrm{ori}_{G,f}(Y)$ *and suppose $k = |\{xy \in X \times Y \mid xy \in E(G)\}| \geq 1$. Further let $X = \{x_1, \dots, x_s\}$, such that $f(x_i)_1 \leq f(x_{i+1})_1$ for all $i \in [s]$, and $Y = \{y_1, \dots, y_t\}$, such that $f(y_j)_1 \leq f(y_{j+1})_1$ for all $j \in [t]$. Then*
$$x_i y_j \in E(G) \;\Leftrightarrow\; \left\lceil \frac{i \cdot t}{k} \right\rceil = \left\lceil \frac{j \cdot s}{k} \right\rceil. \tag{2}$$

Now let $\mathcal{P}$ be a canonical, clique-stable partition of the graph G. We define the vertex and edge-colored graph $G[\mathcal{P}] = (\mathcal{P}, E, c_V, c_E)$ with $E = \{XY \mid X \neq Y \in \mathcal{P}\}$,

$c_V : \mathcal{P} \to \mathbb{N} \colon X \mapsto |X|$

and

$$c_E \colon E \to \mathbb{N} \colon XY \mapsto |\{xy \in X \times Y \mid xy \in E(G)\}|.$$

For $\gamma \in \mathrm{Aut}(G)$ define the permutation $\gamma^{\mathcal{P}} := \varphi(\gamma) \in \mathrm{Sym}(\mathcal{P})$ where $\varphi\colon \mathrm{Aut}(G) \to \mathrm{Sym}(\mathcal{P})$ is the natural action of $\mathrm{Aut}(G)$ on $\mathcal{P}$. Note that φ is well-defined since the partition $\mathcal{P}$ is canonical.

▶ **Theorem 4.6.** *Let G be a twin-free unit square graph and let $\mathcal{P}$ be a canonical, clique-stable partition. Further let $\delta \in \mathrm{Aut}(G[\mathcal{P}])$. Then there is some $\gamma \in \mathrm{Aut}(G)$ with $\gamma^{\mathcal{P}} = \delta$.*

Intuitively, the last theorem states that each automorphism of $G[\mathcal{P}]$ naturally extends to an automorphism of G. In particular, the graph G can be uniquely reconstructed from the graph $G[\mathcal{P}]$. This is the main result on the local structure of unit square graphs which allows us, for a canonical, clique-stable partition $\mathcal{P}$, to restrict to the graph $G[\mathcal{P}]$. For the remainder of this work the goal is to compute a canonical, clique-stable partition $\mathcal{P}$, such that the automorphism group of $G[\mathcal{P}]$ is a Γ_t-group for some constant t. To achieve this goal we require the graph G to have some singleton vertex v_0 (a vertex with a unique color). More precisely, for such a graph we construct the desired partition $\mathcal{P}$ and a canonical, t-circle-bounded graph H, such that $\mathcal{P} \subseteq V(H)$ and $\mathcal{P}$ is invariant under $\mathrm{Aut}(H)$. This results in a good supergroup of the group $\mathrm{Aut}(G[\mathcal{P}])$ which can be used by Luks' algorithm to compute the real automorphism group. To compute the graph H we devise an algorithm that iteratively extends H taking vertices with larger and larger distances to v_0 into account. While doing so the crucial subproblem is to compute canonical clique-partitions for neighborhoods of cliques. This problem is addressed in the next section.

5 Neighborhoods

In order to obtain canonical clique-partitions for neighborhoods we essentially proceed in two steps. First, we use some combinatorial partitioning techniques to obtain some initial coloring of the vertices. Then, considering each color class separately, the main contribution is to prove that each color class can either be described by a co-bipartite graph or a proper circular arc graph. In both cases it is easy to compute a canonical clique-partition.

5.1 Neighborhood graphs

Before considering neighborhoods of cliques we first restrict to neighborhoods of vertices. This occurs as a subcase when analyzing neighborhood of cliques. Also the structure of neighborhoods tends to be simpler than for neighborhoods of cliques.

▶ **Definition 5.1.** A unit square graph is a *neighborhood graph* if there is a realization $f\colon V(G) \to [-1,1]^2$.

Note that every graph induced on a neighborhood of a vertex is indeed a neighborhood graph and every neighborhood graph can be turned into the neighborhood of a vertex by adding a universal vertex located at the origin. Let G be a neighborhood unit square graph. The goal is to prove that, after performing the k-dimensional Weisfeiler-Leman algorithm for sufficiently large k, each color class of vertices is co-bipartite or proper circular arc. We build on the characterization of proper circular arc graphs in terms of forbidden induced subgraphs. We start by giving two general graph-theoretic lemmas.

▶ **Lemma 5.2.** *Let G be a graph, such that*
1. *$G[N[v]]$ is a unit interval graph for each $v \in V(G)$,*
2. *G has no induced subgraph isomorphic to $C_4 \cup K_1$.*
Further let $X = \{w_1 \in V(G) \mid \exists w_2, \dots, w_6 \colon G[w_1, \dots, w_6] \cong \overline{C_6}\}$. Then $G[X]$ is co-bipartite.

▶ **Lemma 5.3.** *Let G be a graph, such that*
1. *$G[N[v]]$ is a unit interval graph for each $v \in V(G)$,*
2. *G has no induced subgraph isomorphic to $C_{n+4} \cup K_1$ for $n \geq 0$,*
3. *there are no $v, w \in V(G)$, such that $N[v] \subsetneq N[w]$.*
Then G has no induced subgraph isomorphic to `net`*.*

Now let G be a neighborhood unit square graph. In order to apply Lemma 2.7 we still need to consider $C_{n+4} \cup K_1$ and $S_3 \cup K_1$.

▶ **Lemma 5.4.** *Let G be a neighborhood unit square graph. Let $X = \{v \in V(G) \mid \exists \ell \geq 4\, \exists w_1, \dots, w_\ell : vw_i \notin E(G) \wedge G[w_1, \dots, w_\ell] \cong C_\ell\}$. Then $X \neq V(G)$.*

Proof. Let $f \colon V(G) \to [-1,1]^2$ be a realization and let $v = \text{argmin}_{v \in V(G)} |f(v)_1|$. Suppose towards a contradiction that $v \in X$. Then there is some $\ell \geq 4$ and $w_1, \dots, w_\ell \in V(G)$, such that $vw_i \notin E(G)$ for all $i \in [\ell]$ and $w_iw_j \in E(G)$ if and only if $i - j \equiv \pm 1 \mod \ell$ for all $i, j \in [\ell]$. Without loss of generality assume that $f(v) \in [-1,0] \times [-1,0]$. Let $i = \text{argmin}_{i \in [\ell]} f(w_i)_2$. Since $G[w_1, \dots, w_\ell]$ is not a unit interval graph it holds that $f(w_i) \in [0,1] \times [-1,0]$ by Observation 3.2. Without loss of generality assume $i = 2$. Now consider the two neighbors w_1 and w_3. Note that $w_1w_3 \notin E(G)$ since $\ell \geq 4$. Then there is some $j \in \{1,3\}$, such that $f(w_j) \in [-1,0) \times [0,1]$. So in particular $f(w_j)_1 < 0$. Further $f(w_j)_1 + 1 \geq f(w_2)_1$ and $f(v)_1 + 1 < f(w_2)_1$. Altogether this means that $f(v)_1 < f(w_j)_1 < 0$ contradicting the definition of v. ◀

▶ **Lemma 5.5.** *Let G be a neighborhood unit square graph. Let $X = \{v \in V(G) \mid \exists w_1, \dots, w_6 : vw_i \notin E(G) \wedge G[w_1, \dots, w_6] \cong S_3\}$. Then $X \neq V(G)$.*

This lemma is proved in a similar fashion to Lemma 5.4. In order to prove the main partitioning result for neighborhood graphs we also require that for sufficiently large k the k-dimensional Weisfeiler-Leman algorithm identifies all interval graphs (cf. [21]).

▶ **Corollary 5.6.** *There is some $k \in \mathbb{N}$, such that for each neighborhood unit square graph the following holds: After performing k-dimensional Weisfeiler-Leman each equivalence class of vertices induces a graph which is co-bipartite or proper circular arc with at most four connected components.*

Proof. Choose k sufficiently large and let $X \subseteq V(G)$ be an equivalence class. Then $G[X]$ is a neighborhood unit square graph. By Lemma 3.3 there is some $v \in X$, such that $N_{G[X]}[v]$ induces a unit interval graph. Since k-dimensional Weisfeiler-Leman identifies all interval graphs this is true for all $v \in X$. From Lemma 5.4 it follows that there exists a vertex $v \in X$, such that every induced cycle contains at least one vertex being a neighbor of v. Again by stability of the set X with respect to k-dimensional Weisfeiler-Leman this is true for all $v \in X$ (note that the maximal length of an induced cycle is at most 8). So there is no induced subgraph isomorphic to $C_{n+4} \cup K_1$. Combining the same argument with Lemma 5.5 we get that $G[X]$ also has no induced subgraph isomorphic to $S_3 \cup K_1$. Since $G[X]$ is regular there are no vertices $v, w \in X$, such that $N_{G[X]}[v] \subsetneq N_{G[X]}[w]$. So we can apply Lemma 5.3 and obtain that there is no induced subgraph isomorphic to `net`. Furthermore $G[X]$ has no induced subgraph isomorphic to $\overline{3K_2}$ by Lemma 3.3 and therefore it has also no induced subgraph $\overline{T_2}$. Now suppose there is an induced subgraph isomorphic to $\overline{C_6}$. Then, by stability, every vertex is part of an induced subgraph $\overline{C_6}$ and thus, $G[X]$ is co-bipartite by Lemma 5.2. Otherwise $G[X]$ is proper circular arc by Lemma 2.7. The bound on the number of components follows from the fact that $K_{1,5}$ is not a unit square graph (cf. Lemma 3.3). ◀

▶ **Theorem 5.7.** *Let G be a neighborhood unit square graph. Then one can compute in polynomial time a canonical clique-partition $\mathcal{P}$ and a canonical colored graph H, such that*
1. $\mathcal{P} = V(H)$,
2. *H is 4-circle-bounded,*
3. $\operatorname{im}(\varphi) \le \operatorname{Aut}(H)$ *where* $\varphi\colon \operatorname{Aut}(G) \to \operatorname{Sym}(\mathcal{P})$ *is the natural action of* $\operatorname{Aut}(G)$ *on* $\mathcal{P}$.

Proof. Choose k according to Corollary 5.6 and let $X \subseteq V(G)$ be an equivalence class after performing k-dimensional Weisfeiler-Leman. Further let c be the color of the equivalence class. First suppose $G[X]$ is co-bipartite. Let t be the number of non-trivial connected components of $\overline{G[X]}$. Then $t \le 2$ by Lemma 3.3. Let $Y_{j,1}, Y_{j,2}$ be the unique bipartition of the j-th connected component, $j \in [t]$. Further let Y be the set of isolated vertices in $\overline{G[X]}$ and $\mathcal{Y} = \{Y\}$ if $Y \neq \emptyset$ and $\mathcal{Y} = \emptyset$ otherwise. Define $\mathcal{P}_X = \{Y_{j,j'} \mid j \in [t], j' \in [2]\} \cup \mathcal{Y}$. Further let $H_X = \{\mathcal{P}_X, E(H_X), c_X\}$ with $YZ \in E(H_X)$ if there are $v \in Y, w \in Z$ with $vw \in E\left(\overline{G[X]}\right)$ and $c_X(Y) = c$.

Otherwise $G[X]$ is proper circular arc according to Corollary 5.6. Let $X_1, \ldots, X_t$ be the connected components of $G[X]$. Then $t \le 4$ by Corollary 5.6. Let $i \in [t]$ and let $\mathcal{P}_{X,i}$ be the partition containing the equivalence classes of the connected twins relation for $G[X_i]$. Further let $H_{X,i}$ be the graph computed by Theorem 2.9 where each vertex is colored by c. Define $\mathcal{P}_X = \bigcup_{i\in[t]} \mathcal{P}_{X,i}$ and $H_X = \bigcup_{i\in[t]} H_{X,i}$.

Finally let $\mathcal{P} = \bigcup_X \mathcal{P}_X$ and $H = \bigcup_X H_X$. It can easily be checked that $\mathcal{P}$ and H have the desired properties. ◀

5.2 Clique neighborhoods graphs

Remember, that our goal is to compute a canonical clique-partition of a given unit square graph with singleton vertex v_0. We first group the vertices according to their distance to v_0. Then, for the first level of vertices which are all the neighbors of v_0, we use the previous theorem to compute a canonical clique-partition. For all other levels we want to build up on the partition computed in the previous level. More precisely, for a given clique in the partition of the previous level we want to partition its neighbors in the current level. Hence, we need to consider neighborhoods of cliques and extend the results of the previous subsection accordingly.

Let G be a colored unit square graph and let $X \subseteq V(G)$ be a clique, such that $V(G) = N[X] = \bigcup_{v\in X} N[v]$. Further suppose there is some color i, such that $X = V_i(G)$, and there is some $k \in [|X|]$, such that $|N[v] \cap X| = k$ for all $v \in V(G) \setminus X$. In this case G is called a *simple clique neighborhood graph with respect to X*. The next theorem extends the result of the previous subsection to simple clique neighborhood graphs. Note that we have to pay a price here, namely the constant for the circle-bounded graph increases from four to eight. This can be explained by the fact that a single vertex can have at most four independent neighbors whereas a clique can have eight independent neighbors (cf. Figure 3).

▶ **Theorem 5.8.** *Let G be a simple clique neighborhood graph with respect to $X \subseteq V(G)$. Then one can compute in polynomial time a canonical clique-partition $\mathcal{P}$ and a canonical colored graph H, such that*

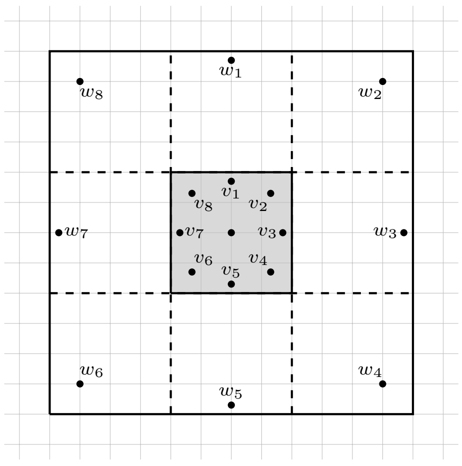


Figure 3 Neighborhood of a clique and realization for the graph G_8

1. $\mathcal{P} \subseteq V(H)$ *and* $\mathcal{P}$ *is* $\mathrm{Aut}(H)$*-invariant,*
2. H *is* 8*-circle-bounded,*
3. $\mathrm{im}(\varphi) \leq \mathrm{Aut}(H)|_{\mathcal{P}}$ *where* $\varphi\colon \mathrm{Aut}(G) \to \mathrm{Sym}(\mathcal{P})$ *is the natural action of* $\mathrm{Aut}(G)$ *on* $\mathcal{P}$*.*

The basic idea for the proof is similar to Theorem 5.7 but the technical details are far more involved. In particular Corollary 5.6 does not hold for neighborhoods of cliques. To circumvent this problem the basic idea is to consider an initial partition which is based on whether two vertices have the same neighbors in X. Then the single sets all define neighborhood graphs whereas on the sets considered as single elements we can define an auxiliary graph in a canonical way so that this auxiliary graph is again proper circular arc. From this point we can use similar arguments as for neighborhoods of single vertices. We omit the details here.

6 Global structure

In this section we are ready construct a canonical, clique-stable partition $\mathcal{P}$ together with some canonical 8-circle-bounded graph H, such that $\mathcal{P} \subseteq V(H)$ and $\mathcal{P}$ is $\mathrm{Aut}(H)$-invariant. This method is the central part of our algorithm and gives us a good supergroup of the natural action of the automorphism group on the computed partition. The computed supergroup is then given to the subroutine, that computes setwise stabilizers for groups in Γ_8, to obtain the automorphism group of $G[\mathcal{P}]$.

▶ **Theorem 6.1.** *Let G be a connected unit square graph with singleton vertex. Then one can compute in polynomial time a canonical, clique-stable partition $\mathcal{P}$ and a canonical colored graph H, such that*
1. $\mathcal{P} \subseteq V(H)$ *and* $\mathcal{P}$ *is invariant under* $\mathrm{Aut}(H)$*,*
2. H *is* 8*-circle-bounded,*
3. $\mathrm{im}(\varphi) \leq \mathrm{Aut}(H)|_{\mathcal{P}}$ *where* $\varphi\colon \mathrm{Aut}(G) \to \mathrm{Sym}(\mathcal{P})$ *is the natural action of* $\mathrm{Aut}(G)$ *on* $\mathcal{P}$*.*

The basic idea for the algorithm is to proceed in two steps. First, we compute a clique-partition $\mathcal{P}$, which is only canonical but not necessarily clique-stable, together with a corresponding graph H. For this part of the algorithm we make use of the partitioning algorithm for neighborhoods of cliques. More precisely we first group the vertices according to their distance to the singleton vertex v_0 and then we iteratively consider vertices with larger and larger distances to v_0. In the first iteration we only consider the neighbors of v_0 and compute a clique-partition and a canonical graph using Theorem 5.7. In the i-th iteration we partition the vertices with distance i to v_0 based on the partition of the vertices in the previous level. For each clique in the partition of the previous level we partition its neighbors in the current level using Theorem 5.8. Then we combine the computed partitions into one partition for the current level and use the computed graphs (which we obtained from Theorem 5.8) to update the graph H.

Then, in a second step, we refine the computed partition using the color refinement algorithm while simultaneously extending the graph H. The crucial idea for extending the graph H is to use additional layers which model the iterations of the color refinement algorithm.

▶ **Corollary 6.2.** *Let G be a connected unit square graph with singleton vertex. Then one can compute in polynomial time a canonical clique-partition $\mathcal{P}$, such that $\operatorname{im}(\varphi) \in \Gamma_8$ where $\varphi\colon \operatorname{Aut}(G) \to \operatorname{Sym}(\mathcal{P})$ is the natural action of $\operatorname{Aut}(G)$ on $\mathcal{P}$.*

▶ Remark. The constant $d = 8$ is tight for the previous corollary. In particular the graph G_8 with $V(G_8) = \{v_i \mid i \in [9]\} \cup \{w_i \mid i \in [8]\}$ and $E(G_8) = \{v_i v_j \mid i \neq j \in [9]\} \cup \{v_i w_i \mid i \in [8]\}$ is a unit square graph (the vertex v_9 may be a singleton vertex). A possible realization of G_8 is depicted in Figure 3.

Together with Theorem 4.6 this gives us sufficient structure to compute the natural action of the automorphism group on the computed partition. This can also be used to solve the isomorphism problem.

▶ **Theorem 6.3.** *Let G be a connected, twin-free unit square graph with a singleton vertex. Then one can compute in polynomial time a canonical, clique-stable partition $\mathcal{P}$ and a set $S \subseteq \operatorname{Sym}(\mathcal{P})$, such that $\langle S \rangle = \operatorname{im}(\varphi) \in \Gamma_8$ where $\varphi\colon \operatorname{Aut}(G) \to \operatorname{Sym}(\mathcal{P})$ is the natural action of $\operatorname{Aut}(G)$ on $\mathcal{P}$.*

Proof. Let $\mathcal{P}$ be the canonical, clique-stable partition and H the canonical, 8-circle-bounded graph obtained from Theorem 6.1. Then $\operatorname{Aut}(H)$ can be computed in polynomial time and $\operatorname{Aut}(H) \in \Gamma_8$ by Theorem 2.5 and 2.4. Further $\mathcal{P}$ is invariant under $\operatorname{Aut}(H)$. Since H is canonical this implies $\operatorname{im}(\varphi) \leq \operatorname{Aut}(H)|_{\mathcal{P}} \in \Gamma_8$. Furthermore $\operatorname{im}(\varphi) = \operatorname{Aut}(G[\mathcal{P}])$ by Theorem 4.6. A generating set for $\operatorname{Aut}(G[\mathcal{P}])$ can be computed in polynomial time using Theorem 2.2. ◀

▶ **Theorem 6.4.** *The Graph Isomorphism Problem for unit square graphs can be solved in polynomial time.*

Proof. Let G_1, G_2 be two unit square graphs. First, it can be assumed that G_1 and G_2 are connected by considering the connected components separately. Furthermore, the graphs can be assumed to be twin-free using modular decompositions of graphs (cf. [26]). Let $c \in \mathbb{N}$ be a fresh color (i.e. a color which does not appear in G_1 or G_2). For a graph G and a vertex $v \in V(G)$ we denote by $G^{v \mapsto c}$ the graph where vertex v is colored by c. Pick $v_1 \in V(G_1)$. For each $v_2 \in V(G_2)$ test whether $G_1^{v_1 \mapsto c} \cong G_2^{v_2 \mapsto c}$ by the following procedure. For $i \in [2]$ let $\mathcal{P}_i$ be the partition and H_i be the graph computed by Theorem 6.1 for the graph $G_i^{v_i \mapsto c}$. Let H be the disjoint union of H_1 and H_2. Note that $H_1 \cong H_2$ if $G_1^{v_1 \mapsto c} \cong G_2^{v_2 \mapsto c}$ because the graph H_i is canonical. Compute a generating set for $\operatorname{Aut}(H) \in \Gamma_8$. This can be done in polynomial time according to Theorem 2.5. Let G be the disjoint union of $G_1^{v_1 \mapsto c}[\mathcal{P}_1]$ and $G_2^{v_2 \mapsto c}[\mathcal{P}_2]$. Then $\operatorname{Aut}(G) \leq \operatorname{Aut}(H)|_{\mathcal{P}_1 \cup \mathcal{P}_2}$ and hence a generating set for $\operatorname{Aut}(G)$ can be computed in polynomial time using Theorem 2.2 (note that $\operatorname{Aut}(G)$ is the set of permutations which stabilize the edge set). By Theorem 4.6 it holds that $G_1^{v_1 \mapsto c} \cong G_2^{v_2 \mapsto c}$ if and only if there is an automorphism $\gamma \in \mathrm{Aut}(G)$ that maps $G_1^{v_1 \mapsto c}[\mathcal{P}_1]$ to $G_2^{v_2 \mapsto c}[\mathcal{P}_2]$. Since G is the disjoint union of of $G_1^{v_1 \mapsto c}[\mathcal{P}_1]$ and $G_2^{v_2 \mapsto c}[\mathcal{P}_2]$ and both of these graphs are connected it holds that if such an automorphism exists then there will also be one present in the generating set of $\mathrm{Aut}(G)$. Thus it can be checked in polynomial time whether $G_1^{v_1 \mapsto c} \cong G_2^{v_2 \mapsto c}$. ◀

▶ Remark. The running time of the presented algorithm is dominated by the running time for the subroutine computing setwise stabilizers for groups in Γ_8, which in turn depends on the maximal size of primitive Γ_8-groups.

The latter was analyzed by Babai, Cameron and Pálfy in [3] and proven to be polynomially bounded in the size of the permutation domain. For a complexity analysis of the setwise stabilizer subroutine we refer to [22, 23, 5]. Note that the setwise stabilizer subroutine is also used for computing the automorphism group of H and the graph H might be much larger than the original graph G.

▶ Remark. The presented algorithm also gives us some insight about the structure of the automorphism group of a unit square graph with singleton vertex. There is an invariant clique-partition, such that the natural action on the partition forms a Γ_8-group.

An interesting question is whether a similar statement still holds if the given graph does not have a singleton vertex. We leave this question open.

7 Discussion

We presented a polynomial time algorithm solving the Graph Isomorphism Problem for unit square graphs. Overall the presented algorithm heavily depends on group theoretic methods. This raises the question whether the problem can also be solved without the use of such methods. In fact, it might be that the k-dimensional Weisfeiler-Leman algorithm can identify every unit square graph for sufficiently large k. This is left as an open question.

Furthermore it is an interesting question whether the methods presented in this work can be adapted to other geometric classes for which the isomorphism problem is still open. At first glance a natural candidate seems to be the class of unit disk graphs. However, it turns out that there are some crucial structural differences to unit square graphs. In particular, there are unit disk graphs with singleton vertex, such that for each canonical clique-partition the natural action of the automorphism group contains a large symmetric group.

Finally we would like to address two natural generalizations of unit square graphs. The first one concerns the dimension of the realization, that is, what is the complexity of graph isomorphism for graphs with d-dimensional L_∞-realization for any constant number d. The second extension concerns squares of arbitrary size. This is still a natural restriction for the class of intersection graphs of rectangles, which is GI-complete, and the reduction does not directly extend to square graphs because it requires large complete bipartite graphs as induced subgraphs (cf. [29]). However, developing an efficient algorithm for this class of graphs would require some new ideas since the number of independent neighbors of a vertex is unbounded.

Acknowledgements. I want to thank Martin Grohe and Pascal Schweitzer for several helpful discussions and comments throughout this work. I also thank the anonymous referees for many comments improving the presentation of the results.

Abstract

Given a set S of integers whose sum is zero, consider the problem of finding a permutation of these integers such that: (i) all prefixes of the ordering are non-negative, and (ii) the maximum value of a prefix sum is minimized. Kellerer et al. referred to this problem as the *stock size problem* and showed that it can be approximated to within 3/2. They also showed that an approximation ratio of 2 can be achieved via several simple algorithms.

We consider a related problem, which we call the *alternating stock size problem*, where the number of positive and negative integers in the input set S are equal. The problem is the same as above, but we are additionally required to alternate the positive and negative numbers in the output ordering. This problem also has several simple 2-approximations. We show that it can be approximated to within 1.79.

Then we show that this problem is closely related to an optimization version of the gasoline puzzle due to Lovász, in which we want to minimize the size of the gas tank necessary to go around the track. We present a 2-approximation for this problem, using a natural linear programming relaxation whose feasible solutions are doubly stochastic matrices. Our novel rounding algorithm is based on a transformation that yields another doubly stochastic matrix with special properties, from which we can extract a suitable permutation.

1 Introduction

Suppose there is a set of jobs that can be processed in any order. Each job requires a specified amount of a particular resource, e.g. gasoline, which can be supplied in an amount chosen from a specified set of quantities. The limitation is that the storage space for this resource is bounded, so it must be replenished as it is used. The goal is to order the jobs and the replenishment amounts so that the required quantity of the resource is always available for the job being processed and so that the storage space is never exceeded.

[†] Supported by ERC Starting Grant 306465 (BeyondWorstCase).

More formally, we are given a set of integers $Z = \{z_1, z_2, \dots z_n\}$ whose sum is zero. For a permutation σ, a prefix sum is $\sum_{i=1}^{t} z_{\sigma(i)}$ for $t \in [1, n]$. Our goal is to find a permutation of the elements in Z such that (i) each prefix sum is non-negative, and (ii) the maximum prefix sum is minimized. (Placing the elements with positive values in front of the elements with negative values satisfies (i) and therefore yields a feasible – although possibly far from optimal – solution.) This problem is known as the *stock size problem.* Kellerer, Kotov, Rendl and Woeginger presented a simple algorithm with a guarantee of $\mu_x + \mu_y$, where μ_x is the largest number in Z, and μ_y is the absolute value of the negative number with the largest absolute value in Z. (We sometimes use $\mu = \max\{\mu_x, \mu_y\}$.) Since both μ_x and μ_y are lower bounds on the value S^* of an optimal solution, this shows that the problem can be approximated to within a factor of 2. Additionally, they presented algorithms with approximation guarantees of 8/5 and 3/2 [11].

1.1 The Alternating Stock Size Problem

In this paper we first consider a restricted version of the stock size problem in which we require that the positive and negative numbers in the output permutation alternate. We refer to this problem as the *alternating stock size problem.* A motivation for this problem is that we could schedule tasks in advance of knowing the input data. For example, suppose we want to stock and remove items from a warehouse and each task occupies a certain time slot. If we want to plan ahead, we may want to designate each slot as a stocking or a removing slot in advance, e.g. all odd time slots will be used for stocking and all even time slots for de-stocking. This could be beneficial in situations where some preparation is required for each type of time slot.

The input for our new problem is two sets of positive integers, $X = \{x_1 \geq \dots \geq x_n\}$ and $Y = \{y_1 \geq \dots \geq y_n\}$, such that $|X| = |Y|$, and the two sets have equal sums. The elements of X represent the elements to be "added" and the elements of Y are those to be "removed". Note that, here, $\mu_y = y_1$ and $\mu_x = x_1$. We now formally define the new problem.

▶ **Definition 1.** The goal of the *alternating stock size problem* is to find permutations σ and ν such that

(i) for $t \in [1, n]$, $\sum_{i=1}^{t} x_{\sigma(i)} - y_{\nu(i)} \geq 0$,

(ii) $\max\limits_{1 \leq t \leq n} \sum_{i=1}^{t} (x_{\sigma(i)} - y_{\nu(i-1)})$ is minimized, where $y_{\nu(0)} = 0$.

Although this problem is a variant of the stock size problem, the algorithms found in [11] do not provide approximation guarantees since they do not necessarily produce feasible solutions for the alternating problem. Indeed, even the optimal solutions for these two problems on the same instance can differ greatly. The following example illustrates this.

$$\begin{aligned} X &= \{\underbrace{p-1, \dots, p-1}_{p \text{ entries}}, 2, \underbrace{1, \dots, 1}_{p(p-1) \text{ entries}}\}, \\ Y &= \{\underbrace{p, \dots, p}_{p-1 \text{ entries}}, \underbrace{1, 1, 1, \dots, 1}_{p(p-1)+2 \text{ entries}}\}. \end{aligned}$$

For this instance, the optimal value for the alternating problem is at least $2p - 3$, while it is p for the original stock size problem. Thus, this example exhibits a gap arbitrarily close to 2 between the optimal solutions for the two problems.

We can show the following facts about the alternating problem. (i) There is always a feasible solution. (ii) The problem is NP-hard (as is the stock size problem). (iii) It is still the case that 2μ is an upper bound on the value of an optimal solution. Our main result for this problem is to give an algorithm with an approximation guarantee of 1.79 in Section 2.

1.2 Connections to the Gasoline Puzzle

The following well-known puzzle appears on page 31 in [12]:

> Along a speed track there are some gas stations. The total amount of gasoline available in them is equal to what our car (which has a very large tank) needs for going around the track. Prove that there is a gas station such that if we start there with an empty tank, we shall be able to go around the track without running out of gasoline.

Suppose that the capacity of each gas station is represented by a positive integer and the distance of each road segment is represented by a negative integer. For simplicity, suppose that it takes one unit of gas to travel one unit of road. Then the assumption of the puzzle implies that the sum of the positive integers equals the absolute value of the sum of the negative integers. In fact, if we are allowed to permute the gas stations and the road segments (placing exactly one gas station between every pair of consecutive road segments), and our goal is to minimize the size of the gas tank required to go around the track (beginning from a feasible starting point), then this is exactly the alternating stock size problem.

This leads to the following natural problem: Suppose the road segments are fixed and we are only allowed to rearrange (i.e. permute) the gas stations. In other words, between each pair of consecutive road segments (represented by negative integers), there is a spot for exactly one gas station (represented by positive integers, the capacities), and we can choose which gas station to place in each spot. The goal is to minimize the size of the tank required to get around the track, assuming we can choose our starting gas station. What is the complexity of this problem?

We show in the full version of this paper that this problem is NP-hard [16]. Our algorithm for the alternating stock size problem specifically requires that there is flexibility in placing both the x-values and the y-values. Therefore, it does not appear to be applicable to this problem, where the y-values are pre-assigned to fixed positions. Let us now formally define the *gasoline problem*, which is the second problem we will consider in this paper.

1.3 The Gasoline Problem

As input, we are given the two sets of positive integers $X = \{x_1 \geq x_2 \geq \cdots \geq x_n\}$ and $Y = \{y_1, y_2, \ldots, y_n\}$, where the y_i's are fixed in the given order and $\sum_{i=1}^n x_i = \sum_{i=1}^n y_i$. Our goal is to find a permutation π that minimizes the value of η:

$$\forall [k,\ell] : \quad \left| \sum_{\pi(i) \in [k,\ell]} x_i - \sum_{i \in [k,\ell-1]} y_i \right| \quad \leq \quad \eta. \tag{1}$$

Given a circle with n points labeled 1 through n, the interval $[k,\ell]$ denotes a consecutive subset of integers assigned to points k through ℓ. For example, $[5,8] = \{5,6,7,8\}$, and $[n-1,3] = \{n-1,n,1,2,3\}$. We will often use μ_x to refer to x_1, i.e. the maximum x-value, which is a lower bound on the optimal value of a solution.

Observe that in (1) we consider only intervals that contain one more x-value than y-value. One might argue that, in order to model our problem correctly, one also has to look at intervals that contain one more y-value than x-value. However, let I be such an interval and let $I' = [1,n] \setminus I$. Then the absolute value of the difference of the x-values and the y-values is the same in I and I' (with inverted signs) due to the assumption $\sum_{i=1}^n x_i = \sum_{i=1}^n y_i$.

We can also write the constraint (1) as:

$$\forall k: \sum_{\pi(i)\in[1,k]} x_i - \sum_{i\in[1,k-1]} y_i \quad \leq \quad \beta, \tag{2}$$

$$\forall k: \sum_{\pi(i)\in[1,k]} x_i - \sum_{i\in[1,k]} y_i \quad \geq \quad \alpha, \tag{3}$$

where $\alpha \leq 0$, $\beta \geq 0$ and $\eta = \beta - \alpha$. This version is slightly more general since it encompasses the scenario where we would like to minimize β for some fixed value of α. (With these constraints, it is no longer required that the sum of the x_i's equals the sum of the y_i's.)

What is the approximability of this problem? Getting a constant factor approximation appears to be a challenge since the following example shows that it is no longer the case that 2μ is an upper bound. Despite this, we show in Section 3 that there is in fact a 2-approximation algorithm for the gasoline problem.

Example showing unbounded gap between OPT and μ

Suppose X and Y each have the following n entries:

$$X = \{\underbrace{1, 1, \ldots, 1, 1, 1, \ldots, 1}_{n \text{ entries}}\}, \quad Y = \{\underbrace{2, 2, \ldots, 2}_{\frac{n}{2} \text{ entries}}, \underbrace{0, 0, \ldots, 0}_{\frac{n}{2} \text{ entries}}\}.$$

In the example above, $\mu = 2$. However, the optimal value is $n/2$.

1.4 Generalizations of the Gasoline Problem

The requirement that the x- and y-jobs alternate may seem to be somewhat artificial or restrictive. A natural generalization of the gasoline problem (which we will refer to as the *generalized gasoline problem*) is where the y-jobs are assigned to a set of predetermined positions, which are not necessarily alternating. As in the gasoline problem, our goal is to assign the x-jobs to the remaining slots so as to minimize the difference between the maximum and the minimum prefix. There is a simple reduction from this seemingly more general problem to the gasoline problem. Let $X = \{x_1 \geq x_2 \geq \cdots \geq x_{n_x}\}$ and $Y = \{y_1, y_2, \ldots, y_{n_y}\}$ be the input, where the y-jobs are assigned to n_y (arbitrary) slots. The remaining n_x slots are for the x-jobs. To reduce to an instance of the gasoline problem (with alternation), we do the following. For each set of y-jobs assigned to adjacent slots, we add them up to form a single job in a single slot. For each pair of consecutive x-slots, we place a new y-slot between them where the assigned y-job has value zero. Thus, we obtain an instance of the gasoline problem as originally defined in the beginning of this section.

Our new algorithm, developed in Section 3 to solve the gasoline problem, can also be applied to a natural generalization of the alternating stock size problem, in which we relax the required alternation between the x- and y-jobs and consider a scenario in which each slot is labeled as an x- or a y-slot and can only accomodate a job of the designated type. In other words, in the solution, the x-jobs and y-jobs will follow some specified pattern that is not necessarily alternating. The goal is to find a feasible assignment of x- and y-jobs to x- and y-slots, respectively, that minimizes the difference between the prefixes with highest and lowest values. Since this is simply a generalization of the stock size problem with the additional condition that each slot is *slated* as an x- or a y-slot, we refer to this problem as the *slated stock size problem.*

Formally, we are given two sets of positive integers $X = \{x_1 \geq x_2 \geq \cdots \geq x_{n_x}\}$ and $Y = \{y_1 \geq y_2 \geq \cdots \geq y_{n_y}\}$, and $n = n_x + n_y$ slots, each designated as either an x-slot or a

y-slot. Let I_x and I_y denote the indices of the x- and y-slots, respectively, and let P denote a prefix. Then, the objective is to find a permutation π that minimizes the value of $\beta - \alpha$, where

$$\forall P: \quad \alpha \; \leq \sum_{\pi(i) \in P \cap I_x} x_i - \sum_{\pi(i) \in P \cap I_y} y_i \; \leq \; \beta. \tag{4}$$

For this problem, we obtain an algorithm with approximation guarantee $OPT + \mu_x + \mu_y$. The details for this analysis as well as all proofs not provided in this extended abstract can be found in the full version [16].

1.5 Related Work

The work most related to the alternating stock size problem is contained in the aforementioned paper by Kellerer et al. [11]. Earlier, Abdel-Wahab and Kameda studied a variant of the stock size problem in which the output sequence of the jobs is required to obey a given set of precedence constraints, but the stock size is also allowed to be negative. They gave a polynomial-time algorithm for the case when the precedence constraints are series parallel [1]. The gasoline problem and its generalization are related to those found in a widely-studied research area known as resource constrained scheduling, where the goal is usually to minimize the completion time or to maximize the number of jobs completed in a given timeframe while subject to some limited resources [4, 6]. For example, in addition to time on a machine, a job could require a certain amount of another resource and would be eligible to be scheduled only if the *inventory* for this resource is sufficient.

A general framework for these types of problems is called scheduling with non-renewable resources. Here, *non-renewable* means not abundantly available, but rather replenished according to some rules, such as periodically and in pre-determined increments (as in the gasoline problem), or in specified increments that can be scheduled by the user (as in the alternating stock size problem), or at some arbitrary fixed timepoints. Examples for scheduling problems in this framework are described by Briskorn et al., by Györgyi and Kis, and by Morsy and Pesch [5, 8, 9, 14]. While the admissibility of a schedule is affected by the availability of a resource (e.g. whether or not there is sufficient inventory), minimizing the inventory is not a main objective in these papers.

For example, suppose we are given a set of jobs to be scheduled on a single machine. Each job consumes some resource, and is only allowed to be scheduled at a timepoint if there is sufficient resource available for that job at this timepoint. Jobs may have different resource requirements. Periodically, at timepoints and in increments known in advance, the resource will be replenished. The goal is to minimize the completion time. If at some timepoint, there is insufficient inventory for any job to be scheduled, then no job can be run, leading to gaps in the schedule and ultimately a later completion time. This problem of minimizing the completion time is polynomial time solvable (sort the jobs according to resource requirement), but an optimal schedule may contain idle times.

Suppose that we have some investment amount α that we can add to the inventory in advance to ensure that there is always sufficient inventory to schedule some job, resulting in a schedule with no empty timeslots, i.e. the optimal completion time. There is a natural connection between this scenario and the gasoline problem: Let $|\alpha|$ in Equation (3) denote the available investment. For this investment, suppose we wish to minimize β, which is the maximum inventory, in order to complete the jobs in the optimal completion time. For any feasible α and β, our algorithm in Section 3 produces a schedule with the optimal completion time using inventory size at most $\beta + \mu$.

There are other works that directly address the problem of minimizing the maximum or cumulative inventory. Monma considers a problem in which each job has a specified effect on the inventory level [13]. Neumann and Schwindt consider a scheduling problem in which the inventory is subject to both upper and lower bounds [15]. However, to the best of our knowledge, our work is the first to give approximation algorithms for the problem of minimizing the maximum inventory for non-renewable resource scheduling with fixed replenishments.

The stock size problem is also closely related to the Steinitz problem, which is a well-known problem in discrepancy theory [2]. Given a set of vectors $v_1, v_2, \dots v_n \in \mathbb{R}^d$ where $||v_i|| \leq 1$ for some fixed norm and $\sum_{i=1}^{n} v_i = 0$, the Steinitz problem is to find a permutation of the vectors so that the norm of the sum of each prefix is bounded. There exists a permutation in which the norm of each prefix is at most d [7, 3]. It has been conjectured that this bound can be improved to $O(\sqrt{d})$, but only $O(\sqrt{d}\log^{2.5} n)$ is known [10]. The stock size problem is the one-dimensional analogue of the Steinitz problem. The variants of the stock size problem that we introduce in this paper can be extended to higher dimensions.

2 Algorithms for the Alternating Stock Size Problem

The existence of a feasible solution for the alternating stock size problem follows from the solution for the gasoline puzzle. Furthermore, the upper bound of 2μ is also tight for the alternating problem. If we modify the example given in [11], we have an example for the alternating problem with an optimal stock size of $2p-3$, while $\mu = p$.

$$X = \{\underbrace{p-1, \dots, p-1}_{p \text{ entries}}, 2\}, \qquad Y = \{\underbrace{p, \dots, p}_{p-1 \text{ entries}}, 1, 1\}.$$

In this section, we will present algorithms for the alternating stock size problem. We will use the notion of a (q,T)-pair, which is a special case of a (q,T)-batch introduced and used by [11] for the stock size problem.

▶ **Definition 2.** [11] A pair of jobs $\{x, y\}$, for $x \in X$ and $y \in Y$, is called a (q,T)-pair for positive reals T and $q \leq 1$, if:
(i) $x, y \leq T$, (ii) $|x - y| \leq qT$.

The following lemma is a special case of Lemma 3 in [11], and the proofs are identical.

▶ **Lemma 3.** *For positive T, $q \leq 1$ and a set of jobs partitioned into (q,T)-pairs, we can find an alternating sequence of the jobs with maximum stock size less than $(1+q)T$.*

2.1 The Pairing Algorithm

We now consider the simple algorithm that pairs x- and y-jobs, and then applies Lemma 3 to sequence the pairs. Suppose that there is some specific pairing that matches each x_i to some y_j, and consider the difference $x_i - y_j$ for each pair. Let $\alpha_1 \geq \dots \geq \alpha_{n_1}$ denote the positive differences, and let $\beta_1 \geq \dots \geq \beta_{n_2}$ denote the absolute values of the negative differences, where $n_1 + n_2 = n$.

▶ **Lemma 4.** *The matching $M^\star$ that matches x_i and y_i for all $i \in \{1, \dots, n\}$ minimizes both α_1 and β_1.*

The pairing given by $M^\star$ directly results in a 2-approximation for the alternating stock size problem, by applying Lemma 3. Without loss of generality, let us assume that $\max\{\alpha_1, \beta_1\} =$

α_1, and observe that $\alpha_1 \leq \mu$. Then $M^\star$ partitions the input into $(\alpha_1/\mu, \mu)$-pairs. Applying Lemma 3, we obtain an algorithm that computes a solution with value at most $\mu + \alpha_1 \leq 2\mu$. We note that if $\alpha_1 \leq (1-\epsilon)\mu$, then we have a $(2-\epsilon)$-approximation.

2.2 Lower Bound for the Alternating Stock Size Problem

In order to obtain an approximation ratio better than 2, we need to use a lower bound that is more accurate than μ. We now introduce a lower bound closely related to the one given for the stock size problem in [11] (Lemma 8). We refer to a real number C, which divides the sets X and Y into sets of small jobs and big jobs, as a *barrier*. Let $C \leq \mu$ be a barrier such that:

$$X = \{a_1 \geq a_2 \geq \ldots \geq a_{n_a} \geq \quad C \quad > v_k \geq v_{k-1} \geq \ldots \geq v_1\}, \tag{5}$$

$$Y = \{\, b_1 \geq b_2 \geq \ldots \geq b_{n_b} \geq \quad C \quad > w'_1 \geq w'_2 \geq \ldots w'_{n_a-n_b} \geq w_1 \geq w_2 \geq \ldots \geq w_k\}, \tag{6}$$

where, without loss of generality, $n_a \geq n_b$. (If not then by swapping the x's and the y's we have a symmetric sequencing problem with $n_a \leq n_b$). The elements of (5) are all the x-jobs (partitioned into the sets A and V) and the elements of (6) are all the y-jobs. The jobs in Y that have value at most C are partitioned into W' and W.

Let $A' = \{a_{n_b+1}, \ldots a_{n_a}\} = \{a'_1, \ldots a'_{n_a-n_b}\}$, let V_i denote the i smallest v_j's, i.e. $\{v_1, v_2, \ldots, v_i\}$, and let W_i denote the i largest w_j's in W, i.e. $\{w_1, w_2, \ldots, w_i\}$. (Note that A', V_i, and W_i each depend on C, but in order to avoid cumbersome notation, we do not use superscript C.) Let $s \in \{1, \ldots, n_a - n_b\}$. After fixing a barrier C, let h be the (unique) index such that $w_h > v_h$ and $w_{h+1} \leq v_{h+1}$, and recall that S^* is the value of an optimal ordering. Then we obtain the following lower bound on S^*.

▶ **Lemma 5.** *For $n_a > n_b$, $1 \leq s \leq n_a - n_b$, the following inequality holds:*

$$S^* \geq LB(C) = \frac{1}{n_a - n_b - s + 1}\left(2\sum_{i=s}^{n_a-n_b} a'_i - \sum_{i=s}^{n_a-n_b} w'_i + \sum_{i=1}^{h}(v_i - w_i)\right).$$

2.3 Alternating Batches: Definition

We need a few more tools before we can outline our new algorithm. The notion of *batches* introduced in [11], to which we briefly alluded before Lemma 3, is quite useful for the stock size problem. For $B \subseteq X \cup Y$, let $x(B)$ and $y(B)$ denote the total value of the x-jobs and y-jobs, respectively, in B. In its original form, the batching lemma (Lemma 3, [11]) calls for a partition of the input into groups or batches such that for some fixed positive real numbers T and $q \leq 1$, each group B has the following properties: $x(B), y(B) \leq T$ and $|x(B) - y(B)| \leq qT$. Given such a partition of the input, a sequence with stock size at most $(1+q)T$ can be produced.

This approach is not directly applicable to the alternating stock size problem, because the output is not necessarily an alternating sequence. However, we will now show that the procedure can be modified to yield a valid ordering. With this goal in mind, we define a new type of batch, which we call an *alternating batch*. An alternating batch will either contain two jobs (small) or more than two jobs (large).

The modified procedure to construct an ordering of the jobs first partitions the input into alternating batches, then orders these batches, and finally orders the jobs contained within each batch. In the case of a small alternating batch, the batch will contain both an x-job and a y-job, and the last step simply preserves this order. A large alternating batch will be required to fulfill certain additional properties that allow the elements to be sequenced in a way that is both alternating and feasible, i.e. all prefixes are nonnegative.

Suppose $B = \{(x'_1, y'_1), (x'_2, y'_2), \ldots, (x'_\ell, y'_\ell)\}$, and consider the following four properties:

(i) $\sum_{i=1}^{\ell} x'_i - \sum_{i=1}^{\ell} y'_i \geq 0$,
(ii) $x'_1 - y'_1 \geq 0$,
(iii) $x'_i - y'_i \leq 0$, for $2 \leq i \leq \ell$,
(iv) $y'_1 \geq y'_2 \geq \ldots \geq y'_\ell$.

▶ **Lemma 6.** *If a batch B satisfies properties (i), (ii), (iii) and (iv), then we can sequence the elements in B so that the items alternate, each prefix is non-negative and the maximum height (or prefix sum) of the sequence is x'_1.*

▶ **Definition 7.** We call a set B a $(1-\epsilon)$-*alternating batch* if $B = \{(x'_1, y'_1), (x'_2, y'_2), \ldots, (x'_\ell, y'_\ell)\}$ such that:
(1) $|\sum_{i=1}^{\ell} x'_i - \sum_{i=1}^{\ell} y'_i| \leq (1-\epsilon)\mu$,
(2) if $\ell > 1$, then conditions (i) to (iv) hold.

▶ **Definition 8.** We say that a $(1-\epsilon)$-alternating batch with more than two jobs is a *large* alternating batch. In other words, a large alternating batch obeys conditions (1) and (2) in Definition 7. A *small* alternating batch contains only two jobs and obeys condition (1) in Definition 7.

Note that, by definition, in a large alternating batch B, the sum of the x-jobs in B is at least the sum of the y-jobs in B.

▶ **Lemma 9.** *If the sets X and Y can be partitioned into large and small $(1-\epsilon)$-alternating batches, then we can find an alternating sequence with maximum stock size less than $(2-\epsilon)\mu$.*

2.4 Alternating Batches: Construction

In this section, we present the final tool required for our algorithm. Suppose that for some some $\epsilon : 0 \leq \epsilon \leq 1$, the following conditions hold for an input instance to the alternating stock size problem: $\alpha_1 > (1-\epsilon)\mu$, and $LB(C) < \frac{2}{2-\epsilon}\mu$, for $C = (1-\epsilon)\mu$. Then, we claim, there is some value of ϵ (to be determined later) for which the above two conditions can be used to partition the input into $(1-\epsilon)$-alternating batches, to which we can then apply Lemma 9. In this section, we will heavily rely on the notation introduced in Section 2.2.

The sets $A' = \{a'_1, \ldots, a'_{n_a - n_b}\}$ and $W' = \{w'_1, \ldots, w'_{n_a - n_b}\}$ contain exactly the pairs in $M^\star$ that are split by barrier C. Let s be the smallest index such that $w'_s < \epsilon\mu$. To see that such an s actually exists, we note the following. Let $i^\star$ denote the index such that $x_{i^\star} - y_{i^\star} = \alpha_1$. Then $y_{i^\star} < \epsilon\mu$ and the pair $(x_{i^\star}, y_{i^\star})$ is split by C. Thus, $y_{i^\star}$ corresponds to some $w'_{i'}$, and therefore $s \leq i'$. See Figure 1 for a schematic drawing.

For i in $\{1, \ldots, n_a - n_b\}$, we define $\alpha'_i = a'_i - w'_i$ and for j in $\{1, \ldots, h\}$, $\beta'_j = w_j - v_j$. (Recall that for $j \in \{1, \ldots, h\}$, $w_j - v_j > 0$.) Furthermore, let $\mathcal{A}_i$ denote the pair $\{a'_i, w'_i\}$ and let $\mathcal{B}_j$ denote the pair $\{v_j, w_j\}$. Since $w'_s < \epsilon\mu$, it follows that all w_i's in W also have value less than $\epsilon\mu$. Moreover, $\beta'_j < \epsilon\mu$ for $j \in \{1, \ldots, h\}$.

Our goal is now to construct $(1-\epsilon)$-alternating batches. For each $i \in \{1, \ldots s-1\}$, note that $\alpha'_i \leq (1-\epsilon)\mu$. The set $\mathcal{A}_i$ therefore forms a small $(1-\epsilon)$-alternating batch. For each $\mathcal{A}_i$ where $i \in \{s, \ldots, n_a - n_b\}$, we will find a set of $\mathcal{B}_j$'s that can be grouped with this $\mathcal{A}_i$ to create a large $(1-\epsilon)$-alternating batch. However, to do this, we require that the condition on ϵ found in Claim 10 be satisfied.

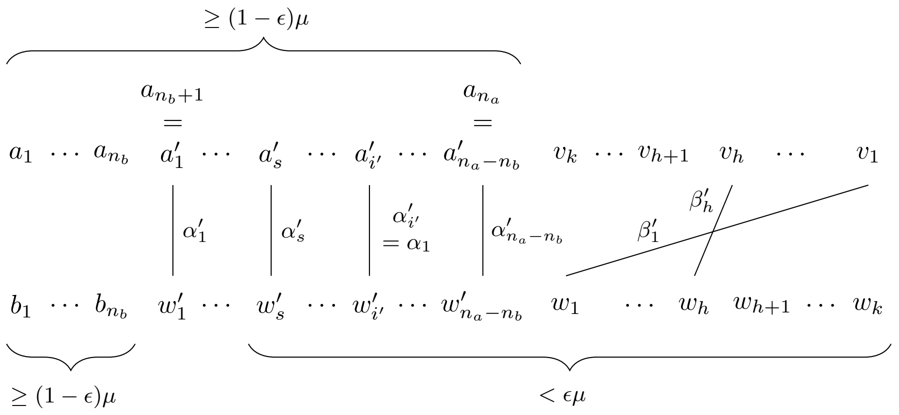

Figure 1 An illustration of the various elements used in the construction of the lower bound.

▶ **Claim 10.** *The condition*

$$2(1-\epsilon) - \frac{2}{2-\epsilon} > 2\epsilon \tag{7}$$

is satisfied when $\epsilon = .21$.

▶ **Lemma 11.** *If* $LB(C) < 2\mu/(2-\epsilon)$, $C = (1-\epsilon)\mu$, *and* $2(1-\epsilon) - \frac{2}{2-\epsilon} > 2\epsilon$, *then* $\sum_{i=1}^{h} \beta'_i + \sum_{i=s}^{n_a-n_b} w'_i > 2\epsilon\mu(n_a - n_b - s + 1)$.

For ease of notation, we set $d = n_a - n_b - s + 1$. In the following lemma, we show that we can also construct a $(1-\epsilon)$-alternating batch for each $\mathcal{A}_i$ for $i \in [s, n_a - n_b]$.

▶ **Lemma 12.** *There exists d disjoint subsets* $S_1, \ldots, S_d$ *of* $\{\mathcal{B}_1, \ldots, \mathcal{B}_h\}$ *such that for all i in* $\{1, \ldots, d\}$, *the set* $S_i \cup \mathcal{A}_{i+s-1}$ *is a* $(1-\epsilon)$*-alternating batch.*

Now we want to complete the construction of the $(1-\epsilon)$-alternating batches, so that we can apply Lemma 9. For the sets $\mathcal{A}_i$, where $i \in \{s, \ldots, n_a - n_b\}$, we construct batches according to Lemma 12. Let $y_{i^*} = w'_s$. For all $i < i^*$, the pair (x_i, y_i) form a small $(1-\epsilon)$-alternating batch. This follows from the fact that for all $i < i^*$, $y_{i^*} \geq \epsilon\mu$, by definition of s. Finally, if there are remaining elements, they are v_i's and w_i's, which can be paired up arbitrarily to construct more small $(1-\epsilon)$-alternating batches, since each remaining v_i has value stictly less than $(1-\epsilon)\mu$ due to our choice of barrier, and each remaining w_i has value at most $\epsilon\mu$. Since the only limits on the value of ϵ are imposed by Lemma 11, we can set $\epsilon = .21$ and partition the input into .79-alternating batches.

2.5 A 1.79-Approximation Algorithm

We are now ready to present an algorithm for the alternating stock size problem with an approximation guarantee of 1.79.

▶ **Theorem 13.** *Algorithm 1 is a* 1.79*-approximation for the alternating stock size problem.*

3 Gasoline Problem

Let the variable z_{ij} be 1 if gas station x_i is placed in position j, and be 0 otherwise. Then we can formulate the gasoline problem as the following integer linear program whose solution matrix Z is a permutation matrix.

Algorithm 1 1.79-approximation

```
1: Input: the sets $X$ and $Y$ of positive numbers sorted in nonincreasing order.
2: Output: a sequence that is a 1.79-approximation.
3: Set $\epsilon = .21, C = (1-\epsilon)\mu$.
4: Match each $x_i$ with $y_i$.
5: if $\alpha_1 \leq (1-\epsilon)\mu$ or if $LB(C) \geq \frac{2}{2-\epsilon}\mu$ then
6:     return solution for the Pairing Algorithm with guarantee of most $\mu + \alpha_1$.
7: else
8:     Partition the input into $(1-\epsilon)$-alternating batches described in Section 2.4.
9:     Run algorithm from Lemma 9 on the $(1-\epsilon)$-alternating batches.
10: end if
```

$$\min \beta - \alpha$$

$$\forall j \in [1,n] : \sum_{i=1}^{n} z_{ij} = 1, \quad \forall i \in [1,n] : \sum_{j=1}^{n} z_{ij} = 1, \quad \forall i,j \in [1,n] : z_{ij} \in \{0,1\},$$

$$\forall k \in \{1,\dots,n\} : \sum_{j=1}^{k}\sum_{i=1}^{n} z_{ij} \cdot x_i - \sum_{j=1}^{k-1} y_j \leq \beta, \tag{8}$$

$$\forall k \in \{1,\dots,n\} : \sum_{j=1}^{k}\sum_{i=1}^{n} z_{ij} \cdot x_i - \sum_{j=1}^{k} y_j \geq \alpha. \tag{9}$$

Observe that (8) and (9) imply that for every interval $I = [k,\ell]$ the sum of the x_i's assigned to I by Z and the sum of the y_i's in I differ by at most $\beta - \alpha$. If we replace $z_{ij} \in \{0,1\}$ with the constraint $z_{ij} \in [0,1]$, then the solution to the linear program, Z, is an $n \times n$ doubly stochastic matrix. Now we have the following rounding problem. We are given an $n \times n$ doubly stochastic matrix $Z = \{z_{ij}\}$ and we define z_j to be the total fractional value of the x_i's that are in position j, i.e., $z_j = \sum_{i=1}^{n} z_{ij} \cdot x_i$. Our goal is to find a permutation of the x_i's such that the x_i assigned to position j is roughly equal to z_j.

A natural approach would be to decompose Z into a convex combination of permutation matrices and see if one of these gives a good permutation of the elements in X. However, consider the following example:

$$X = \{\underbrace{1,1,\dots,1}_{n-k \text{ entries}},\underbrace{B,B,\dots,B}_{k \text{ entries}}\}, \quad \forall i \in [1,n] : \; y_i = \gamma = \frac{k \cdot B + n - k}{n}.$$

In this case, $z_j = \gamma$ for all $j \in [1,n]$. Thus, a possible decomposition into permutation matrices could look like:

$$\{B,B,\dots,B,1,1,\dots,1,1\}$$
$$\{1,B,B,\dots,B,1,1,\dots,1\}$$
$$\dots$$
$$\{1,1,\dots,1,1,B,B,\dots,B\}.$$

Each of these permutations has an interval with very large value, while the optimal permutation of the elements in X is

$$\{1,1,\dots 1,B,1\dots,1,B,1,\dots 1\}.$$

Algorithm 2 SHIFT$(Z, j, i_1, i_2, i_3, \delta)$

```
1: $\forall i \in \{1,\dots,n\} \setminus \{i_1,i_2,i_3\} : a_i = z_{ij}$;
2: $a_{i_2} = z_{i_2 j} + \delta$;
3: if $x_{i_1} = x_{i_3}$ then
4:     $a_{i_1} = z_{i_1 j} - \delta$;    $a_{i_3} = z_{i_3 j}$;
5: else
6:     $a_{i_1} = z_{i_1 j} - \delta \cdot \frac{x_{i_2} - x_{i_3}}{x_{i_1} - x_{i_3}}$;    $a_{i_3} = z_{i_3 j} - \delta \cdot \frac{x_{i_1} - x_{i_2}}{x_{i_1} - x_{i_3}}$;
7: end if
8: return $a$
```

Algorithm 3 TRANSFORM(Z, j, i_1, i_2, i_3)

```
1: The $j^{\text{th}}$ column of $Z'$ equals SHIFT$(Z, j, i_1, i_2, i_3, \delta)$ for $\delta > 0$ to be chosen later.
2: Let $j' > j$ denote the smallest index larger than $j$ with $z_{i_2 j'} > 0$. Such an index
   must exist because row $i_2$ is not finished in $Z$ in column $j$. The $(j')^{\text{th}}$ column of $Z'$
   equals SHIFT$(Z, j', i_1, i_2, i_3, -\delta)$.
3: All columns of $Z$ and $Z'$, except for columns $j$ and $j'$, coincide.
4: The value $\delta$ is chosen as the largest value for which all entries of $Z'$ are in $[0, 1]$. This
   value must be strictly larger than 0 due to our choice of $j$, $j'$, $i_1$, $i_2$, and $i_3$.
5: return $Z'$
```

3.1 Transformation

Given a doubly stochastic matrix $Z = \{z_{ij}\}$, we transform it into a doubly stochastic matrix $T = \{t_{ij}\}$ with special properties. First of all, for each j, $z_j = \sum_{i=1}^{n} t_{ij} \cdot x_i$. This means that if (Z, α, β) is a feasible solution to the linear program then (T, α, β) is also a feasible solution. In particular, if Z is an optimal solution, for which $\beta - \alpha$ is as small as possible, then T is also optimal.

We call a row i in a doubly stochastic matrix $A = \{a_{ij}\}$ *finished* at column ℓ if $\sum_{j=1}^{\ell} a_{ij} = 1$. We say that a matrix T has the *consecutiveness property* if the following holds: for each column j and any rows i_1 and i_3 with $i_1 < i_3$, $t_{i_1 j} > 0$, and $t_{i_3 j} > 0$, each row $i_2 \in \{i_1 + 1, \dots, i_3 - 1\}$ is finished at column j.

Our procedure to transform the matrix Z into a matrix T with the desired property relies on the following transformation rule. Assume that there exist indices j, i_1, i_3, and $i_2 \in \{i_1 + 1, \dots, i_3 - 1\}$ such that $z_{i_1 j} > 0$, $z_{i_3 j} > 0$, and row i_2 is not finished in matrix Z at column j. Then the procedure SHIFT shown as Algorithm 2 computes a column vector $a = (a_1, \dots, a_n)$, which satisfies the following lemma.

▶ **Lemma 14.** *For any $\delta \geq 0$, the vector a returned by* SHIFT$(Z, j, i_1, i_2, i_3, \delta)$ *satisfies* $\sum_{i=1}^{n} a_i \cdot x_i = z_j$.

Let Z' denote the matrix that we obtain from Z if we replace the j^{th} column by the vector a returned by the procedure SHIFT. The previous lemma shows that Z' satisfies (8) and (9) for the same β and α as Z because the value z_j is not changed by the procedure. However, the matrix Z' is not doubly stochastic because the rows i_1, i_2, and i_3 do not add up to one anymore. In order to repair this, we have to apply the SHIFT operation again to another column with $-\delta$. Formally, let us redefine the matrix $Z' = \{z'_{ij}\}$ as the outcome of the operation TRANSFORM shown as Algorithm 3.

Observe that Z' is a doubly stochastic matrix because the rows i_1, i_2, and i_3 sum up to one and all entries are from $[0, 1]$. Applying Lemma 14 twice implies that (Z', β, α) is a feasible solution to the linear program if (Z, β, α) is one.

We will transform Z by a finite number of applications of the operation TRANSFORM. As long as the current matrix T (which is initially chosen as Z) does not have the consecutiveness property, let j be the smallest index for which there exist indices i_1, i_3, and $i_2 \in \{i_1+1,\dots,i_3-1\}$ such that $t_{i_1j} > 0$, $t_{i_3j} > 0$, and row i_2 is not finished in T at column j. Furthermore, let i_1 and i_3 be the smallest and largest index with $t_{i_1j} > 0$ and $t_{i_3j} > 0$, respectively, and let i_2 be the smallest index from $\{i_1+1,\dots,i_3-1\}$ for which row i_2 is not finished at column j. We apply the operation TRANSFORM(T, j, i_1, i_2, i_3) to obtain a new matrix T.

▶ **Lemma 15.** *After at most a polynomial number of* TRANSFORM *operations, no further such operation can be applied. Then T is a doubly stochastic matrix with the consecutiveness property.*

In the remainder, we will not need the matrix Z anymore but only matrix T. For convenience, we will use the notation $t_j = \sum_{i=1}^{n} t_{ij} \cdot x_i$ instead of z_j even though the transformation ensures that t_j and z_j coincide.

We now define a graph whose connected components or *blocks* will correspond to the row indices from columns that overlap. More formally, let $V = \{1,\dots,n\}$ denote a set of vertices and let G_0 be the empty graph on V. Each column j of T defines a set E_j of edges as follows: the set E_j is a clique on the vertices $i \in V$ with $t_{ij} > 0$, i.e., E_j contains an edge between two vertices i and i' if and only if $t_{ij} > 0$ and $t_{i'j} > 0$. We denote by G_j the graph on V with edge set $E_1 \cup \dots \cup E_j$.

▶ **Definition 16.** A *block* in G_j is a set of indices in $[1, n]$ that forms a connected component in G_j. A block in G_j is called finished if all rows in T corresponding to the indices it contains are finished at column j. Similarly, if a block in G_j contains at least one unfinished row at column j, it is called an *unfinished block.*

If $B \subseteq \{1,\dots,n\}$ is a block in G_j with $i \in B$ then we will say that *block B contains row i*. For the following lemma it is convenient to define a matrix $C = \{c_{ij}\}$, which is the cumulative version of T. To be more precise, the j^{th} column of C equals the sum of the first j columns of T.

▶ **Lemma 17.** *The following three properties are satisfied for every j.*

1. *Let B be a block in G_j and let $k = \sum_{i\in B} c_{ij}$ the denote the value of block B at column j. The number of rows in B is k if B is finished and it is $k+1$ if B is an unfinished block.*
2. *The set of blocks in G_j emerges from the set of blocks in G_{j-1} by either merging exactly two unfinished blocks or by making one unfinished block finished.*
3. *Let $B_1,\dots,B_\ell$ denote the unfinished blocks in G_j. Then there exist non-overlapping intervals $I_1,\dots,I_\ell \subseteq [1, n]$ with $B_i \subseteq I_i$ for every i.*

One might ask if the consecutiveness property is satisfied by every optimal extreme point of the linear program. Let us mention that this is not the case. A simple counterexample is provided by the instance $X = \{9, 6, 4, 1\}$ and $Y = \{5, 5, 5, 5\}$. In this instance, an optimal extreme point would be, for example, to take one half of each of the items x_1 and x_4 in steps one and three and to take one half of each of the items x_2 and x_3 in steps two and four. This extreme point does however not satisfy the consecutiveness property. Hence, the transformation described in this section is necessary.

3.2 Rounding

In this section, we use the transformed matrix T to create the solution matrix R, which is a doubly stochastic 0/1 matrix, i.e., a permutation matrix. We apply the following rounding method.

```
1: for $j = 1$ to $n$ do
2:     Let $B$ denote the active block in $G_j$, i.e., the block that contains the rows $i$ with $t_{ij} > 0$.
3:     Let $p$ denote the smallest index in $B$ such that $r_{pi} = 0$ for all $i < j$.
4:     Set $r_{pj} = 1$ and $r_{qj} = 0$ for all $q \neq p$.
5: end for
```

Observe that the first step is well-defined because all non-zero entries in column j belong by definition to the same block of G_j. The resulting matrix R will be doubly stochastic, since each column contains a single one, as does each row. We just need to prove that in Line 3 there always exists a row $p \in B$ that is unfinished in R at column $j-1$. This follows from the first part of the next lemma because, due to Lemma 17, the active block B in G_j emerges from one or two unfinished blocks in G_{j-1} and these blocks each contain a row that is unfinished in R at column $j-1$.

▶ **Lemma 18.** *Let B be a block in G_j for some $j \in \{1,\dots,n\}$.*

1. *If B is an unfinished block in G_j and p is the largest index in B, then $r_{pi} = 0$ for all $i \le j$ and all rows corresponding to $B \setminus \{p\}$ are finished in R at column j.*
2. *If B is a finished block in G_j, then for all $q \in B$, row q is finished in R at column j.*

We define the *value* of a permutation matrix M to be the smallest γ for which there exist α' and β' with $\gamma = \beta' - \alpha'$ such that (M, α', β') is a feasible solution to the linear program.

▶ **Theorem 19.** *Let (T, α, β) be an optimal solution to the linear program. Then $(R, \alpha, \beta + \mu_x)$ is a feasible solution to the linear program. Hence, the value of the matrix R is at most $(\beta - \alpha) + \mu_x \le 2 \cdot OPT$, where OPT denotes the value of the optimal permutation matrix.*

For ease of notation, we define r_j as follows: $r_j = \sum_{i=1}^{n} r_{ij} \cdot x_i$. Note that r_j corresponds to the value of the element from Y that the algorithm places in position j. We will see later that Theorem 19 follows easily from the next lemma.

▶ **Lemma 20.** *For each $k \in \{1,\dots,n\}$,*

$$\sum_{j=1}^{k} (r_j - t_j) \in [0, \mu_x]. \qquad (10)$$

We need the following lemma in the proof of Lemma 20.

▶ **Lemma 21.** *Let b be the largest index in an unfinished block B in G_j. Then,*

$$c_{bj} \quad = \sum_{i \in B \setminus \{b\}} (1 - c_{ij}).$$

Proof. Let the value of the unfinished block B be $k = \sum_{i \in B} c_{ij}$. By property 1 of Lemma 17, block B consists of $k+1$ rows. Thus, we have:

$$c_{bj} = k - \sum_{i \in B \setminus \{b\}} c_{ij} = \sum_{i \in B \setminus \{b\}} (1 - c_{ij}). \qquad ◀$$

Proof of Lemma 20. Let us consider the sets of finished and unfinished blocks in G_k, $\mathcal{B}_F$ and $\mathcal{B}_U$, respectively. For a block $B \in \mathcal{B}_F \cup \mathcal{B}_U$, we denote by

$$\mathrm{er}_k(B) = \sum_{i \in B} \sum_{j=1}^{k} x_i(r_{ij} - t_{ij})$$

its rounding error. Since each row is contained in exactly one block of G_k,

$$\sum_{j=1}^{k}(r_j - t_j) = \sum_{j=1}^{k}\sum_{i=1}^{n} x_i(r_{ij} - t_{ij}) = \sum_{i=1}^{n}\sum_{j=1}^{k} x_i(r_{ij} - t_{ij}) = \sum_{B \in \mathcal{B}_F \cup \mathcal{B}_U} \mathrm{er}_k(B). \tag{11}$$

Hence, in order to prove the lemma, it suffices to bound the rounding errors of the blocks.

If block B is finished in G_k, then all rows that belong to B are finished in T and in R (due to property 2 of Lemma 18) at column k. Hence,

$$\mathrm{er}_k(B) = \sum_{i \in B}\sum_{j=1}^{k} x_i(r_{ij} - t_{ij}) = \sum_{i \in B} x_i \cdot \left(\sum_{j=1}^{k} r_{ij} - \sum_{j=1}^{k} t_{ij}\right) = \sum_{i \in B} x_i \cdot (1-1) = 0. \tag{12}$$

Now consider an unfinished block B in G_k, and let a and b denote the smallest and largest index in B, respectively. By Lemma 18, all rows in the block except for b are finished in R at column k (i.e., $\sum_{j=1}^{k} r_{ij} = 1$ for $i \in B \setminus \{b\}$ and $\sum_{j=1}^{k} r_{bj} = 0$). The rounding error of B can thus be bounded as follows (remember that $c_{ik} = \sum_{j=1}^{k} t_{ij}$):

$$\begin{aligned}
\mathrm{er}_k(B) &= \sum_{i \in B}\sum_{j=1}^{k} x_i(r_{ij} - t_{ij}) = \sum_{i \in B} x_i \sum_{j=1}^{k} r_{ij} - \sum_{i \in B} x_i \sum_{j=1}^{k} t_{ij} \\
&= \sum_{i \in B\setminus\{b\}} x_i - \sum_{i \in B} x_i c_{ik} = \sum_{i \in B\setminus\{b\}} x_i(1 - c_{ik}) - x_b c_{bk} \\
&= \sum_{i \in B\setminus\{b\}} x_i(1 - c_{ik}) - x_b \sum_{i \in B\setminus\{b\}} (1 - c_{ik}) && (13) \\
&= \sum_{i \in B\setminus\{b\}} (x_i - x_b)(1 - c_{ik}) \\
&\le (x_a - x_b) \sum_{i \in B\setminus\{b\}} (1 - c_{ik}) && (14) \\
&= (x_a - x_b) \cdot c_{bj} && (15) \\
&\le x_a - x_b. && (16)
\end{aligned}$$

Equations (13) and (15) follow from Lemma 21. Inequality (16) follows from the fact that $c_{bj} \le 1$. Inequality (14) follows from the facts that $1 - c_{ik} \ge 0$ and $x_i - x_b \ge 0$ for all $i \in B$. These facts also imply that $\mathrm{er}_k(B) \ge 0$. Hence,

$$\mathrm{er}_k(B) \in [0, x_a - x_b]. \tag{17}$$

Together (11) and (12) imply

$$\sum_{j=1}^{k}(r_j - t_j) = \sum_{B \in \mathcal{B}_F \cup \mathcal{B}_U} \mathrm{er}_k(B) = \sum_{B \in \mathcal{B}_F} \mathrm{er}_k(B) + \sum_{B \in \mathcal{B}_U} \mathrm{er}_k(B) = \sum_{B \in \mathcal{B}_U} \mathrm{er}_k(B). \tag{18}$$

Now, let $B_1, \ldots B_h$ denote the unfinished blocks in G_k, and for each block B_f in $\mathcal{B}_U$, let a_f and b_f denote the minimum and maximum indices, respectively, contained in the block.

Property 3 of Lemma 17 implies that the intervals $[a_f, b_f]$ are pairwise disjoint. Hence, (17) implies

$$\sum_{B\in\mathcal{B}_U} \mathrm{er}_k(B) \in \left[0, \sum_{f=1}^{h}(x_{a_f} - x_{b_f})\right] \subseteq \left[0, x_1 - x_n\right] \subseteq [0, \mu_x].$$

Together with (18) this implies the lemma. ◀

Now we are ready to prove Theorem 19.

Proof of Theorem 19. Let (T, α, β) denote an optimal solution to the linear program. By definition, our rounding method produces a permutation matrix R. Lemma 20 implies that $(R, \alpha, \beta + \mu_y)$ is also a feasible solution to the linear program because for each $k \in \{1, \ldots, n\}$,

$$\sum_{j=1}^{k} x_j - \sum_{j=1}^{k-1}\sum_{i=1}^{n} r_{ij}\cdot x_i = \sum_{j=1}^{k} x_j - \sum_{j=1}^{k-1} r_j \le \sum_{j=1}^{k} x_j - \sum_{j=1}^{k-1} t_j + \mu_x \le \beta + \mu_x$$

and

$$\sum_{j=1}^{k} x_j - \sum_{j=1}^{k}\sum_{i=1}^{n} r_{ij}\cdot x_i = \sum_{j=1}^{k} x_j - \sum_{j=1}^{k} r_j \ge \sum_{j=1}^{k} x_j - \sum_{j=1}^{k} t_j \ge \alpha.$$

Now the theorem follows because OPT $\ge \mu_x$ and OPT $\ge \beta - \alpha$. ◀

4 Conclusions

We have introduced two new variants of the stock size problem and have presented non-trivial approximation algorithms for them. The most intriguing question for our variants as well as for the original stock size problem is if the approximation guarantees can be improved. Each of these problems is NP-hard but no APX-hardness is known. So it is conceivable that there exists a PTAS. Closing this gap seems very challenging.

We note that the additive integrality gap of the linear program in Section 3 can be arbitrarily close to μ_y. Consider the following instance:

$$x = \frac{(n-1)+\mu}{n}, \quad X = \{\underbrace{x, \ldots, x}_{n \text{ entries}}\}, \quad Y = \{\mu, \underbrace{1, 1, \ldots, 1}_{n-1 \text{ entries}}\}.$$

Then the value of the linear program is x. However, the optimal value is μ, which can be arbitrarily larger than x.

Acknowledgments. We would like to thank Anupam Gupta for several useful examples and enlightening conversations. We would like to thank Jochen Könemann for pointing out a connection between the alternating stock size problem and the optimization version of the gasoline puzzle. We would also like to thank Tamás Kis for pointing out related papers on scheduling problems.

Part of this work was done during the trimester program on Combinatorial Optimization at the Hausdorff Institute for Mathematics in Bonn and we would like to thank HIM for their organization and hospitality during the program.

Abstract

All Pairs Shortest Path (APSP) is a classic problem in graph theory. While for general weighted graphs there is no algorithm that computes APSP in $O(n^{3-\varepsilon})$ time ($\varepsilon > 0$), by using fast matrix multiplication algorithms, we can compute APSP in $O(n^{\omega} \log n)$ time ($\omega < 2.373$) for undirected unweighted graphs, and in $O(n^{2.5302})$ time for directed unweighted graphs. In the current state of matters, there is a substantial gap between the upper bounds of the problem for undirected and directed graphs, and for a long time, it is remained an important open question whether it is possible to close this gap.

In this paper we introduce a new parameter that measures the *symmetry* of directed graphs (i.e. their closeness to undirected graphs), and obtain a new parameterized APSP algorithm for directed unweighted graphs, that generalizes Seidel's $O(n^{\omega} \log n)$ time algorithm for undirected unweighted graphs. Given a directed unweighted graph G, unless it is highly asymmetric, our algorithms can compute APSP in $o(n^{2.5})$ time for G, providing for such graphs a faster APSP algorithm than the state-of-the-art algorithms for the problem.

1 Introduction

All Pairs Shortest Path (APSP) has a long history, emerging from the 1950's to our present days. In APSP our goal is to compute the distances between all pairs of vertices in the graph. For general directed weighted graphs with n vertices, the algorithm of Floyd-Warshall [6] computes APSP in $O(n^3)$ time. For sparse graphs with m edges, we can obtain an improved algorithm that runs in $O(mn + n^2 \log n)$ time, by first finding and eliminating cycles of negative weight, using Johnson's algorithm [15], and then executing Dijkstra algorithm [6] (implemented with Fibonacci heaps [8]) from each vertex in the graph. This classic result was later improved by Pettie [16] to $O(mn + n^2 \log\log n)$, and for undirected graphs with nonnegative edge weights, APSP can be computed in $O(mn)$ time, using Thorup's algorithm for single source shortest path [24].

All the algorithms mentioned above have a running time of $O(n^3)$ for dense graphs. Fredman was the first to break the $O(n^3)$ (cubic) time barrier, by obtaining an algorithm with a running time of $O(n^3/(\log\log n/\log n)^{1/3})$ [7]. Since then, a line of subsequent improvements to Fredman's algorithm followed (e.g. [22, 12, 23, 27, 13, 3], etc.), where the current best result for the problem was recently obtained by Chan and Williams [4], which showed an algorithm that computes APSP in $O(n^3/2^{\Omega(\log n)^{1/2}})$ time. Nevertheless, these algorithms only provides a slightly improvement to the classic cubic-time algorithm of Floyd and Warshall, and it remains an open question whether an $O(n^{3-\varepsilon})$-time algorithm for APSP exists. The hardness of APSP and other fundamental graph and matrix problems (e.g. minimum weight cycle, replacement paths on directed weighted graphs, etc.) that are all known to have cubic time algorithms but no $O(n^{3-\varepsilon})$-time algorithms, might be explained by the result of V. Vassilevska Williams and R. Williams [25], which proved that these problems are subcubic equivalent, meaning, either all of these problems can be solved in $O(n^{3-\varepsilon})$ time or none of them can be.

By using Fast Matrix Multiplication (FMM) algorithms, truly subcubic time (i.e. $O(n^{3-\varepsilon})$) algorithms can be obtained for unweighted graphs and for graphs with small integer edge-weights. The naïve algorithm for multiplying two $n \times n$ matrices runs in $O(n^3)$ time, however, there exist faster algorithms to compute matrix multiplication (e.g. Strassen's algorithm [6], Coppersmith-Winograd [5]). Denote ω to be the exponent of square matrix multiplication, currently $\omega < 2.373$ ([11]) is the smallest known value for ω. Notice, it is straightforward to reduce Boolean Matrix Multiplication (BMM) to FMM in $O(n^2)$ time, hence BMM can be also computed in $O(n^\omega)$ time. Given this fact, many APSP algorithms use the following basic property: let G be an unweighted graph with adjacency matrix A and let $M = A^k$, it follows $M[i,j] = 1$ if and only if there is a shortest path in G from i to j of length at most k. Alon, Galil and Margalit [2] were the first to obtain a truly subcubic algorithm for APSP. They showed an algorithm that computes APSP in $\widetilde{O}(n^{(\omega+3)/2}) = \widetilde{O}(n^{2.69})$ time[1] for directed graphs with edge-weights from $\{-1,0,1\}$. Zwick in [26] improved Alon, Galil, and Margalit's result [2]. He showed that using fast *rectangular* matrix multiplication algorithms (current fastest rectangular matrix multiplication algorithm is due to Le Gall [10]), APSP for directed graphs with edges of weights $\{-M,\dots,M\}$ can be computed in $O(M^{0.68}n^{2.53})$ time. For undirected graphs with edges of small integers weights $\{1,\dots,M\}$, Galil and Margalit [9] showed an algorithm with a running time of $\widetilde{O}(M^{(\omega+1)/2}n^\omega)$. This result was later improved by Shoshan and Zwick [21] to $\widetilde{O}(Mn^\omega)$. Considering the case of undirected unweighted graphs, Seidel [20] obtained an algorithm for APSP that runs in $\widetilde{O}(n^\omega)$ time. The advantage of Seidel's $\widetilde{O}(n^\omega)$ time algorithm is that it is much simpler than that of [9].

Currently, for unweighted graphs, there is a large gap in the upper bounds for directed and undirected graphs. Many believe that $\omega = 2 + o(1)$, and if this is indeed the case, then the $\widetilde{O}(n^\omega)$ algorithms for undirected (e.g. Seidel's algorithm) match, up to logarithmic factors, the natural $O(n^2)$-time lower bound for the problem. On the other hand, considering this case for directed graphs, both the algorithm of Alon, Galil and Margalit, and the algorithm of Zwick run in $\widetilde{O}(n^{2.5})$ time. Moreover, the improved result of Zwick relies on the fact, that currently there exist faster algorithms for rectangular matrix multiplication (e.g. [10]) than square rectangular matrix multiplication. Actually, if only using square matrix multiplication, the over twenty years old result of Alon, Galil and Margalit is still the best we know so far. Also, currently, the only known way to achieve $\widetilde{O}(n^\omega)$-time APSP algorithm for directed graphs is to settle with an *approximation*: Zwick showed in [26] an algorithm that computes a $(1+\varepsilon)$ approximation to APSP in $\widetilde{O}(\frac{1}{\varepsilon}n^\omega \log \frac{1}{\varepsilon})$ time. This raises an interesting open question, whether an $\Omega(n^{2.5})$-time is the lower bound to compute APSP for directed graphs.

So what are the obstacles that prevent us from obtaining an $\widetilde{O}(n^\omega)$-time algorithm for directed unweighted graphs as well? Consider Seidel's algorithm. The idea of this algorithm

[1] The notation $\widetilde{O}$-notation suppress polylogarithmic factors from the O-notation.

is fairly simple: let $G = (V, E)$ be a directed graph with adjacency matrix A, and assume we have computed recursively the distance matrix for the graph G' induced by A^2. Recall that in G', an edge (u, v) exists if and only if there is a path of length at most 2 from u to v. This implies that either $d_G(u, v) = 2d_{G'}(u, v)$, if $d_G(u, v)$ is even, or $d_G(u, v) = 2d_{G'}(u, v) - 1$, otherwise. Since in each recursion the distances in the induced graph is cut by half, the depth of the recursion is $O(\log n)$. The only thing that is left in order to complete the algorithm, is to determine for every $u, v \in V$, if $d_G(u, v)$ is even or odd. Let $N(v)$ be the set of neighbors of v in G. For every $w \in N(v)$, by the triangle inequality for unweighted *undirected* graphs,

$$d(u, v) - 1 \leq d(u, w) \leq d(u, v) + 1$$

Using this property, it is not hard to verify that $\sum_{w\in N(v)} d_{G'}(u, w) \geq |N(v)| \cdot d_{G'}(u, v)$ when $d_G(u, v)$ is even and $\sum_{w\in N(v)} d_{G'}(u, w) < |N(v)| \cdot d_{G'}(u, v)$ otherwise. Since the sums $\sum_{w\in N(v)} d_{G'}(u, w)$, for every $u, v \in V$, can be computed at once using a single matrix multiplication, the total computation time of a recursion stage is $O(n^\omega)$ (for more details, see [20]). The sole obstacle that prevents us from implementing Seidel's algorithm for directed graphs is that the triangle inequality in *directed* unweighted graphs holds only for one side: for an incoming edge (w, v), it only holds that $d(u, v) - 1 \leq d(w, u)$ (similarly, for an outgoing edge (v, w), we have $d(u, w) \leq d(u, v) + 1$). For an incoming edge (w, v), we can get two-sides bounds for $d(u, w)$, if we have a path from v to w. Specifically, if for an incoming edge (w, v), it holds that $d(v, w) \leq d$ (for some d), then $d(u, w) \leq d(u, v) + d$ (similar argument can be applied for an outgoing edge as well). In other words, for any $u, v \in V$, the more an edge (w, v) is "symmetric" (i.e. $d(v, w)$ is close to 1), the better bounds we get from the triangle inequality on $d(u, w)$, using $d(u, v)$. As by definition, undirected graphs are fully-symmetric, we have that $d(v, u) = 1$ for every edge (u, v) in an undirected unweighted graph. On the other hand, in a directed graph, for an edge (w, v), it might be the case that the graph does not have any path at all from v to w, thus we cannot guarantee a two-sides bound by the triangle inequality for $d(u, w)$ as in unweighted graphs.

In this paper we introduce a new parameter for directed strongly-connected graphs that measures the closeness of a directed strongly-connected graph to symmetric graph (i.e. undirected). The symmetry parameter $s(G)$ of a directed strongly-connected graph $G = (V, E)$ is defined to be $\max_{(u,v)\in E}\{d(v, u)\}$. Interestingly, the definition of the symmetry parameter is very similar to the definitions of the *girth* and *diameter*, both natural and well-studied (e.g. [1, 14, 17, 18, 19]) distance-related graphs parameters: the girth of directed graphs is $\min_{(u,v)\in E}\{d(v, u)\}$, and the diameter of the graph is $\max_{(u,v)\in V\times V}\{d(u, v)\}$. As we shall see later, similarly to the girth and the diameter, we can also compute the symmetry parameter of the graph in $\widetilde{O}(n^\omega)$ time.

Our main contribution in this paper is an algorithm (Theorem 8) that provides a non-trivial generalization of Seidel's algorithm, and computes APSP for a directed strongly-connected graph G with symmetry parameter $s = s(G)$ in $O(s \cdot n^\omega \log_{s+1} n)$ time. The rough idea of the algorithm is as follows. As discussed above, using the symmetry parameter, we can obtain generalized triangle inequalities. In our algorithm we use these new inequalities, and adapt Seidel's algorithm to find all the pairs $(u, v) \in V \times V$, such that $d(u, v) \equiv 1 \mod (s + 1)$, and their distances. However, it is unclear how to deduce the distances for all other pairs of vertices, i.e., for all $(u, v) \in V \times V$, such that $d(u, v) \not\equiv 1 \mod (s + 1)$. Our approach to tackle this obstacle is to find, using one BMM, all the pairs $(u, v) \in V$ such that $d(u, v) \equiv i \mod (s + 1)$, based on that we already know all the pairs $(u, v) \in V$, such that $d(u, v) \equiv j \mod (s+1)$, for all $0 < j < i$. Surprisingly, here comes the parameter into action again. Using a designated matrix multiplication, the parameter allows us to find all the relevant pairs and their distances. Continuing this process inductively, we can compute the distances between all pairs of vertices. Our algorithm can also be applied on general directed unweighted graphs, by using an $\widetilde{O}(n^{\omega})$-time reduction from APSP for general directed unweighted graphs to APSP for directed strongly-connected unweighted graphs.

In the definition of the symmetry parameter, we are taking the maximum over all the edges, thus, even a single edge in a graph can cause the symmetry parameter of the graph to be very large. However, this can be relaxed by the concept of *violating-edge*. Let $z < n$ be some threshold value. An edge (u, v) is a z-violating edge if $d(v, u) > z$. By applying Breadth-First Search (BFS) in and out of the endpoints of all z-violating edges in the graph, we can remove these edges, and by that, decrease the symmetry parameter of the new graph to be as small as our threshold value z. Now, the distance from u to v in the original graph is either their distance in the new graph, or otherwise, equals to $d(u, x) + 1 + d(y, v)$, where (x, y) is some z-violating edge. Using this idea, for any graph that has at most $o(n^{0.53})$ violating edges for a $o(n^{0.157})$-threshold, we can compute APSP faster than the state of the art algorithm for the problem. Notice that a larger threshold is allowed as ω decreases. For example, if $\omega = 2 + o(1)$, then our APSP runs in $o(n^{2.5})$ time for any graph that has at most $o(n^{1/2})$ violating edges for any $o(n^{1/2})$-threshold. This may suggest the following strategy to compute APSP for directed unweighted graphs. First compute in $\widetilde{O}(n^{\omega})$ time (Lemma 13) the number of violating-edges for any $o(n^{0.157})$-threshold. If there are at most $o(n^{0.53})$ violating edges, use our algorithm, otherwise use the state of the art algorithm for the problem.

Another interesting property of our algorithm is that it provides an improvement over a basic parameterized-APSP algorithm for directed unweighted graphs, that is also used sometimes as an ingredient in other algorithms for the problem (e.g. in [2]). For a directed unweighted graph G with adjacency matrix A and *diameter* $D \leq n$, we can easily compute APSP in $O(D \cdot n^{\omega})$ by computing $A, A^2, A^3, \ldots, A^D$. For a large diameter, the running time of this algorithm can be as high as $O(n^{1+\omega})$ (which is even worse than Floyd-Warshall's algorithm), however, it can be turned to be useful for graphs that their diameter is less than $n^{2.5-\omega}$, in this case, the running time of this algorithm will be $o(n^{2.5})$. Our algorithms provide improvements over this basic algorithm in two ways. First they provide a weaker constraint on the graph, as $s(G) = \max_{(u,v)\in E}\{d(v, u)\} \leq \max_{(u,v)\in V\times V}\{d(u, v)\} = D$. Also, using the concept of z-violating edges, we can decrease the value of the symmetry parameter, while, to our best knowledge, there is no such equivalent method for the parameterized-APSP algorithm that is based on the diameter.

The paper is organized as follows. In the next section we provide some preliminaries for our algorithms. Section 3 presents our main algorithm. In Section 4 we show a reduction that allows us to compute APSP on general directed graphs using our parameterized algorithm. In Section 5 we give a hybrid algorithm that allows us to reduce the size of the symmetry parameter of the graph in exchange to additional BFS executions on the graph. We also show in this section how to compute in $\widetilde{O}(n^{\omega})$ time the symmetry parameter of a graph and the violating edges in the graph for some specific threshold.

2 Preliminaries

Let $G = (V, E)$ be a directed graph with n vertices and m edges. Let $u, v \in V$ and let $d_G(u, v)$ be the length of the shortest path from u to v in G. If there is no path from u to v in G, then $d_G(u, v) = \infty$. We use a simplified notation $d(u, v)$, when the referred graph is clear from the context. A directed graph is strongly-connected if for all $u, v \in V$, $d(u, v) < \infty$.

Our goal in this paper is to compute efficiently All Pairs Shortest Path (APSP) for directed unweighted graphs. The general form of the problem is defined as follows.

▶ **Definition 1** (The APSP Problem)**.** Let $G = (V, E)$. Compute a matrix M of size $|V| \times |V|$, such that for every $u, v \in V$, $M(u, v) = d(u, v)$.

The diameter of a graph G is $D(G) = \max_{u,v \in V}\{d(u, v)\}$. Notice that a directed graph G is strongly-connected if and only if $D(G) < \infty$. An extended definition of the diameter that includes non-necessarily strongly-connected graphs (with non-empty edges set) is $\max_{u,v \in V}\{d(u, v) \mid d(u, v) < \infty\}$. Let $v \in V$, $N_{in}(v)$ is the set of all vertices that have an outgoing edge to v, namely, $N_{in}(v) = \{u \mid (u, v) \in E\}$.

The *symmetry parameter* introduced here is a new notion that measures the closeness of a directed strongly-connected graph to a symmetric (undirected) graph. We define the symmetry parameter of an edge (u, v) as $d(v, u)$. The symmetry parameter of a graph is the maximum over the symmetry parameters of all the edges in the graph.

▶ **Definition 2** (Directed Graphs, Symmetry Parameter)**.** Let $G = (V, E)$ be a directed strongly-connected graph. $s(G) = \max_{(u,v) \in E}\{d(v, u)\}$.

Notice that in undirected graphs $s(G) = 1$. Since the definition of the symmetry parameter of the graph takes the maximum over all the edges, we may achieve a smaller value for the parameter if we exclude some of the edges in the graph. This idea is encapsulated in the definition of z-violating edges.

▶ **Definition 3** (z-violating Edges)**.** Let $G = (V, E)$ be a directed strongly-connected graph and let $z < s(G)$ be a threshold value. An edge $(u, v) \in E$ is z-violating if $d(v, u) > z$.

We denote by A_G, the adjacency matrix of a graph G. In A_G, it holds for every $u, v \in V$ that:

$$A_G(u, v) = \begin{cases} 1 & (u, v) \in E \vee u = v \\ 0 & (u, v) \notin E \end{cases}$$

Note that for undirected graphs the adjacency matrix is symmetric.

Let A and B be two $n \times n$ matrices with integral values. We denote $A \cdot B$ as the integer multiplication of A and B. We use the same notation, when A and B are Boolean matrices and the operation is Boolean Matrix Multiplication (BMM).We can multiply two integer/Boolean metrics in $O(n^\omega)$ time, where currently $\omega < 2.373$ [10].

We use the notation A^k ($k > 0$) for the multiplication of A by itself k times. For the rest of the paper, when using A^k, we assume the multiplication that is taken is BMM. Naïvely, we can compute A^k in $O(k \cdot n^\omega)$, however this can be done in $O(n^\omega \log n)$ time using "repeated squaring" method (e.g. [14]). The matrix that is obtained from multiplying the adjacency matrix of a graph by itself is meaningful in respect to the distances of the graph. This relation is given in the following proposition.

▶ **Proposition 4** (Distances vs. the Adjacency Matrix [14])**.** *Let* $D_k = (A_G)^k$. $D_k(u, v) = 1$ *if and only if* $d(u, v) \le k$.

Denote G_k to be the graph induced from the adjacency matrix D_k. The graph G_k is the graph G with some additional new edges. Specifically, G_k has a new edge (u, v), if $(u, v) \notin G$ and there exists a shortest path in G from u to v of length at most k. In other words, in G_k we add "shortcuts edges" to paths of length at most k in G. This leads us to the following definition: let $k > 1$ and $u, v \in V$, we denote r_{uv} to be ($d_G(u, v) \mod k$), that is, the residues of $d(u, v)/k$.

3 Parameterized Algorithm for APSP

In this section we show in Theorem 8 how to compute APSP for a directed strongly-connected graph G in $O(s \cdot n^{\omega} \log_{s+1} n)$ time, where $s = s(G)$ is the symmetry parameter of G. Before we turn to prove the theorem, we give some lemmas that are needed for our theorem.

In undirected graphs, for vertices u, v and a neighbor w of v, using the triangle inequality, we have $d(u, v) - 1 \leq d(u, w) \leq d(u, v) + 1$. Considering the same situation in directed graphs, however, we can only guarantee either that $d(u, v) - 1 \leq d(u, w)$, where (w, v) is an incoming edge of v, or that $d(u, w) \leq d(u, v) + 1$, where (v, w) is an outgoing edge of v. With the symmetry parameter we can obtain both the following lower and upper bounds on $d(u, w)$.

▶ **Lemma 5.** *Let $G = (V, E)$ be a directed, strongly-connected, unweighted graph. Then:*

1. *For every $u, v \in V$ and every $w \in N_{in}(v)$, it follows that $d(u, v) - 1 \leq d(u, w) \leq d(u, v) + s(G)$.*
2. *For every $u, v \in V$ $(u \neq v)$ there exists a $w \in N_{in}(v)$ such that $d(u, w) = d(u, v) - 1$.*

Proof. Let $u, v \in V$. If $w \in N_{in}(v)$, then $d(w, v) = 1$, and from the definition of the symmetry parameter $d(v, w) \leq s(G)$. From the triangle inequality on the pair (u, v), we get that $d(u, v) \leq d(u, w) + d(w, v) \leq d(u, w) + 1$, that is, $d(u, v) - 1 \leq d(u, w)$. From the triangle inequality on the pair (u, w), we get that $d(u, w) \leq d(u, v) + d(v, w) \leq d(u, v) + s(G)$. This proves the first part of the lemma.

For the second part, consider a shortest path P from u to v, and let w be the vertex that immediately preceding v on P. Since $u \neq v$, we have that $w \neq v$, and therefore $w \in N_{in}(v)$. Since w is on a shortest path from u to v, $d(u, v) = d(u, w) + 1$, and thus $d(u, w) = d(u, v) - 1$. ◀

The next lemma shows the relation between the distances in the original graph G and the graph that is induced by $A' = (A_G)^x$.

▶ **Lemma 6.** *Let $G = (V, E)$ be a directed graph and let $0 < x \leq n$ be an integer. Let G' be the graph induced from $A' = (A_G)^x$. Let $r_{uv} = d_G(u, v) \mod x$, for every $u, v \in V$ it follows that:*

1. *$d_{G'}(u, v) = \lceil \frac{d_G(u,v)}{x} \rceil$.*
2. *If $r_{uv} = 0$: $d_G(u, v) = x \cdot d_{G'}(u, v)$.*
3. *If $r_{uv} \neq 0$: $d_G(u, v) = x \cdot (d_{G'}(u, v) - 1) + r_{uv}$.*

Proof. Let $u, v \in V$, such that $d = d_G(u, v)$. Notice that $d_G(u, v) = x \cdot \lfloor \frac{d_G(u,v)}{x} \rfloor + r_{uv}$. Proposition 4 implies that $d_G(u, v) \leq x \cdot d_{G'}(u, v)$. Notice first that it cannot be $d_{G'}(u, v) < \lceil \frac{d_G(u,v)}{x} \rceil$, as otherwise we get $d_G(u, v) \leq x \cdot (\lceil \frac{d_G(u,v)}{x} \rceil - 1) < \lfloor \frac{d_G(u,v)}{x} \rfloor + r_{uv}$. Denote $b = \lfloor \frac{d_G(u,v)}{x} \rfloor$. Let $P = \langle u = v_0, \ldots, v_d = v \rangle$ be a shortest path from u to v in G. From Proposition 4 we have for every $0 \leq i \leq b$ the edges $(v_{i \cdot x}, v_{(i+1) \cdot x})$ are in G'. Also, if $r_{uv} \neq 0$, we have the edge $(v_{b \cdot x}, v_d)$, and otherwise (i.e. when $r_{uv} = 0$) we have $v_{b \cdot x} = v_d$. In both cases, we get that there exists a path from u to v in G' of length $\lceil \frac{d_G(u,v)}{x} \rceil$. Claims (2) and (3) of this lemma follow immediately from the construction of the path in G'. ◀

Lemma 7 guarantees that the symmetry parameter of the graph induced by $A' = (A_G)^x$ is not bigger than $s(G)$.

▶ **Lemma 7.** *Let $G = (V, E)$ be a directed strongly-connected graph and let $0 < x \leq n$ be an integer. Let G' be the graph induced from $A' = (A_G)^x$. It follows that G' is also strongly-connected and $s(G') \leq s(G)$.*

Proof. First note that since G is strongly-connected and we have from Lemma 6 that $d_{G'}(u,v) = \lceil \frac{d_G(u,v)}{x} \rceil$ for every $u, v \in V$, it follows that G' is also strongly-connected. Let (u, v) be an edge in G'. From the way we obtained G', $d_G(u,v) \leq x \cdot d_{G'}(u,v) = 1 \cdot x = x$. Let $P = \langle u = v_0, \ldots v_d = v \rangle$ be a shortest path from u to v in G. By the symmetry parameter of G, there exists a path in G of length $s(G)$ at most from every (v_{i+1}, v_i), $0 \leq i \leq d_G(u,v)$. This implies a shortest path in G from v to u of length $x \cdot s(G)$ at most. By Lemma 6, $d_{G'}(v,u) = \lceil \frac{d_G(v,u)}{x} \rceil \leq \lceil \frac{x \cdot s(G)}{x} \rceil = \lceil s(G) \rceil = s(G)$, as required. ◀

We now turn to present our main theorem. Notice that the algorithm receives as an input the parameter $s(G)$ of G. As we shall show later, $s(G)$ can be computed in $O(n^\omega \log n)$ time. A pseudocode of our algorithm is given in Algorithm 2.

▶ **Theorem 8.** *Let $G = (V, E)$ be a directed strongly-connected unweighted graph with a parameter $s = s(G)$. We can compute APSP for G in $O(s \cdot n^\omega \log_{s+1} n)$ time.*

Proof. Notice first that $s = s(G)$ is well defined, since G is strongly-connected. Let $s' = s+1$. Our algorithm will follow a similar approach as done in Seidel's algorithm [20] for undirected graphs.

Let A be the adjacency matrix of the graph G (recall we assume that A always has 1's in its diagonal). If all entries in A are 1's, we return A as the distance matrix for G. If this is not the case, we compute $A' = A^{s'}$ in $O(s' \cdot n^\omega)$ time. Let G' be the graph of A' and let D' be the distance matrix for G', that is, $D'(u,v) = d_{G'}(u,v)$. We obtain D' by invoking our algorithm recursively. Notice that according to Lemma 7 the parameter $s(G)$ does not increase in G' (i.e. $s(G') \leq s(G)$).

Our goal is to compute D, the distance matrix of G, based on D', the distance matrix computed recursively for G'. According to Lemma 6, for every $u, v \in V$ it follows that $d_{G'}(u,v) = \lceil \frac{d_G(u,v)}{s'} \rceil$ and $d_G(u,v) = s' \cdot (d_{G'}(u,v) - 1) + r_{uv}$ (or $d_G(u,v) = s' \cdot d_{G'}(u,v)$, for the case that $r_{uv} = 0$). Since we know $d_{G'}(u,v)$, this implies we only left to compute r_{uv} in order to find the distance from u to v in G.

Our first step is to compute the distances for all $u, v \in V$ such that $d_G(u,v) = d_{G'}(u,v) + 1$ (i.e. $r_{uv} = 1$).

Let $u, v \in V$. Denote $k = d_{G'}(u,v)$. Examine first the case where $r_{uv} = 1$. Let $w \in N_{in}(v)$. It follows from Lemma 5 that there exists a $w' \in N_{in}(v)$ such that $d_G(u,w') = d_G(u,v) - 1$. Since $r_{uv} = 1$, it must be that $d_{G'}(u,w') = k - 1$, as $r_{uw'} = 0$ and $d_{G'}(u,w') = \lceil \frac{d(u,w')}{s'} \rceil$. From Lemma 5 and from the symmetry parameter s of G it follows that for every $w \in N_{in}(v)$, $d_G(u,w) \leq d_G(u,v) + s$. Therefore, $d_{G'}(u,w) \leq k$, and for $r_{uv} = 1$, we have that $\sum_{w \in N_{in}(v)} d_{G'}(u,w) < |N_{in}(v)|k = |N_{in}(v)| d_{G'}(u,v)$.

For the case that $r_{uv} \neq 1$. We know from Lemma 5 that for every $w \in N_{in}(v)$ we have $d_G(u,v) - 1 \leq d_G(u,w) \leq d_G(u,v) + s$. Since for every $w' \in N_{in}(v)$, such that $d_G(u,w) = d_G(u,v) - 1$, it holds that $d_{G'}(u,w') = k$, it implies that $d_{G'}(u,w) \geq k$ for every $w \in N_{in}(v)$ and we have in this case that $\sum_{w \in N_{in}(v)} d_{G'}(u,w) \geq |N_{in}(v)|k = |N_{in}(v)| d_{G'}(u,v)$.

We conclude that for every $u, v \in V$, $r_{uv} = 1$ if and only if $\sum_{w \in N_{in}(v)} d_{G'}(u,w) < |N_{in}(v)| d_{G'}(u,v)$. We can obtain $\sum_{w \in N_{in}(v)} d_{G'}(u,w)$, for every $u, v \in V$, by computing the integer matrix multiplication $D_1 = D' \cdot A$ in $O(n^\omega)$ time. By computing the integer matrix multiplication $1^{n \times n} \cdot A$, we can obtain $|N_{in}(v)|$ for every $v \in V$. Overall we can check for every $u, v \in V$ if $\sum_{w \in N_{in}(v)} d_{G'}(u,w) < |N_{in}(v)| d_{G'}(u,v)$ in $O(1)$ time. At this stage we set $D(u,v) = s'(D'(u,v) - 1) + 1$, for every $u, v \in V$ such that $r_{uv} = 1$.

It is left to compute the distances for every $u, v \in V$ such that $r_{uv} \neq 1$. We show by induction for $1 \leq i \leq s'$, that we can compute the distances for every $u, v \in V$ such that $r_{uv} = i \mod s'$ in $O(n^\omega)$ time. We already showed the base case of the induction (i.e. for

$i = r_{uv} = 1$). By the hypothesis of the induction, we assume that we have the distances for every $u, v \in V$ such that $r_{uv} = j \mod s'$, $1 \leq j \leq i$, and we show that we can compute the distances for $u, v \in V$ such that $r_{uv} = (i+1) \mod s'$.

Let $N^i_{uv} = \{w \in N_{in}(v) \mid r_{uw} = i \mod s'\}$.

▶ **Claim 9.** *Let $u, v \in V$ ($u \neq v$), such that $d_{G'}(u,v) = k$. For every $w \in N^i_{uv}$, $d_{G'}(u,w)$ is either $k-1$, k or $k+1$. Moreover, if $r_{uv} \neq 1$, it cannot be that $d_{G'}(u,w) = k-1$.*

Proof. By Lemma 5, $d_G(u,v) - 1 \leq d_G(u,w)$. Now, $d_{G'}(u,w) = \lceil \frac{d_G(u,w)}{s'} \rceil \geq \lceil \frac{d_G(u,v)-1}{s'} \rceil \geq \lceil \frac{d_G(u,v)}{s'} \rceil - 1 = d_{G'}(u,v) - 1 = k-1$. Notice that the only case that $\lceil \frac{d_G(u,v)-1}{s'} \rceil = \lceil \frac{d_G(u,v)}{s'} \rceil - 1$ is when $r_{uv} = 1$. Therefore, $d_{G'}(u,w) \geq k-1$, and $d_{G'}(u,w) \geq k$ for $r_{uv} \neq 1$.

Assume toward contradiction that there exists $w \in N^i_{uv}$ such that $d_{G'}(u,w) > k+1$. For such a w, we have $d_G(u,w) > s'(k+1)$. Now, since $(w,v) \in E$ and the symmetry parameter of G is s, it follows that $d_G(v,w) \leq s$, but then $d_G(u,v) + d_G(v,w) \leq s'k + s' = s'(k+1) < d_G(u,w)$, a contradiction to the minimality of $d_G(u,w)$. ◀

Using Claim 9 we can now provide a criteria we will use to identify every $u, v \in V$ ($u \neq v$) such that $r_{uv} = (i+1) \mod s'$.

▶ **Claim 10.** *Let $u, v \in V$ ($u \neq v$), such that $r_{uv} = j \mod s'$. Then:*

1. *If $j = i+1 \Rightarrow \sum_{w \in N^i_{uv}} d_{G'}(u,w) < |N^i_{uv}| \cdot (d_{G'}(u,v)+1)$*
2. *If $i+2 \leq j \leq s' \Rightarrow \sum_{w \in N^i_{uv}} d_{G'}(u,w) \geq |N^i_{uv}| \cdot (d_{G'}(u,v)+1)$*

Proof. Denote $d_{G'}(u,v) = k$. Since the claim only considers $j \geq 2$, we have that $r_{uv} \neq 1$. Now, according to Claim 9 it holds that $d_{G'}(u,w) = k$ or $d_{G'}(u,w) = k+1$ for every $w \in N^i_{uv}$. If $j = i+1$ then there exists a $w' \in N^i_{uv}$ with $d_{G'}(u,w') = k$. Therefore, $\sum_{w \in N^i_{uv}} d_{G'}(u,w) < |N^i_{uv}| \cdot (k+1) = |N^i_{uv}| \cdot (d_{G'}(u,v)+1)$.

If $j \geq i+2$ we cannot have any $w \in N^i_{uv}$ such that $d_{G'}(u,w) = k$, since otherwise we get that $d_G(u,w) + d_G(w,v) = (s' \cdot (k-1) + i) + 1 < s' \cdot (k-1) + (i+2) \leq d_G(u,v)$, a contradiction to the minimality of $d_G(u,v)$. Therefore, $\sum_{w \in W^i_{uv}} (d_{G'}(u,v)+1) = |N^i_{uv}| \cdot (k+1) = |N^i_{uv}| \cdot (d_{G'}(u,v)+1)$. ◀

By Claim 10 we can now identify $r_{uv} = j \mod s'$, $j = i+1$ by first checking whether $\sum_{w \in N^i_{uv}} D'_G(u,w) < |N^i_{uv}| \cdot (D'_G(u,v)+1)$ is satisfied or not. Even if the inequality holds, it still may be that $j < i+1$, but since by the induction hypothesis we already computed the distances for $j \leq i$, we can distinguish between $j = i+1$ and $j < i+1$. We compute the exact distances for $r_{uv} = (i+1) \mod s'$ using Lemma 6. We are left to show how to compute $\sum_{w \in N^i_{uv}} D'_G(u,w)$ and $|N^i_{uv}|$. Notice that at this stage we know the exact distance for every $u, v \in V$ such that $r_{uv} = i \mod s'$. We define $D'_i(u,v)$ to be $D'(u,v)$ if $r_{uv} = i \mod s'$ and 0 otherwise. Similarly, we define $A_i(u,v)$ to be 1 if $r_{uv} = i \mod s'$ and 0 otherwise. We compute by integer matrix multiplications $D_i = D'_i \cdot A$ and $N_i = A_i \cdot A$. Notice that $D_i(u,v) = \sum_{w \in N^i_{uv}} D'_G(u,w)$ and that $N_i(u,v) = |N^i_{uv}|$. This concludes the correctness of the algorithm.

By Lemma 12 the symmetry parameter of the graph can be obtained in $O(n^\omega \log n)$ time. The time to compute $A^{s'}$ is $O(s \cdot n^\omega)$. The time to compute a specific $r_{uv} = i \mod s'$ ($1 \leq i \leq s'$) is also $O(n^\omega)$, therefore, the total running time for a recursive invocation is $(s'+1) \cdot O(n^\omega)$. Since G is an unweighted graph, its diameter is at most $n-1$, and hence we have at most $O(\log_{s'} n)$ recursive invocations. The total time of the algorithm, therefore, is $O(s \cdot n^\omega \log_{s'} n)$. ◀

4 Extending to general directed graphs

As noted earlier, Algorithm 2 works only on strongly-connected graphs, where $s(G)$ is well-defined. Nevertheless, as we shall see here, it is possible to reduce any directed unweighted graph to a directed strongly-connected unweighted graph, where our parameterized-APSP can be applied. Let $G = (V, E)$ be our graph. Let $Diam(G) = \max_{u,v \in V} \{d_G(u, v) \mid d_G(u, v) < \infty\}$ be the diameter of the graph G. In the reduced graph G', we will have $s(G') \leq Diam(G) + 1$.

The reduction is done as follows. Let $G = (V, E)$, and let $d = Diam(G)$. First we build a new directed graph $G' = (V', E')$. The graph G' is initially a copy of G. Next, we add to G' new vertices $v_1, v_2, \dots, v_d$, and the edges (v_i, v_{i+1}), where $1 \leq i \leq d - 1$, and the edge (v_d, v_1). We also add for each vertex $v \in V$ the edges (v, v_1) and (v_d, v).

We can apply on G' our parameterized APSP of Theorem 8.

From our construction $s(G') \leq d + 1$. To see that, first notice that the new vertices $v_1, v_2, \dots, v_d$ are connected by a cycle of length $d - 1$, therefore, for the edges (v_i, v_{i+1}), where $1 \leq i \leq d - 1$, and the edge (v_d, v_1) the symmetry parameter is $d - 2$. Let $v \in V$, the edges (v, v_1) and (v_d, v) are contained in the cycle $v \to v_1 \to v_2 \to \cdots \to v_d \to v$, thus the symmetry parameter of the edges (v, v_1) and (v_d, v) for every $v \in V$ is d. Also, for an edge $(u, v) \in E$ we have the path $\langle v, v_1, v_2, \dots, v_d, u \rangle$ of length $d + 1$. The insertion of the new edges to G may shorten the distance between vertices that were originally in G. However, it is easy to see that any path in G' between two vertices from G, that uses at least one of the new edges, must has a length of at least $d + 1$. Since the original diameter of G is d, this implies that for every $u, v \in V$, if $d_{G'}(u, v) \leq d$ then $d_{G'}(u, v) = d_G(u, v)$, otherwise, if $d_{G'}(u, v) > d$ then $d_G(u, v) = \infty$.

The diameter can be computed, using repeated squaring, in $O(n^\omega \log n)$ time. The time to construct G' and to compute the distances of G from the distances of G' is bound by $O(n^2)$. Thus the total time of the reduction is $O(n^\omega \log n)$.

Any algorithm that computes APSP must take $\Omega(n^\omega)$ time (otherwise matrix multiplication can be computed faster), therefore, using the reduction above, we can convert any algorithm that computes APSP for strongly-connected directed graphs in $T(n)$ time into algorithm that computes $T(2n) + O(n^\omega \log(n)) = O(T(n) \log(n))$ time general directed graphs.

5 A hybrid APSP algorithm for directed graphs

As shown, the efficiency of our parameterized-APSP algorithm strongly depends on the symmetry parameter of the input graph. Since by the definition of the parameter, the *maximum* is taken over all the edges of the graph, even a single edge might cause the parameter of the graph to be large.

Recall that for a threshold value $z < s(G)$ of a directed strongly-connected graph G, an edge (u, v) is z-violating edge, if $d(v, u) > z$. We now show that our algorithm can be easily modified such that even if a graph holds to have $o(n^{0.53})$ edges that are $o(n^{0.16})$-violating, the modified algorithm provides a faster algorithm than the state-of-the-art algorithm for the problem [26].

Let $\beta_z(G)$ be the number of z-violating edges in G. The following theorem gives an algorithm to compute APSP for G in a time that depends on z and $\beta_z(G)$. A pseudocode of the algorithm is also given in Algorithm 3.

▶ **Theorem 11.** *Let $G = (V, E)$ be a directed, strongly-connected graph, with a parameter $s(G)$, and let $z < s(G)$ be an integer. We can compute APSP for G in $O(zn^\omega \log n + n^2\beta_z(G))$ time.*

Proof. Let $E_z(G)$ be the set of edges in G that are z-violating. We first compute $E_z(G)$ in $O(n^\omega \log z)$ time, using Lemma 13. Let $(u, v) \in E_z(G)$, we compute in $O(m) = O(n^2)$ time BFS in and out of u and v. Next we removed from G all the edges in $E_z(G)$. Let H be the new graph after the removal of the edges. For the sake of simplicity we assume H is strongly-connected (otherwise, we can run the parameterized APSP algorithm on each of its strongly-connected components). Notice that $s(H) < z$, since we remove all the edges that violate the threshold, and any non-violating edge must participates in a cycle such that all its edges are non-violating edges (thus removing the violating edges would not affect a non-violating edge). Therefore, we compute in $O(zn^\omega \log n)$ time the distances of H. If a shortest path from u to v in G contains an edge (p, q) from $E_z(G)$, we can find the distance in $|E_z(G)| = \beta_z(G)$ time by taking the minimum from $min_{(p,q)\in E_z(G)}\{d(u, p) + d(q, v) + 1\}$ (the distances $d(u, p)$ and $d(q, v)$ are obtained from the in and out BFS computed for all the endpoints in $E_z(G)$). Otherwise, $d(u, v) = d_H(u, v)$. The time for this step is $O(n^2\beta_z(G))$ and the total time for this algorithm is $O(zn^\omega \log n + n^2\beta_z(G))$. ◀

Since the reduction to strongly-connected graph and the computation of the z-violating edges takes $O(n^\omega \log n)$ time, this leads us to the following hybrid approach. Reduce the graph to strongly-connected and compute the violating edges for z such that it gives faster running time than the current known fastest algorithm for the problem. If the number of violating edges does not exceed the threshold, use Algorithm 3, otherwise use the fastest known algorithm for the problem. Unless an $O(n^\omega \log n)$-time algorithm for the problem is found, this hybrid approach may provide a faster running time for some instances of the problem.

5.1 Fast computation of the parameter and the violating edges

Our algorithms need to know the symmetry parameter of the graph. We show in the next lemma how to compute this parameter in $O(n^\omega \log n)$ time.

▶ **Lemma 12.** *Let $G = (V, E)$ be a directed strongly-connected graph with symmetry parameter $s(G)$. We can compute $s(G)$ in $O(n^\omega \log n)$ time.*

Proof. Denote $D_G = (A_G \bigvee I)$. Compute $D_G, D_G^2, D_G^4, \ldots, D_G^{2^{\log n}}$ using repeated squaring. Let k be the first value in $\{0, \ldots, \lceil \log n \rceil\}$ such that $D_G^{2^k}(v, u) = 1$ for every $(u, v) \in E$. If $k = 0$, then $s(G) = 1$. Otherwise, by Proposition 4 it must be that $s(G) \in [2^{k-1}, 2^k]$. By setting $s'(G) = 2^k$, we have a 2-approximation for $s(G)$. We need only $\lceil \log n \rceil$ matrix multiplication to compute $D_G, D_G^2, D_G^4, \ldots, D_G^{2^{\log n}}$, thus the time for this is $O(n^\omega \log n)$.

Now, we show how to compute $s(G)$ exactly. We have $s(G) \in [2^{k-1}, 2^k]$, we perform a binary search for $s(G)$ in the range $[2^{k-1}, 2^k]$. Let $[a, b]$ $(a < b)$ be the current range, we compute D_G^c for $c = \frac{a+b}{2}$. We check if $D_G^c(v, u) = 1$ for every $(u, v) \in E$. If it is true, we continue the search in the range $[a, c]$, otherwise we continue the search in the range $[c, b]$. There are $O(\log n)$ steps in the binary search. We can compute D_G^c by using only 2 matrix multiplications. To see this, notice first, that since we do our binary search on $[2^{k-1}, 2^k]$, it follows, that at any stage of the binary search, $(b - a)/2$ is a power of 2. Since $c = \frac{a+b}{2} = a + \frac{(b-a)}{2}$, we have that $D_G^c = D_G^a \cdot D_G^{2^j}$ (for some $j \leq k$), where D_G^a and $D_G^{2^j}$ were already computed. This concludes that the total time to compute $s(G)$ exactly is $O(n^\omega \log n)$. ◀

Similarly, we find all z-violating edges for a $z < n$ in time $O(n^\omega \log z)$, by computing D^z_G and returning all the edges $(u, v) \in E$ such that $D^z_G(v, u) = 0$. The statement is given in the following lemma.

▶ **Lemma 13.** *Let $G = (V, E)$ be a directed strongly-connected graph, and let $z < n$ be an integral value. We can find all z-violating edges for a $z < n$ in $O(n^\omega \log z)$ time.*

Abstract

We study the ONLINE BUDGETED MAXIMUM COVERAGE (OBMC) problem. Subsets of a weighted ground set U arrive one by one, where each set has a cost. The online algorithm has to select a collection of sets, under the constraint that their cost is at most a given *budget*. Upon arrival of a set the algorithm must decide whether to accept or to reject the arriving set, and it may also drop previously accepted sets (preemption). Rejecting or dropping a set is irrevocable. The goal is to maximize the total weight of the elements covered by the sets in the chosen collection.

We present a deterministic $\frac{4}{1-r}$-competitive algorithm for OBMC, where r is the maximum ratio between the cost of a set and the total budget. Building on that algorithm, we then present a randomized $O(1)$-competitive algorithm for OBMC. On the other hand, we show that the competitive ratio of any deterministic online algorithm is $\Omega(\frac{1}{\sqrt{1-r}})$.

We also give a deterministic $O(\Delta)$-competitive algorithm, where Δ is the maximum weight of a set (given that the minimum element weight is 1), and if the total weight of all elements, $w(U)$, is known in advance, we show that a slight modification of that algorithm is $O(\min\{\Delta, \sqrt{w(U)}\})$-competitive. A matching lower bound of $\Omega(\min\{\Delta, \sqrt{w(U)}\})$ is also given.

Previous to the present work, only the unit cost version of OBMC was studied under the online setting, giving a 4-competitive algorithm [36]. Finally, our results, including the lower bounds, apply to REMOVABLE ONLINE KNAPSACK which is the preemptive version of the ONLINE KNAPSACK problem.

1 Introduction

The BUDGETED MAXIMUM COVERAGE problem (abbreviated BMC) is the dual of the classical SET COVER problem. In SET COVER the input consists of a collection of sets $\mathcal{S} = \{S_1, \ldots, S_m\}$ over the ground set $U = \{u_1, \ldots, u_n\}$ with cost for each set, and the goal is to find a sub-collection of sets of minimal cost, whose union covers all the elements in the ground set. In BMC we are, in addition, given weights for the elements and a budget cap B. The goal is to find a subcollection of the sets that maximizes the total weight of the union

of those sets, under the constraint that the total cost of the subcollection is at most B. In other words, the goal is to find a subcollection that maximizes coverage given a knapsack constraint. In fact the KNAPSACK problem can be viewed as the special case of BMC in which the sets are pairwise disjoint.

In the ONLINE BUDGETED MAXIMUM COVERAGE problem (OBMC) sets arrive online and the goal of an online algorithm for this problem is to find (in an online manner) a sub-collection of the sets, that maximizes the weight of the covered items, while adhering to the budget constraint. Preemption of previously used sets is allowed, but a preempted (or rejected at arrival) set cannot be used again later. Preemption is necessary in order to achieve an unbounded competitive ratio, for this problem, by a deterministic or randomized online algorithm. BMC has many applications both in its offline and online versions, such as facility location [32, 8, 7], where the budget is the number of facilities, and web streaming [36], where the budget is the number (or total size) of web objects that can be stored in memory.

The BUDGETED MAXIMUM COVERAGE problem, as well as its dual problem, the SET COVER problem, both in their weighted (general costs) and unweighted (unit costs) versions, are fundamental, widely studied problems (cf. [23, 40]). Even in their unweighted versions they are NP-hard problems [20], while approximation algorithms do exist for their weighted versions (with approximation ratios of $O(\log n)$ for SET COVER [13] and $\frac{e}{e-1}$ for BMC [28]). These approximation ratios are best possible unless P = NP [18, 3]. The online version of the SET COVER problem has been studied in many variants (see, e.g., [15, 2, 11, 29]). As to the OBMC problem, only the unweighted case has been studied in the online setting, where a 4-competitive deterministic algorithm is given [36].

In the present paper we give the first results for the *budgeted* (i.e., when sets have varying costs) online maximum coverage problems. We give both upper and lower bounds on the competitive ratio of deterministic and randomized algorithms for this problem, in terms of a number of parameters of the instance.

1.1 Our Contributions

We present a deterministic $\frac{4}{1-r}$-competitive algorithm, where $r \triangleq \max_i \frac{c(S_i)}{B}$ is the maximum fraction of the budget needed for any single set. Our algorithm is inspired by the online algorithms for the case of unit costs [36, 4]. However, several new ideas are needed to cope with general costs, such as working with a fractional solution in the background and rounding it in an online manner to an integral solution while incurring only a small penalty. Furthermore, the natural algorithm, that results from reducing the weighted (set costs) case to the unit cost case by duplicating the sets, does not necessarily yield fractional solutions that can be readily converted to integral ones (i.e., many sets could be used only fractionally). Instead, we give an online algorithm for the weighted fractional setting that computes a solution which has at most one set used fractionally. Such solution can be converted to an integral one in an online manner while incurring only a small penalty (a $1/(1-r)$ factor).

On the negative side, we show that the competitive ratio of any deterministic online algorithm for OBMC must depend on r, by showing a lower bound of $\Omega(\frac{1}{\sqrt{1-r}})$. Building on our deterministic algorithms we then also give an $O(1)$-competitive randomized algorithm for OBMC.

We further give a deterministic $(\Delta + 2)$-competitive algorithm for OBMC, where $\Delta \triangleq \max_{S\in\mathcal{S}} w(S)$ is the maximum weight of a set (defined under the assumption that all element weights are at least 1). Note that for unit weights we have that Δ is the maximum set size. If $w(U)$, i.e., the total weight of all elements in the ground set, is known in advance, we show that a slight modification of that algorithm is $O(\min\{\Delta, \sqrt{w(U)}\})$-competitive. We give a matching lower bound, namely that the competitive ratio of any deterministic online algorithm for OBMC is $\Omega(\min\{\Delta, \sqrt{w(U)}\})$, even for the special case of unit weights. Note that $w(U) = n$ in the unit weights case.

We note that by applying our deterministic upper bounds to the special case of OBMC in which the sets are pairwise disjoint, we obtain results for the Removable Online Knapsack problem. This problem is the version of Online Knapsack in which preemption is allowed. Furthermore, our deterministic lower bounds apply to this problem since they can be obtained using constructions containing pairwise disjoint sets.

Due to lack of space some of the proofs are omitted from this extended abstract.

1.2 Related Work

In the Maximum Coverage problem the goal is, given an integer parameter k, to cover as many elements as possible, using at most k sets. In this case the natural greedy algorithm computes solutions whose weight is within a factor of $1-(1-\frac{1}{k})^k > 1-\frac{1}{e}$ from the optimum (see [33, 24, 23]). This ratio holds even in the more general case of nonnegative, nondecreasing, submodular set function maximization [34, 19].[1] Khuller, Moss and Naor [28] showed that Maximum Coverage cannot be approximated to within a factor better than $\frac{e}{e-1}$, unless NP $\subseteq$ DTIME$(n^{O(\log\log n)})$. Feige [18] did the same under the weaker assumption of P$\neq$NP. Ageev and Sviridenko [1] presented an approximation algorithm for Maximum Coverage that computes solutions whose weight is within a factor of $1-(1-\frac{1}{\Delta})^{\Delta}$ from the optimum, where Δ is the maximum size of a set. Buchbinder et al. [9] studied submodular maximization with cardinality constraints which contain Maximum Coverage as a special case. Khuller et al. [28] showed that BMC can be approximated to within $\frac{e}{e-1}$. Sviridenko [38] extended this result to maximization of a monotone submodular set function subject to a budget constraint.

Saha and Getoor [36] presented a deterministic 4-competitive algorithm for the Online Maximum Coverage problem. Ausiello et al. [4] analyzed a variant of the above algorithm and showed that its competitive ratio is strictly less than 4, but that it tends to 4 as k increases. They also considered the special case of Online Maximum Coverage in which vertices are used to cover edges (i.e., an element appears in exactly two sets) and provided a simple deterministic 2-competitive algorithm for the latter that simply chooses the k largest sets seen so far. Ausiello et al. [4] also gave lower bounds 2 and $\frac{3}{2}$ for Online Maximum Coverage and for that special case, respectively, on the competitive ratio of any deterministic online algorithm. Ashwinkumar [39] and Chakrabarti and Kale [12] presented streaming 4-approximation algorithms for maximizing a monotone submodular function subject to cardinality constraint. Buchbinder, Feldman, and Schwartz [10] provided constant competitive ratio algorithms for online submodular maximization with preemption and a cardinality constraint. They also gave a deterministic 4-competitive algorithm for the monotone case.

We note that Awerbuch et al. [5] studied a problem they called Online Set Cover. However they actually consider a variant of Online Maximum Coverage in which the elements arrive in an online manner, and the sets are revealed during this process. The goal is to cover as many elements as possible using k sets without preemption, where an element is considered covered only by a set that contains it which is added to the solution after the

[1] A function f is called submodular if $f(T)+f(T') \geq f(T \cup T') + f(T \cap T')$ for every two sets T and T' in the domain of f.

arrival of the element. Awerbuch et al. [5] gave a randomized $O(\log n \log \frac{m}{k})$-competitive algorithm for this problem.

The dual of Maximum Coverage is the classical Set Cover problem. For the unweighted Set Cover problem, Johnson [27] and Lovász [30] showed that the greedy algorithm is an H_Δ-approximation algorithm, where H_n the nth harmonic number. This result was generalize by Chvátal [13] to the weighted case. Feige [18] proved a lower bound of $(1 - o(1)) \ln n$ on the approximability of that problem (unless NP $\subseteq$ DTIME$(n^{O(\log\log n)})$). In [35, 3] it was shown that Set Cover cannot be approximated within a factor of $c \log n$, for some $c > 0$, unless P=NP. Set Cover can also be approximated to within a factor of $\Delta_U \triangleq \max_{u \in U} |\{S : u \in S\}|$ [22, 6]. However, it is NP-hard to approximate it within $\Delta_U - 1 - \varepsilon$, for any $\varepsilon > 0$, assuming $\Delta_U > 2$ [16], or within 1.36 for $\Delta_U = 2$ [17].

A certain online version of Set Cover was studied by Alon et al. [2]. In this problem the sets are known in advance, subsets of the elements arrives in an online manner, and the goal is to cover all seen elements with a sub collection of sets of minimal cardinality. A deterministic $O(\log m \log n)$-competitive algorithm and a nearly matching lower bound are given in [2] (n is the number of elements and m the number of sets).

Knapsack is a special case of BMC in which the sets are pairwise disjoint. Knapsack is known to be NP-hard, but admits an FPTAS [37, 25]. Removable Online Knapsack (ROK) is a special case of OBMC in which the sets are pairwise disjoint. In other words, in ROK items arrive one by one, each with its load and value. An online algorithm is required to accept or to reject an incoming item upon arrival, and it is allowed to drop previously accepted items to make room for a new item. The goal is to maximize the value accrued by the accepted items, under the constraint that their total load is within a given maximum load. Iwama and Taketomi [26] considered the special case of ROK in which the value of and item is equal to its load. They provided a deterministic competitive algorithm whose ratio is $\frac{\sqrt{5}+1}{2} \approx 1.62$, and a matching lower bound. Han, Kawase, and Makino [21] and Cygan, Jeż, and Sgall [14] gave a randomized 2-competitive algorithm and showed that the competitive ratio of any randomized online algorithm is at least $\frac{e+1}{e}$. Both lower bounds apply to OBMC. Non-removable Online Knapsack is the variant in which accepted items cannot be dropped. In this case the deterministic [31] and randomized [41] competitive ratios are known to be unbounded.

1.3 The Model

An instance of the BMC problem is composed of a weighted ground set $U = \{u_1, \ldots, u_n\}$, with each element having a known weight $w(u_i) \geq 1$ (we define all weights to be at least 1 to avoid arbitrary scaling of the weights). The instance is further composed of a collection $\mathcal{S} = \{S_1, \ldots, S_m\}$ of sets, where $S_i \subseteq U$, for every i. The cost of a set S_i is denoted $c(S_i)$. W.l.o.g. we assume that the budget cap is 1, and therefore $0 < c(S_i) \leq 1$, for every i.

In OBMC the sets of $\mathcal{S}$ arrive online, where each set S_i is given by the elements that it contains, as well as its cost, $c(S_i)$. When a set arrives the online algorithm has to decide whether to *accept* it or to *reject* it, under the constraint that the currently accepted sets at any given time should have a cumulative cost not larger than 1. The algorithm can *drop* a previously accepted set, i.e., extract it from the currently accepted sets. However, a rejected or dropped set cannot later be re-accepted. The goal of the online algorithm is to maximize the total weight of the elements covered by the accepted sets.

Given a set $S \subseteq U$, we define its weight to be $w(S) = \sum_{u \in S} w(u)$. Given a sub-collection $\mathcal{C} \subseteq \mathcal{S}$, we define its cost to be $c(\mathcal{C}) = \sum_{S \in \mathcal{C}} c(S)$. Given an instance of the OBMC problem we define $\Delta \triangleq \max_{S \in \mathcal{S}} w(S)$, i.e., the maximum weight of a set. Note that for unit weights we have $\Delta = \max_{S \in \mathcal{S}} |S|$. Further we define $r \triangleq \max_i c(S_i)$ to be the maximum cost of a set.

2 Deterministic Lower Bound

In this section we give lower bounds on the competitive ratio of deterministic online algorithms for OBMC in terms of three parameters: the number of elements n, the weight of the heaviest set, Δ, and the maximum cost of a set, r.

We start with our lower bound in terms of n and Δ.

▶ **Theorem 1.** *The competitive ratio of any deterministic online algorithm for OBMC is* $\Omega(\min\{\sqrt{n}, \Delta\})$.

Proof. Let ALG be any deterministic online algorithm for OBMC. Consider an input sequence containing a collection of subsets of a ground set U that contains (at most) k^2 unit weight elements, for an arbitrary integer k. We define the input sequence given by an adversary. The input sequence starts with a set S_0, where $S_0 = \{u_1, \dots, u_k\}$ and $c(S_0) = 1$. If ALG does not accept S_0, then the sequence terminates. Otherwise, the sequence continues with $S_1, S_2, \dots$, such that $S_i = \{u_i\}$ and $c(S_i) = 1/k^2$, for $i \geq 1$, until either ALG drops S_0 or $i = k^2$.

To analyze the competitive ratio of ALG, note that there are three options as to the actual input sequence given by the adversary:

- If ALG rejects S_0, then OPT covers k elements using S_0 while ALG covers nothing.
- If ALG accepts S_0 and when S_i, for some $i \geq 1$, arrives, ALG drops S_0 and (possibly) accepts S_i, then OPT covers k elements using S_0, while ALG covers at most one element.
- If ALG accepts S_0 and never drops it, then ALG covers k elements, while OPT covers k^2 elements using $S_1, \dots, S_{k^2}$.

Hence the competitive ratio of ALG is at least k, and the theorem follows, since $k = \sqrt{n}$ and $k = \Delta$. ◀

A similar construction works for r as well.

▶ **Theorem 2.** *The competitive ratio of any deterministic online algorithm for OBMC is* $\Omega(1/\sqrt{1-r})$. *In particular, if* $r = 1$ *the competitive ratio of any deterministic algorithm is unbounded.*

Proof. The theorem clearly holds for $r \leq \frac{8}{9}$, so we assume for the rest of the proof that $r > \frac{8}{9}$. If $r < 1$, let k be a positive integer such that $\frac{1}{2} \cdot \frac{1}{\sqrt{1-r}} \leq k \leq \frac{1}{\sqrt{1-r}}$. There exists such a k, since $\frac{1}{2} \cdot \frac{1}{\sqrt{1-r}} \geq 1.5$. Also, note that $r + \frac{1}{k^2} \geq r + (1-r) > 1$ and that $\frac{1}{k^2} \leq 4(1-r) \leq \frac{4}{9} < r$. We use the same adversary that is used in Theorem 1 with k defined as above, with $c(S_0) = r$, and with $c(S_i) = 1/k^2$, for $i \geq 1$. The rest of the proof is similar to the proof of Theorem 1, showing that the competitive ratio is $k = \Theta(1/\sqrt{1-r})$.

If $r = 1$, we can pick an arbitrarily large positive integer k, which then shows that the competitive ratio is unbounded. ◀

We can conclude with the following theorem.

▶ **Theorem 3.** *Let* ALG *be a c-competitive deterministic online algorithm for OBMC. Then* $c = \Omega(\min\{\sqrt{n}, \Delta, \frac{1}{\sqrt{1-r}}\})$.

We note that the above constructions can be slightly modified to consist of pairwise disjoint sets.

▶ **Theorem 4.** *Let* ALG *be a c-competitive deterministic online algorithm for* REMOVABLE ONLINE KNAPSACK. *Then* $c = \Omega(\min\{\sqrt{n}, \Delta, \frac{1}{\sqrt{1-r}}\})$.

3 $O(\frac{1}{1-r})$-competitive Algorithm

In this section we present a deterministic $\frac{4}{1-r}$-competitive algorithm for OBMC. In what follows we assume that $r < 1$. Otherwise, the competitive ratio of any deterministic algorithm is unbounded (see Theorem 2).

Roughly speaking, our algorithm is inspired by the online algorithm for the case of unit costs [36]. We use a similar greedy rule: a set joins the solution if its marginal benefit, with respect to the current solution, is high enough. However, in contrast to the unit cost algorithm, we sort the sets in the current solution by cost effectiveness (to be defined later), and consider only sets that are contained in the prefix of the sets of the current solution which sums to a cost of at most 1. This prefix may be fractional, namely there may be a set that is only partly considered, which then complicates both the algorithm and the analysis. In what follows we define some notations and then present formally the algorithm.

Definitions and notations

Our algorithm is defined based on an imaginary fractional solution to the problem that we maintain throughout receiving the input. In this fractional solution, the algorithm can use only a fraction $x(S) \in [0,1]$ of a given set S, paying only $x(S) \cdot c(S)$, and covering by set S at most an $x(S)$ fraction of every element $v \in S$. This fractional solution can be defined using the following variables. In what follows we refer by *time* i to the time *after* the algorithm has processed the ith input set. A variable with a subscript i refers to the value of the variable at time i.

- $x_i(S) \in [0,1]$, for $S \in \mathcal{S}$, is the fraction of set S used by the algorithm at time i.
- $z_i(v,S) \in [0,1]$, for $S \in \mathcal{S}$ and $v \in U$, is the fraction of v that is covered by the algorithm using set S at time i. We set $z_i(v,S) = 0$ if $v \notin S$.

We further define, given any $\vec{z}_i$, for $v \in U$, $\hat{z}_i(v) \triangleq \sum_{S\in\mathcal{S}} z_i(v,S)$.

The (fractional) optimization problem can now be defined by the following linear program:

$$\begin{array}{lll}
\max & \sum_{v\in U} \hat{z}(v)\cdot w(v) & \\
\text{s.t.} & \sum_{S\in\mathcal{S}} x(S)\cdot c(S) \le 1 & \\
& \hat{z}(v) \le 1 & \forall v \in U \\
& z(v,S) \le x(S) & \forall v \in U, S \in \mathcal{S}, \\
& x(S) \in [0,1] & \forall S \in \mathcal{S} \\
& z(v,S) \ge 0 & \forall v \in U, S \ni v \\
& z(v,S) = 0 & \forall v \in U, S \not\ni v
\end{array}$$

Before presenting the algorithm we need the following further notations.

- $w(\vec{z}) \triangleq \sum_v \hat{z}(v)w(v)$, i.e., the total weight covered in a solution defined by the matrix $\vec{z}$.
- $\rho(\vec{z},\vec{x},S) \triangleq \frac{\sum_v z(v,S)w(v)}{x(S)c(S)}$, if $x(S) > 0$, and $\rho(\vec{z},\vec{x},S) \triangleq 0$, otherwise. That is, $\rho(\vec{z},\vec{x},S)$ stands for the total weight covered by set S in a solution defined by the matrix $\vec{z}$, divided by the "actual cost" paid for S. We call this quantity the *efficiency* of set S with respect to the solution $(\vec{z},\vec{x})$.

3.1 The Algorithm

Our algorithm maintains two variables z and x, corresponding to the variables by the same names described above, and which represent a current fractional (imaginary) solution held by the online algorithm. As the algorithm is an online algorithm, we allow it to increase $z(\cdot,S)$ and $x(S)$ only when set S arrives.

Algorithm 1: insert(S, x, z)

```
1  $x' \leftarrow x$; $z' \leftarrow z$
2  $x'(S) \leftarrow 1$
3  foreach $v \in U$ do $z'(v,S) \leftarrow \begin{cases} 1 - \hat{z}'(v) & v \in S, \\ 0 & v \notin S \end{cases}$
4  $\hat{\mathcal{S}} \leftarrow \{S : x'(S) > 0\}$ ; $\ell \leftarrow |\hat{\mathcal{S}}|$
5  Order the sets in $\hat{\mathcal{S}}$ by non-increasing value of $\rho(\vec{z'}, \vec{x'}, S)$; let $S_{j_1}, S_{j_2}, \ldots, S_{j_\ell}$ be the
     ordering.
6  $k \leftarrow \max\left\{k' \leq \ell : \sum_{i=1}^{k'-1} x'(S_{j_i})c(S_{j_i}) < 1\right\}$
7  $\chi \leftarrow \min\left\{\frac{1-\sum_{i=1}^{k-1} x'(S_{j_i})c(S_{j_i})}{c(S_{i_k})}, x'(S_{i_k})\right\}$
8  foreach $v \in S_{i_k}$ do $z'(v, S_{i_k}) \leftarrow \frac{\chi}{x'(S_{i_k})} \cdot z'(v, S_{i_k})$
9  $x'(S_{i_k}) \leftarrow \chi$
10 for $i = k+1$ to $\ell$ do
11     $x'(S_{j_i}) \leftarrow 0$
12     foreach $v \in U$ do $z'(v, S_{j_i}) \leftarrow 0$
13 return $(x', z')$
```

Algorithm 2: α**-greedy**; operations when set S_i arrives.

```
1  $x'(S_i) \leftarrow 1$
2  $z'(v, S_i) \leftarrow \begin{cases} 1 - \hat{z}(v) & \text{if } v \in S_i \\ 0 & \text{otherwise} \end{cases}$
3  if $\rho(\vec{z'}, \vec{x'}, S_i) > \alpha \cdot w(z)$ then $(x, z) \leftarrow \text{insert}(S_i, x, z)$
```

We first define a procedure **insert** that we use in the algorithm. This procedure takes a set S and inserts it into the current solution represented by the variables z and x. This changes the values of z and x to represent the new solution.

We can now define the online algorithm, that we call α-greedy, for any $\alpha > 1$. The optimal value for α will be defined later in the analysis.

α-greedy

We initialize the two (vector) variables $\vec{z} \leftarrow \vec{0}$, $\vec{x} \leftarrow \vec{0}$. Then, for every set S_i that arrives, we use the operations defined in the pseudocode in Algorithm 2.

At any given time, the solution held by the online (regular, integral) algorithm consists of all the sets S for which $x(S) = 1$. As we later prove, the algorithm has, at any given time, at most one set S "used fractionally", i.e., with $x(S) \in (0, 1)$.

We claim that the algorithm is a well defined online algorithm for our problem. That is, that (1) the algorithm accepts a set only when this set arrives, i.e., a set that is not accepted when it arrives, or accepted but subsequently dropped, cannot later be part of the solution; and (2) the solution held by the algorithm at any given time is feasible, i.e., the total budget used by the algorithm is at most 1 at any given time. To see these two points observe that all the changes in the variables held by the algorithm are done in procedure **insert**. Procedure **insert** assigns a value of 1 to variable $x'(S)$, only for S which is the inserted set: an explicit assignment of 1 is only done in Line 1, and in Line 9 the value of $x'(S_{i_k})$ cannot grow compared to the previous round. This proves point (1). Point (2) requires a bit more of formalism, which is given in the proof of the following lemma.

▶ **Lemma 5.** *For any time i, $\sum_{j\in O_i} c(S_j) \le 1$, where $O_i = \{j : x_i(S_j) = 1\}$.*

Proof. We prove this lemma by induction on i. For the base of the induction, i.e., when $i = 0$, we have that $\vec{x}_0 = \vec{0}$. It follows that $O_0 = \emptyset$ and we are done. For the inductive step, we assume that the claim is true for $i - 1$, for $i \ge 1$ and prove it for i. If **insert** is not called during iteration i, then $x_i = x_{i-1}$ and $O_i = O_{i-1}$, and the claim follows from the inductive hypothesis. If **insert** is activated, then x_i is constructed such that $x_i(S_{j_i}) = 0$ if $j_i > k$ and $\sum_{i=1}^{k} x_i(S_{j_i})c(S_{j_i}) \le 1$. Hence $\sum_{j\in O_i} c(S_j) \le 1$. ◀

We now give two technical claims which we use in the analysis. The first claim is immediate from the code of **insert**.

▶ **Claim 6.** *The efficiency of a given set S remains the same throughout the period when $x(S) > 0$.*

The next claim says that at any time i, there may be at most one set S such that $x(S) \in (0, 1)$, and that if such set exists then the whole budget is used. Furthermore, if such set exists then that set is the one with minimum efficiency among the sets with non-zero x-coefficient. We note that these properties of our algorithm are the properties that allow one to obtain in an online manner an integral solution, and that a simple, natural reduction of the weighted fractional case to the unweighted case does not yield an algorithm with such properties.

▶ **Claim 7.** *Let $\mathcal{S}_i^+ = \{S : x_i(S) > 0\}$. There is at most one set $S \in \mathcal{S}^+$ such that $x(S) < 1$. If such a set S exists then (1) $\sum_{S\in\mathcal{S}_i^+} x_i(S)c(S) = 1$; and (2) $\rho(\vec{z}_i, \vec{x}_i, S) \le \rho(\vec{z}_i, \vec{x}_i, S')$, for any $S' \in \mathcal{S}^+ \setminus \{S\}$.*

Proof. We prove the claim by induction on i. For the basis of the induction, i.e., for $i = 0$, the claim is trivial in the empty sense. We now assume that the claim holds for $i - 1$, for $i \ge 1$, and we prove it for i.

If **insert** is not invoked during iteration i, then the claim clearly holds by the induction hypothesis. If procedure **insert** is invoked we have that (according to Line 3 of α-greedy)

$$\rho(z', x', S_i) > \alpha \cdot w(z_{i-1}) = \alpha \cdot \sum_{S\in\mathcal{S}_{i-1}^+} \rho(\vec{z}_{i-1}, \vec{x}_{i-1}, S) \cdot x_{i-1}(S) \cdot c(S) \ .$$

We now consider two cases. The first case is when a set S with $x_{i-1}(S) \in (0, 1)$ exists. In that case, by the induction hypothesis we have that $\sum_{S\in\mathcal{S}_{i-1}^+} x_{i-i}(S)c(S) = 1$. It follows that $\rho(z', x', S_i) > \min_{S\in\mathcal{S}_{i-1}^+}\{\rho(\vec{z}_{i-1}, \vec{x}_{i-1}, S)\}$ (recall that $\alpha > 1$), and therefore the new set S_i is not the last set in the non-increasing order of efficiency defined in Line 5 of procedure **insert**. Points (1) and (2) for time i therefore follow from the code of **insert** and the induction hypothesis of point (2). The second case is when there is no set S with $x_{i-1}(S) \in (0, 1)$. In that case the code of **insert** directly guarantees both points (1) and (2) for time i. ◀

3.2 Competitive Analysis

We analyze the competitive ratio of the algorithm using a charging scheme argument. We first describe the scheme in general terms – more details are given in the following paragraphs. Let OPT be an optimal solution, i.e., an optimal collection of sets. As the sets of OPT arrive, each new element u that is covered by OPT is allotted $w(u)$ monetary units (or simply money). We show that the allotted money can be moved between elements of U such that all the money is allotted to the items covered by ALG, and such that each element v that is covered by ALG has at most $\frac{4}{1-r} \cdot w(v)$ amount of money. This gives an upper bound of $\frac{4}{1-r}$ on the competitive ratio.

We now formally define the charging scheme. Let $\text{OPT}_k = \text{OPT} \cap \{S_1, \ldots, S_k\}$. If $S_i \in \text{OPT}$, let $F_i \triangleq S_i \setminus \cup_{S \in \text{OPT}_{i-1}} S$, i.e., F_i contains all the elements covered by OPT that, when S_i arrives, are covered for the first time by OPT (according to the order of arrival of the sets). When a set $S_i \in \text{OPT}$ arrives, each element $u \in F_i$ is allotted $w(u)$ money. The money that is allotted this way is always held by items covered by ALG, and may sometimes be moved between items covered by ALG; furthermore this money is partitioned into *blue money* and *red money*. We will denote by $\text{blue}_i(v)$ and by $\text{red}_i(v)$ the amount of blue and red money, respectively, held by $v \in U$ at time i.

Now, the rules that govern the allotment and movement of the money are the following rules, applied when a set S_i arrives.

- **Transfer of money**. This rule is applied if the then part of Line 3 of α-**greedy** is reached, i.e., if procedure **insert** is invoked. In this case elements that lost coverage relinquish part of their money, and this money is transferred to elements that gain coverage. Let $\hat{z}'_i(v) \triangleq \sum_{j=1}^{i-1} z_i(v, S_j)$ and $Z_i \triangleq \{v : \hat{z}'_i(v) < \hat{z}_{i-1}(v)\}$. That is, we look at the coverage of an item v by all but the last arriving set, and observe if this coverage reduced during the course of iteration i.
  1. **Out-transfer of money**. For each $v \in Z_i$ let $\delta_v = (1 - \frac{\hat{z}'_i(v)}{\hat{z}_{i-1}(v)})$. We remove from v an amount of R_v red money which is a δ_v-fraction of its current red money, and an amount of B_v blue money which is a δ_v-fraction of its current blue money.
  2. **In-transfer of money**. These total amounts of removed red and blue money are distributed to the various red and blue money variables of $u \in S_i$ proportionally to $z_i(u, S_i) \cdot w(u)$. That is, each element $u \in S_i$ gets additional $\frac{z_i(u,S_i) \cdot w(u)}{\sum_{v \in S_i} z_i(v,S_i) \cdot w(v)} \cdot \sum_{v \in Z_i} R_v$ red money, and gets additional $\frac{z_i(u,S_i) \cdot w(u)}{\sum_{v \in S_i} z_i(v,S_i) \cdot w(v)} \cdot \sum_{v \in Z_i} B_v$ blue money.
- **Creation of new money**. If $S_i \in \text{OPT}$, $w(v)$ money is distributed for each $v \in F_i$ as follows: (1) v gets $\hat{z}_i(v)w(v)$ newly created blue money; and (2) a total amount of $R_i(v) = (1 - \hat{z}_i(v))w(v)$ red money is created, and distributed among the items u currently covered by the algorithm, i.e., each element $u \in U$ gets additional red money in the amount of $R_i(v)\frac{\hat{z}_i(u)w(u)}{w(\vec{z}_i)}$ (i.e., the red money is distributed proportionally to the contribution of each element to the total weight of the current solution).

We now prove upper bounds on the amount of red and blue money held by any element at any given time. We start with a technical claim. In the next lemma we show that if S_i is accepted, then the amount of coverage provided by set S_i is more than α times the coverage lost due to the sets (or part of sets) pushed out.

▶ **Lemma 8.** *Assume that* $x_i(S_i) > 0$. *Then,*

$$\rho(\vec{z}_i, \vec{x}_i, S_i) > \alpha \cdot \frac{\sum_{j<i} \sum_{u \in U} w(u)[z_{i-1}(u, S_j) - z_i(u, S_j)]}{x_i(S_i)c(S_i)} .$$

Proof. Since $x_i(S) > 0$ we know that $\rho(\vec{z}_i, \vec{x}_i, S_i) = \frac{\sum_{u \in U}(1-\hat{z}_{i-1}(u))w(u)}{c(S_i)} > \alpha \cdot w(z_{i-1})$ and that **insert** was invoked. Consider what happens to the solution $(\vec{z}_{i-1}, \vec{x}_{i-1})$ during the invocation of **insert** at iteration i. Some sets do not lose coverage (i.e., sets S for which $x_i(S) = x_{i-1}(S) = 1$). Other sets may leave the cover and their cover is lost (i.e., $x_{i-1}(S) > x_i(S) = 0$). In addition, by Claim 7, there may be at most one set that partly leaves the cover, and so it both retains and loses coverage (i.e., $x_{i-1}(S) > x_i(S) > 0$). Define $\mathcal{Y}_i \triangleq \{S_j : x_{i-1}(S_j) > x_i(S_j)\}$, namely $\mathcal{Y}_i$ contains the sets that lose coverage due to the invocation of **insert** during the ith iteration.

If no coverage is lost during iteration i, namely if $\mathcal{Y}_i = \emptyset$ (or $Z_i = \emptyset$), then $\sum_{j<i} \sum_{u \in U} w(u)[z_{i-1}(u, S_j) - z_i(u, S_j)] = 0$, and we are done since $x_i(S) > 0$ implies that $\rho(\vec{z}_i, \vec{x}_i, S_i) > 0$.

If $\mathcal{Y}_i \neq \emptyset$, then by Claim 7 and the code of **insert** it follows that $\rho(z_{i-1}, x_{i-1}, S) \leq \rho(z_i, x_i, S')$, for every $S \in \mathcal{Y}_i$ and S' such that $x_i(S') > 0$. In words, the efficiency of the sets that retain coverage is at least as high as the efficiency of the sets that lost coverage. As mentioned above, observe that there may be at most one set S_j, such that $S_j \in \mathcal{Y}_i$ and $x_i(S_j) > 0$. Define $\rho^i_{\min} \triangleq \min\{\rho(\vec{z}_{i-1}, \vec{x}_{i-1}, S_j) : x_i(S_j) > 0, j < i\}$ and $\rho(\mathcal{Y}_i) \triangleq \max\{\rho(\vec{z}_{i-1}, \vec{x}_{i-1}, S_j) : S_j \in \mathcal{Y}_i\}$, and we have that $\rho(\mathcal{Y}_i) \leq \rho^i_{\min}$.

Define W^L_i to be the total weight of lost coverage during the ith iteration and define W^R_i to be the total weight of retained coverage at the ith iterations. That is, define: $W^L_i \triangleq \sum_{j<i} \sum_{u \in U} w(u)[z_{i-1}(u, S_j) - z_i(u, S_j)]$ and $W^R_i \triangleq \sum_{j<i} \sum_{u \in U} w(u) z_i(u, S_j)$. Observe that $w(\vec{z}_{i-1}) = W^L_i + W^R_i$. We have that $W^R_i = \sum_{j<i} \rho(\vec{z}_{i-1}, \vec{x}_{i-1}, S_j) x_i(S_j) c(S_j) \geq \rho^i_{\min} \sum_{j<i} x_i(S_j) c(S_j)$, and

$$\begin{aligned}
W^L_i &= \sum_{j<i} \rho(\vec{z}_{i-1}, \vec{x}_{i-1}, S_j)[x_{i-1}(S_j)c(S_j) - x_i(S_j)c(S_j)] \\
&= \sum_{S_j \in \mathcal{Y}_i} \rho(\vec{z}_{i-1}, \vec{x}_{i-1}, S_j)[x_{i-1}(S_j)c(S_j) - x_i(S_j)c(S_j)] \\
&\leq \rho(\mathcal{Y}_i) \sum_{S_j \in \mathcal{Y}_i} [x_{i-1}(S_j)c(S_j) - x_i(S_j)c(S_j)] \\
&= \rho(\mathcal{Y}_i) \sum_{j<i} [x_{i-1}(S_j)c(S_j) - x_i(S_j)c(S_j)] \\
&\leq \rho^i_{\min} \left[1 - \sum_{j<i} x_i(S_j)c(S_j)\right] \\
&\leq W^R_i \cdot \frac{1 - \sum_{j<i} x_i(S_j)c(S_j)}{\sum_{j<i} x_i(S_j)c(S_j)} .
\end{aligned}$$

It follows that

$$w(\vec{z}_{i-1}) = W^L_i + W^R_i \geq W^L_i + W^L_i \cdot \frac{\sum_{j<i} x_i(S_j)c(S_j)}{1 - \sum_{j<i} x_i(S_j)c(S_j)} = \frac{W^L_i}{1 - \sum_{j<i} x_i(S_j)c(S_j)} .$$

Now since $\mathcal{Y}_i \neq \emptyset$, we have that **insert** decreased coverage of at least one set and by the code of **insert** this implies that $\sum_S x_i(S)c(S) = 1$. Hence we have that $w(\vec{z}_{i-1}) \geq \frac{W^L_i}{x_i(S_i)c(S_i)}$, and the lemma follows. ◀

We are now ready to give in the next lemma an upper bound on the amount of blue money that is allotted to any element $u \in U$ at any given time.

▶ **Lemma 9.** *At any given time i and for every $u \in U$, blue$_i(u) \leq w(u)\hat{z}_i(u) \cdot \frac{\alpha}{\alpha-1}$.*

Proof. In this proof we consider separately new blue money, that was not transferred yet, and old blue money, that was transferred at least once. Observe that for each element $u \in U$

there is at most one index j such that $u \in F_j$. We denote this index by $f(u)$. We prove by induction on i that at any given time i and for every $u \in U$, we have that

1. $\text{blue-old}_i(u) \le w(u)\hat{z}_i(u) \cdot \frac{1}{\alpha-1}$, and
2. $\text{blue-new}_i(u) \le \begin{cases} 0 & i < f(u), \\ w(u)\hat{z}_i(u) & i \ge f(u). \end{cases}$

For $i = 0$, i.e., before the first input set arrives, the claims hold as there is no (blue) money. We now prove the claims for time $i \ge 1$, assuming that the claims hold for time $i-1$. We analyze the changes in $\text{blue-old}_i(\cdot)$ and $\text{blue-new}_i(\cdot)$ taking into account one by one, in their order, the operations of the charging scheme defined above. Recall that $\hat{z}'_i(v) \triangleq \sum_{j=1}^{i-1} z_i(v, S_j)$ and that $Z_i \triangleq \{v : \hat{z}'_i(v) < \hat{z}_{i-1}(v)\}$, and observe that the out-transfer and in-transfer phases are performed only if procedure **insert** is invoked.

- **Out-transfer of money**. Blue money (old or new) is removed from elements $u \in Z_i$. For such an element u we have at the end of the out-transfer phase that $\text{blue}_i(u) = \text{blue}_{i-1}(u) \cdot \frac{\hat{z}'_i(u)}{\hat{z}_{i-1}(u)}$. By the induction hypothesis this is at most

$$\text{blue-old}_i(u) \le w(u)\hat{z}_{i-1}(u) \cdot \frac{1}{\alpha-1} \cdot \frac{\hat{z}'_i(u)}{\hat{z}_{i-1}(u)} = w(u)\hat{z}'_i(u) \cdot \frac{1}{\alpha-1}$$

$$\text{blue-new}_i(u) \le w(u)\hat{z}_{i-1}(u) \cdot \frac{\hat{z}'_i(u)}{\hat{z}_{i-1}(u)} = \begin{cases} 0 & i-1 < f(u), \\ w(u)\hat{z}'_i(u) & i-1 \ge f(u). \end{cases}$$

  For $u \in U \setminus Z_i$, $\text{blue-old}_i(u) = \text{blue-old}_{i-1}(u)$ and $\text{blue-old}_i(u) = \text{blue-old}_{i-1}(u)$. Using the induction hypothesis, at the end of the out-transfer phase, the same bound holds for $u \in U \setminus Z_i$ as well.

- **In-transfer of money**. First notice that there is no in-transfer of new blue money. Each element $u \in S_i$ gets old blue money in the amount of

$$\frac{z_i(u, S_i) \cdot w(u)}{\sum_{v \in S_i} z_i(v, S_i) \cdot w(v)} \cdot \sum_{v \in Z_i} \left(1 - \frac{\hat{z}'_i(v)}{\hat{z}_{i-1}(v)}\right) \text{blue}_{i-1}(v) \ .$$

  By the inductive hypothesis this is at most

$$\frac{z_i(u, S_i) \cdot w(u)}{\sum_{v \in S_i} z_i(v, S_i) \cdot w(v)} \cdot \sum_{v \in Z_i} (\hat{z}_{i-1}(v) - \hat{z}'_i(v)) \cdot w(v) \cdot \frac{\alpha}{\alpha-1} \ ,$$

  and by Lemma 8 it follows that this is at most

$$\frac{z_i(u, S_i) \cdot w(u)}{\sum_{v \in S_i} z_i(v, S_i) \cdot w(v)} \cdot \frac{1}{\alpha-1} \cdot \rho(\vec{z}_i, \vec{x}_i, S_i)x_i(S_i)c(S_i) \ \le \ z_i(u, S_i) \cdot w(u) \cdot \frac{1}{\alpha-1} \ .$$

  Hence, using the upper bound on $\text{blue-old}_i(u)$ at the end of the out-transfer phase, we have that at the end of in-transfer phase:

$$\text{blue-old}_i(u) \le w(u)\hat{z}'_i(u) \cdot \frac{1}{\alpha-1} + w(u)z_i(u, S_i) \cdot \frac{1}{\alpha-1} = w(u)\hat{z}_i(u) \cdot \frac{1}{\alpha-1} \ .$$

  Since no transfer of new blue money occurs by the scheme, it holds at the end of the out transfer phase, like at the end of the in-transfer phase that:

$$\text{blue-new}_i(u) \le \begin{cases} 0 & i-1 < f(u), \\ w(u)\hat{z}'_i(u) & i-1 \ge f(u). \end{cases}$$

- **Creation of new money**. if $S_i \in \textsc{opt}$, then any $u \in F_i$ receives $\hat{z}_i(u)w(u)$ new blue money. Observe that for such u, $f(u) = i$. Hence, using our claims as to the end of the in-transfer phase, the inductive claim holds at the end of the creation-of-new-money phase. ◀

We now give an upper bound on the amount of red money an element may have. The proof of the following lemma is omitted from this extended abstract.

▶ **Lemma 10.** *At any given time i and for every $u \in U$, $red_i(u) \leq w(u)\hat{z}_i(u) \cdot \alpha \cdot c(\textsc{opt}_i)$.*

Using Lemmas 9 and 10 we now give a lower bound on the weight of the fractional solution $(\vec{z}, \vec{x})$.

▶ **Lemma 11.** $w(\vec{z}) \geq \frac{1}{4}w(\cup_{S\in\textsc{opt}}S)$ *at termination.*

Proof. First observe that the total amount of blue and red money created during the course of the run is equal to the weight of the elements covered by $\textsc{opt}$, and that all created money remains in the system, held by the various elements $u \in U$, until the end of the run. We therefore compare the total amount of money held at the end by the elements $u \in U$, to the weight of the elements covered by the online algorithm.

Let n be the number of sets in the input sequence. Since $c(\textsc{opt}) = c(\textsc{opt}_n) \leq 1$, we have, for $\alpha = 2$ and using Lemma 9 and Lemma 10, that for each $u \in U$, $\text{blue}_n(u) + \text{red}_n(u) \leq w(u)\hat{z}_n(u) \cdot (\alpha + \frac{\alpha}{\alpha-1}) = w(u)\hat{z}_n(u) \cdot 4$. ◀

We now give a lower bound on the weight of the (integral) solution returned by the online algorithm, in terms of the value of the fractional solution $(\vec{z}, \vec{x})$.

▶ **Lemma 12.** *Let $\textsc{alg}_i$ be the integral solution returned by the online algorithm after processing set S_i. Then, $w(\cup_{S\in\textsc{alg}_i}) \geq (1-r)\cdot w(\vec{z}_i)$.*

Proof. By definition we have that $\textsc{alg}_i = \{S : x_i(S) = 1\}$. Each such set (fully) covers all its elements, hence $w(\cup_{S\in\textsc{alg}_i}) \geq \sum_u \sum_{S\in\textsc{alg}_i} w(u)z_i(u,S)$. By Claim 7 there may be at most one set S' such that $x_i(S') \in (0,1)$. If such a set does not exists, then $w(\hat{z}_i) = \sum_u \sum_{S\in\textsc{alg}_i} w(u)z_i(u,S)$, and we are done. If there exists a set S' such that $x_i(S') \in (0,1)$, then by Claim 7 we have that $\sum_{S\in\textsc{alg}_i} c(S) = 1 - x_i(S')c(S') > 1 - c(S')$. Also, due to Claim 7, $\rho(\vec{z}_i, \vec{x}_i, S') \leq \rho(\vec{z}_i, \vec{x}_i, S)$, for any $S \in \textsc{alg}_i$. Therefore

$$\begin{aligned} w(\cup_{S\in\textsc{alg}_i}) &\geq \sum_{S\in\textsc{alg}_i}\sum_u w(u)z_i(u,S) \\ &\geq \frac{1-c(S')}{c(S')}\cdot\sum_u w(u)z_i(u,S') \\ &\geq \frac{1-r}{r}\cdot\sum_u w(u)z_i(u,S')\ . \end{aligned}$$

(Recall that r is the highest set-cost appearing in the input sequence). It follows that $w(\cup_{S\in\textsc{alg}_i}) \geq (1-r)\cdot\sum_{S\in\textsc{alg}_i\cup\{S'\}}\sum_u w(u)z_i(u,S) = (1-r)\cdot w(\vec{z}_i)$. ◀

It remains to give an upper bound on the competitive ratio of the algorithm.

▶ **Theorem 13.** *Algorithm 2-greedy is $\frac{4}{1-r}$-competitive.*

Proof. By Lemma 11 we have that $w(\vec{z}) \geq \frac{1}{4}w(\cup_{S\in\textsc{opt}}S)$ at termination. By Lemma 12 the total weight of the elements covered by the online algorithm is at least $(1-r)\cdot w(\vec{z})$. ◀

4 $O(1)$-competitive Randomized Algorithm

In this section we give a randomized online algorithm with an $O(1)$ competitive ratio. The algorithm is based on the deterministic $\frac{4}{1-r}$-competitive algorithm from Section 3.

The algorithm is a barely random algorithm that chooses to run one of the following two algorithms with probability 1/2 each:

1. Always keep a single set S_j, which is the set with the highest weight seen so far.
2. Run algorithm α-**greedy** of Section 3, with $\alpha = 2$, only on sets with cost at most $\frac{1}{3}$.

▶ **Theorem 14.** *There is a* 16*-competitive randomized online algorithm for OBMC.*

Proof. Let OPT be an optimal solution, and define $\text{OPT}_{>} = \{S \in \text{OPT} : c(S) > \frac{1}{3}\}$ and $\text{OPT}_{\leq} = \{S \in \text{OPT} : c(S) \leq \frac{1}{3}\}$. Observe that $w(\cup_{S\in\text{OPT}_{>}}S) + w(\cup_{S\in\text{OPT}_{\leq}}S) \geq w(\cup_{S\in\text{OPT}}S)$ and that $|\text{OPT}_{>}| \leq 2$. We have that at least one of the two following options must occur: (i) $w(\cup_{S\in\text{OPT}_{>}}S) \geq \frac{1}{4}w(\cup_{S\in\text{OPT}}S)$, or (ii) $w(\cup_{S\in\text{OPT}_{\leq}}S) \geq \frac{3}{4}w(\cup_{S\in\text{OPT}}S)$.

If $w(\cup_{S\in\text{OPT}_{>}}S) \geq \frac{1}{4}w(\cup_{S\in\text{OPT}}S)$, then there exists a single set in $\text{OPT}_{>}$ whose weight is at least $\frac{1}{8}w(\cup_{S\in\text{OPT}}S)$. In this case, the algorithm that keeps a single set with the maximum-weight coverage seen so far obtains a solution with weight at least $\frac{1}{8}w(\cup_{S\in\text{OPT}}S)$.

If $w(\cup_{S\in\text{OPT}_{\leq}}S) \geq \frac{3}{4}w(\cup_{S\in\text{OPT}}S)$, then α-greedy, for $\alpha = 2$, which runs only on the sets with cost at most $\frac{1}{3}$ is 6-competitive, and therefore it computes a solution whose weight is at least $\frac{1}{6}w(\cup_{S\in\text{OPT}_{\leq}}S) \geq \frac{1}{6}\cdot\frac{3}{4}w(\cup_{S\in\text{OPT}}S) = \frac{1}{8}w(\cup_{S\in\text{OPT}}S)$.

Since the algorithm chooses with equal probability $\frac{1}{2}$ each one of the two algorithms, we have that $\mathbb{E}[\text{ALG}] \geq \frac{1}{2}\cdot\frac{1}{8}\cdot w(\cup_{S\in\text{OPT}}S) = \frac{1}{16}w(\cup_{S\in\text{OPT}}S)$. ◀

5 $O(\Delta)$-competitive Algorithm

In this section we present an $O(\Delta)$-competitive algorithm for OBMC. Given an OBMC instance we define a bipartite graph $G = (\mathcal{S}, U, E)$, where $(S, u) \in E$ if and only if $u \in S$. Given a collection of sets $\mathcal{S}'$, let $G[\mathcal{S}']$ be the subgraph of G that is induced by $\mathcal{S}'$ and U. The algorithm is based on computing maximum cardinality matchings between sets ($\mathcal{S}'$, the left side of G) and elements (U, the right side of G). Let **MaxMatch** be an algorithm that solves the MAXIMUM CARDINALITY MATCHING problem in bipartite graphs.

The OBMC algorithm works as follows. Upon arrival of a set S_i, $i \geq 1$, the algorithm constructs a solution $\mathcal{S}_i$ using the previous solution $\mathcal{S}_{i-1}$ (we initialize $\mathcal{S}_0 = \emptyset$). The algorithm looks for an element to be matched to S_i, where S_i takes precedence over sets that cost more than $c(S_i)$. This is done as follows. First a maximum matching is computed for the collection of sets that includes those sets in the already-computed solution that have cost at most $c(S_i)$, and S_i. If it is impossible to match all these sets, or their total cost exceeds 1, S_i is *rejected*, and the current solution remains unchanged. Otherwise S_i is *accepted*, and all the sets in the already-computed solution that have cost at most $c(S_i)$ are not dropped. In the latter case the algorithm then tries to extend the matching by assigning an element to those sets in $\mathcal{S}_{i-1}$ that cost more than $c(S_i)$. Such a set S_j is *dropped* if a matching cannot be obtained or if the total cost exceeds 1. Algorithm 3 shows a formal pseudo-code of this algorithm.

In what follows ALG denotes the collection of sets that is output by the algorithm. We first prove that the solution is feasible.

▶ **Lemma 15.** $c(\text{ALG}) \leq 1$.

Proof. We prove by induction on i that after each iteration we have $c(\mathcal{S}_i) \leq 1$. The base case is trivial, since $\mathcal{S}_0 = \emptyset$. For the inductive step, assume that $c(\mathcal{S}_{i-1}) \leq 1$. $\mathcal{S}_i$ is initially

Algorithm 3: Match; operations when set S_i arrives.

```
1  $\mathcal{S}_i \leftarrow \{S \in \mathcal{S}_{i-1} : c(S) \leq c(S_i)\}$
2  $M \leftarrow \text{MaxMatch}(G[\mathcal{S}_i \cup \{S_i\}])$
3  if $|M| = |\mathcal{S}_i \cup \{S_i\}|$ then
4      if $c(\mathcal{S}_i \cup \{S_i\}) \leq 1$ then
5          $\mathcal{S}_i \leftarrow \mathcal{S}_i \cup \{S_i\}$; $M_i \leftarrow M$
6          $\mathcal{S}'_i \leftarrow \mathcal{S}_{i-1} \setminus \mathcal{S}_i$
7          while $\mathcal{S}'_i \neq \emptyset$ do
8              $j \leftarrow \text{argmin}_j \{c(S_j) : S_j \in \mathcal{S}'_i\}$
9              $\mathcal{S}'_i \leftarrow \mathcal{S}'_i \setminus \{S_j\}$
10             $M \leftarrow \text{MaxMatch}(G[\mathcal{S}_i \cup \{S_j\}])$
11             if $|M| = |\mathcal{S}_i \cup \{S_j\}|$ then
12                 if $c(\mathcal{S}_i \cup \{S_j\}) \leq 1$ then
13                     $\mathcal{S}_i \leftarrow \mathcal{S}_i \cup \{S_j\}$; $M_i \leftarrow M$
14     else
15         $\mathcal{S}_i \leftarrow \mathcal{S}_{i-1}$; $M_i \leftarrow M_{i-1}$
16 else
17     $\mathcal{S}_i \leftarrow \mathcal{S}_{i-1}$; $M_i \leftarrow M_{i-1}$
```

a subset of $\mathcal{S}_{i-1}$ (Line 1) and therefore it is feasible at this stage due to the inductive hypothesis. Furthermore, we add sets to $\mathcal{S}_i$ only if the budget constraint is not violated (Lines 4 and 12). ◀

We now show that the number of sets in the solution never decreases, and may increase by at most one set in any step (proof omitted from this extended abstract).

▶ **Lemma 16.** $|\mathcal{S}_{i-1}| \leq |\mathcal{S}_i| \leq |\mathcal{S}_{i-1}| + 1$, *for every* $i > 0$.

Since $|\text{ALG}| = |M_m|$ and $|M_m| \leq |\cup_{S \in \text{ALG}} S|$ we have the following observation.

▶ **Observation 17.** $|\cup_{S \in \text{ALG}} S| \geq |\text{ALG}|$.

Let OPT denote an optimal collection of sets. We partition OPT $\setminus$ ALG into two collections. Let τ be the cost of the cheapest set that was either rejected upon arrival due to the budget constraint, or dropped later due to the budget constraint. More formally, define

$$\tau_1 = \min\{\{c(S_i) : S_i \text{ was rejected by Line 4 at the } i\text{th iteration}\} \cup \{\infty\}\} ,$$
$$\tau_2 = \min\{\{c(S_i) : S_i \text{ was dropped by Line 12 at the } j\text{th iteration}\} \cup \{\infty\}\} ,$$
$$\tau = \min\{\tau_1, \tau_2\} ,$$

and define

$$\text{OPT}' = \{S \in \text{OPT} \setminus \text{ALG} : c(S) < \tau\} \quad \text{and} \quad \text{OPT}'' = \{S \in \text{OPT} \setminus \text{ALG} : c(S) \geq \tau\} .$$

The next two lemmas essentially give the upper bound on the competitive ratio of the algorithm. Their proofs are omitted from this extended abstract. The first lemma shows that the elements that are covered by the sets in OPT′ are covered by the sets in ALG. The second one shows that the size of OPT″ is bounded from above by the size of ALG.

▶ **Lemma 18.** $\cup_{S\in\text{OPT}'} S \subseteq \cup_{S\in\text{ALG}} S$.

▶ **Lemma 19.** $|\text{OPT}''| \le |\text{ALG}|$.

It remains to give an upper bound on the competitive ratio of Algorithm **Match**.

▶ **Theorem 20.** *Algorithm* ***Match*** *is* $(\Delta + 2)$*-competitive.*

Proof. We have that

$$\begin{aligned} w(\cup_{S\in\text{OPT}} S) &\le w(\cup_{S\in\text{OPT}\cap\text{ALG}} S) + w(\cup_{S\in\text{OPT}'} S) + w(\cup_{S\in\text{OPT}''} S) \\ &\le 2\cdot w(\cup_{S\in\text{ALG}} S) + w(\cup_{S\in\text{OPT}''} S) && (1) \\ &\le 2\cdot w(\cup_{S\in\text{ALG}} S) + |\text{OPT}''|\cdot\Delta && (2) \\ &\le 2\cdot w(\cup_{S\in\text{ALG}} S) + |\text{ALG}|\cdot\Delta && (3) \\ &\le (\Delta+2)\cdot w(\cup_{S\in\text{ALG}} S)\ , && (4) \end{aligned}$$

where (1) follows from Lemma 18, (2) follows from the assumption that the weight of an element is at least 1, (3) is due to Lemma 19, and (4) is due to Observation 17 and the above assumption. ◀

5.1 $w(U)$ is known in advance

We obtain a deterministic algorithm by running algorithm **Match** with the additional rule that if a set S_i with $w(S_i) \ge \sqrt{w(U)}$ arrives, then we drop all currently taken sets, take set S_i, and never change further the solution (i.e., the final output solution is $\{S_i\}$).

Observe that if there exists a set $S_i \in \mathcal{S}$ with $w(S_i) \ge \sqrt{w(U)}$, then the total weight of the elements in the sets of ALG is at least $\sqrt{w(U)}$, while the total weight of the elements in the sets of OPT is at most $w(U)$. If no such set exists then ALG is equivalent to **Match** which is $(\Delta + 2) < (\sqrt{w(U)} + 2)$-competitive. This leads to the following result.

▶ **Theorem 21.** *There exists a deterministic online algorithm whose competitive ratio is* $O(\min\{\Delta, \sqrt{w(U)}\}$*, provided that* $w(U)$ *is known in advance.*

Note that for the unit-weight case $w(U)$ equals n, and we thus get an $O(\min\{\Delta, \sqrt{n}\})$-competitive deterministic algorithm for this case.

6 Conclusions

We have studied the Online Budgeted Maximum Coverage problem. We presented a deterministic online algorithms in terms of three parameters of the given instance, and we gave deterministic lower bounds bases on these parameters. We also provided a randomized $O(1)$-competitive algorithm. Finally, both our upper and lower bounds on the deterministic competitive ratio apply to Removable Online Knapsack which is the preemptive version of the Online Knapsack problem.

We briefly mention some possible future research directions. Obvious open problems are closing the gap between the deterministic upper and lower bounds ($O(\frac{1}{1-r})$ vs. $\Omega(\frac{1}{\sqrt{1-r}})$), and decreasing the (constant) randomized competitive ratio. Other interesting goals would be to design an $O(\sqrt{w(U)})$-competitive deterministic algorithm that does not require advance knowledge of $w(U)$, and devising a single deterministic algorithm that obtains as a competitive ratio the minimum of all deterministic competitive ratios shown in this paper.

Abstract

In many scheduling situations, it is important to consider non-linear functions of job completions times in the objective. This was already recognized by Smith (1956). Recently, the theory community has begun a thorough study of the resulting problems, mostly on single-machine instances for which all permutations of jobs are feasible. However, a typical feature of many scheduling problems is that some jobs can only be processed after others. In this paper, we give the first approximation algorithms for min-sum scheduling with (nonnegative, non-decreasing) non-linear functions and general precedence constraints. In particular, for $1|\text{prec}|\sum w_j f(C_j)$, we propose a polynomial-time universal algorithm that performs well for all functions f simultaneously. Its approximation guarantee is 2 for all concave functions, at worst. We also provide a (non-universal) polynomial-time algorithm for the more general case $1|\text{prec}|\sum f_j(C_j)$. The performance guarantee is no worse than $2+\epsilon$ for all concave functions. Our results match the best bounds known for the case of linear functions, a widely studied problem, and considerably extend the results for minimizing $\sum w_j f(C_j)$ without precedence constraints.

1 Introduction

We consider a single-machine scheduling problem with non-linear objective function under precedence constraints. Let $f : \mathbb{R}_+ \to \mathbb{R}_+$ be a non-decreasing cost function. Given a set J of n jobs, where each job $j \in J$ is characterized by a weight $w_j \geq 0$ and an integral processing time $p_j \geq 0$, our goal is to find a sequence of the jobs that minimizes $\sum_j w_j f(C_j)$. Here, C_j denotes the completion time of job j in the corresponding nonpreemptive schedule. Additionally, we consider a set of precedence constraints $P \subseteq J \times J$. Now, $(i,j) \in P$ implies that job i must be completed before j can start. Keeping to the standard three-field notation [11], this problem can be denoted by $1|\text{prec}|\sum w_j f(C_j)$.

Our main result is that there exists a *universal* schedule, i.e., a feasible sequence that depends only on (p_j), (w_j) and P (but not on f), which performs well for all f together.

[*] This work was partially supported by FONDECYT project 3130407, by Núcleo Milenio Información y Coordinación en Redes ICM/FIC RC130003, and by the Alexander von Humboldt-Foundation.

This sequence can be computed in polynomial time, and its performance guarantee is

$$\sup_{C\geq 0} \frac{C \cdot f(C)}{\int_0^C f(t)dt} \ .$$

For concave f, the approximation guarantee can be bounded by 2 with a simple geometric argument. It is worth mentioning that for a vast class of concave functions the approximation guarantee is strictly better than 2, which improves upon the best possible[1] 2-approximation for the linear case.

One somewhat surprising lesson of our study is that an important concept from classic work on the strongly NP-hard problem $1|\text{prec}|\sum w_j C_j$ still holds considerable value for the more general problem $1|\text{prec}|\sum w_j f(C_j)$. In his PhD thesis, Sidney introduced a (polynomial-time computable) decomposition of J into mutually disjoint subsets $J_1, J_2, \ldots, J_k$ and showed that there always exists an optimal solution that follows this order [21]. Chekuri and Motwani [4] as well as Margot, Queyranne and Wang [16] later realized that any feasible sequence that is consistent with Sidney's decomposition is a 2-approximation. This observation was preceded by a number of linear programming based 2-approximation algorithms [19, 12, 6]. Correa and Schulz subsequently proved that virtually all known 2-approximation algorithms are of the Chekuri and Motwani/Margot, Queyranne and Wang type; in fact, several common linear programming relaxations follow Sidney's decomposition [7].

We analyze the same sequence as Chekuri and Motwani/Margot, Queyranne and Wang, but for $1|\text{prec}|\sum w_j f(C_j)$. In contrast to the case of linear f, it is not true that one of the sequences following Sidney's decomposition is optimal, which requires us to devise a very different, more complicated analysis. Still, the algorithm is the same, and our analysis implies that its performance depends on a simple geometric ratio defined by the shape of f. For all concave f, this ratio is at most 2 – the same bound that was earlier observed for linear functions f.

Our main technique relies on analyzing a time-indexed LP relaxation that is intimately related to the *partially ordered knapsack* problem (POK) and its fractional relaxation. In POK we are given a set of items J with weights and values, and a knapsack with a given capacity t. The items have precedence constraints $P \subseteq J \times J$, such that if $(i, j) \in P$ and we pack j into the knapsack, also i must be packed. The total weight of the packing cannot exceed t, and the objective is to maximize the total value. In its fractional version, we are allowed to take fractions of the jobs. If a fraction $x_j \in [0, 1]$ is packed into the knapsack and $(i, j) \in P$, then a fraction of i at least as large as x_j has to be packed. POK and its relaxation was previously studied by Kolliopoulos and Steiner [15], who derived an FPTAS for 2-dimensional precedence constraints and characterized cases where the natural LP relaxation has bounded integrality gap. Our main technical contribution is to show that Sidney's decomposition implies an optimal solution for fractional POK for each t. This implies that the solution is optimal for the time-indexed relaxation, *independently* of the cost function f, which in turn allow us to derive the approximation ratio.

Sidney's decomposition and corresponding algorithm can be viewed as an extension of Smith's optimal WSPT rule for $1||\sum w_j C_j$, which sequences jobs in order of non-increasing ratios of weight to processing time, to $1|\text{prec}|\sum w_j C_j$. In this sense, our work also generalizes earlier contributions by Stiller and Wiese [23] and Höhn and Jacobs [13] for $1||\sum w_j f(C_j)$, to instances with precedence constraints. For arbitrary concave f, Stiller and Wiese showed that Smith's rule guarantees an approximation factor of $(\sqrt{3} + 1)/2 \approx 1.366$. Höhn and

[1] Assuming a stronger version of the Unique Games Conjecture [1].

Jacobs built on their analysis to obtain refined and tight bounds of Smith's rule for any specific concave or convex function f. Unlike our LP-based analysis, their techniques rely on identifying a worst-case instance, which can be shown to only contain jobs with the same weight to processing time ratio. The argument then exploits the fact that for concave or convex functions it is easy to identify the worst WSPT solution and the optimal value. For general functions f, Im, Moseley and Pruhs [14] proved that Smith's rule is a $(2+\epsilon)$-speed O(1)-approximate algorithm. Epstein et al. [8] also gave a universal algorithm (quite different from Smith's rule, based on earlier work by Hall et al. [12]), which has performance guarantee $4+\epsilon$, for any cost function f. Additionally, they derived a randomized version of their algorithm with performance guarantee $e+\epsilon$, also for any f. As for non-universal algorithms, Megow and Verschae designed a PTAS for $1| \,|\sum w_j f(C_j)$ [17] for any given function f.

The entire area of min-sum scheduling with non-linear functions of the completion times was arguably revived by Bansal and Pruhs ([2], see also [3]). They considered the more general objective $\sum_j f_j(F_j)$, where f_j is a (nonnegative, non-decreasing) job-dependent cost function, $F_j - r_j$ is the flow time of job j, and r_j its release date. In case $r_j = 0$ for all jobs j, i.e., the setting considered here, their algorithm has performance guarantee 16. Subsequently, a better primal-dual algorithm was given with approximation ratio $4+\epsilon$ [5, 18].

Here, we also give the first polynomial-time approximation algorithm for $1|\text{prec}|\sum f_j(C_j)$, i.e., the case of job-dependent non-linear functions and general precedence constraints; see Section 3. Its approximation guarantee is at most $2+\epsilon$ for concave functions. The algorithm relies on solving a time-indexed LP relaxation and then rounding the fractional solution using randomized α-points. This type of rounding has been extensively used for the sum of weighted completion times objective (see, e.g., [22] for a summary); to the best of our knowledge this is the first time it is applied to a non-linear objective function.

2 A universal algorithm

In this section, we show that the 2-approximation algorithm for the linear case by Margot et al. [16] and Chekuri and Motwani [4] yields the following theorem.

▶ **Theorem 1.** *For any non-decreasing function $f : \mathbb{R}_+ \to \mathbb{R}_+$, the problem $1|prec|\sum w_j f(C_j)$ admits a polynomial-time, purely combinatorial algorithm with approximation guarantee*

$$\Gamma_f := \sup_{C\geq 0} \frac{C \cdot f(C)}{\int_0^C f(t)dt} \ .$$

Moreover, the solution is universal, *that is, it is independent of the cost function f.*

We say that a set of jobs $I \subset J$ is an *ideal* or *initial set* if it is a feasible prefix of a schedule; that is, for any $j \in I$, if $(i,j) \in P$, then $i \in I$. Also, if an ideal I maximizes $w(I)/p(I)$ over all ideals, we say that I is a *density maximal* ideal. Here, $w(I) = \sum_{j\in I} w_j$, and $p(I)$ is defined similarly. We assume that precedence constraints are given by a precedence digraph $G = (J,P)$, with jobs as nodes and arcs given by P. For a given set of jobs K, we denote by G_K the graph induced by set K. A Sidney decomposition is a collection of sets $J_1, J_2, \ldots, J_\ell$ such that J_i is a density maximal ideal in $G_{(J\setminus\cup_{k<i}J_k)}$. The problem of computing a Sidney decomposition can be seen as a parametric network flow problem, and thus it can be computed efficiently [16].

The algorithm computes a Sidney decomposition $J_1, J_2, \ldots, J_\ell$ of set J, and creates a schedule that processes all jobs in the order given by the decomposition; that is, if $j \in J_i, k \in J_s$ and $i < s$, then j is processed before k. Within each set J_i we pick an arbitrary linear ordering of the jobs that is consistent with the precedence constraints. To analyze this algorithm we use a time-indexed linear programming relaxation and find an explicit optimal solution that follows a Sidney decomposition. This is the core of our analysis.

A preemptive relaxation. Unlike in the classic setting, i.e., $1|\text{prec}|\sum w_j C_j$, for non-linear cost functions we cannot necessarily find an optimal solution that follows a Sidney decomposition. Indeed, in the absence of precedence constraints a Sidney decomposition corresponds to a solution given by Smith's rule, and such a solution is not necessarily optimal for non-linear f [13]. However, we will show that for a relaxed version of our problem a Sidney decomposition indeed gives an optimal solution. The relaxation considers preemptive solutions. To model precedence constraints in this relaxation we use the concept of *fractional precedence constraints*; that is, for $(i, j) \in P$ we impose that for any time t the fraction of job i processed in $[0, t]$ is as least as large as that of j.

Let $T = \sum_j p_j$ be the time horizon (assuming, w.l.o.g., that there is no idle-time). In order to avoid discretizing time, or making unnecessary assumptions on the structure of optimal solutions, we describe an arbitrary preemptive solution as a family of non-decreasing piecewise linear functions $x_j : [0, T] \to [0, 1]$ for each $j \in J$, where $x_j(t)$ represents the fraction of job j that is processed up to time t. In our relaxation, a job can be split in small pieces, each with the same density $\rho_j = w_j/p_j$ as the original job j. If a small piece of (infinitesimal) processing time δ finishes at time t, in our relaxation this incurs a cost of $\delta\rho_j f(t)$. Equivalently, function x_j increases by $x_j(t + \delta) - x_j(t) = \delta/p_j$ and we incur a cost of $w_j \cdot f(t) \cdot (x_j(t + \delta) - x_j(t))$. With this in mind, we define the cost of a preemptive solution as

$$\sum_{j\in J} w_j \cdot \int_0^T f(t)x_j'(t)dt,$$

where x_j' is the derivative of x_j, which is defined almost everywhere, except for the breakpoints of the function. More formally, our relaxation is given by the following optimization problem.

$$[\text{Rel}] \quad \textsc{Opt}_f = \inf \sum_{j\in J} w_j \cdot \int_0^T f(t)x_j'(t)dt$$

$$\text{s.t. } x_j(T) = 1 \qquad \text{for all } j \in J, \quad (1)$$

$$\sum_{j\in J} x_j(t)p_j \le t \qquad \text{for all } t \in [0, T], \quad (2)$$

$$x_j(t) \ge x_k(t) \qquad \text{for all } (j, k) \in P, t \in [0, T] \quad (3)$$

$$x_j : [0, T] \to \mathbb{R}_+ \qquad \text{non-decreas., piecew. lin. for all } j \in J. \quad (4)$$

We call any solution $(x_j)_{j\in J}$ that satisfies all conditions of this problem a *preemptive* schedule.

Let $\textsc{Opt}$ be the optimal value of our original, non-preemptive, problem. It is not hard to see that the optimal value of this program is a lower bound on $\textsc{Opt}$. Indeed, let $\mathcal{S}$ be an arbitrary non-preemptive schedule, and let S_j and $C_j = S_j + p_j$ be the starting time and completion time of job j in that solution, respectively. Naturally, we define x_j as a piecewise linear function

$$x_j(t) = \begin{cases} 0 & \text{if } t \le S_j, \\ \frac{t-S_j}{p_j} & \text{if } S_j < t < C_j, \\ 1 & \text{if } t \ge C_j. \end{cases} \quad (5)$$

It is easy to see that this definition yields a feasible solution to [Rel]. Moreover, the objective function can be upper bounded as follows,

$$\sum_{j\in J} w_j \cdot \int_0^T f(t)x_j'(t)dt = \sum_{j\in J} w_j \cdot \int_{S_j}^{C_j} \frac{1}{p_j} f(t)dt \leq \sum_{j\in J} w_j \cdot f(C_j), \tag{6}$$

where the equality holds since x_j has non-zero slope only in (S_j, C_j), where its derivative equals $1/p_j$. The last inequality follows since f is non-decreasing. We conclude that $\text{OPT}_f \leq \text{OPT}$.

An explicit optimal fractional solution. In what follows we explicitly find an optimal solution to [Rel]. Indeed, let $J_1, \dots, J_\ell$ be a Sidney decomposition of the instance. For any set J_i we define its *starting time* by $S(J_i) = \sum_{\ell<i} p(J_\ell)$ and its *completion time* as $C(J_i) = S(J_i) + p(J_i)$. For any given $j \in J_i$, we define

$$x_j^*(t) = \begin{cases} 0 & \text{if } t \leq S(J_i), \\ \frac{t-S(J_i)}{p(J_i)} & \text{if } S(J_i) < t < C(J_i), \\ 1 & \text{if } t \geq C(J_i). \end{cases}$$

We will show that this solution is optimal for [Rel]. Notice that x^* does not depend on f, which is why we can derive a universal schedule. Our solution can be interpreted as a schedule in which we first process all jobs in J_1, and within J_1 we process all jobs in a round robin fashion: we first schedule an infinitesimal fraction δ of each job in J_1, the same fraction for each job, ordering the fractions within J_1 according to any feasible linear ordering. With this we are able to process a set of jobs with density $w(J_1)/p(J_1)$, which gives us the most bang for the buck since J_1 is a density maximal ideal. This operation is repeated until J_1 is completely processed. Then we continue for each J_i for $i = 2, \dots, k$ iteratively with the same strategy. It is straightforward to check that the constructed solution is feasible to [Rel].

To establish that x^* is optimal, we show that it simultaneously solves a family of *fractional partially ordered knapsack problems*. For a given $t \in [0, T]$ we consider the linear program,

$$\begin{aligned} [\text{FK}(t)] \qquad & \max \quad \sum_{j\in J} x_j w_j && && (7)\\ & \text{s.t.} \quad \sum_{j\in J} x_j p_j \leq t && && (8)\\ & \qquad x_j \geq x_k && \text{for all } (j,k) \in P, && (9)\\ & \qquad 0 \leq x_j \leq 1 && \text{for all } j \in J. && (10) \end{aligned}$$

We show that, for a fixed t, the vector $(x_j^*(t))_{j\in J}$ yields an optimal solution to [FK(t)]. To do so we first start by characterizing the structure of feasible solutions to this LP. For a given set $S \subseteq J$ we denote by χ^S the indicator vector of set S, that is, $\chi_j^S = 1$ if $j \in S$ and $\chi_j^S = 0$ otherwise.

▶ **Lemma 2** (Fractional Decomposition). *Let z be any feasible solution to [FK(t)]. Then there exist r sets $A_1, \dots, A_r$ and numbers $1 \geq \gamma_1 > \dots > \gamma_r > 0$ such that*
1. $z = \sum_{i=1}^r \gamma_i \cdot \chi^{A_i}$,
2. *for all $s \in \{1, \dots, r\}$ the set $\cup_{i\leq s} A_i$ is an ideal,*
3. $\sum_{i=1}^r \gamma_i p(A_i) \leq t$, *and*
4. $A_i \cap A_\ell = \emptyset$ *for all $i, \ell \in J$ with $i \neq \ell$.*

Proof. Consider the set $Z = \{z_j \neq 0 : j \in J\}$ and assume that $Z = \{\gamma_1, \ldots, \gamma_r\}$ with $\gamma_1 > \gamma_2 > \ldots > \gamma_r > 0$. Define $A_i = \{j : z_j = \gamma_i\}$. Property 4 is obvious. Property 1 follows by 4 and the definition of A_i. Property 3 follows from Property 1 and Inequality (8) of [FK(t)]. To show Property 2, notice that $\cup_{i \leq s} A_i = \{j \in J : z_j \geq \gamma_s\}$. Consider an arbitrary job $k \in \cup_{i \leq s} A_i$, so that $z_k \geq \gamma_s$. We need to show that for any $j \in J$ with $(j, k) \in P$, it holds that $z_j \geq \gamma_s$. This follows because by Inequality (9) we have that $z_j \geq z_k \geq \gamma_s$. ◀

For a given feasible solution z, we call the sets $A_1, \ldots, A_r$ and numbers $\gamma_1, \ldots, \gamma_r$ given by the lemma a *fractional decomposition* of z.

▶ **Lemma 3** (Extremal Fractional Decomposition). *For any feasible solution z to [FK(t)] there exists another feasible solution $z' = \chi^{A_1} + \gamma \cdot \chi^{A_2}$ such that*
1. $\sum_j z_j w_j \leq \sum_j z'_j w_j$*,*
2. A_1 *and* $A_1 \cup A_2$ *are ideals,*
3. $p(A_1) + \gamma \cdot p(A_2) \leq t$*,*
4. $A_1 \cap A_2 = \emptyset$*.*

Proof. For a given feasible solution z, consider its fractional decomposition given by sets $A'_1, \ldots, A'_r$ and numbers $\gamma_1 > \ldots > \gamma_r$. To show the lemma we write an LP to optimize over the weights γ. We use β_i for the variables representing the weights γ_i.

$$\begin{aligned} \max \quad & \sum_{i=1}^{r} \beta_i w(A'_i) \\ \text{s.t.} \quad & \sum_{i=1}^{r} \beta_i p(A'_i) \leq t, \\ & 1 \geq \beta_1 \geq \ldots \geq \beta_r \geq 0. \end{aligned}$$

Let β^* be an extreme point optimal solution to this LP. Since there are $r + 2$ inequalities and r variables, at most 2 inequalities in $1 \geq \beta_1 \geq \ldots \geq \beta_r \geq 0$ are not satisfied with equality. Let us first assume that β^* is not an integral solution, and let ℓ be the smallest index such that $\beta^*_\ell \in (0, 1)$. This already induces one strict inequality $\beta^*_\ell < \beta^*_{\ell-1} = 1$. Let $\gamma = \beta^*_\ell$. There must exists an index $u \in \{\ell, \ldots, r\}$ such that $\beta^*_i = \gamma$ for all $i \in \{\ell, \ldots, u\}$ and $\beta^*_i = 0$ for all $i > u$, because otherwise there would be in total 3 strict inequalities. We get the following property: there exist a number $\gamma \in [0, 1]$ and two indices $1 \leq \ell \leq u \leq r$ such that $\beta^*_i = 1$ if $i < \ell$, $\beta^*_i = \gamma$ if $i \in \{\ell, \ldots, u\}$, and $\beta^*_i = 0$ if $i > u$. This property holds also if β^* is integral by taking $\gamma = 0$.

Now we can define $A_1 = \cup_{i=1}^{\ell-1} A'_i$, $A_2 = \cup_{i=\ell}^{u} A'_i$ and $\gamma = \beta^*_\ell$. Property 1 follows since β^* is optimal for the LP and setting $\beta_i = \gamma_i$ for all i yields a feasible solution. Properties 2 and 4 hold because of the Fractional Decomposition Lemma. Finally, Property 3 is implied by the first inequality of the LP and since the sets A'_i are pairwise disjoint. ◀

The next lemma shows that, if we are given a density maximal ideal $I \subset J$ such that $t \leq p(I)$, then an optimal solution of [FK(t)] can be constructed by taking each job in I with a fraction of $\frac{t}{p(I)}$. A similar statement was given by Kolliopoulos and Steiner [15], although they used a different proof technique.

▶ **Lemma 4.** *Given any density maximal ideal $I \subseteq J$, then for any $t \leq p(I)$ the vector $x = \frac{t}{p(I)} \chi^I$ is an optimal solution to [FK(t)].*

Proof. Let x be as defined in the statement of the lemma. It is clear that x is a feasible solution to $[FK(t)]$. Consider any optimal solution to [FK(t)] which, by the Extremal

Fractional Decompostion Lemma, can be taken as $\chi^{A_1} + \gamma \cdot \chi^{A_2}$. Recalling that A_1 and $A_1 \cup A_2$ are ideals, and that $A_1 \cap A_2 = \emptyset$, the difference in objective values of the two solutions is given by

$$\begin{aligned}\frac{t}{p(I)}w(I) - (w(A_1) + \gamma w(A_2)) &= \frac{t}{p(I)}w(I) - (\gamma w(A_1 \cup A_2) + (1-\gamma)w(A_1))\\ &= \gamma\left(\frac{t}{p(I)}w(I) - w(A_1 \cup A_2)\right) + (1-\gamma)\left(\frac{t}{p(I)}w(I) - w(A_1)\right)\\ &= \gamma\left(\frac{w(I)}{p(I)}t - \frac{w(A_1 \cup A_2)}{p(A_1 \cup A_2)}p(A_1 \cup A_2)\right) + (1-\gamma)\left(\frac{w(I)}{p(I)}t - \frac{w(A_1)}{p(A_1)}p(A_1)\right)\\ &\geq \frac{w(I)}{p(I)}\left\{\gamma \cdot (t - p(A_1 \cup A_2)) + (1-\gamma)\cdot(t - p(A_1))\right\}\\ &= \frac{w(I)}{p(I)}\left\{t - p(A_1) - \gamma p(A_2)\right\} \geq 0,\end{aligned}$$

where the first inequality follows since I is density maximal, and the last one because $\chi^{A_1} + \gamma \cdot \chi^{A_2}$ is feasible for [FK(t)]. ◀

▶ **Lemma 5.** *For any $t \in [0, T]$, solution $(x_j^*(t))_{j \in J}$ is an optimal solution to [FK(t)].*

Proof. By Lemma 3, there exists an optimal solution z to [FK(t)] such that $z = \chi^{A_1} + \gamma\chi^{A_2}$ where sets A_1 and A_2 satisfy properties 2, 3, and 4 of Lemma 3. Without loss of generality, we assume that $\sum_j z_j p_j = p(A_1) + \gamma p(A_2) = t$, since otherwise we can add to A_2 a dummy job (which does not participate in any precedence constraint) of zero weight and processing time $\frac{1}{\gamma}(t - p(A_1)) - p(A_2)$. We split the proof in two cases.

Case 1: $p(J_1) \geq t$. In this case $x^*(t) = \frac{t}{p(J_1)}\chi^{J_1}$ and thus it is optimal by Lemma 4.

Case 2: $p(J_1) < t$. We modify z to obtain a solution that takes set J_1 integrally. For some number $\gamma' \in [0, 1]$, we will subtract from z the following vector in order to leave space for J_1

$$y = \chi^{A_1 \cap J_1} + \gamma\chi^{A_2 \cap J_1} + \gamma'\chi^{A_1 \setminus J_1} + \gamma'\gamma\chi^{A_2 \setminus J_1}.$$

Notice that if we choose $\gamma' = 0$ then $\sum_{j \in J} p_j y_j = p(A_1 \cap J_1) + \gamma p(A_2 \cap J_1) \leq p(J_1)$, and setting $\gamma' = 1$ we obtain that $\sum_{j \in J} p_j y_j = p(A_1) + \gamma p(A_2) = t > p(J_1)$. Therefore, by continuity we can choose $\gamma' \in [0, 1]$ so that $\sum_{j \in J} p_j y_j = p(J_1)$, that is,

$$\gamma' = \frac{p(J_1 \setminus A_1) - \gamma p(A_2 \cap J_1)}{p(A_1 \setminus J_1) + \gamma p(A_2 \setminus J_1)} \in [0, 1].$$

We first notice that the total weight of y is larger than the weight of χ^{J_1}. To this end, we first show that y is a feasible solution to [FK($p(J_1)$)]. This suffices to conclude that $w(J_1) \geq \sum_{j \in J} w_j y_j$, since χ^{J_1} is optimal to [FK($p(J_1)$)] by Lemma 4. To show that y is feasible to [FK($p(J_1)$)], notice that Inequality (8) is satisfied by our choice of γ'. Let us check (9) for some $(j, k) \in P$. Notice that if $k \notin A_1 \cup A_2$ then $z_k = 0$ and thus the corresponding inequality in (9) is satisfied immediately. Similarly, if $j \notin A_1 \cup A_2$ then, since $A_1 \cup A_2$ is an ideal, $k \notin A_1 \cup A_2$ and thus (9) holds. Thus it suffices to consider $j, k \in A_1 \cup A_2$. Since J_1, A_1, and A_2 are ideals, the only precedence constraints that we need to check are: $(j, k) \in (A_1 \cap J_1) \times (A_2 \cup (A_1 \setminus J_1))$, $(j, k) \in (A_1 \setminus J_1) \times (A_2 \setminus J_1)$, $(j, k) \in (A_2 \cup J_1) \times (A_2 \setminus J_1)$.

For each of these cases, it holds that $y_j \geq y_k$ since $1 \geq \gamma \geq \gamma\gamma'$ and $1 \geq \gamma' \geq \gamma\gamma'$. We conclude that y is feasible for [FK($p(J_1)$)] and thus $w(J_1) \geq \sum_{j\in J} w_j y_j$.

We are now ready to construct a new solution for [FK(t)],

$$z' = z - y + \chi^{J_1} = (1-\gamma')\left(\chi^{A_1\setminus J_1} + \gamma\chi^{A_2\setminus J_1}\right) + \chi^{J_1},$$

has a weight that is less or equal to z. Moreover, we can check that this solution is also feasible for [FK(t)]. Indeed, by construction it holds that $\sum_j p_j z'_j = \sum_j p_j z_j \leq t$. Similarly as before, the only precedence constraints $(j,k) \in P$ that we need to check are when $(j,k) \in J_1 \times ((A_1 \setminus J_1) \cup (A_2 \setminus J_1))$, and $(j,k) \in (A_1 \setminus J_1) \times (A_2 \setminus J_1)$. All of these constraints hold since $1 \geq \gamma \geq \gamma\gamma'$.

We conclude that there exists an optimal solution z' to [FK(t)] that assigns integrally J_1, that is, $z'_j = 1$ for all $j \in J_1$. As well we have that $x^*_j(t) = 1$ for all $j \in J_1$. We can then remove J_1 from our instance and consider a residual problem with precedence graph $G_{J\setminus J_1}$ for a remaining fractional knapsack problem with capacity $t - p(J_1)$. The lemma follows by recursing on this argument. ◀

▶ **Lemma 6.** *The solution $(x^*_j)_{j\in J}$ is an optimal solution for [Rel].*

Proof. Integrating by parts, the objective function of [Rel] can be rewritten as[2]

$$\sum_{j\in J} w_j \cdot \int_0^T f(t)x'_j(t)dt = w(J)\cdot f(T) - \int_0^T \sum_{j\in J} w_j x_j(t)df(t),$$

and hence we can obtain a problem equivalent to [Rel] if we change the objective to maximize $\int_0^T \sum_{j\in J} w_j x_j(t)df(t)$. Since any solution $(x_j(\cdot))_{j\in J}$ for [Rel] defines a feasible solution $(x_j(t))_{j\in J}$ to [FK(t)], and $(x^*_j(t))_{j\in J}$ optimizes [FK(t)], we obtain that $\sum_{j\in J} w_j x_j(t) \leq \sum_{j\in J} w_j x^*_j(t)$. Because f is non-decreasing, then

$$\int_0^T \sum_{j\in J} w_j x_j(t)df \leq \int_0^T \sum_{j\in J} w_j x^*_j(t)df,$$

which helps us to conclude that $(x^*_j(\cdot))_{j\in J}$ is an optimal solution to [Rel]. ◀

We are finally ready to prove Theorem 1.

Proof of Theorem 1. Consider a feasible schedule $\mathcal{S}$ that follows the Sidney decomposition $J_1,\dots,J_k$. Since for any $j \in J_i$ we have that $C_j \leq C(J_i)$, the cost of that solution can be bounded from above by $\sum_{i=1}^k w(J_i)f(C(J_i))$. On the other hand, the optimal fractional value, attained at solution x^*, can be rewritten as

$$\sum_{j=1}^n w_j \int_0^T f(t)\frac{dx^*_j(t)}{dt}dt = \sum_{i=1}^k w(J_i)\int_{S(J_i)}^{C(J_i)} \frac{f(t)}{p(J_i)}dt,$$

[2] Here the integral taken is the Riemann-Stieltjes integral. This is well defined since f is of bounded variation (since it is non-decreasing) and x_j is continuous. Integration by parts is then valid [10, Theorem 12.14]. Notice that if f were differentiable we could simply write $\int_0^T \sum_{j\in J} w_j x_j(t)f'(t)dt$.

and thus the approximation ratio is at most

$$\frac{\sum_{i=1}^{k} w(J_i) f(C(J_i))}{\sum_{i=1}^{k} w(J_i) \int_{S(J_i)}^{C(J_i)} \frac{1}{p(J_i)} f(t)dt} \leq \max_i \frac{f(C(J_i))}{\int_{S(J_i)}^{C(J_i)} \frac{1}{p(J_i)} f(t)dt} \leq \sup_{0\leq S<C} \frac{f(C)}{\frac{1}{C-S}\int_S^C f(t)dt}$$

$$\leq \sup_{0\leq C} \frac{C \cdot f(C)}{\int_0^C f(t)dt},$$

where the last inequality follows since $\frac{1}{C-S}\int_S^C f(t)dt \geq \frac{1}{C}\int_0^C f(t)dt$, because f is non-decreasing. This shows the theorem. ◀

▶ **Corollary 7.** *There exists a universal solution that, for any concave function f, achieves an approximation guarantee of* 2*. This solution can be computed in polynomial time.*

Proof. It is enough to notice that if f is concave and non-negative, then $f(t) \geq tf(C)/C$ for any $t \in [0, C]$. Hence, $\int_0^C f(t)dt \geq Cf(C)/2$ and thus $\Gamma_f \leq 2$. ◀

It is worth noticing that the result of Theorem 1 is tight, in the sense that the integrality gap of [Rel] is exactly Γ_f. Indeed, note that for any $C \geq 0$ we can take an instance with one job of processing time C and weight 1. Then the optimal LP solution has a cost of $(1/C)\int_0^C f(t)dt$, whereas the optimal schedule has a cost of $f(C)$.

3 A Rounding Procedure for Job-Dependent Cost Functions

The more general case with objective function $\sum_j f_j(C_j)$ for f_j non-decreasing can also be tackled based on [Rel]. For this we simple generalize the objective function to $\sum_j \int_0^T f_j x'_j$. We call the new relaxation [G-Rel]. In this case we are not able to give an analytic optimal solution for the relaxation. Instead, we discretize the time in the relaxation in order to compute $(1+\epsilon)$-approximate solutions. Afterwards, we round this solution to obtain a non-preemptive schedule. Notice that this does not yield a universal solution. The approximation guarantee is not the same as in Theorem 1, however it also yields a guarantee of $2+\epsilon$ for concave functions.

We first show the rounding procedure, which is based on the concept of α-points. Consider a feasible solution $(x_j)_j$ for [G-Rel]. For a given number $\alpha \in [0, 1]$, we define the α-point of job j as $C_j^{\text{LP}}(\alpha) := \min\{t \geq 0 : x_j(t) \geq \alpha\}$, that is, the first point in time in which an α fraction of j is processed. We schedule the jobs in the order of α-points, for some (random) value of α. For simplicity, relabel the jobs so that $C_1^{\text{LP}}(\alpha) \leq \ldots \leq C_n^{\text{LP}}(\alpha)$, and thus the completion time of job j in the algorithm is $C_j^{\text{ALG}} = \sum_{k\leq j} p_j$. The next lemma relates the α-point of a job to its actual completion time. The one thereafter relates the function $C_j^{\text{LP}}(\cdot)$ with the objective function of [G-Rel]. The exposition here takes cues from that in [20].

▶ **Lemma 8** (Goemans [9])**.** *For any $\alpha \in [0, 1]$ and $j \in J$ it holds that*

$$C_j^{\text{ALG}} \leq \frac{1}{\alpha} C_j^{\text{LP}}(\alpha).$$

Proof. Notice that for all $k \leq j$ it holds that $x_k\left(C_j^{\text{LP}}(\alpha)\right) \geq x_k\left(C_k^{\text{LP}}(\alpha)\right) = \alpha$ (since x_k is non-decreasing), and thus

$$C_j^{\text{ALG}} = \sum_{k\leq j} p_k \leq \frac{1}{\alpha}\sum_{k\leq j} p_k x_k(C_j^{\text{LP}}(\alpha)) \leq \frac{1}{\alpha}\sum_{k\in J} p_k x_k(C_j^{\text{LP}}(\alpha)) \leq \frac{1}{\alpha} C_j^{\text{LP}}(\alpha),$$

where the last inequality follows from (2). ◀

▶ **Lemma 9.** *For any j it holds that*

$$\int_0^1 f_j(C_j^{\mathrm{LP}}(\alpha))d\alpha = \int_0^T f_j(t)x'_j(t)dt.$$

Proof. Consider a fixed job j and let $0 = s_1 < s_2 < \ldots < s_\ell = T$ be the breakpoints of the piecewise linear function x_j. Let us also denote by δ_k the derivative of x'_j in (s_k, s_{k+1}), and denote by $\alpha_k = x_j(s_k)$ the fraction of job j processed up to time s_k. Notice that $0 = \alpha_1 \le \alpha_2 \le \ldots \le \alpha_\ell = 1$. Then

$$\int_0^1 f_j(C_j^{\mathrm{LP}}(\alpha))d\alpha = \sum_{k=1}^{\ell-1} \int_{\alpha_k}^{\alpha_{k+1}} f_j(C_j^{\mathrm{LP}}(\alpha))d\alpha$$

Notice that if $\alpha_k < \alpha_{k+1}$, within the interval $\alpha \in (\alpha_k, \alpha_{k+1})$ the function $C_j^{\mathrm{LP}}(\alpha)$ is linear and has a slope of $1/\delta_k$ (observe that $\alpha_k < \alpha_{k+1}$ iff $\delta_k \neq 0$). Hence, using the change of variable $t = C_j^{\mathrm{LP}}(\alpha)$ we obtain that

$$\begin{aligned}\sum_{k=1}^{\ell-1} \int_{\alpha_k}^{\alpha_{k+1}} f_j(C_j^{\mathrm{LP}}(\alpha))d\alpha &= \sum_{k:\alpha_k<\alpha_{k+1}} \int_{\alpha_k}^{\alpha_{k+1}} f_j(C_j^{\mathrm{LP}}(\alpha))d\alpha = \sum_{k:\alpha_k<\alpha_{k+1}} \int_{s_k}^{s_{k+1}} f_j(t)\delta_k dt \\ &= \sum_{k=1}^{\ell-1} \int_{s_k}^{s_{k+1}} f_j(t)\delta_k dt = \int_0^T f_j(t)x'_j(t)dt.\end{aligned}$$ ◀

In our algorithm we take α randomly in $[0,1]$ with density 2α.

▶ **Lemma 10.** *Let $\Gamma'_f = \sup_{0\le t\le\tau} \frac{tf(\tau)}{\tau f(t)}$. Taking $\alpha \in [0,1]$ randomly with density 2α yields a solution such that*

$$\mathbb{E}\left(\sum_{j\in J} f_j(C_j^{\mathrm{ALG}})\right) \le 2(\max_{k\in J}\Gamma'_{f_k}) \cdot \sum_{j\in J}\int_0^T f_j x'_j(t)dt.$$

Proof. Due to the Lemma 8,

$$\mathbb{E}(f_j(C_j^{\mathrm{ALG}})) \le \int_0^1 f_j\left(\frac{1}{\alpha}C_j^{\mathrm{LP}}(\alpha)\right)2\alpha d\alpha.$$

Since for any $0 \le t \le \tau$ it holds that $t \cdot f_j(\tau) \le \Gamma'_{f_j} \cdot \tau \cdot f_j(t)$, we can take $\tau = \frac{1}{\alpha}C_j^{\mathrm{LP}}(\alpha)$ and $t = C_j^{\mathrm{LP}}(\alpha) \le \tau$ and thus $f_j(\frac{1}{\alpha}C_j^{\mathrm{LP}}(\alpha)) \le \Gamma'_{f_j} \cdot \frac{1}{\alpha} \cdot f_j(C_j^{\mathrm{LP}}(\alpha))$ we obtain that

$$\mathbb{E}(f_j(C_j^{\mathrm{ALG}})) \le 2\Gamma'_{f_j}\int_0^1 \frac{1}{\alpha} f_j(C_j^{\mathrm{LP}}(\alpha))\alpha d\alpha = 2(\Gamma'_{f_j}) \cdot \int_0^T f_j(t)x'_j(t)dt.$$

The lemma then follows by summing over j and using linearity of expectations. ◀

Notice that if f_j is concave then $\Gamma'_{f_j} \le 1$, and hence taking x to be optimal for [G-Rel] we would obtain a 2-approximation algorithm.

Moreover generally, if we can compute in polynomial time a solution x that is a $(1+\epsilon)$-approximate solution to [G-Rel], then this lemma shows that the problem admits a $(2(\max_{k\in J}\Gamma'_{f_k})(1+\epsilon))$-approximation algorithm. In what follows we show how to compute such solution x. The proof relies in the classic technique of discretizing the time axis in polynomially many intervals. Similar techniques were used by Bansal and Pruhs [2] and Cheung and Shmoys [5].

In what follows we must assume that we are given an oracle that allows us to query the values $f_j(t)$ for any $t \in \mathbb{N}$ (recall that we assume the processing times to be integral, and thus we only need to query f_j at integral points). Recall also that $T = \sum_j p_j$ is our time horizon. We assume that $f_{\max} := \max_j f_j(T)$ and $f_{\min} := \min\{f_j(t) : j \in J, t \in \{1, \ldots, T\}, f_j(t) > 0\}$ are part of the input, and thus we can manipulate these values in polynomial time. Notice that in any feasible (non-preemptive) schedule the functions f_j get evaluated only at integral points. Hence, without loss of generality, we assume that $f_j(t) = f_j(\lceil t \rceil)$ for all $t \in [0, T]$.

Let us fix a job j now. We partition the time horizon $\{0, 1, 2, \ldots, T\}$ in consecutive sets. The first set is defined as $I_j^0 = \{t \in \mathbb{N} : f_j(t) = 0\}$, and for any integer $\ell \geq 1$ we define

$$I_j^\ell = \{t \in \mathbb{N} : f_{\min} \cdot (1+\epsilon)^{\ell-1} < f_j(t) \leq f_{\min} \cdot (1+\epsilon)^\ell\}.$$

Notice that the intervals I_j^ℓ for $\ell \in \{0, 1, \ldots, \nu\}$ completely cover $\{0, 1, \ldots, T\}$ if $\nu = \lceil \log_{1+\epsilon}(f_{\max}/f_{\min}) \rceil$, and thus a polynomial number of interval suffices. Let t_j^ℓ be the largest number in I_j^ℓ and consider the set $\mathcal{T} = \{0, T\} \cup \{t_j^\ell : \text{for all } j \in J, \ell \in \{0, \ldots, \nu\}, t_j^\ell \leq T\}$. Let us relabel the elements in $\mathcal{T} = \{\tau_1, \tau_2, \ldots, \tau_h\}$ such that $0 = \tau_1 < \tau_2 < \ldots < \tau_h$. We remark that $|\mathcal{T}| = h \leq (\nu + 1)n + 2$.

With this we define a rounded version of the cost function $\tilde{f}_j$. For any $t \in [0, T]$ the value $\tilde{f}_j(t)$ is defined as $f(\tau_{\ell(j,t)})$, where $\ell(j, t)$ is defined such that $\tau_{\ell(j,t)-1} < t \leq \tau_{\ell(j,t)}$. We obtain that $f_j(t) \leq \tilde{f}_j(t) = f_j(\tau_{\ell(j,t)}) \leq (1+\epsilon) f_j(\lceil t \rceil) = (1+\epsilon) f_j(t)$ for all $t \in [0, T]$. Hence, obtaining an optimal solution [G-Rel] with cost functions $\tilde{f}_j$ yields a $(1+\epsilon)$-approximate solutions for the original cost functions.

▶ **Lemma 11.** *We can compute in polynomial time an optimal solution to [G-Rel] with cost functions $\tilde{f}_j$.*

Proof. Consider any solution x for [G-Rel] with cost functions $\tilde{f}_j$. Consider a new solution $\tilde{x}$ obtained by interpolating the values at $\mathcal{T}$, that is,

$$\begin{aligned} &\tilde{x}_j(0) = x_j(0) && \text{for all } j \in J, \\ &\tilde{x}_j(t) = \frac{\tau_\ell - t}{\tau_\ell - \tau_{\ell-1}} x_j(\tau_{\ell-1}) + \frac{t - \tau_{\ell-1}}{\tau_\ell - \tau_{\ell-1}} x_j(\tau_\ell) && \text{for all } \ell, t \in (\tau_{\ell-1}, \tau_\ell], j \in J. \end{aligned} \tag{11}$$

Since the functions $\tilde{f}_j$ are constant within an interval $(\tau_{\ell-1}, \tau_\ell]$, it is easy to see that the new solution achieves the same objective function, and it is also feasible. Hence, we can restrict [G-Rel] to have solutions as in (11) for all $j \in J$ and $t \in [0, T]$. We can regard this LP as having variables $x_j(\tau_\ell)$ for all $j \in J, \tau_\ell \in \mathcal{T}$. This yields a problem with a polynomial number of variables:

$$|J| \cdot |\mathcal{T}| = nh \leq n((\nu+1)n + 2) = O(n^2 \log_{1+\epsilon}(f_{\max}/f_{\min})) = O((n^2/\epsilon) \log(f_{\max}/f_{\min})).$$

Hence, it suffices to argue that we can impose a polynomial number of inequalities that imply the restrictions of the LP. Notice that any solution given by (11) is piecewise linear. The fact that x_j is non-decreasing is equivalent to $x_j(\tau_{\ell-1}) \leq x_j(\tau_\ell)$ for all j, ℓ. Since the value $x_j(t)$ for $t \in (\tau_\ell, \tau_{\ell+1}]$ is a convex combination of $x_j(\tau_\ell)$ and $x_j(\tau_{\ell+1})$, restriction (3) is implied by $x_j(\tau_\ell) \geq x_k(\tau_\ell)$ for all $(j, k) \in P$ and $\ell \in \{1, \ldots, h\}$. For the same reason (2) is implied by

$$\sum_{j \in J} x_j(\tau_\ell) p_j \leq \tau_\ell \qquad \text{for all } \ell \in \{1, \ldots, h\}.$$

Combining all these inequalities yields an equivalent problem of polynomial size. ◀

Collecting our results, we obtain the following theorem.

▶ **Theorem 12.** *For any $\epsilon > 0$, the problem $1|prec|\sum_j f_j(C_j)$ admits a polynomial-time approximation algorithm with approximation factor $(1+\epsilon)\cdot 2\cdot \max_{j\in J} \sup_{t,\tau} \left\{ \frac{t f_j(\tau)}{\tau f_j(t)} \,:\, 0 \le t \le \tau \right\}$. This implies the existence of a $(2+\epsilon)$-approximation algorithm if f_j is concave for all $j \in J$.*

Abstract

We investigate the power of migration in online scheduling for parallel identical machines. Our objective is to maximize the total processing time of accepted jobs. Once we decide to accept a job, we have to complete it before its deadline d that satisfies $d \geq (1+\varepsilon)\cdot p + r$, where p is the processing time, r the submission time and the slack $\varepsilon > 0$ a system parameter. Typically, the hard case arises for small slack $\varepsilon \ll 1$, i.e. for near-tight deadlines. Without migration, a greedy acceptance policy is known to be an optimal deterministic online algorithm with a competitive factor of $\frac{1+\varepsilon}{\varepsilon}$ (DasGupta and Palis, APPROX 2000). Our first contribution is to show that migrations do not improve the competitive ratio of the greedy acceptance policy, i.e. the competitive ratio remains $\frac{1+\varepsilon}{\varepsilon}$ for any number of machines.

Our main contribution is a deterministic online algorithm with almost tight competitive ratio on any number of machines. For a single machine, the competitive factor matches the optimal bound of $\frac{1+\varepsilon}{\varepsilon}$ of the greedy acceptance policy. The competitive ratio improves with an increasing number of machines. It approaches $(1+\varepsilon)\cdot\ln\frac{1+\varepsilon}{\varepsilon}$ as the number of machines converges to infinity. This is an exponential improvement over the greedy acceptance policy for small ε. Moreover, we show a matching lower bound on the competitive ratio for deterministic algorithms on any number of machines.

1 Introduction

We address a basic scheduling problem on parallel identical machines. Given a sequence of jobs, we are required to use the available resources as best as possible such that no accepted job exceeds its deadline. The deadline of a job is at least $(1+\varepsilon)\cdot p_j$ time units after its submission time, where p_j is the processing time of the job and $\varepsilon > 0$ is the (typically small) slack parameter. We model resource utilization by maximizing the total processing time. In addition to the slack, we require the system to support preemption and migration.

From a system's perspective, migration is an important topic. Not only is it technically feasible, at least to some degree, in some cases it is even required [2, 8, 26]. For instance, when

[*] The first author wants to acknowledge the German Research Council (DFG) for its support of this research within the Collaborative Research Center SFB 876, project A2.

outsourcing jobs to an external provider, these jobs are often executed via virtual machines instead of given access to a real server. Since the underlying systems are highly adaptive environments dealing with machine failure and maintenance, migration is a necessary part of such virtual infrastructure management [25].

From a theoretical perspective, assuming migration is a convenient simplification when designing algorithms. Additionally, understanding when and how much migration improves performance can ease the decision whether implementing migration in a system is worthwhile. For a few examples where migration improves the performance of online algorithms, we refer to [1, 6, 9, 22, 24].

1.1 Our Contribution

In this paper, we consider a system of m parallel identical machines supporting preemption with migration and process jobs in an online fashion. A job can be interrupted at any given time and resumed at a later date on a possibly different machine without overhead. At any given time, a job can only be executed on one machine and each machine can process at most one job. The slack $\varepsilon > 0$ is known to the algorithm a-priori and upon submission of a job J_j at time r_j, the processing time p_j and deadline $d_j \geq (1+\varepsilon)\cdot p_j + r_j$ are revealed to the algorithm. We must immediately decide whether or not to accept J_j, denoted by the indicator variable $U_j = 1$ if rejected and $U_j = 0$ if accepted and receive a payoff proportionate to p_j, if J_j is accepted. Once a job is accepted, we must complete it on time, i.e. we cannot postpone completion of a job beyond its deadline in favor of another job. Using the three-field notation, the problem is $P_m|\varepsilon, \text{online}, \text{pmtn}|\sum p_j \cdot (1-U_j)$. We measure the performance of online algorithms via the competitive ratio. Since we have a maximization problem, the competitive ratio is the maximum value of $\frac{\text{OPT}(J)}{\text{Alg}(J)}$ over all input sequences J, where $\text{OPT}(J)$ is the objective value of an optimal offline algorithm and $\text{Alg}(J)$ is the objective value achieved by our online algorithm.

To accurately present our results, we require the definition of the function $g(x) = \varepsilon\cdot\left(\frac{1+\varepsilon}{\varepsilon}\right)^x$. Our main contribution is the design of a deterministic algorithm with an almost tight competitive factor.

▶ **Theorem 1.** *The $P_m|\varepsilon$, online, pmtn$|\sum p_j \cdot (1-U_j)$ problem admits a deterministic online algorithm with competitive ratio at most* $\max\{\frac{m\cdot(1+\varepsilon)}{\sum_{i=0}^{m-1} g\left(\frac{i}{m}\right)}, \frac{4}{3}\}$.

We are especially interested in the behavior of the function $\frac{m\cdot(1+\varepsilon)}{\sum_{i=0}^{m-1} g\left(\frac{i}{m}\right)}$ for small ε and large m, though we note that for any value of $0 < \varepsilon \leq 1$ and $m > 1$, the competitive ratio of our algorithm is an improvement over the greedy algorithm. For a single machine, there is no migration and the expression reduces to $\frac{1+\varepsilon}{\varepsilon}$. As m tends to infinity, the expression approaches $(1+\varepsilon)\ln\frac{1+\varepsilon}{\varepsilon}$. For small ε, this is an exponential improvement over greedy. We also note that the competitive ratio improves quickly, i.e. even for a comparatively small number of machines a parallel system drastically outperforms a single machine environment. Generally, for m machines, the competitive factor of our algorithm is $O(\sqrt[m]{1/\varepsilon})$. For an arguably more immediate feel for the competitive ratios of various choices of ε and m, we refer to Figure 1.

We further prove the following lower bound.

▶ **Theorem 2.** *Any deterministic online algorithm for the $P_m|\varepsilon$, online, pmtn$|\sum p_j \cdot (1-U_j)$ problem has a competitive ratio of at least* $\frac{\lfloor m\cdot(1+\varepsilon)\rfloor}{\sum_{i=0}^{m-1} g\left(\frac{i}{m}\right)}\cdot(1-\delta)$ *for any $\delta > 0$.*

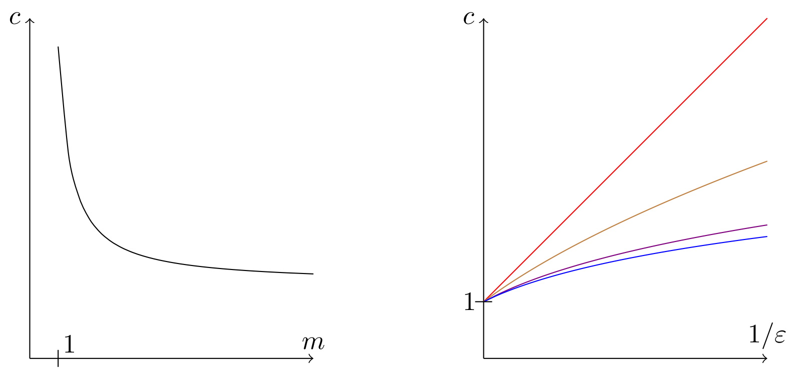

Figure 1 Performance of the online algorithm for increasing number of machines. The plots contain parameterizations of the function $\frac{m\cdot(1+\varepsilon)}{\sum_{i=0}^{m-1}\varepsilon\cdot(\frac{1+\varepsilon}{\varepsilon})^{i/m}}$, which is the competitive ratio of our algorithm for $0<\varepsilon\le 1$. We have $\varepsilon = 0.1$ in the left figure and the x-axis and the y-axis denote the number of machines and the competitive ratio, respectively. In the right figure, the x-axis and y-axis denote the dependency on $1/\varepsilon$ (i.e. $1/\varepsilon$ is large when the slack ε is small) and the competitive ratio, respectively. The red line is the competitive ratio of the greedy algorithm for increasingly smaller slack; the brown, violet and blue lines are the competitive ratios of our algorithm for 2, 10 and an infinite number of machines, respectively. Note that the competitive ratio is not equivalent to the plotted function for large ε (i.e. $1/\varepsilon$ close to 0).

When $m\cdot(1+\varepsilon)$ is integral and $c_A \ge \frac{4}{3}$, our algorithm achieves a tight competitive ratio.

The greedy acceptance policy accepts any job that can be completed on time provided no other accepted job is delayed beyond its deadline. For the same problem without migrations, this algorithm is known to guarantee an optimal competitive ratio of $\frac{1+\varepsilon}{\varepsilon}$ [7]. We show that the greedy acceptance policy cannot benefit from migrations:

▶ **Theorem 3.** *The greedy acceptance policy for the $P_m|\varepsilon, online, pmtn|\sum p_j\cdot(1-U_j)$ problem has a competitive ratio of at least $\frac{1+\varepsilon}{\varepsilon}-\delta$ for any $\delta>0$.*

Since the non-migratory and the migratory models are identical for a single machine, the greedy algorithm is optimal in this case. But its performance is exponentially worse than the performance of our algorithm as $\varepsilon\to 0$ and $m\to\infty$.

1.2 Related Work

The offline problems $1|r_j,\text{pmtn}|\sum w_j\cdot(1-U_j)$ and $P_2|r_j,\text{pmtn}|\sum U_j$ are NP hard [5]. Lawler [18] proposed a dynamic programming algorithm over the range of weights for the former problem, i.e. $1|r_j,\text{pmtn}|\sum(1-U_j)$ is solvable in polynomial time. Kalyanasundaram and Pruhs [13] showed that any schedule for the $P_m|r_j,pmtn|\sum w_j\cdot(1-U_j)$ problem can be transformed into a non-migratory schedule with $O(1)$ additional machines.

Early preemptive online algorithms assumed that every job can be accepted, but possibly delayed arbitrarily. A payoff w_j is only received if the job is completed prior to deadline. In this case there exists a tight 4-competitive deterministic algorithm on a single machine for a class of well-behaved payoff functions including $w_j = p_j$ [3, 17, 27]. For arbitrary payoff functions and without further restrictions on the input, the competitive factor is unbounded [27]. Kalyanasundaram and Pruhs [14] gave a $O(1)$ competitive randomized algorithm for maximizing the number of completed jobs and also showed that no constant competitive deterministic algorithm exists.

When further requiring that any accepted job must be completed before its deadline, there exists no constant competitive algorithm in general. To obtain more meaningful results, research incorporated the slack $\varepsilon > 0$[1]. For $1|\varepsilon, \text{online}, \text{pmtn}|\sum p_j \cdot (1 - U_j)$, Baruah and Haritsa [4] showed that a greedy acceptance policy achieves an optimal $\frac{1+\varepsilon}{\varepsilon}$ competitive ratio. This result was extended to parallel machines supporting preemption but not migration by DasGupta and Palis [7]

A lot of work has also been done for the non-preemptive variants of the problem. In this case, the difficulty of obtaining a meaningful competitive ratio was first addressed by bounding the aspect ratio $\Delta = \frac{\max p}{\min p}$. Lipton and Tomkins [20] gave a lower bound of $\Omega(\log \Delta)$ for the competitive factor of any randomized online algorithm on a single machine and additionally assuming $d_j = p_j + r_j$ for all jobs, obtained an upper bound of $O(\log^{1+\delta} \Delta)$ for any $\delta > 0$. For arbitrary deadlines, Goldman, Parwatikar, and Suri [10] were able to obtain a $6(\lceil \log \Delta \rceil + 1)$ competitive algorithm. They further studied the problem with slack ε and achieved a competitive factor of $1 + \frac{\lceil \varepsilon \rceil}{\varepsilon}$ if there are only two different job processing times. Goldwasser [11] distinguished between exactly two distinct processing times or arbitrary processing times and gave tight deterministic competitive factors of $1 + \max\left\{\frac{\lceil \varepsilon \rceil + 1}{\lceil \varepsilon \rceil}, \frac{\lfloor \varepsilon \rfloor + 1}{\varepsilon}\right\}$ and $2 + \frac{1}{\varepsilon}$, respectively. Kim and Chwa [16] later proved the same competitive factor for a greedy acceptance policy on multiple machines. Lee [19] studied small slack factors $\varepsilon \ll 1$ by way of parallel systems. For $P_m|\text{online}|\sum p_j(1 - U_j)$, he gave a deterministic $m + 1 + m \cdot \varepsilon^{1/m}$ competitive algorithm. Hence, if $m = \log 1/\varepsilon$, the algorithm is $O(\log 1/\varepsilon)$ competitive. By simulating the parallel algorithm and picking one machine uniformly at random, Lee further obtained an expected competitive factor of $1 + 3 \log 1/\varepsilon$.

1.3 Outline

In Section 3, we describe properties of schedules if all jobs are completed prior to their deadlines. In a first order, it allows us to check whether a new job can be added to the schedule without determining the whole schedule. Furthermore, using a series of transformations and employing the slack factor property for deadlines, we are able to derive a canonical schedule without improving the competitive factor. The canonical schedule contains jobs with exponentially increasing deadlines. This exponential sequence represents a tradeoff between already accepted total processing time and the potential to accept more processing time in the future. Having determined the existence of such a schedule, the competitive ratio of our acceptance procedure follows almost immediately if all jobs have the same release date, see Section 4. When jobs arrive over time, the acceptance condition is insufficient due to the existence of jobs with large processing times. However, by introducing a careful charging scheme, we can leverage processing time of accepted jobs against processing time of rejected jobs without impacting the competitive factor, provided ε is small enough. Due to space restrictions, we omit a detailed calculus. We conclude by proving our lower bounds in Section 5.

2 Notations

Formally, we have a system of m parallel identical machines to schedule the jobs of a job sequence $\mathcal{J}$. The system allows preemption with migration, that is, it can interrupt the execution of any job and immediately or later resume the execution on a possibly different

[1] In literature the stretch $f = 1 + \varepsilon$ is often used instead. The two notions are equivalent.

machine without any preemption penalty (increase in processing time or forced additional idle time on the machine). A job $J_j \in \mathcal{J}$ has processing time p_j, release date r_j and deadline $d_j \geq (1+\varepsilon) \cdot p_j + r_j$ with $\varepsilon > 0$ being the slack factor of the system. We say that a schedule for a job system is *legal* if it completes all accepted jobs before or at their respective deadlines and each machine executes at most one job at any moment. The system receives the jobs one by one in sequence order and must irrevocably and without knowledge of any later jobs decide whether it accepts the actual job or not. However, it can only accept a job if there is a legal schedule for this job and all previously accepted jobs. We use the binary variable U_j to express the decision for job J_j: $U_j = 0$ denotes acceptance of job J_j while the rejection of J_j produces $U_j = 1$. It is our goal to maximize the total processing time of all accepted jobs $(\sum p_j \cdot (1 - U_j))$. Therefore, an (online) algorithm A determines $U_j(A)$ for all jobs in $\mathcal{J}$ and produces utilization $\sum p_j \cdot (1 - U_j(A))$.

We evaluate our algorithm by determining bounds for the competitive factor, that is the largest ratio between the optimal objective value and the objective value produced by online algorithm A for all possible job sequences $\mathcal{J}$: A has a competitive factor c_A if $c_A \geq \frac{p^*(\mathcal{J})}{\sum_{J_j \in \mathcal{J}}(1-U_j(A))\cdot p_j}$ holds for any job sequence $\mathcal{J}$ with $p^*(\mathcal{J}) = \max\{\sum_{J_j \in \mathcal{J}}(1-U_j)\cdot p_j\}$ being the maximum total processing time of any legal schedule for $\mathcal{J}$. Finally, c^* is a lower bound of the competitive factor if $c^* \leq c_A$ holds for any online algorithm A.

Next we introduce function $g(x) = \varepsilon \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^x$. Straightforward calculus yields the identity:

$$\sum_{j=i}^{m+i-1} g\left(\frac{j}{m}\right) + \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{i}{m}} = \sum_{j=i+1}^{m+i} g\left(\frac{j}{m}\right) \tag{1}$$

We further use g to define the following threshold expression:

$$f(m,\varepsilon) = \frac{1}{\varepsilon} \cdot \sum_{i=1}^{m} g\left(\frac{i}{m}\right) = \frac{1}{1+\varepsilon} \cdot \frac{\left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}}{\left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}} - 1}. \tag{2}$$

3 Legal Schedules

$\max\left\{\max_{J_j}\{p_j\}, \frac{1}{m}\sum_{J_j} p_j\right\}$ is the optimal makespan for the problem $P_m|\text{pmtn}|C_{\max}$, see, for instance, Pinedo [21]. Therefore, there is a legal schedule on m parallel identical machines for a set of jobs $\mathcal{J}$ with a common deadline d if and only if $p_j \leq d$ for all $J_j \in \mathcal{J}$ and $\sum_{J_j \in \mathcal{J}} p_j \leq d \cdot m$ hold. We use this result and a function $V_{\min}(t)$ to derive a similar necessary and sufficient condition for the extended problem with different deadlines. For a set of jobs $\mathcal{J}$ with possibly different deadlines, $V_{\min}(t)$ is the minimum total processing time that we must execute in interval $[0, t)$ of a legal schedule for time $t > 0$:

$$V_{\min}(t) = \sum_{J_j \in \mathcal{J}} \begin{cases} 0 & \text{for} \quad d_j - p_j \geq t \\ p_j & \text{for} \quad t \geq d_j \\ p_j - d_j + t & \text{else} \end{cases} \tag{3}$$

We sort all ν different deadlines in increasing order with d_ν being the largest deadline and set $d_0 = 0$.

▶ **Lemma 4.** *There is a legal preemptive schedule for a set of jobs $\mathcal{J}$ with deadlines on m parallel identical machines if and only if*

$$p_j \leq d_j \text{ for all } J_j \in \mathcal{J} \text{ and} \tag{4}$$

$$V_{min}(t) \leq t \cdot m \text{ for all } t > 0. \tag{5}$$

Proof. Due to Equation (3), $V_{\min}(t)$ is monotonically increasing and continuous. $\frac{d}{dt}V_{\min}(t)$ is piecewise constant and can only decrease if t is a deadline. Therefore, Inequalities (5) are valid if they hold for every deadline.

only if: Clearly if we have either $V_{\min}(d_i) > m \cdot d_i$ for at least one deadline d_i or least one job $J_j \in \mathcal{J}$ with $p_j > d_j$ then there is no legal schedule for $\mathcal{J}$.

if: We assume that Inequalities (4) and (5) hold. Then we generate a schedule for each interval $[d_{i-1}, d_i)$ in a backward order starting with $[d_{\nu-1}, d_\nu)$.

To this end, we generate an LRPT (Least Remaining Processing Time first) schedule for all jobs with deadline d_i. Since LRPT generates an optimal schedule for $P|\text{pmtn}|C_{\max}$, it produces a legal schedule within interval $[0, d_i)$ for these jobs due to the validity of Inequalities (4) for all jobs with deadline d_i and Inequality (5) for deadline d_i. We denote $\Delta = d_i - d_{i-1}$ and use interval $[0, \Delta)$ of the LRPT schedule as interval $[d_{i-1}, d_i)$ of our schedule. Then we reduce the processing time of each job by its total amount of processing within this interval and assign the new deadline d_{i-1} to all jobs with deadline d_i.

Now we must show that Inequalities (4) and (5) hold for the new largest deadline d_{i-1}. Since the LRPT schedule is legal, the total processing of a job in interval $[\Delta, d_i)$ of the LRPT schedule cannot exceed d_{i-1}. Therefore, Inequalities (4) hold for all these jobs after the modifications while Inequalities (4) remain valid for all unmodified jobs.

If there is some idleness in interval $[0, \Delta)$ of the LRPT schedule then we process $\min\{\Delta, p_j\}$ of each job J_j with deadline d_i within this interval, that is, the total processing in this interval is identical to $V_{\min}(d_i) - V_{\min}(d_{i-1})$. Therefore, $V_{\min}(d_{i-1})$ remains unchanged.

If no machine is idle in interval $[0, \Delta)$ of the LRPT schedule then $V_{\min}(d_{i-1})$ may increase and we have

$$V_{\min}(d_{i-1}) \quad = \quad V_{\min}(d_i) - m \cdot \Delta \leq m \cdot d_i - m \cdot \Delta = m \cdot d_i - m \cdot (d_i - d_{i-1}) = m \cdot d_{i-1}.$$

In both cases Inequality (5) is valid for deadline d_{i-1}. ◀

Since Lemma 4 does not consider the slack we introduce another function that leads to a sufficient but not necessary condition. First we say that a job J_j is large if $p_j > \frac{d_j}{1+\varepsilon}$ holds. Although there is no submission of large jobs, the progression of time may turn jobs into large jobs. Therefore, we must consider large jobs as well and define for every time $t > 0$:

$$V_{\text{accept}}(t) \quad = \quad \sum_{J_j \in \mathcal{J}} \begin{cases} p_j & \text{for } d_j \leq t \\ \max\{p_j - \frac{d_j}{1+\varepsilon}, 0\} & \text{for } d_j > t > d_j - \frac{d_j}{1+\varepsilon} \\ p_j - d_j + t & \text{for } d_j - \frac{d_j}{1+\varepsilon} \geq t > d_j - p_j \\ 0 & \text{for } d_j - p_j \geq t \end{cases} \tag{6}$$

Informally, we use $V_{\text{accept}}(t)$ to define a reduced threshold for accepting a new job J_j, that is, we reject a new job if for at least one time $t \geq d_j$, the new jobs leads to $V_{\text{accept}}(t) > t \cdot f(m, \varepsilon)$ - see Equation (2) - even if the acceptance of the job may produce a legal schedule.

Before formally describing this algorithm we must show that the validity of

$$V_{\text{accept}}(t) \quad \leq \quad t \cdot f(m, \varepsilon) \text{ for all } t > 0 \tag{7}$$

always guarantees a legal schedule. Therefore, the next lemma is the key lemma for our algorithm. Its proof is based on a reduction of the instance space with the help of several transformations until we obtain an instance space that we can analyze with the help of a few equations. Schwiegelshohn [23] used a similar approach to generate an alternative proof for

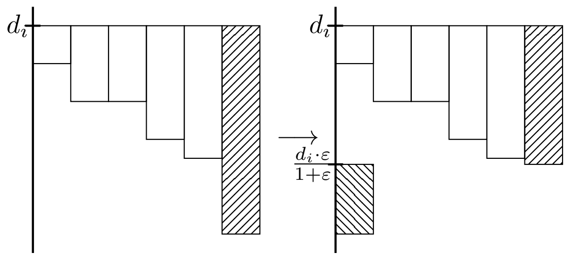

Figure 2 Large Job Splitting. The large job is marked as hatched area.

approximation factor of the lrf (largest ratio first) algorithm for the $P||\sum w_j C_j$ problem, see Kawaguchi and Kyan [15].

▶ **Lemma 5.** *There is a legal preemptive schedule for a set of jobs $\mathcal{J}$ with possibly different deadlines on m parallel identical machines if Inequalities (4) and (7) hold.*

Proof. As with function $V_{\text{min}}(t)$ we need not examine all t to check the validity of Inequalities (7). Due to Equation (6), $V_{\text{accept}}(t)$ has the following properties:

- It is monotonically increasing.
- It is continuous unless t is a deadline.
- $\frac{d}{dt}V_{\text{accept}}(t)$ is piecewise constant.
- $\frac{d}{dt}V_{\text{accept}}(t)$ can only decrease if $t = \frac{d_j}{1+\varepsilon}$ for a large job J_j.

Therefore, Inequalities (7) are valid if they hold for every deadline d_i and the corresponding time instance $\frac{d_i}{1+\varepsilon}$ if there is a large job with deadline d_i.

We use contradiction to prove this lemma and assume that Inequalities (4) and (7) hold while there is no legal schedule for $\mathcal{J}$, that is, there is at least one deadline d_h with $V_{\text{min}}(d_h) > d_h \cdot m$, see Lemma 4. Let d_j be the largest deadline with $V_{\text{min}}(d_j) > d_j \cdot m$. We apply several transformations that do not decrease $V_{\text{min}}(d_j)$ while the validity of Inequalities (4) and (7) is maintained. We use the notation $d_{>i}$ and $d_{i>}$ to describe the next larger and the next smaller deadline of deadline d_i, respectively.

First, we introduce and discuss our transformations.

Large job splitting. We split a large job J_i into one job J_{i_1} with deadline $d_{i_1} = d_i$ and processing time $p_{i_1} = \frac{d_i}{1+\varepsilon}$, and one job J_{i_2} with deadline $d_{i_2} = d_i \cdot \frac{\varepsilon}{1+\varepsilon}$ and processing time $p_{i_2} = p_i - \frac{d_i}{1+\varepsilon} \le d_i - \frac{d_i}{f} = d_{i_2}$, see Fig. 2.
This transformation neither changes $V_{\text{min}}(t)$ for any t nor $V_{\text{accept}}(t)$ for any $t \ge d_{i_2}$. Further, it may decrease but cannot increase $V_{\text{accept}}(t)$ for any $t < d_{i_2}$. Therefore, we assume that our job sequence does not contain any large job.

Job removal. We remove any job J_i with $d_i - p_i \ge d_j$. This transformation does not change $V_{\text{min}}(t)$ for $t \le d_j$ and cannot increase $V_{\text{accept}}(t)$ for any $t > 0$. Since other transformations may generate jobs with $d_i - p_i \ge d_j$ we must apply this transformation repeatedly.

Spread generation. Assume two jobs J_{i_1} and J_{i_2} with

$$d_{i_1} \quad = \quad d_{i_2} > d_j > d_{i_1} - p_{i_2} \ge d_{i_1} - p_{i_1} \ge d_{i_1} - \frac{d_{i_1}}{f}.$$

For job J_{i_2} we reduce its processing time p_{i_2} and its deadline d_{i_2} by $\delta < d_{i_1} - d_{i_1>}$, see Fig. 3. Due to $d_j - d_{i_1} + p_{i_2} = d_j - (d_{i_1} - \delta) + (p_{i_2} - \delta)$ this transformation does not change $V_{\text{min}}(d_j)$ while it does not increase $V_{\text{accept}}(t)$ for $t \ne d_{i_1} - \delta$. Clearly, the

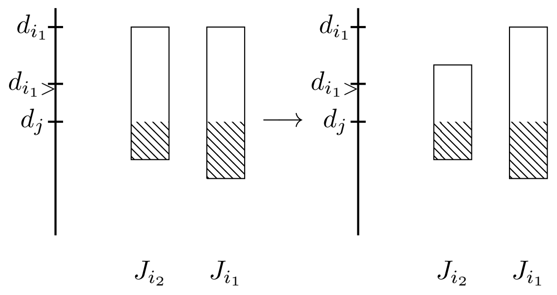

Figure 3 Spread Generation. Hatched areas contribute to $V_{\min}(d_j)$.

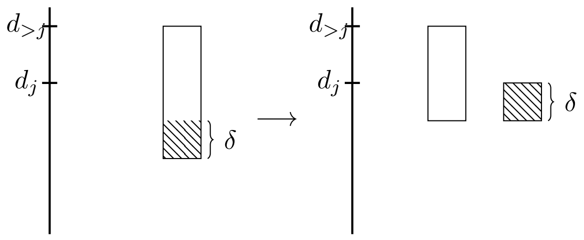

Figure 4 V_0-transformation. The hatched area becomes a new job and continues to contribute to $V_{\min}(d_j)$.

modified job J_{i_2} is not large, and we have

$$\begin{aligned} V_{\text{accept}}(d_{i_1}-\delta) &= V_{\text{accept}}(d_{i_1}) - p_{i_1} - \delta \\ &\leq d_{i_1}\cdot f(m,\varepsilon) - p_{i_1} - \delta \leq (d_{i_1}-\delta)\cdot f(m,\varepsilon) \end{aligned}$$

for $\delta \leq \frac{p_{i_1}}{f(m,\varepsilon)-1}$. Therefore, we can use any δ with $0<\delta<\min\{d_{i_1}-d_{i_1>}, \frac{p_{i_1}}{f(m,\varepsilon)-1}\}$.

V$_0$-transformation. Assume $V_{\text{accept}}(d_j) = d_j\cdot f(m,\varepsilon) - \delta$ with $\delta > 0$ and a job J_i with $d_i = d_{>j}$ and $d_j > d_i - p_i$. We introduce a new job with deadline d_j and processing time $p' = \min\{\delta, d_j - d_i + p_i\}$. Note that the new job is not large since job J_i is not large. Then we reduce processing time p_i by p', see Fig. 4. This transformation does not change $V_{\min}(d_j)$ and $V_{\text{accept}}(t)$ for $t<d_j$ and $t\geq d_{>j}$. For $d_{>j} > t \geq d_j$ we increase $V_{\text{accept}}(t)$ to $d_j\cdot f(m,\varepsilon) - \delta + p' \leq d_j\cdot f(m,\varepsilon)$.

V-transformation. Assume a job J_i with $V_{\text{accept}}(d_i) = d_i\cdot f(m,\varepsilon) - \delta_V < d_i\cdot f(m,\varepsilon)$ and $V_{\text{accept}}(d_{i>}) = d_{i>}\cdot f(m,\varepsilon)$ for $d_{i>}\geq d_j$: We reduce processing time p_i of job J_i by $p' = \frac{\delta_V}{(1+\varepsilon)\cdot f(m,\varepsilon)-1}$ to p_i' and its deadline d_i by $(1+\varepsilon)\cdot p'$ to d_i', respectively, see Fig. 5. This transformation produces $p_i' = p_i - p' \leq \frac{d_i}{1+\varepsilon} - \frac{d_i - d_i'}{1+\varepsilon} = \frac{d_i'}{1+\varepsilon}$ and

$$\begin{aligned} V_{\text{accept}}(t) &= V_{\text{accept}}(d_i) - p' = d_i\cdot f(m,\varepsilon) - \delta_V - \frac{\delta_V}{(1+\varepsilon)\cdot f(m,\varepsilon)-1} \\ &= d_i\cdot f(m,\varepsilon) - \frac{(1+\varepsilon)\cdot\delta_V\cdot f(m,\varepsilon)}{(1+\varepsilon)\cdot f(m,\varepsilon)-1} = (d_i - (1+\varepsilon)\cdot p')\cdot f(m,\varepsilon) \end{aligned}$$

for $d_i > t \geq d_i'$. It increases $V_{\min}(d_j)$ by $\varepsilon\cdot p'$ and decreases $V_{\text{accept}}(t)$ by p' for $t\geq d_i$. $V_{\text{accept}}(t)$ remains unchanged for $t<d_i'$. We have $d_i' > d_{i>}$ since $V_{\text{accept}}(d_i) - p_i \geq V_{\text{accept}}(d_{i>})$ holds. We apply this transformation in the order of increasing deadlines.

p-transformation. Assume two jobs J_{i_1} and J_{i_2} with $d_{i_1} > d_{i_2} > d_j > d_{i_1} - p_{i_1}$, $p_{i_1} < \frac{d_{i_1}}{1+\varepsilon}$, and $p_{i_2} < \frac{d_{i_2}}{1+\varepsilon}$. We reduce p_{i_2} by $p' = \min\{d_j - d_{i_2} + p_{i_2}, \frac{d_{i_1}}{1+\varepsilon} - p_{i_1}\}$ and increase p_{i_1} by p', see Fig. 6. This transformation does change $V_{\min}(d_j)$ and does not increase $V_{\text{accept}}(t)$ for any t.

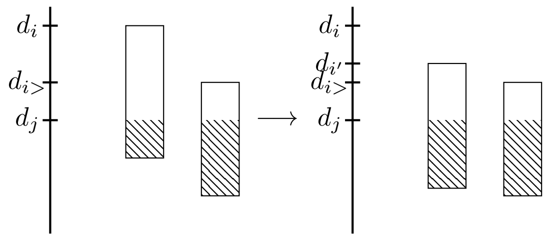

Figure 5 V-transformation. Hatched areas contribute to $V_{\text{min}}(d_j)$.

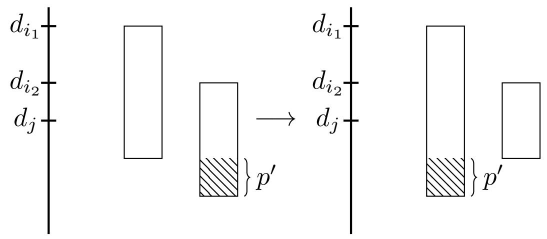

Figure 6 p-transformation. The hatched area moves to another job and continues to contribute to $V_{\text{min}}(d_j)$.

After repeatedly applying these transformations we obtain a job sequence with the following properties:

1. $V_{\text{accept}}(d_i) = d_i \cdot f(m, \varepsilon)$ for $d_i \geq d_j$
2. $p_i < \frac{d_i}{1+\varepsilon}$ for at most one deadline $d_i > d_j$
3. $p_i = \frac{d_i}{1+\varepsilon}$ for every other deadline $d_i > d_j$
4. There are no jobs with $d_i - p_i \geq d_j$.
5. There are no two jobs with the same deadline $d_i > d_j$.

We determine the value of $V_{\text{accept}}(d_i)$ for a job J_i with $d_i > d_j$:

$$V_{\text{accept}}(d_i) \quad = \quad d_i \cdot f(m, \varepsilon) = d_i \cdot \frac{\varepsilon}{1+\varepsilon} \cdot \sum_{z=1}^{m} \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{z}{m}} = d_i + d_i \cdot \frac{\varepsilon}{1+\varepsilon} \cdot \sum_{z=1}^{m-1} \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{z}{m}}$$

For $p_i = \frac{d_i}{1+\varepsilon}$ we have

$$V_{\text{accept}}(d_i) \quad = \quad V_{\text{accept}}(d_{i>}) + p_i = d_{i>} \cdot \frac{\varepsilon}{1+\varepsilon} \cdot \sum_{z=1}^{m} \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{z}{m}} + \frac{d_i}{1+\varepsilon}.$$

Combining these two equations yields $d_i = d_{i>} \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}$.

First assume that $p_i = \frac{d_i}{1+\varepsilon}$ holds for every deadline $d_i > d_j$. Then we have a geometric sequence of deadlines $d_j, d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}, d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{2}{m}}, \ldots$. In this sequence, the contribution $v_{\text{min}}(h)$ of the job with deadline $d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{h}{m}}$ to $V_{\text{min}}(d_j)$ is:

$$v_{\text{min}}(h) \quad = \quad d_j - d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{h}{m}} \cdot \left(1 - \frac{1}{1+\varepsilon}\right) = d_j \cdot \left(1 - \frac{\varepsilon}{1+\varepsilon} \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{h}{m}}\right)$$

Therefore, our sequence ends with $d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{m-1}{m}}$ since no job with deadline $d_j \cdot \frac{1+\varepsilon}{\varepsilon}$ or larger can influence $V_{\text{min}}(d_j)$ unless the job is large.

Alternatively we assume a sequence that contains a job J_i with deadline $d_i = d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s-1}{m}} \cdot z$ for $1 \le s \le m$ and $1 < z < \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}$ and calculate p_i using Equation (2):

$$\begin{aligned} d_i \cdot f(m,\varepsilon) &= d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s-1}{m}} \cdot z \cdot f(m,\varepsilon) = d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s-1}{m}} \cdot f(m,\varepsilon) + p_i \\ \Leftrightarrow p_i &= d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s}{m}} \cdot \frac{1}{1+\varepsilon} \cdot \frac{z-1}{\left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}} - 1}. \end{aligned}$$

Then we determine the difference between the contribution to $V_{\text{min}}(d_j)$ by the new sequence and the original geometric sequence. We calculate this difference for the deadlines at position s

$$\begin{aligned} \Delta(s) &= d_j - d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s}{m}} \cdot \left(1 - \frac{1}{1+\varepsilon}\right) - \left(d_j - \left(d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s-1}{m}} \cdot z - p_i\right)\right) \\ &= d_j \cdot \frac{z - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}}{\left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}} - 1} \cdot \left(\left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s-m}{m}} - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s-1}{m}}\right) \end{aligned}$$

and for a deadline at position q with $s+1 \le q \le m$:

$$\begin{aligned} \Delta(q) &= d_j - d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{q}{m}} \cdot \left(1 - \frac{1}{1+\varepsilon}\right) - \left(d_j - d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{q-1}{m}} \cdot z \cdot \left(1 - \frac{1}{1+\varepsilon}\right)\right) \\ &= d_j \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{q-1}{m}-1} \cdot \left(z - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}\right) \end{aligned}$$

The total difference over the sequence of deadlines is

$$\begin{aligned} \sum_{q=s+1}^{m} \Delta(q) &= d_j \cdot \left(z - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}\right) \cdot \frac{\varepsilon}{1+\varepsilon} \cdot \sum_{q=s+1}^{m} \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{q-1}{m}} \\ &= d_j \cdot \frac{z - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}}{\left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}} - 1} \cdot \left(1 - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s}{m}-1}\right). \end{aligned}$$

$$\sum_{q=s}^{m} \Delta(q) = d_j \cdot \frac{z - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}}}{\left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{1}{m}} - 1} \cdot \left(\left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s-m}{m}} - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s}{m}} + 1 - \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{s-m}{m}}\right) \ge 0.$$

Due to the restrictions on z, we have $\sum_{q=s}^{m} \Delta_{\text{min}}(q) = 0$ if and only if $s = 0$ holds. Therefore, we obtain the largest contribution to $V_{\text{min}}(d_j)$ with a sequence of geometrically increasing deadlines. For this sequence, we calculate $V_{\text{min}}(d_j)$:

$$V_{\text{min}}(d_j) = d_j \cdot f(m,\varepsilon) + \sum_{i=1}^{m-1} \left(d_j - \frac{\varepsilon}{1+\varepsilon} \cdot \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{i}{m}} \cdot d_j\right) = d_j \cdot m$$

This result contradicts our assumption. ◀

Algorithm 1 Admission_Control

```
1: for each newly submitted job $J_j$ do
2:     tentatively accept $J_j$
3:     for each accepted job $J_i$ do
4:         if $d_i \geq d_j$ then
5:             calculate $v = V_{\text{accept}}(d_i)$
6:             if $v > f(m,\varepsilon) \cdot d_i$ then
7:                 reject $J_j$
```

4 Upper Bound of the Online Algorithm

In this section we present our online algorithm for the $P_m|\varepsilon, \text{online}, \text{pmtn}|\sum p_j(1-U_j)$ problem. First we address the admission control case with all jobs arriving at time 0, i.e., the online property only considers the sequence of jobs but no progression of time. Our Algorithm 1 Admission_Control simply applies the threshold of Lemma 5: If no accepted job (including the newly submitted one) exceeds the threshold then the job is accepted, otherwise it is rejected. Since no job is large, a job J_j does not influence $V_{\text{accept}}(t)$ for $t < d_j$. Due to the first paragraph of the proof of Lemma 5, we only must consider time instances that are deadlines. Having accepted the jobs, a schedule can be generated by applying Lemma 4. Next we prove the competitive factor of this algorithm.

▶ **Theorem 6.** *The $P_m|\varepsilon$, online, pmtn$|\sum p_j \cdot (1-U_j)$ problem with $r_j = 0$ for all jobs admits a deterministic online admission control algorithm with competitive ratio at most $\frac{m\cdot(1+\varepsilon)}{\sum_{i=0}^{m-1} g(\frac{i}{m})}$.*

Proof. Since any algorithm produces an optimal result if it accepts all jobs we assume that some jobs are rejected. Since the deadline condition Inequality (4) is valid for every submitted job J_j, algorithm Admission_Control only rejects a job J_j if there is a $t \geq d_j$ with

$$\begin{aligned} V_{\text{accept}}(t) &\geq t \cdot f(m,\varepsilon) - p_j \geq t \cdot \left(f(m,\varepsilon) - \frac{1}{1+\varepsilon}\right) \\ &\geq \frac{t}{1+\varepsilon} \cdot \left(\varepsilon \cdot \sum_{h=1}^{m} \left(\frac{1+\varepsilon}{\varepsilon}\right)^{\frac{h}{m}} - 1\right) = \frac{t}{1+\varepsilon} \cdot \sum_{h=0}^{m-1} g(\frac{h}{m}) \end{aligned}$$

Due to Equations (3) and (6), we have $V_{\text{min}}(\tau) \geq V_{\text{accept}}(\tau)$ for all $\tau \geq 0$ while no algorithm can yield more than $V_{\text{min}}(\tau) = \tau \cdot m$. In the following we consider two intervals: $I_1 = [0, t_s)$ with t_s being the largest time with $V_{\text{min}}(t) = t \cdot \frac{1}{1+\varepsilon} \cdot \sum_{h=0}^{m-1} g(\frac{h}{m})$. Interval $I_2 = [t_s, d_\nu)$ only exists for $d_\nu > t_s$. If this case the maximum total processing in I_2 is $V' = V_{\text{min}}(d_\nu) - V_{\text{min}}(t_s)$ otherwise we say $V' = 0$. Note that $t_s > d_j$ holds. Since there is no rejected job with deadline t_s or larger it is not possible to increase V' in an optimal schedule. Then we have

$$c_A \leq \frac{t_s \cdot m + V'}{t_s \cdot \frac{1}{1+\varepsilon} \cdot \sum_{h=0}^{m-1} g(\frac{h}{m}) + V'} < \frac{t_s \cdot m}{t_s \cdot \frac{1}{1+\varepsilon} \cdot \sum_{h=0}^{m-1} g(\frac{h}{m})} = \frac{m}{\frac{1}{1+\varepsilon} \cdot \sum_{h=0}^{m-1} g(\frac{h}{m})}. \quad ◀$$

For the general case with progression of time we use Algorithm 2 Online_Utilization. Lines 9 to 12 of Algorithm Online_Utilization are identical to Algorithm Admission_Control. Our reference time t_{ref} is the latest submission time (Line 2). Since progression of time may produce large jobs we must also examine the acceptance condition for those time instances at which the large part of a job ends due to the first paragraph of the proof of Lemma 5, see

Algorithm 2 Online_Utilization

```
1: for each newly submitted job $J_j$ do
2:     $t_{ref} = r_j$;
3:     $U_j = 0$;
4:     for each job $J_i$ with $U_i = 0$ do
5:         if $p_i > (d_i - t_{ref})/(1+\varepsilon)$ and $(d_i - t_{ref})/(1+\varepsilon) + t_{ref} \geq d_j$ then

11:            if $v > f(m,\varepsilon) \cdot (d_i - t_{ref})$ then
12:                $U_j = 1$
13:        if $d_i > d_j - p_j$ and $d_i < d_j$ then
14:            calculate $v = V_{\text{min}}(d_i)$
15:            if $v > m \cdot (d_i - t_{ref})$ then
16:                $U_j = 1$
```

Lines 5 to 8. We must use the current reference time when determining these time instances (Lines 5 and 6).

Progression of the reference time may lead to large jobs and it may produce a violation of the acceptance condition for some time instances. To prevent such a situation, we introduce the additional *legal test* based on Lemma 4 for all jobs that have passed the acceptance test of Lemma 5, see Lines 13 to 16 in Algorithm 2 Online_Utilization. If a job passes all tests it is accepted.

▶ **Lemma 7.** *There is a legal schedule for all jobs accepted by Algorithm 2 Online_Utilization.*

Proof. The proof directly follows from Lemma 4. ◀

In the next theorem we derive the competitive factor of our algorithm.

▶ **Theorem 1** (restated). *The $P_m|\varepsilon, online, pmtn|\sum p_j \cdot (1-U_j)$ problem admits a deterministic online algorithm with competitive ratio at most* $\max\{\frac{m\cdot(1+\varepsilon)}{\sum_{i=0}^{m-1} g(\frac{i}{m})}, \frac{4}{3}\}$.

Proof. We use induction on the number of submission times. For a single submission time, the claim holds due to Theorem 6. Therefore, we assume validity of the claim for k different submission times. As in the proof of Theorem 6 let t_s be the largest time instance with $V_{\text{min}}(t_s) = t_s \cdot \frac{1}{1+\varepsilon} \cdot \sum_{h=0}^{m-1} g(\frac{h}{m})$ with respect to any previous reference time (release date of a job). If we use the expression *with respect to a reference time* then we reduce all times by the reference time when calculating $V_{\text{min}}(t)$ and $V_{\text{accept}}(t_s)$ while we keep the original values for the purpose of time comparison. We divide the rest of our proof into four cases.

1. There is no rejection of any job with release date r_{k+1} due to the legal test in Algorithm 2 Online_Utilization and $t_s \geq r_{k+1}$. Since the progression of the reference time to r_{k+1} cannot increase t_s in a non-delay schedule without the acceptance of a new job we can assume that all job parts that are not completed before r_{k+1} have release date r_{k+1} and apply the proof of Theorem 6 to all jobs with release date r_{k+1}.

2. There is no rejection of any job with release date r_{k+1} due to the legal test in Algorithm 2 Online_Utilization and $t_s < r_{k+1}$. We assume that the optimal schedule uses all available resources before t_s. Then we define V' as in the proof of Theorem 6 and split all job parts contributing to V' into a job part that can be executed before r_{k+1} and a job part that must be executed after r_{k+1}. We denote the total processing time of the first type of job parts by $V'(t_s)$. If our scheduling algorithm executes the $V'(t_s)$ completely within interval $[t_s, r_{k+1})$ then we can apply the proof of Theorem 6 to all jobs with release date r_{k+1} and obtain the claim. Therefore, we assume that not the total processing time of $V'(t_s)$ is scheduled within interval $[t_s, r_{k+1})$. Such situation is only possible if a job J_j from $V'(t_s)$ with processing time p_j is started at time $\tau > r_{k+1} - p_j$. In a non-delay schedule such delayed start requires all machines to be busy in interval $[t_s, \tau)$. In order to maximize the total processing time of $V'(t_s)$ that is scheduled after r_{k+1} we assume that we have b long jobs each with the maximum processing time $r_{k+1} - t_s$ and each starting at time τ while all other jobs contributing to $V'(t_s)$ are only executed in interval $[t_s, \tau)$, that is, we have $V'(t_s) = (\tau - t_s) \cdot m + (r_{k+1} - t_s) \cdot b \leq m \cdot (r_{k+1} - t_s)$. We denote the total processing time of jobs with release date r_{k+1} in our schedule including $V' \backslash V'(t_s)$ by $\bar{V}$. Due to Theorem 6, the total processing time in the optimal schedule cannot exceed $c_A \cdot (\bar{V} + b \cdot (\tau - t_s))$. This situation cannot influence the competitive factor if the following condition holds:

$$\begin{aligned} c_A &\geq \frac{c_A \cdot (\bar{V} + b \cdot (\tau - t_s)) + b \cdot (r_{k+1} - t_s) + m \cdot (\tau - t_s)}{\bar{V} + b \cdot (r_{k+1} - t_s) + m \cdot (\tau - t_s)} \\ \Leftrightarrow 1 - \frac{1}{c_A} &\geq \frac{\frac{b}{m} \cdot \frac{\tau - t_s}{r_{k+1} - t_s}}{\frac{b}{m} + \frac{\tau - t_s}{r_{k+1} - t_s}} \end{aligned}$$

The term on the right side has the maximum value for $\frac{b}{m} = \frac{\tau - t_s}{r_{k+1} - t_s} = \frac{1}{2}$ resulting in $c_A \geq \frac{4}{3}$, see also Hussein and Schwiegelshohn [12]. Therefore, the competitive factor is not affected for small ε.

3. A least one job with release date r_{k+1} is rejected due to the legal test in Algorithm 2 Online_Utilization and $t_s \leq r_{k+1}$. This case leads to a contradiction since we have $V_{\text{accept}}(t) \leq V_{\min}(t) \leq t \cdot \frac{1}{1+\varepsilon} \cdot \sum_{h=0}^{m-1} g(\frac{h}{m})$ for all $t \geq r_{k+1}$ with respect to reference time r_{k+1}. Therefore, we can apply Lemma 5 for all jobs with release date r_{k+1} and any accepted job with release date r_{k+1} passes the legal test.

4. A least one job with release date r_{k+1} is rejected due to the legal test in Algorithm 2 Online_Utilization and $t_s \leq r_{k+1}$. Before discussing this case we consider the worst case example in the proof of Lemma 5 for $V_{\min}(t_s) = t_s \cdot \frac{1}{1+\varepsilon} \cdot \sum_{h=0}^{m-1} g(\frac{h}{m})$ and a single release time. Let $t_0 = t_s \cdot \frac{\varepsilon}{1+\varepsilon}$. Then we have for $t \geq t_0$

$$\begin{aligned} V_{\min}(t) &\leq m \cdot \left(\int_{t_0}^{t} \left(1 - \log_{\frac{1+\varepsilon}{\varepsilon}} \left(\frac{y}{t_0} \right) \right) dy + t_0 \right) \\ &\leq m \cdot \left(t - \frac{1}{\ln \frac{1+\varepsilon}{\varepsilon}} \cdot \left(t \cdot \ln \frac{t}{t_0} - t + t_0 \right) \right). \end{aligned} \tag{8}$$

Progression of time without accepting any new jobs can only increase the bound for $V_{\min}(t)$. Since any new accepted job must also pass the acceptance test of Lemma 5, Inequality (8) must always hold for a possibly new t_s. Therefore, any job J_h with release date r_{k+1} and a deadline $d_h \geq t_s$ cannot fail the legal test. ◀

5 Lower Bounds for Deterministic Online Algorithms

▶ **Theorem 2** (restated). *Any deterministic online algorithm for the $P_m|\varepsilon, online, pmtn|\sum p_j \cdot (1-U_j)$ problem has a competitive ratio of at least $\frac{\lfloor m\cdot(1+\varepsilon)\rfloor}{\sum_{i=0}^{m-1} g(\frac{i}{m})} \cdot (1-\delta)$ for any $\delta > 0$.*

Proof. In our proof the job sequence consists of several series of jobs all with $d_j \geq p_j \cdot (1+\varepsilon)$. In every step the adversary submits identical jobs until we have either accepted the planned number of jobs or until $\lfloor m \cdot (1+\varepsilon)\rfloor$ jobs have been submitted. We will show that the latter case produces a competitive ratio $c_A \geq \frac{\lfloor m\cdot(1+\varepsilon)\rfloor}{\sum_{i=0}^{m-1} g(\frac{i}{m})}$. Therefore, we are forced to accept the desired number of jobs.

Furthermore, we must show that there is a legal schedule for all accepted jobs. To this end, we use Lemma 4 with deadlines $d_i = \frac{1+\varepsilon}{\varepsilon} \cdot g(\frac{i-1}{m}) = g(\frac{i-1}{m}+1)$ for $1 \leq i \leq m$ and $d_{m+1} = (1+\varepsilon)\cdot(\frac{1+\varepsilon}{\varepsilon} - \delta)$ for an arbitrarily small $\delta > 0$. Since there is only a single accepted job for every deadline d_i with $1 < i \leq m$, less than m jobs contribute to the total processing time in $V_{\min}(d_{i+1}) - V_{\min}(d_i)$ for $1 \leq i < m$. Therefore, we must only consider $V_{\min}(d_1)$ to show the existence of a legal schedule.

1. The adversary submits a job with processing time $\sum_{i=0}^{m-1} g(\frac{i}{m}) - \lfloor\sum_{i=0}^{m-1} g(\frac{i}{m})\rfloor < 1$ and deadline $(1+\varepsilon)$. We must accept this job to prevent $c_A \to \infty$.
2. The adversary submits identical jobs with processing time 1 and deadline $1+\varepsilon$ until $\lfloor\sum_{i=0}^{m-1} g(\frac{i}{m})\rfloor + 1$ such jobs have been accepted. If we accept this number of jobs then our total processing time is
$$\sum_{J_j\in\mathcal{J}} (1-U(j))\cdot p_j = \sum_{i=0}^{m-1} g(\frac{i}{m}) + 1 = \sum_{i=1}^{m} g(\frac{i}{m}) = V_{\min}(1+\varepsilon),$$
see Equation (1). There is a legal schedule since we have $V_{\min}(1+\varepsilon) < m\cdot g(1) = m\cdot(1+\varepsilon)$. If we accept at most $\lfloor\sum_{i=0}^{m-1} g(\frac{i}{m})\rfloor$ of these jobs then we have a total processing time $\sum_{J_j\in\mathcal{J}}(1-U(j))\cdot p_j = \sum_{i=0}^{m-1} g(\frac{i}{m})$ and a competitive factor
$$c_A = \frac{\lfloor m\cdot(1+\varepsilon)\rfloor}{\sum_{i=0}^{m-1} g(\frac{i}{m})}.$$
3. The adversary executes $m-1$ similar submission iterations. We assume that at the beginning of iteration k we have
$$\sum_{J_j\in\mathcal{J}} (1-U(j))\cdot p_j = \sum_{i=k}^{m+k-1} g(\frac{i}{m}) \text{ and}$$
$$V_{\min}(1+\varepsilon) = \sum_{i=1}^{m} g(\frac{i}{m}) + (k-1)\cdot(1+\varepsilon) - \sum_{i=1}^{k-1} g(\frac{i}{m}),$$
respectively. Clearly, this assumption holds for $k=1$. The adversary submits jobs with processing time $p = \frac{1}{\varepsilon}g(\frac{k}{m})$ and deadline $d = \frac{1+\varepsilon}{\varepsilon}g(\frac{k}{m}) = g(\frac{k}{m}+1)$ until we accept one job. If we do not accept any of these jobs then the total processing time remains unchanged and we obtain
$$c_A = \frac{\lfloor m\cdot(1+\varepsilon)\rfloor\cdot\frac{1}{\varepsilon}g(\frac{k}{m})}{\sum_{i=k}^{m+k-1} g(\frac{i}{m})} = \frac{\lfloor m\cdot(1+\varepsilon)\rfloor}{\sum_{i=0}^{m-1} g(\frac{i}{m})}.$$
Otherwise we have
$$\sum_{J_j\in\mathcal{J}} (1-U(j))\cdot p_j = \sum_{i=k}^{m+k-1} g(\frac{i}{m}) + \frac{1}{\varepsilon}\cdot g(\frac{k}{m}) = \sum_{i=k+1}^{m+k} g(\frac{i}{m})$$
$$\Leftrightarrow V_{\min}(1+\varepsilon) = \sum_{i=1}^{m} g(\frac{i}{m}) + k\cdot(1+\varepsilon) - \sum_{i=1}^{k} g(\frac{i}{m})$$
due to $1+\varepsilon-(d-p) = 1+\varepsilon - g(\frac{k}{m})$ and Equation (1).

4. After iteration $m-1$ we have

$$\sum_{J_j \in \mathcal{J}} (1-U(j)) \cdot p_j = \sum_{i=m}^{2m-1} g(\frac{i}{m}) \text{ and}$$

$$V_{\min}(1+\varepsilon) = g(1) + (m-1)\cdot(1+\varepsilon) = m\cdot(1+\varepsilon).$$

Finally, the adversary submits $\lfloor m\cdot(1+\varepsilon)\rfloor$ jobs with processing time $p = \frac{1+\varepsilon}{\varepsilon}\cdot(1-\delta)$ and deadline $d_{m+1} = (1+\varepsilon)\cdot\frac{1+\varepsilon}{\varepsilon}\cdot(1-\delta)$ for an arbitrarily small $\delta > 0$. Since any such job must start at the latest at time

$$d_{m+1} - p = \varepsilon\cdot\left(\frac{1+\varepsilon}{\varepsilon}\cdot(1-\delta)\right) < (1+\varepsilon),$$

we cannot accept any such job and obtain the competitive factor

$$c_A = \frac{\lfloor m\cdot(1+\varepsilon)\rfloor\cdot\frac{1+\varepsilon}{\varepsilon}\cdot(1-\delta)}{\sum_{i=m}^{2m-1} g(\frac{i}{m})} = \frac{\lfloor m\cdot(1+\varepsilon)\rfloor}{\sum_{i=0}^{m-1} g(\frac{i}{m})}\cdot(1-\delta). \blacktriangleleft$$

We now turn our attention to the greedy acceptance policy. Here, we accept any job that can be computed prior to its deadline without delaying the currently accepted jobs beyond their respective deadlines.

▶ **Theorem 3** (restated). *The greedy acceptance policy for the $P_m|\varepsilon, online, pmtn|\sum p_j\cdot(1-U_j)$ problem has a competitive ratio of at least $\frac{1+\varepsilon}{\varepsilon} - \delta$ for any $\delta > 0$.*

Proof. We consider an arbitrarily small $\delta > 0$ and use at the beginning a sequence of $1+\lceil m\cdot(1+\varepsilon)\rceil$ jobs with the following processing times:

$$p_1 = \varepsilon\cdot m\cdot\delta$$

$$p_2 = \begin{cases} m\cdot(1+\varepsilon) - \lfloor m\cdot(1+\varepsilon)\rfloor - \varepsilon\cdot m\cdot\delta & \text{for } m\cdot(1+\varepsilon) \neq \lfloor m\cdot(1+\varepsilon)\rfloor \\ 1-\varepsilon\cdot m\cdot\delta & \text{for } m\cdot(1+\varepsilon) = \lfloor m\cdot(1+\varepsilon)\rfloor \end{cases}$$

$$p_3 = p_4 = \ldots = p_{1+\lceil m\cdot(1+\varepsilon)\rceil} = 1$$

All jobs $p_1, \ldots p_{1+\lceil m\cdot(1+\varepsilon)\rceil}$ have deadline $1+\varepsilon$ and must be accepted according to our policy since we have

$$V_{\min}(1+\varepsilon) = \sum_{i=1}^{1+\lceil m\cdot(1+\varepsilon)\rceil} p_i = m\cdot(1+\varepsilon). \tag{9}$$

Then the adversary submits m identical jobs with processing times $p = \frac{1+\varepsilon}{\varepsilon} - \delta$ and deadline $d = (1+\varepsilon)\cdot p = \frac{(1+\varepsilon)^2}{\varepsilon} - (1+\varepsilon)\cdot\delta$. Since the acceptance of any one of these jobs leads to

$$V_{\min}(1+\varepsilon) = m\cdot(1+\varepsilon) + 1 + \varepsilon - (d-p) = m\cdot(1+\varepsilon) + \varepsilon\cdot\delta > m\cdot(1+\varepsilon) \tag{10}$$

we must reject everyone of these jobs.

However, the rejection of job J_1 allows acceptance of all other jobs since we have $V_{\min}(1+\varepsilon) = m\cdot(1+\varepsilon)$ and $V_{\min}(\frac{(1+\varepsilon)^2}{\varepsilon} - (1+\varepsilon)\cdot\delta) = m\cdot\left(\frac{(1+\varepsilon)^2}{\varepsilon} - (1+\varepsilon)\cdot\delta\right)$ due to Equations (9) and (10).

Therefore, the greedy acceptance algorithm has a competitive factor of at least

$$c_{A_{\text{greedy}}} = \frac{m\cdot\left(\frac{(1+\varepsilon)^2}{\varepsilon} - (1+\varepsilon)\cdot\delta\right)}{m\cdot(1+\varepsilon)} = \frac{1+\varepsilon}{\varepsilon} - \delta. \blacktriangleleft$$

Since the lower bound of the competitive factor for the common preemption model is identical to the competitive factor for preemption without migration, see Lemma 5 and DasGupta and Palis [7], we can state that a greedy acceptance policy cannot exploit the benefits of migration.

Abstract

We describe a general probabilistic framework to address a variety of Fréchet-distance optimization problems. Specifically, we are interested in finding minimal *bottleneck*-paths in *d*-dimensional Euclidean space between given start and goal points, namely paths that minimize the maximal value over a continuous cost map. We present an efficient and simple sampling-based framework for this problem, which is inspired by, and draws ideas from, techniques for robot motion planning. We extend the framework to handle not only standard bottleneck pathfinding, but also the more demanding case, where the path needs to be monotone in all dimensions. Finally, we provide experimental results of the framework on several types of problems.

1 Introduction

This paper studies the problem of finding near-optimal paths in *d*-dimensional Euclidean space. Specifically, we are interested in *bottleneck* paths which minimize the maximal value the path obtains over a generally-defined continuous cost map. As an example, suppose that one wishes to plan a hiking route in a mountainous region between two camping grounds, such that the highest altitude along the path is minimized [17]. In this case, the map assigns to each two-dimensional point its altitude. A similar setting, albeit much more complex, requires to find a pathway of low energy for a given protein molecule (see, e.g., [37]).

Our main motivation for studying bottleneck optimization over cost maps is its tight relation to the Fréchet distance (or matching), which is a popular and widely studied similarity measure in computational geometry. The problem has applications to various domains such as path simplification [19], protein alignment [27], handwritten-text search [48], and signature verification [53]. The Fréchet distance, which was initially defined for curves, is often considered to be a more informative measure than the popular *Hausdorff* distance as it takes into consideration not only each curve as a whole but also the location and the ordering of points along it. Usually one is interested not only in the Fréchet distance between two given curves, but also in the parametrization which attains the optimal alignment.

Since its introduction by Alt and Godau [2] in 1995, a vast number of works has been devoted to the subject, and many algorithms have been developed to tackle various settings of the problem. However, from a practical standpoint the problem is far from being solved: for many natural extensions of the Fréchet problem only prohibitively-costly algorithms are known. Furthermore, in some cases it was shown, via hardness proofs, that efforts for finding polynomial-time algorithms are doomed to fail. For some variants of the problem efficient algorithms are known to exist, however their implementation requires complex geometric machinery that relies on geometric kernels with infinite precision [30].

Contribution. We describe a generic, efficient and simple algorithmic framework for solving pathfinding optimization problems over cost maps. The framework is inspired by, and draws ideas from, sampling-based methods for robot motion planning. We provide experimental results of the framework on various scenarios. Furthermore, we theoretically analyze the framework and show that the cost of the obtained solution converges to the optimum, as the number of samples increases. We also consider the more demanding case, where paths need to be monotone in all dimensions.

Organization. In Section 2 we review related work. In Section 3 we provide a formal definition of the bottleneck pathfinding problem. In Section 4 we describe an algorithmic framework for solving this problem. In Section 5 we provide an analysis of the method. Finally, in Section 6 we report on experimental results.

2 Related work

This section is devoted to related work on Fréchet distance and robot motion planning.

2.1 Fréchet distance

The *Fréchet distance* between two curves is often described by an analogy to a person walking her dog: each of the two creatures is required to walk along a predefined path and the person wishes to know the length of the shortest *leash* which will make this walk possible. In many cases one also likes to know how to advance along the path given the short leash.

Formally, let $\sigma_1, \sigma_2 : [0,1] \rightarrow \mathbb{R}^d$ be two continuous curves. We wish to find a traversal along the two curves which minimizes the distance between the two traversal points. The traversal is defined by two continuous parametrizations $\alpha_1, \alpha_2 : [0,1] \rightarrow [0,1]$ of σ_1, σ_2 respectively, where for a given point in time $\tau \in [0,1]$, the positions of the person and her dog are specified by $\sigma_1(\alpha_1(\tau))$ and $\sigma_2(\alpha_2(\tau))$, respectively. The *Fréchet distance* between σ_1, σ_2 is defined by the expression

$$\min_{\alpha_1,\alpha_2:[0,1]\rightarrow[0,1]} \max_{\tau\in[0,1]} \|\sigma_1(\alpha_1(\tau)) - \sigma_2(\alpha_2(\tau))\|_2.$$

Alt and Godau [2] described an $O(n^2 \log n)$-time algorithm for the setting of two polygonal curves, where n is the number of vertices in each of the two curve. Buchin et al. [12] described a different method for solving this problem for the same running time. Recently, Buchin et al. [10] developed an algorithm with a slightly improved running time $O(n^2 \log^2 \log n)$. Har-Peled and Raichel [22] introduced a simpler randomized algorithm with running time of $O(n^2 \log n)$. Bringmann [6] showed that an algorithm with running time of $O(n^{2-\delta})$, for some constant $\delta > 0$, does not exist, unless a widely accepted conjecture, termed

SETH [25], is wrong. In a following work [7] this conditional lower bound was extended to $(1+\varepsilon)$-approximation algorithms of the Fréchet problem, where $\varepsilon \leq 0.399$.

The notion of Fréchet distance can be extended to k curves in various ways. One natural extension can be described figuratively as having a pack of k dogs, where each of the dogs has to walk along a predefined path, and every pair of dogs is connected with a leash. The goal now is to find a parametrization which minimizes the length of the longest leash. Dumitrescu and Rote [18] introduced a generalization of the Alt-Godau algorithm to this case, which runs in $O(kn^k \log n)$ time, i.e., exponential in the number of input curves. They also describe a 2-approximation algorithm with a much lower running time of $O(k^2n^2 \log n)$. In the work of Har-Peled and Raichel [22] mentioned above they also consider the case of k input curves and devise an $O(n^k)$ algorithm. Notably, their technique is flexible enough to cope with different Fréchet-type goal functions over the k curves. Furthermore, their algorithm is also applicable when the k curves are replaced with k *simplicial complexes*, and the problem is to find k curves—one in each complex—which minimize the given goal function. A recent work [9], which extends the conditional lower bound mentioned earlier for the setting of multiple curves, suggests that a running time that is exponential in the number of curves is unavoidable.

The notion of Fréchet distance can be generalized to more complex objects. Buchin et al. [13] considered the problem of finding a mapping between two simple polygons, which minimizes the maximal distance between a point and its image in the other polygon. More formally, given two simple polygons $P, Q \subset \mathbb{R}^2$ the problem consists of finding a mapping $\delta : P \rightarrow Q$ which minimizes the expression $\max_{p\in P} \|p - \delta(p)\|_2$, subject to various constraints on δ. They introduced a polynomial-time algorithm for this case. In a different paper, Buchin et al. [11] showed that the decision problem is NP-hard for more complex geometric objects, e.g., pairs of polygons with holes in the plane or pairs of two-dimensional terrains. Another interesting NP-hard problem that was studied by Sherette and Wenk [41] is *curve embedding* in which one wishes to find an embedding of a curve in $\mathbb{R}^3$ to a given plane, which minimizes the Fréchet distance with the curve. In a similar setting Meulemans [34] showed that it is NP-hard to decide whether there exists a simple cycle in a plane-embedded graph that has at most a given Fréchet distance to a simple closed curve.

The Fréchet distance between curves in the presence of obstacles have earned some attention. Cook and Wenk [16] studied the *geodesic* variant, which consists of a simple polygon and two polygonal curves inside it. As in the standard formulation, the main goal is to minimize the length of the leash, but now the leash may wrap or bend around obstacles. Their algorithm has running time of $O(m + n^2 \log mn \log n)$, where m is the complexity of the polygon and n is defined as the total complexity of the two curves, as before. The more complex *homotopic* setting is a special case of the aforementioned geodesic setting, with the additional constraint that the leash must continuously deform. Chambers et al. [14] considered this problem for the specific setting of two curves in planar environment with polygonal obstacles. They developed an algorithm whose running time is $O(N^9 \log N)$, where $N = n + m$ for n and m as defined above.

2.2 Motion planning

Motion planning is a fundamental problem in robotics. In its most basic form, the problem consists of finding a collision-free path for a robot $\mathcal{R}$ in a workspace environment $\mathcal{W}$ cluttered with obstacles. Typically, the problem is approached from the configuration space $\mathcal{C}$—the set of all robot configurations. The problem can be reformulated as finding a continuous curve in $\mathcal{C}$, which entirely consists of collision-free configurations and represents a path for the robot from a given start configuration to another, target, configuration. An important attribute of the problem is the number of *degrees of freedom* of $\mathcal{R}$, using which one can specify every configuration in $\mathcal{C}$. Typically the dimension of $\mathcal{C}$ equals the number of degrees of freedom.

For some cases of the problem, which involve a small number of degrees of freedom, efficient and exact analytical techniques exist (see, e.g., [4, 21, 40]), which are guaranteed to find a solution if one exists, or report that none exists otherwise. Recently, it was shown [46, 1, 50] that efficient and complete techniques can be developed for the *multi-robot* motion-planning problem, which entails many degrees of freedom, by making several simplifying assumptions on the separation of the start and target positions. However, it is known that the general setting of the motion-planning problem is computationally intractable (see, e.g., [38, 23, 47, 43]) with respect to the number of degrees of freedom.

Sampling-based algorithms for motion planning, which were first described about two decades ago, have revolutionized the field of robotics by providing simple yet effective tools to cope with challenging problems involving many degrees of freedom. Such algorithms (see, e.g., PRM by Kavraki et al. [29], RRT by Kuffner and LaValle [32], and EST by Hsu et al. [24]) explore the high-dimensional configuration space by random sampling and connecting nearby samples, which result in a graph data structure that can be viewed as an approximation of the *free space*—a subspace of $\mathcal{C}$, which consists entirely of collision-free configurations. While such techniques have weaker theoretical guarantees than analytical methods, many of them are *probabilistically complete*, i.e., guaranteed to find a solution if one exists, given sufficient processing time. More recently, *asymptotically optimal* sampling-based algorithms, whose solution converges to the optimum, for various criteria, have started to emerge: Karaman and Frazzoli introduced the RRT* and PRM* [28] algorithms, which are asymptotically optimal variants of RRT and PRM. Following their footsteps Arslan and Tsiotras introduced RRT# [3]. A different approach was taken by Janson and Pavone who introduced the FMT* algorithm [26], which was later refined by Salzman and Halperin [39].

3 Problem statement

In this section we describe the general problem of bottleneck pathfinding over a given cost map, to which we describe an algorithmic framework in Section 4. We conclude this section we several concrete examples of the problems that will be used for experiments in Section 6.

We start with several basic definitions. Given $x, y \in \mathbb{R}^d$, for some fixed dimension $d \geq 2$, let $\|x - y\|_2$ denote the Euclidean distance between two points. Denote by $\mathcal{B}_r(x)$ the d-dimensional Euclidean ball of radius $r > 0$ centered at $x \in \mathbb{R}^d$ and $\mathcal{B}_r(\Gamma) = \bigcup_{x \in \Gamma} \mathcal{B}_r(x)$ for any $\Gamma \subseteq \mathbb{R}^d$. We will use the terms "path" and "curve" interchangeably, to refer to a continuous curve in $\mathbb{R}^d$ parametrized over $[0, 1]$. Given a curve $\sigma : [0, 1] \to \mathbb{R}^d$ define $\mathcal{B}_r(\sigma) = \bigcup_{\tau \in [0,1]} \mathcal{B}_r(\sigma(\tau))$. Additionally, denote the image of a curve σ by $\text{Im}(\sigma) = \bigcup_{\tau \in [0,1]} \{\sigma(\tau)\}$. Let $A_1, A_2, \ldots$ be random variables in some probability space and let B be an event depending on A_n. We say that B occurs *almost surely* (a.s., in short) if $\lim_{n \to \infty} \Pr[B(A_n)] = 1$.

Let $\mathcal{M} : [0, 1]^d \to \mathbb{R}$ be a *cost map* that assigns to each point in $[0, 1]^d$ a real value. For simplicity, we assume that the domain of $\mathcal{M}$ is a d-dimensional unit hypercube. Let $S, T \in [0, 1]^d$ denote the start and target points. Denote by $\Sigma(S, T)$ the collection of paths that start in S and end in T. Formally, every $\sigma \in \Sigma(S, T)$ is a continuous path $\sigma : [0, 1] \to [0, 1]^d$, where $\sigma(0) = S, \sigma(1) = T$. Given a path σ we use the notation $\mathcal{M}(\sigma) = \max_{\tau \in [0,1]} \mathcal{M}(\sigma(\tau))$ to represent its bottleneck cost.

In some applications, monotone paths are desired. For instance, in the classical problem of Fréchet matching between two curves it is often the case that backward motion along the curves is forbidden. Here we consider monotonicity in all d coordinates of points along the path. Formally, given two points $p, p' \in \mathbb{R}^d$, where $p = (p_1, \ldots, p_d), p' = (p'_1, \ldots, p'_d)$, we use the notation $p \preceq p'$ to indicate that $p_i \leq p'_i$, for every $1 \leq i \leq d$. A path $\sigma \in \Sigma(S,T)$ is said to be *monotone* if for every $0 \leq \tau \leq \tau' \leq 1$ it holds that $\sigma(\tau) \preceq \sigma(\tau')$.

▶ **Definition 1.** Given the triplet $\langle \mathcal{M}, S, T \rangle$, the *bottleneck-pathfinding problem* (BPP, for short) consists of finding a path $\sigma \in \Sigma(S,T)$ which minimizes the expression $\max_{\tau\in[0,1]} \mathcal{M}(\sigma(\tau))$. A special case of the bottleneck pathfinding problem, termed *strong*-BPP, requires that the path will be *monotone*.

3.1 Examples

We provide three examples of BPPs, which will be used for experiments in Section 6. Each example is paired with the d-dimensional configuration space $\mathcal{C} := [0,1]^d$, start and target points $S, T \in \mathcal{C}$, and a cost map $\mathcal{M} : [0,1]^d \rightarrow \mathbb{R}$. The examples below are defined for two-dimensional input objects, but can generalized to higher dimensions.

Problem 1: We start with the classical *Fréchet distance among k curves* (see, e.g., [22]). Let $\sigma_1, \ldots, \sigma_k : [0,1] \rightarrow [0,1]^2$ be k continuous curves embedded in Euclidean plane. Here $\mathcal{C} = [0,1]^k$ is defined as the Cartesian product of the various positions along the k curves. Namely, a point $P = (p_1, \ldots, p_k) \in \mathcal{C}$ describes the location $\sigma_i(p_i)$ along σ_i, for each $1 \leq i \leq k$. To every such P we assign the cost $\mathcal{M}(P) = \max_{1\leq i<j\leq k} \|\sigma_i(p_i) - \sigma_j(p_j)\|_2$. We note that more complex formulations of $\mathcal{M}$ can be used, depending on the exact application. The start and target positions are defined to be $S = (\sigma_1(0), \ldots, \sigma_k(0)), T = (\sigma_1(1), \ldots, \sigma_k(2))$.

Problem 2: We introduce the problem of *Fréchet distance with visibility*, whose basis is similar to **P1** with $k = 3$. In addition to the curves, we are given a subspace $\mathcal{F} \subseteq [0,1]^2$. The goal is to find a traversal of the curves which minimizes $\mathcal{M}$ as defined in **P1**, with the additional constraint that the traversal point along σ_1 must be "seen" by one of the traversal points of σ_2, σ_3. Formally, for every $P = (p_1, p_2, p_3) \in \mathcal{C}$ it must hold that $p_1p_2 \subset \mathcal{F}$ *or* $p_1p_3 \subset \mathcal{F}$ (but not necessarily both), where p_ip_j is the straight-line path from p_i to p_j.

Problem 3: In *curve embedding* (see, [41, 34]), the input consists of a curve $\sigma : [0,1] \rightarrow [0,1]^2$, a subspace $\mathcal{F} \subseteq [0,1]^2$ and a pair of two-dimensional points $s, t \in \mathcal{F}$. A point $P = (p_1, p_2, p_3) \in \mathcal{C} = [0,1]^3$ describes the location $\sigma(p_1)$ along σ and the point $(p_2, p_3) \in \mathcal{F}$. The BPP is defined for the start and target points $S = (0, s), T = (1, t) \in \mathcal{C}$ and the cost map $\mathcal{M}(P) = \|\sigma(p_1) - (p_2, p_3)\|_2$.

4 Algorithmic framework

In this section we describe an algorithmic framework that will be used for solving standard and strong regimes of BPP (Definition 1). The framework can be viewed as a variant of the PRM algorithm [28], and we chose to describe it here in full detail for completeness. However, the analysis provided in Section 5 is brand new.

The framework consists of three conceptually simple steps: In the first step, we construct a random graph embedded in $[0,1]^d$, whose vertices consist of the start and target points S, T, and of a collection of randomly sampled points; the edges connect points that are separated by a distance of at most a given connection threshold r_n. In the second step the edges of the graph are assigned with weights corresponding to their bottleneck cost over $\mathcal{M}$.

In the third and final step, the discrete graph is searched for a path connecting S to T which minimizes the bottleneck cost.

Before proceeding to a more elaborate description of the framework we provide a formal definition of the random graphs that are at the heart of the technique. Let $\mathcal{X}_n = \{X_1, \ldots, X_n\}$ be n points chosen independently and uniformly at random from the Euclidean d-dimensional cube $[0,1]^d$. The following definition corresponds to the standard and well-studied model of random geometric graphs (see, e.g., [36, 51, 5] and the literature review in [45]).

▶ **Definition 2.** The *random geometric graph* (RGG) $\mathcal{G}_n = \mathcal{G}(\mathcal{X}_n; r_n)$ is a *directed* graph with vertex set $\mathcal{X}_n$ and edge set $\{(x,y) : x \neq y,\ x, y \in \mathcal{X}_n,\ \|x-y\|_2 \leq r_n\}$.

We are ready to describe the framework, which has two parameters: n represents the number of samples generated and r_n defines the Euclidean connection radius used in the construction of the graphs. In the next section we show that for a range of values of r_n, which is a function of the number of samples n, the cost of the returned solution converges to the optimum, as n tends to infinity. The framework consists of the following steps:

Step I: We construct the RGG $\mathcal{G}_n = (\mathcal{X}_n \cup \{S,T\}; r_n)$. For the purpose of generating $\mathcal{G}_n$ a collection of n samples $\mathcal{X}_n$ is generated and a nearest-neighbor structure is employed to find for every $x \in \mathcal{X}_n \cup \{S,T\}$ the set of samples that located within a Euclidean distance of r_n from it.

Step II: We assign to each edge of the graph the bottleneck cost of the straight-line path connecting its endpoints under $\mathcal{M}$. In particular, for the standard BPP, for every edge (x,y) the cost $\max_{\tau\in[0,1]} \mathcal{M}(x+\tau(y-x))$ is assigned. The same applies for strong-BPP, unless $x \not\preceq y$, in which case the value $+\infty$ is assigned.

Step III: For the final step we find a path over $\mathcal{G}_n$ from S to T which minimizes the bottleneck cost. Several efficient algorithms solving this problem exist (see, e.g., [52, 15]).

5 Theoretical foundations

We study the behavior of the framework for the standard and the strong case of BPP (Definition 1). Recall the framework uses the two parameters n and r_n, which specify the number of samples and the connection radius.We establish a range of connection radii, r_n, for which the cost of the returned solution is guaranteed to converge to a relaxed notion of the optimum.

The analysis below does not restrict itself to a specific type of cost maps $\mathcal{M}$, e.g., continuous or smooth. Thus, due to the stochastic nature of the framework, and the general definition of $\mathcal{M}$, we cannot guarantee that the returned solution will tend to the absolute optimum. As an example consider the cost map $\mathcal{M}$ such that for a given $x = (x_1, x_2)$, $\mathcal{M}(x) = 0$ if $x_1 = x_2$, and $\mathcal{M}(x) = 1$ otherwise. For the start and target points $S = (0.1, 0.1), T = (0.9, 0.9)$ the optimal solution is a subset of the diagonal. Obviously, the probability of having a single point of $\mathcal{X}_n$, let alone a whole path in $\mathcal{G}_n$, that lie on the diagonal is equal to 0.

We can however guarantee convergence to a *robustly-optimal* path, which is defined below. Informally, such paths have "well-behaved" neighborhoods, in terms of the value of $\mathcal{M}$. We provide below a formal definition of this notion for the bottleneck cost function. Recall that given a path σ the notation $\mathcal{M}(\sigma)$ represents its bottleneck cost.

▶ **Definition 3.** Given the triplet $\langle \mathcal{M}, S, T\rangle$, a path $\sigma \in \Sigma(S,T)$ is called *robust* if for every $\varepsilon > 0$ there exists $\delta > 0$ such that $\mathcal{M}(\sigma') \leq (1+\varepsilon)\mathcal{M}(\sigma)$, for any $\sigma' \in \Sigma(S,T)$ such that $\text{Im}(\sigma') \subset \mathcal{B}_\delta(\sigma)$. A path that attains the infimum cost, over all robust paths, is termed *robustly optimal.*

5.1 (Standard) Bottleneck cost

For a given triplet $\langle \mathcal{M}, S, T\rangle$ representing an instance of BPP, denote by σ^* a robustly-optimal solution. Note that we do not require here that σ^* or the returned solution will be monotone. We obtain the following result. All logarithms stated henceforth are to base e.

▶ **Theorem 4.** *Let $\mathcal{G}_n = \mathcal{G}(\mathcal{X}_n \cup \{S,T\}; r_n)$ be an RGG with*

$$r_n = \gamma \left(\frac{\log n}{n}\right)^{1/d}, \quad \gamma > 2(2d\theta_d)^{-1/d},$$

where θ_d denotes the Lebesgue measure of a unit ball in $\mathbb{R}^d$. Then $\mathcal{G}_n$ contains a path $\sigma_n \in \Sigma(S,T)$ such that $\mathcal{M}(\sigma_n) = (1+o(1))\mathcal{M}(\sigma^*)$, a.s.

We mention that this connection radius is also essential for connectivity of RGGs, i.e., a smaller radius results in a graph that is disconnected with high probability (see, e.g.,[8]). This fact is instrumental to our proof. We also mention that a result similar to Theorem 4 can be obtained through a different proof technique [28], albeit with a larger value of the constant γ.

For simplicity, we assume for the purpose of the proof that exists a finite constant $\delta' > 0$ such that $\mathcal{B}_{\delta'}(\sigma^*) \subset [0,1]^d$, namely the robustly-optimal solution is at least δ' away from the boundary of the domain $[0,1]^d$. This constraint can be easily relaxed by transforming $\langle \mathcal{M}, S, T\rangle$ into an equivalent instance $\langle \mathcal{M}', S', T'\rangle$ where this condition is met. In particular the original input can be embedded to a cube of side length $1-\varepsilon$ for some constant $\varepsilon > 0$, which is centered in the middle of $[0,1]^d$. The cost along the boundaries of the smaller cube should be extended to the remaining parts of the $[0,1]^d$ cube.

Given an RGG $\mathcal{G}_n$ and a subset $\Gamma \subset [0,1]^d$ denote by $\mathcal{G}_n(\Gamma)$ the graph obtained from the intersection of $\mathcal{G}_n$ and Γ: it consists of the vertices of $\mathcal{G}_n$ that are contained in Γ and the subset of edges of $\mathcal{G}_n$ that are fully contained in Γ. Each edge is considered as a straight-line segment connecting its two end points.

A main ingredient in the proof of Theorem 4 is the following Lemma. We employ the *localization-tessellation* framework [45], which was developed by the authors. The framework allows to extend properties of RGGs to domains with complex geometry and topology.

▶ **Lemma 5.** *Let $\mathcal{G}_n$ be the RGG defined in Theorem 4. Additionally let $\Gamma \subset [0,1]^d$ be a fixed subset, where $S,T \in \Gamma$, and let $\rho > 0$ be some fixed constant, such that $\mathcal{B}_\rho(\Gamma) \subset [0,1]^d$. Then S,T are connected in $\mathcal{G}_n(\mathcal{B}_\rho(\Gamma))$ a.s.*

Proof. We rely on the well-known result that $\mathcal{G}_n$ is connected a.s. in the domain $[0,1]^d$ for the given connection radius r_n (see, e.g., [45, Theorem 1]). We then use Lemma 1 and Theorem 6 in [45] which state that if $\mathcal{G}_n$ is connected a.s., and is *localizable* (see, Definition 6 therein), then S,T are connected a.s. over $\mathcal{G}_n(\mathcal{B}_\rho(\Gamma))$. ◀

Proof of Theorem 4. We first show that for any $\varepsilon > 0$ it follows that $\mathcal{M}(\sigma_n) \leq (1+\varepsilon)\mathcal{M}(\sigma^*)$ a.s. Fix some $\varepsilon > 0$. Due to the fact that σ^* is robustly optimal, there exists $\delta_\varepsilon > 0$ independent of n such that for every $\sigma \in \Sigma(S,T)$ such that $\text{Im}(\sigma) \subset \mathcal{B}_{\delta_\varepsilon}(\sigma^*)$ we have that $\mathcal{M} \leq (1+\varepsilon)\mathcal{M}(\sigma^*)$ a.s. Additionally, recall that there exists some $\delta' > 0$ such $\mathcal{B}_{\delta'}(\sigma^*) \subset [0,1]^d$.

Set $\delta = \min\{\delta_\varepsilon, \delta'\}$ and define the sets $\Gamma_{\delta/2} = \mathcal{B}_{\delta/2}(\sigma^*), \Gamma_\delta = \mathcal{B}_\delta(\sigma^*)$ and notice that $S, T \in \Gamma_{\delta/2}$. By Lemma 5 we have that S, T are connected in $\mathcal{G}_n(\Gamma_\delta)$. Moreover, a path connecting S, T in $\mathcal{G}_n(\Gamma_\delta)$ must a have a bottleneck cost of at most $(1+\varepsilon)\mathcal{M}(\sigma^*)$.

We have shown that for any fixed $\varepsilon > 0$, $\mathcal{M}(\sigma_n) \leq (1+\varepsilon)\mathcal{M}(\sigma^*)$ a.s. By defining the sequence $\varepsilon_i = 1/i$ one can extend the previous result and show that $\mathcal{M}(\sigma_n) \leq (1+o(1))\mathcal{M}(\sigma^*)$. This part is technical and its details are omitted (see a similar proof in [44, Theorem 6]). This concludes the proof. ◀

5.2 Strong bottleneck cost

We now focus on the strong case of the problem, where the solution is restricted to paths that are monotone in each of the d coordinates. Denote by $\vec{\sigma}^*$ the robustly-optimal monotone solution for a given instance $\langle \mathcal{M}, S, T\rangle$.

► **Theorem 6.** *Let $\mathcal{G}_n = \mathcal{G}(\mathcal{X}_n \cup \{S,T\}; r_n)$ be an RGG with $r_n = \omega(1)\left(\frac{\log n}{n}\right)^{1/d}$. Then $\mathcal{G}_n$ contains a monotone path $\vec{\sigma}_n \in \Sigma(S,T)$ such that $\mathcal{M}(\vec{\sigma}_n) = (1+o(1))\mathcal{M}(\vec{\sigma}^*)$, a.s.*

Let $x, x' \in [0,1]^d$ be two points such that $x \preceq x'$. For a given $\delta > 0$ the notation $x \preceq_\delta x'$ indicates that $\delta = \min\{x'_i - x_i\}_{i=1}^d$, where $x = (x_1, \ldots, x_d), x' = (x'_1, \ldots, x'_d)$. Given two points $x, x' \in [0,1]^d$, such that $x \preceq x'$, denote by $\mathcal{H}(x,x')$ the d-dimensional box $[x_1, x'_1] \times \ldots \times [x_d, x'_d]$. In addition to the assumption that the robustly-optimal solution $\vec{\sigma}^*$ is separated from the boundary of $[0,1]^d$ that we have taken in the previous analysis, we also assume that there exists a constant $0 < \delta'' \leq 1$ such that $S \preceq_{\delta''} T$.

In preparation for the main proof we prove the following lemma.

► **Lemma 7.** *Choose any[1] $f_n \in \omega(1)$ and set $r_n = \omega(1)\left(\frac{\log n}{n}\right)^{1/d}$. Let $q, q' \in [0,1]^d$ be two points such that $q \preceq_\delta q'$, where δ is independent of n. Then a.s. there exist $X, X' \in \mathcal{X}_n$ with the following properties: (i) $\|X - q\|_2 \leq r_n/2, \|X' - q'\| \leq r_n/2$; (ii) $q \preceq X, X' \preceq q'$; (iii) X, X' are connected in $\mathcal{G}_n$ with a monotone path.*

Proof. We apply a tessellation argument similar to the one used to show that the standard (and undirected) RGG is connected (see, e.g., [51, Section 2.4]). Set $\ell = \left\lceil \frac{2\|q'-q\|_2}{r_n} \right\rceil$ and observe that $\ell \leq 2\sqrt{d}/r_n$. Define the normalized vector $\vec{v} = \frac{q'-q}{\|q'-q\|_2}$ and let $H_1, \ldots, H_\ell$ be a sequence of ℓ hyperboxes, where

$$H_j = \mathcal{H}\left(q + (j-1)\cdot\frac{r_n}{2}\cdot\vec{v}, q + j\cdot\frac{r_n}{2}\cdot\vec{v}\right),$$

for every $1 \leq j \leq \ell$ (see Figure 1). Observe that for every $1 \leq j < \ell$ and every $X_j \in H_j, X_{j+1} \in H_{j+1}$, we have

$$X_j \preceq X_{j+1}, \|X_{j+1} - X_j\|_2 \leq r_n. \tag{1}$$

We show that for every $1 \leq j \leq \ell$ it follows that $\mathcal{X}_n \cap H_j \neq \emptyset$, a.s. We start by bounding the volume of H_j. Denote by $c_1, \ldots, c_d$ the side lengths of H_j, and denote by $\delta_1, \ldots, \delta_d$ the

[1] For instance, f_n can be either one of the following functions: $\log n, \log^* n$, or the inverse Ackerman function $\alpha(n)$.

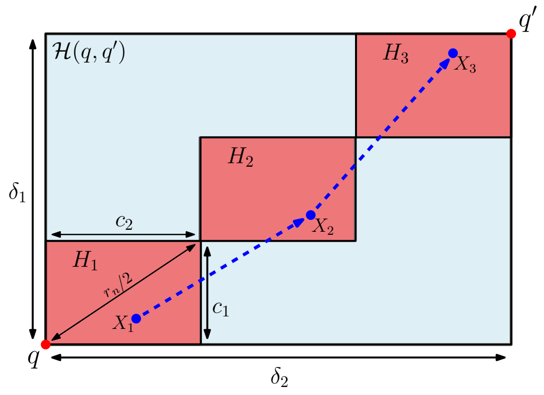

Figure 1 Visualization of the proof of Lemma 7 for $d = 2$. The blue rectangle represents $\mathcal{H}(q, q')$ and the three red rectangles represent $H_1, \ldots, H_\ell$ for $\ell = 3$ (the small value of ℓ was selected for the clarity of visualization and in reality $r_n \ll \delta_1$). The length of the largest diagonal in each of the small rectangles is $r_n/2$, which implies that a distance between $X_j \in H_j, X_{j+1} \in H_{j+1}$ is at most r_n. The blue dashed arrows represent the directed graph edges $(X_1, X_2), (X_2, X_3)$ which correspond to a monotone path connecting X_1 to X_3.

side lengths of $\mathcal{H}(q, q')$. Note that δ_i is independent of n and $c_i = \delta_i/\ell$. Consequently, we can represent $c_i = \alpha_i r_n$, where $\alpha_i > 0$ is constant, for every $1 \leq i \leq d$. Thus, $|H_j| = c r_n^d$ for some constant $c > 0$. Now,

$$\Pr[\mathcal{X}_n \cap H_j = \emptyset] = (1 - |H_j|)^n \leq \exp\{-n|H_j|\} = \exp\{-\omega(1) \cdot c \log n\} \leq n^{-1}.$$

In the last transition we used the fact that the function $f_n \in \omega(1)$ can "absorb" any constant c. We are ready to show that every H_i contains a point from $\mathcal{X}_n$ a.s.:

$$\begin{aligned}\Pr[\exists H_j : \mathcal{X}_n \cap H_j = \emptyset] &\leq \sum_{j=1}^{\ell} \Pr[\mathcal{X}_n \cap H_i = \emptyset] \\ &\leq \ell \cdot n^{-1} \leq \frac{2\sqrt{d}}{r_n} \cdot n^{-1} \\ &= \frac{2\sqrt{d}}{\omega(1) \cdot n^{1-1/d} \log^{1/d} n}.\end{aligned}$$

Thus, a.s. there exists for every $1 \leq j \leq \ell$ a point $x_j \in H_j$. Observe that $X := X_1, X' := X_\ell$ satisfy (i),(ii). Condition (iii) follows from Equation 1. ◀

Proof of Theorem 6. Similarly to the proof of Theorem 4, we fix $\varepsilon > 0$ and select $\delta \leq \min\{\delta', \delta''\}$ such that $\mathcal{M}(\vec{\sigma}) \leq (1+\varepsilon)\mathcal{M}(\vec{\sigma}^*)$ for every $\vec{\sigma} \in \vec{\Sigma}(S, T)$ with $\mathrm{Im}(\vec{\sigma}) \subset \mathcal{B}_\delta(\vec{\sigma}^*) \subset [0,1]^d$.

The crux of this proof is that there exists a sequence of k points $q_1, \ldots, q_k \in \mathrm{Im}(\vec{\sigma}^*)$, where $S = q_1, T = q_k$, such that $q_j \prec_{\delta/2} q_{j+1}$ for every $1 \leq j < k$ (see Figure 2). Moreover, due to fact that $\vec{\sigma}^*$ is monotone we can determine that such k is finite and independent of n. Thus, by Lemma 7, for every $1 \leq j < k$ there exist $X_j, X'_j \in \mathcal{X}_n$ which satisfy the following conditions a.s.: (i) $\|X_j - q_j\|_2 \leq r_n/2, \|X'_j - q_{j+1}\|_2 \leq r_n/2$; (ii) $q_j \preceq X_j, X'_j \preceq q_{j+1}$; (iii) X_j, X'_j are connected in $\mathcal{G}_n$. By conditions (i),(ii), for every $1 \leq j < k$ the graph $\mathcal{G}_n$ contains the edge (X'_j, X_{j+1}). Combined with condition (iii) this implies that S is connected to T in $\mathcal{G}_n$ a.s.

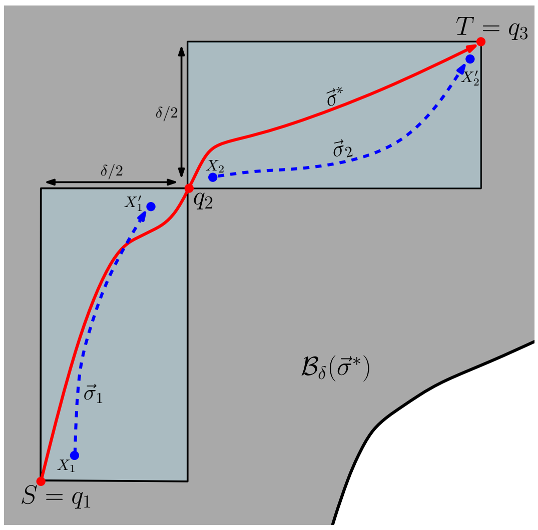

Figure 2 Visualization of the proof of Theorem 6 for $d = 2$ and $k = 3$. The red curve represents $\vec{\sigma}^*$, on which lie the points q_1, q_2, q_3 such that $q_1 \prec_{\delta/2} q_2 \prec_{\delta/2} q_3$. The dashed blue curves represent $\vec{\sigma}_1, \vec{\sigma}_2$. The gray area represents $\mathcal{B}_\delta(\vec{\sigma}^*)$.

It remains to show that the path constructed above has a cost of at most $(1+\varepsilon)\mathcal{M}(\vec{\sigma}^*)$. For every $1 \leq j \leq k$ denote by $\vec{\sigma}_j$ the path induced by Lemma 7 from X_j to X_j', i.e., $\vec{\sigma}_j(0) = X_j, \vec{\sigma}_j(1) = X_j'$ and $\text{Im}(\vec{\sigma}_j) \subset H_i$. Additionally, for every $1 \leq j < k$ denote by $\vec{\sigma}_j'$ the straight-line segment (sub-path) from X_j' to X_{j+1}. Now, define $\vec{\sigma}$ to be a concatenation of $\vec{\sigma}_1, \vec{\sigma}_1', \ldots, \vec{\sigma}_{k-1}, \vec{\sigma}_{k-1}', \vec{\sigma}_k$. We showed in the previous paragraph that such a path exists in $\mathcal{G}_n$ a.s. Observe that for every $1 \leq j \leq k$ it holds that $\vec{\sigma}_j \subset \mathcal{H}(q_j, q_{j+1})$, where $\mathcal{H}(q_j, q_{j+1}) \subset \mathcal{B}_{\delta/2}(\vec{\sigma}^*)$. This implies that $\mathcal{M}(\vec{\sigma}_i) \leq (1+\varepsilon)\mathcal{M}(\vec{\sigma}^*)$. Additionally, recall that for every $1 \leq j < k$ it holds that $\|X_j' - q_{j+1}\|_2 \leq r_n/2, \|X_{j+1} - q_{j+1}\|_2 \leq r_n/2$, which implies that $\text{Im}(\vec{\sigma}_j') \subset \mathcal{B}_{r_n}(q_{j+1}) \subset \mathcal{B}_\delta(\vec{\sigma}^*)$, and consequently $\mathcal{M}(\sigma_j') \leq (1+\varepsilon)\mathcal{M}(\vec{\sigma}^*)$. Finally, $\mathcal{M}(\vec{\sigma}_n) \leq \mathcal{M}(\vec{\sigma}) \leq (1+\varepsilon)\mathcal{M}(\vec{\sigma}^*)$. This concludes the proof. ◀

6 Experimental results

In this section we validate the theoretical results that were described in the previous section. We observe that the framework can cope with complex scenarios involving two or three degrees of freedom ($d \in \{2, 3\}$), and converges quickly to the optimum.

Before proceeding to the results we provide details regrading the implementation. We implemented the framework in C++, and tested it on scenarios involving two-dimensional objects. Nearest-neighbor search, which is used for the construction of RGGs, was implemented using FLANN [35]. We note that other nearest-neighbor search data structures that are tailored for the implementation of RGGs exist (see, e.g., [31]). Geometric objects, such as points, curves, and polygons were represented with CGAL [49]. For the representation of graphs and related algorithms we used BOOST [42]. Experiments were conducted on a PC with Intel i7-2600 3.4GHz processor with 8GB of memory, running a 64-bit Windows 7 OS.

We proceed to describe the implementation involving the computation of non-trivial cost maps. For curve embedding we used PQP [20] for collision detection, i.e., determining whether a given point lies in the forbidden region $[0, 1]^2 \setminus \mathcal{F}$. Finally, the cost of an edge with respect to a given cost map was approximated by dense sampling along the edge, as is customary in motion planning (see, e.g., [33]).

The majority of running time (over %90) in the experiments below is devoted to the computation of $\mathcal{M}$ for given point samples or edges. Thus, we report only the overall running time in the following experiments. We mention that we also implemented a simple grid-based method for the purpose of comparison with the framework. However, it performed poorly in easy scenarios and did not terminate in hard cases. Thus, we chose to omit theses results here.

Unless stated otherwise, we use in the experiments the connection radius which is described in Theorem 4, and denote it by r_n^*. This applies both to the standard and strong regimes of the problem. A discussion regarding the connection radius in the strong regime appears below in Section 6.3.

6.1 Various scenarios

In this set of experiments we demonstrate the flexibility of the framework and test it on the three different scenarios. We emphasize that we employ a shared code framework to solve these three problems and the ones described later. The only difference in the implementation lies in the type of cost function used. The following problems are solved using a planner for the *strong* case of BPP.

Figure 3 (left) depicts an instance of **P1** (see Section 3.1), which consists of two geometrically-identical curves (red and blue). The curves are bounded in $[0, 1]^2$ and the red curve is translated by $(0.05, 0.05)$ from the blue curve. The optimal solution has a cost of 0.07, in which the curves are traversed identically. Our program was able to produce a solution of cost 0.126 in 27 seconds and $n = 100{,}000$ samples. Results reported throughout this section are the averaged over 10 trials.

Figure 4 (left) depicts an instance of **P2**. The goal is to find a traversal of the three curves such that the traversal point along the purple curve is visible from either the blue or red curve, while of course minimizing the lengths of the leashes between the three curves. Note that the view can be obstructed by the gray rectangular obstacles. A trivial, albeit poor, solution is to move the point along the purple curve from start to end, while the traversal point of, say, the red curve stays put in the start position. A much better solution, which maintains short leashes, is described as follows: we move along the purple curve until reaching the first resting point, indicated by the leftmost black disc. Then we move along the red curve until we reach to the position directly below the black circle. Only then we move along the blue curve from start until reaching the point directly below the first black disc. We use a similar parametrization with respect to the second "pit stop", and so on. Such a solution was obtained by our program in 11 seconds using $n = 20{,}000$ samples.

Figure 4 (right) depicts an instance of **P3**. The input consists of a curve (depicted in red), and polygonal obstacles (depicted in gray). The solution obtained by our program after 600 seconds with $n = 100{,}000$, is drawn in blue.

6.2 Increasing difficulty

Here we focus on **P1** for two curves in the standard regime. We study how the difficulty of the problem affects the running time and the rate of convergence of the returned cost. We start with a base scenario, depicted in Figure 3 (right), and gradually increase its difficulty. In the depicted scenario the bottom (blue) curve consists of five circular loops of radius 0.15, where the entrance and exit point to each circle is indicated by a bullet. The top curve

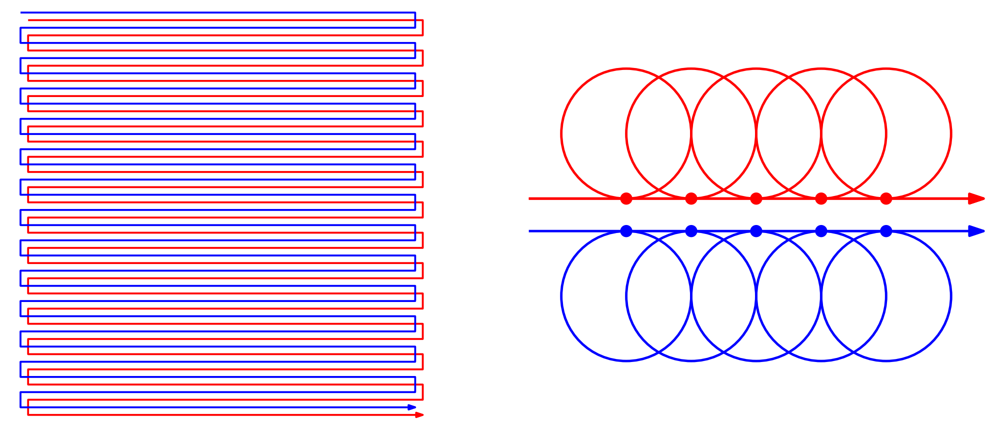

Figure 3 Scenarios involving two curve.

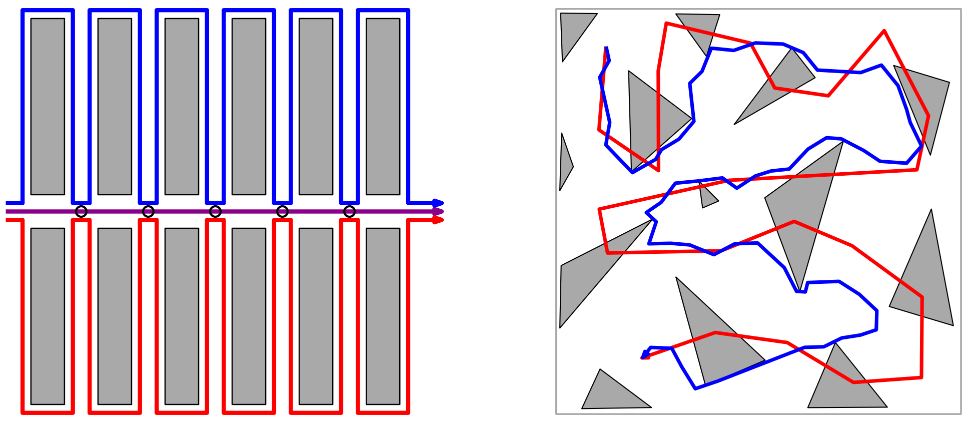

Figure 4 Scenarios involving curves and obstacles.

is similarly defined, and the two curves are separated by a vertical distance of 0.04. The optimal matching of cost 0.34 is obtained in the following manner: when a given circle of the red curve is traversed, the position along the blue curve is fixed to the entrance point of the circle directly below the traversed circle, and vice versa. In a similar fashion we construct scenarios with 10,20,40 and 80 loops in each curve.

In Figure 5 we report for each of the scenarios the cost of the obtained solution as a function of the number of samples n. We set $n = 2^i$ for the integer value i between 12 and 18. For $i = 12$ and $i = 18$ the running times were roughly 2 and 66 seconds, respectively. In between, the values were linearly proportional to the number of samples (results omitted). Observe that as the difficulty of the problem increases the convergence rate of the cost slightly decreases, but overall a value near the optimum is reached fairly quickly.

6.3 Connection radius in the strong regime

Here we consider the *strong* regime and study the behavior of the framework for varying connection radii. For this purpose, we use the two-curves scenario with 20 loops that was described in Section 6.2. We set the connection radius to $r_n := g_n \cdot r_n^*$, where r_n^* is the radius of the standard regime (see Theorem 4). We set $g_n \in \{1, 1.1, \log\log n + 1, \sqrt{\log n}\}$. Results are depicted in Figure 6.

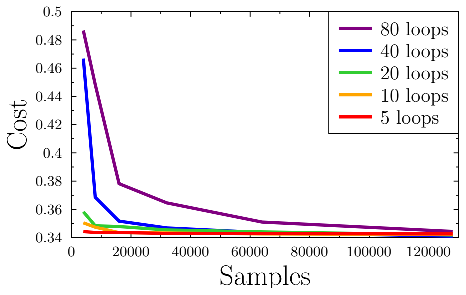

Figure 5 Results for scenarios of increasing difficulty, as described in Section 6.2.

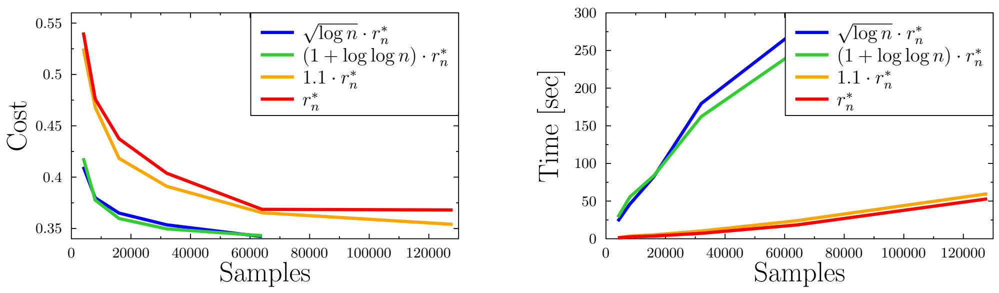

Figure 6 Results for varying connection radii in the strong regime, as described in Section 6.3.

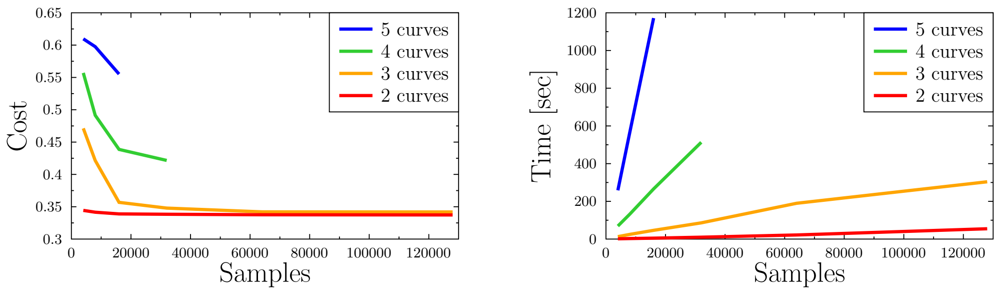

Figure 7 Figures for the first set of experiments, as described in Section 6.4.

Not surprisingly, larger values of r_n lead to quicker convergence, in terms of the number of samples required, to the optimum. However, this comes at the price of a denser RGG, which results in poor running times. Note that the program terminated due to lack of space for the two largest functions of g_n for $n = 128{,}000$. Interestingly, the connection radius r_n^* of the standard regime seems to converge to the optimum, albeit slowly. This leads to the question whether such a function also results in connectivity in the strong regime. Note that our proof of the convergence in the strong regime requires a larger value of r_n (see Theorem 6).

6.4 Increasing dimensionality

We test how the dimension of the configuration space d affects the performance. For this purpose we study the behavior of the framework on *weak* k-curve Fréchet distance with k ranging from 2 to 5. For $k = 2$ we use the scenario described in Section 6.2 with 10 loops. For $k = 3$ we add another copy of the blue curve, for $k = 4$ an additional copy of the red curve, and another blue curve for $k = 5$. We report running time and cost in Figure 7 for various values of n, as described earlier.

Note that that for $k = 4$ the program ran out of memory for $n = 64{,}000$, and for $k = 5$ around $n = 32{,}000$. This phenomena occurs since the connection radius obtained in Theorem 4 grows exponentially in d. In particular, for $r_n = \gamma \left(\frac{\log n}{n}\right)^{1/d}$, where $\gamma = 2(2d\theta_d)^{-1/d}$, each sample has in expectancy $\Theta(2^d \log n)$ neighbors in the obtained RGG.

On the Geodesic Centers of Polygonal Domains

Haitao Wang[*]

Department of Computer Science, Utah State University, Logan, UT, USA

Abstract

In this paper, we study the problem of computing Euclidean geodesic centers of a polygonal domain $\mathcal{P}$ of n vertices. We give a necessary condition for a point being a geodesic center. We show that there is at most one geodesic center among all points of $\mathcal{P}$ that have topologically-equivalent shortest path maps. This implies that the total number of geodesic centers is bounded by the size of the shortest path map equivalence decomposition of $\mathcal{P}$, which is known to be $O(n^{10})$. One key observation is a *π-range property* on shortest path lengths when points are moving. With these observations, we propose an algorithm that computes all geodesic centers in $O(n^{11}\log n)$ time. Previously, an algorithm of $O(n^{12+\epsilon})$ time was known for this problem, for any $\epsilon > 0$.

1 Introduction

Let $\mathcal{P}$ be a polygonal domain with a total of h holes and n vertices, i.e., $\mathcal{P}$ is a multiply-connected region whose boundary is a union of n line segments, forming $h+1$ closed polygonal cycles. A simple polygon is a special case of a polygonal domain with $h = 0$. For any two points s and t, a *shortest path* or *geodesic path* from s to t is a path in $\mathcal{P}$ whose Euclidean length is minimum among all paths from s to t in $\mathcal{P}$; we let $d(s,t)$ denote the Euclidean length of any shortest path from s to t and we also say that $d(s,t)$ is the *shortest path distance or geodesic distance* from s to t.

A point s is a *geodesic center* of $\mathcal{P}$ if s minimizes the value $\max_{t\in\mathcal{P}} d(s,t)$, i.e., the maximum geodesic distance from s to all points of $\mathcal{P}$.

In this paper, we study the problem of computing the geodesic centers of $\mathcal{P}$. The problem in simple polygons has been well studied. It is known that for any point in a simple polygon, its farthest point must be a vertex of the polygon [20]. It has been shown that the geodesic center in a simple polygon is unique and has at least two farthest points [18]. Due to these helpful observations, efficient algorithms for finding geodesic centers in simple polygons have been developed. Asano and Toussaint [2] gave an $O(n^4\log n)$ time algorithm for the problem, and later Pollack, Sharir, and Rote [18] improved the algorithm to $O(n\log n)$ time. Recently, Ahn et al. [1] solved the problem in linear time.

Finding a geodesic center in a polygonal domain $\mathcal{P}$ is much more difficult. This is partially due to that a farthest point of a point in $\mathcal{P}$ may be in the interior of $\mathcal{P}$ [3]. Also, it is easy to construct an example where the geodesic center of $\mathcal{P}$ is not unique (e.g., see Fig. 1). Bae, Korman, and Okamoto [4] gave the first-known algorithm that can compute a geodesic center

[*] This research was supported in part by NSF under Grant CCF-1317143.

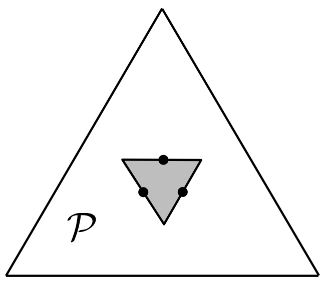

Figure 1 The boundary of $\mathcal{P}$ consists of an outer and inner equilateral triangles with their geometric centers co-located. Each of the three thick points is a geodesic center of $\mathcal{P}$.

in $O(n^{12+\epsilon})$ time for any $\epsilon > 0$. They first showed that for any point its farthest points must be vertices of its shortest path map in $\mathcal{P}$. Then, they considered the shortest path map equivalence decomposition (or SPM-equivalence decomposition) [7], denoted by $\mathcal{D}_{spm}$; for each cell of $\mathcal{D}_{spm}$, they computed the upper envelope of $O(n)$ graphs in 3D space, which takes $O(n^{2+\epsilon})$ time [10], to search a geodesic center in the cell. Since the size of $\mathcal{D}_{spm}$ is $O(n^{10})$ [7], their algorithm runs in $O(n^{12+\epsilon})$ time.

A closely related concept is the *geodesic diameter*, which is the maximum geodesic distance over all pairs of points in $\mathcal{P}$, i.e., $\max_{s,t,\in\mathcal{P}} d(s,t)$. In simple polygons, due to the property that there always exists a pair of vertices of $\mathcal{P}$ whose geodesic distance is equal to the geodesic diameter, efficient algorithms have been given for computing the geodesic diameters. Chazelle [6] gave the first algorithm that runs in $O(n^2)$ time. Later, Suri [20] presented an $O(n \log n)$-time algorithm. The problem was eventually solved in $O(n)$ time by Hershberger and Suri [11]. Computing the geodesic diameter in a polygonal domain $\mathcal{P}$ is much more difficult, partially because the diameter can be realized by two points in the interior of $\mathcal{P}$, in which case there are at least five distinct shortest paths between the two points [3]. As for the geodesic center, this makes it difficult to discretize the search space. By an exhaustive-search method, Bae, Korman, and Okamoto [3] gave the first algorithm for computing the diameter of $\mathcal{P}$, which runs in $O(n^{7.73})$ or $O(n^7(\log n + h))$ time.

Refer to [5, 8, 13, 15, 16, 17, 19] for other variations of geodesic diameter and center problems (e.g., the L_1 metric and the link distance case).

1.1 Our Contributions

We conduct a "comprehensive" study on geodesic centers of $\mathcal{P}$. We discover many interesting observations, and some of them may be even surprising. For example, we show that even if a geodesic center is in the interior of $\mathcal{P}$, it may have only one farthest point, which is somewhat counter-intuitive. We give a necessary condition for a point being a geodesic center. We show that there is at most one geodesic center among all points of $\mathcal{P}$ that have topologically-equivalent shortest path maps in $\mathcal{P}$. This immediately implies that the interior of each cell or each edge of the SPM-equivalence decomposition $\mathcal{D}_{spm}$ can contain at most one geodesic center, and thus, the total number of geodesic centers of $\mathcal{P}$ is bounded by the combinatorial size of $\mathcal{D}_{spm}$, which is known to be $O(n^{10})$ [7]. Previously, the only known upper bound on the total number of geodesic centers of $\mathcal{P}$ is $O(n^{12})$, which is suggested by the algorithm in [4].

These observations are all more or less due to an interesting observation, which we call the *π-range property* and is one key contribution of this paper. Here we only demonstrate an application of the π-range property. Let s and t be two points in the interior of $\mathcal{P}$ such

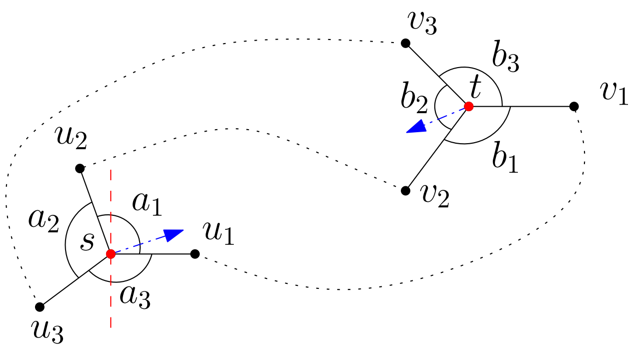

Figure 2 Illustrating the π-range property. Suppose there are three shortest s-t paths through vertices u_i and v_i with $i = 1, 2, 3$, respectively. If s and t move along the blue arrows simultaneously (possibly with different speeds), then all three shortest paths strictly decreases (it is difficult to tell whether this is true from the figure, so these two blue directions here are only for illustration purpose). The special case happens when the six angles a_i and b_i satisfy $a_i = b_i$ for $i = 1, 2, 3$.

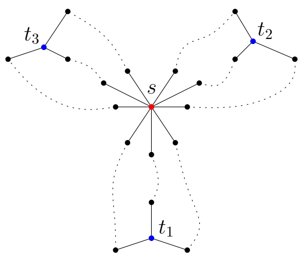

Figure 3 Illustrating a geodesic center s with three farthest points t_1, t_2, t_3 such that all these four points are in the interior of $\mathcal{P}$. There are three shortest paths from s to each of t_1, t_2, t_3.

that t is a farthest point of s in $\mathcal{P}$. Refer to Fig. 2 for an example. Suppose there are three shortest paths from s to t as shown in Fig. 2. The π-range property says that unless a special case happens, there exists an open range of exactly size π (e.g., delimited by the right open half-plane bounded by the vertical line through s in Fig. 2) such that if s moves along any direction in the range for an infinitesimal distance, we can always find a direction to move t such that the lengths of *all three* shortest paths strictly decrease. Further, if the special case does not happen, we can explicitly determine the above range of size π. In fact, it is the special case that makes it possible for a geodesic center having only one farthest point.

With these observations, we propose an exhaustive-search algorithm to compute a set S of *candidate points* such that all geodesic centers must be in S. For example, refer to Fig. 3, where a geodesic center s has three farthest points t_1, t_2, t_3 and all these four points are in the interior of $\mathcal{P}$. The nine shortest paths from s to t_1, t_2, t_3 provide a system of eight equations, which give eight (independent) constraints that can determine the four points s, t_1, t_2, t_3 if we consider the coordinates of these points as eight variables. This suggests our exhaustive-search to compute candidate points for such a geodesic center s. However, if a geodesic center s has only one farthest point (e.g., Fig. 2), then we have only three shortest paths (in the non-degenerate case), which give only two constraints. In order to determine s and t, which have four variables, we need two more constraints. It turns out the π-range property (i.e., the special case) provides exactly two more constraints (on the angles as shown in Fig. 2). In this way, we can still compute candidate points for such s. Also, if s has two farthest points, we will need one more constraint, which is also provided by the π-range property (the non-special case).

The number of candidate points in S is $O(n^{11})$. To find all geodesic centers from S, a straightforward solution is to compute the shortest path map for every point of S, which takes $O(n^{12} \log n)$ time in total. Again, with the help of the π-range property, we propose a *pruning algorithm* to eliminate most points from S in $O(n^{11} \log n)$ time such that none of the eliminated points is a geodesic center and the number of the remaining points of S is only $O(n^{10})$. Consequently, we can find all geodesic centers in additional $O(n^{11} \log n)$ time.

Although we improve the previous $O(n^{12+\epsilon})$ time algorithm in [4] by a factor of roughly $n^{1+\epsilon}$, the running time is still huge. We feel that our observations (e.g., the π-range property) may be more interesting than the algorithm itself. We suspect that they may also find other applications. The paper is lengthy, which is mainly due to a considerable number of cases depending on whether a geodesic center and its farthest points are in the interior, on an edge, or at vertices of $\mathcal{P}$, although the essential idea is quite similar for all these cases.

The rest of the paper is organized as follows. In Section 2, we introduce notation and review some concepts. In Section 3, we give our observations. We present the π-range property in Section 4. Computing the candidate points is discussed in Section 5. Finally, we find all geodesic centers from the candidate points in Section 6. Due to the space limit, many details and proofs are omitted but can be found in the full paper.

2 Preliminaries

Consider any point $s \in \mathcal{P}$. Let $d_{\max}(s)$ be the maximum geodesic distance from s to all points of $\mathcal{P}$, i.e., $d_{\max}(s) = \max_{t\in\mathcal{P}} d(s,t)$. A point $t \in \mathcal{P}$ is a *farthest point* of s if $d(s,t) = d_{\max}(s)$. Let $F(s)$ denote the set of all farthest points of s. For any two points p and q in $\mathcal{P}$, we say that p is *visible* to q if the line segment $\overline{pq}$ is in $\mathcal{P}$ and the interior of $\overline{pq}$ does not contain any vertex of $\mathcal{P}$. We use $|pq|$ to denote the (Euclidean) length of any line segment $\overline{pq}$. Note that two points s and t in $\mathcal{P}$ may have more than one shortest path between them, and if not specified, we use $\pi(s,t)$ to denote any such shortest path.

For simplicity of discussion, we make a general position assumption that any two vertices of $\mathcal{P}$ have only one shortest path and no three vertices of $\mathcal{P}$ are on the same line.

Denote by $\mathcal{I}$ the set of all interior points of $\mathcal{P}$, $\mathcal{V}$ the set of all vertices of $\mathcal{P}$, and E the set of all relatively interior points on the edges of $\mathcal{P}$ (i.e., E is the boundary of $\mathcal{P}$ minus $\mathcal{V}$).

Shortest path maps. A *shortest path map* of a point $s \in \mathcal{P}$ [7], denoted by $\mathit{SPM}(s)$, is a decomposition of $\mathcal{P}$ into regions (or cells) such that in each cell σ, the combinatorial structures of shortest paths from s to all points t in σ are the same, and more specifically, the sequence of obstacle vertices along $\pi(s,t)$ is fixed for all t in σ. Further, the *root* of σ, denoted by $r(\sigma)$, is the last vertex of $\mathcal{V} \cup \{s\}$ in the path $\pi(s,t)$ for any point $t \in \sigma$ (hence $\pi(s,t) = \pi(s, r(\sigma)) \cup \overline{r(\sigma)t}$; note that $r(\sigma)$ is s if s is visible to t). As in [7], we classify each edge of σ into three types: a portion of an edge of $\mathcal{P}$, *an extension segment*, which is a line segment extended from $r(\sigma)$ along the opposite direction from $r(\sigma)$ to the vertex of $\pi(s,t)$ preceding $r(\sigma)$, and *a bisector curve/edge* that is a hyperbolic arc. For each point t in a bisector edge of $\mathit{SPM}(s)$, t is on the common boundary of two cells and there are two shortest paths from s to t through the roots of the two cells, respectively (and neither path contains both roots). The *vertices* of $\mathit{SPM}(s)$ include $\mathcal{V} \cup \{s\}$ and all intersections of edges of $\mathit{SPM}(s)$. If a vertex t of $\mathit{SPM}(s)$ is an intersection of two or more bisector edges, then there are more than two shortest paths from s to t. The map $\mathit{SPM}(s)$ has $O(n)$ vertices, edges, and cells, and can be computed in $O(n \log n)$ time [12]. It was shown [4] that any farthest point of s in $\mathcal{P}$ must be a vertex of $\mathit{SPM}(s)$. For differentiation, we will refer to the vertices of $\mathcal{V}$ as *polygon vertices* and refer to the edges of E as *polygon edges*.

The SPM-equivalence decomposition $\mathcal{D}_{spm}$ [7] is a subdivision of $\mathcal{P}$ into regions such that for all points s in the interior of the same region or edge of $\mathcal{D}_{spm}$, the shortest path maps of s are topologically equivalent. Chiang and Mitchell [7] showed that the combinatorial size of $\mathcal{D}_{spm}$ is bounded by $O(n^{10})$ and $\mathcal{D}_{spm}$ can be computed in $O(n^{11})$ time.

Directions and ranges. We will have intensive discussions on moving points along certain directions. For any direction r, we represent r by the angle $\alpha(r) \in [0, 2\pi)$ counterclockwise from the positive direction of the x-axis. For convenience, whenever we are talking about an angle α, unless otherwise specified, depending on the context we may refer to any angle $\alpha + 2\pi \cdot k$ for $k \in \mathbb{Z}$. For any two angles α_1 and α_2 with $\alpha_1 \leq \alpha_2 < \alpha_1 + 2\pi$, the interval $[\alpha_1, \alpha_2]$ represents a *direction range* that includes all directions whose angles are in $[\alpha_1, \alpha_2]$, and $\alpha_2 - \alpha_1$ is called the *size* of the range. Note that the range can also be open (e.g., (α_1, α_2)) and the size of any direction range is no more than 2π.

Consider a half-plane h whose bounding line is through a point s in the plane. We say h *delimits* a range of size π of directions for s that consists of all directions along which s will move towards inside h. If h is an open half-plane, then the range is open as well.

A direction r for $s \in \mathcal{P}$ is called a *free direction* of s if we move s along r for an infinitesimal distance then s is still in $\mathcal{P}$. We use $R_f(s)$ to denote the range of all free directions of s. Clearly, if $s \in \mathcal{I}$, $R_f(s)$ contains all directions; if $s \in E$, $R_f(s)$ is a (closed) range of size π; if $s \in V$, $R_f(s)$ is delimited by the two incident polygon edges of s.

3 Observations

Consider any point $s \in \mathcal{P}$ and let t be any farthest point of s. Recall that t is a vertex of $\mathit{SPM}(s)$ [4]. Suppose we move s infinitesimally along a free direction r to a new point s'. Since $|ss'|$ is infinitesimal, we can assume that s and s' are in the same cell σ of $\mathcal{D}_{spm}$. Further, if s is in the interior of σ, then s' is also in the interior of σ. Regardless of whether s is in the interior of σ or not, there is a vertex $t' \in \mathit{SPM}(s')$ *corresponding to* the vertex t of $\mathit{SPM}(s)$ in the following sense [7]: If the line segment $\overline{s't'}$ is a shortest path from s' to t', then $\overline{st}$ is a shortest path from s to t; otherwise, if $s', u_1, u_2, \ldots, u_k, t'$ is the sequence of the vertices of $\mathcal{V} \cup \{s', t'\}$ in a shortest path from s' to t', then $s, u_1, u_2, \ldots, u_k, t$ is also the sequence of the vertices of $\mathcal{V} \cup \{s, t\}$ in a shortest path from s to t.

In the case that s is on the boundary of σ while s' is in the interior of σ, there might be more than one such vertex $t' \in \mathcal{D}_{spm}$ corresponding to t (refer to [7] for the details) and we use $M_t(s')$ to denote the set of all such vertices t'. We should point out that although a vertex in $\mathit{SPM}(s)$ may correspond to more than one vertex in $\mathit{SPM}(s')$, any vertex in $\mathit{SPM}(s')$ can correspond to one and only one vertex in $\mathit{SPM}(s)$ (because s' is always in the interior of σ).

We introduce the following definition which is crucial to the paper.

▶ **Definition 1.** A free direction r is an *admissible direction* of s with respect to t if as we move s infinitesimally along r to a new point s', $d(s', t') < d(s, t)$ holds for each $t' \in M_t(s')$.

For any $t \in F(s)$, let $R(s,t)$ denote the set of all admissible directions of s with respect to t; let $R(s) = \bigcap_{t \in F(s)} R(s,t)$. The following Lemma 3, which gives a necessary condition for a point being a geodesic center of $\mathcal{P}$, explains why we consider admissible directions. Before presenting Lemma 3, we introduce some notation and Observation 2.

Consider any two points s and t in $\mathcal{P}$. Suppose the vertices of $\mathcal{V} \cup \{s, t\}$ along a shortest s-t path $\pi(s,t)$ are $s = u_0, u_1, \ldots, u_k = t$. By our definition of "visibility", s is visible to t if and only if $k = 1$. If s is not visible to t, then $k \neq 1$ and we call u_1 an *s-pivot* and u_{k-1} a *t-pivot* of $\pi(s,t)$. It is possible that there are multiple shortest paths between s and t, and thus there might be multiple s-pivots and t-pivots for (s,t). We use $U_s(t)$ and $U_t(s)$ to denote the sets of all s-pivots and t-pivots for (s,t), respectively. By our above definition, for any $u \in U_s(t)$, the line segment $\overline{su}$ does not contain any polygon vertex in its interior.

We have the following observation. Similar results have been given in [3].

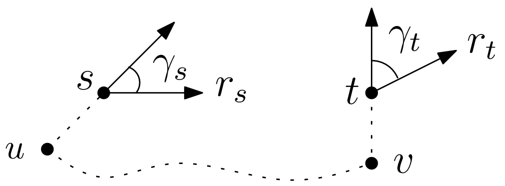

Figure 4 The definitions of the angles γ_s and γ_t.

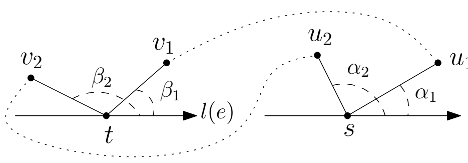

Figure 5 The definitions of the angles.

▶ **Observation 2.** Suppose t is a farthest point of a point s.

1. If t is in $\mathcal{I}$, then $|U_t(s)| \geq 3$ and t must be in the interior of the convex hull of the vertices of $U_t(s)$.
2. If t is in E, say, $t \in e$ for a polygon edge e of E, then $|U_t(s)| \geq 2$ and $U_t(s)$ has at least one vertex in the open half-plane bounded by the supporting line of e and containing the interior of $\mathcal{P}$ in the small neighborhood of e. Further, $U_t(s)$ has at least one vertex in each of the two open half-planes bounded by the line through t and perpendicular to e.

▶ **Lemma 3.** *If s is a geodesic center of $\mathcal{P}$, then $R(s) = \emptyset$.*

As explained in Section 1, we will compute candidate points for geodesic centers. As a necessary condition, Lemma 3 will be helpful for computing those candidate points.

Consider any point $s \in \mathcal{P}$. Let t be a farthest point of s. To determine the admissible direction range $R(s,t)$, we will give a sufficient condition for a direction being in $R(s,t)$. We first assume that s is not visible to t, and as will be seen later, the other case is trivial.

Let u and v respectively be the s-pivot and the t-pivot of (s,t) in a shortest s-t path $\pi(s,t)$. Clearly, $d(s,t) = |su| + d(u,v) + |vt|$. We define $d_{u,v}(s,t) = |su| + d(u,v) + |vt|$ as a function of $s \in \mathbb{R}^2$ and $t \in \mathbb{R}^2$. Suppose we move s along a free direction r_s with the unit speed and move t along a free direction r_t with a speed $\tau \geq 0$. Let γ_s denote the smaller angle between the following two rays originated from s (e.g., see Fig. 4): one with direction r_s and one with direction from u to s. Similarly, let γ_t denote the smaller angle between the following two rays originated from t: one with direction r_t and one with direction from v to t. In fact, as discussed in [3], if we consider $d(s,t)$ as a four-variate function, the triple (r_s, r_t, τ) corresponds to a vector ρ in $\mathbb{R}^4$, and the directional derivative of $d_{u,v}(s,t)$ at $(s,t) \in \mathbb{R}^4$ along ρ, denoted by $d'_{u,v}(s,t)$, and the second directional derivative of $d_{u,v}(s,t)$ at (s,t) along ρ, denoted by $d''_{u,v}(s,t)$, are

$$d'_{u,v}(s,t) = \cos\gamma_s + \tau\cos\gamma_t, \quad d''_{u,v}(s,t) = \frac{\sin^2\gamma_s}{|su|} + \tau \cdot \frac{\sin^2\gamma_t}{|tv|}. \tag{1}$$

Since $\tau \geq 0$, $d''_{u,v}(s,t) \geq 0$. Further, if $\tau \neq 0$, then $d''_{u,v}(s,t) = 0$ if and only if $\sin^2\gamma_s = \sin^2\gamma_t = 0$, i.e., each of γ_s and γ_t is either 0 or π. Below, in order to make the discussions more intuitive, we choose to use the parameters r_s, r_t, and τ, instead of the vectors of $\mathbb{R}^4$.

For each vertex $u \in U_s(t)$, there must be a vertex $v \in U_t(s)$ such that the concatenation of $\overline{su}$, $\pi(u,v)$, and $\overline{vt}$ is a shortest path from s to t, and we call such a vertex v a *coupled t-pivot* of u (if u has more than one such vertex, then all of them are coupled t-pivots of u). Similarly, for each vertex $v \in U_t(s)$, we also define its coupled s-pivots in $U_s(t)$.

The following lemma provides a sufficient condition for a direction being in $R(s,t)$.

▶ **Lemma 4.** *Suppose t is a farthest point of s and s is not visible to t.*

1. *For $t \in \mathcal{I}$, a free direction r_s is in $R(s,t)$ if there is a free direction r_t for t with a speed $\tau \geq 0$ such that when we move s along r_s with unit speed and move t along r_t with speed τ, each vertex $v \in U_t(s)$ has a coupled s-pivot u with either $d'_{u,v}(s,t) < 0$, or $d'_{u,v}(s,t) = 0$ and $d''_{u,v}(s,t) = 0$.*
2. *For $t \in E$, a free direction r_s is in $R(s,t)$ if there is a free direction r_t for t that is parallel to the polygon edge of E containing t with a speed $\tau \geq 0$ such that when we move s along r_s with the unit speed and move t along r_t with speed τ, each vertex $v \in U_t(s)$ has a coupled s-pivot u with either $d'_{u,v}(s,t) < 0$, or $d'_{u,v}(s,t) = 0$ and $d''_{u,v}(s,t) = 0$.*
3. *For $t \in \mathcal{V}$, a free direction r_s is in $R(s,t)$ if we move s along r_s with the unit speed, each vertex $v \in U_t(s)$ has a coupled s-pivot u with either $d'_{u,v}(s,t) < 0$, or $d'_{u,v}(s,t) = 0$ and $d''_{u,v}(s,t) = 0$.*

Lemma 4 is on the case where s is not visible to t. If s is visible to t, the result is trivial.

▶ **Observation 5.** Suppose t is a farthest point of s and s is visible to t. Then t must be a polygon vertex of $\mathcal{V}$. Further, a free direction r_s of s is in $R(s,t)$ if and only if r_s is towards the interior of $h_s(t)$, where $h_s(t)$ is the open half-plane containing t and bounded by the line through s and perpendicular to $\overline{st}$.

By Observation 5, if s is visible to t, then the range $R(s,t)$ is the intersection of the free direction range $R_f(s)$ and an open range of size π delimited by the open half-plane $h_s(t)$.

The next lemma is proved by using Lemmas 3 and 4 as well as Observation 5.

▶ **Lemma 6.** *Among all points of $\mathcal{P}$ that have topologically equivalent shortest path maps in $\mathcal{P}$, there is at most one geodesic center. This implies that each cell or edge of $\mathcal{D}_{spm}$ contains at most one geodesic center in its interior, which further implies that the number of geodesic centers of $\mathcal{P}$ is $O(|\mathcal{D}_{spm}|)$, where $|\mathcal{D}_{spm}|$ is the combinatorial complexity of $\mathcal{D}_{spm}$.*

The following corollary implies that if t is a farthest point of s, then slightly moving s along a free direction that is not in $R(s,t)$ can never obtain a geodesic center.

▶ **Corollary 7.** *Suppose t is a farthest point of s. If we move s infinitesimally along a free direction that is not in $R(s,t)$, then $d_{\max}(s)$ will become strictly larger.*

To compute the candidate points, we need to determine $R(s,t)$. It turns out that it is sufficient to determine $R(s,t)$ when t is at a non-degenerate position of s in the following sense: Suppose t is a farthest point of s; we say that t is *non-degenerate* with respect to s if there are exactly three, two, and one shortest s-t paths for t in $\mathcal{I}$, E, and $\mathcal{V}$, respectively (by Observation 2, this implies that $|U_t(s)|$ is 3, 2, and 1, respectively for the three cases).

Lemma 4 gives a sufficient condition for a direction in $R(s,t)$. The following lemma gives both a sufficient and a necessary condition for a direction in $R(s,t)$ when t is non-degenerate, and the lemma will be used to explicitly compute the range $R(s,t)$ in Section 4. Note that Observation 5 already gives a way to determine $R(s,t)$ when s is visible to t.

▶ **Lemma 8.** *Suppose t is a non-degenerate farthest point of s and s is not visible to t. Then, a free direction r_s is in $R(s,t)$ if and only if*

1. *for $t \in \mathcal{I}$, there is a free direction r_t for t with a speed $\tau \geq 0$ such that when we move s along r_s with unit speed and move t along r_t with speed τ, each vertex $v \in U_t(s)$ has a coupled s-pivot u with $d'_{u,v}(s,t) < 0$.*
2. *for $t \in E$, there is a free direction r_t for t that is parallel to the polygon edge containing t with a speed $\tau \geq 0$ such that when we move s along r_s with unit speed and move t along r_t with speed τ, each vertex $v \in U_t(s)$ has a coupled s-pivot u with $d'_{u,v}(s,t) < 0$.*
3. *for $t \in \mathcal{V}$, when we move s along r_s with unit speed, each vertex $v \in U_t(s)$ has a coupled s-pivot u with $d'_{u,v}(s,t) < 0$.*

4 Determining the Range $R(s,t)$ and the π-Range Property

In this section, we determine the admissible direction range $R(s,t)$ for any point s and any of its non-degenerate farthest point t. In particular, we will present the π-range property.

Depending on whether t is in $\mathcal{V}$, E, and $\mathcal{I}$, there are three cases. Recall that $R_f(s)$ is the range of free directions of s. In each case, we will show that $R(s,t)$ is the intersection of $R_f(s)$ and an open range $R_\pi(s,t)$ of size π. We call $R_\pi(s,t)$ the *π-range*. As will be seen later, $R_\pi(s,t)$ can be explicitly determined based on the positions of s, t, and the vertices of $U_s(t)$ and $U_t(s)$. In fact, for each case, we will give a more general result on shortest path distance functions. These general results will be useful for computing the candidate points.

4.1 The Case $t \in \mathcal{V}$

We first discuss the case $t \in \mathcal{V}$. The result is relatively straightforward in this case. If s is visible to t, the π-range $R_\pi(s,t)$ is defined to be the open range of directions delimited by the open half-plane $h_s(t)$ as defined in Observation 5; by Observation 5, $R(s,t) = R_f(s) \cap R_\pi(s,t)$.

Below, we assume s is not visible to t. We first present a more general result on a shortest path distance function. Let s and t be any two points in $\mathcal{P}$ such that t is in $\mathcal{V}$ and s is not visible to t. Let $\pi(s,t)$ be any shortest s-t path in $\mathcal{P}$. Let u and v be the s-pivot and t-pivot in $\pi(s,t)$, respectively. Thus, $d_{u,v}(s,t) = |su| + d(u,v) + |vt|$. Now we consider $d_{u,v}(s,t)$ as a function of s and t in the entire plane $\mathbb{R}^2$ (not only in $\mathcal{P}$; namely, when we move s and t, they are allowed to move outside $\mathcal{P}$, but the function $d_{u,v}(s,t)$ is always defined as $|su| + d(u,v) + |vt|$, where $d(u,v)$ is a fixed value).

The *π-range* $R_\pi(s,t)$ is defined with respect to t and the path $\pi(s,t)$ as follows: a direction r_s for s is in $R_\pi(s,t)$ if $d'_{u,v}(s,t) < 0$ when we move s along r_s with unit speed.

▶ **Lemma 9.** *$R_\pi(s,t)$ is exactly the open range of size π delimited by $h_s(u)$, where $h_s(u)$ is the open half-plane containing u and bounded by the line through s and perpendicular to $\overline{su}$.*

Now we are back to our original problem to determine $R(s,t)$ for a non-degenerate farthest point t of s with $t \in \mathcal{V}$. Since t is non-degenerate and t is in $\mathcal{V}$, there is only one shortest path $\pi(s,t)$ from s to t. We define $R_\pi(s,t)$ as above. Based on Observation 5 and Lemmas 8(3), we have Lemma 10, and thus $R(s,t)$ can be determined by Observation 5 and Lemma 9.

▶ **Lemma 10.** *$R(s,t) = R_f(s) \cap R_\pi(s,t)$.*

4.2 The Case $t \in E$

The analysis for this case is substantially more complicated than the previous case, although the next case for $t \in \mathcal{I}$ is even more challenging. As in the previous case, we first present a more general result that is on two shortest path distance functions.

Let s and t be any two points in $\mathcal{P}$ such that t is in E and there are two shortest s-t paths $\pi_1(s,t)$ and $\pi_2(s,t)$ (this implies that s is not visible to t). Let e be the polygon edge containing t and let $l(e)$ denote the line containing e. For each $i = 1, 2$, let $\pi_i(s,t) = \pi_{u_i,v_i}(s,t)$, i.e., u_i and v_i are the s-pivot and t-pivot of $\pi_i(s,t)$, respectively. We further require the set $\{v_1, v_2\}$ to satisfy the same condition as $U_t(s)$ in Observation 2(2), i.e., $\{v_1, v_2\}$ has at least one vertex in the open half-plane bounded by $l(e)$ and containing the interior of $\mathcal{P}$ in the small neighborhood of e, and it has at least one vertex in each of the two open half-planes bounded by the line through t and perpendicular to e. We say that the two shortest paths $\pi_1(s,t)$ and $\pi_2(s,t)$ are *canonical* with respect to s and t if $\{v_1, v_2\}$ satisfies the above condition. In the following, we assume $\pi_1(s,t)$ and $\pi_2(s,t)$ are canonical. Note

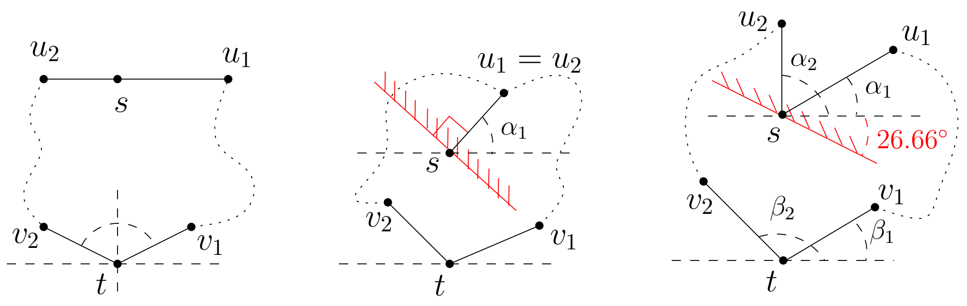

Figure 6 Illustrating some examples for Lemma 11. Left: the special case (the vertical line through t bisects $\angle v_1tv_2$); in this case, $R_\pi(s,t) = \emptyset$. Middle: the case where $\alpha_1 = \alpha_2$, and thus $\alpha = 0$, $\sin(\alpha) = 0$, and $u_1 = u_2$; in this case, $R_\pi(s,t) = (\alpha_1 - \pi/2, \alpha_1 + \pi/2)$, which is delimited by the open half-plane (marked with red color in the figure) bounded by the line through s and perpendicular to $\overline{su_1}$. Right: the most general case where $\alpha_1 = 30°$, $\alpha_2 = 90°$, $\beta_1 = 30°$, $\beta_2 = 135°$; by calculation, $\lambda \approx 1.3165$, $\arctan(\frac{\gamma}{\sin(\alpha)}) \approx 56.66°$, and thus, $R_\pi(s,t) \approx (\alpha_1 - 56.66°, \alpha_1 + 56.66°) = (-26.66°, 153.34°)$; the open half-plane that delimits $R_\pi(s,t)$ is marked with red color in the figure.

that the condition implies that $v_1 \neq v_2$. However, $u_1 = u_2$ is possible. For each $i = 1, 2$, we consider $d_{u_i,v_i}(s,t) = |su_i| + d(u_i, v_i) + |v_it|$ as a function of $s \in \mathbb{R}^2$ and $t \in e$.

In this case, the *π-range* $R_\pi(s,t)$ of s is defined with respect to t and the two paths $\pi_1(s,t)$ and $\pi_2(s,t)$ as follows: a direction r_s for s is in $R_\pi(s,t)$ if there exists a direction r_t parallel to e for t with a speed $\tau \geq 0$ such that when we move s along r_s with unit speed and move t along r_t with speed $\tau \geq 0$, $d'_{u_i,v_i}(s,t) < 0$ holds for $i = 1, 2$.

In Section 4.1, we showed that the π-range for the case $s \in \mathcal{V}$ is an open range of size π. Here we will show a similar result in Lemma 11 unless a special case happens. Although the result in Section 4.1 is quite straightforward, the result here for two functions $d_{u_i,v_i}(s,t)$ with $i = 1, 2$ is somewhat surprising. We first introduce some notation.

For any two points p and q in the plane, define $\overrightarrow{pq}$ as the direction from p to q.

Recall that the angle of any direction r is defined to be the angle in $[0, 2\pi)$ counterclockwise from the positive direction of the x-axis. Let α_1 denote the angle of the direction $\overrightarrow{su_1}$, and let α_2 denote the angle of the direction $\overrightarrow{su_2}$ (e.g., see Fig. 5). Note that by our way of defining pivot vertices, $\alpha_1 = \alpha_2$ if and only if $u_1 = u_2$.

Note that v_1 and v_2 are in a closed half-plane bounded by the line $l(e)$. We assign a direction to $l(e)$ such that each of v_1 and v_2 are to the left or on $l(e)$. Define β_i as the smallest angle to rotate $l(e)$ counterclockwise such that the direction of $l(e)$ becomes the same as $\overrightarrow{tv_i}$, for each $i = 1, 2$ (e.g., see Fig. 5). Hence, both β_1 and β_2 are in $[0, \pi]$. Without of loss of generality, we assume $\beta_1 \leq \beta_2$ (otherwise the analysis is symmetric). Since $\{v_1, v_2\}$ contains at least one vertex in each of the open half-planes bounded by the line through t and perpendicular to e, we have $\beta_1 \in [0, \pi/2)$ and $\beta_2 \in (\pi/2, \pi]$. Further, since at least one of v_1 and v_2 is not on $l(e)$, it is not possible that both $\beta = 0$ and $\beta = \pi$ hold.

Let $\alpha = \alpha_2 - \alpha_1$. We refer to the case where $\beta_1 + \beta_2 = \pi$ and $\alpha = \pm\pi$ (i.e., α is π or $-\pi$) as the *special case*. In the special case, s is on $\overline{u_1u_2}$ and the vertical line through t and perpendicular to $l(e)$ bisects the angle $\angle v_1tv_2$.

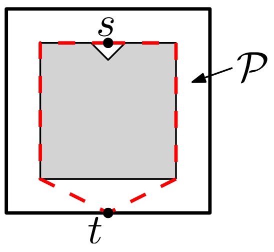

Figure 7 Illustrating an example in which a geodesic center s is in $\mathcal{I}$ and has only one farthest point t. The polygonal domain $\mathcal{P}$ is between two (very close) concentric squares plus an additional (very small) triangle so that s is in $\mathcal{I}$. The point s is at the middle of the top edge of the inner square, and t is at the middle of the bottom edge of the outer square. One can verify that s is a geodesic center and t is the only farthest point of s. The two shortest paths from s to t are shown with red dashed segments. Note that the middle point of every edge of the inner square is a geodesic center.

▶ **Lemma 11.** *The π-range $R_\pi(s,t)$ is determined as follows (e.g., see Fig. 6).*

$$R_\pi(s,t) = \begin{cases} (\alpha_1 - \arctan(\frac{\lambda}{\sin(\alpha)}), \alpha_1 - \arctan(\frac{\lambda}{\sin(\alpha)}) + \pi) & \textit{if } \sin(\alpha) > 0, \\ (\alpha_1 - \arctan(\frac{\lambda}{\sin(\alpha)}) - \pi, \alpha_1 - \arctan(\frac{\lambda}{\sin(\alpha)})) & \textit{if } \sin(\alpha) < 0, \\ (\alpha_1 - \pi/2, \alpha_1 + \pi/2) & \textit{if } \sin(\alpha) = 0 \textit{ and } \lambda > 0, \\ (\alpha_1 - 3\pi/2, \alpha_1 - \pi/2) & \textit{if } \sin(\alpha) = 0 \textit{ and } \lambda < 0, \\ \emptyset & \textit{if } \sin(\alpha) = 0 \textit{ and } \lambda = 0, \end{cases}$$

where $\lambda = \cos\alpha - \frac{\cos\beta_2}{\cos\beta_1}$. Further, $\alpha = \pm\pi$ and $\beta_1 + \beta_2 = \pi$ (i.e., the special case) if and only if $\sin(\alpha) = 0$ and $\lambda = 0$.

By Lemma 11, if the special case happens, $R_\pi(s,t) = \emptyset$; otherwise, it is an open range of size π. Since $\alpha = 0$ if and only if $u_1 = u_2$, the case $u_1 = u_2$ is also covered by the lemma.

Now consider our original problem of determining the range $R(s,t)$ for a non-degenerate farthest point $t \in E$ of s. By Observation 5, s is not visible to t. Further, s and t have exactly two shortest paths $\pi_1(s,t)$ and $\pi_2(s,t)$. Clearly, by Observation 2(2), the two paths are canonical. Therefore, the π-range $R_\pi(s,t)$ of s with respect to t and the two shortest paths $\pi_1(s,t)$ and $\pi_2(s,t)$ can be determined by Lemma 11. Lemma 8(2) leads to Lemma 12.

▶ **Lemma 12.** *$R(s,t) = R_\pi(s,t) \cap R_f(s)$.*

Suppose t is the only farthest point of s and t is non-degenerate. By Lemma 11, if the special case happens, $R_\pi(s,t) = \emptyset$ and $R(s,t) = \emptyset$. By Corollary 7, if we move s along any free direction infinitesimally, $d_{\max}(s)$ will be strictly increasing. Therefore, it is possible that the point s, which is in $\mathcal{I}$ and has only one farthest point, is a geodesic center. It is not difficult to construct such an example by following the left figure of Fig. 6; e.g., see Fig. 7. Hence, we have the following corollary.

▶ **Corollary 13.** *It is possible that a geodesic center is in $\mathcal{I}$ and has only one farthest point.*

4.3 The Case $t \in \mathcal{I}$

The analysis for this case is substantially more difficult than the case $t \in E$. As before, we first present a more general result that is on three shortest path distance functions.

Let s and t be two points in $\mathcal{P}$ such that t is in $\mathcal{I}$ and there are three shortest s-t paths $\pi_1(s,t)$, $\pi_2(s,t)$, and $\pi_3(s,t)$ (this implies that s is not visible to t). For each $i = 1,2,3$, let $\pi_i(s,t) = \pi_{u_i,v_i}(s,t)$, i.e., u_i and v_i are the s-pivot and t-pivot of $\pi_i(s,t)$, respectively. We say that the three paths are *canonical* with respect to s and t if they have two properties:

1. t is in the interior of the triangle $\triangle v_1v_2v_3$.
2. Suppose we reorder the indices such that v_1, v_2, and v_3 are *clockwise* around t, then u_1, u_2, and u_3 are *counterclockwise* around s (e.g., see Fig. 2).

The above first property implies that v_1, v_2, and v_3 are distinct, but this may not be true for u_1, u_2, u_3. In the following, we assume that the three shortest paths $\pi_i(s,t)$ with $1 \leq i \leq 3$ are canonical, and we reorder the indices as in the above second property. For each $i = 1,2,3$, we consider $d_{u_i,v_i}(s,t) = |su_i| + d(u_i,v_i) + |v_it|$ as a function of $s \in \mathbb{R}^2$ and $t \in \mathbb{R}^2$. In this case, the *π-range* $R_\pi(s,t)$ of s is defined with respect to t and the three paths $\pi_i(s,t)$ for $i = 1,2,3$ as follows: a direction r_s for s is in $R_\pi(s,t)$ if there exists a direction r_t for t with a speed $\tau \geq 0$ such that when we move s along r_s with unit speed and move t along r_t with speed τ, $d'_{u_i,v_i} < 0$ holds for $i = 1,2,3$.

As Lemma 11 in the previous cases, we will have a similar lemma (Lemma 14), which says that unless a special case happens $R_\pi(s,t)$ is an open range of size exactly π. The proof is much more challenging. Before presenting Lemma 14, we introduce some notation.

For each $i = 1,2,3$, let β_i denote the angle of the direction $\overrightarrow{tv_i}$ (i.e., the angle of $\overrightarrow{tv_i}$ counterclockwise from the positive x-axis). Further, we define three angles b_i for $i = 1,2,3$ as follows (e.g., see Fig. 2). Define b_1 as the smallest angle we need to rotate the direction $\overrightarrow{tv_1}$ *clockwise* to $\overrightarrow{tv_2}$; define b_2 as the smallest angle we need to rotate the direction $\overrightarrow{tv_2}$ clockwise to $\overrightarrow{tv_3}$; define b_3 as the smallest angle we need to rotate the direction $\overrightarrow{tv_3}$ clockwise to $\overrightarrow{tv_1}$.

For any two angles α' and α'', we use $\alpha' \equiv \alpha''$ to denote $\alpha' = \alpha'' \mod 2\pi$.

It is easy to see that $b_1 \equiv \beta_1 - \beta_2$, $b_2 \equiv \beta_2 - \beta_3$, and $b_3 \equiv \beta_3 - \beta_1$. Note that since t is in the interior of $\triangle v_1v_2v_3$, it holds that $b_i \in (0,\pi)$ for $i = 1,2,3$. Note that $b_1 + b_2 + b_3 = 2\pi$.

For each $i = 1,2,3$, let α_i denote the angle of the direction $\overrightarrow{su_i}$. According to our definition of pivot vertices, $u_i = u_j$ if and only if $\alpha_i = \alpha_j$ for any two $i,j \in \{1,2,3\}$. We define three angles a_i for $i = 1,2,3$ as follows (e.g., see Fig. 2). Define a_1 as the smallest angle we need to rotate the direction $\overrightarrow{su_1}$ *counterclockwise* to $\overrightarrow{su_2}$; define a_2 as the smallest angle we need to rotate the direction $\overrightarrow{su_2}$ clockwise to $\overrightarrow{su_3}$; define a_3 as the smallest angle we need to rotate the direction $\overrightarrow{su_3}$ clockwise to $\overrightarrow{su_1}$. Hence, $a_1 \equiv \alpha_2 - \alpha_1$, $a_2 \equiv \alpha_3 - \alpha_2$, and $a_3 \equiv \alpha_1 - \alpha_3$.

We refer to the case where $a_i = b_i$ for each $i = 1,2,3$ as the *special case.*

▶ **Lemma 14.** *The π-range $R_\pi(s,t)$ is determined as follows (e.g., see Fig. 8).*

$$R_\pi(s,t) = \begin{cases} (\alpha_1 - \arctan(\frac{\delta_1-\delta_2}{\delta}), \alpha_1 - \arctan(\frac{\delta_1-\delta_2}{\delta}) + \pi) & \text{if } \delta > 0, \\ (\alpha_1 - \arctan(\frac{\delta_1-\delta_2}{\delta}) - \pi, \alpha_1 - \arctan(\frac{\delta_1-\delta_2}{\delta})) & \text{if } \delta < 0, \\ (\alpha_1 - \pi/2, \alpha_1 + \pi/2) & \text{if } \delta = 0 \text{ and } \delta_1 > \delta_2, \\ (\alpha_1 - 3\pi/2, \alpha_1 - \pi/2) & \text{if } \delta = 0 \text{ and } \delta_1 < \delta_2, \\ \emptyset & \text{if } \delta = 0 \text{ and } \delta_1 = \delta_2, \end{cases}$$

where $\delta = \frac{\sin(\alpha_3-\alpha_1)}{\sin(\beta_3-\beta_1)} - \frac{\sin(\alpha_2-\alpha_1)}{\sin(\beta_2-\beta_1)}$, $\delta_1 = \frac{\cos(\beta_2-\beta_1)-\cos(\alpha_2-\alpha_1)}{\sin(\beta_2-\beta_1)}$, *and* $\delta_2 = \frac{\cos(\beta_3-\beta_1)-\cos(\alpha_3-\alpha_1)}{\sin(\beta_3-\beta_1)}$. *Further, $a_i = b_i$ for each $i = 1,2,3$ (i.e., the special case) if and only if $\delta = 0$ and $\delta_1 = \delta_2$.*

According to Lemma 14, if the special case happens, then $R_\pi(s,t)$ is empty; otherwise, it is an open range of size exactly π.

Now we are back to our original problem to determine the range $R(s,t)$ for a non-degenerate farthest point $t \in \mathcal{I}$ of s. Since there are exactly three shortest s-t paths $\pi_i(s,t)$

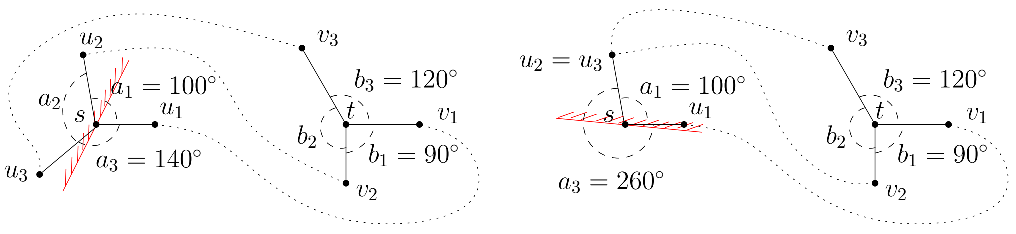

Figure 8 Illustrating two examples for Lemma 14. Left: The sizes of the angles of a_i and b_i for $1 \leq i \leq 3$ are already shown in the figure with $\alpha_1 = 0$. By calculation, $\delta \approx 0.2426$, $\delta_1 \approx -0.1736$, $\delta_2 \approx 0.3072$, $\arctan(\frac{\delta_1-\delta_2}{\delta}) \approx -63.23°$, and thus $R_\pi(s,t) \approx (\alpha_1 + 63.23°, \alpha_1 + 63.23° + 180°) = (63.23°, 243.23°)$. Right: a case where $\alpha_2 = \alpha_3$ with $\alpha_1 = 0$. Thus, $a_2 = 0$ and $u_2 = u_3$. The sizes of other angles are already shown in the figure. By calculation, $\delta \approx 2.1220$, $\delta_1 \approx -0.1736$, $\delta_2 \approx -0.3768$, $\arctan(\frac{\delta_1-\delta_2}{\delta}) \approx 5.47°$, and thus $R_\pi(s,t) \approx (\alpha_1 - 5.47°, \alpha_1 - 5.47° + 180°) = (-5.47°, 174.53°)$. The open half-planes that delimit $R_\pi(s,t)$ in both examples are marked with red color.

for $i = 1,2,3$, the three paths must be canonical. To see this, by Observation 2, t is in the interior of $\triangle v_1v_2v_3$. Further, it is easy to see that no two of the three paths cross each other since otherwise there would be more than three shortest s-t paths, this implies that the second property of the canonical paths holds. Let $R_\pi(s,t)$ be the π-range of s with respect to t and the above three shortest paths. By Lemma 8(1), we have the following lemma.

▶ **Lemma 15.** *$R(s,t) = R_\pi(s,t) \cap R_f(s)$.*

5 Computing the Candidate Points

In this section, with the help of the observations in Sections 3 and 4, we compute a set S of candidate points such that all geodesic centers must be in S.

Let s be any geodesic center. Recall that $F(s)$ is the set of all farthest points of s. Depending on whether s is in $\mathcal{V}$, E, or $\mathcal{I}$, the size $|F(s)|$, whether some points of $F(s)$ are in $\mathcal{V}$, E, or $\mathcal{I}$, whether s has a degenerate farthest point, there are a significant (but still constant) number of cases. For each case, we use an exhaustive-search approach to compute a set of candidate points such that s must be in the set. In particular, there are four cases, called *dominating cases*, for which the number of candidate points is $O(n^{11})$. But the total number of the candidate points for all other cases is only $O(n^{10})$. Therefore, the set S has a total of $O(n^{11})$ candidate points. We will show that S can be computed in $O(n^{11} \log n)$ time.

To find the geodesic centers in S, a straightforward algorithm works as follows. For each point $\hat{s} \in S$, we can compute $d_{\max}(\hat{s})$ in $O(n \log n)$ time by first computing the shortest path map $SPM(\hat{s})$ of $\hat{s}$ in $O(n \log n)$ time [12] and then obtaining the maximum geodesic distance from $\hat{s}$ to all vertices of $SPM(\hat{s})$. Since all geodesic centers are in S, the points of S with the smallest $d_{\max}(\hat{s})$ are geodesic centers of $\mathcal{P}$.

Since $|S| = O(n^{11})$, the above algorithm runs in $O(n^{12} \log n)$ time. Let S_d denote the set of the candidate points for the four dominating cases. Clearly, the bottleneck is on finding the geodesic centers from S_d. To improve the algorithm, when we compute the candidate points of S_d, we will maintain the corresponding *path information*. By using these path information and based on new observations, we will present in Section 6 an $O(n^{11} \log n)$ time "pruning algorithm" that can eliminate most of the points from S_d such that none of the eliminated points is a geodesic center and the number of remaining points in S_d is only $O(n^{10})$. Consequently, we can find all geodesic centers in additional $O(n^{11} \log n)$ time.

The dominating cases. In order to discuss our pruning algorithm in Section 6, we explain the four dominating cases as follows. Suppose s is a geodesic center in $\mathcal{I}$ that has the following three properties. (1) s does not have a degenerate farthest point. (2) For any farthest point t of s, the π-range $R_\pi(s,t) \neq \emptyset$ (i.e., the special cases in Lemmas 11 and 14 do not happen). (3) s has at least three farthest points. By Lemma 3, these properties further imply that s must have three farthest points t_1, t_2, t_3 such that $R_\pi(s,t_1) \cap R_\pi(s,t_2) \cap R_\pi(s,t_3) = \emptyset$ since the size of $R_\pi(s,t_i)$ is π for each t_i. Depending on whether each t_i for $i = 1,2,3$ is in $\mathcal{I}$, E, $\mathcal{V}$, there are several cases. We use (x,y,z) to refer to the case where x, y, and z points of t_1,t_2,t_3 are in $\mathcal{I}, E$, and $\mathcal{V}$, respectively, with $x+y+z=3$. For example, $(3,0,0)$ refers to the case where t_1,t_2,t_3 are all in $\mathcal{I}$. The four dominating cases are: $(3,0,0)$, $(2,1,0)$, $(1,2,0)$, and $(0,3,0)$. For any geodesic center s, if s does not belong to the dominating cases, then our algorithm guarantees that s is in $S \setminus S_d$. Below, due to the space limit, we only sketch how to compute candidate points for three "representative" cases, and other details are omitted.

Case 1. Consider the dominating case $(3,0,0)$ discussed above. We compute the candidate points for the geodesic center s as follows. For each $i=1,2,3$, since t_i is in $\mathcal{I}$, there are three shortest paths from s to t_i: $\pi_{u_{ij},v_{ij}}(s,t)$ with $j=1,2,3$ (i.e., u_{ij} and v_{ij} are the s-pivot and t-pivot, respectively). Hence, we have the following

$$\begin{aligned}
&|t_1v_{11}| + d(v_{11},u_{11}) + |u_{11}s| = |t_1v_{12}| + d(v_{12},u_{12}) + |u_{12}s| = |t_1v_{13}| + d(v_{13},u_{13}) + |u_{13}s|\\
=&|t_2v_{21}| + d(v_{21},u_{21}) + |u_{21}s| = |t_2v_{22}| + d(v_{22},u_{22}) + |u_{22}s| = |t_2v_{23}| + d(v_{23},u_{23}) + |u_{23}s|\\
=&|t_3v_{31}| + d(v_{31},u_{31}) + |u_{31}s| = |t_3v_{32}| + d(v_{32},u_{32}) + |u_{32}s| = |t_3v_{33}| + d(v_{33},u_{33}) + |u_{33}s|.
\end{aligned}$$

By considering the coordinates of s,t_1,t_2, and t_3 as eight variables, the above equations on the lengths of the nine shortest paths provide eight (independent) constraints, which are sufficient to compute all four points. Correspondingly, we compute the candidate points for s by the exhaustive-search algorithm below (similar methods were also used before, e.g., [3, 7]).

We enumerate all possible combinations of nine polygon vertices as v_{i1},v_{i2},v_{i3}, with $i=1,2,3$. For each combination, we compute the overlay of the shortest path maps of the nine vertices. The overlay is of size $O(n^2)$ and can be computed in $O(n^2\log n)$ time [3, 7]. For each cell C of the overlay, we obtain nine roots of the shortest path maps and consider them as u_{i1},u_{i2},u_{i3} for $i=1,2,3$. We form the above system of eight equations and solve it to obtain a constant number of quadruples $(\hat{s},\hat{t}_1,\hat{t}_2,\hat{t}_3)$ and each such $\hat{s}$ is a candidate point. In this way, for each combination of nine polygon vertices, we can obtain $O(n^2)$ candidate points in $O(n^2\log n)$ time. Since there are $O(n^9)$ combinations, we can compute $O(n^{11})$ candidate points in $O(n^{11}\log n)$ time and s must be one of these candidate points.

If this were not a dominating case, we would have done for this case. Since this is a dominating case, we need to maintain certain path information. To this end, we perform a "validation procedure" on each such quadruple $(\hat{s},\hat{t}_1,\hat{t}_2,\hat{t}_3)$ computed above, as follows.

In the above procedure for computing $(\hat{s},\hat{t}_1,\hat{t}_2,\hat{t}_3)$, we also obtain a path length, denoted by $d(\hat{s})$, which is equal to the value in the above equations, e.g., $d(\hat{s}) = |\hat{s}u_{11}|+d(u_{11},v_{11})+|v_{11}\hat{t}_1|$. First, we check whether $\hat{s}$ is in C, which can be done in $O(\log n)$ time by using a point location data structure [9, 14] with $O(n^2)$ time and space preprocessing on the overlay. If yes, for each t_i with $i=1,2,3$, we check whether $d(\hat{s})$ is equal to $d(\hat{s},\hat{t}_i)$, which can be computed in $O(\log n)$ time by using the two-point shortest path query data structure [7] with $O(n^{11})$ time and space preprocessing on $\mathcal{P}$. If yes, we check whether v_{i1},v_{i2},v_{i3} satisfy the condition in Observation 2(1), i.e., whether $\hat{t}_i$ is in the interior of the triangle $\triangle v_{i1}v_{i2}v_{i3}$ for each $i=1,2,3$. If yes, for each $\hat{t}_i$ with $i=1,2,3$, we check whether the order of the vertices of v_{i1},v_{i2},v_{i3} around $\hat{t}_i$

are consistent with the order of the vertices of u_{i1}, u_{i2}, u_{i3} (we say that the two orders are *consistent* if after reordering the indices, v_{i1}, v_{i2}, v_{i3} are clockwise around $\hat{t}_i$ while u_{i1}, u_{i2}, u_{i3} are counterclockwise around s; note that this consistency is needed for determining the π-range in Lemma 14). If yes, for each $\hat{t}_i$ with $i = 1, 2, 3$, we compute the π-range $R_\pi(s, \hat{t}_i)$ determined by Lemma 14, and then check whether $R_\pi(\hat{s}, \hat{t}_1) \cap R_\pi(\hat{s}, \hat{t}_2) \cap R_\pi(\hat{s}, \hat{t}_3)$ is empty. If yes, we say that the quadruple $(\hat{s}, \hat{t}_1, \hat{t}_2, \hat{t}_3)$ *passes* the validation procedure and we call $\hat{s}$ a *valid* candidate point and add $\hat{s}$ to the set S_d. In addition, we maintain the following *path information*: $d(\hat{s})$, $\hat{t}_i$, v_{ij}, and u_{ij}, with $1 \leq i \leq 3$ and $1 \leq j \leq 3$.

In the worst case, we can have $O(n^{11})$ valid candidate points for S_d. Note that the geodesic center s and the quadruple (s, t_1, t_2, t_3) discussed above must pass the validation procedure, and thus the quadruple (s, t_1, t_2, t_3) will be computed by our exhaustive-search algorithm and s will be computed as a valid candidate point in S_d.

Based on our validation procedure, the following observation summarizes the properties of the valid candidate points, which will be useful for our pruning algorithm in Section 6.

▶ **Observation 16.** Suppose $(\hat{s}, \hat{t}_1, \hat{t}_2, \hat{t}_3)$ a quadruple that passes the validation procedure, with u_{ij} and v_{ij}, $i = 1, 2, 3$ and $j = 1, 2, 3$ defined as above. Then the following hold.

1. For each $i = 1, 2, 3$, $\overline{\hat{s}u_{ij}} \cup \pi(u_{ij}, v_{ij}) \cup \overline{v_{ij}\hat{t}_i}$ is a shortest path from $\hat{s}$ to $\hat{t}_i$ for each $j = 1, 2, 3$.
2. For each $i = 1, 2, 3$, v_{i1}, v_{i2}, v_{i3} satisfy the condition of Observation 2(1), i.e., $\hat{t}_i$ is in the interior of the triangle $\triangle v_{i1}v_{i2}v_{i3}$.
3. $d(\hat{s}) = d(\hat{s}, \hat{t}_i)$ for each $i = 1, 2, 3$.
4. $R_\pi(\hat{s}, \hat{t}_1) \cap R_\pi(\hat{s}, \hat{t}_2) \cap R_\pi(\hat{s}, \hat{t}_1) = \emptyset$.

Case 2. Consider the case where s is a geodesic center that has only one farthest point t such that t is non-degenerate with respect to s, with both s and t in $\mathcal{I}$. We compute the candidate points for s as follows. We will need the π-range property in this case.

Since t is non-degenerate, there are exactly three shortest s-t paths: $\pi_{u_i,v_i}(s,t)$ with $i = 1, 2, 3$. We have $|su_1| + d(u_1, v_1) + |v_1t| = |su_2| + d(u_2, v_2) + |v_2t| = |su_3| + d(u_3, v_3) + |v_3t|$. If we consider the coordinates of s and t as four variables, the equations give two constraints, and to determine s and t, we need two more constraints, which are provided by the π-range property (this kind of situation does not appear in the previous work [3, 7] and thus they do not need the π-range property). Indeed, since t is the only farthest point of s, we have $R(s) = R(s, t)$. By Lemma 3, $R(s) = \emptyset$. Hence, $R(s, t) = \emptyset$. Since $s \in \mathcal{I}$, $R_\pi(s, t) = R(s, t) = \emptyset$. Since $t \in \mathcal{I}$, $R_\pi(s, t)$ is determined by Lemma 14. We define the angles a_i, b_i, for $i = 1, 2, 3$, in the same way as those for Lemma 14 in Section 4.3. By Lemma 14, $R_\pi(s, t) = \emptyset$ if and only if $a_i = b_i$ for $i = 1, 2, 3$. The identities of the three pairs of angles provide another two (independent) constraints. Using the above four constraints, we can determine s and t. Correspondingly, the candidate points for s can be computed in an exhaustive manner, as follows.

We enumerate all possible combinations of three polygon vertices as v_1, v_2, v_3. We compute the shortest path maps of v_1, v_2, and v_3 in $O(n \log n)$ time. Next we compute the overlay of the three shortest path maps. Then, for each cell of the overlay, we obtain the three roots of the cell in the three shortest path maps and consider them as u_1, u_2, u_2. Finally, we use the above four constraints to determine a constant number of pairs $(\hat{s}, t)$ (we assume this can be done in constant time since the angles a_i and b_i can be parameterized by the coordinates of $\hat{s}$ and t), and each such $\hat{s}$ is considered as a candidate point. In this way, for each combination of v_1, v_2, v_3, we can compute $O(n^2)$ candidate points in $O(n^2 \log n)$ time. Since there are $O(n^3)$ combinations, we can compute $O(n^5)$ candidate points in $O(n^5 \log n)$ time.

Case 3. Consider the case where s is a geodesic center that has only two farthest point t_1 and t_2 such that both t_1 and t_2 are non-degenerate, with s, t_1, t_2 all in $\mathcal{I}$.

For each t_i, $i = 1, 2$, there are exactly three shortest paths from s. The equations on the lengths of the six paths give five constraints for s, t_1, t_2 if we consider their coordinates as six variables. To determine s, t_1, t_2, we need one more constraint, which is provided by the π-range property as follows. Since s, t_1, t_2 are all in $\mathcal{I}$, for each $i = 1, 2$, $R(s, t_i) = R_\pi(s, t_i)$, and $R_\pi(s, t_i)$ is determined by Lemma 14. We assume neither $R_\pi(s, t_1)$ nor $R_\pi(s, t_2)$ is empty since otherwise the candidate points could be computed by the algorithm for the above Case 2. Hence, each $R_\pi(s, t_i)$, $i = 1, 2$, is an open range of size π. By Lemma 3, $R(s) = R(s, t_1) \cap R(s, t_2) = R_\pi(s, t_1) \cap R_\pi(s, t_2) = \emptyset$. Since each $R_\pi(s, t_i)$, $i = 1, 2$, is an open range of size π (i.e., it is delimited by an open half-plane whose bounding line contains s), to have $R_\pi(s, t_1) \cap R_\pi(s, t_2) = \emptyset$, the two bounding lines of the two half-planes delimiting the two π-ranges must be overlapped, and this provides the sixth constraint to determine s, t_1, t_2. Correspondingly, the candidate points for s can be computed in an exhaustive way.

6 Computing the Geodesic Centers

In this section, we find all geodesic centers from the candidate point set S. Recall that S_d is the set of candidate points for the four dominating cases. Let S' denote the set of candidate points for all other cases, and thus $S = S_d \cup S'$. As discussed in Section 5, $|S'| = O(n^{10})$ and we can find all geodesic centers in S' in $O(n^{11} \log n)$ time by computing shortest path maps. Below, we focus on finding all geodesic centers in S_d.

We first remove all points from S_d that are also in S', which can be done in $O(n^{11} \log n)$ time (e.g., by first sorting these points by their coordinates). Then, according to our definitions of the four dominating cases in Section 5, for any point $s \in S_d$, if s is a geodesic center, s does not have any degenerate farthest point since otherwise s was also in S' and thus would have already been removed from S_d. Recall that each point s of S_d is a valid candidate point and we have maintained its path information (in particular, the value $d(s)$).

We first perform the following *duplication-cleanup* procedure: for each point $s \in S_d$, if there are many copies of s, we only keep the one with the largest value $d(s)$ (if more than one copy has the largest value, we keep an arbitrary one). This procedure can be done in $O(n^{11} \log n)$ time (e.g., by first sorting all points of S_d by their coordinates). According to our algorithm for computing the candidate points of S_d, we have the following observation.

▶ **Lemma 17.** *After the duplication-cleanup procedure, for any point $s \in S_d$, if s is a geodesic center, then $d_{\max}(s) = d(s)$.*

Recall that all points of S_d are in $\mathcal{I}$. In the following, we give a *pruning algorithm* that can eliminate most of the points from S_d such that none of these eliminated points is a geodesic center and the number of remaining points of S_d is $O(n^{10})$. Our pruning algorithm relies on the property that each candidate point s of S_d is valid. Specifically, if s is computed for the dominating case $(3, 0, 0)$, then s is associated with the following path information $d(s)$, t_i, v_{ij}, and u_{ij} for $1 \leq i \leq 3$ and $1 \leq j \leq 3$, such that Observation 16 holds (i.e., s is $\hat{s}$ and each t_i is $\hat{t}_i$). For other three dominating cases (e.g., $(2, 1, 0)$, $(1, 2, 0)$, and $(0, 3, 0)$), there are similar properties. By using these properties, we have the following key lemmas.

▶ **Lemma 18.** *Let s be any point in S_d. If s is in the interior of a cell or an edge of $\mathcal{D}_{spm}$, then for any other point s' in the interior of the same cell or edge of $\mathcal{D}_{spm}$, it holds that $d_{\max}(s') > d(s)$.*

▶ **Lemma 19.** *For any two points s_1 and s_2 of S_d that are in the interior of the same cell or the same edge of $\mathcal{D}_{spm}$, if $d(s_1) < d(s_2)$, then s_1 cannot be a geodesic center, and if $d(s_1) = d(s_2)$, then neither s_1 nor s_2 is a geodesic center.*

Based on Lemma 19, our pruning algorithm for S_d works as follows. For each point s of S_d, we determine the cell, edge, or vertex of $\mathcal{D}_{spm}$ that contains s in its interior, which can be done in $O(\log n)$ time by using a point location data structure [9, 14] with $O(n^{10})$ time and space preprocessing on $\mathcal{D}_{spm}$. For each edge or cell, let S'_d be the set of points of S_d that are contained in its interior. We find the point s of S'_d with the largest value $d(s)$. If there are more than one such point in S'_d, we remove all points of S'_d from S_d; otherwise, remove all points of S'_d except s from S_d. By Lemma 19, none of the points of S_d that are removed above is a geodesic center. After the above pruning algorithm, S_d contains at most one point in the interior of each cell, edge, or vertex of $\mathcal{D}_{spm}$. Hence, $|S_d| = O(|\mathcal{D}_{spm}|)$. Since $|\mathcal{D}_{spm}| = O(n^{10})$ [7], we obtain $|S_d| = O(n^{10})$. Consequently, we can find all geodesic centers in S_d in $O(n^{11} \log n)$ time by computing shortest path maps.

We thus conclude that all geodesic centers of $\mathcal{P}$ can be computed in $O(n^{11} \log n)$ time.

▶ **Theorem 20.** *All geodesic centers of $\mathcal{P}$ can be computed in $O(n^{11} \log n)$ time.*

Acknowledgment. We wish to thank Yan Sun for the discussions on proving the π-range property.

Abstract

The `k-means` method is a widely used technique for clustering points in Euclidean space. While it is extremely fast in practice, its worst-case running time is exponential in the number of data points. We prove that the `k-means` method can implicitly solve PSPACE-complete problems, providing a complexity-theoretic explanation for its worst-case running time. Our result parallels recent work on the complexity of the simplex method for linear programming.

1 Introduction

The `k-means` method, also known as Lloyd's algorithm [15], is a widely used technique for clustering points in Euclidean space. It can be viewed as a local search algorithm for the problem of, given n data points in $\mathbb{R}^d$, choosing k centers in $\mathbb{R}^d$ to minimize the sum (or average) of squared Euclidean distances between each point and its closest center.[1] The method begins with an arbitrary set of k initial centers. Each point is then reassigned to the center closest to it, and each center is recomputed as the center of mass of its assigned points. Every iteration decreases the objective function value of the clustering, and these two steps are repeated until the algorithm stabilizes.

Three basic facts about the `k-means` method are:

1. It is extremely fast in practice, and for this reason is widely used, perhaps more than any other clustering algorithm. For example, Berkhin [6] states that it "is by far the most popular clustering algorithm used nowadays in scientific and industrial applications."
2. The worst-case running time of the method is exponential in the number of points. This was first proved by Arthur and Vassilvitskii [4], and extended to the plane by Vattani [18].
3. It has polynomial smoothed complexity in the sense of Spielman and Teng [17]: for every choice of data points, in expectation over Gaussian perturbations with standard deviation σ of these points, the running time of the method is polynomial in the input size and in $1/\sigma$ [3].[2]

* This work was supported in part by NSF grant CCF-1524062 and a Stanford Graduate Fellowship.

1 This problem is *NP*-hard, even in the plane [16].

2 We focus on properties that concern the running time of the `k-means` method. Like with any local search algorithm, one can also consider the approximation quality of the solution output by the method; see the well-known `k-means++` method [5] for an initialization technique with a provable guarantee, and [8, 7] for matching lower bounds on this particular method. Constant-factor guarantees are also known for different local search algorithms [13].

These three properties of the `k-means` method illustrate a clear parallel with the simplex method for linear programming. The simplex method is famously fast in practice, but Klee and Minty [14] showed that it has exponential worst-case running time. These lower bounds have since been extended to many different pivot rules (see e.g. Amenta and Ziegler [2]), and also to restricted classes of linear programs, such as minimum-cost flow [19]. On the other hand, both the average-case and smoothed running times of the simplex method are polynomial (see Spielman and Teng [17] and the references therein).

Disser and Skutella [9] initiated a fresh take on the worst-case exponential running time of the simplex method, by showing that it inadvertently solves problems that are much harder than linear programming. Specifically, they showed how to efficiently embed an instance of the (NP-complete) Partition problem into a linear program so that the trajectory of the simplex method immediately reveals the answer to the instance. In this sense, the simplex method can solve NP-hard problems, thereby providing an explanation of sorts for its worst-case running time. A similar line was taken by Adler et al. [1], who exhibited a pivot rule with which the simplex method can solve PSPACE-complete problems, and Fearnley and Savani [10], who proved analogous results with Dantzig's original pivot rule. These results echo earlier works on PLS-complete local search problems, where computing the specific local minimum computed by local search is a PSPACE-complete problem (assuming completeness is proved using a "tight" reduction, as in almost all known examples) [12], and the results of Goldberg et al. [11] showing that computing the outcome of various algorithms that solve $PPAD$-complete problems, such as the Lemke-Howson algorithm for computing a Nash equilibrium, are PSPACE-complete problems.

Our contribution is a proof that the `k-means` method, just like the simplex method, inadvertently solves PSPACE-complete problems. That is: computing the outcome of the `k-means` method, given an instance of `k-means` and an initialization for the k centers, is a PSPACE-complete problem.[3] Like with the earlier results on the simplex method, this result provides a new interpretation of the worst-case running time of the `k-means` method – it is exponential not because the work done is inherently wasteful, but rather because it solves a much harder problem than the one it was originally designed for. Our result also implies, under appropriate complexity assumptions, that there is no way of significantly "speeding up" the `k-means` method (in the worst case) without changing its final state.

▶ **Theorem 1.** *Given a `k-means` input $(\mathcal{X}, \mathcal{C})$, it is PSPACE-hard to determine the final cluster centers.*

2 Preliminaries

We briefly review the C-PATH problem, which serves as the starting point for our reduction. The C-PATH problem was used by Adler, Papadimitriou, and Rubinstein to show that determining whether a particular basis occurs on the path of the simplex algorithm, under certain pivoting rules, is PSPACE-complete [1]. The C-PATH problem is as follows: we are given as input a boolean circuit C with fan-in 2 which takes in its own input of n bits, and a target binary string t. For every input x, $C(x)$ is at most Hamming distance one from x, i.e. C computes an index (if any) to flip. Note that this means that C's input and output are the same size. Suppose we begin with the all-zeroes binary string and repeatedly apply C.

[3] Determining the complexity of computing *any* local minimum of the local search problem corresponding to the `k-means` method – not necessarily the local minimum computed by the method on a given initialization – is an intriguing open problem.

The sequence we get, $(0, C(0), C(C(0)), \ldots)$, is the path of C. We want to compute whether this path includes t.

▶ **Lemma 2** ([1]). *There is a family of circuits C of size polynomial in the number of inputs and of polynomial complexity such that C-PATH is PSPACE-complete.*

3 Reduction Sketch

In this section, we sketch the reduction we use to prove Theorem 1. For the sake of clarity and brevity, we omit some technical details here which are addressed in the full construction.

▶ **Theorem 1** (restated). *Given a `k-means` input $(\mathcal{X}, \mathcal{C})$, it is PSPACE-hard to determine the final cluster centers.*

Recall that we reduce from the C-PATH problem, where we have a circuit C and target binary string t. We know that if the path of C ever reaches t, it must do so within 2^n steps. Our plan of attack is to encode circuit C into `k-means`, and then use the reset gadget of Arthur and Vassilvitskii [4] to repeatedly run the encoded circuit on its own output. It is worth noting that although Vattani [18] showed that `k-means` can be made to run for an exponential number of iterations even in the plane, this planar construction is different in a fundamental detail that we depend on. In Arthur and Vassilvitskii's construction, a reset gadget is capable of resetting *all* earlier cluster centers. In Vattani's construciton, a reset gadget resets only the previous cluster center, but does so twice. These gadgets both suffice when the base instance is a single cluster, but only the former can handle a more complex base instance with multiple clusters.

Encoding the Circuit

One benefit of choosing the C-PATH problem is that encoding the circuit is simply a matter of encoding its gates. We use the location of a certain cluster center to represent a boolean value of our gate. When we compute that a gate evaluates to false, its cluster center moves from a starting location to a false region. If it evaluated to true, it would move into a disjoint true region instead.

We can assume without loss of generality that our circuit only uses NAND gates. We go through these gates in topological order; with each new NAND gate we introduce a new dimension to our `k-means` instance. Hence, the inputs to our current gate always lie in a lower-dimensional space. Our NAND gate has two inputs, each with their own false and true region in the space below. Suppose we place an intermediate point roughly $d - \epsilon$ units above each of these regions which are part of cluster i whose center is currently another d units above them, for some large distance $d > 0$ and tiebreaking constant $\epsilon > 0$. When the input cluster centers move to their false or true regions, they steal the respective point above them from cluster i. Depending on which points are stolen, the center of cluster i moves to a predictable location. With additional arranging of the intermediate points, the center moves to either a false region or a true region, the two of which are disjoint.

Repeatedly Running the Circuit

Unfortunately, we cannot immediately apply Arthur and Vassilvitskii's reset gadgets, because they are designed to return a set of cluster centers from specific final locations to initial locations [4]. We care about the final locations of our cluster centers because they represent the output value of our circuit and should affect the input value for the next iteration.

We solve this by, instead of using a single AV reset gadget to reset all cluster centers, using two AV reset gadgets for each input/output bit. One gadget detects when the output bit is false and returns the cluster center to its initial position while also setting the input bit to false. The other gadget does the same but for true bits. Furthermore, we can still layer these gadgets; gadgets reset all corresponding gadgets in previous layers. With only n layers, we can run the circuit 2^n times, enough to guarantee that t will appear if it is indeed in the path of the circuit.

As a final step, we add a gadget to track whether t has appeared. To do this, suppose we modify the circuit so that a special bit is 1 if and only if the input was t. We can use the same idea as with NAND gates; we add an intermediate point roughly $d - \epsilon$ units above the true region of this special bit, which are part of a cluster whose center is an additional d units above the intermediate point. The only other point in this cluster, in fact, is d units above the center. If the special bit ever becomes 1, the intermediate point will be stolen and the cluster center will move to the top point. After this, the center is $2d$ from any other point and can neither gain nor lose data points. All we need to check in the `k-means` output is the location of this center to know whether the path of C includes t.

4 Formal Reduction Proof

In this section, we formally prove Theorem 1. We follow the sketch given in Section 3. Missing tables can be found in Appendix A.

Encoding the Circuit

Recall that we begin with an instance of the C-PATH problem, (C, t) where we want to know if t is on the path of C. It will be convenient to convert C so that it only has NAND gates instead of the standard AND, OR, and NOT gates. We also require that each gate has a fan-out of at most two, but introduce a special SPLIT gate which takes in a single bit and outputs it back. This can be implemented with only a constant blowup in the number of gates, since fan-in larger than two can be simulated with a binary tree of SPLIT gates (and the number of nodes is at most twice the number of leaves). We require that the inputs of a NAND gate can only SPLIT gates, which can be guaranteed by inserting a SPLIT gate of fan-out one before each NAND gate. This at most doubles the number of gates. We also require that the inputs of a NAND gate must be at the same depth and that all outputs are at the same depth. One slightly inefficient, yet still polynomial method to guarantee this is to take every NAND gate and place it in its own layer. Inside a layer, there is only a single NAND gate, but we use SPLIT gates to pass on the other values. We add SPLIT gates after outputs which occur too early. This synchronizes the circuit with only a quadratic blowup in the number of gates.

We represent boolean values in our circuit with the location of a cluster center. Each cluster center serves to signal the output of a gate to only one other gate (why we bound the fan-out). Gate i uses cluster centers c_{2i-1} and c_{2i}. Cluster center c_j has an initial location $\mathbf{s}_j$, a false region centered at $\mathbf{b}_{j,0}$ with radius r_j, a true region centered at $\mathbf{b}_{j,1}$ with the same radius r_j, and a final location $\mathbf{t}_j$. At some timestep, the center will move from its initial location to either its false region or its true region, which serves as a signal to the gate that takes it as input. It then eventually moves to its final location. We guarantee that no two initial locations, false regions, true regions, or final locations overlap, even over different clusters. This property remains true when moving the final location towards the average of

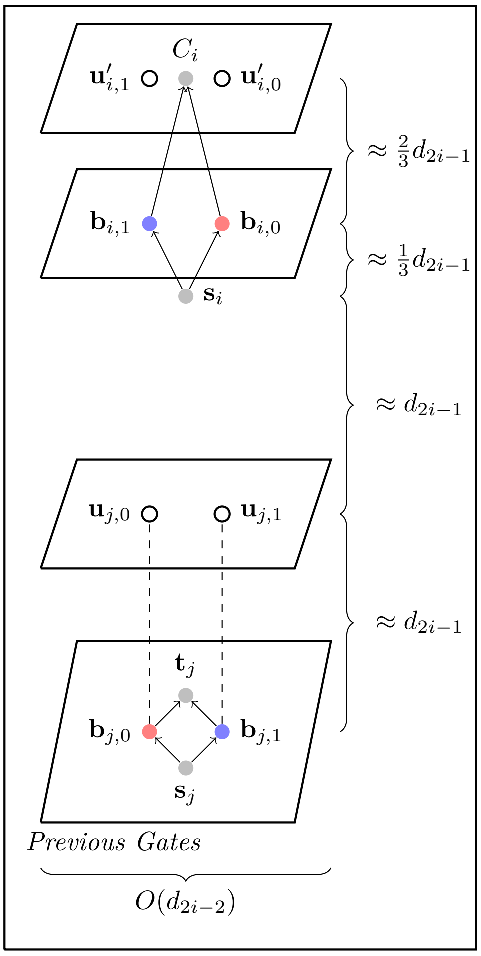

Figure 1 SPLIT Gadget, Upper Half.

the false and true region centers. Finally, we guarantee a cluster center is always the closest center to any of its locations or regions.

We construct gates in topological order. For each gate i, we introduce two new dimensions: $(2i-1)$ and $(2i)$. We let $\mathbf{e}_j$ be the standard basis vector for dimension j. We also grow the scale of our construction at each step; for each dimension, we choose a scaling factor $d_i > 0$ so that $d_1 \ll d_2 \ll \cdots \ll d_{2m}$. The data points we introduce with dimension i are within $O(d_i)$ of the origin. The idea is that d_{i+1} is large enough compared to d_i so that two points which differ by d_{i+1} in their $(i+1)^{th}$ coordinate and by $O(d_i)$ in their first i coordinates are still roughly d_{i+1} apart. We also use a small $\epsilon > 0$ to break ties (note $\epsilon \ll d_1$). We also use $d(\mathbf{u}, \mathbf{v})$ to represent the Euclidean distance between points $\mathbf{u}$ and $\mathbf{v}$.

SPLIT Gadget

We first explain the construction of the simpler SPLIT gadget. Suppose we have the i^{th} gate which takes the j^{th} cluster center as input. The data points and regions we use in this construction are listed in Table 1 and the upper half of the gadget is depicted in Figure 1.

Suppose that at time T, the j^{th} cluster center moves to its false or true region. We want to notice when this occurs, so we place an intermediate point $\mathbf{u}_{j,0}$ roughly $(d_{2i-1} - \epsilon)$ above the false region, an intermediate point $\mathbf{u}_{j,1}$ roughly $(d_{2i-1} - \epsilon)$ above the true region, an intermediate point $\mathbf{v}_{j,0}$ roughly $(d_{2i-1} - \epsilon)$ below the false region, and an intermediate point $\mathbf{v}_{j,1}$ roughly $(d_{2i-1} - \epsilon)$ below the true region. Note that the actual heights are actually scaled to account for the radius of each of these regions; *every* point in the region at most $(d_{2i-1} - \epsilon)$ away from its two intermediate points.

We want the $(2i - 1)^{th}$ cluster center to be d units away from the top two intermediate points and the $(2i)^{th}$ cluster center to be d units away from the bottom two intermediate points. For each intermediate point u, we add a counterbalancing point u' so that the average of the two is our desired initial center location.

At time $T + 1$, the j^{th} cluster steals either $\mathbf{u}_{j,0}$ and $\mathbf{v}_{j,0}$ or $\mathbf{u}_{j,1}$ and $\mathbf{v}_{j,1}$, depending on whether it was false or true. This causes the $(2i - 1)^{th}/(2i)^{th}$ cluster centers to move up/down to their respective false or true regions (which are actually balls of radius zero). This does not affect the $(2i - 1)$-coordinate of the j^{th} cluster since the two points it stole cancel out. However, it does move the center towards the center of the region it was in.

At time $T + 2$, because the $(2i - 1)^{th}$ and $(2i)^{th}$ cluster centers moved away from the lower-dimensional space, the other intermediate points are stolen by cluster j (recall we guarantee that cluster center j is the closest center to any of its regions, and in particular to the false or true region it was not in). This causes the $(2i - 1)^{th}/(2i)^{th}$ cluster centers to move up/down to their final locations. Again, this does not affect the $(2i - 1)$-coordinate of the j^{th} cluster because the points cancel out. However, it does move the center towards the center of the region it was not in. Notice we have affected the final location of the j^{th} cluster center, but we already assumed that moving it towards the average of the false and true regions would keep all locations and regions disjoint.

We see that we satisfy the assumptions made about the construction; the locations and regions we create are disjoint from all others because the other locations and regions are within $O(d_{2i-2})$ of the origin and all of ours are at least $\Omega(d_{2i-1})$ from the origin. This also makes our cluster center the closest to all of our locations and regions (since other centers cannot escape the lower-dimensional space due to our balancing). Finally, moving our final location towards the average of the false and true regions keeps it disjoint.

NAND Gadget

We now proceed to the constrution of the NAND gadget. Suppose we have the i^{th} gate which takes the j^{th} and k^{th} cluster centers as input. For simplicity, we concern ourselves with the data points and cluster center regions for cluster $(2i - 1)$ only. The $(2i)^{th}$ cluster's points and regions can be found by negating the $(2i - 1)^{th}$ and $(2i)^{th}$ coordinates. The points and regions we do present are listed in Table 2 and depicted in Figure 2. For this gadget, we talk about dimension $2i - 1$ as left/right and dimension $2i$ as up/down.

We have the same core plan as the SPLIT gadget. We add intermediate points above the two false regions and above the two true regions. We also slide these intermediate points left and right slightly; we shift intermediate points above false regions to the right and intermediate points above true regions to the left. Because $d_{2i-1} \ll d_{2i}$, these points are still roughly $d_{2i} - \epsilon$ from their respective regions.

The initial center of cluster $(2i - 1)$ is d_{2i} above all four intermediate points; we achieve this by adding counterbalancing points so that the average of a point and its counterbalancing partner is our desired center.

Suppose at time T both cluster centers j and k move to false or true regions. Then at time $T + 1$, they each steal an appropriate intermediate point above them. This causes the center of cluster $(2i - 1)$ to definitely upwards, and possibly left or right depending on what

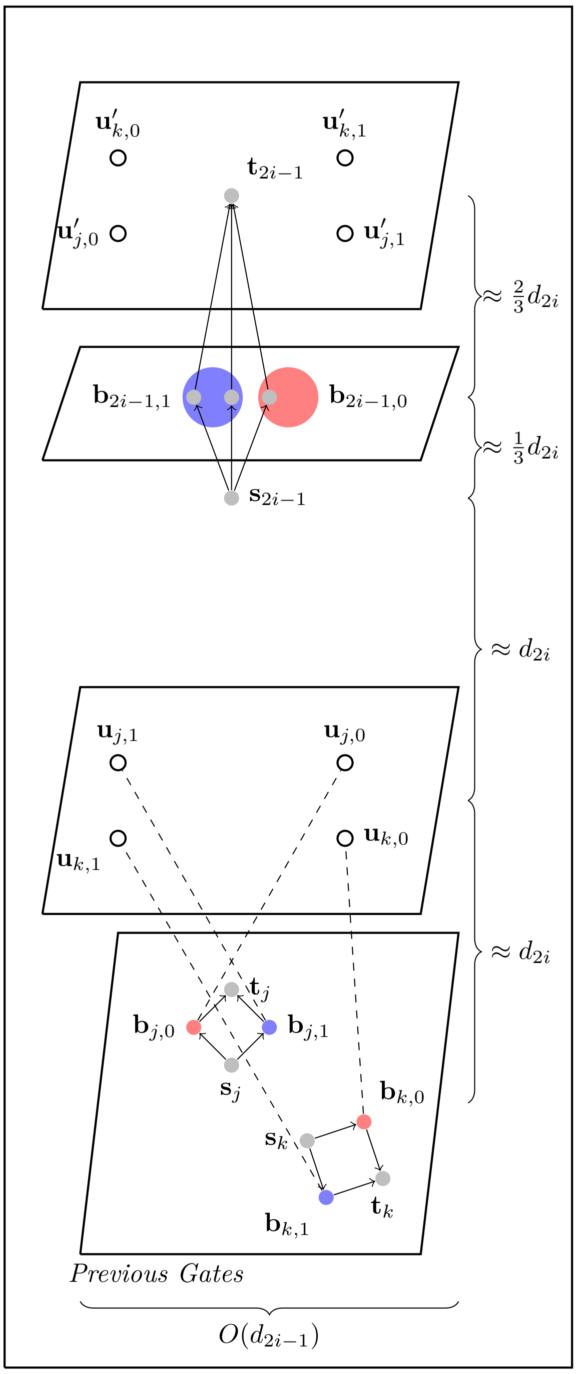

Figure 2 NAND Gadget, Upper Half.

values j and k had. If both j and k are false, they steal intermediate points on the right and our center moves to the left. If they are both true, our center moves to the right. If we have one of each, the center does not move left or right. We can place our false region to capture the right possibility and our true region to capture both the center and left possibilities.

At time $T+2$, cluster centers j and k steal the intermediate point for the region they did not enter, because cluster center $(2i-1)$ moved up and they are the closest center to any of

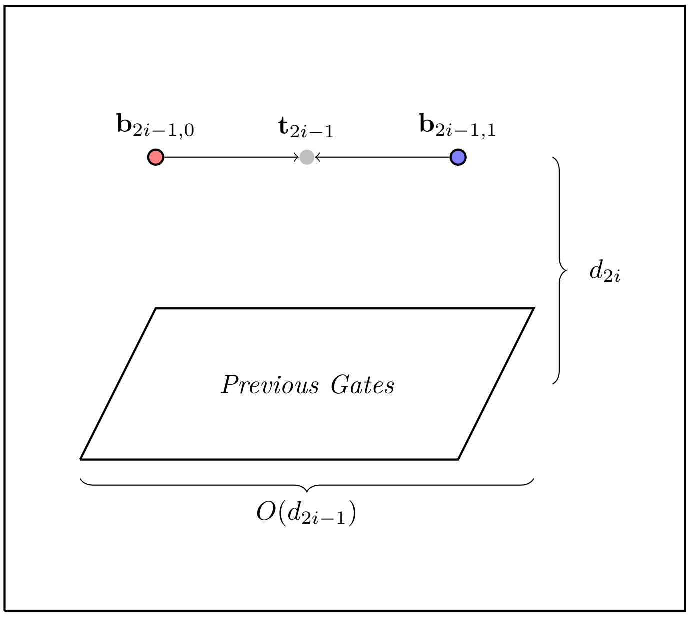

Figure 3 Input Gadget.

their respective regions. This moves the cluster center $(2i - 1)$ to its final location. Note that we have shifted the final location of cluster centers j and k, but this keeps locations and regions disjoint by assumption.

We satisfy all assumptions made about the construction for essentially the same reasons as before. The one difference is regarding moving our final location towards the average of the false and true regions. It remains disjoint because $d_{2i-1} \ll d_{2i}$, so it descends approximately straight from above, avoiding the false and true regions.

Input Gadget

We also provide a simple gadget which is used to signal the value of an input bit. We only use the $(2i - 1)^{th}$ cluster center and do not actually provide an initial location. Instead, the center is intended to start in either the false or true region, which signals its value. It then immediately moves to its final location. Dimension $(2i - 1)$ is used to separate the false and true regions while dimension $(2i)$ is used to separate the gadget from previous gadgets. The points and regions are listed in Table 3 and depicted in Figure 3. Note that unlike previous gadgets, there is no corresponding bottom half to this gadget, since we do not need to balance its effect on previous gadgets.

AV Reset Gadget Review

Before we describe how we repeatedly run the circuit, we briefly review the reset gadgets of Arthur and Vassilvitskii [4]. A configuration is signaling if at least one final cluster center is distinct from every cluster center arising in previous iterations. A configuration is super-signaling if all final cluster centers are distinct from every cluster center arising in previous iterations and there is an alternate initial configuration of centers that is essentially identical except at least one final cluster center is different.

AV gadgets are a result of two constructions (Lemma 3.3 and Lemma 3.4 in their paper). One construction (Lemma 3.3) converts a super-signaling configuration into a signaling configuration which runs from the initial configuration and then swaps to the alternate intial configuration. The other (Lemma 3.4) converts a signaling configuration into a super-signaling configuration. They share similar ideas to our gadget constructions above; intermediate points are placed above and below the expected locations. Similar to our NAND gadget shifting the intermediate points left/right, they shift the intermediate points in a *circle* using two additional dimensions. They then use a second set of intermediate points which are stolen according to how points were shifted in a circle. This enables them to correct every center to its new initial location. There are also two additional clusters which represent an alternate initial configuration.

Taken together, these two constructions take a lower-dimensional signaling configuration and make it run twice by resetting its final cluster positions to their initial positions. Layering n gadgets results in 2^n resets of the bottom-level circuit.

We make two key observations about the capabilities of AV reset gadgets. First, they need not reset the positions of all lower-dimensional clusters; we be selective and only reset some. Second, the signaling cluster may reach its distinct location one step before it reaches its final position. This works because intermediate points may be placed above and below its distinct location, and the signaling cluster will steal them and reach its final position in the same time step. The location of the intermediate point which corrects its final location to its initial location still uses its real final location. These observations enable us to use AV reset gadgets to set the input of the circuit to its previous output, despite our particular method of signalling boolean values.

Repeatedly Running the Circuit

We are now ready to explain how to repeatedly run our encoded circuit. We need to run it up to 2^n times to guarantee we reach t, if at all possible. We plan to do this with AV gadgets. Unfortunately, AV reset gadgets work by knowing the exact final locations of cluster centers and moving them to exact initial locations. We want to copy circuit output to input. Not only do we not have exact final locations, but we also want them to influence the new initial locations. This is solved by using one AV reset gadget chain per input bit and each boolean value it can take on. An AV reset gadget for bit i being false is signaled by the cluster center of output bit i entering its false region. It corrects the final location of the cluster center to the false region of input bit i and it corrects the final location of input bit i to the initial location of output bit i.

We want to run the circuit 2^n times, so a first attempt is to reset each (input bit, value) pair that many times. Unfortunately, this has unintended behavior if the path of C has unbalanced parity. For example, suppose we had a circuit C where $C(00) = 01$ and $C(01) = 00$. In four iterations, we follow the path $(00, 01, 00, 01, 00)$. The false AV reset gadget for the first input bit is now fully expended and stops resetting, but the AV reset gadgets for the second input bit still reset it, causing only part of the circuit input to be copied from the output. In a more complex example, this could evaluate the circuit on an input not actually in the path of C.

To avoid this, we transform C so that it follows a balanced path, i.e. in every bit it alternates between true and false. Circuit C_2 has an additional parity bit in its input. When this auxiliary bit is zero, it simply flips the entire input. When the auxiliary bit is one, it again flips the entire input, and then applies C_2 to the standard input. This can be be implemented with only polynomially many extra gates. More formally:

$$C_2(\mathbf{x}b_1) = \begin{cases} \bar{\mathbf{x}}1 & \text{if } b_1 = 0 \\ C(\bar{\mathbf{x}})0 & \text{if } b_1 = 1 \end{cases}$$

We now have $n+1$ input bits and plan to reset each 2^n times, for each value. It will also be convenient to keep track of whether we have reached t yet, so that we can simply examine the final `k-means` state. We add another auxiliary bit, which transitions from zero to one when the input is t. This also can be implemented with only polynomially many extra gates. Formally:

$$C_3(\mathbf{x}b_1b_2) = \begin{cases} C_2(\mathbf{x}b_1)0 & \text{if } b_2 = 0, \mathbf{x}b_1 \neq t0 \\ C_2(\mathbf{x}b_1)1 & \text{if } b_2 = 0, \mathbf{x}b_1 = t0 \\ C_2(\mathbf{x}b_1)1 & \text{if } b_2 = 1 \end{cases}$$

Note that for our second auxiliary bit, we want to reset a false value 2^{n+1} times and we do not worry about resetting a true value. Also, we can conveniently use the AV reset widget of this bit to reset the inner gates of the circuit. This completes our circuit reset construction.

Output Gadget

Our final gadget records whether $b_2 = 1$ at any point. Suppose that b_2 is represented by the position of cluster center i. We assume without loss of generality that it is computed by a SPLIT gate. We use one final additional dimension, with the largest scale. Suppose this is dimension D. We add points at $(\mathbf{b}_{i,1} + (d_D - \epsilon)\mathbf{e}_D)$ and $(\mathbf{b}_{i,1} + (3d_D - \epsilon)\mathbf{e}_D)$. We also add a final cluster center at $(\mathbf{b}_{i,1} + (2d_D - \epsilon)\mathbf{e}_D)$. The former point can only be stolen from this cluster if $b_2 = 1$, and when this happens the cluster center will move to the latter point. But the latter point is $2d_D$ from the former point, so the cluster center can never recapture it.

As review, the completed construction uses gadgets in the following order (from low-dimensional to high-dimensional):

1. $n+2$ input gadgets which represent the input bits,
2. $poly(n)$ NAND and SPLIT gadgets which represent gates and output bits,
3. $(n+1)(2n) + (n+1)$ reset gadgets to repeatedly run the circuit,
4. and one output gadget which represents the final result.

We have produced a polynomially-sized `k-means` instance from a C-PATH instance. The final state of our output gadget indicates the answer to the C-PATH instance, so computing the final state of `k-means` is enough to solve a PSPACE-complete problem. This completes the proof.

5 Conclusions

This paper proved that the `k-means` method inadvertently solves PSPACE-complete problems, echoing analogous results for the simplex method [1, 9, 10]. There are at least three interesting directions in which our result might be extended.

1. We conjecture that the following problem is PLS-complete: given an instance of `k-means`, compute an arbitrary local minimum of the `k-means` method. Such a result, if proved

using “tight” reductions[4] (see [12]), would imply our Theorem 1.[5]

2. The worst-case running time of the `k-means` method is exponential even in two dimensions [18], while our PSPACE-completeness reduction produces instances with a large number of dimensions. Is computing the outcome of `k-means` still PSPACE-complete in planar instances? Recall that Vattani’s reset gadgets work by resetting only the previous gadget, but doing so twice. Our reduction depended on the ability of AV reset gadgets to reset all previous clusters so that the entire circuit could be reset.
3. Does the problem of computing the outcome of `k-means` remain PSPACE-complete when the initial centers are chosen greedily, as in `k-means++` [5]?

[4] In a tight PLS reduction, there is also a correspondence between improving moves in the two instances, not just between solutions.

[5] For this question to be interesting, it is important to rule out degenerate local minima. A partial solution is to insist that each of the k initial centers lies in the convex hull of the point set. (Otherwise, placing one center at the center of mass of the entire point set and the other $k-1$ centers “at infinity” is an easy-to-compute local minimum.) Similarly, dealing with (or avoiding) co-located centers requires some care.
